

Contrast-Induced Acute Kidney Injury: Specialty-Specific Protocols for Interventional Radiology, Diagnostic Computed Tomography Radiology, and Interventional Cardiology

STANLEY GOLDFARB, MD; PETER A. McCULLOUGH, MD, MPH;
JOHN McDERMOTT, MD; AND SPENCER B. GAY, MD

Contrast-induced acute kidney injury (AKI) (also known as contrast-induced nephropathy) is an abrupt deterioration in renal function that can be associated with use of iodinated contrast medium. Although the increase in serum creatinine concentration is transient in most cases, contrast-induced AKI may lead to increased morbidity and mortality rates in selected at-risk populations. This review summarizes the findings of a multidisciplinary panel composed of computed tomography radiologists, interventional radiologists, cardiologists, and nephrologists convened to address the specialty-specific issues associated with minimizing the incidence of contrast-induced AKI. As part of this initiative, the panel developed specialty-specific protocols for preventing contrast-induced AKI, taking into account, for example, the variations in patient risk profile, inpatient or outpatient status, and staffing resources that characterize various clinical settings. The 3 protocols, each reflecting a consensus of expert opinion, address the prevention of contrast-induced AKI in interventional radiology, diagnostic computed tomography radiology, and interventional cardiology settings. The protocols are presented in the context of a review of recent guidelines and published reports of trials that discuss contrast-induced AKI and its prevention. The panel reviewed materials retrieved by a PubMed search covering the period January 1990 through January 2008 and used combinations of key words associated with the prevention and treatment of contrast-induced AKI. In addition, the panel reviewed the reference lists of selected articles and the tables of contents posted on the Web sites of selected journals for relevant publications not retrieved in the PubMed searches.

Acute kidney injury (AKI) is a heterogeneous disorder with multiple etiologies, risk factors, and clinical presentations. Although patients with AKI are ultimately cared for by nephrologists, AKI occurs in various clinical settings and is associated with a specific etiology in each. The term *contrast-induced AKI* refers to the disorder as it

occurs after exposure to iodinated contrast media, a disorder that has been more commonly known as *contrast-induced nephropathy* (CIN). The Acute Kidney Injury Network, recognizing the need for improving outcomes associated with the various forms of AKI, recently proposed using the following standardized diagnostic definition in all cases: an abrupt (within 48 hours) reduction in kidney function, evidenced by an increase in the serum creatinine concentration of at least 0.3 mg/dL (to convert to $\mu\text{mol/L}$, multiply by 88.4) or at least 50% from baseline or a reduction in urine output (documented oliguria of <0.5 mL/kg/h for >6 hours).^{1,2} The criterion of oliguria does not apply for many cases of contrast-induced AKI because patients are treated with intravenous fluids before and after the procedure with the goal of increasing periprocedural urine output. The most commonly used definition of CIN is an increase from the baseline serum creatinine concentration of at least 0.5 mg/dL or at least 25% within 48 to 72 hours after exposure to contrast media.³⁻⁵ Because the medical community is moving to adopt the concept and terminology of the American College of Radiology (ACR) in reference to studies of contrast-induced renal dysfunction and its prevention,⁶ this report will do the same. However, we recognize that the clinical effect of the slightly different definitions of CIN and AKI has yet to be clarified.

The incidence of contrast-induced AKI is low (2%) in the general population,⁴ but it is higher in certain at-risk

groups of patients. Patients who have both chronic kidney disease (CKD) (defined as an estimated glomerular filtration rate [eGFR] <60 mL/min/1.73 m²)⁷ and diabetes mellitus are at highest risk⁸⁻¹⁰; the incidence of contrast-induced AKI is as high as 50% for patients with multiple risk factors.¹¹

Contrast-induced AKI has serious prognostic implications; it is linked to increases in length of hospital stay and to higher rates of in-hospital cardiovascular events, in-hospital mortality, and 1-year and 5-year mortality rates.^{5,9,12-14} Even relatively small changes in renal function after administration of contrast medium are associated with substantial increases in mortality rates¹⁴; this finding suggests that renal insufficiency is a sensitive marker of poor outcomes for patients at risk or perhaps that transient episodes of renal ischemia may produce secondary hemodynamic or vascular changes in other organs.¹⁵

The materials cited in this review include recent guidelines and published reports of clinical trials of contrast-induced AKI and its prevention. These materials were retrieved by a PubMed search covering the period January 1990 through January 2008. The search used combinations of the following key words: *contrast agent, nephrotoxicity, hydration, N-acetylcysteine, sodium bicarbonate nephropathy, and acute kidney injury*. In addition, we reviewed the reference lists of published articles and the tables of contents posted on the Web sites of selected journals for relevant publications not retrieved by the PubMed search.

EXISTING PRACTICE GUIDELINES

Several official organizations representing the disciplines of cardiology, nephrology, and radiology have recognized the importance of addressing the management of contrast-induced renal complications in their formal practice guidelines. The extent to which preventive measures for contrast-induced AKI are addressed varies across guidelines.

The most recent American Heart Association (AHA)/American College of Cardiology (ACC) guidelines for the management of patients with unstable angina or non-ST elevation myocardial infarction and for percutaneous coronary intervention (PCI) highlight the importance of using iso-osmolar contrast media as a preventive measure for patients with CKD who require coronary intervention: "In chronic kidney disease patients undergoing angiography, isosmolar contrast agents are indicated and are preferred."^{16,17} This is a class I recommendation at level of evidence A and is based on the findings of clinical trials and meta-analyses.^{18,19} The guidelines advise that patients with cardiovascular disease should be screened for CKD according to the AHA/National Kidney Foundation (NKF) recommendations⁷ and that use of iso-osmolar contrast media should be guided by the results of such screening.

The latest ACR formal practice guidelines for using iodinated contrast media focus on determining which patients have an increased overall risk of adverse effects because such patients are likely to benefit from the use of low-osmolar rather than high-osmolar contrast media.²⁰ Specific ACR recommendations (as they appear in the updated ACR Manual on Contrast Media) for preventing contrast-induced AKI include the following: initiating intravenous volume expansion with saline both before and after CM administration, administering the antioxidant *N*-acetylcysteine (NAC) to patients at risk, measuring the serum creatinine concentration of patients with suspected renal dysfunction, and using either low-osmolar or iso-osmolar contrast media for all patients with renal insufficiency.²⁰

The NKF has issued clinical practice guidelines for evaluating and managing cardiovascular disease in patients undergoing dialysis: use of iso-osmolar contrast media and administration of NAC are appropriate because of their potential benefit in preserving renal function. The NKF guidelines caution against routine use of sodium bicarbonate and volume expansion for these patients.²¹

The European Society of Urogenital Radiology (ESUR) has issued guidelines for using contrast media. These guidelines incorporate risk factors for CIN, recommendations for identifying patients at risk, and strategies for reducing risk, such as using either low-osmolar or iso-osmolar contrast media, initiating intravenous volume expansion, and discontinuing administration of nephrotoxic drugs.²²

THE NEED FOR SPECIALTY-SPECIFIC GUIDELINES

The existing guidelines often lack detail and do not cover all aspects of patient management. In particular, they often fail to address specialty-specific issues. Such issues may be associated with variation in risk-benefit ratios across different patient populations or with practical aspects of implementing risk assessment and prophylactic strategies for contrast-induced AKI in certain settings, such as a busy computed tomography (CT) unit with a large number of patients, limited space, and limited nursing resources or an interventional cardiology setting for patients undergoing elective PCI. Specialty-specific technical and procedural factors may also dictate management choices. In studies of peripheral vessels, particularly runoff studies, the choice of contrast media is dictated by patient tolerability because image quality is easily reduced by motion artifacts driven by patient discomfort. Local pain associated with injection of contrast media has been correlated with osmolality.^{23,24} Several studies that have compared the tolerability of the iso-osmolar contrast medium iodixanol with that of low-osmolar contrast medium report that iso-osmolar contrast

medium is associated with a decrease in the intensity of discomfort (heat sensations) and pain.²⁴⁻³⁰

Overall, the key issue that becomes important to define for each specialty is the degree of risk that makes the effort needed to screen patients, identify those at risk, and then implement prevention strategies, a requirement despite any impracticality.

COMPONENTS OF AN EFFECTIVE PROTOCOL

SCREENING

Should all patients be screened for CKD, or should screening be reserved for a select group? Routinely performing serum creatinine assays for all patients may be costly, cumbersome, and inconvenient.³¹ In most cases, the clinical history provides enough information to allow determination of which patients are likely to have CKD and therefore the risk of contrast-induced AKI. In outpatient and emergency settings, a basic questionnaire that addresses the patient's history of renal disorders and additional risk factors may be simpler and more cost-effective than universal serum creatinine screening.^{31,32} Another approach, developed and validated for patients undergoing PCI, is to assess a patient's degree of risk by using a scoring system based on risk factors for contrast-induced AKI.³³

What measurement should be used? Serum creatinine concentration alone is an insensitive indicator of kidney function. The commonly used cutoff, a serum creatinine concentration of 1.5 mg/dL or higher, fails to detect 40% of patients at risk of contrast-induced AKI.³⁴ The GFR is thought to provide the best overall index of renal function, but measuring it may be impractical. Instead, estimates of renal function, either the eGFR or the calculated creatinine clearance (CrCl) rate, are determined by empirically derived formulas based on the serum creatinine concentration. The eGFR is calculated by using the Modification of Diet in Renal Disease (MDRD) formula; the CrCl rate, by using the Cockcroft-Gault formula.^{35,36} Although both methods have limitations,³⁷ estimating the GFR from the serum creatinine concentration is recommended because it provides a more sensitive and specific measure of renal function than does the serum creatinine concentration alone. The 4-variable MDRD formula, which uses the serum creatinine concentration and the patient's age, with adjustments for sex and race, is preferable to the Cockcroft-Gault formula,³⁷ particularly for patients with diabetes.^{38,39}

Should the eGFR be assessed immediately before the procedure? If not, how recent should the assessment be? For many inpatients, a current serum creatinine measurement should be available. In outpatient settings, should the referring physician be expected to provide results of a recent assay? For high-risk patients, should the procedure be de-

ferred until results of a recent assessment of kidney function are available? Point-of-care testing, which can provide the serum creatinine concentration within minutes, is likely to be useful in such situations.⁴⁰ With regard to timing the serum creatinine assay, it is important to establish the baseline serum creatinine concentration before intravenous volume expansion is initiated (discussed subsequently). Otherwise, estimates of renal function may be misleading because of the decrease in the serum creatinine concentration that is induced by increased extracellular fluid volume.

In an emergency situation, the importance of a procedure using contrast medium and the risk of delaying that procedure must be balanced against the risk of kidney injury. Because specialties that use contrast-enhanced procedures differ in the extent to which inpatient or outpatient populations and emergency or nonemergency procedures are represented, the issues raised by the preceding questions are probably best addressed by specialty-specific, rather than general, protocols.

DETERMINING WHICH PATIENTS ARE AT RISK

The risk of contrast-induced AKI is considered increased and clinically important when the eGFR is lower than 60 mL/min/1.73 m².³⁶ However, this threshold probably includes too many patients to allow a focus on those who are truly at high risk. For example, patients with an eGFR of 30 mL/min/1.73 m² have a 30% to 40% risk of contrast-induced AKI and a 2% to 8% risk of requiring dialysis.⁴¹ Furthermore, because an eGFR cutoff of less than 60 mL/min/1.73 m² places a large number of patients in the at-risk group, the practicality and implementation of guidelines may be reduced. Also, a moderate reduction in eGFR is common among elderly patients, for whom eGFR levels of 50 to 59 mL/min/1.73 m² may not have the same clinical importance as similar values in younger patients with underlying specific forms of CKD.⁴² Therefore, using a lower eGFR threshold (<30, 45, or 50 mL/min/1.73 m²) to define contrast-induced AKI risk may be more appropriate in some situations.

MINIMIZING RISK

Volume Expansion. Extracellular volume expansion plays a well-established role in reducing the risk of contrast-induced AKI, although few trials have directly addressed the ideal protocol.⁴³ Intravenous volume expansion before and after administration of contrast medium appears to be more effective than either bolus volume expansion during the procedure⁴⁴ or removal of restrictions on oral fluid intake.⁴⁵ Isotonic saline has been found to be better than 0.45% saline and is given intravenously before and after administration of contrast medium for a total of 24 hours.⁴⁶ The findings of several recent trials⁴⁷⁻⁵¹ and a meta-analysis⁵² indicate that

volume expansion with bicarbonate is more effective than volume expansion with saline. However, these collective findings await confirmation in light of other recent reports that argue against a clear benefit for bicarbonate volume expansion in preventing contrast-induced AKI.^{53,54}

Pharmacological Prophylaxis. Prophylactic administration of NAC was first reported to be beneficial for patients with CKD who were undergoing CT with a low-osmolar contrast medium; oral NAC plus volume expansion with 0.45% saline was associated with a significantly lower rate of contrast-induced AKI (2%) than placebo plus 0.45% saline (21%; $P=.01$).⁵⁵ Since this early report, the numerous clinical studies and meta-analyses performed have yielded conflicting results; however, some have found substantial efficacy for NAC, as illustrated by a recent meta-analysis,⁵⁶ and most have found no benefit.⁵⁷

Another antioxidant that has been investigated for preventing contrast-induced AKI is ascorbic acid. In a multicenter, blinded, placebo-controlled trial ($N=231$), oral ascorbic acid (over-the-counter vitamin C) at a dose of 3 g administered the night before the procedure and a dose of 2 g administered twice after the procedure (on the same day) reduced the occurrence of contrast-induced AKI to 9%, compared with 20% with placebo.⁵⁸

Contrast Medium. Volume, dose, and type of contrast medium also may alter the risk of contrast-induced AKI. Generally, a volume of contrast medium of no more than 100 mL is preferable for patients with an eGFR lower than 60 mL/min/1.73 m²,⁵⁹ and even small (about 30 mL) volumes of contrast medium may cause AKI in patients at very high risk.¹¹ A volume limit of 5 mL/kg body weight normalized to the serum creatinine concentration has also been proposed as a threshold for contrast-induced AKI in patients with CKD (serum creatinine concentration >1.8 mg/dL).⁶⁰ A retrospective study has confirmed the validity of this threshold dose as a predictor of AKI that requires dialysis and of in-hospital mortality.⁶¹ Similarly, the ratio of contrast medium volume to CrCl has recently been suggested to be a more accurate predictor of AKI than other factors; a ratio higher than 3.7 is associated with increased risk. This ratio could be applied prospectively to determine the maximum contrast medium volume that can be administered without substantially increasing the risk of AKI.⁶²

Central to concerns about contrast-induced AKI and its prevention is the role played by the type of contrast medium used, specifically, the contribution of contrast medium osmolality to comparative nephrotoxicity. Although there is general agreement that high-osmolar contrast media pose a greater risk of AKI than low-osmolar contrast media in patients at risk,^{8,63} does a further reduction in contrast medium osmolality minimize the risk of contrast-induced AKI even more? Randomized controlled trials in the interven-

tional cardiology setting have shown that iodixanol has no advantage over iopromide (a low-osmolar agent) for patients with normal renal function.⁶⁴ However, in higher-risk populations, iodixanol has been shown to reduce the incidence of nephrotoxicity significantly more than iohexol (the Nephrotoxicity in High-Risk Patients Study of Iso-Osmolar and Low-Osmolar Non-Ionic Contrast Media [NEPHRIC]: 3% vs 26%; $P=.002$)⁶⁵ and ioxaglate (the Renal Toxicity Evaluation and Comparison Between Visipaque and Hexabrix in Patients With Renal Insufficiency Undergoing Coronary Angiography [RECOVER] study: 8% vs 17%; $P=.02$).¹⁸ Two trials compared iodixanol with iopamidol for patients with CKD who were undergoing coronary angiography or PCI (the Cardiac Angiography in Renally Impaired Patients [CARE] study)⁶⁶ or various CT procedures (the Isovvue-370 and Visipaque-320 in renally IMPaired PATients undergoing Computed Tomography [IMPACT] study).⁶⁷ These studies found low incidences of contrast-induced AKI with no significant difference in incidence between the iso-osmolar and low-osmolar groups. A third trial, the Patients with RENal impairment and DIabetes undergoing Computed Tomography [PREDICT] study, which also compared iopamidol and iodixanol in the CT setting but included patients with both CKD and diabetes, found similarly low incidences of contrast-induced AKI for the 2 agents (5.6% vs 4.9%).⁶⁸ In a recent trial (the Abdominal Computed Tomography: Iomeron-400 versus Visipaque-320 Enhancement [ACTIVE] study) that compared iodixanol and the low-osmolar contrast medium iomeprol in patients undergoing CT, iodixanol was found to be associated with a significantly higher incidence of contrast-induced AKI (6.9%) than iomeprol (0%; $P=.03$).⁶⁹

The inconsistency of these findings may be explained in part by important differences in study design, such as timing and standardization of postprocedural serum creatinine assays. In the NEPHRIC and RECOVER trials, patients underwent at least 2 follow-up serum creatinine assays after receiving contrast medium; the timing of each assessment was mandated for all patients. The IMPACT, CARE, PREDICT, and ACTIVE trials required a single serum creatinine assay after administration of the contrast medium dose, but the timing of this assessment varied, in some cases widely, across the studies. Another factor that may contribute to the inconsistency of results is the differing risk profiles of the study populations; the proportion of high-risk patients with CKD and diabetes ranged from 0% to 100% across the 6 trials.

FOLLOW-UP PROCEDURES

Procedures for ensuring follow-up serum creatinine assays at an appropriate time point must be in place. Timing and

setting may vary across specialties, but follow-up is an essential part of an effective protocol. Systems are also required for further follow-up of patients with evidence of contrast-induced AKI.

MULTIMODALITY PREVENTION APPROACHES

If the previously mentioned interventions have minimal effects on various pathophysiological elements of contrast-induced AKI, including vasoconstriction, ischemic injury, oxidative stress, and inflammation, then multimodality approaches using multiple interventions for the same patient may yield benefit whereas singular approaches may not. The findings of clinical trials suggest that this concept may hold true for patients at risk of contrast-induced AKI. Therefore, using iso-osmolar contrast agents and volume expansion, maintaining high urinary flow rates to reduce contrast medium dwell time in the renal tubules, initiating urinary alkalization with bicarbonate, and using antioxidants may provide synergistic protection against kidney injury.^{6,70}

SPECIALTY-SPECIFIC PROTOCOLS

With these collective considerations, the following specialty-specific protocols for minimizing the risk of contrast-induced AKI have been developed by a multidisciplinary Advisory Board on Contrast-Induced Nephropathy, based on expert opinion. Board members had specific research interests, publications, and professional activities in the specialties of radiology, cardiology, and nephrology. The materials presented and reviewed were determined at the independent discretion of each panel member.

INTERVENTIONAL RADIOLOGY

In this specialty, it is impractical and unnecessary to perform serum creatinine assays for all patients. A review of the patient's clinical history and an interview with the patient will generally be sufficient for determining which patients are aged 40 years or younger and have no risk factors. For outpatients taking stable medication regimens and exhibiting no change in health status, measuring the serum creatinine concentration within 30 days of the procedure is acceptable. For inpatients, the serum creatinine concentration and the eGFR should be assessed within 24 hours of the procedure (Figure 1).

Patients with an eGFR lower than 30 mL/min/1.73 m² are at very high risk of contrast-induced AKI; for these patients, all recommended prophylactic strategies should be used, as guided by a consultant nephrologist, and alternatives to the administration of iodinated contrast medium should be considered. Intravenous volume expansion is considered a requirement for patients with an eGFR lower

than 60 mL/min/1.73 m² and is considered good practice for other patients. For patients determined to be at increased risk of contrast-induced AKI, iso-osmolar contrast medium should be used, as recommended by the AHA/ACC and NKF.^{16,17,21} Either iso-osmolar contrast medium or low-osmolar contrast medium may be used for patients with an eGFR higher than 60 mL/min/1.73 m², although for these low-risk patients with mild or no renal impairment, other issues such as comparative cost should probably factor into the selection of contrast medium (Figure 1).

Prophylactic NAC may be administered, with the proviso that the baseline serum creatinine concentration should be determined before the medication is administered. Metformin use should be discontinued by diabetic patients with preexisting renal impairment (but not by those considered at no or at low risk of contrast-induced AKI) because lactic acid toxicity may be caused by critical levels of metformin accumulation in response to contrast-induced deterioration in these patients whose renal function is already compromised. According to both ESUR and ACR recommendations, diabetic patients with an elevated serum creatinine concentration should discontinue the use of metformin before the contrast medium is administered and should not resume it for 48 hours after the procedure. The decision to resume metformin use should be based on the results of follow-up serum creatinine assays. The ESUR and ACR differ in their recommendations about when metformin use should be discontinued (either 48 hours before administration of contrast medium or just before its administration) and about whether metformin use should be interrupted for diabetic patients with normal renal function.^{20,22}

Follow-up serum creatinine assays should be performed 48 to 96 hours after the administration of a contrast agent. Interventional radiology staff members are responsible for ordering this laboratory test and for ensuring that systems are in place to alert others involved in the patient's care if contrast-induced AKI is detected (Figure 1).

DIAGNOSTIC CT

In urgent cases, screening and preventive measures may not be possible. Screening is recommended when ACR criteria indicate that the patient is at increased risk of adverse events.²⁰ Preventive measures should be focused on patients with stage 4 or 5 CKD, for whom the risk of contrast-induced AKI is sufficiently high to warrant the extra cost and effort involved. For patients at very high risk (eGFR <30 mL/min/1.73 m² and diabetes mellitus), a nephrology consultation is necessary, and iodinated contrast medium should be used only if there is no alternative (Figure 2).

Intravenous volume expansion is required for patients with an eGFR lower than 45 mL/min/1.73 m² and is recom-

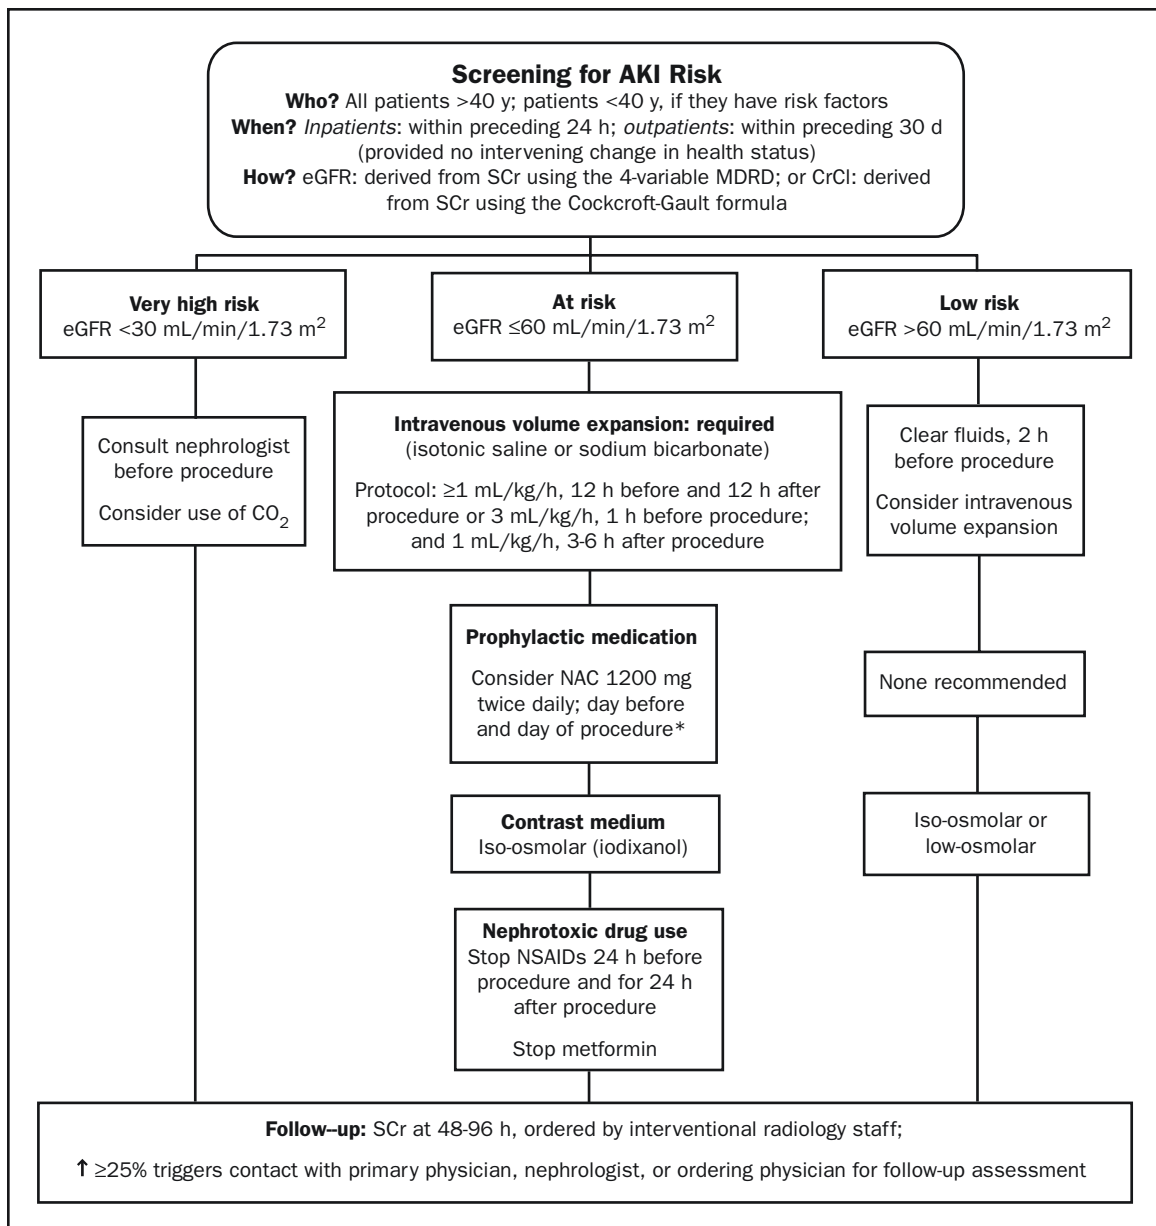

FIGURE 1. Protocol for interventional radiology. AKI = acute kidney injury; CO₂ = carbon dioxide; CrCl = creatinine clearance; eGFR = estimated glomerular filtration rate; MDRD = Modification of Diet in Renal Disease; NSAIDs = nonsteroidal anti-inflammatory drugs.

*Do not measure the baseline serum creatinine (SCr) concentration after administration of *N*-acetylcysteine (NAC); do not cancel or delay the procedure if NAC is not administered.

mended for those at intermediate risk of AKI (eGFR 45-60 mL/min/1.73 m²). Volume expansion is sufficiently important as a preventive measure to justify the burden it imposes on radiology departments. A protocol recommending rapid volume expansion with bicarbonate is most practical. When patients with an eGFR lower than 45 mL/min/1.73 m² undergo diagnostic CT, whether or not they have diabetes, the iso-osmolar contrast medium iodixanol should be used. If an

iodinated contrast medium is essential, iodixanol is indicated for patients with an eGFR lower than 30 mL/min/1.73 m². The referring physician should perform a follow-up assessment 48 to 72 hours after the procedure (Figure 2).

INTERVENTIONAL RADIOLOGY

The interventional radiology protocol focuses on patients at very high risk and those undergoing dialysis (Figure 3).

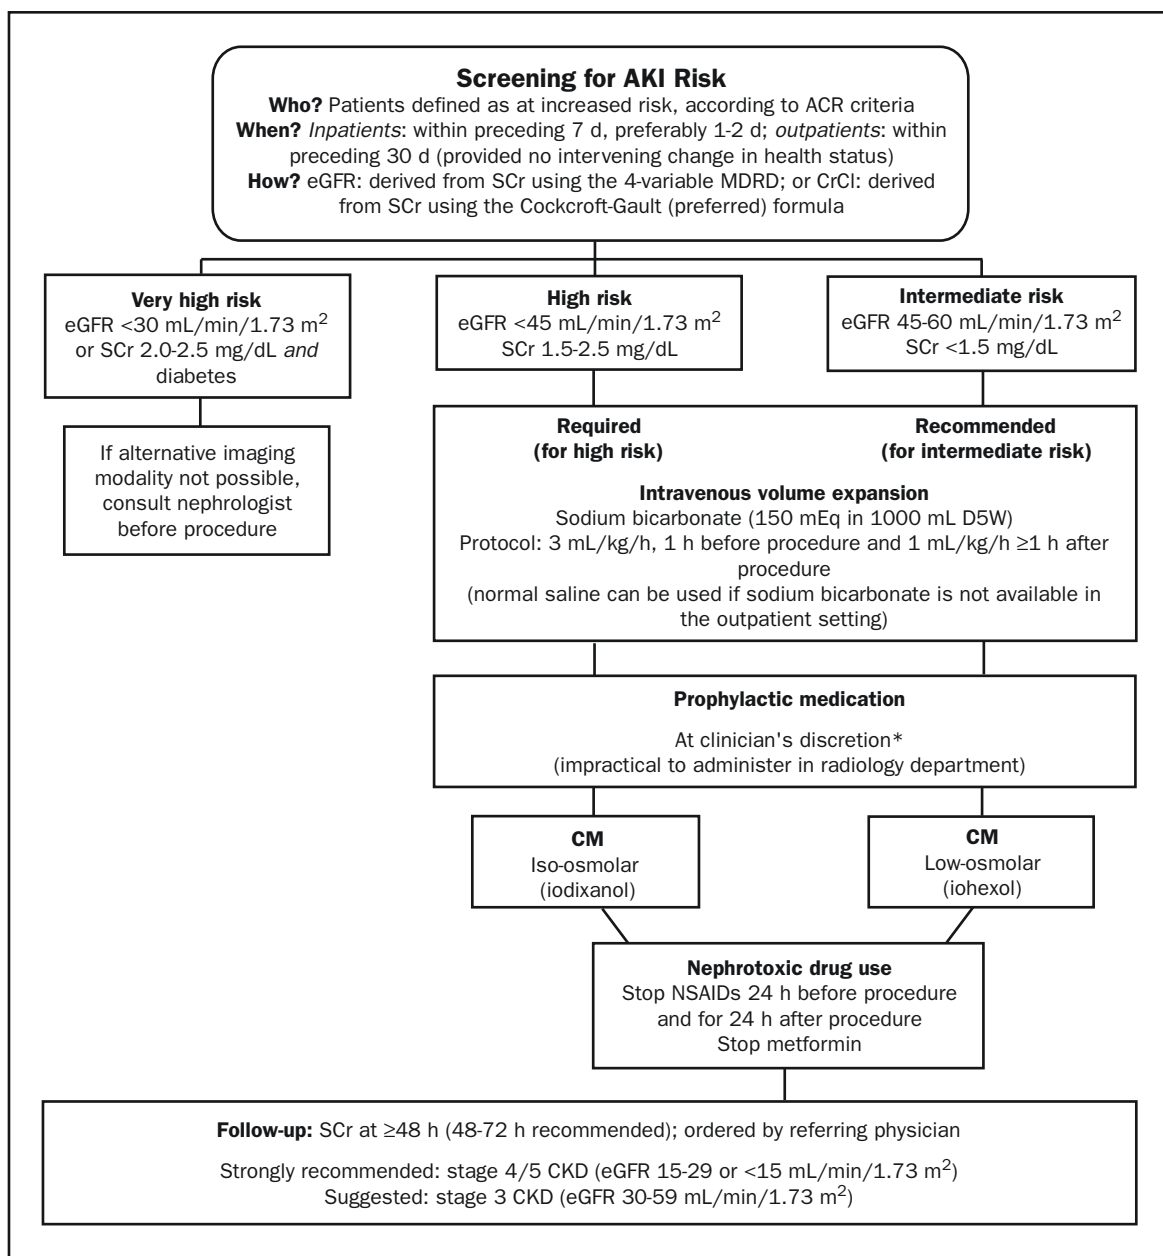

FIGURE 2. Protocol for diagnostic computed tomography risk defined according to American College of Radiology (ACR) criteria.²⁰ AKI = acute kidney injury; CKD = chronic kidney disease; CM = contrast medium; CrCl = creatinine clearance; eGFR = estimated glomerular filtration rate; MDRD = Modification of Diet in Renal Disease; NSAIDs = nonsteroidal anti-inflammatory drugs.

*Do not measure the baseline serum creatinine (SCr) concentration after administration of *N*-acetylcysteine (NAC); do not cancel or delay the procedure if NAC is not administered.

It is not feasible to recommend that none of these patients should undergo contrast-enhanced procedures because their risk of AKI is too high. Of note, patients with CKD are often denied the benefit of indicated contrast-enhanced coronary procedures because of concerns about nephrotoxicity. The findings of a large registry study showed that,

although patients with CKD would probably be eligible for coronary angiography according to standard eligibility criteria, only 25.2% of such patients underwent the procedure compared with 46.8% of patients who did not have CKD. Thus, a large proportion of patients with CKD were denied the benefit of a reduction in the risk of death.⁷¹

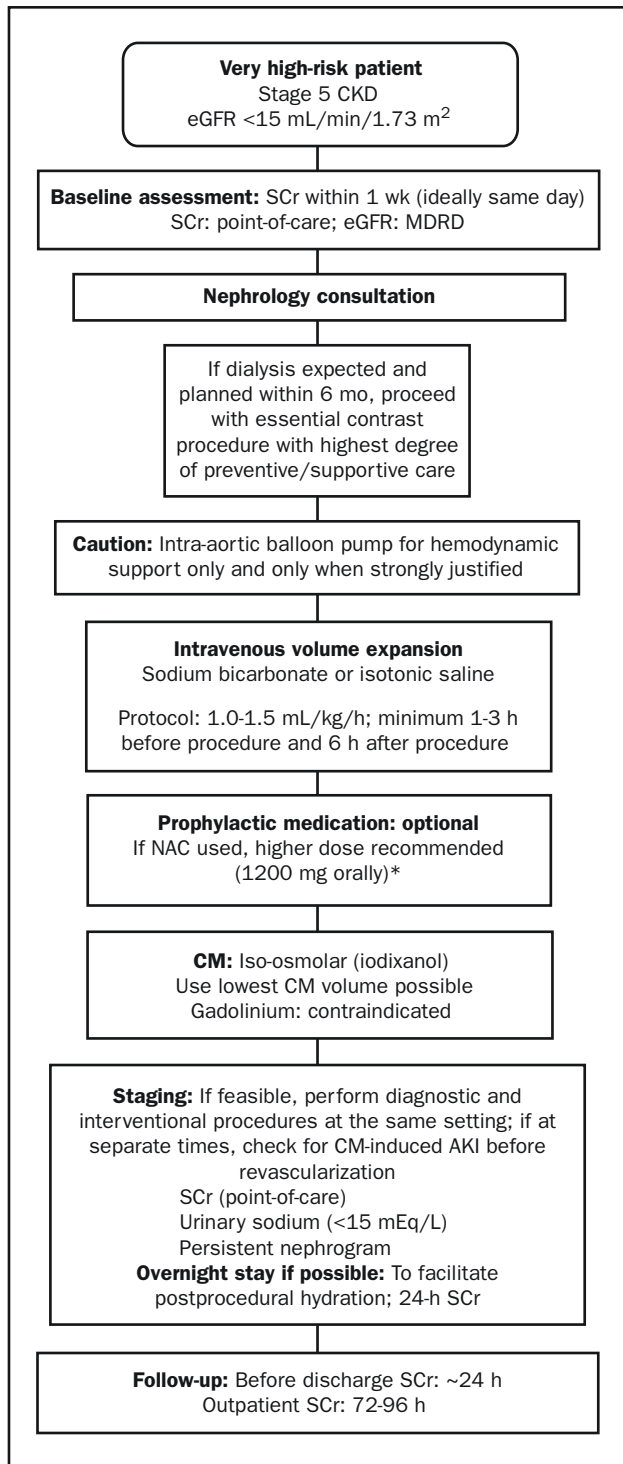

FIGURE 3. Protocol for interventional cardiology. AKI = acute kidney injury; CKD = chronic kidney disease; CM = contrast medium; eGFR = estimated glomerular filtration rate; MDRD = Modification of Diet in Renal Disease.

*Do not measure the baseline serum creatinine (SCr) concentration after administration of *N*-acetylcysteine (NAC); do not cancel or delay the procedure if NAC is not administered.

Because of their advanced disease, patients already undergoing maintenance hemodialysis for end-stage renal disease require no specific attention to volume expansion or other approaches for preservation of renal function. Also, these patients do not require emergent dialysis treatment after exposure to contrast medium unless they have incipient congestive heart failure and the volume expansion induced by the contrast material itself results in acute cardiac decompensation.

A nephrology consultation is mandatory for the assessment of potential renal damage; the findings should be factored into any decision made. If dialysis is expected within 6 months and the incidence of contrast-induced AKI would likely precipitate the need for dialysis, the contrast-enhanced coronary procedure should be conducted with the highest level of preventive and supportive care. Because the use of intra-aortic balloon pumps is associated with the incidence of AKI in patients with CKD,⁷² these pumps should be used for hemodynamic support only; their use in this high-risk patient population requires strong justification (Figure 3).

A recent (within 1 week, ideally on the same day) assessment of the serum creatinine concentration is required for determining baseline eGFR. Intravenous volume expansion should be performed as detailed in Figure 3. An overnight stay in the hospital is recommended to facilitate postprocedural volume expansion and to enable postprocedural (24-hour) serum creatinine assays. In accordance with NKF and AHA/ACC guidelines, iodixanol is the indicated contrast medium for these high-risk patients.^{16,17,21} The lowest possible volume of contrast medium should be used, and therapeutic intervention, if required, should be performed immediately after diagnostic angiography so that the risk incurred by sequential contrast-enhanced procedures can be avoided. Patients are often referred for therapeutic intervention after undergoing coronary angiography at another institution; such patients should be evaluated for AKI before the interventional procedure is performed. In these cases, a persistent nephrogram density⁷³ or a urinary sodium concentration lower than 15 mEq/L indicates that the patient may already be experiencing contrast-induced AKI. Point-of-care serum creatinine assays would also be useful in this situation (Figure 3).

CONCLUSION

Contrast-induced AKI is an important clinical entity faced by practitioners across a wide range of specialties. Patient management guidelines must consider risk factors for contrast-induced AKI and the most up-to-date information about preventive strategies. The specialty-specific, multimodality protocols outlined here are intended to promote best care while taking into account the practicalities

that may limit screening and preventive measures in various situations.

Editorial support and research assistance over the course of the preparation of the submitted manuscript were provided, under the direction of the authors, by Joan Sobel, PhD, and Lisa Cowen, PhD, at PAREXEL Inc and funded by GE Healthcare Limited.
