## INFORMATION TO USERS

The most advanced technology has been used to photograph and reproduce this manuscript from the microfilm master. UMI films the text directly from the original or copy submitted. Thus, some thesis and dissertation copies are in typewriter face, while others may be from any type of computer printer.

The quality of this reproduction is dependent upon the quality of the copy submitted. Broken or indistinct print, colored or poor quality illustrations and photographs, print bleedthrough, substandard margins, and improper alignment can adversely affect reproduction.

In the unlikely event that the author did not send UMI a complete manuscript and there are missing pages, these will be noted. Also, if unauthorized copyright material had to be removed, a note will indicate the deletion.

Oversize materials (e.g., maps, drawings, charts) are reproduced by sectioning the original, beginning at the upper left-hand corner and continuing from left to right in equal sections with small overlaps. Each original is also photographed in one exposure and is included in reduced form at the back of the book. These are also available as one exposure on a standard 35 mm slide or as a $17^{\prime \prime} \times 23^{\prime \prime}$ black and white photographic print for an additional charge.

Photographs included in the original manuscript have been reproduced xerographically in this copy. Higher quality $6^{\prime \prime} \times 9^{\prime \prime}$ black and white photographic prints are available for any photographs or illustrations appearing in this copy for an additional charge. Contact UMI directly to order.

## CHAPTER 1. INTRODUCTION

One of the most important issues facing the Malaysian Government today is mounting population and unemployment pressures. Malaysia's population has been growing at 2.6 percent per annum, from a population of 10.9 million in 1970 to 13.9 million in 1980 and 16.5 million in 1987. The labor force however grew faster than population at 3.5 percent per annum, which has resulted in an increasing rate of unemployment from around 3 percent in 1970 to 5.7 percent in 1980 and 8.7 percent in 1987. The rate of unemployment is expected to increase further to 10.1 percent by 1990 (Government of Malaysia, 1987).

Since the New Economic Policy was formulated in 1970, the manufacturing sector is envisaged to play the pivotal role in creating new employment opportunities. Due to vigorous efforts to develop the industrial sector, manufacturing has become one of the fastest growing activities in the economy. However, there is a growing body of evidence to show that the growth of industrial employment is lagging behind the growth of output and exports (Hoffman and Tan, 1980; Young, 1980; Jomo, 1985).

As shown in Table 1.1 , despite fairly rapid rates of growth of output and exports, the rate of employment growth has persistently been relatively low. For example, in the boom years of late 1970 s the rate of growth of output and net exports reached double digit figures of 13 and 20 percent respectively. The rate of growth of employment for the same period was only 3.7 percent.

Table 1.1. Comparison of growth rates of output, net exports and employment in Malaysian manufacturing sector 1971-1987 (Government of Malaysia, 1974, p. 142; 1978, pp. 146147; 1984, p. 249.)

| Output | Net Exports | Employment |  |
| :---: | :---: | :---: | :---: |
| $1971-73$ | 16.1 | 18.8 | 9.5 |
| $1976-80$ | 13.0 | 20.0 | 3.7 |
| $1981-83$ | 4.9 | 17.1 | 2.2 |
| $1986-87$ | 12.5 | 14.3 | 6.2 |

In recent years, a voluminous literature has emerged attempting to explain this poor employment performance. Most of the research comes to the conclusion that the unemployment problem is multi-faceted and related to the structure of the economy. The consensus is that the problem of generating more employment opportunities involves a substantial redefinition of appropriate development strategies involving these fundamental and inter-related questions: Is there a conflict between increasing employment and accelerating growth? Which goods should be produced (output-mix problem)? How should capital and labor be used to produce final goods (choice of technique problem)?

The last question above has emerged as an important area for research and policy in LDCs. Many observers have felt that modern manufacturing techniques do not permit much substitution between labor and capital, and consequently that the ability of the manufacturing sector to absorb labor is quite limited. Others have pointed out, however, that imperfections in the factor markets might account for the relatively slow growth of manufacturing employment. Firms may have been encouraged to adopt capital - intensive techniques by macro and foreign trade policies that in fact subsidize the importation of machinery. Furthermore, capital subsidies in the form of $10 w$ interest rates and tax incentives, intended to attract investments from abroad, may have also the unwanted effects of stimulating capital - intensive production and encouraging excess capacity. Wage rates in the manufacturing sector have also been pushed up above the supply price of labor from the traditional sector by legislation on fringe benefits, shift differentials,
penalties on firing, and trade union pressures. It is likely that these factor market imperfections have affected the rate of labor absorption in the manufacturing sector. The central issue involved here concerns the degree of substitutability or the elasticity of substitution between labor and capital.

The Concept and Significance of the Elasticity of Substitution ( $\sigma$ )
The elasticity of substitution ( $\sigma$ ) is a technical parameter characterizing a production function (Nadiri, 1970). It is a measure of the ease with which any two inputs such as capital and labor can be substituted for each other. The elasticity of substitution is defined as the ratio of the proportionate change in factor proportions to the proportionate change in the slope of the isoquant or the marginal rate of technical substitution (MRTS). With the assumption of cost-minimizing behavior of firms, the marginal rate of technical substitution is equal to the ratio of factor prices. Thus, for a general production function of the form,

$$
\begin{gathered}
Q=f(K, L) \quad \text { where } K \text { is capital, } L \text { is labor and } Q \\
\text { is output, } \\
\text { cost minimization is shown by the Lagrangian function, }
\end{gathered}
$$

$$
{\underset{\min }{-}}_{\ell_{-}}=W L+R K+[f(K, L)-Q]
$$

Taking first partial derivatives and setting them equal to zero gives

$$
\frac{\delta \ell}{\partial \mathrm{K}}=\mathrm{R}+\mathrm{f}_{\mathrm{K}} \quad=0
$$

The marginal rate of technical substitution between capital and labor ( MRIS $_{K, L}$ ) is equal to the wage-rental ratio at the optimal point.

$$
\operatorname{MRTS}_{K, L}=\frac{\mathbf{f}_{\mathbf{L}}}{-\mathbf{f}_{\mathbf{K}}}=\frac{\mathbf{W}}{\mathbf{R}}
$$

The elasticity of substitution between capital and labor can thus be defined as

$$
\sigma=\frac{\text { \% change } \text { in }(K / L)}{\text { \% change in } M R T S_{K, L}}=\frac{d \log (K / L)}{d \log (W / R)}
$$

i.e., the proportionate change in factor proportions to a proportionate change in relative factor prices. Thus, for example, if the elasticity of substitution is 0.1 , then a 10 percent change in relative factor prices will bring about a one percent change in factor proportions (0.1 x 10). Graphically, when the elasticity of substitution is low a relatively large change in the wage-rental ratio from $(W / R)^{A}$ to $(W / R)^{B}$ will result in only a small change in the capital-labor ratio. Demand for labor increases from $L^{*}$ to $L_{1}$ while demand for capital decreases from $K^{*}$ to $K_{1}$ (Figure 1.1).

Figure 1.1: $\sigma$ is small

If on the other hand, the elasticity of substitution is 5.0 , then a 10 percent change in relative factor prices will bring about a 50 percent change in factor proportions. The high elasticity of substitution between capital and labor is depicted by Figure 1.2. An equal change in wage-rental ratio from $(W / A)^{A}$ to $(W / R)^{B}$ will cause a larger change of capital-labor ratio and result in an increase in demand for labor from

Figure 1.2: $\sigma$ is high
$L^{*}$ to $L_{2}$. In the case of fixed proportions, i.e., $\sigma=0$, then changes in the relative factor prices will not change factor proportions at all, as shown in Figure 1.3.

The elasticity of substitution ranges from zero to infinity. In the two-factor production function, a positive elasticity of substitution indicates that efficient factor substitutability is possible. Theoretically, when the elasticity of substitution is negative, it implies complementarity. In the two-factor case considered here, it is not

Figure 1.3: $\quad \sigma=0$
possible to maintain production and decrease the use of both inputs as would be implied by complementarity when wages are increased. For the neo-classical two-factor production function, negative elasticities therefore imply inefficiencies. Only when more than two factors are considered is it possible for complementarity to exist. However, at least two of the n factors must be substitutes.

Conceptually, the elasticity of substitution has a number of important policy implications. The elasticity of substitution is a measure of the ease with which any two inputs such as capital and laboi can be substituted for each other. If substitution between factors is relatively easy, then competitive firms will be induced to absorb increased employment by a relatively small reduction in the wage-rental ratio. It follows that knowledge of the values of the elasticity of substitution in industrial sectors and sub-sectors is not only useful for policymakers for changing the market signals to ensure greater labor absorption, but is also useful in identifying appropriateness of techniques that are being used. If the value of the elasticity of substitution is found to be near zero in a labor-surplus economy, then it is imperative to adopt a new technology with greater substitutability. Furthermore, encouraging labor-intensive industries through factor-price manipulations would be meaningless and costly if factor substitution is in fact low. It is therefore important to discuss the following questions concerning Malaysian industrial production;

1) Are elasticities of substitution between capital and labor significantly different from zero?
2) What conclusions can be drawn about the influence of policies from the experience of Malaysia's industrialization process?
3) What are the policy implications that can be derived from the results of this study?

Objectives of the Study
The principal objective of this dissertation is to provide an econometric analysis of the capital - labs: substitution possibilities in Malaysian manufacturing industries. Specifically, the objectives are:

1. To provide the theory, specification and the estimation procedures for the elasticity of substitution between labor and capital in Malaysian manufacturing industries using three different approaches, i.e., The Constant Elasticity of Substitution (CES) Production Function

The Translog Cost Function
The CES - Translog Cost Function
2. To discuss comparability of alternative estimates of the elasticity of substitution
3. To evaluate and draw policy implications from the empirical findings

The present study is organized as follows:
Chapter II presents a brief review of the relevant literature on the alternative approaches to estimating the elasticity of substitution. Chapter III presents the theoretical model, the appropriate estimation procedure and the interpretation of results based on the CES production function. Chapter IV provides the theoretical models, the estimation and interpretation of results based on the translog cost function and the CES - translog cost function approaches. Chapter $V$ provides a discussion of factors which may have influenced the choice of technique
in Malaysia. Conclusions and some policy implications are discussed in the final chapter.

CHAPTER II. REVIEW OF LITERATURE
Since the early 1970s the question of capital-1abor substitution possibilities in industrial production in developing countries has received widespread attention by policy makers and researchers. While most researchers focus on the question of appropriate factor proportions, other studies apply engineering or process analysis. Still others provide reports which do not offer precisely quantified estimates of the efficient production frontier. This last group of studies is referred to as anecdotal evidence. This review of literature will focus on factor proportions and the various ways of improvement on the methodology to measure the elasticity of substitution between labor and capital.

## Anecdotal Evidence

This category includes studies that discuss labor-capital substitution and other factors affecting technological choice but do not offer precisely quantified estimates of the frontier of efficient combinations; since the 1960 s anecdotal literature has grown tremendously. This form of literature offers useful insights into the problems of appropriate technology transfer to LDCs and point to the same conclusions as other studies. Some of this literature is reviewed below.

Stewart (1972) argued that multinational corporations are the major deterrent in appropriate choice of technology in LDCs, since they are tied to their capital-intensive technology in the developed countries. Efforts to change and adapt their technology to LDC conditions are costly and risky. They ignore the possibility of using local raw material
inputs. And, even if they are considering adaptations, they frequently pay higher wages than local firms and hence use less labor per unit of output.

Schumacher (1973), who first introduced the concept of intermediate technology and was the founder of the Intermediate Technology Development Group (ITDG), believed that developing countries need the kind of technology which is cheap, can be used without sophisticated technical or organizational skills and is associated with small-scale enterprises.

Costa (1973) suggested that, in order to compensate for their scarcity of capital and to provide jobs for rural populations, the developing countries should adopt labor-intensive methods. The laborintensive programs need to be flexible and constantly adjustable to changes in manpower ability.
R. S. Eckaus (1977) pointed out that the criteria of appropriateness of technical decisions depend on the goals of development. These criteria are concerned not only with income and quantities of outputs but also with the way outputs are produced and distributed. These. criteria for appropriate technology include maximization of net national output and income, maximization of availability of consumption goods, maximization of rate of economic growth, redistribution of income and wealth, regional development, promotion of political development and national political and social goals and improvement in the quality of 1ife. Technological choices, according to Eckaus, are affected by resource and product markets, taxes, and other regulations and policies.

As such, it is very difficult to achieve the most appropriate technology.

Ranis (1979) defined appropriate technology relative to society's resources and goals. Ranis emphasized institutional and social factors as well as prices as important in determining the choice of appropriate technology.

Wells (1984) argued that firms in LDCs choose inappropriate technolugy because decisions are made by the 'engineering man' and monopolistic firms. Engineering man tends to choose highly advanced capitalintensive technologies in order to produce high quality products. Monopolistic firms tend to adopt capital-intensive technologies because they can afford to pay for insurance coverage against risks.

Engineering or.Process Analysis Studies
In these kinds of studies, researchers investigate individual manufacturing processes or individual products in order to determine appropriate technologies. The investigators usually use engineering or other technical information to determine the inputs necessary to produce a given volume of products. A principal part of the investigation is to see if there are alternative means of producing a product; that is, if more workers and fewer machines (or simpler or cheaper machines) can produce more cheaply than fewer workers and more machines. Published evidence exists for only a dozen or so products and processes, a few of which are reviewed below. Such studies involve very high costs and are normally funded by international organizations.

Fong Chan Onn (1980) attempted to operationalize the analysis of appropiriate technology based on Eckaus's criterion for evaluating appropriateness in reference to the development goals of Malaysia. Using detailed engineering and cost data for the bicycle manufacturing industry, he concluded that Raleigh technology is not appropriate technology. He suggested that the most appropriate technology for bicycle manufacturing in Malaysia is an improved version of Chinese bicycle technology (with improvements in finishing and quality control).

Hill (1983) modified the neoclassical approach to the choice of technology. Using detailed cost data on four alternative techniques in the Indonesian weaving indusiry, he constructed a modified isoquant representing the capital and labor requirements for each technique. Hill then discussed the results and concluded that the Indonesian Government's policies (prohibition of the import of used machinery, exemption of the duty on imported machinery, an overvalued exchange rate) have encouraged the use of excessively capital-intensive techniques in the Indonesian weaving industry.

Timmer (1984) studied four alternative rice-milling processes and rice marketing systems in Indonesia. He found that the most capitalintensive technique required $\% 85,000$ investment per worker and the most labor-intensive technique requires only $\$ 700$ per worker.

Pack (1984) analyzed past choices of technology and present levels of productivity in the Philippines' cotton spinning and weaving industries. Detailed engineering and economic information was used to assess the costs of alternative technologies and to estimate the levels of
productivity relative to international standards of best practice. He then concluded that high costs of production are due both to inappropriate technological choices and low productivity in the use of the technologies chosen.

## Econometric Investigations

Since the seminal work of Arrow, Chenery, Minhas, and Solow (1961), a number of researchers have used LDC data to econometrically measure the degree of substitutability between capital and labor. The efforts have often involved measurements of the elasticity of substitution using a CES production function involving capital and labor inputs. Since the CES production function is nonlinear and cannot be estimated through ordinary least-squares estimation techniques and since data on capital is frequently not available or not considered reliable, an indirect method is used. Normally, the logarithm of value-added per worker is regressed against the logarithm of the wage. The coefficient of the latter is an estimate of the elasticity of substitution. Some studies regress the output-capital ratio against the return of capital (both in logarithms), or regress the capital-labor ratio against the wage (both in logarithms) to provide alternative estimates. These estimates have been made for both cross-section and time-series data (Diwan, 1965; Hoffman and Tan, 1980).

Behrman (1972) used estimating equations based on CES and semi-Cobb-Douglas production functions to measure sectoral elasticities of substitutions between capital and labor in Chile. Using the Koyck-Cagan-Nerlove adjustment process, Behrman concluded that the degree of
sectoral flexibility in response to factor price changes was limited in the Chilean case.

Lianos (1975) reported his estimation of the elasticity of the capital-labor substitution and the rate of technical change in the manufacturing sector of the Greek economy. Using the Cobb-Douglas production function with technical progress, four sets of substitution elasticity estimates were obtained; two time-series sets and two cross section sets. He found that the elasticity of substitution for Greek marufacturing industries exceeded unity, and the annual rate of neutral technical change was $\mathrm{e}^{0.05}(=1.05)$.

O'Donnell and Swales (1979) generated the elasticity of substitution for UK manufacturing industries by using a variant of the normal logarithmic transformation of the CES production function. Using pooled data and Maximum Likelihood estimation procedures, their 'best' estimates of the substitution elasticity for UK manufacturing industries ranged between 0.4 and 1.6 .

Claque (1979) modified the estimating equation to conform to a number of limiting assumptions for the Peruvian manufacturing sector. His estimating equation was a ratio of the Peruvian and the American situation which he regarded as the standard measure for comparison. He concluded that underdeveloped countries (Peru) buy the vast majority of their machines and technology from high-wage countries (USA). Furthermore, the capital-labor ratio was lower in Peru because Peruvian workers, being less skilled, cannot handle machines as well as American workers. More recent estimations of the elasticity of substitution
using the CES production function approach were based on Korean manufacturing data (Jae Won Kim, 1984) and Singaporean manufacturing data (Toh Mun Heng, 1985). The CES production function approach has also been applied in studying substitution betweren production labor and other inputs in the unionized and nonunionized American manufacturing sectors (Freeman and Medoff, 1982).

This review of the literature on the estimation of elasticity of substitution based on the CES production function- and its variants highlights two important issues, namely the statistical problems associated with cross-section and time-series studies of production functions and the choice of estimating equations. With respect to the first issue, time-series data usually reflect a dynamic adjustment due to a combination of factors such as changes in relative prices and external shocks, which are generally excluded in cross-section data. The time-series estimates are often biased because of simultaneity between the inputs and their prices (simultaneous equation bias) and mis-specification of adjustment lags between inputs and outputs, and the dominance of cyclical conditions -- like under-utilization of capacity.

The cross-section results are also plagued by certain conceptual and estimation problems. In a competitive market there is no reason for relative prices to differ among production units. Any observed differences in intrafirm managerial ability and consequently the individual production function is not identified. If the input differentials are due to differences in skill or in the quality of inputs, then cross-
section estimates of the elasticity of substitution will be biased towards unity (Gaude, 1975).

Attempts which have been made to remove the restrictive features of the CES production function have taken two forms: amendments to the CES production function and indirect estimation of the production function by formulating relevant cost functions (quadratic, Leontief, transcendental, Box-Cox) and other flexible functional forms (Diewert, 1971; Christensen, Jorgenson and Lau, 1973).

Lu and Fletcher (1968) provide an amendment to the CES production function. This is known as the Variable Elasticity of Substitution (VES) production function. Using this function, the invariance of the elasticity of substitution ( $\sigma$ ) to capital - intensity is tested by fitting the relation:

$$
\ln (Q / L) \cdots \ln a+b \ln (w / p)+c \ln (K / L)+e
$$

and the elasticity of substitution for this function is

$$
\sigma=\frac{1}{1+\rho-m_{p} / s_{k}}
$$

where

$$
\begin{aligned}
& \rho=[(1-b) / b] \\
& m_{p}=[c /(1-b)] \\
& s_{k}=\text { the share of capital }
\end{aligned}
$$

## Applications of Duality Theory

In recent years, the application of the duality theory has become increasingly popular among economists in applied economic analysis. This is because tie methodology not only allows researchers greater flexivility in the specification of factor demand and output supply equation, but also permits a very close relationship between economic theory and empirical practice. Furthermore, there are a number of advantages in estimating the elasticity of substitution by the cost function approach. Firstly, the multicollinearity problems which are inherent in the production function approach due to high correlation between inputs are less severe, because prices are formed in separate factor markets. Secondly, the elasticity of substitution is linearly related to the estimated parameters and thus their econometric properties are well defined. Finally, no matter what the properties of the production function are, the dual cost function is always linearly homogeneous in prices and, as a result, the estimating procedure is more general.

Several functional forms have been used to estimate the cost function. They are the Cobb-Douglas (CD), the Constant-Elasticity of Substitution (CES), the Generalized Leontief (GL), the Generalized Box-Cox (GBC), the Fourier Flexible Form and the Transcendental Logarithmic (translog) Form (TLC).

The translog cost function approach is the most popular functional form that has been used to analyze factor substitution in manufacturing sector (Berndt and Christensen, 1973; Halvorsen, 1977; Wills, 1979;

Rushdi, 1982; Tsao Yuan, 1985). The translog cost function approach has also been used to study energy substitution effects (Berndt and Wood, 1975; Fuss, 1977; Vashist, 1985), factor substitution and technical change in the agricultural sector (Binswanger, 1974; Lopez, 1980; Ray, 1982) and other branches of economics such as natural resources (Halvorsen and Smith, 1986) and labor economics (Freeman and Medoff, 1982).

Berndt and Wood (1975) used a transiog cost function to test for price elasticity and the elasticity of substitution of capital, labor, energy and raw material inputs in US manufacturing for 1947-1971). By using the iterative 3-stage least-square procedure (13SLS) on timeseries data, Berndt and Wood have been noted as pioneers in effectively providing statistical procedures which meet the translog restrictions of equality, symmetry, homogeneity, and concavity.

Griffin and Gregory (1986) attempted to improve Berndt and Wood's work by applying a similar translog methodology to a pooled international data for manufacturing. They concluded that their model provided a reasonable long-run alternative to the time-series model. Pooled data however require the use of a weighted least-square procedure which may result in simultaneous-equation bias and specification error problems in the estimation of a translog cost-function.

The development of literature of the cost-function approach has taken two trends: (a) application of the translog cost approach and (b) further testing and development of improved functional forms and improved data-specifications. Vashist (1985) applied the translog cost
function approach to estimate the substitution possibilities and price sensitivity of energy demand in Indian manufacturing for the period 1961-1970, following a similar procedure as Brendt and Wood. Tsao Yuan (1985) similarly applied the translog cost function to estimate factor substitutability in the Singaporean manufacturing industries.

Most recent literature proposed alternative ways to measure the Allen Elasticities of Substitution (AES). These include Pollack, Sickles and Wales (1984); Elbadawi, Gallant and Souza (1983); and Jae Wan Chung (1987).

Pollack, Sickles and Wales (1984) proposed and estimated a new single product cost function, called the CES-translog cost function. Like the translog, it is a flexible functional form, but if is compatible with a wider range of substitution possibilities than either the CES or the translog. As the name suggests, the CES-translog includes both the CES production function and the translog cost function as special cases and thus permits nested testing using conventional statistical techniques. Using the same time-series data used by Berndt and Wood (1975), they estimated the new CES-translog function to the US manufacturing sector and concluded that it was significantly superior to the transiog. The CES-translog function, however, must satisfy additional restrictions of regularity conditions globally, which were not tested in this paper.

Elbadawi, Gallant and Souza (1983) digressed from using the translog cost approach in their estimation of price and substitution elasticities. They explored the possibility of estimating the
elasticities using the Fourier flexible form with commonly used statistical methods: multivariate least-squares, maximum likelihood (MLE) and three-stage least squares (3SLS). They concluded that the elasticities can be estimated consistently without a priori knowledge of functional form provided the number of fitted parameters were chosen adaptively by observing the data. The number of fitted parameters must increase as the number of observations increases. However, credibility of their estimates has not been tested for negative-semi-definiteness of the Fourier flexible form.

Jae Wan Chung (1987) estimated elasticities of substitution via a truncated, single translog cost-share equation. Jae attempted to make comparisons and to reconcile elasticity estimates using different methods of estimation, differing data and observations and under differing assumptions.

This section has summarized the available literature on the possibilities of capital-labor substitution in the manufacturing sector. Each subsection has presented the development of different aspects of evidence, encompassing anecdotal literature, engineering or process analysis studies and econometric analysis.

The focus of this dissertation is the study of capital-labor substitution possibilities in Malaysian manufacturing sector through different types of econometric analysis which will be dealt with in Chapters III and IV, respectively.

CHAPTER III. CAPITAL-LABOR SUBSTITUTION IN MALAYSIAN MANUFACTURING USING CONSTANT ELASTICITY OF SUBSTITUTION (CES) PRODUCTION FUNCTION APPROACH

## Methodology

- The Arrow - Chenery - Minhas - Solow or the CES production function has been well received and extensively analyzed since its introduction in 1961 (Arrow et al., 1961), both theoretically and empirically. The CES production function is given by

$$
\begin{equation*}
Y=\gamma\left[\delta K^{-\rho}+(1-\delta) L^{-\rho}\right]^{-v / \rho} \tag{3:0}
\end{equation*}
$$

where $Y$ is output, $K$ and $L$ are factors of capital and labor, and $\gamma, \delta$ and $\rho$ are constants denoting efficiency, distribution and substitution parameters. $\nu$ denotes the degree of homogeneity. With assumptions of perfect competition in both commodity and factor markets and constant returns to scale, the CES production function is

$$
\begin{equation*}
Y=\gamma\left[\delta K^{-\rho}+(1-\delta) L^{-\rho}\right]^{-1 / \rho} \tag{3:1}
\end{equation*}
$$

The elasticity or substitution is derived from the marginal products of labor and capital, respectively.

$$
\begin{align*}
& \frac{\delta Y}{\delta L}=\gamma(1-\delta) L^{-\rho-1}\left[\delta K^{-\rho}+(1-\delta) L^{-\rho}\right]^{-1 / \rho-1}  \tag{3:2}\\
& \frac{\delta Y}{\delta K}=\gamma(\delta) K^{-\rho-1}\left[\delta K^{-\rho}+(1-\delta) L^{-\rho}\right]^{-1 / \rho-1} \tag{3:3}
\end{align*}
$$

In competitive equilibrium, the marginal rate of technical substitution MRTS $_{K, L}$ equals the factor price ratio. Thus,

$$
\begin{equation*}
\text { MRTS } \left._{K, L}=\frac{(1-\delta)}{\delta} \frac{K}{L}\right]^{1+\rho}=\frac{W}{R} \tag{3:4}
\end{equation*}
$$

The elasticity of substitution is defined as

$$
\begin{aligned}
\sigma & =\frac{\text { \% change in }(\mathrm{K} / \mathrm{L})}{\text { \% change in } \mathrm{RRTS}_{\mathrm{KL}}} \\
& =\frac{\mathrm{d} \ln (\mathrm{~K} / \mathrm{L})}{\mathrm{d} \ln \mathrm{MRTS}_{\mathrm{KL}}}
\end{aligned}
$$

From (3:4)

$$
\begin{align*}
& \ln \text { MRTS }_{\mathrm{KL}}=\ln \left(\frac{1-\delta}{\delta}\right)+(1+\rho) \ln (\mathrm{K} / \mathrm{L}) \\
& \left.\ln (K / L)=\frac{1}{1+\rho} \ln (K / L)-(-\cdots) \ln \frac{1-\delta}{1+\rho} \frac{1-\infty}{\delta}\right] \\
& \frac{d \ln (K / L)}{d \ln \operatorname{MRTS}_{K L}}=\sigma=\frac{1}{1+\rho} \tag{3:5}
\end{align*}
$$

For $\sigma>1$, an increase in the $\mathrm{MRTS}_{\mathrm{KL}}=\frac{\mathrm{W}}{\mathrm{R}}$ by 1 percent implies that the capital - labor ratio ( $\mathrm{K} / \mathrm{L}$ ) will increase by more than 1 percent. This means a small increase in the wage - rental ratio will lead to a relatively large reduction in the demand for labor resulting in greater unemployment.

## The theoretical and empirical model of the elasticity of substitution

## under perfect competition

Statistical estimation of the elasticity of substitution cannot be derived directly from equation (3:1). Furthermore, since data on capital stock in Malaysia are questionable, an indirect method following Ferguson (1965) is used to derive the estimating equations without using the capital stock data. Starting with the CES production function,

$$
\begin{aligned}
Y & =\gamma\left[\delta K^{-\rho}+(1-\delta)_{L}^{-\rho}\right]^{-1 / \rho} \\
\text { Let } y & =Y / L
\end{aligned}
$$

Then $y=\gamma\left[\delta\left(\frac{K}{L}\right)^{-\rho}+(1-\delta)\right]^{-1 / \rho}$

Raising both sides of equation (3:6) to the $\rho$, we obtain

$$
\begin{align*}
& y^{\rho}=\gamma^{\rho}\left[\delta\left(\frac{K}{L}\right)^{-\rho}+(1-\delta)\right]^{-1}  \tag{3:7}\\
& \left.y^{\rho} \cdot \gamma^{-\rho}=\left[\frac{K}{L}-\frac{K}{L}\right)^{-\rho}+(1-\delta)\right]^{-1} \tag{3:8}
\end{align*}
$$

Assuming competitive equilibrium, where the value of the marginal product of labor equals the wage rate, we have

$$
\begin{equation*}
\left.\frac{\delta Y}{\gamma_{L}}=W=\gamma(1-\delta) L^{-\rho-1}\left[\frac{K}{L}-\frac{K}{L}\right)^{-\rho}+(1-\delta)\right]^{-1 / \rho-1} \tag{3:9}
\end{equation*}
$$

Substituting equation (3:6) into equation (3:9),
$\left.W=y(1-\delta)\left[\gamma(--)^{\mathrm{K}}\right)^{-\rho}+(1-\delta)\right]^{-1}$

Then, we substitute equation (3:8) into (3:10) and we get

$$
\begin{align*}
W & =y(1-\delta) y^{\rho} \cdot \gamma^{-\rho}  \tag{3:11}\\
& =(1-\delta) y^{1+\rho} \gamma^{-\rho} \tag{3:12}
\end{align*}
$$

Transforming,

$$
\begin{equation*}
y^{(1+\rho)}=W^{\rho} \rho_{(1-\delta)^{-1}} \tag{3:13}
\end{equation*}
$$

Taking the logarithm of equation (3:13), and dividing by ( $1+\rho$ ), and transforming, we get
$\left.\ln y=\left(-\frac{1}{1+\rho}\right) \ln (1-\delta)^{-1}+\frac{1}{1+\rho}\right) \ln W$
$\ln y=\sigma_{1} \ln \gamma^{\rho}(1-\delta)^{-1}+\sigma_{2} \ln W$

In equation (3:15), the efficiency parameter is considered a constant. However, if we assume that the technology becomes more efficient through time, then the production function will be shifted upwards in a neutral way. To show this change in technology, the efficiency parameter can be written as

$$
\begin{equation*}
\gamma=e^{\lambda t} \tag{3:16}
\end{equation*}
$$

where $\lambda$ indicates the rate of neutral technical progress.

Replacing the value of $\gamma$ in equation (3:13) we have

$$
\begin{equation*}
y^{(1+\rho)}=W\left(e^{\lambda t}\right)^{\rho}(1-\varepsilon)^{-1} \tag{3:17}
\end{equation*}
$$

Proceeding the same way as before,

$$
\begin{equation*}
\ln y=\left(-\frac{1}{1+\rho}\right) \ln W+\left(-\frac{\rho}{1+\rho}\right)^{\lambda t}-\frac{1}{1+\rho} \ln \ln (1-\delta) \tag{3:18}
\end{equation*}
$$

Equation (3:18) can now be written as

$$
\begin{equation*}
\ln (Y / L)=a_{1}+a_{2} \ln W+a_{3} t \tag{3:19}
\end{equation*}
$$

where

$$
\begin{aligned}
& a_{1}=-\left(-\frac{1}{1+\rho} \ln (1-\delta)\right. \\
& a_{2}=\text { estimate of the elasticity of substitution }=\binom{1}{1+\rho} \\
& a_{3}=\left(\begin{array}{l}
\rho \\
1+\rho
\end{array} \text {, which. permits the estimation of } \lambda\right. \text { once we } \\
& \text { have estimated } \rho \\
& =\left(-\frac{a_{3}}{1-\sigma}\right) \text { is the annual rate of technical progress } \\
& \text { [Note } \rho=\frac{1}{-\quad-1]} \\
& \left.\lambda=\frac{\left(-a_{3}\right.}{1-\sigma}\right) \\
& \text { Y/L = output per unit of labor } \\
& \mathrm{W} \quad=\text { wages and salaries }
\end{aligned}
$$

# Data, Estimation and Discussion of Results for CES <br> Production Function 

This section consists of discussion of the data base, the operational definition of variables, the estimation procedure in the calculation of the elasticity of substitution and a discussion of results of the estimation of the CES production function in Malaysian manufacturing industries.

## Sources of data and measurement of variables

The data required for the estimation of the CES production functions are reported in the Censuses/Surveys of Manufacturing Industries, West Malaysia, for the period 1963 to 1976 , and the industrial surveys of Malaysia for 1978 to 1984. Consistency of time series data was achieved for the 5-digit Malaysian industrial classification by focusing only on West Malaysia. Since the industrial surveys of Malaysia report revenues and expenditures, the value-added figures for 1982,1983 and 1984 were obtained directly from the Manufacturing division, Department of Statis:ics, Malaysia. Furthermore, missing observations for 1977 and 1980 for all reported industries were estimated using the linear interpolation method by fitting the average of the two intervening years. An attempt was made to estimate the missing values using the zero-order interpolation method, i.e., by fitting in the missing values for 1977 and 1980 by their forecasted values. This is carried out for 10 industries as a test of whether zero-order interpolation will produce better results. Since it made little difference to the results, the final estimation was based on the first method, whereby, given $Y_{t}$ and $Y_{t+2}$
then $\quad \hat{y}=-Y_{t+2}-Y_{t}$
2
and $Y_{t+1}=Y_{t}+T \hat{y}$

For each industry, the data required for estimation are as follows: value-added in current Malaysian Ringgit (VA), wages and salaries (W), labor (L), time (T), Consumer Price Index (CPI) and Industrial Production Index (IPI). The number of workers is calculated as full-time plus half of part-time workers. No attempt is made to construct the Divisia quality index of labor because the data on hours utilized per person and educational attainment of labor in each 5-digit classification industry groups are not available in the Surveys/Censuses of Manufacturing Industries of Malaysia. Estimated adjustments may result in inconsistent time series. The construction of the Divisia Quality index of labor is based on the stock of labor as measured by persons engaged, adjusted for effective hours per person, and changes in the composition of labor by educational attainment, age distribution and sex composition of the labor force (Christensen and Jorgenson (1970), Feldstein (1967)).

The concept of wages and salaries includes the total wage bill of the establishments as reported. In addition, output is measured as value-added. Consequently the treatment of intermediate input is concealed. There is an implicit assumption that the share of intermediate input in gross output is nearly constant, which can be interpreted as that the elasticity of substitution between intermediate input and value-added is zero. Gross sales is excluded because detailed
experimentation with Philippine manufacturing data by Sicat (1970) led to the conclusion that it matters little whether gross sales or valueadded is used to measure output. Furthermore, value-added is the normal measure for output (Ferguson, 1965; Sicat 1970; Behrman, 1972; Jae Won Kim, 1984).

Estimation of the CES production function, elasticity of substitution and technical change under perfect competition

The estimation of the elasticity of substitution implies an analysis of the production function and its translation into an estimating form as shown by equation 3:19. The estimating form of this concept correlates labor productivity ard the real wage rate. The former is explained by a number of variables such as technical progress, scale of output and changes in the wage rate. For example, the expansion of output would tend to lead to a further division of labor and to a higher labor productivity because of internal and external economies which depend on the structure of final demand, the "state of the art", supply of labor and other resources and the existing organization of the industry.

A series of regression equations were fitted to time-series data 1963 - 1984 for fifty 5-digit industry groups in the Malaysian manufacturing sector. The first series of equations (Models A1 - Al2) were applied to equation ( $3: 19$ ), to determine the elasticity of substitution between capital and labor based on competitive conditions in commodity and factor markets.
[MODEL A1] $\frac{V A}{\ln (---)}=a+b_{1} \ln W_{t}+b_{2} T+\varepsilon_{t}$
[MODEL A2] $\frac{\text { VA }}{\ln (---)}=a+b_{1} \ln W_{1}+b_{2} \ln T+\varepsilon_{t}$
$\begin{array}{ll}\text { [MODEL A3] } & \ln (-\underset{L}{\text { VA }}) \\ & =a+b_{1} \ln W_{t}+b_{2}(\text { IPI })\end{array}+\varepsilon_{t}$

[MODEL A5] $\underset{L}{\ln (-\underset{L}{\text { VA }}}=a+b_{1} \ln (-\underset{\sim}{W})+b_{2} \ln T+\varepsilon_{t}$
[MODEL A6] $\frac{\ln \left(-\frac{R V A}{L}\right)}{\mathrm{L}}=\mathrm{a} \quad \mathrm{b}_{1} \ln \left(-\frac{\mathrm{RW}}{\mathrm{L}}\right)+\mathrm{b}_{2} \ln \mathrm{ln}+\varepsilon_{\mathrm{t}}$

$$
+b_{3} \ln T+\varepsilon_{t}
$$

$\begin{aligned} {\left[\text { MODEL A10] } \ln \left(-\frac{V A}{L}\right)\right.} & =a+b_{1} \ln (\underset{L}{W})+b_{2} \ln \left(-\frac{V A}{L}\right. \\ & +b_{3} \ln (W)+b_{4} \ln T+\varepsilon_{t}\end{aligned}$

$$
+b_{3} \ln T+b_{4} \ln T^{2}+\varepsilon_{t}
$$

[MODEL A12] $\frac{\mathrm{VA}}{\mathrm{L}}(-\mathrm{H})=a+b_{1} \ln W_{t}+b_{2} \ln W_{t}$ $+b_{3} \ln T+\varepsilon_{t}$
where
$v_{A}=$ value added in current value
$\mathrm{L}=$ number of workers
W = wages and salaries in current value
I = time
RVA = value-added deflated with Consumer Price Index (CPI)
RW = wages and salaries deflated with CPI
IVA $=$ value-added deflated with Industrial Production Index (IPI)

IW = wages and salaries deflated with IPI
$\varepsilon_{t}=$ error term

Using the Time-Series Processing Package (TSP), models A1, A2, and A3 were estimated by Ordinary Least Squares (ols) for fifty 5-digit Industry groups in the Malaysian manufacturing sector. The initial results show a number of problems including serial correlation, multicollinearity, and negative signs for the elasticity estimates in a large number of industry groups. Multicollinearity in Model A2 is, however, not serious. For most industry groups the elasticity estimate is significant and the covariance matrix between the dependent and independent variables is less than 0.5 .

Models A1 and A3 are excluded because the coefficient of determination, $R^{2}$, is as low as 0.003 for a number of industries. Furthermore, the elasticity estimate is negative in forty-one out of fifty industry groups.

The next procedure is to test for the aptness of the OLS to be applied to the Malaysian data. A rigorous residuals test is carried out to determine linearity of the regression functions, constancy of variance, and normality of error terms as well as the presence of outliers, based on Model A2. These tests are carried out to ensure that the assumptions of the OLS are not violated. Scatter diagrams and plots of overall residuals against the explanatory variables and the dependent variables, the logarithm of value-added per worker and the logarithm of time are examined. Although there are some outliers outside two standard deviations from the mean, it was concluded that OLS will give efficient estimates of the elasticity of substitution between capital and labor for the 5-digit industry groups in the Malaysian manufacturing sector.

The next procedure was to fit OLS to models A4, A5, A6, A7, A8, A9, A10, All and A12. Model A5 is an adjustment of model A2, whereby the logarithm of value-added per labor is regressed against the logarithm of wages and salaries per labor and the logarithm of time. Models A4 and A6 are replications of models A2 and A5 using data which are deflated by the consumer price index (CPI). Similarly, model A9 is a replication of model A5 with data which are deflated by the Industrial Production Index (IPI). Attempts to check for nonlinearity effects were
made by fitting quadratic models All and A12. The Partial Adjustment Model A7 and Serial Correlation Model A10 were fitted to see whether there would be improvements in the results of the previous regression models. Finally a search procedure was carried out to determine the best fitting models.

## Discussion of empirical results

There are a number of conceptual and data problems connected with the estimation of the elasticity of substitution using the CES production function. First, the classical procedure of estimation assumes an exogenous determination of the wage rate. If the wage rate is not exogenously determined, the CES procedure yields a biased and inconsistent estimate of the elasticity even if returns to scale are constant and the wage rate is equal to the marginal product of labor. The exogenous determination of the wage rate is more likely to be a more relevant assumption for an international sample than for an aggregate time series within a single country (Feldstein, 1967). Secondly, the data are assumed to represent points on the production frontier; that is, all firms are assumed to have adjusted fully to the prevailing factor prices within the observation period. Thirdly, no attempt is made to allow for variations in capacity utilization, or for fluctuations in the level of economic activity. In time series analysis, much of the variation in value-added may be attributed to different rates of capacity utilization over a business cycle. Furthermore, during the period 1963 - 1984, a mild recession occurred in 1972 and a stronger one after
1980. This would impart a downward bias to the estimate of the elasticity of substitution, attributed to changes in the quality of labor services. Theoretically, in recession years, an increase in unemployment is normally accompanied by an increase in the quality of labor services since the more efficient workers will be retained. Thus valueadded per worker tends to increase during periods of recession. Hence, the estimate of the time-series elasticity of substitution may be biased to some unknown extent.

Leaving aside the data and estimation problems, which are always present to a greater or lesser degree in any einpirical work, evaluation of these results hinges on the causality between wages and capital labor ratios. If there is evidence to show that capital - labor ratios are sufficiently flexible and that entrepreneurs do respond to factor price incentives, then the results of the regressions provide support for the view that making capital cheaper relative to labor tends to cause factor substitution toward greater capital-intensity. In the Malaysian manufacturing sector, an average of $67.5 \%$ of local and foreign entrepreneurs applied for tax incentives, especially pioneer status, between 1974-1984 (MIDA, Annual Reports). This gives some credence to the view that Malaysian entrepreneurs do respond to factor price incentives.

Models Al - A12 are fitted to time series data covering 35 5-digit Malaysian manufacturing industries over the period 1963-1984, 5 industries over the period 1968-1984, and 10 industries over the period 1970-1984. The statistical search procedure shows Models A2,

A5 and A6 as best fitting models to estimate the elasticity of substitution in Malaysian manufacturing industries. The results of models A2, A5 and A6 are given in Table 3.1.

Model A6 is finally chosen as the best regression equation based on both statistical and conceptual considerations. All three models are subjected to autocorrelative disturbances and are corrected using the AR(1) meťhod (Cochrane and Orcutt 1949).

The $A R(1)$ method provides efficient estimates of an equation whose disturbances display first order serial correlation; that is, $u(t)=e(t)$ + rho\% $u(t-1)$ (Rao and Griliches, 1969). This method estimates rho from ordinary least squares residuals, transforms the dependent and independent variables so that the residuals from the transformed equation will be roughly serially uncorrelated, and then runs a regression using the transformed variables. This process is repeated until rho converges or a maximum number of iterations is reached. The Cochrane - Orcutt procedure is asymptotically equivalent to the maximum likelihood procedure (Beach and MacKinnon, 1978).

In model $A 2$, the regression estimated is

Except for seven industries, the coefficient of determination, $\mathbf{R}^{\mathbf{2}}$, is very high and highly significant. The logarithms of wages and salaries explain the greater amount of total variation in value-added in fifty-two industries. There is however serious multicollinearity in thirty-eight industries, including tobacco manufacturing, sawilling, cement and concrete manufacturing, and others. As seen in Table 3.1, 2 the $R$ ranges between $0.28-0.98$. However, the $t$-ratios for a majority of industries, as shown in Table 3.1, are very low, and none of the partial regression coefficients is individually statistically significant. It is suspected that with time series data for 1963 - 1984 , both valueadded per employee and wages and salaries are moving in the same direction. One way of optimizing this dependence and correcting for multicollinearity is by transforming the explanatory variables. The logarithm of value-added per worker can be regressed against the logarithm of wages and salaries per worker and the logarithm of time as shown in Model A5.

Model A5 shows a great improvement in the results. The coefficient of determination $\mathbf{R}^{2}$ is still statistically significant. However, it is not as high as in Model A2. Based on conventional t-statistics, the partial regression coefficients are statistically significant at $5 \%$ significance level in 42 industries.

Ner love (1967) and others have shown that when wages are not highly negatively correlated with prices, failure to deflate data on output and
wages will tend to bias upwards the estimated elasticity of substitution. Furthermore, if time series data are undeflated in an inflationary situation, variations in the rate of inflation will result in further bias of the estimates of the elasticity of substitution upwards. In an attempt to reduce such potential sources of bias, Model A5 was reestimated, by Models A6 and A9, respectively. Model A6 is

where (-- VAR - is value added per labor deflated by the
L
Consumer Price Index (CPI)
(----) is wages and salaries per labor deflated by 1 the CPI

I is time
and Model A9 is

VAI
where (----) is value added per labor deflated by the
L Industrial Production Index (IPI)
(---) is wages and salaries per labor deflated
L by the (IPI)
T is time

Theoretically, deflating the time series data will yield efficient and unbiased estimators. A further advantage of using deflated time
series is that extreme observations will have less effect on the estimation (Kuh and Meyer, 1955) and will reduce the bias due to those outlying observations.

Statistically, we can observe the impact of deflatirg the series by comparing the results of models A 5 and A 6 . As shown in Table 3.1 , the elasticity of substitution between capital and labor is reduced in 31 cases basing on models A5 and A6. This can be interpreted as a reduction in the various biases present in Model A5 which are due to the data as well as the postulated model itself (Draper and Smith, 1981). Statistically, model A5 exhibits superior results in terms of $\mathbb{R}^{2}$, adjus2 ted $\mathbf{R}^{2}$, t-statistics and minimum standard errors of the elasticity coefficient. The elasticity coefficient is statistically significant at the $5 \%$ significance level in 42 industry groups in model A5. However, it is statistically significant at a similar level in only 32 industry groups in Model A6. We are thus faced with the dilemma that model A5 with superior statistical results is biased while model A6 with not as good statistical results contains lesser bias. Faced with choosing between model A5 which yields good statistical results but with lesser meaning and model A6 which yields more meaningful though not as good statistical results, it seems clear that the latter alternative is the better choice.

Model A9 is rejected because the industrial production index is available only from 1970 , thus reducing the time series to 15 observations. Model A6 is therefore chosen as the most appropriate estimating form to analyze substitution possibilities, technical change, structural

adjustments and technological change in the Malaysian manufacturing industries, based on the CES Production functions.

The estimates of the elasticity of substitution between capital and labor in Malaysian manufacturing sector based on model A6 are still not free from bias. The simultaneity problem biases the elasticity estimates downward. Secondly, errors of measurement in the variables as discussed earlier result in asymptotically downward biases in estimates of $\sigma$ from Ordinary Least Squares (OLS) procedures. Thirdly, omitting inter-industry differentials in the quality of labor will bias the estimate of the elasticity towards unity (Griliches, 1967). The choice of Model A6 is based on the consideration that it contains the least bias compared to other estimates.

## Elasticity of substitution and technical change under perfect

 competition. 1963 - 1984Based on Model A6, the time-series estimates of the elasticity of substitution are positive in forty-one industries indicating that efficient factor substitutability is possible. The coefficient denoting the elasticities are statistically significant at the $5 \%$ level for thirtyfive industries. More than half of the coefficients (34 out 50) are numerically less than unity, while in sixteen industries, the elasticity of substitution exceeds unity. In 48.0 percent of the cases, the value of elasticity is less than 0.80 . In 20.0 percent of the cases it is greater than 1.10 , while for the remaining 32.0 percent of the cases, it lies between 0.80 and 1.10 . The time-series estimates of the elasticity
of substitution of 5-digit industrial classification of Malaysian manufacturing industries ranged from 3.51 for petroleum refining to - 1.27 for clothing manufacturing. Table 3.3 shows the ranking of industries according to the elasticity of substitution between capital and labor. The numerical value of elasticity of substitution is unity in the Cobb-Douglas case and zero in the fixed-proportions case; therefore a t-test is needed whether or not $\sigma$ is significantly different from zero or unity. The results of the hypotheses $\sigma=1$ and $\sigma=0$ are presented in Table 3.4.

Twenty-six estimates which show positive elasticity of substitution are significantly different from zero at $95 \%$ level of confidence. This evidence should discredit the notion of fixed proportions in the industrial sector of developing countries. The belief that capital-intensive manufacturing processes similar to those found in developed countries (current western technology) are the only alternatives for developing countries such as Malaysia was quite strong in the 1950 s and the 1960 s. The major argument in favor of them was that they were simply more efficient than more labor-intensive alternatives. The latter, it was claimed, would always use more labor and more capital per unit of output than would the process with the high capital-labor ratio. Thus, although alternatives might exist in a technical sense, they would always be found to be inferior (Samir, 1969; Ady, 1971; Barber, 1969). The evidence presented in Table 3.4 shows that at least twenty-six industries in Malaysian manufacturing sector with positive elasticities are not characterized by fixed proportions. In eight industries (sugar

factories and refineries, soft drinks and carbonated beverages, manufacture of leather and leather products, sawmilling, paints, varnishes and lacquer industries, perfumes and cosmetics industries, hydraulic cement industries and industrial machinery and parts), the elasticity of substitution is statistically greater than unity, indicating that the general form of the CES production function is the only suitable model. Given the time series data 1963 - 1984, these industries have shown a small degree of factor substitutability in the Malaysian manufacturing sector.

However, as shown in Table 3.4, more than half of the industries, constituting twenty-seven out of fifty (54.0\%), have elasticities that are not statistically different from unity. In these cases, the CES function, with unitary elasticity of substitution between capital and labor is reduced to the Cobb-Douglas form; thus the latter model may provide a more suitable statistical representation of the underlying production function for these industries.

The impact of the substitution elasticity ( $\sigma$ ) upon factor use composition and factor shares is well-known. In the process of growth with technical progress, the labor absorption depends crucially on the substitution elasticity. In the case of $\sigma=1$, neither labor- nor capitalaugmenting technical progress affects the labor intensity, assuming a constant factor price ratio. However, when $\sigma>1$, a labor-augmenting progress increases the labor intensity and consequently the demand for labor while a capital-augmenting progress reduces the labor absorption. The reverse holds for $\sigma<1$. Thus a discussion of the relationship
between elasticity of substitution and the rate of technical progress can provide a better understanding of the Malaysian manufacturing sector.

Table 3.5 shows the rate of technical progress ( $\lambda$ ) corresponding to significant estimates of the elasticity of substitution ( $\sigma$ ) in the Malaysian manufacturing industries. Between 1963-1984, only sugar refineries and factories experienced a negative rate of technical progress. The average annual rate of technical progress is 0.95 percent. Fifteen industries (hydraulic cement, sawmilling, cocoa, chocolate and confectionery, vegetable, oii and fats, soaps and detergents, pineapple canning, ice factories, architectural metal products, tobacco manufacturing, biscuit factories, prepared animal feeds, rubber products manufacturing, industrial chemicals and perfumes and cosmetics industries) experienced technical progress higher than the average rate. On the other hand, sugar refineries and factories show a negative rate of technical progress. The majority of industries, however, experience a relatively small rate of technical progress, well below the average of 0.95.

It is noted that the industries which experience technical progress higher than the average rate are those with elasticities which are greater than unity. These industries such as hydraulic cement, sawmilling, cocoa, chocolate and confectionery are however capital-intensive industries (see Appendix). Thus, even with relatively higher but capital-augmenting technical progress, labor absorption is low.

Comparison of the CES estimates tc other estimates of the elasticity

## of substitution

Table 3.6 shows a comparison of the time series estimates of the elasticity of substitution between capital and labor in 5-digit Malaysian industries for the period 1963-1984 and cross-section estimates based on a 1974 survey of 338 manufacturing establishments in West Malaysia. Both cross-section estimates are derived from the CES production. The ACMS ${ }^{\sigma}$ estimate is based on the equation,

$$
\frac{V A}{L} \ln \left(--a+\sigma \ln \left(-\frac{W}{L}\right)\right.
$$

and the DIWAN estimate is based on the equation

$$
\ln \left(-\frac{C}{L}\right)=b+\sigma\left(-\frac{W}{L}\right)
$$

```
where C is capital
    L is labor
    W is wages and salaries
    VA is value-added
    \sigma is elasticity of substitution between
        capital and labor
```

It is striking to observe that there are some discrepancies between the values of the elasticity of substitution obtained for each industry, when this parameter is estimated with cross-sectional data or with timeseries data. This is to be expected as pointed out by Nerlove (1967),

"even slight variations in the period or concepts tend to produce drastically different estimates of the elasticity".

Comparing industry - wise the values of estimated elasticity of substitution (columns 1,2 , and 3 in Table 3.6), we note that in the majority of cases, the time-series value of this parameter came out invariably lower than its cross-sectional counterparts. We may observe that this pattern fits entirely with the general experience in this field.

Another interesting point to note is that the cross-sectional estimates using ACMS range between 1.62 and -0.03 . While there are discrepancies in industry estimates, all the estimates seem to cluster around a similar range. Both cross-section and time-series estimates give the impression of generally low substitution possibilities between factors capital and labor in the Malaysian manufacturing sector.

The estimates of the elasticity of substitution in the Malaysian manufacturing sector gain further credence by comparing them with estimates in other developing countries. Ferguson's estimates for U.S. manufacturing industries ranged from 0.24 to 1.30 . Two sets of estimates of $\sigma$ exist for the Peruvian manufacturing sector by industry. One set, obtained by Claque (1979) under alternative assumptions regarding capital inputs and interest rates, contains estimates which range between 0.125 and 1.106 . Behrman (1972) presents estimates for the Chilean manufacturing sector of 0.21 in the short run and 0.76 in the long run. Recent estimation of elasticities of substitution in Korean manufacturing industries (Jae Won Kim, 1984) shows a similar clustering
between 0.01 and 0.89 . Thus, except for Lianos's estimates for Greek manufacturing industries which range between -10.111 and 15.873 , the majority of time-series estimates cluster between 0.1 and 1.3. Our estimates of the elasticity of substitution between capital and labor in Malaysian manufacturing industries cluster between 0.1 and 1.5. The average estimate is $\mathbf{0 . 7 2}$.

It is interesting to note the consistencies and similarities in the estimates of elasticities across countries. The time-series estimates of the elasticity of substitution in Greek manufacturing industries show negative elasticities for food manufacturing, electrical machinery appliances and transport equipment, and relatively low elasticities for textiles, footwear, leather products, rubber and plastic products manufacturing (Lianos, 1975). Similarly, Ferguson (1965) found relatively lower elasticities in food, textiles, rubber and plastics, leather products, stone, clay and glass, and professional instruments manufacturing industries. Both Lianos and Ferguson reported the highest elasticities for petroleum manufacturing of 12.658 and 1.30 in Greek and American manufacturing industries, respectively.

Thus, although the comparison of the estimates of the elasticity of substitution is drawn from different sample bases, different levels of aggregation and different estimating equations, there seems to be a consistent trend in the results of the time-series estimates. Strict comparability of estimates for policy purposes, however, would require strict comparability of both the treatment of data and the estimation procedures. Although no generalization can be made about the size of
the elasticity of substitution in the developing countries, the Malaysian estimates presented in this study are comparable to the timeseries estimates in other countries based on the CES production functions.

Given the regression results, what can one conclude about the estimates of the elasticity of substitution in the Malaysian manufacturing sector? The analysis based on the CES production function shows that the estimates cluster between 0.1 and 1.5. These estimates are, however, subjected to a number of biases in the specification of variables as well as in their estimation. Considering these biases, one tends to conclude that the actual elasticities are probably lower than the calculated elasticities.

An alternative method based on the duality between production and cost functions can be used to estimate the elasticity of substitution. An attempt is made in the next chapter to determine the elasticity of substitution between capital and labor in the Malaysian manufacturing sector using the translog cost function.

# CHAPTER IV. CAPITAL-LABOR SUBSTITUTION IN MALAYSIAN MANUFACTURING USING TRANSLOG COST FUNCTION APPROACH 

Methodology
From the neo-classical production function and the assumption of cost minimization, factor demands are based on the necessary conditions for optimization. These are readily obtained for simple production functions. However, factor demands are difficult to determine when the production technology is more complex. Furthermore, it is not possible to estimate the CES production function either in its original or logarithmic form because the bracketed term contains two of the parameters to be measured. It is preferable, therefore, to study the factors of production or the factor demands in a manner which preserves the complexity of the structure of input decisions, yet simplifies the derivation. The duality between production and cost functions has provided this alternative. Varian (1978) and Diewert (1974) illustrate that the cost function contains all of the information about the production technology present in the conventional production function. Furthermore, given the regularity conditions, every cost function implies a wellbehaved production technology. Thus, a logical approach in factor demand analysis is to proceed directly to a cost function without prior regard to a functional form for the production technology.

## The theoretical and empirical model of the translog cost function

Given a production function of the form

$$
Y=f(K, L)
$$

f summarizes the underlying technology, where
$Y=$ output
$K=$ capital input
$L=$ labor input

Given the regularity conditions, and assuming factor prices ( $\mathrm{P}_{\mathrm{K}}$ ) and ( $P_{L}$ ) and output levels ( $Y$ ) are exogenously determined, the theory of duality between production and cost functions states that by minimizing cost, a cost function will be derived as follows:

$$
\begin{aligned}
& \ell=P_{K} K+P_{L} L+[F(K, L)-Y] \\
& -\frac{\delta \ell}{\delta K}=P_{K}-F_{K}=0 \\
& -\frac{\delta \ell}{\delta L}=P_{L}-F_{L}=0 \\
& \left.-\frac{\delta \ell}{\delta}=-F(K, L)-Y\right)=0
\end{aligned}
$$

Assuming second order conditions are not violated, the three first order conditions solved simultaneously give the optimal factor demands $K^{*}\left(P_{K}, P_{L}, Y\right)$
$L^{*}\left(P_{K}, P_{L}, Y\right)$
where $K^{*}$ and $L^{*}$ are optimal capital and labor inputs.

The cost function is derived as

$$
\begin{equation*}
c^{*}\left(P_{K}, P_{L}, Y\right)=P_{K_{K}}{ }^{*}\left(P_{K}, P_{L}, Y\right)+P_{L}{ }^{*}\left(P_{K}, P_{L}, Y\right) \tag{4:1}
\end{equation*}
$$

Equation (4:1) is a general functional form. For purposes of empirical estimation, it is necessary to specify an explicit functional form for $C^{*}$. In this study, a popular cost function is estimated with Malaysian manufacturing data.

Christensen, Jorgenson and Lau (1973) proposed the translog as an approximation to unknown cost or production functions by expressing them as a second-order polynomial in logarithms of input prices and output. Following Diewert (1971), the translog cost function which satisfies certain regularity conditions does correspond to a well-behaved production technology.

The translog cost function is expressed as

$$
\begin{align*}
& +\sum_{i} a_{i} \ln P_{i} \\
& +1 / 2 \sum_{i} \sum_{j} \beta_{i j} \ln P_{i} \ln P_{j} \\
& +1 / 2 \beta_{i y} \ln Y \ln P_{i} \tag{4:2}
\end{align*}
$$

where $\quad i, j=K, L$
where $\quad \ln C^{*}$ is the logarithm of total costs
In $P_{i}$ is the logarithm of the ith input price
In $Y$ is the logarithm of output

By Shephards' lemma, factor shares are derived by differentiating equation (4:2) with respect to each logged input price. Then

$$
\ln C / \ln P_{i}=P_{i} X_{i} / C^{*}=s_{i}
$$

and the input demand functions, in terms of cost shares, take the form

$$
\begin{equation*}
s_{i}=a_{i}+\sum_{j} \beta_{i j} \ln P_{j}+\beta_{i y} \ln Y \tag{4:3}
\end{equation*}
$$

where $\quad i, j=K, L$.

In order for the translog to satisfy linear homogeneity in input prices, and other properties of a well behaved production function, the following parameter restrictions are required.

$$
\begin{aligned}
\sum_{i} a i & =1 \text { [1inear homogeneity] } \\
\sum_{i} \beta_{i j} & =\sum_{i} \quad \beta_{i j}=0 \quad \text { [Cournot aggregation] } \\
\sum_{i} \beta_{i y} & =0 \text { [Engel aggregation] } \\
\beta_{i j} & =\beta_{j i} \quad \text { [Slutsky symmetry] }
\end{aligned}
$$

The appearance of output in the translog cost function in equation (4:2) introduces nonhomotheticity. Thus, by restricting $\beta_{i y}=0$ produces the linear expansion path of the homothetic case. Further restricting $\theta$ to equal zero produces a technology which is homogeneous of degree $1 / \beta$. Setting $\beta=1$, would then yield a cost function homogeneaus of degree one.

The popularity of the translog cost function is due to the ease of estimation. Furthermore, the translog cost function allows arbitrary configurations of the matrix of elasticities of substitution. It also permits variations in these elasticities across input pairs. Únlike elasticities derived from Cobb-Douglas or CES production functions, the translog cost. function permits input complementarities.

Mundlak (1968) provides three alternative measures of substitutability between pairs of inputs $X_{i}, X_{j}$. When the elasticity of substitution is positive inputs are considered as substitutes and if the elasticity of substitution is negative, inputs are complements. Uzawa (1962) has measured the Allen partial elasticity of substitution between inputs i \& j as

$$
c^{*} \cdot \delta^{2} c^{*} / \delta \rho i \delta \rho j
$$

$$
\begin{equation*}
\sigma_{i j}=-\delta c / \delta \rho i \cdot \delta \mathrm{C} / \delta \rho j \tag{4:4}
\end{equation*}
$$

Berndt-Wood (1975) show that for the translog cost function, the Allen partial elasticity of substitution is

$$
\begin{align*}
& \sigma_{i j} A= \frac{\beta_{i j}+s_{i} s_{j}}{s_{i} s_{j}}  \tag{4:4a}\\
& \sigma_{i i^{A}}=\frac{\beta_{i i}+s_{i}^{2}-s_{i}}{s_{i}} \tag{4:4b}
\end{align*}
$$

where $\quad \sigma_{i j}=$ cross partial elasticity of substitution between inputs i, $j$
$\beta_{i i}=$ own partial elasticity of substitution between inputs i,j

The Morishima elasticity of substitution is written by Koizumi (1976) as

$$
\begin{equation*}
c_{i j}{ }^{M}=s_{j}\left(\sigma_{i j}^{A}-\sigma_{j j}^{A}\right) \tag{4:5a}
\end{equation*}
$$

and the shadow elasticity of substitution by McFadden (1963) is

$$
\begin{align*}
\sigma_{i j} S^{S}= & s_{i} s_{j}\left(2 \sigma_{i j}^{A}-\sigma_{i i}^{A}-\sigma_{j j}^{A}\right)  \tag{4:5b}\\
& s_{i}+s_{j}
\end{align*}
$$

Further, it has been shown by Binswanger (1974) that the elasticity of substitution between pairs of inputs can be calculated as

$$
\begin{align*}
\sigma_{i j}^{B} & =\beta_{i j} / s_{i} s_{j}+1  \tag{4:6a}\\
\sigma_{i \mathrm{i}}^{\mathrm{B}} & =\beta_{i \mathrm{i}} / s_{i}-1 / s_{i}+1 \tag{4:6b}
\end{align*}
$$

Assuming Hick's neutral technical change (homotheticity) and constant returns to scale (CRTS), the translog cost function can be rewritten as

$$
\begin{align*}
\ln C\left(P_{i}, P_{j}\right)= & a_{0}+\sum_{i} a_{i} \ln P_{i} \\
& +1 / 2 \sum_{i} \sum_{j} \beta_{i j} \ln P_{i} \ln P_{j} \tag{4:7}
\end{align*}
$$

and the factor demands in terms of cost shares are,

$$
\begin{equation*}
s_{i}=a_{i}+\sum_{j} \beta_{i j} \ln P_{j} \tag{4:8}
\end{equation*}
$$

where $\mathbf{i , j}=\mathrm{K}, \mathrm{L}$

## alternatively

$$
\begin{align*}
& S_{K}=a_{K}+\beta_{K K} \ln P_{K}+\beta_{K L} \ln P_{L}  \tag{4:8a}\\
& S_{L}=a_{L}+\beta_{L K} \ln P_{K}+\beta_{L L} \ln P_{L} \tag{4:8b}
\end{align*}
$$

In order that the system of cost share equations [4:8a] and [4:8b] satisfy the regularity conditions and the properties of the neoclassical production function, the following restrictions are required.

$$
\begin{aligned}
a_{K}+a_{\mathrm{L}} & =1 & & \text { [1inear homogeneity] } \\
\beta_{\mathrm{KL}}+\beta_{\mathrm{KK}} & =0 & & \text { [Cournot aggregation] } \\
\beta_{\mathrm{KL}}+\beta_{\mathrm{LL}} & =0 & & \\
\beta_{\mathrm{KL}} & =\beta_{\mathrm{LK}} & & \text { [Slutsky symmetry] }
\end{aligned}
$$

To see the effects of restrictions on the estimating form of the cost share equations, the following restrictions are imposed on the cost share equations as follows; by linear homogeneity,

$$
\begin{gather*}
a_{K}+a_{L}=1 \\
\text { i.e., } a_{K}=1-a_{L} \text { or } a_{L}=1-a_{K} \tag{4:9}
\end{gather*}
$$

By symmetry,

$$
\beta_{\mathrm{KL}}=\beta_{\mathrm{LK}}
$$

and by Cournot aggregation, i.e., the row and column sum of the matrix is zero.

$$
\begin{align*}
& \beta_{\mathrm{KK}}+\beta_{\mathrm{KL}}=0  \tag{4:10}\\
& \beta_{\mathrm{LK}}+\beta_{\mathrm{LL}}=0 \tag{4:11}
\end{align*}
$$

' Given the cost share equations [4:8a] and [4:8b] and using [4:10] and [4:11], gives

$$
\begin{aligned}
& \beta_{\mathrm{KK}}=-\beta_{\mathrm{KL}} \\
& \beta_{\mathrm{LL}}=-\beta_{\mathrm{LK}}
\end{aligned}
$$

Therefore, one equation is redundant. Thus, with these regularity restrictions, the cost share equation to be estimated is

$$
\begin{align*}
S_{K} & =a_{K}+\beta_{K K} \ln P K+\beta_{K L} \ln P L  \tag{4:12a}\\
\text { or } \quad S_{L} & =a_{L}+\beta_{L K} \ln P K+\beta_{L L} \ln P L \tag{4:12b}
\end{align*}
$$

The estimates for $a L, \beta_{L K}$ and $\beta_{L L}$ can be calculated ex-post by substituting the parameter estimates into equations [4:9], [4:10] and [4:11]. Since the set of simultaneous equations has been reduced to a single linear equation, equation $[4: 12]$ can be estimated using ols. In this two-factor case, therefore, there is no computational problems related to which equation is omitted.

Further conditions of a well-behaved production function are that output should increase monotonically with all inputs and that the isoquants are convex. The translog does not satisfy these restrictions globally. In fact, when at least one $\beta_{i j}=0$, there exist configurations of inputs such that neither monotonicity nor convexity is satisfied. This follows simply from the quadratic nature of the translog function. On the other hand, there are regions in the input space where these conditions are satisfied. For any set of parameters and input
levels the monotonicity and convexity conditions can be easily checked. Monotonicity requires that $\delta F / \delta X_{i}>0$. Since $F$ and $X_{i}$ are always positive, an equivalent set of conditions is that the cost share equations are positive. Assuming markets are competitive, the set of necessary conditions for efficient production is that $\delta \boldsymbol{F} / \delta X_{i}=R_{i}$ where $R i$ is the price of ith input. Then monotonicity conditions can be written as

$$
S_{i}=\frac{\delta \operatorname{In} F}{\delta \operatorname{In} X_{i}}=\frac{\delta F}{\delta X_{i}} \cdot \frac{X_{i}}{F}=\frac{\rho_{i} X_{i}}{F}>0
$$

The isoquants of the translog function are strictly convex if the corresponding bordered Hessian matrix of first and second partial derivatives is negative definite. This can be evaluated at each data point for any estimated translog function.

## Measurement of technical change via the translog cost function approach Assuming homotheticity and constant returns to scale, the translog cost function is

$$
\begin{equation*}
\ln C\left(P_{i}, P_{j}\right)=a_{0}+\sum_{i} a_{i} \operatorname{In} P_{i}+1 / 2 \sum_{i} \sum_{j} \beta_{i j} \ln P_{i} \ln P_{j} \tag{4:7}
\end{equation*}
$$

The above function assumes Hick's-neutral technical change. A further property of the translog cost function is that it permits respecification of the estimation equation to include the effects of factor augmented technical change. As shown by Berndt and Khaled (1979) and Lopez (1980), variations in factor shares can be explained not only by
relative prices but by technical change by relating the dependent variables to time. The translog cost function becomes

$$
\begin{align*}
\ln C^{*}= & a_{0}+\underset{i}{\sum} a_{i} \ln P_{i}+1 / 2 \underset{i}{\sum} \underset{j}{\sum} \beta_{i j} \ln P_{i} \ln P_{j} \\
& +\beta_{T} \cdot T+\sum_{i} \beta_{i T} \ln P_{i} \cdot T \\
& +1 / 2 \beta_{T T} \cdot T^{2} \tag{4:13}
\end{align*}
$$

Differentiating equation [4:13] with respect to $\log P_{i}$ and invoking Shephard's Lemma yields the factor demand equations which are expressed in terms of factor cost shares with an additional variable time ( $T$ ).

$$
\begin{equation*}
S_{i}=a_{i}+\sum_{i} \beta_{i j} \ln P_{j}+\sum_{i} \beta_{i T} T \tag{4:14}
\end{equation*}
$$

Examples of respecifying the translog cost function to permit technical change by adding the independent variable time ( $T$ ) include Berndt and Wood (1975), Binswanger (1974), and Ray (1982).

Data, Estimation and Results of the Translog
Cost Function for the Malaysian Manufacturing Industries
This section consists of discussion of the data and related problems concerning the operational definition of variables for the translog cost estimation, the estimation procedures and the discussion of results of the translog cost function. Since the CES-translog cost function is only a variant of the CES and translog cost function, the discussion of its estimation is also included in this section.

## Sources of data and measurement of variables

To ensure comparability of alternative estimates of the elasticity of substitution in 5-digit Malaysian manufacturing industries, all data for the estimation of the translog cost function and the CES-translog cost function are from the Surveys/Censuses of Manufacturing Industries, West Malaysia, the Industrial Surveys of Malaysia and Manufacturing Division, Department of Statistics, Malaysia. However, data for value of fixed assets and value of depreciation are available for only a number of years beginning in 1969. As such, the estimation of the translog cost function and the CES-translog cost function are based on a timeseries from 1969 to 1984 for fifty 5-digit Malaysian manufacturing industries.

The chief sources of data are the Surveys/Censuses of Manufacturing Industries which have been conducted annually up to 1976. The surveys/ censuses are followed by the Industrial Surveys of Malaysia from 1978 to 1984. The information in the Surveys and Censuses includes value added (VA), number of workers employed (L), wages and salaries (W), cost of inputs ( $c$ ), and value of fixed assets (FA). There were no surveys for 1977 and 1980. Furthermore, the information on value of fixed assets is not consistently given for the whole period 1970-1984.

Information on value of depreciation (D), value of fixed assets (FA) and the breakdown for cost of inputs are derived from the Manufacturing Division, Department of Statistics, Malaysia. Consumer Price Index (CP1) and Industrial Production Index (IPI) are taken from Bank Negara Annual Report, 1985.

The final data required for the estimation of the translog cost function and the CES-translog cost function are the cost share of capital $\left(S_{K}\right)$, the cost share of labor $\left(S_{L}\right)$, the service price of capital ( $P_{K}$ ) and the service price of labor ( $P_{L}$ ), and the first derivative of the logarithm of total cost with respect to time $\left(S_{T}\right)$.

The estimation of the translog cost function and the CES-translog cost function for Malaysia would be facilitated if data on cost shares and service prices of capital and labor could be constructed following procedures outlined by Christensen-Jorgenson (1969, 1970) and Berndt and Christensen (1970). Such procedures, however, would require extra information on variations of effective tax rates, rates of return, capital gains, years of education of labor force and others in order to construct the Divisia quality indexes for capital and labor.

The estimation in this study is, however, based on less sophisticated procedures of constructing the final data for $S_{K}, S_{1}, S_{T}, P_{K}$ and $P_{L}$. Following Wills (1979) and Vashist (1985), the cost shares of capital and labor are constructed as follows,

$$
S_{K}=\left(V_{A}-S_{L}\right) / T C
$$

$S_{L}=W / T C$
and following procedures by Ioannides and Caramanis (1979), Wills (1979) and Vashist (1985), the service prices of capital and labor, $P_{K}$ and $P_{L}$ are constructed as follows,

$$
\begin{aligned}
& P_{K}=S_{K} / K \\
& P_{K}=S_{L} / L
\end{aligned}
$$

```
where VA = value-added
    L = number of full-time workers plus half of part-time
        workers
    W = total wages and salaries
    TC = total cost to industry measured as total cost of inputs +
        fixed cost + wages and salaries
        value of fixed assets + value of circulating capital
        (materials + electricity, fuel, lubricants and water +
        intermediate supplies).
    Initially it was intended to construct the capital stock series by
the well-known perpetual inventory method (Christensen and Jorgenson,
1969). However, there is no benchmark available and there is also a
serious deficiency of information on the age structure of existing
capital stock.
```

Another problem in the measurement of capital is related to the computation of total cost and hence the service prices of capital and labor. Total cost includes cost of circulating capital and fixed cost as the cost of capital while the wage bill is the cost of labor. Thus, despite various limitations, such as reconciling stock and flow concepts, the value of fixed assets and value of circulating capital is taken to represent our capital data, $K$. Another reason is that the objective of the research is to calculate the substitution possibilities between capital and labor only. As such capital should be the residual of labor inputs (Fuss, 1977).

## Estimation of the translog cost function

Assume that there exists in the Malaysian manufacturing sector a twice differentiable aggregate production function relating the flow of gross output to the services of capital and labor. Further, assume that production is characterized by constant returns to scale and that any technical change affecting capital and labor is Hicks-neutral. For purposes of estimation, the set of simultaneous equations (4:8a) and ( $4: 8 \mathrm{~b}$ ) can be used. However, data from Surveys and Censuses of Manufacturing Companies, West Malaysia and the Industrial Surveys of Malaysia are subject to errors. These errors can result in deviations of the actual cost shares from the cost minimizing shares. Kulatilaka (1985) shows that stochastic specifications introduce additive errors due to errors in measurement of output and.cost shares. These errors are specified in the error term ( $e_{i}$ ) and the estimating equation takes a stochastic form

$$
\begin{equation*}
s_{i}=a_{i}+\underset{i}{\Sigma} \beta_{i j} \ln P_{j}+e_{i} \tag{4:15}
\end{equation*}
$$

In a two-factor case, the estimating equations are sets of simultaneous equations, in the following stochastic form,

$$
\begin{align*}
& S_{K}=a_{K}+\beta_{K K} \ln P_{K}+\beta_{K L} \ln P_{L}+e_{K}  \tag{4:16}\\
& S_{L}=a_{L}+\beta_{L K} \ln P_{K}+\beta_{L L} \ln P_{L}+e_{L} \tag{4:17}
\end{align*}
$$

The parameters of the translog cost function in Malaysian manufacturing sector can be estimated using equations (4:16) and (4:17). For the
system of share equations (4:16) and (4:17), the disturbances are likely to be correlated across equations. Therefore, $e_{K}$ and $e_{L}$ will be correlated. This suggests that the Iterative Zellner Efficient Method or the Seemingly Unrelated Regression (SUR) method will give efficient parameter estimates. Zellner (1962) has shown that when disturbances across equations are correlated, and if the correlation is known, then the parameters can be estimated more efficiently by taking this information into account. Furthermore, Zellner (1962) has demonstrated that even when the correlation is unknown, it is likely that using an estimate of the correlation will improve estimation efficiency.

Firstly, alternative versions of Model (B1) to Mode1 (B6) are estimated without restrictions using the Seemingly Unrelated Regression method from time-series data 1969-1984 in 5-digit Malaysian manufacturing industries.

| [MODEL B1] | $\mathrm{s}_{\mathrm{K}}$ | $\mathrm{a}_{\mathrm{K}}+\beta_{\mathrm{KK}} \ln \mathrm{P}_{\mathrm{K}}+\beta_{\mathrm{KL}} \ln \mathrm{P}_{\mathrm{L}}+\varepsilon$ |
| :---: | :---: | :---: |
|  | $S_{L}$ | $=a_{L}+\beta_{L K} \ln { }_{P K}+\beta_{L L} \ln \mathrm{P}_{\mathrm{L}}+\varepsilon_{\mathrm{L}}$ |
| [MODEL B2] | $\mathrm{S}_{\mathrm{K}}($ AR1 $)$ | $=a_{K}+\beta_{K K} \ln \mathrm{P}_{\mathrm{K}}+\beta_{\mathrm{KL}} \ln \mathrm{P}_{\mathrm{L}}+\varepsilon_{\mathrm{K}}$ |
|  | $\mathrm{S}_{\mathrm{L}}$ (AR1) | $=a_{L}+\beta_{L K} \ln \mathrm{P}_{\mathrm{K}}+\beta_{L L} \ln \mathrm{P}_{\mathrm{L}}+\varepsilon_{\mathrm{L}}$ |
| [model b3] | SKR | $=\mathrm{a}_{\mathrm{K}}+\beta_{\mathrm{KK}} \ln \mathrm{P}_{\mathrm{KR}}+\beta_{\mathrm{LK}} \ln \mathrm{P}_{\mathrm{LR}}+\varepsilon_{\mathrm{K}}$ |
|  | SLR | $=a_{L}+\beta_{L K} \ln \mathrm{P}_{\mathrm{KR}}+\beta_{L L} \ln \mathrm{P}_{\mathrm{LR}}+\varepsilon_{\mathrm{L}}$ |
| [MODEL B4] | SKR(AR1) | $=\mathrm{a}_{\mathrm{K}}+\beta_{\mathrm{KK}} \ln \mathrm{P}_{\mathrm{KR}}+\beta_{\mathrm{KL}} \ln \mathrm{P}_{\mathrm{LR}}+\varepsilon_{\mathrm{K}}$ |
|  | SLR(AR1) | $=a_{L}+\beta_{L K} \ln P_{K R}+\beta_{L L} \ln P_{L R}+\varepsilon_{L}$ |
| [MODEL B5] | SK1 | $=\mathrm{a}_{\mathrm{K}}+\beta_{\mathrm{KK}} \ln \mathrm{P}_{\mathrm{K} 1}+\beta_{\mathrm{KL}} \ln \mathrm{P}_{\mathrm{L} 1}+\varepsilon_{K}$ |
|  | SL1 | $=a_{L}+\beta_{L K} \ln P_{K 1}+\beta_{L L} \ln P_{L 1}+\varepsilon_{L}$ |

```
[MODEL B6]
\(\operatorname{SKI}(A R I)=a_{K}+\beta_{K K} \ln P_{K I}+\beta_{K L} \ln P_{L I}+\varepsilon_{K}\) \(\operatorname{SLI}(\operatorname{ARI})=a_{L}+\beta_{L K} \ln P_{K I}+\beta_{L L} \ln P_{L I}+\varepsilon_{L}\)
```

where
$\mathrm{S}_{\mathrm{K}} \quad$ is cost share of capital
$S_{L} \quad$ is cost share of labor
$\mathrm{P}_{\mathrm{K}} \quad$ is service price of capital
$P_{L} \quad$ is service price of labor
$S_{K}$ (AR1) is cost share of capital corrected for autocorrelation
$S_{L}$ (ARI) is cost share of labor corrected for autocorrelation

SKR is real cost share of capital with CPI as
deflator, $1980=100$
SLR is real cost share of labor with CPI as deflator, $1980=100$
$\operatorname{SKR}(A R 1)$ is real cost share of capital (CP1) corrected for auto-correlation

SLR(ARI) is real cost share of labor (CP1) corrected for auto-correlation

SKI is real cost share of capital with Industrial Production Index (IPI) as deflator, $1980=100$

SLI is real cost share of labor
Next, the equations ( $4: 16$ ) and (4:17) are estimated with restrictions. A number of methods can be used, including Zellner's generalized least squares (GLS) estimation procedure which yields estimators which
are sensitive to which cost share equation is deleted from the system of equations. A maximum likelihood procedure would provide parameter estimates which are invariant to the choice of equations to be actually estimated (Barten, 1969). However, Kmenta and Gilbert (1968) have demonstrated that Full Information Maximum Likelihood (FIML) and Iterated Zellner Efficient Estimation (IZEF), commonly known as Seemingly Unrelated Regression (SUR), lead to identical estimates. Rubble (1968) has also shown the computational equivalence of IZEF and FIML estimators.

However, in order to use FIML procedure, input prices ( $P_{K}, P_{L}$ ) and output must be exogenous and, thus, orthogonal to the additive errors (Kulatilaka, 1985). If the data are for a complete economy then output and factor prices are likely to be endogenous. Furthermore, as demonstrated by Berndt and Savin (1975), neither the maximum likelihood estimators nor the Zellner's estimators will be invariant to the equation deleted if the error terms in the model are not well behaved (i.e., presence of autocorrelation).

In this case of the two-input translog function, one equation is redundant and can be omitted. Basing on Models [B1] - [B6] both cost share equations $S_{K}$ and $S_{L}$ are estimated separately using oLS procedures. In the two-input case, it does not matter which equation is deleted. The final choice of the estimating equation will be based on the statistical results.

The third procedure is to determine the effect of technical change. The estimating equations to measure the effect of technical change in
the Malaysian manufacturing sector are as follows:

$$
\begin{align*}
& S_{K}=a_{k}+\beta_{k k} \ln P_{k}+\beta_{K L} \ln P_{1}+\beta_{k k} T+\beta_{K L} T  \tag{4:18}\\
& S_{L}=a_{L}+\beta_{L K} \ln P_{K}+\beta_{L L} \ln P_{L}+\beta_{K 1} T+\beta_{L L} T  \tag{4:19}\\
& S_{T}=a_{T}+\beta_{K T} \ln P_{k}+\beta_{L T} \ln P_{L}+\beta_{T T} T \tag{4:20}
\end{align*}
$$

where $\quad S_{T}=\frac{\delta \ln C^{*}}{\delta \ln T}$

The terms $\left(\beta_{\mathrm{LT}}\right)$ and $\left(\beta_{\mathrm{KT}}\right)$ are estimates of the factor-saving Hicks' biases of technical change, since they measure the rate of change in the cost shares not attributable to prices.

Thus,
if $\quad \beta_{i T}=0 \quad$ implies Hicks neutral technical change

$$
\begin{array}{ll}
\beta_{\mathrm{LT}}>0 & \text { implies labor-saving technical change } \\
\beta_{K T}>0 & \text { implies capital-saving technical change }
\end{array}
$$

through a series of simple manipulation equations [4:18] [4:19] and [4:20] can be rewritten as follows:

$$
\begin{align*}
& S_{K}=a_{K}+\beta_{K K}\left[\ln P_{k}+T\right]+\beta_{K L}\left[\ln P_{L}+T\right]  \tag{4:21}\\
& S_{L}=a_{L}+\beta_{K L}\left[\ln P_{K}+T\right]+\beta_{L L}\left[\ln P_{L}+T\right] \tag{4:22}
\end{align*}
$$

The final estimating equations to measure the effect of technical change in the Malaysian manufacturing sector are the set of simultaneous equations $(4: 23),(4: 24)$ and $(4: 25)$. These oquations are deterministic. However errors of optimization can arise due to deviations of the firm's
actual behavior from its cost-minimizing behavior. To account for such random errors, disturbance terms were added to the equations so that they take the following set of stochastic simultaneous equations
$S_{K}=a_{K}+\beta_{K K}\left[\ln P_{K}+T\right]+\beta_{K L}\left[\ln P_{L}+T\right]+\varepsilon_{K}$
$\mathrm{S}_{\mathrm{T}}=\mathrm{a}_{\mathrm{T}}+\beta_{\mathrm{KT}}{ }^{\ln \mathrm{P}_{\mathrm{K}}}+\beta_{\mathrm{LT}}{ }^{\ln \mathrm{P}_{\mathrm{L}}}+\beta_{\mathrm{TT}} \mathrm{T}$
Based on these equations, alternative regression models [B7] to [B12]
are estimated using the Seemingly Unrelated Regression procedure.
MODEL [b7]

$$
\begin{aligned}
& \mathrm{s}_{\mathrm{K}}=\mathrm{a}_{\mathrm{K}}+\beta_{\mathrm{KK}} \ln \mathrm{PKT}+\beta_{\mathrm{KL}} \ln \mathrm{PLT}+\varepsilon_{\mathrm{k}} . \\

\end{aligned}
$$

where

In PKT is the logarithm of service price of capital plus time; $1060=1$
In PLT is the logarithm of service price of labor plus time; $1969=1$
$S_{T} \quad$ is the lagged values of total cost
SKR is the real cost share of capital deflated with CPI; $1980=100$
SLR is the real cost share of labor deflated with CPI; $1980=100$
In PKRT is the logarithm of real service price of capital deflated by CPI

In PLRT is the logarithm of real service price of labor deflated by CPI SKR(ARI) is real cost share of capital (CPI) corrected for autocorrelation

SLR(AR1) is real cost share of labor (CPI) corrected for autocorrelation
SKI is real cost share of capital deflated by Industrial Production Index (IPI), $1980=100$

SLI is real cost share of labor deflated by the Industrial Production Index (CPI), $1980=100$

In PKIT is the logarithm of the service price of capital plus time In PLIT is the logarithm of the service price of labor plus time

CTR is the lagged values of real total cost deflated by CPI
CII is the lagged values of real total cost deflated by IPI

The final choice of the model to estimate the elasticity of substitution with nonneutral technical change is based on various statistical results.

## Discussion of empirical results

Elasticity of substitution without technical change. The most appropriate equation to estimate the elasticity of substitution between capital and labor in the Malaysian manufacturing sector is chosen based on both statistical and theoretical reasons. A statistical search for the best fitting equation based on parameter estimates, the conventional $R^{2}$ and the Durbin - Watson statistic, is carried out for 50 5-digit industry groups. As shown in Table 4.1, in 25 cases, Model [B4] has the best fit while in the other half of the 5-digit industry groups, Model [B6] is the best fitting equation. The differences of the results of these two models however are very small. For example, for Pineapple Canning, in Model [B4], $\mathrm{R}^{2}=96 ; \mathrm{D}-\mathrm{W}$ statistic is 1.8. In Model [B6], $R^{2}=.96$ and $D-W$ statistics is 1.6. Similarly, for Cement and Concrete Manufacturing, in Model [B4], $R^{2}=.96$, D-W Statistic is 1.1 while in Model [B6], $\mathrm{R}^{2}=.95$ and $\mathrm{D}-\mathrm{W}$ Statistic is 1.2 .

Theoretically, in Model [B4], the variables are real values deflated by the consumer price index which will eliminate biases due to inflation and cyclical price movements. In Model [B6], on the other hand, the variables are also real values deflated by the industrial production index which take into account biases due to under-utilization of capacity. In order to make comparisons with the estimates based on the CES production function, empirical results based on Model [B4] are

reported. In both cases, the parameter estimates were derived from real values deflated by the consumer price index and corrected for auto-correlation by the $A R$ (1) method. As such we can expect some consistency in the potential biases of the parameter coefficients of the CES production function and the translog cost function. Furthermore, Model B4 exhibits good statistical performance in terms of the $F$ - statistics, the parameter estimates and the variance covariance matrix. Except for Palm Kernel Oil manufacturing, and Leather and Leather Products Industries, the coefficients of determination are high and statistically significant at 99 percent confidence level. The Durbin-Watson statistics for all industries based on Model [B4] are above 1.1 and below 2.3. Basing on Model B4, Table 4.2 presents the unrestricted parameter estimates, asymptotic t-ratios and standard errors, and the log of likelihood function of the multivariate translog cost function for the Malaysian manufacturing sector, 1968 - 1984. Most of the coefficients are statistically significant at the $95 \%$ percent confidence level and the standard errors are small. The statistical results shown in Tables 4:1 and 4:2 indicate a good fit for the systems of equations for the translog cost estimation in the Malaysian manufacturing sector.

Of the 300 estimated parameters, approximately 75 percent are significant at $10 \%$ percent or higher. For a structural model of this magnitude, the results are very encouraging.

Slope parameters in the cost share equations reflect changes in the cost shares resulting from changes in logarithmic prices in real terms. The slope coefficients may either be positive or negative, since the
second derivatives of $\operatorname{lnC}$ with respect to $\ln P_{i}$ and $\ln P_{j}$ may be of either sign. If the cost share is inversely related to $\ln P_{j}$, i.e., $\boldsymbol{\beta}_{i j}<0$, this suggests that $i$ and $j$ are substitute inputs. If the cost share increases with a rise in the real price, i.e., $\boldsymbol{\beta}_{\mathrm{ij}} \gg \boldsymbol{0}$, this suggests that input substitution is limited.

As depicted in Table 4.2, the cost share of the labor parameter estimates ( $\beta_{\text {LK }}$ ) shows that substitution between capital and labor is rather limited in 36 out of the 50 industries studied.

When restrictions of linear homogeneity and symmetry constraints are imposed, one equation becomes redundant and only one equation is estimated. Based on Model B4, the equation with superior statistical results in terms of $R^{2}$, $D$-W statistics, variance - covariance matrix, $F$ - statistics and the $\beta$ - coefficients were chosen for each industry. In Ice Cream Manufacturing, for example, the cost share of capital was chosen instead of cost share of labor equation. On the other hand, in the case of Manufacturt of Other Dairy Products, the cost share of labor equation was chosen. Elasticity of substitution estimates are based on the chosen equation under restrictions.

Several tests are also conducted to determine if the model [B4] estimated is compatible with the neoclassical theory of cost and production. Further restrictions implied by economic theory include the mono-士ouicity and concavity of the cost function. Neither monotonicity nor concavity of the cost function with respect to input prices will be satisfied globally, however, since the translog specification is only an approximation to the true cost function. Sufficient conditions for

these are positive fitted cost shares and negative definiteness of the second order partials of the cost share equations. The fitted cost shares from OLS or SUR estimates are positive for all industries. This can be verified from Table 4.2. However, not all diagonal elements of a Hessian Matrix, i.e., $\boldsymbol{\beta}_{\mathrm{KK}}$ and $\boldsymbol{\beta}_{\mathrm{LL}}$, are negative. This implies that in a number of industries, the cost function is not concave in input prices. The primary objective of this section is to measure the elasticities of substitution between capital and labor in 5-digit Malaysian manufacturing industries. Basing on Model [B4], the Allen partial elasticity of substitution between capital and labor was calculated at the mean cost shares, at beginning year of analysis (1969), base year (1980) and at ending year of analysis (1984). The elasticities of substitution are reported in Table 4.4.

Interestingly, the elasticities evaluated at the mean cost shares and in different years show insignificant variations. In 16 cases, the elasticity increases very slightly between 1968 and 1984. Evaluated at mean cost shares, more than half of the elasticities are numerically less than unity. In 32 percent of the cases, the value of the elasticity is less than 0.8 . In 14 percent of the cases, it exceeds 1.10 while in more than 50 percent of the cases, it lies between 0.8 and 1.10. The elasticity of substitution between labor and capital in 5digit Malaysian manufacturing industries ranged between -3.716 for clothing industries to 4.649 for petroleum refining. This is a most interesting result since it confirms similar findings based on the CES production function estimation. In the earlier estimation of the CES

production function, the range was -1.27 and 3.51 (for clothing and petroleum refining, respestively). Another interesting point to be noted is the generally low substitution possibilities between capital and labor inputs measured either by the CES production function approach or the translog cost function approach.

Elasticity of substitution with technical change. Alternative versions of Model [B7] to Model [B12] are estimated and a statistical search procedure is carried out to determine the best fitting model in order to estimate the effect of technical change. Although Model [B8] shows superior results in terms of $R^{2}$ and $D-W$ statistics, the results cannot be reported. None of the coefficients of $\ln S_{T}$ in the 50 industries estimated is statistically significant. Experiments with alternative versions of estimation fail to produce any meaningful results. For example, in Rice Milling and Leather Products Industries, the coefficients are meaningless with small t-ratios and very large standard errors. Since respecification of this model also implies respecification of the complete system of equations, the estimates with technical change are not reported.

The theoretical and empirical model of the cES-translog cost function
The third specification is the CES - translog cost function, which was recently developed by Pollack, Sickles and Wales (1984). The CES translog cost function combines the CES production function and the trans log cost function. Like the translog, it is a flexible form, but it is compatible with a wider range of substitution possibilities compared to either the CES or the translog cost function. Since the CES - translog includes both the CES production function and the translog cost function as special cases, it permits nested testing using conventional statistical techniques.

The CES - translog cost function pivots off the CES production function and the trans log cost function by adding another parameter to the trans log cost function. Cost minimization entails

$$
\left.\ell=-P_{L} L-P_{K} K+\lambda\left\{\left[\delta K^{-\rho}+(1-\delta)_{L}^{-\rho}\right]^{-V / \rho}-Y^{*}\right]\right\}
$$

and the first order conditions,

$$
\begin{aligned}
& -\frac{\delta \ell}{\delta K}=\delta K^{-(\rho+1)} \mathrm{Y}^{-(\mathrm{V} / \rho+1)}-\mathrm{P}_{\mathrm{K}}=0 \\
& -\frac{\delta \ell}{\mathrm{L}}=(1-\delta)_{\mathrm{L}}{ }^{-(\rho+1)} \mathrm{Y}^{-(\mathrm{v} / \rho+1)}-\mathrm{P}_{\mathrm{L}}=0 \\
& -\frac{\delta L}{\delta}=\left[\delta K^{-\rho}+(1-\delta) L^{-\rho}\right]^{-v / \rho}-\mathrm{Y}^{*}=0 \\
& \text { MaTS }_{K, L}=\frac{\delta K^{-(\rho+1)}}{(1-\delta)_{L}}=\frac{P_{K}}{-(\rho+1)}=\frac{P_{L}}{}
\end{aligned}
$$

$$
\begin{aligned}
\frac{\mathrm{K}}{\mathrm{~L}} & =\left[\left(-\frac{1-\delta}{\delta}\right) \frac{\mathrm{P}_{\mathrm{L}}}{\mathrm{P}_{\mathrm{K}}}\right] \quad \text { where } \sigma=\frac{1}{1 / 1+\rho} \\
& =\left[\left(\frac{1-\delta}{\delta}\right) \frac{\mathrm{P}_{\mathrm{L}}}{-1+\rho} \mathrm{P}_{\mathrm{K}}\right.
\end{aligned}
$$

Solving simultaneously the first order conditions gives optimal factor demand functions,

$$
\begin{aligned}
& L^{*}\left(P_{K}, P_{L}, Y\right)=Y^{1 / V}\left[\delta+(1-\delta)(-\underset{L}{K})^{-\sigma}\right]^{1 / \sigma} \\
& K^{*} K\left(P_{K}, P_{L}, Y\right)=Y^{1 / V}\left[(1-\delta)+\delta\left(-\frac{L}{K}\right)^{-\sigma}\right]^{1 / \sigma} \\
& C^{*}\left(P_{K}, P_{L}, Y\right)=P_{K} K^{*}+P_{L} L^{k}
\end{aligned}
$$

Substituting $L^{*}$ and $\rho=\frac{1-\sigma}{\sigma}$, we have the specific CES cost function of the form,

$$
\mathrm{C}^{*}\left(\mathrm{P}_{\mathrm{K}}, \mathrm{P}_{\mathrm{L}}, \mathrm{Y}\right)=\delta^{1 / \rho} \mathrm{Y}^{1 / V}\left[\mathrm{P}^{1-\sigma}+\mathrm{P}^{1-\sigma}\left(-\frac{1-\delta}{\delta}\right)^{\sigma}\right]_{1 / 1-\sigma}
$$

The first order approximation of the CES - translog cost function takes the form,

$$
\begin{align*}
\ln C\left(P_{K}, P_{L}, Y\right) & =1 / \rho \ln \delta+1 / V \ln Y \\
& +\ln \left[P^{1-\sigma}+P^{1-\sigma}\left(-\frac{1-\delta}{\delta}\right)\right]^{1 / 1-\sigma} \\
& +1 / 2 \sum_{i} \sum_{j} \beta_{i j} \ln P_{L} \ln P_{K} \\
& +\sum_{i} \beta_{i Y} \ln Y \ln P_{L} \ln P_{K} \tag{4:17}
\end{align*}
$$

Assuming homotheticity, the CES-translog cost function is of the form, -

$$
\begin{align*}
\ln C\left(P_{K}, P_{L}\right) & =a_{0}+\ln \left[\sum_{i} a_{i} P_{i}^{1-\sigma}\right]^{1 / 1-\sigma} \\
& +1 / 2 \sum_{i} \sum_{j} \beta_{i j} \ln P_{K} \ln P_{L} \tag{4:28}
\end{align*}
$$

where $\quad a_{0}=1 / \rho \ln \delta$

$$
\begin{aligned}
\sum_{i} a_{i} & =1 \\
\beta_{i j} & =\beta_{j i} \\
\sum_{i} \beta_{i j} & =0
\end{aligned}
$$

Invoking Shepherd's Lemma,

$$
\begin{aligned}
& \frac{\delta C\left(P_{i}, P_{j}\right)}{\delta P_{i}}=X_{i}^{*} \text {, the cost -minimizing input demand } \\
& \text { and } \frac{\ln C\left(P_{i}, P_{j}\right)}{\delta \ln P_{i}}=\frac{P_{i} X_{i}}{C}=S_{i}
\end{aligned}
$$

Thus, in terms of cost shares ( $S_{i}$ ), the factor demand functions are of the form,

$$
\begin{equation*}
S_{i}=\left[\frac{a_{i} P_{i}^{1-\sigma}}{a_{i} P_{j}}{ }^{1=\sigma}\right]+\underset{j}{\sum} \beta_{i j} \ln P_{j} \tag{4:29}
\end{equation*}
$$

The Cross Allen Elasticities (AES) are now given by

$$
\begin{aligned}
& +\boldsymbol{\beta}_{\mathrm{i} j}+\mathbf{S}_{\mathrm{i}} \mathrm{~S}_{\mathrm{j}} / \mathbf{S}_{\mathrm{i}} \mathbf{S}_{\mathrm{j}}
\end{aligned}
$$

where $\mathbf{i}$ \# $\mathbf{j}$
and $\quad i, j=K, L$
$\sigma^{*} \quad$ is the elasticity of substitution calculated from the icES production function.

For the two-factor case, the estimation equations for the cEstranslog cost function are as follows,

$$
\begin{align*}
& \mathrm{s}_{\mathrm{K}}=a_{\mathrm{K}}+\beta_{\mathrm{KK}} \ln \mathrm{PK}+\beta_{\mathrm{KL}} \ln \mathrm{P}_{\mathrm{L}}+\dot{\varepsilon}_{\mathrm{k}}  \tag{4:30}\\
& \mathrm{~s}_{\mathrm{L}}=a_{\mathrm{L}}+\beta_{\mathrm{LK}} \ln \mathrm{P}_{\mathrm{K}}+\beta_{\mathrm{LL}} \ln \mathrm{P}_{\mathrm{L}}+\varepsilon_{\mathrm{L}} \tag{4:31}
\end{align*}
$$

where $a_{K}=\frac{a_{L} P_{L}^{1-\sigma}}{a_{K} P_{K}}$

$$
a_{L}=\frac{a_{K} P_{K}^{1-\sigma}}{a_{L} P_{L}}
$$

and

$$
\sigma_{K L}=\left\{\left[\left(\sigma^{*}-1\right) a_{K} \cdot a_{L}\right]+\beta_{K L}+s_{K} s_{L}\right\} / s_{K} s_{L}
$$

Note that equations [4:30] [4:31] are exactly the same as equations [4:16] [4:17]. Thus the same estimation procedures as the translog cost function can be used to recalculate the elasticity of substitution derived from the CES - translog cost function.

Attempts were made to recalculate the elasticity of substitution based on the CES - translog cost function at mean cost shares for the beginning and ending years of analysis as well as at base year, 1980. The results of both attempts at calculation, based on unrestricted as well as restricted parameter estimates, could not be validated. The elasticities based on CES - translog cost function approach seem to differ widely compared to the elasticities based on CES production function and the translog cost function approaches. For example, in the Manufacture of Perfumes, Cosmetics and Toiletries, the CES $\boldsymbol{\sigma}=0.59$, TLC ${ }^{\boldsymbol{\sigma}}=1.32$ while the CES $-\operatorname{TLC}{ }^{\boldsymbol{\sigma}}=-29.7$. Similarly, in the case of Manufacture of Drugs, Medicines and Pharmaceuticals, CES ${ }^{\boldsymbol{\sigma}}=0.06$, $\operatorname{TLC}^{\boldsymbol{\sigma}}=1.04$ while the CES - TLC ${ }^{\boldsymbol{\sigma}}=-50.8$. The only consistent pattern shown by all three alternative measures is the generally low substitutability between capital and labor in the Malaysian manufacturing sector. This conclusion of generally low substitutability is based on the fact that the actual elasticities are probably lower than the calculated elasticities. This is in consideration of numerous biases affecting their estimation as discussed earlier.

## CHAPTER V. CHOICE OF APPROPRIATE TECHNIQUE AND EMPLOYMENT GENERATION

The choice of appropriate techniques presupposes a certain degree, however small, of technological feasibility. If industries are flexible in the sense that numerous techniques with widely diverging factor proportions exist, then policies to reduce the wage-rental ratios, such as wage subsidies or capital - use taxes, can be effective in stimulating firms to choose more labor-intensive techniques. If, on the contrary, in an industry only one technique exists, factor price policies have no effect on the choice of technique. The success of such policies depends on the following conditions,

1. whether technical substitution possibilities exist
2. the effectiveness of policies in changing factor prices
3. the extent to which firms are influenced by price signals in their choice of techniques
4. the availability of factors which influence the choice of appropriate techniques

The basic question which this section tries to answer is whether the economic policies of the Malaysian government and the decisions taken by private local and foreign firms are likely to have influenced the choice of inappropriate techniques in the manufacturing sector.

One of the procedures consists of testing whether capital-intensive industries have been systematically promoted by fiscal incentives and by trade policies. A second method would be that of direct questioning of private firm managers and government planners and executives. Unfortu-
nately, such an undertaking is beyond the scope of this study. This chapter will focus on a discussion based on past literature to shed some understanding on these issues. The first part of the chapter discusses the factors which may influence the choice of technique in a developing country. The second part discusses other possible reasons for the choice of inappropriate techniques and low labor absorption in the manufacturing sector of developing countries such as Malaysia.

Assessment of Technical Substitution Possibilities

The foregoing Chapters III and IV have focused on the measurement of the elasticity of substitution between capital and labor in 5-digit Malaysian manufacturing industries. Chapter III focuses on the CES production function approach while Chapter IV focuses on the translog cost function approach. The estimated values of the elasticity of substitution are presented in Tables 3.2 and 4.4 . Most of the indus tries exhibit elasticities whish are significantly different from zero, thus discrediting the notion of fixed-proportions.

The elasticity of substitution is chosen as an indicator of substitution possibilities because it directly answers the question policy makers are interested in: how much can factor proportions be expected to change when factor prices are changed by a given proportion?

Despite differences in the two estimation procedures, the alternative estimates do not produce substantially different results. Although in a number of cases, the two estimates contradict each other with regard to whether the elasticity is greater or lesser than unity, in
most industries, the elasticity is rather low. The impression that low substitution elasticities are more common in Malaysia's manufacturing industries is reinforced by Hoffman and Tan's study. Furthermore, due to the upward biases of elasticity measurement, as discussed in Chapter III, the true elasticities are probably in fact lower than the calculated elasticities.

The practical significance of these results is, however, not immediately clear due to the underlying assumptions of the production function. One of the major criticism of econometric estimates of elasticity of substitution is the assumption of homogeneous inputs and homogeneous single output (Morawetz, 1974; Gaude, 1975). When more than one homogeneous product is included in the industry definition, the elasticity of substitution has a different meaning. Substitution is no longer only a matter of choice of technique but also a matter of choice of productmix. It follows that choice between different factor combinations depends not only on the production function and relative factor prices, but also on consumer demand. Not only the firms, but also the consumers decide how output-mix changes due to changes in factor prices.

In practice, however, the separation of the choice of technique from the choice of output involves several problems. First, when appropriate technology is defined in terms of social optimum, it may be necessary to use product-mix as a policy variable in order to achieve employment and distributional goals (Morley and Smith, 1977). In this sense, it would seem unnecessary to separate the choice of technique from the choice of output-mix. The main argument for separating the
choice of technique from the choice of product is to ensure that the effects of factor prices are predictable. If changes in product-mix are also desirable, they may require different or additional policy measures.

In addition to encouraging more appropriate or labor-intensive industries through factor-price manipulation, it may also be possible to encourage the production of more appropriate goods within each industry (rattan rather than glass and steel furniture, as an example). According to Lancaster (1966) and Stewart (1972, 1979), products may be classified in at least three different ways. First, they may be grouped according to cross-elasticities of demand, identical products having infinite cross elasticities. A more practical way, however, is to group products according to their physical attributes. Thirdly, products may be classified on the basis of needs that they fulfill. The third classification may enable the development of products which are more appropriate to the factor endowments of labor-abundant countries. For example, production of detergents would be more capital-intensive compared to the manufacture of other types of soap.

Despite the conceptual problems mentioned, the range of the elasticity of substitution measured through the CES production function and the translog cost function approaches seem to concur with similar studies in other LDCs. Various factors are identified which may influence the range and density of substitution between capital and labor in manufacturing industries. These factors are discussed below.

## Degree of product differentiation

In most developing countries such as Malaysia with a limited and less diversified domestic market, product differentiation is rather limited. Product differentiation is understood here in a physical sense which has implications for production techniques and factor use. The following example of the tobacco industry is frequently mentioned as technologically flexible (Baranson, 1979). This is so when it includes cigarettes, cigars and other products. While cigarette production is fairly capital-intensive and offers relatively little flexibility in factor proportions, cigar production is more labor-intensive. If the industry includes both products, the range of substitution in the tobacco industry is likely to be large. However, since the Malaysian market is less diversified, the industry produces mainly cigarettes. Although there is quite substantial differentiation in terms of brand names, they essentially involve the same technique of production and factor use.

## Depth of transformation

A second determinant of substitution possibilities is the depth of industrial transformation which can be defined by the number of stages or sub-processes. If there is a single stage with three alternative processes, then there are only three alternative techniques to choose from. If, however, there are three stages in manufacturing a product, and at each stage three process alternatives exist, then the number of theoretically possible combinations is twenty-seven. In practice the
number of transformations will be much smaller for two reasons. First, some alternative combinations may have the same factor proportions. Second, not all combinations are feasible, because they may not fit in terms of quality standards, rates of output, and other dimensions. Some combinations may also be inefficient. In Malaysia, the concern with quality and standards would mean choosing modern techniques, thus reducing further alternative techniques available.

## Ease of mechanization

In industries with techniques which are easily mechanically operated and controlled, such as chemical industries, technical flexibility is small. Mechanical procedures in such industries are more efficient and cost effective. Highly mechanized processes are also likely to be more integrated than less mechanized ones. Consequently, process stage is less distinguishable. Great ease of mechanization, therefore, seems to be associated with low substitutability.

## Skill_constraint

The scarcity of skills in LDC manufacturing industries strongly influences the range of factor substitution. The pool of experienced managers, supervisors and technicians is normally supplied by expatriates. Even if they are local personnel, they tend to command relatively higher wages. The choice of techniques is then affected through the high cost of this factor. The lack of skilled technicians and artisans has more constraining consequences. It explains low labor productivity and also explains why certain advanced techniques are inefficient. The
lack of specialized and skilled workers tends to reduce the range of substitution in the sense that both most advanced and most labor-intensive techniques may be excluded from the set of efficient techniques.

Factors Responsible for the Choice of Inappropriate Techniques In conventional economic theory, labor-abundant countries such as Malaysia would use more labor-intensive methods of production while capital-rich countries such as the advanced industrialized countries would use more capital-intensive methods. In practice, however, many industries in labor-abundant countries in the developing world including Malaysia tend to be capital-intensive (Lim, 1973; Abdullah, 1979). The empirical investigation on the elasticity of substitution also suggests that inappropriate choice of techniques may have resulted in low substitutability.

A substantial literature has developed recently dealing with the causes of biases in the choice of techniques. It is possible to distinguish two dominant themes in the literature. One attributes non-optimal choices of technique to biases in government policies resulting in price distortions and the other to the behavior of private entrepreneurs and in particular that of multinational firms.

## The influence of government policy biases

The basic question which needs to be answered is whether economic policies of the Malaysian government are likely to have influenced the choice of inappropriate technologies and in what manner. The large number of possibilities for the government to influence the choice of
appropriate technologies can be subdivided by distinguishing three types of intervention.
a) direct intervention through the government's role as entrepreneur and through public spending,
b) direct intervention through legislation or equivalent policy instruments,
c) indirect intervention through the alteration of market signals.

In general, all interventions have some bearing on prices. However, the biases resulting from the last type of interventions are mainly discussed in the literature as the major reasons for the distortionary effects on factor prices in developing countries (Siggel, 1986). The price-incentive school stresses the price distortions as a major cause of many of the problems of LDCs, including inappropriate choice of techniques and the consequent unemployment problems. Of major concern are relatively high wages in the modern sector; relatively low prices of capital, caused by low interest rates; tax incentives related to investment promotion; and over-valuation of the exchange rate as well as high levels of protection.

In Malaysia, a wide variety of government policies have made capital artificially cheap. Capital is made cheaper than its true value through government subsidized loans, especially for small and mediumscale industries, and over-valued exchange rates. According to the strict Purchasing Power Parity criterion, the Malaysian Ringgit effective exchange rate was over-valued by 5 percent in 1982 , 9 percent in

1984 and 7 percent in 1985 (Gan, 1987). The price of capital is also affected by low tariffs for imported capital goods, tax holidays and other investment incentives, accelerated depreciation allowances on capital goods and investment tax credits offered by the government to investing firms in Malaysia. Coupled with relatively high urban wages, the low price of capital has resulted in a higher wage-rental ratio in the manufacturing sector than its true value in terms of the available factors of production in the country.

## Biases in private decision making

The second large group of factors responsible for the choice of inappropriate techniques concerns the behavior of private decision makers as opposed to government policies. Several researchers concerned with the choice of technique in developing countries have argued recently that entrepreneurial or business firm's decisions may be responsible for the use of inappropriate techniques even if the price signals are correct, and even more so under distortionary price signals (Wells, 1973; Lecraw, 1984; Morley and Smith, 1977). Paul Chan (1979) found that foreign firms in Malaysia tend to obtain their machinery and transfer their technology more or less intact from their parent companies in their home countries. Little adaptation is made to take advantage of the relatively abundant labor in Malaysia. Adaptations made are mainly to suit the requirements of the smaller domestic market. Chan's conclusions concur with findings in Brazil, Pakistan and Puerto Rico (Morley and Smith, 1977; White, 1978; Strassman, 1968) that firms use
inappropriate production technique especially in the context of employment creation in developing countries such as Malaysia.

Several reasons have been advanced for the lack of modification of technology transferred from advanced to developing countries.
"Engineering" versus "economic" man
Perhaps the most convincing explanation of choice of techniques which are not compatible with cost and resource considerations is provided by Wells (1984). In a number of Indonesian manufacturing industries, Wells noted that investment decisions are strongly influenced by the objectives of engineers which are not necessarily the same as those of the "economic man". The "engineering man" prefers to solve operational problems by managing machines rather than persons; he typically aims at producing the highest quality products, and tends to believe that the most technically advanced machines in an engineering sense are also the most economically efficient ones. Firms managed by "engineering man" would then tend to use more capital-intensive, less appropriate techniques of production.

## Costs and risks of technology search

Morley and Smith (1977) suggest other factors in addition to the "engineering man" motives of private firms in their decisions on the choice of techniques. According to Morley and Smith, firms in Brazil are willing to reduce their profits by choosing an inappropriate capital-intensive technique when this choice reduces the risks of their operations. Thus, firms do not search for a lower cost technology or
try to adapt to the factor proportions in the country when they perceive a higher risk of technological failure, breakdowns, delays, cost overrun, unacceptable quality, etc. More importantly, they conclude that firms in Brazil are not forced to use an appropriate technology, since the competitive environment in Brazil allowed inefficient firms to exist.

Morley and Smith's observations are of interest because the experiences in the Brazilian manufacturing sector may be similar to the conditions in Malaysia.

## Position in international trade

A particularly interesting explanation of the choice of capitalintensive technology by firms in developing countries such as Malaysia is their position in international trade. This operates through both imports and exports. If developing countries are to make real inroads into advanced country markets, they have to produce goods with acceptable quality and tastes for these markets. The exporting developing country also has to keep abreast with product and technology changes over time if it is to maintain its position in export markets. Competition in other developing countries where goods from developed countries are available make it essential to keep up with advanced country product developments. Thus even in the markets of neighboring LDCs, unless there are special trading arrangements, the exported products have to compete with developed country technology and the best way of doing so seems to be to adopt it.

For "market-oriented" firms that follow a strategy of product differentiation, branding and high advertising and selling costs, appropriate technology is relatively unimportant. Production costs for these firms are a less important component of total costs.

## Role of multinational corporations

Most empirical evidences point out that multinational firms investing in developing countries utilize advanced country techniques with little modification to the core plant or process and product, but with some variation in labor use in ancillary activities. Branson (1975) concludes, on the basis of a survey of fifty multinational firms with automative parts manufacturing affiliates in developing countries, that there is little technical adjustment in product designs or production techniques. Hughes and You (1969) conclude that foreign firms in Singapore use capital-intensive methods. Similarly, in a study of the transfer of technology based on 338 manufacturing establishments in Malaysia (Hoffman and Tan, 1980), it is found that all MNC subsidiaries are turnkey projects which are heavily dependent on their parent companies for equipment and machine parts, professional and technical personnel, and even marketing support. Lim and Cheong (1981) also find that multinational electronic firms rely on their parent firm for capital equipment.

Although Pack (1972) and Boon (1969) provide counter evidences in Kenya and Mexico, most researchers believe that multinational firms are capital-intensive except in the electronics and textiles industries.

They tend to be capital-intensive for a number of reasons. The basic reason is that the multinationals are more interested in maximizing their profits than in maximizing their output or employment (Stobaugh, 1984). Even if investors are not fully profit-motivated, other reasons for the lack of modification of techniques by multinationals are low labor productivity, lack of local backup R\&D, and the danger of having their technologies "stolen" if they are too simple. Furthermore, it is on the basis of advantages of possessing these unmodified capital-intensive technologies that they have become multinationals. The very essence of profiting from international operations lies in the ability to apply a given package to different areas with as little cost adaptation as possible. Hence, there really may be little incentive for multinational firms to adopt labor-intensive techniques in developing host countries.

## Differences in labor productivity

Theoretically, when a certain technique of production is employed with labor of varying quality, it may yield a varying quantity and/or quality of output. Thus, when a profit-maximizing firm chooses the optimal technique according to the relative factor prices, it must also take into account the factor productivities. Since most technology is transferred to developing countries from advanced countries without much modification, both advanced countries with a highly-trained labor force and developing countries with relatively low labor skills face the same set of alternative techniques. Due to their productivity differences,
the firms in developing countries have the incentive to choose a more capital-intensive technique than would be expected on the basis of nominal factor prices. The incentive is especially strong if the productivity differential between the countries increases with the labor intensity of the technique chosen.

The effect of productivity differences on the choice of technique is a substitution process of different quality of labor. Cost-minimizing firms or those concerned with quality of products would substitute capital for labor by choosing a more capital-intensive technique in order to compensate for the lower labor productivity.

The foregoing discussion of the range and density of the elasticity of substitution between capital and labor, and the choice of inappropriate capital-intensive technique of production, helps to clarify why there is low generation of employment opportunities in developing countries' manufacturing sector. Choice of inappropriate technique of production by the modern manufacturing sector has often been cited as a major cause of unemployment, since excessively capital-intensive technology consumes the scarce capital resources of developing countries without generating sufficient increases in employment in the modern industrial sector. Three explanations for the choice of inappropriate technique of production have been advanced:

1. Besides the obviously labor-intensive technologies in electronic, textile and footwear industries, only a limited range of efficient technologies, which tend to be capital-intensive, are available to firms in developing countries such as Malaysia.
2. The factor prices faced by firms in developing countries may be distorted by laws concerning industrial employment, exchange rate policies, government tax and capital-investment incentives.
3. The decisions and the nature of the firms themselves also determine the choice of more capital-intensive techniques with minimal adaptation or modifications to the factor proportions of developing countries.

When firms in developing countries are seen to choose inappropriate techniques in their operations, and when efficient substitution possibilities are limited, the policy implications are striking both for the firms themselves and for the development policies of the developing countries. The conclusions to this study, the policy implications and recommendations for further research are discussed in the following section, Chapter VI.

CHAPTER VI. CONCLUSIONS AND POLICY IMPLICATIONS
A number of major conclusions related to the utility of the elasticity of substitution for policy making may be distilled from the foregoing research and discussion. The first concerns the usefulness of comparing estimates of the elasticity of substitution drawn from different sample bases and levels of aggregation and different equations reflecting varying assumptions about the production function. Although a generalization of relatively low elasticity of substitution in Malaysian manufacturing sector can be inferred from the study, strict comparability of estimates requires very strict comparability of both the treatment of data, assumptions and the estimation procedures. Nerlove (1967) and Morawetz (1976) conclude that even slight variations in the period or concepts can produce different estimates of the elasticity of substitution. It is not possible to identify industries with consistently high or low elasticities. In this study, however, it is interesting to note the similarities in the range and the generally low elasticity of substitution in the Malaysian manufacturing sector, either through the CES production function or the translog cost function approaches. It is, however, not possible to identify industries with consistently high or low elasticities and industry rankings, too, tend to be quite unstable. As such, it is not possible to interpret with confidence the point estimates of each industry.

Furthermore, attempts to estimate elasticities of substitution using econometric methods suffer from a number of shortcomings. Among the most important of these is the assumption of homogeneous inputs to
produce a single homogeneous output. No account is taken of other factors such as the quality of management, existence of different qualities of labor and different types of capital equipment. Econometric measurements also suffer from the difficulties of incorporating technical change, working capital and varying rates of capital utilization over time. Attempts are made in this study to overcome possible biases from aggregation problems, the effects of technical change, economies of scale and imperfections in both product and commodity markets. The results, however, are not satisfactory.

In light of these empirical problems, the utility of the substitu-tion-possibility indicator could be greatly reinforced by estimates based on a better quality firm-level data based on empirical surveys, field investigations and interviews with entrepreneurs. Since. Morawetz's criticisms of the elasticity estimated by econometric methods, there have been substantial developments and improvements in estimation procedures and econometric techniques especially concerning simultaneity problems and technical procedures for improving the quality of data for estimation purposes. Being relatively less costly, econometric measurements can still be useful.

Alternatively, detailed product-by-product or process-by-process engineering analysis studies have to be carried out to investigate the degree of factor substitutability and the extent to which the adoption of appropriate techniques can be expected to absorb employment. Such microeconomic tasks can be undertaken only for a number of products since such detailed investigations are costly and time consuming.

The second significance of this study is the role of substitution elasticities with respect to employment generation in the Malaysian manufacturing industries. In the short-term, the possibilities for substitution between capital and labor in the majority of industries appear to be rather limited. Thus, factor price policies are not likely to result in important changes in the techniques of production and employment in the Malaysian manufacturing sector. In the long-term, however, the establishment of proper factor prices to reflect the true scarcities of capital and labor is very important. This has been a familiar refrain from economists over the past ten years, but it can still bear repeating. Efforts must be made to reduce the subsidies to capital use. The cumulative employment effect of setting factor prices right can be quite substantial. The new factor prices would favor the investment of new capital in more labor-intensive industries. Furthermore, where alternative technologies are available, each industry would be encouraged to use the more labor-intensive technique of production. Moreover, increasing the price of capital relative to labor would induce an increase in the prices of capital-intensively produced goods. This will in turn result in shifting the composition of output in favor of goods with a higher employment content.

Limited factor substitution is due to the limited range of alternative technologies available. An obvious policy implication to increase employment generation is to expand the range of appropriate technologies available to the firms. This involves not only improving the information and technology networking systems, but also determining the
channels and types of investments associated with the transfer of technology from industrialized countries, and improving local scientific research and technological development.

The correct choice of technique and appropriate factor proportions can positively influence employment generation in the manufacturing sector. However, changing one policy in isolation may not provide the impact on the demand for labor as envisaged. As such, other policies which affect employment need to be addressed simultaneously. These policies include the output composition or the product-mix to be manufactured, the types and scale of industries to be promoted, the increase in productivity and capacity utilization of the manufacturing sector.

Product composition has obvious affects on the magnitude of employment opportunities which can be generated with a. given level of output. The composition of output at the industry level is determined by the structure of aggregate demand consisting of demand by domestic consumers, foreign consumers in the export market, the government sector and private investors. For each of these sectors, the policy implication is to influence the demand for goods which are produced labor-intensively. Thus, efforts to increase exports of labor-intensive products such as textiles, footwear, electronics must be intensified. Furthermore, the government can influence the level of employment by directing their spending favoring labor-intensive projects rather than large-scale capital-intensive projects in public works and construction.

Another area of interest which has employment implications is the intra-industry-mix. In addition to the possibility that more labor-
intensive industries are encouraged, it may also be possible to encourage more labor-intensively produced goods within each industry. For example, the production of soap is more labor-intensive relative to the production of detergent, and the production of leather or canvas footwear is similarly more labor-intensive relative to the production of rubber-molded footwear.

Another policy implication is related to the rate of capacity utilization in the manufacturing sector. Utilizing the existing capital stock more intensively will lower the capital-labor ratio, and at the same time, increase employment in the industry. Furthermore, as capital utilization is increased, the subsequent increased need for maintenance will add further to total employment.

Although references have been made in the literature to Malaysian industrial development, few systematic studies have been undertaken, especially in quantifying the employment effects of various policy measures.

## Directions for Further Research

The issues of technological choice and employment generation are important to the Malaysian economy. This research has provided the econometric estimates of the elasticity of substitution between capital and labor and a discussion of the factors which may influence the range and density of substitution, as well as the capital-intensity bias of the manufacturing firms in Malayṣia. This attempt to estimate the elasticities of substitution using econometric methods, however, suffers
from a number of theoretical and empirical shortcomings. These shortcomings render the estimates of the elasticity of substitution a doubtful indicator on which to base economic policy formulation. Its utility could be greatly enhanced if support for prima facie estimates could be obtained from empirical surveys, investigation of the firms and interviews with entrepreneurs. Since the major shortcoming of this study is the available data, reestimation with an improved firm level data will provide more confident estimates of the elasticity of substitution. Future research to estimate the elasticity of substitution can take alternative approaches as discussed below.

1. The elasticity of substitution can be reestimated using econometric methods with improvements of the data base, as well as the model specifications. It is suggested that both the capital and labor data be reformulated, as the Divisia quality indices would take account of the various qualitative aspects of capital and labor, such as capacity utilization, the rate of depreciation of capital and educational as well as age structure of labor. Furthermore, the model can be respecified to estimate elasticity of substitution between capital and different categories of labor, i.e., skilled and unskilled labor.
2. An alternative approach in estimating the elasticity of substitution between capital and labor is to investigate technological choices at the micro level, where all of the specific determinants relevant to a given choice can be ascertained and analyzed in detail. This approach, known as engineering process analysis, permits the evaluation of alternative techniques using project appraisal methods. A principal part of
the investigation is to see if there are alternative means of producing the same volume of output, that is, if more workers and fewer machines (or, usually, simpler and cheaper machines) can produce the same volume as fewer workers and more machines. This is, of course, the heart of substitutability question. Thus the appropriate technique may be identified as that which minimizes production cost. Policies to increase labor use in LDCs manufacturing sector have often being discussed in the literature. Policies involving factor prices, output and industry-mix, capacity utilization and productivity have also been discussed in the Malaysian context. However, there has been little systematic analysis to quantify the direct and indirect employment effects of the various policy instruments. Future research should concentrate on systenatic analysis of policy-oriented issues. Some areas of study which merit further research are:
i) The magnitude of factor price distortions and the problem of technical substitution and employment generation. Such studies should include the calculations of the effective rate of protection, the effective subsidy of profits, the impact of capital use subsidies and the implicit taxation of the use of labor. Such studies are useful in determining the impact of distortionary pricing policies of the Malaysian economy, especially on employment generation.
ii) The influence of product mix and quality standards on the nature of appropriate technology and employment creation. This includes stuclies on demand elasticities of different categories of consumers and the impact of income distribution on final demand.
iii) Finally, systematic research needs to be carried out to determine the employment impact of increasing productivity and capacity utilization.

On the whole, therefore, our estimates do not provide a very optimistic outlook on manufacturing employment possibilities and it underscores the need for a more cogent employment-oriented industrialization policy. Factor price policies are not likely to result in important changes in technique and employment in Malaysian manufacturing sector. The conclusion derived from the empirical estimates of the generally low capital-labor substitution possibilities is reinforced by the discussion of responsiveness of firms to factor prices in Chapter $v$. Nonetheless, policies to increase labor absorption through price incentives, though limited, can still be important. Getting factor, product and foreign exchange prices right is very important in an open competitive economy such as Malaysia. The practice of reducing import duties on capital goods for certain industries can result in the negative impact on labor absorption. As such more equal treatment of exports and import substitutes will ensure that countries produce according to comparative advantage.

The third and perhaps the most important policy implication of this study is that the problem of employment absorption in developing countries such as Malaysia is mainly structural in nature. The eventual resolution of the employment problem depends not only on the direct employment effects of the year-to-year choice of techniques but more importantly on the general development strategies in the country. The
issues related to employment absorption are multi-faceted. Besides the choice of techniques, other aspects of importance are output and industry-mix, scale of production, the rate of population growth, the location of resources, the behavioral and cultural characteristics of households and communities, the organization and capacity to plan and implement, international trade, capital flows and transfer of technology, the ownership and management of resources and the structure of political and economic power. Long-term labor absorption in manufacturing as well as other sectors require policies which are intended to affect these conditions. They involve technical as well as social and political conditions.

With respect to the choice of technique, the policy implication is the possibility for the government to intervene by influencing the coun-try-specific production function. In the shortrun the government can modify the product-mix of industries. Product composition has obvious effects on the magnitude of employment opportunities which can be generated with a given level of output. Some products require more labor per unit of output than do others and, if total costs are comparable, more labor per unit of capital employed in production. Thus, present efforts to increase exports of labor-intensive products such as textiles, footwear, and electronics must be intensified. Consideration, however, must also be given to secondary effects of manufacturing activities. Each product requires other material and capital inputs and may itself be an input in the production of other goods; when these secondary employment effects are taken into account, product preferences may have to be
reordered. Another issue is the argument that employment considerations tend to favor import-substitution over export-promotion since importsubstitutes are produced to meet lower income needs. It is argued that production of such goods may on average employ more labor. This argument is less persuasive when secondary employment effects are introduced, when it is applied to intermediate goods. More careful study is necessary to determine these effects on employment in the manufacturing sector.

Domestic income distribution affects the product-mix demanded within a country. Normally, high income groups demand imported goods from building materials for their houses to their food. This aspect, too, requires quantitative research before quantitative effects on employment can be determined. There are, however, various policy tools which can be used to modify income distribution and the product-mix purchased domestically. These include progressive taxation, subsidies on essential goods and encouragement of production of non-1uxury goods. Technical strategies for improving employment in Malaysia require continuing research and empirical study. The more critical problems continue to be first to modify ideal strategies to conform to the settings in which they are to be implemented. Second is to operationalize and find ways and means of transferring the knowledge and information about strategies to policy-makers so as to be implementable.

## ACKNOWLEDGEMENTS

I extend my deepest appreciation and thanks to Professor Lehman B. Fletcher for his unwavering and excellent guidance, contribution and support throughout my Ph.D. program. Professor Fletcher has also taught me the truest meaning of kindness.

Dr. Roslan A. Ghaffar deserves special recognition for helping with the computer program at a critical time. I also gratefully acknowledge the help from Professor Mokhtar Tamin, Professor Mohd. Ariff Hussein, Professor Osman-Rani Hassan and Professor Ismail Mohd. Salleh for their suggestions and concern. I also would like to acknowledge my other POS committee members; Professors J. Stephenson, A. Paulson, and R. E. Gwiasda. I am especially indebted to Professor D. G. Luckett for his willingness to come to Ruala Lumpur.

Acknowledgement is made to Universiti Pertianian Malaysia for funding this study.

Finally, I wish to express my gratitude to Ridzwan Halim for his example and love throughout the period of study.

[^0]:    *Implies significant at 5\% significance level.

[^1]:    afor each industry group, row one shows the cofficients, row tuo shows the t-statistics and row three shows the standarderrors of each coefficient.
    *Implies significant at $\alpha=.10$ uith a 2-tailed t-test.

    * Implies significant at $a=.05$ with a 2-tailedt-test.

[^2]:    ${ }^{c}$ Elasticity of substitution calculated at base year $=1980$. Elasticity of substitution calculated at ending year of analysis.
