# HISTORY OF LINEAR PROGRAMMING AS IT APPLIES

#### TO FARM PLANNING

Since linear programming was developed shortly after World War II economists have found many uses for it. Agricultural economists have found it particularly useful in determining optimum organizations of farms, in specifying farm adjustments, in determining profit maximizing mixes of commodities, and in indicating optimum patterns of interregional resource use and product specialization (4,8).

Agricultural economists dealing with problems in farm management have found the technique of linear programming especially useful in farm planning. The first attempts in 1953-54 to use linear programming as a farm planning tool were somewhat crude and gave rather general answers. However, much of the difficulty with the early work resulted from the necessity to seek solutions with the aid of desk calculators (7,15). With the advent of better, more refined methods and high speed electronic computers with large capacities, linear programming has become extremely useful as a farm planning tool.

In the recent past much of the effort in using linear programming for farm planning has been directed into one of two areas. Either the work has been solely research oriented, using linear programming as a tool to solve a specific problem defined by the researcher or specific farms in separate soil associations have been programmed with a wide variety of alternatives. In turn, the results from these farms have been published as general guidelines for farms in that same association (9,10,18,22).

Linear programming has been an excellent tool for research and for

setting general guidelines, but it has been used little in solving problems or in forward planning at the individual farm level. The advantages of using the tool in farm planning are many, and more and more farmers are becoming interested in its use (1,6).

There seem to be two basic reasons why linear programming has not been used extensively for individual farm planning. First, input-output data is difficult to estimate accurately for the individual farm. Most farmers, even those who keep excellent records, do not have sufficient data to construct a usable programming model (16). In addition, historic data may be of little use in estimating production coefficients when shifts in production methods or volume are anticipated.

Second, even if all the necessary data were available, it would take considerable technical manpower to construct a linear programming matrix of sufficient size to include all the desired alternatives.

With present and potential data storage capacities of computers, it seems logical that some "master model" containing a wide variety of alternatives reflecting various production, cost, and management levels could be constructed and stored in the computer. A farm operator or planner could then choose those activities which best describe his unique situation. By specifying important resource or facility constraints, he could obtain an optimum plan, using a given set of price expectations, also stored, or a set specified by him.

Past arguments against using previously determined input-output data, or budgeting data, have been directed at the idea of non-applicability. In other words, if the data is not derived from the individual farm, it will not be accurate enough to give a usable solution. McFarquhar counters the

argument by stating that derived data also involves a considerable amount of questionable estimating. He believes that if enough alternatives are considered using localized budgeting materials, one method may be as accurate as the other (19).

During the last two years, the Extension Farm Management staff at Iowa State University has programmed several farm situations. These examples have been used primarily for teaching management principles. However, during the presentation of the programming material, farmers often raised questions about the possible results of the examples under wider ranges of production methods, price expectations or resource constraints. It became evident that farm operators prefer to compare several alternative plans and/or relate them to one optimum plan.

Since linear programming typically provides only one optimum solution, the planner does not know how close other plans might compare in income or resource use. The Extension Farm Management staff at Iowa State University has also found that many farmers find it difficult to think in terms of shifting completely into or out of a given enterprise as prices or resources change. Rather they prefer to hold certain enterprises constant while allowing others to change, given the fixed level of resources.

If a method could be devised to allow for partial optimization, it could be useful for the individual farm operator who might wish to compare various farm plans to his present operation and to some optimum plan. Such a method could also prove helpful in the classroom situation in teaching farm management principles.

Such a model could also allow for decreasing cost or increasing income activities. Past methods of farm planning using linear programming alone

have not been able to properly evaluate decreasing cost enterprises. Coupling such enterprises with a budgeting or partial optimization routine would increase the effectiveness of such a model.

# Thesis Objective

The objective of this thesis is to attempt to construct a sample linear programming model which would meet the goals just mentioned, thus making linear programming both available and useful to larger numbers of farm operators. First of all, the model needs to be constructed in such a manner that the basic input-output data can be stored easily or left undisturbed as various farm situations are programmed.

Second, the model must be constructed in such a way that price expectations and resource availabilities can be easily altered from one solution to the next. Activity prices, therefore, must be formulated in terms of commonly used marketing units, such as livestock prices in hundredweight units instead of animal units. Crop selling or buying activities must be in terms of tons or bushels instead of acres.

Third, the printed output for each problem should include a written description of the optimum solution. Such an output report would allow farm operators or farm management specialists who are unfamiliar with the model to understand and interpret the output report. Professional staff time in the field could thereby be reduced. The output report should, therefore, give a written, instead of a numerically coded, identification of the activities included in or excluded from the optimum plan. An accurate description of resource use and income generated should also be provided.

Fourth, the model should be built to allow for complete budgeting, partial optimization, or complete optimization of a given situation. Such a model would permit a farm operator to try out several farm plans to compare incomes or resource use or to keep certain facets of his business organization fixed while optimizing on the remainder of his resources.

Such a model would seem to have a wide range of possible uses. It would eliminate much of the preparatory work usually encountered in gathering data and constructing a model. The possibility of optimizing, partially optimizing, or budgeting would give much greater flexibility with the same model. Because budgeting problems would be computed with a linear programming method, the user could also learn the computed marginal value of scarce resources and the income penalties associated with activities not in the solution. This information has not been available from conventional budgeting methods.

#### REVIEW OF FARM PLANNING APPLICATION OF LINEAR PROGRAMMING

As mentioned earlier, linear programming first was applied to farm planning problems during 1953-54. The early attempts in farm planning were somewhat crude and did not give real insight into the nature of the farm businesses being considered, primarily because the computational methods at that time still forced the planner to compute the problems with a desk calculator, limiting the number of possible alternatives and production coefficients.

King presented an example of an early attempt to use activity analysis, a computational method of linear programming, in 1953 (15). One of his examples involved a family farm with 60 acres of cropland in the Northern Tidewater of North Carolina. He considered only six enterprises: Irish potatoes, corn, soybeans, cropland pasture used for beef production, fall lettuce and fall cabbage. The fixed resources specified were cropland, production capital, and operator labor defined in two-month intervals. His method of budgeting the input-output coefficients entailed defining factor requirements in terms of \$100 net revenue units. Capital requirements were given in terms of yearly cash expenditure requirements to produce \$100 of net revenue.

With resources limited to 60 acres of cropland and \$2000 of production capital, the optimum solution was determined to be 61.086 units of Irish potatoes, 16.773 units of beef, and 0.213 units of fall lettuce. Net revenue produced was \$7807.20.

While such a model is satisfactory mathematically, its accuracy and applicability for farm planning purposes may be questioned. The first item

that comes into question is the unit of production, \$100 of net revenue, associated with the activities. While such a unit may give the same answer as any other unit, determining and understanding the input coefficients is confusing. Cost-of-production data is seldom listed in any other way than animal or acre units. Because the production units are specified in terms of \$100 net revenue, the net prices of the activities are equal. If the planner wished to change the price expectations or interpret the income penalties computed for activities not in the solution, much additional calculating would be necessary to relate the price changes or income penalties to animal or acre units.

Offering only six activities illustrates the potential of activity analysis for farm planning, but someone who wished to seriously look at the alternatives open to an individual farm operator would want to consider many more alternatives. If the six activities are the only ones the farmer wished to consider, a farm planning model should include alternatives within potato, corn, soybean, lettuce or cabbage production. There may be as much difference among activities formulated within enterprises as between them.

Much the same comment could be made about the resource restrictions. King included land, labor and capital, the three basic limitations in most businesses. If the 60 acres of land are homogeneous, one could scarcely argue with a single land restriction. The weakness of the resource restrictions lies in the difference between the labor and capital restrictions. Labor is precisely defined in terms of operator hours available in twomonth intervals. Capital, on the other hand, is defined as a single yearly restriction on production capital, which is not defined clearly. King

states that it includes basic production expenses, but he does not state if it includes other costs. Acknowledging that labor is a flow resource while capital is a stock resource, a single yearly capital requirement lacks precision. The various activities considered may require capital at different times of the year and may cease requiring capital long before the year is completed. They may also generate income which in turn can be used for succeeding activities. Thus, a \$2000 capital limitation may mean the peak net capital usage will be much less than the total limitation.

In summary, King's model serves the purpose of illustrating the procedure of activity analysis. However, his model falls short of meeting the needs of adequate farm planning methods. More activities need to be considered, capital usage should be more clearly defined, and the production units should be defined in more conventional terms.

A much more thorough application of linear programming reported about the same time is illustrated by Bowlen (3). Bowlen's objective was to determine the crop combinations that would maximize income under various resource situations for the major soil associations in Iowa. He had 14 representative townships throughout the state selected on the basis of the major soil association in each township. Land resources for each farm were limited to 160 acres, which was the most common size of farm at that time. For each township farm it was assumed that 154 acres would be tillable. The minimum acreage of hay and oats was determined for each farm, leaving the remainder open to other crop alternatives.

Labor resources for the operator were defined as 260 hours per month. Labor requirements for cropping activities were determined on a monthly basis. The amount of labor available for cropping activities was determined

by first computing labor availability for field work considering the weather factor. After total available cropping labor was determined, that amount of labor necessary for the minimum hay and oat acreage on each farm was subtracted, leaving the residual labor available for other cropping activities.

Two other labor resource situations were also considered. The first was for an additional 130 hours of family labor per month. The second was for unlimited hired labor available at an hourly wage.

Capital resources were divided into three levels. The first level was the average capital expenditure level for all Iowa farms in 1952. The second level was for 150 percent of the first level. The third level allowed for an unlimited supply of capital, which meant the farmer had access to all the capital he considered would be profitable in his operation.

As with land and labor, capital requirements for the minimum hay and oat acreage were first subtracted, with the remainder available for other cropping activities. Capital coefficients for each cropping activity were given as a single yearly figure on a per acre basis. The capital coefficient for each crop included both fixed and variable costs.

The defined fixed costs included overhead tractor costs, tractor operating costs, machinery depreciation, seed costs, and building costs. The variable costs were defined as real estate taxes, machine and labor hire. It should be noted that a fixed labor requirement was included in the capital costs of some of the cropping activities.

The cropping activities considered were corn, soybeans, oats, and flax and wheat in some areas. Each activity was defined in terms of acre units.

The net price for each acre activity was total revenue minus total costs. Because it was not the objective to consider livestock enterprises, they were omitted.

The results from such a model list the acres planted of each cropping enterprise, the monthly labor use, and capital use. In comparison to King's model mentioned earlier, Bowlen's use of activity analysis for farm planning was superior. The manner in which Bowlen derived his labor coefficients was thorough and entirely applicable to farm planning models being used at the present time. The acre units of production are much easier to interpret in terms of input-output data. The land resources were realistically separated into minimum required legume production, with only the remaining acreage available for optimization.

Analysis of Bowlen's model in terms of its applicability to general farm planning situations reveals some of the same shortcomings as King's model.

The first shortcoming is the lack of marketing units or activities to facilitate consideration of alternative price expectations. With Bowlen's method, a cropping activity included the growing costs and the sale price per acre. With 14 different farm situations and possibly as many cost and yield differences, each farm situation required recalculating the net price for each crop activity. A method of transfer rows and crop marketing activities would have facilitated much of the detail work required for price or yield changes.

The second shortcoming in Bowlen's model involves two aspects of his method of handling production capital. He indicated that each capital coefficient involved such costs as overhead tractor costs, tractor operating

costs, machinery depreciation, seed costs, building costs, real estate taxes, and machine and labor hire. Since Bowlen assumed a specific land resource and a given set of machinery, many of the capital costs he listed would be fixed costs to the entire business and not allocable to a given unit of production. The fixed costs should have been independently subtracted from the total income generated, since linear programming maximizes returns to the fixed factors to reach an optimum plan (8).

Bowlen also used King's method of listing his capital coefficients. The capital requirements are given as a single yearly requirement for each crop, regardless of the length and season of time each crop activity requires capital. The actual variable capital required in any one time period may be much less than would be indicated by Bowlen's model, especially with unlimited capital. Some work has, however, been done with redefining capital requirements and time periods.

Stewart stated that more attention needs to be placed on the derivation of capital coefficients since capital is so often the crucial limiting resource (23). In considering the single yearly capital coefficient, Stewart states:

"It is difficult to attach realistic meaning to the relationship given in this form (single yearly requirement). Clearly the operating capital requirements for any farm programme may not be expressed in terms of discrete coefficients for each activity unless there is some account taken of the time pattern of income from and expenditure on each activity. If no such account is taken, then the relationship in the above form (single linear relationship) violates the assumption of independence which is implicity in the linear model. That is, unless the total farm product is sold on the 365th day of the year being considered, then the total effective capital requirements of the whole farm programme will be less than the sum of the capital requirements of each enterprise." (23, p. 464)

Stewart then proceeded to set up a theoretical "capital profile" similar to the manner in which labor requirements are allocated seasonally or monthly. The major difference is that, unlike unused labor, unused capital in one period can be carried forward and used in the next period. Therefore, the capital profile was actually a series of cumulative balances. During the year, a production activity either requires more capital, enlarging the profile, or gives up capital in the form of receipts, decreasing the profile.

Nonassignable, or fixed, costs were deducted from the original capital available, leaving the residual to meet the variable cost requirements. With such a method, all capital costs, including fixed costs, must be met with the capital resource, but fixed costs are not broken down among the activities, as they are in Bowlen's work.

Stewart then constructed a linear programming problem using a New Zealand farm with 305 acres for mixed cropping and lamb feeding. The activities considered were five cash crops, five intermediate crops, and three sheep enterprises. Capital requirements were listed on a monthly basis, starting June 1. The solution showed capital was limiting in two of the twelve months. Each of the remaining months had a positive capital balance.

By allocating the capital requirements on a monthly or seasonal basis, a farm planner might determine the months or seasons in which capital would be limiting. If the limiting period was short in duration, the operator might be able to gain an extension of credit use and expand his operation to more fully utilize available capital the rest of the year. In such a case, the capital limitation in the restricting period might be

relaxed because of the positive balances maintained during the rest of the year.

In summary, Stewart illustrated that single seasonal capital coefficients may not be of sufficient accuracy to describe meaningfully the relationship between capital requirements and availability. Because capital is a stock resource it doesn't follow that monthly or seasonal capital coefficients are not as important as monthly or seasonal labor coefficients. Capital, like labor, may be limiting in only one period. The capital resource would have a positive marginal value only in the limiting period and not for the whole year as it would with the single sum coefficient.

Mention has been made that farmers are becoming increasingly familiar with linear programming and its potential applications to farm planning problems. An example of how farmers are learning of linear programming and how it is being used to assist in specific farm situations is illustrated in a popular journal by Huheey (12). The article cites the work done by R. J. Becker of Arizona State University and Becker's earlier work at the University of Pennsylvania.

After describing what linear programming is and what it can and cannot do, Huheey reports the planning process using an actual farm situation. The necessary input-output data was collected by an on-the-farm visit lasting little more than an hour. Two staff members then developed the enterprise budgets in a matrix form. The types of activities and resource restrictions used are listed in Table 1.

From the table one can observe immediately that no capital restrictions or requirements are included. The assumption was made that capital would not be a limiting factor within the resource restrictions specified.

\*(12, p. 65).

This obviated the necessity of specifying capital requirements on the activities.

Realizing that the model was built for a specific farm problem, one can identify several shortcomings that would lead to unnecessary difficulties in interpretation and/or to additional computational work. First, the cropping activity units are divided between acre units and hundredweight units, depending upon whether the crop is sold or bought. Such a division requires that the program planner always reinterpret the results to the farm operator. Also, if additional solutions are sought with crop price changes, the producing and selling activities would require additional computational work to arrive at a new net price.

The same argument can be applied to the dairy cow activity if milk prices were to be varied. The inclusion of several milk and grain transfer rows and selling activities with the activities defined in conventional marketing units would simplify the interpretation of results and facilitate multiple price programming.

Huheey emphasized the small amount of time required to derive the necessary input-output data, build the model, and make the machine computation. The farm visit took 75 minutes, constructing the matrix took eight technical man-hours and the machine computation took 30 seconds. Considering the small number of alternatives considered and amount of technical labor to build the rather small model, one wonders at the possibility of increasing the efficiency further. Certainly if additional alternatives or price situations were to be considered, additional staff time would be necessary to rebuild a matrix. Staff time would also be necessary to interpret the results to the farm operator.

One additional factor was noted briefly, but no importance was given to it. With the Becker approach each problem solution requires that a new set of data cards be written and punched. In addition to requiring additional time, writing and punching data cards risks additional errors and consumes time.

The only way to avoid the time lost by punching, computing and checking errors would be a linear programming model that has already been punched and tested. Such a model would also eliminate much of the need for staff time to set up the necessary input-output data.

#### THE CASE FARM

The case farm selected for this study was not an actual situation, but rather was synthesized from several actual farm situations. The case farm is composed of a total of 360 acres. Out of the total acreage, 35 acres are in farmstead, roads and waste and 75 acres are in permanent pasture. The 250 acres of tillable land are divided into two basic productivity levels. The higher productivity soil is composed of 200 acres capable of maintaining row crops three years out of five. The remaining 50 acres of cropland can maintain row crops only one year out of five. Out of the total of 250 tillable acres, therefore, a maximum of 130 acres can be in row crops during any one year.

#### The Soil Association

The Ida Monona soil association was chosen for the case farm. These soils are found primarily in western Iowa.<sup>1</sup> Because this soil type has rather limited production potential and includes a relatively large amount of permanent pasture, the question may be raised why a more productive soil was not selected.

It was felt that, given the objectives of this study, a model containing several land classes with restricted cropping use would be more desirable. If a model can be developed to consider these land use restrictions, a model to consider fewer restrictions, such as might be found in more productive soil associations, would certainly be feasible.

Table 2. Seasonal labor supply for the case farm

#### The Labor Supply

The labor supply on the case farm was chosen to be typical of the supply on farms of similar size. Operator labor averaged 230 hours per month. However, it was also assumed that the operator would be willing to work longer periods during planting and harvesting seasons. Therefore, the operator labor supply was set at 260 hours per month during the peak labor periods.

Labor and capital constraints were formed for seasonal production periods. Table 2 indicates the seasonal labor supply used for this study. Any hired labor used on the farm was available at an hourly rate of \$1.50.

.

#### The Capital Coefficients

The capital coefficients for the case farm reflected all cash expenses to the farm business. The coefficients were also allocated into the same seasonal pattern as labor requirements. An annual requirement for breeding stock was also included for livestock raising activities.

If, in any production period, an activity required cash expenses, that amount of expense was defined as a capital requirement. If in the succeeding period additional expenses were required, only the additional expenses were defined as a capital requirement in the succeeding period. Similarly, when the activity was concluded, no additional coefficients were defined for succeeding periods.

It was assumed that the case farm had adequate grain storage and livestock facilities to accommodate the activities at any level at which they might enter. Therefore, no capital coefficients were specified for facilities other than the amount required for repairs to maintain them. Likewise, an adequate line of machinery was assumed to be available. The only machinery costs included in the capital coefficients were repairs and operating costs.

### Cash Accounting System

To assist in better describing the solutions obtained from linear programming, a system of cash accounting was defined. All capital expenses and receipts were divided into three categories--breeding stock investment, livestock purchases and receipts, and basic production expenses and receipts.

Investments in breeding stock were separated from livestock purchases because, in an ongoing business, breeding stock may be raised rather than purchased. Nevertheless, a definite investment in parent stock would be required to start production at a given time. In addition, breeding stock represent a relatively liquid asset. A single-value requirement was defined for each activity that included breeding stock.

The second category of capital accounts was livestock purchases and receipts. All livestock purchased and fed for resale required a cash outlay during the season purchased. By specifying the seasonal purchase cost of the livestock, the output report would list the seasonal cash outlay for all livestock purchases. Similarly, livestock receipts were credited to the capital account during the season of sale.

The third category of capital accounts--production expenses and receipts--included such items as seed, fertilizer, fuel, repairs and other variable costs related to the cropping program, as well as supplement costs, veterinary and medical expenses, and other variable expenses related to livestock production. Cash rental charges for land and hourly wages for hired labor were also defined as production expenses. Production receipts included all crop sales as well as rent payments from pasture land.

The output report would include a description of total breeding stock investment, seasonal livestock purchases and sales, and seasonal production expenses and crop receipts. It will be shown later how the cash accounting system was used with crop and livestock marketing activities.

Table 3. Crop rotation alternatives

Class I Land

Class II Land

C-O-M-M-M

#### Cropping Activities

The crop activities considered were defined in a crop rotation framework. Four different crop rotations were considered for the 200 acres of Class I productive land. Only one crop rotation was defined for the 50 acres of Class II land. To account for total crop production and to assist in accounting for the cash flow within the business, the crop activities included all variable costs for growing and harvesting the crops. However, the crops produced were not sold from each activity but rather were listed in a transfer row from which they could be either fed to livestock or sold at the market price. The crop growing and harvesting activities, therefore, all have negative net prices. The latter reflect the total variable costs associated with each activity. The crop rotation alternatives are listed in Table 3.

The soybean yield was assumed to be 28 bushels per acre, and corn yields were assumed to be 80 bushels per acre for the Class I land and 70 bushels per acre for the Class II land. Oat yields were assumed to be 50 bushels and 40 bushels per acre, respectively. Hay yields were three tons per acre and decreased 0.2 tons per acre for each additional year the land

ž

<sup>a</sup>Source (11,14,20,24).

 $b_{\mathrm{TWo}}$  bushels of oats is assumed to equal one bushel of corn equivalent.

remained in meadow. Table 4 lists the production coefficients for the cropping activities.

Two additional crop activities involved crop harvesting.<sup>1</sup> One activity was a corn silage harvesting activity that, in terms of costs and labor inputs, transferred corn grain out of storage and into corn silage. The activity does not realistically describe the physical production methods, but it is mathematically correct. The second activity was a hay baling activity, since the hay activity listed in Table 4 is only a growing activity.

The model was also constructed to allow for either renting additional crop or pasture land or renting out unused rotated or permanent pasture land at prevailing cash rental rates.

#### The Livestock Activities

The livestock enterprises considered in this model included beef cows, dairy cows, beef feeding and hog farrowing and/or feeding. One beef cow activity was considered, two dairy cow activities differing only in the feed rations used, seven beef feeding activities, two hog farrowing activities differing only in the farrowing periods, and six hog feeding activities differing only in their timing. The production coefficients for these livestock activities are given in Table 5.

Like the cropping activities, the livestock activities provide for neither the purchasing nor selling of livestock. Rather, only the variable production costs associated with that enterprise enter the C-row value.

<sup>&</sup>lt;sup>1</sup>See Appendix B.

For the beef cow activity, the calves produced were offered for sale or could be fed to market weight. Milk from dairy activities was offered for sale at the market price minus marketing costs. Likewise, for the beef and hog feeding activities, the purchasing and selling activities were separate from the feeding activities. All livestock marketing activities were in terms of hundred weight units and included the capital expenses or receipts discussed earlier. The complete list of marketing activities and their respective prices are listed in Table 6.

The marketing activities were defined separately from the growing and feeding activities so that 1) variable price programming for livestock activities would be facilitated since only the net price of the marketing activity would be changed from one solution to the next, and 2) the shadow prices (i.e., estimates of marginal value products and income penalties) would be reported in terms of commonly used marketing units.

#### Accounting Activities

Along with the marketing activities, other activities were added to give a fuller description of what the computed solution of the farm business organization actually contained. In terms of linear programming computation, these accounting activities could be thought of as purchasing activities with a zero net price. In recording the use of hired labor and capital, the activities purchased the inputs at appropriate wage and interest rates. Aside from activities that actually purchased an input, the accounting activities served no purpose in the computational procedures other than to make the printed output more informative. The list of accounting activities is given in Table 7.

The accounting activities were combined with a relatively new feature, the bounding device, of the computer program. Previously, no simple method existed to limit an individual activity within the model. The new feature allows the planner to place a minimum or maximum restraint on each activity without specifying a separate restraint row for each restraint imposed.

When this feature is combined with the accounting activities, the planner can specify nearly all of the restraints and desired enterprise levels merely by specifying an upper or lower bound on each activity.

As an example, the planner might desire that the final plan contain exactly 50 head of fed cattle, and that 20 of those should be steer calves on a silage ration. The planner would then specify an equality or fixed bound of 20 on the steer calf activity with the silage ration. The computing routine would first choose the 20 steer calves, then select the most profitable of all of the remaining fed beef activities to meet the requirement of the remaining 30 head.

With the availability of the bounding feature on each activity, it then becomes possible to use the linear programming model for partial optimization or complete budgeting.

The level of each activity can be specified in such a manner that no choices for optimization are left to the computational procedure. The advantage of doing the budgeting within the linear programming framework is that, unlike usual budgeting techniques, the marginal value product of resources and the income penalties of activities not in the solution are also computed.

#### Fixed Costs

Because one of the purposes in constructing the model was to provide a detailed description of the computed solution, it was decided to include the fixed costs for the farm in the model. Since fixed costs cannot be included with a production activity, the bounding feature of the model permitted the use of separate fixed cost activities. With a net price of \$-1.00, the fixed cost activities are simply bounded at the same upper and lower bound as the level of the fixed costs. Where all fixed costs are accounted for in the model, the computed value of the final solution, whether budgeted or optimized, becomes an estimate of net farm income. If the planner desired, he could also include additional fixed cost activities allowing for family living expenses. Income taxes, however, would need to be omitted or only roughly approximated. If income taxes were debited, the value of the computed solution would then be an estimate of the increment in capital available to start the next production period.

# The Annual Repeating Cycle

Several possibilities for defining the planning periods are available to a farm planner for use in linear programming. Traditionally, budgeting and linear programming applications to farm planning have used the one-year repeating cycle planning period. With this form of planning period, the optimum solution is reached immediately and, until some resource restriction changes, the organization of the farm is assumed to remain the same.

If one were to start with a beginning farmer and allow his business to change as the supply of resources increased, the single-year repeating

cycle could be used if the increase in capital from one solution were made available as a resource for the next problem. This method has its faults, however. If the increase in capital becomes irregular or large, the optimum business organization may shift erratically from one solution to the next, making the transitions in business organization difficult to interpret for an actual farm situation.

The computational procedure for more understandable business organization transitions is that of dynamic programming. This form of programming allows for multi-production period or multi-year planning periods in which the closing business organization is transferred directly to the beginning of the succeeding period. Such a programming model can describe more fully the transitions that occur as the business expands towards an optimum goal.

However, the dynamic model also requires a considerably larger inputoutput matrix to allow for the multi-period planning. For a dynamic model, defining and storing the amount of data necessary for the kind of master model intended in this study would require many times the effort needed for the present desired model. It was decided that at this time, the additional effort was not worth the additional benefit gained.

The planning model used, therefore, was the annual repeating cycle model. No attempt was made to estimate a value of beginning liquid assets. Rather, all capital used was simply accounted within the model. No attempt was made to allow for capital accumulation during the production cycle. Instead, all receipts and expenses were computed independently in the period in which they occurred. In other words, no capital restraints were specified.

One problem encountered with the repeating cycle model is that there

is no beginning and no end. Because livestock and crop activities overlap a twelve month period, there is no time when all production ceases. This situation corresponds to the actual circumstances on a typical grain and livestock farm.

### PRESENTATION OF RESULTS

The demonstration model was applied in four different situations on the case farm to test its potential use. An optimum organization of enterprises was sought first with labor, land and livestock facilities as the resource constraints. This optimization is referred to hereafter as Situation A. The only change made for the second optimization, hereafter labeled Situation B, was to raise feeder pig prices. The third and fourth optimizations, labeled Situation C and D respectively, were partial optimization problems in which hogs or beef cattle were either specified at fixed levels or not considered.

### The Printed Output

The tables of results given in this section illustrate the format of the printed output that ought to be used. This format is not now available with the linear programming routine being used at Iowa State University (13). However, because the format in which output is presented in this thesis had been developed for a linear programming routine previously used by members of the farm management staff, the assumption was made that a similar format could and would be developed for the present routine.

### Situation A

As stated above, the first situation analyzed was one in which labor, land, and livestock facilities were resource constraints. The resource and facility constraints for Situation A are given in Table 8. All of the constraints unique to Situation A were implemented by placing upper bounds on

Table 8. Resource and facility constraints for Situation A

activities rather than specifying B-column, or right-hand-side, elements.

It was assumed that capital would not be a limiting factor, given the other resource constraints. Similarly, it was assumed that labor would or could be hired only during the spring and fall seasons. The assumptions for labor were not meant to approximate a realistic labor supply, but rather were meant to test the potential size of the business with additional labor during the periods of typical labor shortage. The amount of additional cropland that could be rented was restricted to the amount the operator could manage with his existing machinery inventory.

The livestock facility restrictions were selected to approximate the buildings commonly found on many farms of similar size. The seasonal restrictions were placed on hog farrowing and feeding activities to keep hog production within the facility limitations during each season.

The optimum solution to Situation A is given in Table 9. The total computation time required for this optimization was 1.27 minutes.

The optimum solution shown in the table indicates that all of the operator labor was utilized, and labor was hired in both spring and fall. Since available hired labor was not fully used in the spring and fall, however, the report indicates that labor was not restricting in those two seasons. By contrast, Section 3 shows that the marginal value product of winter and summer labor is \$3.63 and \$5.23 respectively.

Section 1 of the output report shows that a total of \$54,875.14 was required for cash expense and livestock investment. Seasonal cash expenditures, livestock purchases, and livestock receipts describe the seasonal cash flow. By subtracting all cash expenditures within a season, excluding the yearly breeding stock investment, from all cash receipts, it can be

shown that only in the fall season are the cash expenses greater than the cash receipts. Thus, if all capital for cash expenses and livestock purchases were borrowed, the interest payments would be less than the amount that is charged in the model because capital would be borrowed for less than the full year. It should be noted that all cash receipts to the business during the year came from livestock sales, indicating that all crops were fed to livestock. No corn was bought but more than 200 tons of hay were purchased. Twenty-one acres of additional cropland were rented.

The description of the cropping program indicates that corn production dominated the cropping system, given the rotation constraints for the land. From Section 2 of Table 9 the income penalty for (growing and) selling one bushel of soybeans is \$0.53. This indicates that with the crop coefficients assumed the sale price of soybeans must increase by \$0.53 per bushel before soybeans can begin to compete with corn production. The minimum competing sale price of soybeans is also found in Section 3 in the soybean transfer row.

Similarly, there is an income penalty for either buying or selling corn. The income penalty for selling corn is \$0.13 per bushel. Therefore, the sale price of corn must increase by that amount before it becomes competitive with feeding the corn to livestock. One may conclude, therefore, that the marginal feeding value of corn is \$1.33 per bushel. Such a value, however, is greater than the purchase price of \$1.30 for corn, and yet there is a \$0.06 income penalty per bushel for buying corn. The apparent discrepancy is explained by the fact that there is a seven percent interest charge on all production expenses. This increases the cost of purchasing and feeding a bushel of corn to \$1.39. Subtracting the \$1.33 marginal

feeding value of corn leaves an income penalty of \$0.06 per bushel.

The marginal value product of both Class I and Class II land is given in Section 3 of the output report. It should be noted that the marginal value product of the Class I land is more than three times that of the Class II land. The farm planner could use these values to estimate the value of an additional acre of either class of land to the operator. By subtracting the annual fixed costs associated with each class of land and capitalizing the remainder at the desired interest rate, the break even purchase price could be determined for an additional acre of each class of land.

The advantages of the use of marketing activities is clearly evident in the description of the livestock program. The marketing activities in Section 1 account for the total weight of each type and grade of livestock bought and sold. Of more importance, however, are the marketing activities in Section 2.

The first livestock marketing activity reported in Section 2 is P071 (selling choice steer calves). The income penalty attached to this activity is \$3.88 per hundredweight. The income penalty indicates the reduction in net income that would have occurred if the operator had sold his steer calves after having once bought them. The reduction in net income is also the amount that must be added to the present selling price of choice steer calves to bring the selling price of choice steer calves in line with the buying price. As with the income penalty for buying corn, the income penalty for selling calves is composed of the difference in the selling and buying price and the interest charge on the purchase cost.

The income penalties for the sale of choice fed steers in the summer

or fall indicate the relative disadvantage of the two feeding systems associated with those two seasons. Although only one cattle feeding activity entered at the maximum level, Section 3 indicates that the marginal value product of feeding space for an additional steer is \$11.36.

The income penalty for selling 100 pounds of milk is \$0.67. Even though there is no income penalty associated with one of the dairying activities, the \$0.67 indicates that an increase of this amount in the price of milk would be necessary to make either of the dairying activities competitive. The minimum price of milk to make dairying competitive is then shown in the milk transfer row in Section 3.

Stated another way, the income penalty for milk sales indicates that with cows producing at the 11,000 pounds level, the income penalty per cow, on the margin, would be \$73.70.

The optimum solution also indicated that only two litters of hogs would be farrowed, but that 458 pigs would be fed. All the pigs that were not raised were purchased as feeder pigs. Given the production coefficients, the price relationships favored purchasing feeder pigs rather than raising them. Section 3 of the output report indicates the marginal value product of feeder pigs in five out of six of the feeding periods is \$38.52 per hundredweight.

# Situation B

The case farm was optimized again, using the same resource and facility restriction as in Situation A, but the purchase price of feeder pigs was raised from \$36.00 per hundredweight, or \$14.40 per head, to test if more hogs would be farrowed instead of purchased. To have an impact on the

profitability of purchasing feeder pigs the cost would need to be equal to or greater than \$38.52 mentioned above. A price of \$40.00 per hundredweight, or \$16.00 per pig was selected.

The advantage of using marketing activities with conventional units of measurement is illustrated by the price adjustment in feeder pigs. To raise the price to \$40.00 per hundredweight, the ten cards that included the prices for the sale or purchase of feeder pigs were taken from the input data deck and replaced with ten new cards specifying the \$40.00 price. No additional budgeting was necessary. Had conventional activity definitions been used in the model or had the original C-row value on marketing activities been stated in terms other than hundredweights, more work would have been required. The optimum solution is shown in Table 10. The total computation time was 1.31 minutes.

The results from Situation B reveal some of the interdependencies that occur in farm planning which are difficult or impossible to illustrate with budgeting alone. The increase in the price of feeder pigs decreased the number of feeder pigs purchased, increased the number of litters farrowed, and decreased the total number of pigs fed to market.

Along with the changes in the hog enterprise, beef cows were eliminated and total cash expenses and livestock purchases were reduced more than \$10,000. No additional cropland was rented, and the amount of labor hired was reduced. In addition, 33 acres of rotated pasture were rented out.

With all of the reductions in capital expenditures and livestock and crop production, net farm income was reduced by only \$290.78. This small income reduction for Situation B suggests that the additional capital required for Situation A was returning very little above the 6 and 7% borrow-

ing price.

The shift to hog farrowing increased the labor requirements during the winter and summer periods, forcing out beef cows and reducing crop production. The marginal value product of both winter and summer labor was also increased. In turn, the higher price on feeder pigs made baling hay unprofitable. Therefore, some rotated pasture was rented out while the hay requirements were purchased.

Two enterprises remained the same from Situation A to Situation B. First, corn production still dominated the cropping system on all land managed in Situation B. Second, the maximum number of long fed choice steer calves were still fed.

After optimizing the case farm under the two sets of price expectations in Situations A and B, two additional problems were specified in which either beef or hog production was fixed, and other enterprises were optimized within the added restraint of either a beef or hog activity forced in at a specified level. These two situations were intended to test the feasibility and usefulness of the model was a device for partial optimization.

# Situation C

Situation C was specified to maximize beef production under given facility constraints and to eliminate all hog production on the case farm. All resource and enterprise constraints for Situation C are specified in Table 11.

The livestock production constraints were specified by bounding the livestock accounting activities. Hired labor was not restricted to avoid

All constraints are the same as those listed 2005 Hours of winter labor hired 2006 Hours of spring labor hired 2007 Hours of summer labor hired	for Situation A e Level	<pre>ccept the following:    Type    No bounds    No bounds    No bounds    No bounds </pre>

Table 11. Resource and facility constraints for Situation C

the possibility of an infeasibility or a result of the forced level of beef production. However, if hired labor and capital were both unrestricted, land rental had to be constrained to avoid an unbounded solution. Therefore, no opportunity to rent either crop or pasture land was provided. The results from Situation C are given in Table 12. Total computation time was 1.11 minutes.

In comparing the results of Situation C with Situation A, the net income is \$2,614 less, but the total capital requirement is only \$3,395 less. Very little summer labor and no winter is hired. About a third of the corn grain crop is sold, and some corn silage was harvested. All of the meadow was pastured rather than harvested for hay.

The restraints on hay and dairy production are shown in Section 2 to be costly under Situation C. Adding a dairy cow would have increased income by \$87.98. Similarly, adding a litter of pigs would have increased income by \$29.39. Section 3 repeats the same information and, in addition, indicates that adding another beef cow would have decreased income by \$28.26. Forcing in all 50 beef cows in Situation C was not profitable.

Even with the emphasis on beef production, beef feeding facilities have a higher marginal value in Situation C than they do in Situation A.

In summarizing the partial optimization problem in Situation C, the most important comparison with Situation A is that the total resources required in Situation C are nearly as great as those in Situation A, but the income is considerably less.

Table 12. Optimum solution to farm Situation C

#### Situation D

The last model, Situation D, was structured so as to maximize hog production within the facility constraints while eliminating beef feeding. A beef cow activity was provided in the model but was not forced into the solution. The resource and enterprise constraints are specified in Table 13.

To make the data changes from Situation C to Situation D, no data within the matrix were altered. Instead, a new bounds section was substituted at the end of the data deck. Eighteen cards were substituted to specify both the new bounds and those that were unchanged from Situation C.

The results from Situation D are reported in Table 14. Total computation time was 1.15 minutes.

The total resource demands for the plan which results from Situation D are generally less than those required in Situation C. Labor requirements are slightly less while some winter operator labor is unused. Total capital requirements are reduced from \$51,389.82 to \$35,527.85. Almost half of the capital requirement in Situation D arises from breeding stock investment.

Corn production again dominated the cropping system, and about onethird of the crop was sold. Even though the total number of hogs fed equaled the number farrowed, the optimum plan specified selling the pigs farrowed in February and June as feeder pigs rather than finishing them for sale as slaughter hogs. Additional feeder pigs were purchased in December to feed during a period when unused operator labor was available.

The marginal value products of the facility and/or enterprise con-

straints indicate that all livestock enterprises are still profitable. Dairy cows have an especially high marginal value of \$125.12 per head. The beef feeding activity also shows a marginal income contribution of \$59.90 per head. It should be noted that the marginal value product of additional farrowing capacity is greater in Situation D than in Situation C, where no hogs were produced.

The increases in marginal income contributions are explained by the fact that in Situation C a considerable amount of rotated pasture was required to meet the needs of the beef animals. Producing additional pasture consuming livestock, including litters of pigs, would have forced some corn acres into rotated pasture. Additional pasture consuming livestock would be competing with corn production in Situation C but not in Situation D, where little pasture was needed.

## Application of the Model

The four situations programmed illustrate several unique applications of a linear programming model. In terms of solving individual farm planning problems, the use of the partially optimized or even a completely budgeted problem can serve at least two purposes.

First, the present organization of enterprises for the farm under study can be approximated with the model to determine a resource use and income base with which to compare optimized solutions. The bounding of particular individual activities, as shown in all four situations presented, would accommodate such an approximation of a business organization.

To optimize the same set of resources would only require replacing the data cards that restrict the various activities. None of the production

coefficients within the data deck need be disturbed.

The second application of the partial optimization model would be in comparing alternative business organizations to either the optimum organization or the existing organization of the farm business. If the optimum organization indicates an unsatisfactory return to capital or some other resource, the farm planner may be able to specify some alternative organization in which net income is reduced only slightly while the use of resources with a low marginal productivity are cut back substantially.

The relative ease of changing resource or activity restraints makes the model useful for a variety of farm planning problems. In addition to its potential use as a farm planning tool for individual farm situations, the model has potential in the classroom or extension situation in which farm organization principles are taught. Students can test various plans evolved by methods such as budgeting or even informed guesses against optimum resource use.

The description of total capital requirements and cash flow could also assist the farm operator in determining what his credit needs would be in each of the production seasons. Such a description could assist in acquiring additional credit in short period of capital limitations if it could be shown that the productivity of the additional capital warranted the extension of additional credit.

The use of the marketing activities defined in terms of commonly used units, especially with livestock, can assist the planner in better defining the prices that must be paid or received to equate the profitability of alternative livestock activities. These marketing activities eliminate much

of the additional hand budgeting formerly required to interpret the shadow prices from a solution.

.

## SHORTCOMINGS OF THE MODEL

Although the programming model illustrated in the previous chapter generally meets the original goals specified, there are several shortcomings that ought to be considered.

First, the capital used in each production period was charged a full year's interest, even though the capital may have been invested during only two or three periods. The original intent was to charge only the amount of interest due for the actual time the capital was required for each activity. However, to do so would have required capital profiles for each activity. Such an accounting system would have recorded the accrued amount of capital required in each activity for each season. Cash flow accounting would have been more difficult with the capital profile system, however. It was decided that an accounting of cash flow was more useful than the insights into the farm business provided by a more elaborate profile of capital needs. Because of the manner in which capital coefficients and capital supplying activities have been structured, however, the actual interest charge would be less than the cost of capital implied in the present model.

The second problem also involves the cash flow accounting system. Although the marketing activities for all commodities are defined in conventional marketing units and the net prices are easily changed, the accounting for the cash expenses and receipts for such activities is defined within the programming matrix. Therefore, when the net prices are changed, the cash expenses and receipts remain the same. The activity mix is optimized with altered net prices, but the expenses and receipts record

the original cost or sale price. The seasonal cash accounting activities become only approximations as the price expectations of the marketing activities deviate from those prices built into the cash accounting section of the matrix.

At this time, the only method visualized to deal with the cash accounting problem would be to add a computer program that would multiply the units of each marketing activity on the optimum solution times the net price of that activity. The product totals for each activity would then be added to the product totals of other marketing activities that occurred in the same season. These totals, in turn, would be the seasonal marketing receipts and expenses. Receipts and expenses computed in this manner would reflect variations in cash flow when variable price programming was used.

An additional problem encountered with the model was in the printed output. The income penalties for some activities not in the optimum plan were sometimes difficult to trace. Two examples are soybean and beef production.

Soybeans did not enter the solution in any of the four situations programmed. However, no income penalty for growing soybeans was printed for the crop rotation activity that included soybeans. Instead the income penalty was associated with marketing the crop. In this instance, the income penalty was easier to interpret than if it had been printed with the crop growing activity. Interpretation of the shadow prices for beef production was not as straightforward.

As an example, the printed output for Situation A showed that the maximum amount of beef cattle were fed. Section 2 listed the income penalties for the beef feeding activities that were not in the optimum plan. How-

ever, the only marginal value product associated with beef feeding given in Section 3 was for the total feeding capacity. No value was given to indicate which feeding activity would be the most profitable. The interpretation must be made that since a single feeding activity entered at the maximum level, that same activity would be the most profitable one to expand.

The conclusion is that, even though most of the desired information is given in the report, some additional interpretation may be necessary by someone who is familiar with linear programming techniques and interpretation of results.

Therefore, the printed output from each farm planning problem may not be satisfactory to send directly to a typical farm operator. It may always be necessary to include an additional written interpretation or to require a return visit by the planner to the farm being programmed.

# CONCLUSIONS AND SUGGESTED MODIFICATIONS OF THE MODEL

Through the development of the demonstration model and presentation of several problem situations, it has been shown that a linear programming model can be constructed to 1) leave the basic input-output data undisturbed from one farm situation to another, 2) formulate activity prices in such a manner that price expectations can be easily altered, 3) provide a readily interpretable descriptive output report for each solution, and 4) allow for partial optimization or complete budgeting of a given farm situation. To make this model more applicable to a variety of farm situations, several additional steps need to be taken.

The model constructed for this project needs additional production alternatives. The present model allows for only five cropping activities, eight beef raising and/or feeding activities, two dairy activities, and eight hog raising and/or feeding activities. To more accurately define the alternatives for a variety of farm businesses, a greater number of crop and livestock activities are needed. Most additional production activities would not require additional marketing activities since the present marketing activities define a wide variety of alternatives.

Production activities are needed to define different levels of management and production methods. Three levels of management should be defined within each production method. The farm operator and/or the farm planner could identify the historic or potential management level for each activity. Allowing for differences in management ability among enterprises would more closely approximate a farm operator's ability. Few farmers have the

same management ability for all crop and livestock enterprises.

In addition to increasing the number of production activities based on management levels and production methods, activities describing economies or costs of volume could be added, especially for partial optimization problems. If minimum levels of production are specified, activities that define increasing or decreasing costs of production would assist in more accurately describing input-output relationships.

After the model has been enlarged to include a satisfactory number of production methods with their associated management levels and increasing or decreasing costs, the next step should be to store all of the inputoutput data within a computer system in such a manner that any or all activities could be called out of storage for use in a farm planning problem. Storing the data in computer accessory would alleviate the many problems and potential errors associated with handling a large number of data cards. Solving a farm planning problem with computer-stored activities would then require four steps.

First, the resource restrictions would need to be defined for each farm by listing the B-column row number for each non-zero resource constraint and its associated value. Such resources as seasonal operator labor, acres of each class of land and tons of permanent pasture would be defined in this manner.

Second, the activities to be used for a farm planning problem would need to be called out of storage by punching the number of each activity desired on a data card. All activities not listed would not be considered as alternatives in solving the problem. Reducing the number of possible activities in this manner rather than bounding all unnecessary activities

at zero level would both reduce computation time and provide an output report that considered only the relevant activities.

Third, the price expectations would need to be defined if they were different from those stored with the input-output data. A set of price expectations would be provided within the stored data, but if the farm planner and/or operator desired some changes, those price expectations would need to be specified by listing the activity number, the C-row, and the changed price.

Fourth, all facility constraints and minimum or maximum levels of production would need to be specified by bounding the necessary accounting activities. Upper bounds would need to be specified to define the physical capacity of livestock or crop facilities. Lower or fixed bounds would need to be specified for minimum or fixed levels of production for partial optimization problems. In some instances it would be desirable to specify minimum or fixed levels of production of a specific production activity rather than of the accounting activity. All bounding would be done as it is with the present model. The program should be designed so that upon completion of each farm planning problem, all resources, selected activities, specified prices, and bounds would be erased before a new problem was encountered. There would be no chance of carrying restrictions or price expectations from one problem to another. Instead, each problem would be handled independently of any other preceding or following it.

After a satisfactory method has been developed to store the inputoutput data and select activities from it, the next step would be to design information sheets for the farm operator or planner to specify the necessary information to solve a planning problem. The sheets should be designed

in such a manner that the operator or planner would answer specific printed questions relating to resource constraints, activity selection, price expectations, and minimum, fixed, or maximum levels of production. The answers printed in the blanks following the questions could be copied on a second page with carbon paper. The second sheet, listing additional necessary column and row identification numbers, could be detached and used as a guide for punching the data cards. Such a system would help eliminate much of the intermediate work usually needed to translate information gathered on the farm to data sheets before card punching is done. An example of the type of information sheet described above is shown in Table 15.

Before such data sheets could be used, however, a master catalog would need to be printed identifying all stored activities by number and name and defining all production coefficients. From this catalog, the farm operator and/or planner could choose those activities desired as possible alternatives. In addition, the stored set of price expectations would be listed so the operator could decide whether he wanted to define a different set or select the stored set. The master catalog would be printed in much the same format as the present "Suggested Costs and Returns for Use in Farm Budgeting" but, of course, would contain much more detailed information (24).

- Suggested costs and returns for use in farm budgeting. Iowa State University Cooperative Ext. Serv. Bul. FM-1186. 1966.

### ACKNOWLEDGEMENTS

The assistance and encouragement received from Dr. Raymond Beneke is gratefully acknowledged. His patience and guidance were always appreciated.

The advice of Professors H. B. Howell and E. G. Stoneberg is also acknowledged. When several sample farms were programmed for use in the Extension Farm Management program, their suggestions proved to be invaluable in making the model more applicable.

Frequent discussions with fellow student Roger Selley concerning the defining of activities proved to be very helpful and saved considerable experimental time.

### APPENDIX A

# Description of the Monona-Ida-Hamburg Soil Association Area\*

The Monona-Ida-Hamburg soil association area covers about 2,900 square miles or 5 percent of the state. It extends from Plymouth County on the north to Fremont County on the south. It is most extensive in Woodbury, Monona, Harrison and West Pottawattamie counties but also occurs in parts of seven additional counties.

The topography of the area is characterized by narrow, gently-sloping ridges and steep side slopes which gradually change to well-defined alluvial valleys. Deeply entrenched streams and gullies are common in the alluvial valleys. In the Missouri River bluff area, very steep upland side slopes have eroded to form small natural benches called catsteps.

Nearly all upland soils of the area formed from thick deposits of loess which covered the rolling glacial till plain. Till-derived soils such as Shelby and Adair occur but are monor. A few areas of Malvern, a soil developed from Loveland loess, also occur. Silty materials eroded from the uplands formed the parent materials of the stream valleys.

The native vegetation was primarily prairie, although some small trees and shrubs grew on some steep east and north-facing slopes.

Monona, Ida and Hamburg are the major upland soils. Napier and McPaul are two of the major soils of the stream valleys.

Monona are well-drained soils that occur on the gently sloping narrow

\*Source: (20, pp. 55-58).

ridges and strongly sloping side slopes. Slopes of 5 to 14 percent are most common, but these soils do occur on slopes ranging from 1 to 30 percent. The surface layer is a very dark brown silt loam 8 to 14 inches thick. The surface layer is frequently partially or completely removed by erosion. The subsoil is a dark brown to brown silt loam. The substratum is silt loam loess which may be calcareous at depths of 30 to 100 inches.

Ida soils occur on narrow divides and steep side flanks on slopes of 6 to 30 percent. Slopes of 10 to 20 percent are common. They are calcareous throughout the profile and do not have B horizons. In uneroded areas, the surface layer is a very dark grayish-brown calcareous silt loam 6 to 10 inches thick. The substratum is yellowish-brown calcareous silt loam loess. In most cultivated areas, the surface layer has eroded away and the substratum is exposed.

Dow soils have surface layers which are similar to the Ida soils in color and texture but have calcareous olive gray silt loam substrata. They are monor soils in the area.

Hamburg soils occur on steep (30 to 60 percent) catstep slopes adjacent to the Missouri River bottomlands and along drainageways which outlet into the bottomland. They formed from thick, coarse loess with prairie the principal vegetation. They have a very thin calcareous, dark brown silt to silt loam surface layer over a substratum of calcareous, pale brown coarse silt loess.

Castana soils are forming from calcareous colluvial materials which washed or slumped down from the steep Hamburg and Ida soils. They occur on High upland footslopes primarily of 10 to 30 percent. They have very dark brown to very dark grayish-brown surface layers 20 to 24 inches thick that

are calcareous in the lower part. The substratum is a calcareous yellowishbrown silt loam.

Napier soils occur along upland drainageways and narrow streams and on footslopes. These well-drained soils occur on slopes of 1 to 10 percent. Napier soils have a very dark brown silt loam surface layer, 20 to 30 inches thick, and moderately permeable, dark brown silt loam subsoil and substratum. In some areas recent sediments have formed a layer up to 10 inches thick on the surface.

McPaul soils are forming from alluvial materials in stream valleys. They consist of 24 to 36 inches or more of light colored sediments over buried dark colored silty clay loam soils.

A moderately high percentage of this association is used for cultivated crops. The steep slopes, including the catsteps bordering the Missouri River valley and some of its main tributaries, are in permanent pasture. Some areas of shrubs and trees occur. Yields are low from both pasture and timber on these steep slopes.

The valleys, less steep side slopes and the ridges are usually cultivated. Some of the streams in the area have been straightened to permit cultivation of much of the valley land. Gullying is a serious problem throughout most of the association, as gullies enlarge rapidly and attain huge proportions. Nitrogen and phosphorous are commonly needed. Ida soils are especially deficient in available phosphorous. Lime is not generally needed since most of the soils are neutral or slightly acid. Gently sloping to sloping Monona soils are often acid and may need lime. The sloping soils of the area are very erosive and require terracing, contour listing and other soil conservation practices for adequate erosion control.
