ELECTRON DONOR CONTRIBUTIONS TO DENITRIFICATION IN THE ELK VALLEY AQUIFER, NORTH DAKOTA

by

Amanda Marie Krieger

Bachelor of Science, University of North Dakota, 2012

A Thesis

Submitted to the Graduate Faculty

of the

University of North Dakota

in partial fulfillment of the requirements

for the degree of

Master of Science

Grand Forks, North Dakota May 2014

This thesis, submitted by Amanda Marie Krieger in partial fulfillment of the requirements for the Degree of Master of Science from the University of North Dakota, has been read by the Faculty Advisory Committee under whom the work has been done and is hereby approved.

Dr. Scott F. Korom, Chairperson

Dr. Philip J. Gerla, Committee Member

Dr. Charles Moretti, Committee Member

This thesis is being submitted by the appointed advisory committee as having met all of the requirements of the School of Graduate Studies at the University of North Dakota and is hereby approved.

Dr. Wayne Swisher Dean, School of Graduate Studies

Date

PERMISSION

Title	Electron donor contributions to denitrification in the Elk Valley Aquifer, North Dakota
Department	Environmental Engineering
Degree	Master of Science

In presenting this thesis in partial fulfillment of the requirements for a graduate degree from the University of North Dakota, I agree that the library of this University shall make it freely available for inspection. I further agree that permission for extensive copying for scholarly purposes may be granted by the professor who supervised my thesis work or, in his absence, by the Chairperson of the department or the dean of the School of Graduate Studies. It is understood that any copying or publication or other use of this thesis or part thereof for financial gain shall not be allowed without my written permission. It is also understood that due recognition shall be given to me and to the University of North Dakota in any scholarly use which may be made of any material in my thesis.

Amanda Marie Krieger 3/31/2014

ACKNOWLEDGMENTS

First and foremost, I would like to thank Dr. Scott F. Korom for his diligence in keeping this project moving forward throughout the years, not only for this thesis but previous students' work. I am also thankful for the direction he provided me during every step of my time as a student at the University of North Dakota (UND). I wish to express my sincere appreciation to the members of my advisory committee, Dr. Charles Moretti, and Dr. Philip J. Gerla, for their guidance and support during my time in the master's program.

The UND Denitrification Team deserves recognition for the immense amount of work done prior to my time at UND. The data collected over the years was diligently documented and provided an excellent foundation for this thesis and perhaps several to come. I am also grateful for sample analyses by the Environmental Analytical Research Laboratory (EARL) at UND and by the North Dakota Department of Health (NDDH).

I would like to thank the North Dakota Water Resources Research Institute and the UND Graduate Program in Environmental Engineering for providing financial assistance for my graduate research.

Х

ABSTRACT

Six denitrification tracer tests were performed over eight and a half years in insitu mesocosms (ISMs) in the Elk Valley Aquifer (EVA) in east-central North Dakota. Groundwater samples were analyzed to determine how much nitrate was lost beyond that explained by dilution of the bromide tracer. Additional losses were attributed to denitrification. The denitrification rates varied from 0.10 to 0.23 mg N/L/day for the six tests. In general, the major electron donors for denitrification are organic carbon (OC), pyrite (FeS₂), and ferrous iron silicate minerals. In the EVA tracer tests, increases in sulfate indicated that the oxidation of pyrite explained a significant of the denitrification. The contributions of the three electron donors varied between tests and from test to test with pyrite, ferrous iron from silicate minerals, and OC apparently contributing 38-84%, 1-3%, and 14-59% to denitrification, respectively.

CHAPTER I

INTRODUCTION AND HYPOTHESIS

Nitrate (NO₃⁻) is associated with some important environmental issues of our time because of its widespread use and its mobility in soil. Nitrate is a significant threat to surface and subsurface waters, where it is costly to remediate, it elevates trophic levels, and it is related to hypoxic zones throughout the world, notably that in the Gulf of Mexico (e.g., Justic et al., 2002). Furthermore, 44% of the US population depends on groundwater for its drinking water supply — be it from either a public source or private well (National Groundwater Association, 2010). Rural regions in the US are especially susceptible to nitrate contamination of aquifers because of the predominance of agriculture and the associated use of fertilizers. Therefore, nitrate is considered one of the most common groundwater contaminants (Korom, 1992). Sustained ingestion through drinking water has been linked to several health problems, for example methemoglobinemia in infants, commonly referred to as blue baby syndrome (Comly, 1945).

Denitrification, the conversion of nitrate to nitrogen gas (N₂), can remove nitrate from groundwater (Seitzinger et al., 2006). The four general requirements for denitrification are: (1) the presence of N oxides (NO₃⁻, NO₂⁻, NO, and N₂O) as terminal electron acceptors, (2) the presence of bacteria possessing the metabolic capacity, (3) suitable electron donors, and (4) anaerobic conditions or restricted O₂ ability (Firestone, 1982). Korom (1992) showed that the most important requirement for denitrification in

1

aquifers is the presence of suitable electron donors. The main three types of electron donors that contribute to aquifer denitrification are organic carbon, pyrite (FeS₂), and ferrous iron (Korom, 1992). These electron donors have been shown to be relatively abundant in our region and particularly in aquifer sediments in eastern ND (Schuh et al., 2006 and Klapperich, 2008).

This research was apparently the first to study the variation in the contributions of electron donors in aquifer sediments for such a long period of time, nearly eight and a half years. This was yet another step in the UND research group's progress in predicting aquifer denitrification parameters based on the electron donors present in aquifer sediments.

Hypothesis

This thesis hypothesizes that pyrite (FeS₂) contributes to most of the denitrification in the EVA, although it might not explain it consistently. The rest of the denitrification will be attributed to organic carbon (OC) and ferrous iron silicate minerals.

CHAPTER II

BACKGROUND AND PRIOR WORK

Studying the geochemistry of a particular aquifer has its challenges. It is difficult and time consuming to recreate hydrogeological processes accurately in a laboratory; therefore in situ experiments may be appropriate. However, the configuration of a field setup could hinder the results of an experiment. Simply injecting amended water and sampling from a single well limits sampling time as the slug of water travels down gradient, lowering the sensitivity of the technique (Gilham et al., 1990). A balance between the level of control achieved in a laboratory and observing the behavior of the aquifer in nature is pertinent for a reliable experiment.

In Situ Mesocosms and Network

Korom et al. (2005) have developed a novel way to isolate aquifer sediments in stainless steel chambers called "in situ mesocosms" (ISMs). The US regional network of ISMs is shown on Fig 1. Two ISMs have also been installed near Lake Taupo on the north island of New Zealand.

The ISMs are large (186 L) stainless steel chambers installed in the saturated zone. The chambers are hammered into final position at the bottom of a bore hole such that the aquifer sediments remain relatively undisturbed, providing an in situ experimentation environment. The large size of the chambers allows for long-term monitoring of the geochemical evolution of the groundwater during denitrification so that insights into the electron donors that contributed to the denitrification may be gained.

Figure 1. U.S. Network of Denitrification ISMs.

To date, there are 13 denitrification ISMs installed in which 21 denitrification tracer tests have been completed. Of the 13 ISM sites, eight ISMs have had several repeat tracer tests, with seven of these sites having had two tracer tests performed in them. This study focuses on the Elk Valley Aquifer ISM, at which six tracer tests have been performed. Groundwater denitrification rates measured at this site are among the fastest in the world (Green et al., 2008; Korom et al., 2010).

The construction, placement, and use of ISMs are described in detail in Korom et al. (2005), but a brief description of how denitrification tracer tests are performed follows. After installation each ISM was purged to make sure that natural formation water filled the ISMs. Groundwater was then pumped from each ISM into a reservoir on the ground surface with the tubing outlet placed on the bottom of the reservoir to avoid air contact for all but the earliest drawn water. Reservoir water was amended with either sodium nitrate (NaNO₃) and sodium bromide (NaBr), or potassium nitrate (KNO₃) and

potassium bromide (KBr). Bromide was considered a tracer species because it does not naturally occur in the aquifer in high concentrations and it does not undergo oxidationreduction reactions. The amended water was stirred and then siphoned back into the ISMs; the reservoir was periodically stirred gently to keep it well-mixed during the injection period. Several days after amendment an initial sample was taken from the ISM; it was then resampled every one or two months thereafter. Groundwater samples were filtered and analyzed using the standard methods listed on Table 1b in Korom et al. (2005).

Geology of Elk Valley Aquifer

The Elk Valley Aquifer lies in east-central North Dakota and stretches across 500 square kilometers of Grand Forks County (Figure 2). The aquifer is unconfined and the water table is relatively shallow at an average of 3 m below the ground surface. Average thickness is approximately 10 m and maximum thickness is 19 m. The EVA consists of coarse, subangular, quartzose sand, detrital shale sand, and some gravel (Kelly and Paulson, 1970). There is a gradation in aquifer sediment texture from courser sediments in the north to finer sediments in the south. The sandy, permeable soils coupled with the relatively small topographical relief of eastern ND allow a large percentage of precipitation to infiltrate to the groundwater system as measured by seasonal changes in the water table (Kelly and Paulson, 1970).

5

Figure 2. Location of Elk Valley Aquifer.

Vulnerability of Elk Valley Aquifer

In 1987 the US Environmental Protection Agency (EPA) developed DRASTIC, a standardized system for evaluating groundwater pollution potential of aquifers in the US. The acronym DRASTIC stands for *d*epth to water, net *r*echarge, *a*quifer media, *s*oil media, *t*opography, *i*mpact of the vadose zone, and hydraulic *c*onductivity. These factors are compiled by rating each parameter and entering it into an equation, resulting in a numerical score (Aller, et al., 1987). Aquifers rated with the same physical parameters could then be compared and ranked. In 1996 the EVA was rated with a DRASTIC score of 167, ranking it the fifth most vulnerable aquifer out of 192 aquifers in the state (Radig, 1997).

6

In 1997 the ND Department of Health (NDDH) Division of Water Quality developed a system adapted from the EPA's DRASTIC model, known as a Geographic Targeting System (GTS) (Radig, 1997). The GTS not only prioritized aquifers throughout the state according to physical properties with DRASTIC, but also prioritized them according to permitted water use and susceptibility to agricultural chemical contamination per county. Total numerical monitoring scores of the GTS range between 3 and 9, with 9 being the most vulnerable. Figure 3 shows the results of the GTS study, with several aquifers, including EVA, ranked at a score of 9. The combined DRASTIC and GTS scores placed EVA as the first most vulnerable aquifer in the state (Radig, 1997).

Overall, the EVA is classified as one of the most vulnerable aquifers in North Dakota by both national and statewide standards. The most vulnerable aquifers receive the most funding in prevention and monitoring efforts. It is imperative that aquifer rankings are accurate so that funding is properly allocated.

Figure 3. Classification of Aquifer Monitoring Prioritization in ND (Adapted from Radig, 1997).

Sampling

Groundwater sampling from the EVA ISM began in October, 1997 with the first tracer test and ended March, 2006 with the last sample of the sixth tracer test. Tracer tests were concluded when the NO₃-N concentrations were approximately less than 5 mg/L.

Groundwater samples were analyzed by both the NDDH laboratory and the Environmental Analytical Research Laboratory (EARL) at UND. Table 1 lists the important ions and species analyzed specifically from which laboratory. Field pH values were measured on-site.

Prior Work

The UND Denitrification Team performed a similar assessment at the Karlsruhe-S ISM, at which two tracer tests were conducted. Those tracer tests indicated that contributions to denitrification from individual election donors were about 4 - 18% from pyrite, 2 - 43% from non-pyrite Fe(II) in amphiboles, and 43 - 92% from organic carbon, depending on the sample date (Korom et al., 2012). The models showed that denitrification by some non-pyrite Fe(II) was essential to explain the evolution of the groundwater quality parameters observed at the sites in Karlsruhe. That was the first time the distribution of electron donors contributing to aquifer denitrification had ever

been reported. The current EVA study presented in this thesis differs from the Karlsruhe-S study in that it is a much longer study; over eight years at EVA compared to two years at Karlsruhe-S.

Tesoriero and Puckett (2011) reported on denitrification rates in shallow aquifers. Twelve areas across the US were studied by using monitoring well transects located along hypothesized groundwater flow paths. Tracers were utilized to provide an estimate of groundwater age. Air samples were taken downstream when the amended water was calculated to transect the downstream wells. Amounts of N₂ were then calculated to determine the amount derived from denitrification. Their study suggested that denitrification tends to occur more quickly with sulfide oxidation rather than with carbon oxidation (Tesoriero et al., 2011). However, groundwater flow paths tend to cause physical mixing such as eddies as fluid flows around sediment particles. The physical mixing tends to create the appearance of lower reaction rates and fractionation parameters when measured at larger scales and longer flow paths (Green et, al., 2010).

CHAPTER III

METHODOLOGY

The objective of this research was to study the geochemical evolution of the groundwater in the EVA ISM during each of the six denitrification tracer tests to estimate the contributions of electron donors to the denitrification. Before any determinations were made, the data were verified for analytical quality control. Two laboratories, EARL and NDDH, provided analyses for each sampling event. Duplicate samples provided for better discrepancy evaluation. Appendices A-E list the initial data and show the processes used to determine the final data set.

The next step was to estimate the denitrification rates in each of the six tracer tests. The percent contributions to denitrification by ferrous iron minerals, pyrite (FeS₂), and organic carbon were then estimated.

Dilution

The process of pumping NO_3^- -amended water back into the ISM chamber caused some dilution with the native groundwater present in the chamber. The NO_3^- -amended water was also amended with Br⁻, which is naturally in the aquifer, but only at low concentrations (< 1 mg/L). The Br⁻ tracer in the amended water was used to estimate the dilution rate with native groundwater. Loss of NO_3^- beyond that explained by dilution of the Br⁻ tracer was attributed to denitrification.

www.manaraa.com

The ratios of the concentration of Br⁻ at each sampling event to the concentration of Br⁻ at the initial sampling event (day 0) was assumed to be equal to the ratios of the concentration of NO₃⁻N present by the process of dilution at each sampling event to the concentration of NO₃⁻N at the initial sampling event (day 0). The concentration of NO₃⁻ N present by the process of dilution (NO₃⁻N by dilution) served as a starting point to estimate how much NO₃⁻N should have been measured had there been no denitrification. The results of Equation 1 are tabulated in Table 2-7.

$$(NO_3-N \text{ by dilution}) = \left(\frac{Br_{t\neq 0}}{Br_{t=0}}\right)(NO_3-N_{t=0})$$
(1)

Denitrification Rates

The concentration of NO_3 -N attributed to denitrification was calculated by subtracting the concentration of NO_3 -N measured from the concentration of NO_3 -N calculated to be present by dilution only. The results of Equation 2, the concentration of NO_3 -N assumed to have been denitrified, are tabulated in Table 2-7.

$$(NO_3-N \text{ denitrified}) = (NO_3-N \text{ by dilution}) - (NO_3-N \text{ measured})$$
 (2)

Denitrification rates were calculated by assuming a linear relationship between sampling events. For each of the six tracer tests, concentrations of NO₃-N in mg/L denitrified were plotted versus time in days. The zero-order denitrification rate in mg/L/day was the slope of a linear fit line generated for each tracer test. For all tracer tests in the EVA, zero-order rates provided better fits for the data than first-order rates (Korom, 2005). The zero-order denitrification rate graphs of each tracer test are located in CHAPTER IV.

Denitrification by Ferrous Iron Silicate Minerals

X-ray diffraction (XRD) analyses by Tefsay (2006) showed that the sediments in the EVA and Karlsruhe Aquifer have similarities. Both aquifers are composed of amphiboles, clinochlore, muscovite, biotite, plagioclase, alkali feldspar, quartz, calcite, dolomite, and pyrite. One amphibole identified in both aquifers was hornblende, a double chain silicate. Amphiboles are known to weather relatively slowly, as demonstrated by Bowen's reaction series (Faure, 1998).

It was assumed that hornblende will weather similarly and therefore contribute to denitrification similarly from aquifer to aquifer in ND. Korom at al. (2012) found denitrification by ferrous iron (Fe(II)) in hornblende to be between 2.2 x 10^{-5} M/year and 1.3 x 10^{-4} M/year in the Karlsruhe aquifer. The average of those two rates was assumed valid for EVA as well. The average denitrification rate of 0.003 mg/L/day was applied to all tracer tests to estimate the percent contribution by ferrous iron as hornblende.

Denitrification by Pyrite

Some denitrification was explained by the increase of sulfate, which was attributed to the oxidation of pyrite (FeS₂), the only sulfide mineral found by XRD in the EVA sediments (Tesfay, 2006). As NO_3^- is reduced to nitrogen gas, the sulfide in FeS₂ is oxidized to sulfate, as shown in the redox reaction below (Equation 3). Unlike hornblende, pyrite has the ability to weather rapidly to goethite (FeOOH), which is a well-documented observation during acid mine drainage (Larese-Casanova et al., 2012).

$$6NO_3^- + 2FeS_2 + 2H_2O \leftrightarrow 3N_2 + 4SO_4^{2-} + 2FeOOH + 2H^+$$
(3)

For every 2 moles of FeS₂ and 6 moles of NO_3^- consumed, 4 moles of SO_4^{2-} are produced. The ratio of SO_4^{2-} produced to NO_3^- consumed allows for the estimation of the

increase in SO_4^{2-} in the water if all of the denitrification was due to the oxidation of pyrite.

Equation 3 also indicates potential Fe(II) contributions of one fifteenth of the denitrification by pyrite. No increase in Fe(II) was demonstrated in the groundwater samples during the tracer tests (Tables 46-51), indicating that the Fe(II) in pyrite had apparently been consumed. The apparent disappearance of Fe(II) from pyrite was also attributed to denitrification by pyrite.

The maximum increase of SO_4^{2-} (max ΔSO_4^{2-}) by total denitrification with pyrite was calculated for each sampling event with Equation 4, where concentrations are in mg/L and molecular weights (MWs) are in g/mol. The results of Equation 4 are tabulated in Tables 14-19.

$$(\max \Delta SO_4^{2^-}) = \frac{(NO_3 - N \text{ denitrified})}{MW \text{ of } NO_3 - N} * \frac{4 \text{ mol } SO_4^{2^-}}{6 \text{ mol } NO_3^{-}} * MW \text{ of } SO_4^{2^-}$$
(4)

The fraction of max Δ SO₄²⁻ measured in a water sample was found using Equation 5. This was calculated for each sampling event subsequent to the initial one (Day 0) and is the estimate of denitrification by pyrite for each sampling event. The results of Equation 5 are tabulated in Tables 14-19.

fraction of max
$$\Delta$$
 SO₄²⁻ = $\frac{(SO_{4\ t\neq 0}^{2-} - SO_{t=0}^{2-})}{(\max \Delta SO_{4}^{2-})}$ (5)

The average fraction of denitrification by FeS_2 weighted by time was also calculated for each tracer test. The change in time was in days since the previous sample. The results of the Equation 6 are listed in Tables 14-19.

average fraction of denitrification by
$$\text{FeS}_2 = \frac{\sum \text{fraction of } \max \Delta \text{ SO}_4^{2-*} \Delta t}{t_{\text{total}}}$$
 (6)

Denitrification by Organic Carbon

The remainder of the denitrification not attributed to the oxidation of ferrous iron in amphibole or the oxidation of pyrite was attributed to organic carbon (OC). This assumption was made on the basis that the three major electron donors in aquifer denitrification are: OC, inorganic sulfide (FeS₂), and ferrous iron (Korom, 1992).

CHAPTER IV

RESULTS AND DISCUSSION

Denitrification Rates

The results of Equations 1 and 2 and were used to estimate the denitrification

rates of each tracer test (Tables 2-7).

Table 7. cont.

*NDDH value

Denitrification amounts from Tables 2-7 were plotted versus time to establish the denitrification rates of each tracer test (Figures 4-9). A linear trend was generated for each graph. In the upper right hand corner of each graph is the equation of the line with the slope representing the denitrification rate (mg/L/day) and the coefficient of determination, R². R² values range between 0 and 1.0, with 1.0 representing a perfectly linear fit. Therefore, the closer the R² value is to 1.0, the better the fit to the reported denitrification rate. All R² values in Figures 4-9 were \geq 0.90.

Figure 4. Tracer Test 1 Denitrification Rate.

Figure 5. Tracer Test 2 Denitrification Rate.

The two gray squares in Figure 5 represent data with very low NO₃-N concentrations (0.02 mg/L). Detectable denitrification had ceased at that point, and therefore those points were not included in the denitrification rate determination.

Figure 6. Tracer Test 3 Denitrification Rate.

Figure 7. Tracer Test 4 Denitrification Rate.

Figure 8. Tracer Test 5 Denitrification Rate.

Figure 9. Tracer Test 6 Denitrification Rate.

Average denitrification rates in the EVA ranged from 0.10 to 0.23 mg/L/day for

all six tracer tests (Table 8).

Table 8.	Denitrification	Rates of Elk	Valley Aquifer.

3	0.19	69.4
4	0.20	73.0
5	0.12	43.8
6	0.10	36.5

Contribution by Ferrous Iron Silicate Minerals

As previously stated, the EVA ISM is assumed to have the same ferrous iron denitrification rates from amphibole as hornblende as the Karlsruhe-S ISM. The rate of 0.003 mg/L/day was applied to all tracer tests to estimate the percent contribution by ferrous iron silicates (Tables 9-14).

9/22/2005	465	27.7	42.83	1.40	0.03

Average fraction contribution to denitrification weighted by time by Fe(II) silicate minerals = 0.03.

The contributions to denitrification weighted by time from ferrous iron as

hornblende varied from 1 to 3% at the EVA ISM.

Contribution by Pyrite

The fraction of denitrification by pyrite was estimated by the increase of SO_4^{2-} . Tables 15-20 tabulate the results of Equations 4-6. The weighted averages of the fraction of increase of SO_4^{2-} by FeS₂ are listed at the bottom of the tables. That value is the average fraction FeS₂ contributed to denitrification for each tracer test.

Table 15. Tracer Test 1 Contribution from Pyrite.

Date	∆time (days)	SO4 ²⁻ mg/L Measured	$\begin{array}{c} Max \ \Delta \\ SO_4^{2-} \end{array}$	Fraction of Max Δ SO ₄ ²⁻	Fraction of Max $\Delta \operatorname{SO4}^{2-} * \Delta t$

Weighted average fraction of denitrification by $\text{FeS}_2 = 0.71$.

The average contributions to denitrification from pyrite varied from 38 to 84% at the Elk Valley Aquifer ISM. The average denitrification rates from each tracer test were plotted with the average percent contribution of pyrite to denitrification in Figure 10.

Figure 10. Pyrite Contribution and Denitrification Rate.

One hypothesis suggests that denitrification rates increase with the increase of denitrification by S⁻ (Tesoriero et al., 2011; references therein). Denitrification did not increase as contribution from pyrite increases in the EVA ISM, as indicated by the R² value of essentially zero. Pyrite nonetheless contributed significantly to denitrification in the EVA, up to 84% as indicated in Tracer Test 4. Schuh et al. (2006) determined that with the current loading rate of NO_3^- in the EVA there is sufficient pyrite to support lithotrophic denitrification for 11,000 to 175,000 years depending on specific location.

Contribution by Organic Carbon

The remainder of NO₃-N denitrified not by ferrous iron silicate minerals or by pyrite was assumed to be by OC. The contributions of OC to denitrification were

29

tabulated in Tables 21-26 along with the contributions from pyrite and ferrous iron as hornblende.

Table 27. Average Contributions to Denitrification Weighted by Time.

A plot of the OC contributions to denitrification rates (Figure 11) was utilized to identify possible trends from test to test. The low R^2 value signifies that there was no correlation between denitrification rates and OC contributions.

Figure 11. OC Contribution and Denitrification Rate.

The results in Figures 10 and 11 show that there is no correlation between the amount of denitrification contributed by the two largest electron donors (pyrite and OC) to denitrification rates, respectively, at the Elk Valley ISM. The data in Table 27 (shown

on Figure 12) show that the contributions of electron donors at the site were variable, with no apparent pattern.

Figure 12. Percent Contributions to Denitrification.

The source(s) of the organic electron donor (OC) have not yet been positively identified. One possible source is OC in the native groundwater. However, OC concentrations did not decrease during tracer tests. In some cases the OC concentrations had increased as the tracer tests progressed (Appendix B). Other prospective sources are OC from glacial outwash derived from Cretaceous shale and likely to have low reactivity because of its age, which is relatively common (Korom et al., 2012; and references therein), other organic matter deposited during the formation of the aquifer, and decayed bacterial bodies (biofilm).

The sources of the electron donors, whether organic (OC) or inorganic (pyrite and ferrous iron silicate minerals), remain fixed in the ISM chamber once installed. The results suggest that the noted variability in denitrification rates was not caused by the

source of electron donors so much as the consumers of the electron donors, the bacterial population.

Chapelle (2001) noted that the bacterial populations in soils are dynamic when there is a constant flux of nutrients, but commented that it is less clear what happens in deeper groundwater systems. More recently Williamson et al. (2012) showed that biofilm dynamics in an alluvial aquifer is also dynamic along a nutrient gradient; however, the conditions were generally aerobic, not denitrifying. The results reported herein suggest that the bacterial population involved with denitrification in aquifers may also be dynamic and this is apparently the first study to do so.

Microorganisms obtain energy during denitrification by transferring electrons from electron donors, such as pyrite, OC, and ferrous iron minerals, to nitrate, which is a compound that accepts electrons (Chapelle, 2001). Based on the electron donors used there are two types of bacteria involved with denitrification at the EVA site: lithotrophic and heterotrophic. Bacteria using inorganic electron donors, such as pyrite and ferrous iron, are lithotrophic, "rock-eaters," and use inorganic carbon (derived from CO₂) in groundwater to provide carbon for cell growth and maintenance. Sulfur-oxidizing bacteria are specific lithotrophic bacteria that are able to use pyrite to denitrify (Friedrich, et a., 2001). Bacteria using organic carbon are heterotrophic, "self-feeders," and use their energy source, OC, also as a source of carbon for cell growth and maintenance.

The type of electron donor consumed at a higher rate during denitrification is theorized to be a result of the type of bacteria forming the majority of the biofilm population. When the lithotrophic bacteria population increases in response to the increase in nitrate concentrations during a tracer test, the resulting biofilm produced

35

could be used as an energy source by heterotrophic bacteria. Organic carbon consumption by heterotrophs could at times surpass pyrite consumption by lithotrophs. Once the biofilm source of organic carbon becomes limiting, lithotrophic bacteria may then be able to outcompete heterotrophic bacteria for nitrate supplies. Such a relationship in population dynamics between the lithotrophic and heterotrophic bacteria is postulated to explain the variability observed in the contributions of electron donors during denitrification at the EVA site.

CHAPTER V

CONCLUSIONS AND FUTURE STUDY

Based on physical parameters, EVA is highly susceptible to pollution, including that from agricultural activities. Tracer tests showed that the EVA ISM responded rapidly to NO₃⁻ pollution with the ability to denitrify between 37 and 84 mg NO₃-N per liter of aquifer over the course of a year. Although this study only analyzed NO₃⁻ contamination, it brought to light the importance of aquifer geochemistry. This aquifer, albeit physically susceptible to contamination, has exhibited the ability to cleanse itself of nitrates with no addition of outside energy sources.

Contributions to denitrification from ferrous iron silicate minerals, pyrite, and OC in the EVA ISM ranged from 1-3%, 38-84%, and 14-59%, respectively. Pyrite contributed the most to denitrification overall. However, no trends were implied by the comparison of denitrification rates and pyrite or OC contributions. Denitrification will continue to be vital to the overall quality of EVA, as long as NO_3^- contamination continues in the area, e.g. via agricultural practices. At the current loading rate of NO_3^- in the EVA there is sufficient pyrite to support autotrophic denitrification for 11,000 to 175,000 years depending on specific location (Schuh et al., 2006).

Future Study

Recommendations for future study include biofilm sampling of the EVA before and after nitrate amendment. Positive identification of bacterial populations could lead to more insight as to why the EVA is able to denitrify so quickly. Categorization of the

37

bacterial population as more heterotrophic or more lithotrophic during greater contributions to denitrification from OC or pyrite as electron donors, respectively, could verify the influence of bacterial dynamics in denitrifying groundwater systems.

Perhaps the denitrification rates exhibited at EVA are common in similar aquifers. ISM experiments on other highly susceptible aquifers could be performed to determine if vulnerability to NO_3^- is truly an issue. Such experiments could augment the ranking systems used for prioritizing aquifer monitoring and consequently ensure money is spent appropriately using the most up-to-date scientifically-based methods.

PHREEQC Example

PHREEQC (Parkhurst and Apello, 1999), a computer program developed by the U.S. Geological Survey for simulating geochemical reactions, was used to speculate inorganic C (IC) in the forms of bicarbonate and carbonate in groundwater quality during the denitrification tracer tests in the ISMs. A temperature of 10 degrees Celsius was considered constant. The values for SO₄⁻ entered into PHREEQC were an average of the NDDH and EARL concentrations. Lab pH was used when field pH was not available. EARL values were used for NO₃-N, except when NO₃-N values were under 5 mg/L, and then NDDH values were used due to their increased accuracy at low concentrations.

A typical PHREEQC entry is shown below:

Solution Larimore Dataset1 12-01-97 temp 10 7.4 pН units ppm 12.7 Na Mg 41 Κ 349 Ca 119 .678 Mn Fe .112 F .67 Cl 9.8 64.3 S(6) 135.2 N(5) 76.4 Br 69.7 as C C(4) End

After the calculations were run, the output was analyzed for bicarbonate and carbonate concentrations. The HCO₃⁻, CaHCO₃⁺, MgHCO₃⁺, MnHCO₃⁺, FeHCO₃, and NaHCO₃ values in molality were given by PHREEQC and then converted to mg/L and

summed to provide the value in the PHREEQC HCO₃⁻ column. Similarly, the CO₃²⁻, CaCO₃, MgCO₃, MnCO₃, FeCO₃, and NaCO₃⁻ were converted to mg/L and summed to provide the value in the PHREEQC CO_3^{2-} column.

The following is the output reading from the input example, Larimore Dataset1 12-01-97.

End of simulation.

Reading input data for simulation 2.

End of run.

Appendix B

Initial Tracer Test Data

Tables 28-33 list the initial data analyzed for each tracer test. Subsequent winnowing of data involved removing data that was either not pertinent to the study or data that did not accurately represent the aquifer, such as the following cases.

Several sampling events were at the ground surface, before injection into the chamber. Denitrification occurring before the amended water was introduced back into the aquifer was not considered for this study. Such events precede "Day 0". They are: 10/30/1997 (Tracer Test 1), 10/8/1998 (Tracer Test 2), 8/17/2000 (Tracer Test 3), and 6/8/2004 (Tracer Test 6), including any duplicates.

Two sampling events only included analyses done by EARL, which provided very incomplete data sets. They are: 12/13/2005 and 3/8/2006, both from Tracer Test 6. The two samples were not considered further.

One sampling event had an apparently erroneous Br⁻ measurement which was twice the expected concentration, based on samples taken before and afterwards. The sampling date is 8/2/2005 from Tracer Test 6. The analyses from this date were not considered further.

Another sampling event had an apparently erroneous EARL NO₃-N value, and was subsequently replaced by the respective NDDH measurement. The sampling event took place 10/2/2000 during Tracer Test 3.

Charge Balance Error

One common criterion for verifying the accuracy of laboratory analyses is charge balance error (CBE). CBEs provide a comparison of the summations of cations and anions in an aqueous solution, whereas significant deviation from electroneutrality indicates a possible error in sampling, handling, or analytical procedures. Freeze and Cherry (1979) suggest an acceptable absolute CBE is less than 5%. CBEs for all EVA samples were calculated using the following equation, where ion concentrations were in meq/L.

$$CBE = \frac{(\sum Cations - \sum Anions)}{(\sum Cations + \sum Anions)} \times 100\%$$

Since two separate laboratories were utilized in the detection of some major anions, a system for calculating CBEs from each laboratory was established. Tables 34 and 35 list the major cations and anions used in the calculations and which laboratory detected their presence. All cations identified were results from the NDDH laboratory, therefore the summation of cations was the same for both NDDH and EARL CBEs. The summation of anions was different due to the duplication of analyses from both laboratories. The summation of anions for the NDDH were simply the major anions detected plus the bromide ion reported by the EARL. The summation of anions for the EARL CBE consisted of all anions reported by the EARL, plus carbonate and bicarbonate concentrations calculated by PHREEQC, as well as chloride and fluoride concentrations reported by the NDDH laboratory.

In the case of 3/23/2004 in Tracer Test 5, PHREEQC was not able to speciate

 HCO_3^- or CO_3^{2-} due to the lack of IC data evaluated at that date. Final HCO_3^- and CO_3^{2-} values were from NDDH laboratory.

Cations	NDDH	EARL

SO_4^{2-}	Х	X
NO ₃ -N	Х	X
Br		X
A a increania C and	painted by D	LIDEEOC

*As inorganic C speciated by PHREEQC.

CBEs for the NDDH values and EARL values are listed in Tables 36-41. A higher concentration of anions results in a negative CBE, while a higher concentration of cations produces a positive CBE. The average absolute CBEs for the laboratories are tabulated at the bottom of the respective absolute CBE columns as a tool for comparison as a whole between the two laboratories.

Not used in final tabulation. Average CBE:

CBE proved to be a successful way to compare the duplicate sample analyses of 10/21/2002 in Tracer Test 4. The second set of analyses had much better CBE and consequently it was the data set utilized.

An effort to keep ion analyses consistent from one laboratory or the other was made, versus mixing and matching data. Since Br^- was analyzed by EARL only, the EARL CBEs were reviewed for deviation of more than \pm 5.0%. Three EARL CBEs from Tracer Test 1 were beyond -5.0%: 2/27/1998, 3/27/1998, 8/4/1998. The corresponding

NDDH CBEs were also beyond -5.0%. Sorting by CBEs was rejected for these cases due to the lack of improvement from using CBE from either laboratory. However the NDDH CBE on 4/26/2001 of Tracer Test 3 was a great improvement from the EARL CBE values. NO₃-N and SO₄²⁻ values for this sampling event will be from NDDH analyses.

In all sampling events, EARL NO₃-N values under 5.0 mg/L were replaced with NDDH NO₃-N values. The NDDH was believed to be more accurate at lesser concentrations than the EARL was. All other data are results from EARL, with the exception of NDDH substitutions which were noted in the final data sets, Tables 46-51.

Appendix D

Cation Exchange Capacity

Soils tend to have a general negative charge due to the presence of colloids, which are the most active part of the soil. The soil colloids retain cations on their surfaces, which can be exchanged for other cations. Cation exchange capacity (CEC) is the quantity of cations the soil can hold for exchange with groundwater system. In order to establish if CEC was a factor in EVA tracer tests, the actual concentrations of cations was compared to the relative concentrations of cations due to dilution. The distribution of major exchangeable cations in productive soils is $Ca^{2+} > Mg^{2+} > K^+ \sim NH_4^+ \sim Na^+$. (Bohn et al., 1985)

The cation considered for CEC in this study was sodium (Na⁺) due to its addition as NaNO₃ and NaBr in the amended water for Tracer Tests 3-6. Na⁺ was assumed to undergo dilution similar to the Br⁻ tracer. However, Na⁺ was already present in the native groundwater, as shown in the initial data of Tracer Tests 1 and 2 (Tables 28 and 29). An average Na⁺ concentration was extrapolated from the initial data, as opposed to backcalculation from the Br⁻ tracers. The average Na⁺ concentrations from Tracer Tests 1 and 2 were 10.3 mg/L and 8.3 mg/L, respectively. An initial concentration of 9.3 mg/L was assumed for the native groundwater.

The first steps of determining the CEC of the EVA were to determine the relative concentrations of Na^+ measured (Na^+ actual rel. conc.), the concentration of Na^+ due to dilution, and the relative concentrations of Na^+ due to dilution (Na^+ dilution rel. conc.). The difference between the actual relative concentrations and the relative concentrations

57

by dilution can then be calculated. These values were calculated using the following equations and are tabulated in Tables 42-45.

$$(Na^{+} \text{ actual rel. conc.}) = \frac{(Na_{t\neq0}^{+})}{(Na_{t=0}^{+})}$$

$$(Na^{+} \text{ dilution}) = \frac{Br_{t\neq0}^{-} * Na_{t=0}^{+}}{Br_{t=0}^{-}} + \left(1 - \frac{Br_{t\neq0}^{-}}{Br_{t=0}^{-}}\right) * Na_{\text{initial}}^{+}$$

$$(Na^{+} \text{ dilution rel. conc.}) = \frac{(Na^{+} \text{ dilution}_{t\neq0})}{(Na^{+} \text{ dilution}_{t=0})}$$

 Δ relative conc. = (Na⁺ actual rel. conc.)- (Na⁺ dilution rel. conc.)

The change in relative concentrations of Na⁺ actual and Na⁺ dilution were compiled and plotted on a graph against time, as shown in Figure 13. A strong deviation between relative concentrations would entail a linear relationship with an R² value close to 1.0. Figure 13 shows no such relationship. The relative concentrations of Na⁺ dilution and Na⁺ actual did not deviate from one another, therefore CEC is considered insignificant at this EVA ISM.

Figure 13. Cation Exchange Capacity Consideration.
