An elevated risk of poor fetal outcome is associated with myotonic dystrophy. There is an increased incidence of spontaneous abortion, preterm labor and delivery, and neonatal death.[179] Polyhydramnios is frequently present and may be associated with an affected fetus.[184] Preterm labor is likely a result of the increased amniotic fluid volume and myotonic involvement of the uterus.[185] Congenital myotonic dystrophy presents as generalized hypotonia and weakness. The respiratory muscles may be involved, resulting in inadequate ventilation at birth. Neonatal death is frequent, but if the affected infant is able to survive the first few weeks, some improvement may be seen.[186] The overall long-term prognosis remains generally poor, however. Developmental milestones are delayed and the incidence of mental retardation is increased.[187] Congenital myotonic dystrophy is usually found only in neonates born to mothers with the disease and differs from the adult form of the disease.[188]

Management Options

PREPREGNANCY AND PRENATAL

Any maternal cardiac or pulmonary compromise should be determined. A baseline electrocardiogram and pulmonary function tests should be obtained and the patient informed of the signs and symptoms of arrhythmias. Physical activity should be encouraged to slow clinical progression. Genetic counseling and prenatal diagnosis using DNA linkage analysis should be offered. Serial ultrasonography should be used to assess the amniotic fluid volume. In the presence of polyhydramnios, patients need to be followed for evidence of preterm labor. In the third trimester, fetal surveillance may be indicated.

LABOR AND DELIVERY AND POSTNATAL

Despite the risk of preterm labor, myotonic involvement of the uterine smooth muscle can result in dysfunctional labor. Augmentation with oxytocin is often effective.[189] Shortening of the second stage of labor may be helpful in women with significant weakness. Postpartum hemorrhage is a common complication and should be anticipated.

Respiratory muscle weakness may be present and must be considered when offering analgesia and anesthesia. Local or regional anesthesia is preferred. The risk of apnea with narcotics may be increased, and these agents should be used with caution. Nondepolarizing neuromuscular blocking agents should be avoided because of generalized muscle contracture resulting in difficulty with airway management.[190] Prenatal consultation with an anesthesiologist may be prudent.

A pediatrician should be present in the delivery room to aid in neonatal resuscitation and ventilation. There are no newborn tests for myotonic dystrophy. In those cases in which there are no maternal symptoms and neonatal myotonia is suspected, electromyographic studies on the mother can confirm the neonatal diagnosis.

SUMMARY OF MANAGEMENT OPTIONS
Myotonic Dystrophy

DEMYELINATING DISEASES

Multiple Sclerosis

Maternal and Fetal Risks

Multiple sclerosis (MS) is a demyelinating disease that affects the central nervous system at different levels and at varying times.[191] It is a relatively common neurologic disease among young adults, peaking at age 30. The prevalence in the United States is 1 per 1000. Women are affected twice as often as men.

Common symptoms include acute onset of diplopia, vertigo, gait instability, bladder incontinence, loss of vision, and fatigue. Any central nervous system symptom can be a manifestation of MS, however. The disease course in an individual patient is unpredictable. Different general disease patterns are recognized. One type is characterized as relapsing and remitting with an identified onset and resolution of symptoms. The chronic progressive pattern follows a protracted course with worsening of symptoms over a prolonged period of time. Finally, a relapsing progressing course displays identifiable exacerbations with no clear return to baseline neurologic function. Poor prognostic factors include prominent weakness, poor response to steroids, and older age at onset. The common pathologic lesion called a plaque demonstrates myelin loss and gliosis associated with inflammatory infiltrates.

Previous research on the effects of pregnancy on MS has generally been flawed, and well-controlled studies are needed.[192] Pregnancy itself may exert a short-term beneficial effect on the course of MS, including fewer, less severe relapses, especially in the third trimester. However, this protection is lost in the postpartum period. The incidence of new cases of MS is decreased during pregnancy, as is the risk of exacerbation and progression of existing disease. Postpartum, the incidence of new-onset disease is not different from that in the nonpregnant population.[193] Exacerbation is reported to increase 20% to 40% during the first 6 months after delivery.[34,194] Despite the increase in disease activity postpartum, there does not appear to be any increase in long-term disability related to pregnancy.[195–197] Objective evidence of decreased MS activity during the latter half of gestation with a return to baseline postpartum has been demonstrated using serial MRI scans in two patients.[198] The relative immunosuppression associated with pregnancy may play a role in pregnancy-related changes seen in MS. Children of MS mothers have a 3% risk of developing MS compared with a 0.1% risk seen in the general population.[199]

Management Options

PREPREGNANCY

The diagnosis of MS is made clinically. Brain imaging and CSF studies are used to support the clinical impression. High-intensity signal lesions are found in the central nervous system white matter on MRI scanning, and oligoclonal banding is seen in the CSF. There are few data available during pregnancy on the three FDA-approved treatments for MS patients with relapsing-remitting disease. The therapies include copolymer 1 or glatiramer acetate (category B), interferon-β1b, and interferon-β1a (both category C). Corticosteroid therapy is also used.

Preconceptual evaluation and counseling is desirable. Disease activity should be assessed. In times of remission, with the lack of information regarding MS therapies during gestation, and the fact that most patients show improvement during pregnancy, consideration should be given to stopping the drugs or minimizing the dose. Patients should also be informed of the increased risk of their offspring developing the disease.

PRENATAL

Patients should be monitored for evidence of increased disease activity and the risks of therapy weighed against the potential concerns associated with lack of information. In those patients with urinary tract involvement, regular screening for asymptomatic bacteriuria should take place. Physical therapy and stretching exercises required prior to conception should be continued.

LABOR AND DELIVERY AND POSTNATAL

Labor and delivery should not be significantly affected in patients with MS. Prolonged antepartum corticosteroid use requires stress dose steroids during labor. Hydrocortisone

25 mg parenterally every 8 hours in addition to the usual daily dose is an acceptable regimen.[200] Maternal exhaustion seen in the second stage can be managed with operative vaginal delivery. The use of spinal anesthesia has traditionally been avoided owing to fear of increasing the risk of exacerbation. There are no data to support this concern, however, and spinal, epidural, and general anesthesia can all be used safely.[201] Breast-feeding may be encouraged, because there does not appear to be an increase in the frequency or severity of postpartum relapse.[202]

CEREBRAL TUMORS

Primary Brain Tumors

Maternal and Fetal Risks

All types of brain tumors have been described in pregnant women, but the overall incidence of primary brain tumors in pregnancy is small and not different from that seen in nonpregnant women of childbearing age. Nevertheless, normal physiologic changes such as increased fluid volumes and increased sex hormone levels occurring during gestation may have a profound effect on tumor growth and neurologic symptoms. Growth of some tumors with estrogen and progesterone receptors can be altered.[203,204] Although tumor growth may lead to initial diagnosis during pregnancy, signs and symptoms at presentation are the same as those in nongravid individuals.

Presenting symptoms relate to increased ICP or local mass effect. Common complaints or neurologic findings include headache, nausea, vomiting, visual changes, hemiparesis, cranial nerve deficits, and seizures. Most of these findings are nonspecific and commonly associated with normal pregnancy, potentially leading to a delay in diagnosis.

Management Options
PREPREGNANCY AND PRENATAL

Management of primary brain tumors in pregnancy depends on the type of tumor and whether it is benign or malignant. Maternal outcome will be dependent on these factors as well as the histologic grade of malignant lesions.[205] Gestational age will also be an important consideration in determining timing and mode of therapy as well as maternal and fetal risks and benefits.

The diagnosis is made with neuroimaging studies. MRI is preferred because low-grade tumors may present as nonenhancing lesions on brain CT, making their classification difficult. Surgical therapy is the treatment of choice for most lesions. Resection is best performed prior to conception when a diagnosis is made before pregnancy. In benign tumors such as most meningiomas or in low-grade malignant gliomas diagnosed during pregnancy, resection can often be

delayed until after delivery, providing the patient is neuro-logically stable. Malignant tumors should be resected promptly. Adjuvant chemotherapy can be given after the first trimester when maternal benefit outweighs fetal risk.

In tumors in which radiation therapy is indicated as a primary treatment modality or an adjuvant, this should be delayed until after delivery, if possible. Preterm delivery may be undertaken in the presence of fetal pulmonary maturity to expedite therapy. If gestational age prohibits timely delivery, localized brain radiation may be used with careful abdominal shielding to minimize fetal exposure.

Vasogenic cerebral edema is seen with some tumor types and may require glucocorticoid therapy. Dexamethasone is the drug of choice. Because this agent readily crosses the placenta, if prolonged high-dose treatment is required, prednisone may be considered as a substitiute to decrease fetal exposure. Seizure prophylaxis with appropriate AEDs is also indicated where there is a significant risk of convulsions.

LABOR AND DELIVERY

Little information exists to guide labor and delivery management. Vaginal delivery may be allowed with cesarean section reserved for obstetric indications. The second stage may be shortened with forceps or vacuum to avoid increased ICP with pushing.

Metastatic Brain Tumors (See also Chapter 52)

Maternal Risks and Management Options

The brain is a common site of metastatic cancer. Lung, breast, and gastrointestinal tract are the most frequent site of the primary tumors. Rarely do maternal cancers spread to the fetoplacental unit.

Choriocarcinoma is a trophoblastic tumor that is rarely found associated with a normal pregnancy. The tumor spreads rapidly by the hematogenous route with brain metastasis discovered at the time of diagnosis in as many as 20% of patients.[206–208] Brain involvement presenting as an ischemic stroke,[209] intracerebral hemorrhage,[210] or subdural hematoma resulting from metastatic infiltration and proliferation in vascular spaces may actually lead to the diagnosis. Chemotherapy is considered the treatment of choice in choriocarcinoma. Alternatives in special circumstances include surgical resection of single brain metastasis and cranial irradiation. The presence of brain lesions is associated with an overall worse prognosis.

Prolactinoma (See also Chapter 46)

Maternal Risks

Prolactinomas are the most common type of pituitary tumor. Most are microadenomas found during an evaluation for amenorrhea, galactorrhea, or infertility. In addition, macroadenomas (>10 mm diameter) may present with headache or bitemporal hemianopia. The use of bromocriptine to treat infertility has allowed women with prolactinomas to become pregnant. Pregnancy can stimulate tumor growth. Although this is rarely a problem with microadenomas, symptomatology may develop or worsen in the presence of a macroadenoma.[211]

Management Options

If adenoma size has not previously been determined, neuroimaging studies are indicated to define the extent of the tumor. MRI is able to identify small adenomas and their relation to the optic nerve, whereas CT scan provides better definition of any bony erosion resulting from the tumor expansion.[212] With microadenomas, bromocriptine can be stopped once pregnancy is diagnosed, with less than a 5% chance of the lesion becoming symptomatic.[213] Visual fields are periodically tested to detect evidence of tumor growth. Headaches are a useful early symptom of tumor enlargement. Bromocriptine may be started during pregnancy if symptoms develop.[214] Macroadenomas have a 15% to 35% chance of enlargement. Bromocriptine may be continued throughout gestation or patients must be followed closely for symptoms. Hypophysectomy or radiotherapy is reserved for cases that fail medical management. Adenomas generally decrease in size after delivery.[215]

MOVEMENT DISORDERS

Maternal and Fetal Risks

Life-threatening, new-onset movement disorders are extremely rare during pregnancy.[216,217] Movement disorders are classified based on either excessive ("hyperkinetic" or "dyskinetic") or slowed ("hypokinetic") motor activity. The findings can be persistent or intermittent. In reproductive-age women, the hyperkinetic or dyskinetic disorders predominate. Several of the movement disorders are associated with abnormalities of tone, but most are not associated with actual weakness.

Most movement disorders are the result of disease involving the basal ganglion (caudate nucleus, globus pallidus, putamen, substantia nigra) and its connections. However, abnormalities of the thalamus, cerebellum, spinal cord, and peripheral nerves can cause abnormal movements. A wide spectrum of pathologic processes including degenerative conditions, toxins, metabolic aberrations, cerebrovascular disease, neoplasms, autoimmune conditions, infections, and trauma can lead to movement disorders.[217] In addition, dopamine receptor antagonists commonly used to treat nausea and vomiting in early pregnancy may rarely induce new-onset dystonia, chorea, tremors, and parkinsonism.

Chorea Gravidarum

Maternal and Fetal Risks

Chorea gravidarum, a hyperkinetic disorder, is an uncommon condition that encompasses any cause of chorea occurring during pregnancy.[218–220] In the preantibiotic era, it was commonly due to group A streptococcal infection and rheumatic fever. Clinical manifestations of chorea include abrupt, rapid, unsustained, involuntary, purposeless, irregular, and nonrhythmic movement of a limb or axial structure. The movements may be isolated and of brief duration or they may be more flowing and sustained. Patients are often unable to persist with voluntary motor activity. This is illustrated by difficulty in maintaining protrusion of their tongue or closure of their eyes. There are multiple causes of chorea gravidarum. Most cases are due to medications, toxins,

TABLE 48–9

Theophylline derivatives
Lithium
Tricyclic antidepressants
Lead toxicity
Amphetamines
Cocaine
Metaclopramide

infections (such as HIV or cerebral toxoplasmosis), autoimmune disorders, cerebrovascular disorders, or an endocrinopathy. Specific causes are shown in Table 48–9.

Management Options

Management of chorea depends on the underlying etiology and its severity. The diagnostic evaluation is complex and aimed at excluding the conditions listed in Table 48–9. Therapeutic intervention is aimed primarily at the underlying etiology. The actual chorea is usually benign and of secondary concern. Treatments typically offer only symptomatic relief and have the potential for adverse effects. Expectant management is preferred except in situations in which the movements may lead to dehydration, malnutrition, or insomnia or when they are exceedingly violent and pose a risk of maternal injury. Short-term use of low-dose haloperidol (category C) can reduce chorea movements.

Wilson's Disease

Maternal and Fetal Risks

Wilson's disease is an autosomal recessive disorder of copper metabolism associated with a deficiency of the copper-binding and carrier protein ceruloplasmin. Disease manifestations include chorea, tremors, hypersalivation, dystonia, myoclonus, and slurred speech. Copper deposition in the brain is responsible for the clinical findings. Kayser-Fleischer rings describe copper deposition in the cornea and represent one of the classic physical findings. Other organ systems are also affected. The defective gene is located on chromosome 13 (p14).[216,217] The carrier frequency in the population is between 1 in 90 and 1 in 200.

Management Options

Typically, the diagnosis is made when serum ceruloplasmin levels are less than 20 mg/dL. Half of patients with Wilson's

disease will have levels less than 5 mg/dL. The diagnosis may be complicated in pregnancy because increased estrogen levels increase ceruloplasmin levels leading to false-negative assays. Prior to penicillamine therapy, pregnancy was uncommon because of the development of infertility, and when conception did occur, the rate of spontaneous abortions was increased.[221,222]

Penicillamine (category D) therapy is the first-line treatment of Wilson's disease.[223] Five consecutive successful pregnancies in the same woman with Wilson's disease have been reported.[224] Therapy has been associated with adverse fetal effects. Fetal connective tissue anomalies secondary to an inhibition of collagen synthesis can result.[223,225] Also, neonatal inguinal hernia, reversible cutis laxa,[216,217] hyperflexible joints, vascular fragility, and poor wound healing have all been reported.[226,227] Many infants born to mothers taking penicillamine during pregnancy are found to be free of defects, however.

With proper therapy, the course of Wilson's disease does not appear to be affected by pregnancy. Penicillamine therapy should be continued during pregnancy. Halting therapy could lead to irreversible damage to the maternal brain, liver, and other organs. To minimize the risk of poor wound healing following delivery, the daily penicillamine dose should be decreased from 1 g to 250 mg during the third trimester. An alternative therapy uses zinc and trientine. Collagen synthesis is not adversely affected, but experience with this regimen in pregnancy is limited.[221]

Restless Leg Syndrome

Maternal Risks

Restless leg syndrome is a common condition with 11% to 19% of pregnant women affected.[228] It consists of an unpleasant sensation of the legs often associated with periodic movements during or just before sleep or in the late evening when fatigue is present. Clinically, there is flexion of the hip and knee with dorsiflexion of the ankle and extension of the great toe. The etiology is unclear; however, in nonpregnant patients, there has been an association with iron deficiency. Treatment aimed at iron replacement has been associated with an improvement in symptoms.[229] Symptoms are also often noted to disappear with walking.

Management Options

Treatment is supportive and includes reassurance, massage, flexion and extension leg exercises, and walking. With the high incidence of iron deficiency in pregnancy, iron supplementation may be a prudent early intervention. Severe cases can be managed with opiates.

Parkinson's Disease

Maternal and Fetal Risks

Parkinson's disease is an idiopathic hypokinetic disorder typically seen after the age of 40, but approximately 5% of cases may present earlier.[216] Thus, Parkinson's disease may be seen in women of childbearing age. The condition is a

degenerative disorder of unknown etiology related to a deficiency of dopamine-secreting neurons in the substantia nigra of the brainstem mesencephalon (midbrain). Manifestations include slowed movements (bradykinesia), increased tone (rigidity), resting tremor, loss of postural reflexes, masked facies, and transient akinesia. Patients often have difficulty initiating movements and automatic movements are reduced. This constellation of findings is termed *parkinsonism* and represents a common clinical presentation for a variety of conditions in addition to Parkinson's disease. The differential diagnosis includes intracranial processes such as hydrocephalus, head trauma, subdural hematomas, cerebrovascular disease, and encephalitis. Carbon monoxide poisoning, metabolic abnormalities, and cyanide and manganese toxicity have also been implicated. Also, several medications including α-methyldopa, disulfiram, dopamine receptor antagonists, lithium, methanol, reserpine, and tetrabenazine may lead to parkinsonism. Discontinuation of the offending drug, if clinically feasible, may lead to varying degrees of symptomatic improvement.

Information describing the course of Parkinson's disease in pregnancy is limited. There are reports of worsening during pregnancy with improvement postpartum.[216,217] Symptoms may be exacerbated by several factors including hormonal changes, medications, weight gain, increased fatigue, and dehydration.

Management Options

Initial evaluation of a patient suspected of having Parkinson's disease should exclude other conditions associated with parkinsonism. As with the condition itself, information regarding the safety of antiparkinsonism medications during pregnancy is limited. Use of the combination of levodopa/carbidopa (category C), a mainstay in the treatment of Parkinson's disease, has been associated with malformations in animals, but adequate human data are not available. These medications should be used with caution. Amantidine (category C) has also been associated with malformations in animals. In humans, the overall malformation rate is reported to be higher, but there is no specific pattern. Again, data are limited and caution should precede its use.[1] Bromocriptine (category C) is a second-line agent for the treatment of Parkinson's disease. Although it is not as efficacious as the levodopa/carbidopa combination, there is considerably more experience during pregnancy. The information is based on lower doses used to treat prolactinomas.[230] It is considered safe without excess risk of complications based on 1335 women receiving it during pregnancy for a prolactinoma. Bromocriptine may be added to the levodopa/carbidopa combination when disabling symptomatology appears such as dopa-induced dyskinesias. Selegiline (category C) and pergolide (category B) are newer treatments that also lack adequate pregnancy data.[231]

CEREBRAL ABSCESS

Maternal Risks

Pregnancy and puerperium-associated cerebral abscesses are exceedingly rare with fewer than 15 cases reported.[232] Although the majority of abscesses are supratentorial and solitary (Fig. 48–7), focal neurologic deficits are not always present despite headache, fever, seizures, or depressed level of consciousness. Sources of infection include otitis media, venous sinus thrombosis, and hemorrhage into the basal ganglia. In most cases, a source is not found. Cerebral abscesses have been reported in immunocompetent hosts. Approximately half the cases have been associated with eclampsia. Overall mortality is 35%, and when the abscess is associated with eclampsia, mortality reaches 50%.

Management Options

Although rare, a cerebral abscess should be a part of the differential diagnosis when a mass lesion is seen on brain imaging. As a rule, aggressive medical management of the abscess is often adequate and surgical evacuation may not be necessary. Medical therapy includes the appropriate use of intravenous antibiotic(s) to cover a broad spectrum of potential organisms. A source for the infection should be promptly and thoroughly sought and treated and, when found, might give information about the responsible organism(s). Surgical drainage may be indicated if there is an initial poor response to the antibiotics.

Renal Disorders

ALEX C. VIDAEFF and SUSAN M. RAMIN

INTRODUCTION

Although renal disorders are relatively uncommon in pregnancy, obstetricians will encounter pregnant women with known underlying renal disease or previously subclinical renal conditions uncovered during pregnancy. In addition, complications of pregnancy such as severe preeclampsia may include acute renal deterioration as part of the clinical spectrum. This chapter discusses the management of acute and chronic renal conditions from an obstetric perspective. Unfortunately, the cumulative knowledge in this field is based almost exclusively on retrospective studies addressing only a small number of cases, underscoring the critical need for large prospective observational studies.

When considering the interaction between renal disease and pregnancy, maternal outcomes are related to the initial level of renal dysfunction more than to the specific underlying disease. With regards to fetal outcomes though, a distinction may exist between renal dysfunction resulting from primary renal disease and that in which renal involvement is part of a systemic condition. Although maternal and fetal outcomes in pregnancies complicated by kidney disease have improved in recent years owing to continuous progress in obstetrics and neonatology, as well as better medical management of hypertension and renal disease, every pregnancy in these women remains a high risk pregnancy.

RENAL CHANGES DURING NORMAL PREGNANCY (Table 49–1)

In normal pregnancy, renal plasma flow (RPF) increases progressively up to a maximum of 80% above nonpregnant levels in the second trimester, before falling to about 50% above nonpregnant levels in the late third trimester.[1] It is presumed that the third trimester decline in RPF is at least in part related to the compression of the intra-abdominal large vessels by the gravid uterus. The increased RPF in pregnancy is the consequence of renal vasodilation. Women with preexisting nephropathy who have further renal deterioration during pregnancy frequently do not manifest the early renal hyperperfusion present in a normal pregnancy because their renal vasodilation is already maximal. Unlike the hyperperfusion that may precede some renal pathologic conditions, gestational hyperperfusion does not lead to increased glomerular capillary pressure as demonstrated by animal studies and indirect evidence from mathematical models of data from fractional dextran sieving in humans.[2]

Renal hyperperfusion is the primary determinant of renal hyperfiltration in pregnancy with resulting increased urinary output and frequency. An increase in glomerular filtration rate (GFR) of approximately 25% is seen as early as 3 to 4 weeks from conception, and by 16 weeks' gestation, GFR is 55% above nonpregnant levels.[3] Consequently, creatinine clearance increases from the nonpregnant normal range of 100 to 180 mL/min to 150 to 200 mL/min, and blood urea nitrogen (BUN) and serum creatinine decline. Thus, values considered normal in the nonpregnant state may be abnormal during pregnancy. A BUN or serum creatinine value greater than 14 mg/dL and 0.9 mg/dL, respectively, may indicate preexisting renal disease or pregnancy-induced complications. In parallel with the decline in effective RPF toward term, the creatinine clearance will decrease by approximately 20% after 36 weeks' gestation and serum creatinine will increase. This should not be interpreted as a decline in renal function. In general, at least a 25% change in creatinine clearance or serum creatinine is required in order to suspect significant alterations in GFR.

The increased RPF in pregnancy is the consequence of renal vasodilation with profound reductions in renal afferent and efferent arteriolar resistances. The mechanism of vasodilation with decrease in vascular resistance in pregnancy is still poorly defined. The ovarian hormone relaxin has been implicated as a mediator.[4] However, relaxin is not the only determinant. Smith and coworkers[5] studied women who conceived with ovum donation, therefore without circulating relaxin, and still demonstrated an increase in creatinine clearance in the first trimester, albeit to a smaller degree than in women with normal ovarian function. A possible role has also been assigned to the natriuretic peptides, a family of peptide hormones shown to be potent natriuretic, diuretic, and vasodilatory agents. It has been posited that natriuretic peptides contribute to the systemic vasodilation of pregnancy, thus increasing RPF, either by a cyclic guanosine monophosphate (cGMP)–mediated vasorelaxant effect or indirectly by antagonizing the activity of the renin-angiotensin system. Sala and colleagues[6] have shown that plasma natriuretic peptides increase in the first trimester and then

TABLE 49-1

Urinary Tract Physiologic Changes during Normal Pregnancy

Renal vasodilation and RPF increase of 50%–80% above nonpregnant level

Renal hyperperfusion and hyperfiltration causing increased urine output, frequency, nocturia

Increased GFR (by 25%–55%) causing increase in proteinuria and creatinine clearance with decline in SCr and BUN

Reduced tubular glucose reabsorption causing glycosuria (in 70% of nondiabetic mothers)

Hypercalciuria

Increased renal size

Pelvicaliceal, ureteral, bladder, and urethral morphologic changes contributing to urinary stasis and VUR

Symptoms mimicking cystitis

BUN, blood urea nitrogen; GFR, glomerular filtration rate; RPF, renal plasma flow; SCr, serum creatinine; VUR, vesicoureteric reflux.

tend to decrease in late pregnancy, a pattern consistent with the reciprocal changes in RPF. Interestingly, the increase in plasma natriuretic peptides is demonstrable only in the supine position, not in the sitting position.[6] This is reflected in the nocturia typically experienced by gravid women, with mobilization of dependent edema and dilution of urine at night.

Urinary excretion of protein is also increased during normal pregnancy secondary to increased GFR, reduced proximal reabsorption, and possibly alterations in the electrostatic charge of the glomerular filter.[4] Proteinuria up to 300 mg/24 hr is considered normal in pregnancy. The specific excretion of albumin in the urine increases three times, contributing to a decline in serum albumin of 0.5 to 1.0 U/L.[7]

The results of a 24-hour urine specimen for proteinuria may be influenced by ambulation, exercise, cold, or heat exposure. Such inaccuracies and practical difficulties associated with the outpatient attempts to collect 24-hour urine specimens have led to an evolving interest in calculating instead the random spot urine protein-to-creatinine ratio or at least obtaining supervised 8- to 12-hour urine collections. A random urine protein (mg)-to-creatinine (mmol) ratio of more than 0.19 predicts significant proteinuria, but is not a substitute for a 24-hour urine collection, owing to the high incidence of both false-negative and false-positive results.[8]

Any gravida with preexisting renal disease or those at risk for renal deterioration during pregnancy should have a baseline determination of serum creatinine, proteinuria, and creatinine clearance early in pregnancy. Ideally, baseline values should be obtained before conception if possible. Baseline creatinine clearance appears to be a more sensitive indicator than a baseline serum creatinine level because the latter can be influenced by muscle mass, physical exercise, racial differences, and dietary intake of meat.[9] After the baseline workup, surveillance with monthly serum creatinine levels is usually sufficient. Although serum creatinine is not linearly correlated with creatinine clearance, a doubling in serum creatinine roughly suggests a 50% reduction in GFR. A 24-hour urine collection may be repeated when indicated.

Another renal tubular change in pregnancy is the reduced tubular glucose reabsorption, which leads to a 10- to 100-fold increase in urine glucose, causing glycosuria in 70% of healthy pregnant women.[10] There is also a threefold increase in urinary calcium excretion during normal pregnancy. However, the additional active vitamin D production by the placenta increases the circulating vitamin D to twice the nongravid levels, resulting in essentially no change in maternal plasma ionized calcium levels.[11]

The gestational rise in RPF causes an increased renal interstitial volume reflected in a 30% increase in overall renal volume and an approximately 1 cm increase in renal bipolar length. Dilation of the urinary tract is another common renal modification in pregnancy. The renal pelvicaliceal system and ureters progressively dilate, particularly on the right side. In 6% of pregnant women, the maximal caliceal diameter may reach 20 mm on the right and 8 mm on the left, as early as 20 weeks' gestation.[12] The pelvicaliceal dilation may persist in the immediate postpartum period. In 90% of pregnant women, the ureters are also dilated, elongated, kinked, and displaced laterally, suggesting obstruction, although in reality, these are normal physiologic changes. In contrast to pathologically dilated ureters, in pregnancy, the physiologically dilated ureter is expected to narrow below the pelvic brim. Physiologic ureteral dilation may begin as early as 6 weeks' gestation and peak at 22 to 24 weeks. At the level of the bladder, pregnancy-related changes include a wider trigon, increased vascular congestion, and increased pressure from approximately 8 to 20 cm H_2O. The urethra is 20% longer and has a higher closure pressure. All these mechanical changes contribute to increased urinary stasis and vesicoureteral reflux (VUR).[13] The changes at the level of the urinary tract may be responsible for an increased risk of urinary tract infection (UTI) in pregnancy. Mechanical effects from the enlarged uterus and the smooth muscle relaxation secondary to changes in the hormonal milieu additionally promote urostasis, incomplete emptying of the bladder, and reflux. Furthermore, glycosuria may encourage bacterial growth, whereas the increases in urinary progesterone and estrogen may lead to decreased ability of the lower urinary tract to repel bacterial attachment to the urothelium.[13]

LOWER URINARY TRACT INFECTION

General

Colonization of the vaginal introitus and periurethral region by *Enterobacteriaceae* and gram-positive organisms from the distal gastrointestinal tract is thought to be the initial step in the bacterial contamination of the lower urinary tract in women. Bacteria ascend into the bladder via the short female urethra, and the incidence of asymptomatic bacteriuria in pregnancy is 2% to 7%, similar to the rate observed in nonpregnant reproductive-age women.[14] Asymptomatic bacteriuria is defined as the growth of 10^5 or more colony-forming units per milliliter of urine (CFU/mL) of a single uropathogen from a first-void midstream clean-catch specimen in a woman with no urinary complaints. If the urine is obtained by urethral catheterization or the specimen is non–first-void, even 10^2 CFU/mL of a single organism may indicate significant bacteriuria. The changes at the level of the urinary tract during pregnancy make it more likely that asymptomatic bacteriuria will progress to a lower UTI (cystitis) that may

subsequently ascend to cause acute pyelonephritis. Once infected, the patient becomes symptomatic and the examination of the urine may reveal pyuria, proteinuria, and hematuria in approximately 50% of cases. Acute cystitis affects 1% to 2% of pregnancies.[15]

Diagnosis

Symptoms suggestive of a UTI are dysuria, frequency, nocturia, urge incontinence, voiding difficulty, suprapubic pain, and cloudy, malodorous urine. However, these symptoms are frequently found in healthy pregnant women, and the diagnosis needs to be confirmed by microscopic examination and culture of a freshly voided midstream urine sample. The microscopic examination will visualize the bacteria and allow quantification of leukocytes in the urine. The presence of at least one bacterium per oil-immersion field at gram stain correlates well with a positive urine culture.[16] Pyuria is defined as the presence of more than 10 leukocytes per high-power field in an unspun urine specimen or more than 50 leukocytes per high-power field in a spun urine specimen. Urine yielding more than 10^5 CFU/mL of a single uropathogen in a symptomatic woman is by convention diagnostic of UTI. However, 30% to 50% of women with acute symptoms of lower UTI may have lower counts (10^2–10^4 CFU/mL) that are still significant and may be explained by high fluid intake or a slow-growing organism. According to Tomson,[17] women with "low-count bacteriuria" left untreated will have 10^5 CFU/mL 2 days later.

Positive dipstick testing for nitrites (produced by most uropathogens by conversion of urinary nitrate) or leukocyte esterase (produced by leukocytes) in a symptomatic woman may strongly suggest UTI, allowing the initiation of empirical treatment before the urine culture results are available. The majority of cystitis cases remain uncomplicated and respond readily to empirical treatment with antibiotics, most of which are concentrated in the urine and thus achieve exceedingly high bladder levels. However, for screening of asymptomatic women in early pregnancy, these biochemical urine dipstick tests are not sensitive enough and cannot replace the urine culture. In a prospective international study, the dipstick tests missed 46% of all pregnant women with asymptomatic bacteriuria.[18]

Maternal and Fetal Risks

The major rationale behind screening for asymptomatic bacteriuria in pregnancy is that in the absence of treatment, about 25% to 30% of women with asymptomatic bacteriuria will develop acute pyelonephritis.[19] In a Cochrane review, antibiotic treatment of asymptomatic bacteriuria, compared with placebo or no treatment, significantly reduced the incidence of pyelonephritis (odds ratio [OR] 0.24, 95% confidence interval [CI] 0.19–0.32).[20] Following successful treatment of asymptomatic bacteriuria, rescreening is necessary, because approximately 30% of women will have a relapse of bacteriuria. Women at increased risk of pyelonephritis or renal impairment (previous UTI, diabetes mellitus [DM], hemoglobinopathy, nephropathy, immunodeficiency, neurologic dysfunction such as spinal cord injuries or multiple sclerosis, calculi, anatomic abnormalities of the urinary system, genitourinary instrumentation) should be screened

for asymptomatic bacteriuria every 4 to 6 weeks throughout pregnancy.

Asymptomatic bacteriuria has also been associated with an increased risk of preterm delivery and low birth weight.[21] Treatment of asymptomatic bacteriuria has been shown to reduce the incidence of preterm delivery and low–birth weight newborns (OR 0.60, 95% CI 0.45–0.80).[20]

Management Options

The most common uropathogens are gram-negative bacteria such as *Escherichia coli* (about 80% of cases), *Klebsiella*, *Proteus*, *Enterobacter*, *Citrobacter*, and *Pseudomonas* species. Other contributing uropathogens may be gram-positive bacteria including *Staphylococcus saprophyticus* (the most common gram-positive bacteria), *Staphylococcus epidermidis*, enterococci, and group B β-hemolytic streptococci. The increasing resistance rate of gram-negative uropathogens, particularly *E. coli*, to penicillins (28-39%) has disqualified these agents as first-line treatment choices. Even sulfa regimens and first-generation cephalosporins have been reported to be less efficacious (31% resistance rate for trimethoprim-sulfamethoxazole and 9%–19% for cefazolin).[22] For treating asymptomatic bacteriuria or a first episode of cystitis, nitrofurantoin macrocrystals (100 mg twice daily for 7 days) remains an inexpensive and effective oral agent, for which plasmid-mediated resistance is unlikely. In an international double-blind, placebo-controlled, randomized trial conducted by the World Health Organization, the standard 7-day regimen of nitrofurantoin was demonstrated to be significantly more effective than a 1-day nitrofurantoin regimen, reinforcing the current treatment recommendations.[23] Nitrofurantoin should be avoided in patients with glucose-6-phosphate dehydrogenase deficiency owing to the risk of hemolytic anemia. There are a few case reports suggesting a very rare association between the use of nitrofurantoin and pulmonary fibrosis as acute pulmonary toxicity in pregnancy.[24]

A test-of-cure urine culture should be obtained 2 weeks after treatment for cystitis is completed. Women treated for cystitis may have a recurrence in 33% of cases, requiring the use of a second-line antimicrobial agent for prolonged 10-day treatment.[14] The treatment should be based on urine culture with antibiotic sensitivity determination. The recurrence represents either a reinfection or a relapse. Reinfections usually occur more than 2 weeks after cessation of a previous therapy, and are due to a different organism. Reinfections indicate the need for low-dose antibiotic daily suppression guided by the sensitivities of the most recent infective organism until 4 weeks postpartum. Suppressive therapy should not be initiated until a negative test-of-cure confirms eradication of the acute infection. Suitable regimes for long-term antibiotic prophylaxis include nitrofurantoin 100 mg orally at night or cephalexin 250 mg orally at night.[25] Relapse is more rare and usually occurs within 2 weeks of cessation of initial therapy. Relapse or persistence may be associated with calculi or structural abnormalities of the urinary tract and ultrasound evaluation may be necessary.

Quinolone antibiotics should be avoided in pregnancy because of the risk of arthropathy in infants exposed in utero. Single-dose intravenous therapy with gentamicin is

not adequately evaluated and should be reserved for those rare cases of allergy to both penicillin and sulfa that markedly limits the options.

Women who remain symptomatic despite treatment and an infecting uropathogen cannot be isolated should be evaluated for other conditions, such as trichomoniasis, herpetic infection, urethritis (possibly with *Chlamydia trachomatis*), or interstitial cystitis. *Lactobacillus* bacteriuria should be treated with erythromycin or clindamycin only if persistent on two consecutive cultures.

SUMMARY OF MANAGEMENT OPTIONS

Prenatal Treatment		
For treating asymptomatic bacteriuria or a first episode of cystitis, use nitrofurantoin macrocrystals (100 mg orally twice daily for 7 days) or treat according to antibiotic sensitivities.	Ib/A	22,23
A test-of-cure urine culture should be obtained 2 wk after treatment is completed.	III/B	14
For cystitis recurrence (33% rate), treat with a second-line agent based on urine culture with antibiotic sensitivity for 10 days.	III/B	14
For relapse or persistence, ultrasound evaluation is necessary to exclude calculi or structural abnormalities of the urinary tract.	IV/C	14,25
Reinfections indicate the need for continued low-dose antibiotic suppression guided by the sensitivities of the most recent infective organism until 4 wk postpartum.	IV/C	14,25

UTI, urinary tract infection.

ACUTE PYELONEPHRITIS

Clinical Presentation

Acute pyelonephritis involves the upper urinary tract. Over 80% of women will present with lumbar pain, fever, chills, and costovertebral angle tenderness. Other signs of systemic illness often present include myalgia, headache, malaise, and confusion. Only about half of the cases have associated symptoms of lower urinary tract irritation (urgency, frequency, dysuria) in addition to nausea, vomiting, and anorexia.[26] Costovertebral tenderness is right-sided in 54% of cases, left-sided in 16%, and bilateral in 27%.[26] The right kidney is most commonly affected because of greater obstructive changes owing to the dextrorotated uterus and the course of the right ovarian vessels. Most women (91%) with antepartum pyelonephritis present in the second and third trimester, possibly in relation to increasing urinary obstruction during late pregnancy.[26] In 19% of the peripartum cases, the presentation is in the postpartum period.[26] The same uropathogens that cause asymptomatic bacteriuria and cystitis are responsible for acute pyelonephritis.[26] In a population screened and treated for asymptomatic bacteriuria, the incidence of acute pyelonephritis in pregnancy is less than 1%.[19]

Maternal and Fetal Risks

Unless acute pyelonephritis is treated promptly, there is considerable maternal and fetal morbidity. Treatment itself may be associated with an initial phase of significant side effects secondary to the massive endotoxemia resulting from the lytic action of antibiotics on the cell wall of

gram-negative bacteria (Table 49–2). Pregnant women are very sensitive to the effects of endotoxins, and it is not uncommon for the patient to appear worse and even more febrile during the first 12 to 24 hours of therapy. Endotoxins increase the release of cytokines and prostaglandins and cause endothelial damage and capillary leak. They may also induce alveolar damage and pulmonary edema. Almost 25% of pregnant women with acute pyelonephritis will manifest mild hemolytic anemia, thrombocytopenia, and transient decrease in GFR with a rise in serum creatinine, and 2% of patients will develop pyelonephritis-associated acute respiratory distress syndrome (ARDS).[27] Pulmonary injury may be further compounded by injudicious fluid replacement or by the use of tocolytic agents (β-adrenergic agents or magnesium sulfate).[28] Increased uterine activity is present in about 20% of gravidas presenting with acute pyelonephritis, and the frequency of contractions increases significantly within the first 2 hours from initiation of antibiotics in response to bacterial endotoxin release.[29] However, uterine activity during treatment for pyelonephritis often occurs in the absence of cervical change.

Approximately 15% of pregnant women with acute pyelonephritis have bacteremia, and a small proportion may develop septic shock.[26] It is important to differentiate on initial presentation cases with impending septic shock from those in which hypotension is secondary to hypovolemia as a result of fever, vomiting, and dehydration. The potent bacterial endotoxins are capable of generating hypothalamic instability and high fever in these patients may be followed by hypothermia during the same day.

Management Options

Women suspected of having acute pyelonephritis should be admitted to the hospital. Laboratory tests should include, but are not limited to, a complete blood count, serum creatinine, BUN, electrolytes, lactate dehydrogenase (LDH), urinalysis, and urine culture. Urinary sediment reveals many leukocytes in clumps and bacteria. Hemolysis is confirmed by a peripheral blood smear and elevation in LDH concentration. Blood culture is indicated if the patient has high fever (>39.4°C), tachycardia (>110), or hypotension. With prior use of antibiotics, the urine culture may be negative while the blood culture will be positive. Another possible cause for a negative urine culture may be the complete obstruction of the unilaterally affected collecting system.

Intravenous antibiotics should be started empirically until sensitivities on blood and urine cultures are known.

Intravenous crystalloid solutions are administered along with antibiotics as part of the initial treatment in order to restore the contracted blood volume. In addition to close monitoring of blood pressure, pulse, urinary output, uterine activity, and fetal heart rate patterns, one should promptly investigate any respiratory difficulties by pulmonary auscultation, chest radiography, pulse oximetry, and arterial blood gas analysis. Most respiratory manifestations are transient and respond to increased oxygen delivered by face mask, but the occasional ARDS may require tracheal intubation with mechanical ventilation and positive end-expiratory pressure. Infections caused by *Klebsiella pneumoniae*, second most common after *E. coli*, are more susceptible to pulmonary injury and other organ system derangements. Pregnant women with pyelonephritis and septic shock often require invasive hemodynamic monitoring of fluid balance in order to reduce the risk of pulmonary edema and acute tubular necrosis (ATN).

The outpatient management of pyelonephritis in pregnancy has been evaluated in a randomized clinical trial of 120 women at less than 24 weeks' gestation.[30] Inpatients received intravenous cefazolin until 48 hours afebrile, and the outpatients received ceftriaxone intramuscularly. Both arms completed the antibiotic course with oral cephalexin. Following this regimen, 10% of outpatients required hospital admission owing to sepsis or recurrent pyelonephritis. Based on available data, outpatient management of pyelonephritis in pregnancy cannot be recommended. Women with acute pyelonephritis should always be admitted to the hospital to observe the maternal condition that can deteriorate rapidly and to monitor uterine activity and fetal condition. Acute pyelonephritis increases the risk for preterm birth.[31]

Depending on the severity of the patient's condition, a second- or third-generation cephalosporin (such as cefoxitin sodium 2 g q6–8h or ceftriaxone sodium 1g daily) is an effective (95%) first choice until sensitivities are known. Women allergic to β-lactam antibiotics can be given intravenous gentamicin (100 mg q8h). Gentamicin should be carefully used in cases of renal dysfunction because of possible synergistic nephrotoxicity.[32] Clinically, renal dysfunction is identified by serum creatinine concentrations in excess of 1 mg/dL persisting after adequate hydration. Serum concentrations of gentamicin can be measured and dose adjustments made accordingly. One advantage of gentamicin is that aminoglycosides do not lyse the bacterial cell wall, producing less endotoxemia than other antibiotics.[29] Some practitioners add gentamicin to the initial first-line agent in patients with a poor clinical response.

Intravenous antibiotics should be continued until the patient has been afebrile and asymptomatic for 48 hours. Oral antibiotics should then be given according to bacterial sensitivities to complete a 14-day course.[32] In most women with uncomplicated pyelonephritis, fever abates in 2 to 3 days. Failure of treatment to improve the maternal clinical condition within 96 hours suggests an underlying structural abnormality if microbial resistance to the employed antibiotic has been ruled out. Ultrasonography may be inconclusive in excluding urinary stones. If clinical suspicion is high, a plain abdominal radiograph will identify 90% of renal stones, and an one-shot intravenous pyelography at 20 to 30 minutes after injection of contrast will identify the rest, also excluding other abnormalities of the collecting system.[33]

The risk to the fetus from radiation after one or two radiographs is minimal, especially when compared with the clinical benefit of identifying an obstructed, nonfunctioning kidney. Urinary tract obstruction can also be detected using magnetic resonance urography, especially during the second and third trimesters.[34] Continuing sepsis may also be caused by a renal or perinephric abscess, a rare complication of acute pyelonephritis in pregnancy. Except for obstructive cases requiring the placement of a double-J ureteral stent, instrumentation during pyelonephritis in pregnancy should be avoided because it can precipitate septic shock. If the stent fails, percutaneous nephrostomy should be considered, and ultimately surgical removal of calculi. For pyonephrosis, nephrectomy may be life-saving.

Following one episode of pyelonephritis, pregnant women should have a test-of-cure urine culture 2 weeks after completion of the acute therapy, and the risk of recurrent pyelonephritis can be reduced (from 20% to 8%) with nitrofurantoin 100 mg orally at night continued until 6 weeks postpartum.[33] Alternatively, monthly urine cultures can be obtained to screen for recurrence.[33] Suppressive therapy is always necessary when abnormalities of the urinary tract are present.

SUMMARY OF MANAGEMENT OPTIONS
Acute Pyelonephritis

Management Options	Evidence Quality and Recommendation	References

ACUTE RENAL FAILURE IN PREGNANCY

Maternal and Fetal Risks and Management Options

Acute renal failure (ARF) is a rare complication of pregnancy. The causes are listed in Table 49–3. It may be associated with septic shock (endotoxemia or septic abortion), dehydration related to hyperemesis gravidarum, amniotic fluid embolism, severe preeclampsia, obstructive uropathy, or severe hemorrhage. The principles of management are aimed at identification and correction of the precipitating insult and optimal fluid resuscitation. Fluid balance is critical to the management of ARF during pregnancy. Too little intravascular fluid may be especially damaging to chronically

TABLE 49–3

Obstructive uropathy
Postoperative oliguria
Idiopathic postpartum acute renal failure

HUS, hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

impaired kidneys, whereas too much fluid risks pulmonary edema and ARDS.

An acute prerenal insult such as hemorrhage, dehydration, or septic shock may lead to transient ATN if inadequately treated. Pregnancy, being associated with heightened inflammation, changes to the vascular endothelium, and a prothrombotic state, is more likely to favor the development of ATN and subsequent progression from temporary ATN to bilateral renal cortical necrosis (BRCN) with permanent renal impairment. This is even more likely to occur if the prerenal insult coexists with preeclampsia, a condition characterized by volemic constriction and endothelial dysfunction. The associated prerenal insult, such as abruption or hemorrhage, will exacerbate the hypovolemic state and precipitate the development and progression of ATN. In a cohort of South African women with severe preeclampsia and renal impairment, 7 of 72 (10%) required temporary dialysis and all had either hemorrhage due to abruptio placentae or HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome.[35]

With the development of ATN, the amount of sodium in the urine will exceed 25 mEq/L, as opposed to prerenal azotemia without intrinsic renal damage in which the amount of sodium in the urine is expected to be lower than 20 mEq/L. The urine sediment may also help in differentiating uncomplicated prerenal azotemia from renal causes of renal dysfunction. In uncomplicated prerenal azotemia, the urine sediment is negative or has only occasional hyaline and granular casts, whereas with the development of ATN, tubular cell debris and brown granular (pigmented) casts will appear in the sediment. Half of the ATN cases may be nonoliguric.

As a consequence of thrombosis in segments of the renal vascular system, about 20% of ARF cases of obstetric origin progress to BRCN.[36] In early phases, it is not possible to differentiate ATN from BRCN. When anuria persists for longer than a week, BRCN should be suspected. Without dialysis, a patient with BRCN cannot survive more than 3 weeks. Computed tomography with contrast or selective renal angiography may help in confirming the diagnosis, revealing delayed filling and poor arborization of the interlobar arteries, with absent or nonhomogeneous filling at the level of the cortex. Imaging, however, is usually unnecessary

and may cause further nephrotoxicity. If oliguria persists longer than 30 days, renal biopsy may be considered, although the patchy nature of cortical necrosis in pregnancy may often preclude the definitive diagnosis. Other forms of BRCN, such as focal, confluent, or gross, are less likely to be encountered in pregnancy. Recovery depends on the extent of cortical necrosis, which is often incomplete (patchy) in pregnancy, and for those women who survive the acute illness, renal function usually returns slowly over the next 6 to 24 months. Long-term renal function remains, however, uncertain because hyperfiltration through remnant glomeruli may lead to subsequent progressive decline in renal function.

Acute Renal Failure Associated with Preeclampsia (See also Chapters 35 and 78)

The histopathologic renal changes classically described in preeclampsia as glomerular endotheliosis consist of swollen, vacuolated endothelial cells with fibrils, swollen mesangial cells (mesangiosis), subendothelial deposits of protein reabsorbed from the glomerular filtrate, and tubular casts. As a consequence of all these changes, glomeruli are enlarged by about 20%. The swollen endothelial cells may block the capillary lumen.

Preeclampsia frequently causes mild transient renal impairment (serum creatinine ≤ 1.4 mg/dL), but with appropriate management, recovery of renal function is usually complete. As in other cases of azotemia of intrinsic renal etiology, urine sodium is increased. Proteinuria in preeclampsia is nonselective as a result of increased tubular permeability to most large-molecular-weight proteins (albumin, globulin, transferrin, and hemoglobin). Urinary calcium declines because of an increased tubular reabsorption of calcium.

The cure for severe preeclampsia with renal failure is delivery of the fetus and placenta. Women with preeclampsia who have a rise in serum creatinine from normal to greater than 1.3 mg/dL should be delivered to prevent ongoing renal impairment. When serum creatinine increases by 1 mg/dL/day, ATN is very probable, but with delivery, the condition is reversible in 80% of cases. Recovery is only 20% in women with preexistent renal pathology. It has been reported that 2% to 5% of women with preeclampsia may have undiagnosed underlying renal disease.[37] Delivery may halt the general progression of preeclampsia, but postpartum maternal renal function usually deteriorates before improving.[35] Doubling of serum creatinine within 48 hours is suggestive of progression to BRCN. BRCN and need for dialysis are rare in preeclampsia, occurring more frequently in association with other obstetric complications.[35]

Oliguria in severe preeclampsia is a consequence of intrarenal vasospasm, with about 25% reduction in GFR. Transient oliguria (<100 mL over 4 hr) is a common observation in labor or the first 24 hours postpartum and a fluid challenge, consisting of 500 mL of an isotonic solution over 20 minutes, may be used to correct the usually inadequate vascular volume, unless signs of pulmonary edema are present (basal crackles and oxygen pressure [PO_2] < 95% on room air). If a preeclamptic woman is not obviously hypovolemic and has a BUN less than 14 mg/dL and serum creatinine less than 1.0 mg/dL, repeated fluid challenges to increase urine

output are unnecessary and will only increase the maternal risk of pulmonary edema.

Women with severe preeclampsia and serum creatinine greater than 1.36 mg/dL, refractory hypertension, or multisystem organ failure should have their fluid replacement therapy guided by a pulmonary artery catheter in an intensive care unit.[38] Monitoring only the central venous pressure (CVP) may be inadequate in preeclampsia because in those cases with high systemic vascular resistance (SVR), there is a resultant disparate left and right ventricular function. As a consequence, CVP becomes a poor reflection of the left ventricular tolerance to volume expansion; the increase in CVP may be insignificant despite a markedly increased pulmonary capillary wedge pressure (PCWP). In normal pregnancy, this concern does not exist because SVR is always decreased by 25% compared with the nonpregnant state (600–900 dyne sec cm^{-5} from 800–1200 dyne sec cm^{-5}), and CVP and PCWP are unchanged (1–7 mm Hg and 6–12 mm Hg, respectively).

Once invasive hemodynamic monitoring has been instituted in preeclamptic women based on the previously discussed clinical indications, three different situations may be uncovered:

- Low PCWP and high SVR. The best treatment in this situation is continuation of fluid therapy at 250 mL/hr until the PCWP is 10 to 12 mm Hg. In hypovolemic preeclamptic women, volume expansion will decrease SVR, increase cardiac output, and may even reduce the increased arterial pressure, improving both maternal and fetal well-being.[39] It is important to correct hypovolemia before any attempt to reduce blood pressure in order to avoid abrupt drops in blood pressure. A vasodilator given without such precautions can cause profound hypotension that may threaten maternal renal, cerebral, and uteroplacental blood flow.
- Normal or elevated PCWP and normal SVR. The best treatment in this situation is vasodilator therapy (intravenous hydralazine) or low-dose dopamine. Low-dose "renal" dopamine infusion (2.5 μg/kg/min) will induce vasodilation of the renal vessels, with increased RPF, favoring diuresis and solute excretion.
- Markedly elevated PCWP and high SVR. This situation is rare and requires aggressive afterload reduction with diuretics (furosemide infusion 5 mg/hr) and fluid restriction. Unguided fluid therapy in this group of patients who display poor cardiac function may be detrimental.

Once the patient is euvolemic, the fluid balance has to be rigorously monitored hourly, with a Foley catheter in place. The rate of intravenous fluid replacement should equal the previous hour's urine output plus insensible losses—usually 30 mL/hr, if afebrile. Intravenous fluid regimens administered at a fixed hourly rate can lead to fluid overload in oliguric women or to reduced intravascular volume in those undergoing diuresis. The amount of intravenous fluid replacement can be reduced when the mother can take oral fluids and her renal impairment starts to improve. The invasive central hemodynamic monitoring is continued until the diuretic phase occurs in the postpartum period.

Fluid replacement should include blood to replace blood loses, then isotonic sodium chloride solution or Ringer's lactate solution. Dextrose solutions are hypotonic and lead to maternal hyponatremia (5% dextrose solution contains

Hyperkalemia and Associated Electrocardiographic Changes

SERUM POTASSIUM LEVEL	ECG CHANGES
>5.5 mEq/L	Peaked T waves, atrioventricular block
7.0–7.5 mEq/L	Widening QRS complex
8.0–9.0 mEq/L	Atrial standstill
>9.0 mEq/L	Ventricular fibrillation, asystole

ECG, electrocardiographic.

---

only 30 mmol/L NaCl, compared with 150 mmol/L NaCl in 0.9% NaCl solution). Colloid solutions (albumin) given to women with severe preeclampsia have the risk of markedly increasing PCWP, even in cases with low serum albumin level, and should be avoided.

Persistent oliguria and a rising serum creatinine despite adequate intravascular volume and blood pressure correction would indicate the presence of ATN. Fluid intake should then be restricted to avoid fluid overload. Indications for dialysis are volume overload with congestive heart failure not responding to standard therapy, intractable electrolyte abnormalities, severe metabolic acidosis, or BUN greater than 39.2 mg/dL and serum creatinine greater than 5.65 mg/dL (Tables 49–4 and 49–5). The risk of fetal demise is significantly increased if BUN exceeds 60 to 80 mg/dL. Maternal acidosis will result in progressive fetal acidemia. The goal is to maintain the maternal blood pH greater than 7.2. In a series of 60 postpartum preeclamptic women with oliguric renal failure treated with both furosemide infusion and low-dose dopamine, 13 required at least temporary dialysis.[40] Dialysis in pregnancy should be started before the patient becomes symptomatic secondary to acidosis or electrolyte abnormalities.

Acute Renal Failure Due to Renal Obstruction in Pregnancy

Obstruction of the renal tracts during pregnancy may be due to renal calculi (see later discussion), an overdistended uterus, congenital renal tract abnormalities, or the gestational overdistention syndrome. Women with urinary tract surgery in childhood for congenital obstructive uropathy are at increased risk for urine outflow obstruction in the second half of pregnancy, besides a higher incidence of UTI.[41] Obstruction can cause high back-pressures with damaging

effect on the renal medulla, leading to loss of renal concentrating ability and production of dilute urine. Patients may also develop hypertension. With incomplete obstructions, in spite of the renal impairment, the patient may still have an apparently good urine output and the urine sediment is usually negative. The serum and urinary indices are not helpful in differentiating renal from postrenal causes of ARF, and imaging studies must be used to confirm the diagnosis. Urinary outflow obstruction requires ureteric stents that can remain in place for up to 3 months during pregnancy and will be removed 4 to 6 weeks after delivery. A temporary nephrostomy may be necessary if the ureteric stents are ineffective.[42]

During pregnancy, the renal tracts can rarely become grossly overdistended. If untreated, this overdistention can rarely lead to rupture of the kidney or urinary tract.[43] Women with overdistention of the urinary tract present with mild to severe back pain, most commonly on the right side and radiating to the lower abdomen. The pain is characteristically relieved by lying on the opposite side and tucking the knees up to the chest. A palpable, tender flank mass and gross or microscopic hematuria suggest renal tract rupture.[43] Rupture of the kidney usually occurs with preexistent renal conditions, such as hamartomas or chronic infections.[43] Occasionally, a urinoma will be evident around the kidney on ultrasound examination. Rupture of the kidney necessitates immediate surgery and almost invariably an emergency nephrectomy.[43]

Other Causes of Acute Renal Failure during Pregnancy

Nephrotoxic Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs), when given to the mother peripartum, reduce renal blood flow and can cause acute renal impairment to both mother and fetus.[44] Women with reduced intravascular volume, especially if they have preexisting renal impairment, are particularly vulnerable and should be prescribed NSAIDs with caution. Indomethacin may also precipitate hyperkalemia.

Postoperative Oliguria

Postoperatively, oliguria is usually secondary to hypovolemia from hemorrhage and third-space losses, although renal function may also be depressed by general anesthetics. A decrease in RPF may be seen with regional anesthesia causing sympathetic blockade and cardiac preload reduction. Volume depletion with oliguria may sometimes occur several days after surgery owing to continuous nasogastric suction or third-space sequestration (ileus, ascites, pleural effusion). In the assessment of oliguria after pelvic surgery, exclusion of obstructive uropathy or nephrotoxic agents (drugs or radiologic contrast) should always be considered before proceeding with adequate volume and electrolyte replacement.

Acute Fatty Liver of Pregnancy (See also Chapter 47)

Acute fatty liver of pregnancy (AFLP) is a rare but potentially fatal complication of the third trimester or postpartum period. The typical presentation is with nausea, vomiting, anorexia, malaise, epigastric or right upper quadrant pain, headaches, and jaundice. The laboratory studies usually reveal hemoconcentration, elevated white blood cell count, hypofibrinogenemia, prolonged prothrombin time, low antithrombin, metabolic acidosis, elevated liver enzymes and bilirubin, increased ammonia, and elevated serum creatinine and uric acid. In a series of 28 women with AFLP, mean serum creatinine at the time of delivery was 2.32 mg/dL and mean uric acid 11 mg/dL.[45] Intensive care by a multidisciplinary team is necessary because, in addition to hepatic impairment and coagulopathy, other complications frequently arise. Pulmonary edema and ARDS develop in about 25% of cases, pancreatitis in about 15%, sepsis in 10%, and renal failure in 44% to 50% of cases.[46] The ultimate treatment is maternal stabilization and delivery, with close monitoring before and after delivery of vital signs, intake-output balance, and any hemorrhagic diathesis. It is important to treat maternal hypotension aggressively to avoid further injury to liver, kidneys, and other organs. It may be necessary to use invasive hemodynamic monitoring to adequately correct and maintain the intravascular volume, cardiac output, and renal perfusion. In general, patients with AFLP will start to improve 3 days after delivery and will recover normal renal and liver function. Occasionally, temporary dialysis may be necessary.

THROMBOTIC THROMBOCYTOPENIC PURPURA–HEMOLYTIC UREMIC SYNDROME (See also Chapters 41 and 78)

Maternal and Fetal Risks and Management Options

Thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) are very similar, sometimes even undistinguishable, syndromes characterized by microangiopathic hemolytic anemia and thrombocytopenia (thrombotic microangiopathy). They are extremely rare during pregnancy and postpartum, occurring in less than 1 case in 100,000 pregnancies.[46]

Thrombotic Thrombocytopenic Purpura

The classic pentad of TTP, first described in 1925 by Moschcowitz,[47] consists of thrombocytopenia, hemolytic anemia, neurologic abnormalities, fever, and renal impairment. The complete pentad is present in only 40% of cases, but the first three components are manifested by 50% to 75% of patients.[46] Thrombocytopenia is frequently severe (<25,000 platelets/mm^3), the same as anemia, which often requires transfusion. Although neurologic abnormalities are reported to be present in as many as 90% of patients, they may be nonspecific or difficult to diagnose (headaches, visual changes, confusion, aphasia, weakness, paresis, seizures, and stroke). Fever is usually mild (<38.4°C), being present in 30% to 40% of cases. Renal impairment is manifested as proteinuria, hematuria, increase in serum creatinine, and oliguria. Long-term renal and neurologic impairment is possible. Presenting signs and symptoms may also include abdominal pain, nausea and vomiting, gastrointestinal bleeding, epistaxis, petechiae, purpura, jaundice, and syncope.

There are both congenital (familial) and acquired types of TTP. The familial form is characterized by a chronic relapsing course. The underlying pathologic disturbance involves microthrombi in end-organ microvessels typically resulting in ischemia and multiorgan disorder (kidneys, liver, pancreas, heart, and lungs).[48] ADAMTS13 is a von Willebrand factor–cleaving metalloprotease that normally prevents the persistence in circulation of unusually large von Willebrand's factor multimers. This enzyme produced mainly in the liver is markedly reduced (<5% of normal) in most patients with congenital TTP,[49] and antibodies that neutralize ADAMTS13 have been found in women with acquired TTP.[50] Consequently, large multimers of von Willebrand's factor are in high concentration in the circulation, inducing aberrant platelet aggregation and adhesion with formation of microthrombi, thrombocytopenia, and mechanical injury to erythrocytes with microangiopathic hemolytic anemia. Testing for ADAMTS13 is not readily available in clinical laboratories. On a peripheral blood smear, schizocytosis is noted, and the increased compensatory hematopoiesis is denoted by a high reticulocyte count, many nucleated red blood cells in circulation, and leukocytosis. In the bone marrow, normoblastic erythroid hyperplasia and increase in megakaryocytes may be noted. Hemolysis is responsible for increase in LDH and indirect bilirubin.

During pregnancy, the levels of ADAMTS13 progressively fall.[51] This may explain why TTP is common in association with pregnancy (~13% of all cases).[52] In 89% of cases, the presentation is antepartum with 58% in the second trimester. TTP shares many similarities with preeclampsia, and it is most important to differentiate them, not least because their management is different (Table 49–6). In HUS-TTP, typically there are no coagulation abnormalities, antithrombin III level is unchanged, and liver transaminases may be only modestly elevated, whereas in preeclampsia, anemia is not expected to be so severe. In TTP, maternal condition does not improve with delivery, but pregnancy usually cannot be prolonged for more than 4 weeks from the acute presentation, and given the increased risk of fetal loss,

it seems advisable to deliver earlier. Undoubtedly, consideration should also be given to sepsis when the prevailing manifestations are fever, thrombocytopenia, and renal failure.

Without adequate treatment, women with TTP do not survive more than 3 months. With the use of plasmapheresis, first introduced in 1976, 90% maternal survival is expected and the rate of fetal loss is only 20% to 30%.[53] Maternal hypoxia, reduced uteroplacental blood flow, and vascular lesions in the placenta may be contributors to the adverse perinatal outcomes.[54]

Until recently, it was unclear why plasmapheresis worked, but the recent discovery of antibodies to ADAMTS13 (removed with old plasma) and a congenital deficiency of ADAMTS13 (replenished with infusion of fresh plasma) may, at least in part, explain the efficacy of the process. Plasma exchange also helps remove the abnormally large multimers of von Willebrand's factor. Plasma infusion alone has a response rate of 64% and may be employed as the first-line approach in cases with less severe thrombocytopenia. Plasma exchange is effective in approximately 90% of cases and is preferable in cases with severe hematologic manifestations.[46] Plasmapheresis commonly causes mild urticaria or hypotension. Plasma exchanges are performed daily at a rate of 40 mL/kg until a few days after normalization of the platelet count, correction of neurologic symptoms, and elimination of hemolysis as evidenced by decline in LDH and stable hematocrit. If there is a suboptimal response, the rate can be increased to 80 mL/kg, but the risk of hypovolemia should be carefully avoided. When the adequate response is achieved, the frequency of plasma exchanges will be tapered to weekly sessions but never discontinued during pregnancy because relapses are common. Some patients, especially those with high antibody titers against ADAMTS13, may not respond to plasma exchange alone, requiring immunosuppressive therapy (prednisone, cyclophosphamide, vincristine, or rituximab), or splenectomy, or both.[55] Antiaggregant treatment with low-dose aspirin and dipyridamole (225 mg/day) may also be beneficial in conjunction with plasma exchange.[56] Conversely, administration of platelets to thrombocytopenic patients with TTP-HUS can result in a precipitous decline in clinical status due to an increase in microvascular thrombosis. Platelets may still be necessary when there is a potential for life-threatening bleeding.[57] Red cell transfusions are used as needed according to clinical guidelines.

Based on case reports, there may be a risk of recurrence of TTP in subsequent pregnancies, sometimes as early as the first trimester, and also with hormonal contraception.[53] Based on such limited data, the risk magnitude cannot be estimated.

Hemolytic Uremic Syndrome

HUS was first described by Gasser in 1955 in children,[58] in whom it is more frequent and milder than in adults. It is rarely associated with pregnancy, almost universally occurring in the postpartum period (≤10 wk).[54] Clinically, HUS is very similar to TTP, but the microvascular injury mainly affects the kidneys. Thrombi are seen in afferent arterioles and glomerular capillaries, and the renal functional impairment is more severe than in preeclampsia or TTP. Patients

present with edema, hypertension, and renal failure. In about 40% of cases, there is a flulike prodromal phase with gastrointestinal symptoms suggesting a possible endotoxin-mediated etiology at least in some cases.[59] The serum creatinine levels increase rapidly, by at least 0.5 mg/dL/day, in addition to proteinuria and microscopic hematuria. Oliguria progresses to anuria, and most patients will need dialysis, with risk for long-term renal deficit.[60] Anemia may be severe, requiring transfusion of red cells, and LDH may be elevated. Thrombocytopenia is less severe than in TTP, there are no coagulation abnormalities, and with the exception of seizures, other neurologic abnormalities are uncommon.

The treatment of HUS is similar to that of TTP. However, the response to plasma infusions alone is not so favorable. A combination of plasma exchange and prednisone at 1 mg/kg/day is frequently used as in nonpregnant protocols. After improvement, the rate of plasma exchange may be reduced and the dose of prednisone tapered down to 5 mg/day and maintained at this dose until 3 weeks postpartum. Thereafter, the prednisone can be completely tapered off.

Until 1996, only nine cases of HUS had been reported during pregnancy.[61] Such cases have been associated with an extremely poor prognosis, including maternal mortality of up to 55% and frequent preterm birth and fetal demise.[62] Because of these major risks, immediate delivery upon diagnosing HUS seems advisable, although in a case report of HUS developing at 18 weeks' gestation, the pregnancy was continued until term.[61]

Another thrombotic microangiopathy with thrombocytopenia and hemolysis similar to TTP/HUS is the *idiopathic postpartum acute renal failure* first described by Robson and associates in 1968.[63] About 100 cases have been reported so far. The diagnosis is made by renal biopsy, which shows thrombosis of the afferent arterioles, necrosis, and glomerular endothelial proliferation. No other organs are affected. The condition is irreversible and may lead to chronic hypertension. Severe forms are complicated by seizures, coma, and cardiac failure. Many treatments have been proposed so far, with different levels of efficacy: plasmapheresis, immunosuppression, heparin, dialysis, dipyridamole, and uterine curettage.

SUMMARY OF MANAGEMENT OPTIONS
Acute Renal Failure

Management Options	Evidence Quality and Recommendation	References
Management is aimed at identification and correction of the precipitating insult and optimal fluid resuscitation.	—/GPP	—
Differentiate uncomplicated prerenal azotemia from renal causes of renal dysfunction.	—/GPP	—
Suspect BRCN when anuria persists longer than a week and consider dialysis.	III/B	36
Severe Preeclampsia (See also Chapters 35 and 78)		
Delivery for oliguria or a rise in serum creatinine from normal to > 1.3 mg/dL	III/B	35
Fluid challenge (500 mL isotonic solution over 20 min) may be considered in cases with suspicion of hypovolemia, serum creatinine 1.0–1.36 mg/dL, and no clinical signs of pulmonary edema.	—/GPP	—
In cases with serum creatinine > 1.36 mg/dL, refractory hypertension, or multisystem organ failure, continuation of fluid therapy should be guided by a pulmonary artery catheter in an intensive care unit. Monitoring only the central venous pressure is inadequate.	IV/C	38
IV hydralazine or low-dose dopamine infusion (2.5 μg/kg/min) if necessary.	Ib/A	35,38,39,40
Furosemide infusion (5 mg/hr) and fluid restriction if necessary.	Ib/A	35,38,39,40
Correct hypovolemia before any attempt to reduce blood pressure to avoid abrupt drops in blood pressure.	IIa/B	39
Once the patient is euvolemic, the rate of IV fluid replacement should equal the previous hour's urine output plus insensible losses. Reduce the amount of IV fluid replacement when the mother can take oral fluids and her renal impairment starts to improve. Continue invasive central hemodynamic monitoring until the diuretic phase in postpartum.	—/GPP	—
Dialysis in rare cases.	IIa/B	40

SUMMARY OF MANAGEMENT OPTIONS
Acute Renal Failure—cont'd

Management Options	Evidence Quality and Recommendation	References
Postoperative Oliguria		
Exclude obstructive uropathy or nephrotoxic agents (drugs or radiologic contrast) before proceeding with adequate volume and electrolyte replacement.	—/GPP	—
Thrombotic Thrombocytopenic Purpura (See also Chapters 41 and 78)		
Differentiate from preeclampsia.	III/B	46
Plasma infusion may be first-line approach in cases with less severe thrombocytopenia (64% response rate).	III/B	46
Plasmapheresis is preferable in cases with severe hematologic manifestations (90% response rate).	Ib/A	46,52,57
Antiplatelet therapy (aspirin, dipyridamole) in conjunction with plasma exchange.	Ib/A	56
Immunosuppressive therapy (prednisone, cyclophosphamide, vincristine, or rituximab), or splenectomy, or both, for non responders to plasma exchange.	III/B	55
Consider delivery at 34 wk.	—/GPP	—
Hemolytic Uremic Syndrome (See also Chapters 41 and 78)		
Dialysis for most cases.	III/B	60
Red cell transfusion for severe anemia.	III/B	62
Plasma exchange and prednisone until 4 wk postpartum.	III/B	57,62
Delivery upon diagnosis.	IV/C	61
Acute Fatty Liver of Pregnancy (See also Chapter 47)		
Admit to intensive care unit. Invasive hemodynamic monitoring may be necessary.	III/B	45,46
Maternal stabilization and delivery.	III/B	45,46
Monitor clotting, hypoglycemia, and fluid balance before and after delivery.	III/B	45,46
Temporary dialysis occasionally.	III/B	45,46
Urinary Tract Obstruction		
Ureteric stents until 4–6 wk postpartum. If ineffective, temporary nephrostomy.	III/B	42
Nephrotoxic Drugs		
Prescribe NSAIDs with caution.	III/B	44

BRCN, bilateral renal cortical necrosis; GPP, good practice point; NSAIDs, non-steroidal anti-inflammatory drugs.

CHRONIC RENAL DISEASE IN PREGNANCY

Maternal and Fetal Risks and Management Options

When considering the interaction between renal disease and pregnancy, two salient questions are frequently asked: what effect will the pregnancy have on the mother's already affected kidneys and what effect will the mother's kidney disease have on the pregnancy? It appears that the major determinant for maternal outcome and for the likelihood of further pregnancy-induced renal damage is the degree of renal function impairment at the beginning of pregnancy. Another overriding prognosticator is the presence of hypertension, which is also associated with increased obstetric

risks regardless of the underlying specific renal pathology. Proteinuria, conversely, although predictive for the mother's long-term renal outcome, is poorly correlated with immediate obstetric outcomes.[64] The specific underlying disease becomes relevant when fetal outcomes are considered. A distinction may be drawn from a fetal/neonatal perspective between renal dysfunction resulting from primary renal disease and that in which renal involvement is part of a systemic disease. One has to note, however, that such conclusions are based on studies including only a small number of cases, without an appropriate control group, and virtually all retrospective, underscoring the critical need for large prospective observational studies in this field.

The Influence of Preexisting Renal Impairment

There is a relationship between the degree of renal impairment and the physiologic adaptation to pregnancy. With mild renal impairment (serum creatinine < 1.4 mg/dL), there is normal intravascular volume expansion and only minimal attenuation of the gestational increment in GFR.[65] With moderate impairment (serum creatinine between 1.4 mg/dL and 2.4 mg/dL), in spite of a normal blood volume expansion, only 50% of women will have the expected increase in GFR, whereas with severe impairment (serum creatinine > 2.4 mg/dL), there is a markedly attenuated increase in blood volume and no increase in GFR.[66]

Large multicenter series appear to suggest a linear relationship between the preconception serum creatinine level and the likelihood of further renal damage during pregnancy, although a more reliable interpretation of data should have been based on creatinine clearance rather than conventional serum creatinine levels. Women with mild renal disease who become pregnant have only a slightly increased risk of long-term damage to their kidneys from pregnancy compared with women with mild renal disease who had never become pregnant.[66] Even with moderate renal disease, irreversible deterioration of maternal renal function is uncommon. In an analysis of 82 pregnancies complicated by primary renal disease, Jones and Hayslett[64] reported that pregnancy-related deterioration in renal function occurs in 40% of women with initial serum creatinine level of 1.4 to 2.0 mg/dL. In half of these cases, the deterioration will persist postpartum, but only 2% will rapidly decline to end-stage renal disease (ESRD). When the serum creatinine level is above 2.0 mg/dL at the beginning of pregnancy, 66% of women will have gestational deterioration in renal function, deterioration that nearly always persists in postpartum and progresses to ESRD within 6 months after delivery in 23% of cases.[64] The risk of accelerated progression to ESRD within a few years after pregnancy is 45% when the serum creatinine level is greater than 2.6 mg/dL.

Although termination of pregnancy per se will not result in an improvement in renal function,[67] a rapid and significant decline reflected by changes in serum creatinine or creatinine clearance of at least 25% may justify delivery or termination of pregnancy. However, if the gestational age is between 24 and 31 weeks, with a normally grown fetus and controllable hypertension, expectant management with dialysis as indicated may be considered.

With regard to obstetric outcomes, available data indicate that fetal survival of pregnant women with mild or moderate renal disease is only slightly diminished. In contrast, fetal outcome is particularly reserved with severe disease, when the perinatal mortality rate is approximately four times higher compared with mild or moderate disease (36% vs, 8%).[68] In a Japanese retrospective study of 240 pregnancies in women with underlying renal disease, the rate in perinatal mortality was correlated with the decline in GFR.[69] The rate of perinatal morbidity as a consequence of low birth weight or prematurity doubles from mild to moderate renal insufficiency and again from moderate to severe disease. Reported rates of fetal growth restriction are 24% for pregnancies complicated by mild renal disease, 35% for moderate disease, and approximately 50% for severe disease.[68] Preterm delivery occurs with a frequency of 20%, 48%, and 80%, respectively, for mild, moderate, and severe degrees of renal failure.[68] Furthermore, early pregnancy losses, which are often ignored in analyses of pregnancy outcome, are more common in women with severe renal impairment.[64]

The Influence of Associated Hypertension

The degree of renal function impairment is not the only outcome modifier. Hypertensive renal disease is associated with increased maternal-fetal risk compared with normotensive renal disease, and the presence of hypertension increases the risk of further decline in renal function during pregnancy. Hypertension present at conception or early in pregnancy increases the perinatal mortality rate 6- to 10-fold.[69,70] In a retrospective study of 51 pregnancies from India, all women delivered prematurely when the diastolic blood pressure was greater than 100 mm Hg at initiation of prenatal care.[9] Pregnancy outcome is improved when blood pressure is optimized prior to conception and the control is maintained throughout gestation.[71]

Pregnant women with renal disease have a 50% increased risk of preeclampsia.[72,73] The risk increases to 80% with preexisting hypertension.[66] Such risk levels might have been overestimated as a result of the inherent pitfalls in differentiating an exacerbation of the renal disease with new-onset hypertension from superimposed preeclampsia.

The Influence of Associated Proteinuria

Limited postpartum follow-up of women with proteinuria identified in early pregnancy has shown an increased risk of progressive renal impairment.[74] Approximately 20% of women with nephrotic syndrome (proteinuria > 3 g/day, hypoalbuminemia, and hyperlipidemia) will progress to ESRD within 4 years. It is, therefore, important that women with proteinuria recognized in early pregnancy be investigated for previously occult renal disease and monitored serially throughout pregnancy for changes in renal function, hypertension, and urinary infection. Frequently, in the absence of pregestational information, the diagnosis of preexistent renal disease will be possible only retrospectively, when the manifestations are still present at 6 months postpartum. The only certain way of first making the diagnosis during pregnancy is by renal biopsy, with the theoretical advantage that some primary glomerular diseases that are adversely influenced by pregnancy may be

steroid-responsive. However, renal biopsy is considered potentially beneficial only in highly selected women before 28 weeks' gestation who are found to have sudden unexplained deterioration of renal function or new-onset heavy proteinuria (>5 g/24 hr) with no history of renal disease, in the absence of preeclampsia.[68,75] After 28 weeks' gestation, if progressive renal deterioration is noted, early delivery can be considered, with biopsy postpartum if necessary.

There is a poor correlation between the degree of proteinuria and obstetric outcomes. Significant proteinuria may result, however, in a poorer nutritional status and inappropriate maternal weight gain, a known risk factor for both fetal growth restriction and preterm delivery. These women also have an increased risk of preeclampsia (~30%).[74]

Severe proteinuria may contribute to hypoalbuminemia and a diminished capacity to excrete sodium. Retention of salt and water may lead to extensive edema, a situation particularly seen in diabetic nephropathy. In order to reduce the edema, it may be necessary to prescribe a low-sodium diet (1.5 g Na) close to term, bedrest in the lateral decubitus position to increase GFR, and an intermittent, small dose of a loop diuretic.[71] The use of diuretics in these patients should be undertaken very cautiously because they may increase the risk of uteroplacental hypoperfusion and may precipitate circulatory collapse or thromboembolic episodes. Nephrotic syndrome increases the risk of arterial and venous thrombosis, including renal vein thrombosis, but the efficacy of prophylactic anticoagulation has never been proved in pregnancy or outside of pregnancy.

Based on available data, it is difficult to separate the independent contribution to poor fetal outcome of maternal renal impairment, hypertension, and sometimes proteinuria. The evidence suggests that especially the first two parameters are individually and cumulatively detrimental to fetal outcome. For both maternal and fetal monitoring, more frequent prenatal visits are recommended, initially every 2 weeks, and weekly after 32 weeks' gestation. It may be necessary to initiate weekly or twice-weekly biophysical profiles at 28 weeks' gestation depending on the degree of renal insufficiency, hypertension, proteinuria, fetal growth velocity, and past obstetric outcome. In the absence of maternal or fetal deterioration, consideration should be given to delivery at or near term, with cesarean delivery reserved for the usual obstetric indications.

SUMMARY OF MANAGEMENT OPTIONS
Chronic Renal Failure

Management Options	Evidence Quality and Recommendation	References
Any gravida with preexisting renal disease or at risk for renal deterioration during pregnancy needs a baseline determination of proteinuria and creatinine clearance early in pregnancy, then monitoring with monthly serum creatinine levels. Repeat 24-hr urine collections when indicated.	III/B	9
Women with proteinuria recognized in early pregnancy should be investigated for previously occult renal disease. Renal biopsy is potentially beneficial only in highly selected women < 28 wk gestation with sudden unexplained deterioration of renal function or new-onset heavy proteinuria (>5 g/24 hr), with no history of renal disease, in the absence of preeclampsia.	IV/C	68,75
Pregnancy outcome is improved when blood pressure is optimized prior to conception and the control is maintained throughout gestation.	III/B	71
Changes in serum creatinine or creatinine clearance of at least 25% may justify delivery or termination of pregnancy. If the gestational age is between 24 and 31 wk, with a normally grown fetus and controllable hypertension, manage expectantly, with dialysis as indicated.	IV/C	64,67,68
For extensive edema in nephrotic syndrome, prescribe a low-sodium diet (1.5 g Na), bedrest in lateral decubitus to increase GFR, and cautiously, an intermittent, small dose of a loop diuretic.	IV/C	71
Prenatal visits initially every 2 wk, then weekly after 32 wk gestation. Serial measurement of fetal growth and umbilical artery Doppler recordings.	—/GPP	—
Weekly or twice weekly biophysical profiles starting at 28 wk gestation depending on the degree of renal insufficiency, hypertension, proteinuria, fetal growth velocity and umbilical artery Doppler values.	—/GPP	—
In the absence of maternal or fetal deterioration, delivery at or near term, with cesarean delivery reserved for the usual obstetrical indications.	—/GPP	—

GFR, glomerular filtration rate; GPP, good practice point.

SPECIFIC RENAL DISEASES IN PREGNANCY

Maternal and Fetal Risks and Management Options

Primary Glomerulonephritis

Immunoglobulin A (IgA) glomerulonephritis is the most common type of primary nephropathy in young people and the most frequently occurring variety in pregnancy. Information derived from small case series appears to suggest that the histologic type of glomerulonephritis influences the fetal and maternal outcomes, although this conclusion has been challenged in the literature.[76] There is consensus, however, that clinical parameters, such as the presence of impaired renal function, hypertension, and nephrotic range proteinuria in the first trimester, correlate with less favorable fetal and maternal outcomes, regardless of histopathologic diagnosis.[71] No increase in adverse outcomes occurs when nephrotic syndrome develops late in pregnancy.[76] The presence of severe vascular lesions on renal biopsy has also been associated with increased perinatal mortality, but this has no significant effect on maternal complications during pregnancy.[71] Based on more recent data, the overall fetal loss rate in primary glomerular disease is 21%, with the highest fetal loss rate (23%–45%) and low birth weight (32%) being associated with focal glomerulosclerosis.[77]

About 20% of women with chronic primary glomerulonephritis will experience worsening of preexisting hypertension or new-onset hypertension during pregnancy.[78] Changes in the preconceptional immunosuppressive regimen are not advisable during pregnancy.[79] However, chlorambucil is preferably avoided in pregnancy, and cyclophosphamide should not be used in the first trimester. Based on a large cohort study with patient follow-up over an average of 15 years, pregnancy is not an independent contributor to renal function deterioration in patients with chronic primary glomerulonephritis provided that they have normal or near-normal renal function (serum creatinine < 1.4 mg/dL) at conception.[80]

Women who had Henoch-Schönlein purpura (HSP) with primary glomerulonephritis in childhood are at an increased risk of preeclampsia during their pregnancies (70%) according to a small Finnish retrospective study.[81] There are also case reports of pregnancy triggering recurrent HSP.[82] In one such case, early pregnancy was associated with progressive renal failure, purpura, and arthralgia, unresponsive to corticosteroids, requiring treatment with cyclophosphamide.[83]

Autosomal Dominant Polycystic Kidney Disease

Pregnant women with autosomal dominant polycystic kidney disease (ADPKD) frequently manifest hypertension, which may predate the pregnancy or develop during the pregnancy, including superimposed preeclampsia. Increases in serum creatinine and proteinuria may also develop with advancing gestation, but in general, unless renal insufficiency was present before conception, the chance of a successful pregnancy outcome is unaffected.[84]

Extrarenal manifestations are seen in 50% of patients, including cerebral aneurysms (in up to 10%), liver and choledochal cysts, cardiac valvular defects, and aortic aneurysms.[85] The risk of rupture of asymptomatic intracranial aneurysms in pregnant ADPKD women has never been

defined, but the event may be devastating, with over 50% mortality or permanent disability.[86] Although the detection of an aneurysm may not lead to immediate treatment, the presence of the aneurysm would influence the mode of delivery. The general consensus is that cesarean delivery is indicated for uncorrected arterial lesions such as arteriovenous malformations and berry aneurysms, because blood pressure elevations with pushing during the second stage can elicit hemorrhage.[87] For these reasons, we feel that screening with magnetic resonance angiography in pregnancy, or ideally in the immediate preconceptional period, is advisable.[88] Genetic counseling should also be considered in pregnancy or preconceptionally because, as with any autosomal dominant condition, the chance for the offspring to be affected is 50%. Genetic linkage analysis is available for in utero molecular diagnosis, but although the results are essentially unequivocal, it is impossible to predict the severity of disease or clinical outcome.

Reflux Nephropathy

Reflux nephropathy is common in women of childbearing age and is characterized by renal scarring and reduced GFR. Women with surgically corrected VUR in childhood remain at increased risk of reflux nephropathy in pregnancy. Pregnancy increases the risk of irreversible renal function deterioration as result of tubulointerstitial disease (in up to 13% of cases) and gestational overdistention (in ~4%).[89] Close monitoring is necessary to detect significant hydroureteronephrosis, particularly if the woman develops flank pain, decreased urinary output, persistent infections, or hypertension. Ultrasonography of the renal pelvis at the end of the first trimester will provide a useful baseline measurement to be compared with subsequent imaging. Worsening proteinuria is rare and more indicative of preeclampsia. Detection of renal deterioration on serial serum creatinine measurements may require temporary urinary drainage. The changes may be reversible, and unnecessary surgical procedures soon after delivery should be avoided.

VUR at the time of conception increases the risk of pyelonephritis. Monitoring for asymptomatic bacteriuria every 4 to 6 weeks throughout pregnancy is essential, and for women with persistent bacteriuria, low-dose prophylactic antibiotics chosen according to the sensitivity of the most recent UTI would prevent symptomatic infection. Women with surgically corrected VUR in childhood also have a high incidence of UTIs in pregnancy (18%–57%), a much higher rate than in women who had correction at adult age or in whom the reflux subsided spontaneously.[89]

The risk of superimposed preeclampsia (≤75%), and the rate of fetal morbidity and mortality are influenced by maternal hypertension and serum creatinine at conception.[89,90] When serum creatinine levels are increased over 1.24 mg/dL, the rate of preterm delivery is as high as 20%, and the fetal loss rate, excluding elective abortions, may reach 37%.[89]

There is increasing evidence that VUR may be a familial disorder affecting 20% of infants who have a parent with a family history of VUR, compared with a 1% to 2% frequency of VUR in the general population.[91] If kidney damage is to be prevented, early diagnosis and treatment of VUR are necessary, before the neonate develops a UTI.[92] It has

been suggested that infants of mothers with reflux nephropathy be prescribed prophylactic antibiotics immediately after birth and undergo renal ultrasound and voiding cystourethrogram.[91] Evidence for renal scarring can be sought in those positive for VUR using a 2,3-dimercaptosuccinic acid (DMSA) radioisotope scan at 3 months of age.[91] It seems prudent to also offer screening to infants whose father has VUR.

SUMMARY OF MANAGEMENT OPTIONS
Primary Glomerulonephritis, Autosomal Dominant Polycystic Kidney Disease, and Reflux Nephropathy

Management Options	Evidence Quality and Recommendation	References
Primary Glomerulonephritis		
Changes in the preconceptional immunosuppressive regimen are not advisable.	III/B	79
Autosomal Dominant Polycystic Kidney Disease		
Screen for cerebral aneurysms with magnetic resonance angiography in the immediate preconceptional period or in pregnancy.	IV/C	88
Cesarean delivery for uncorrected cerebral aneurysms.	IV/C	87,88
Hereditary autosomal dominant condition requires preconceptional or prenatal genetic counseling.	—/GPP	—
Reflux Nephropathy		
Baseline renal ultrasound at 12 wk gestation.	III/B	89,90
Repeat renal ultrasound if flank pain, decreased urinary output, hypertension, persistent infections, or increase in serum creatinine.	—/GPP	—
Monitor for asymptomatic bacteriuria with urine cultures every 4–6 wk.	III/B	89
Low-dose prophylactic antibiotics if persistent bacteriuria.	III/B	89
Renal function deterioration may require temporary urinary drainage.	III/B	89
Screen fetus and neonate for VUR and consider neonatal prophylactic antibiotics.	III/B	91

GPP, good practice point; VUR, vesicoureteric reflux.

Urolithiasis

The incidence of urolitiasis during pregnancy is similar to that in the nongravid state.[93] Although gestational hypercalciuria, urinary stasis, and urinary tract dilation may appear as an ideal environment for stone formation, de novo formation of stones during pregnancy is prevented by a concomitant increase in the urinary excretion of crystallization inhibitors, such as magnesium, citrate, and nephrocalcin.[94] Uric acid and cystine stones rarely form in pregnancy owing to the physiologic alkalinization of the urine. The physiologic ureteropelvic dilation in pregnancy favors migration of preexisting stones. Pregnant women in the process of passing a renal calculus usually develop severe colicky lumbar pain associated with fever and hematuria. In the absence of a typical acute renal colic, urolithiasis may be suggested by flank pain or tenderness, hematuria, or persistent bacteriuria.

Symptomatic calculi are more common in white than in African American women and in multigravidas than in primigravidas.[93] Renal colic is also more common in the second and third trimesters.[93] Based on large published series of pregnancies complicated by renal stones, the affected women have an increased frequency of UTI, preterm labor, and preterm rupture of membranes.[95]

The diagnosis may be confirmed by a renal tract ultrasound in about half of the cases.[96] When inconclusive, more definitive information may be obtained with a plain abdominal radiograph or an one-shot intravenous pyelograph.[33] The radiation exposure of the fetus from one or two radiographs is minimal, only 0.4 to 1.0 rads.[96] Alternatively, in an effort to avoid even a small dose of radiation to the fetus, magnetic resonance urography can be used.[34]

Initial conservative management of renal colic during pregnancy is successful in close to 70% of cases.[96] Hydration, bedrest, analgesia with meperidine, and antibiotics will allow the spontaneous passage of the stones in many cases. The passage of the stone may be facilitated by epidural anesthesia, which will relieve the ureteral spasm. Continued

symptoms may necessitate cystoscopy for stone removal by ureteroscopy or passage of a double-J stent catheter that will relieve the obstruction and then be maintained in place under antibiotic prophylaxis until delivery. A percutaneous or open nephrostomy is another option, especially for an obstructed single kidney. Nephrostomy is also likely to have to remain in place for the rest of the pregnancy.

Invasive procedures do place the gravida at increased risk of preterm delivery and other complications. They are indicated only in cases of intractable pain, severe infection, or deterioration of renal function. Lithotripsy is generally contraindicated in pregnancy because of fetal safety concerns. An alternative with a 91% success rate for ureteral calculi, as reported in a series of eight pregnant women, is the flexible ureteroscopy with holmium laser lithotripsy.[97] This technique appears to have a good margin of safety because the direct stone-crushing energy is confined to within 0.5 mm of the laser fiber tip. It can be used in all stages of pregnancy.[97]

Women who are recurrent stone formers with persistent gross hypercalciuria, despite increased fluid intake, can use thiazide diuretics in pregnancy to increase distal tubular resorbtion of calcium. For problematic cases of cystinuria or recurrent uric acid calculi, high diuresis should be maintained and the urine should be further alkalinized to a pH greatrer than 6, preferably with potassium citrate.[98] During pregnancy, xanthine oxidase inhibitors for prevention of uric acid stones should be avoided, especially during the first trimester. Although the outcome of most pregnancies is normal under D-penicillamine for the prevention of cystine stones,[99] a teratogenic effect of the drug is suggested by animal studies, and a few cases of children with cutis laxa whose mothers received D-penicillamine during pregnancy are reported in the literature, dictating extreme caution.[100]

SUMMARY OF MANAGEMENT OPTIONS
Urolithiasis

Management Options	Evidence Quality and Recommendation	References
Identify renal calculus with renal tract ultrasound and when inconclusive, KUB, one-shot IV pyelography, or MRU.	III/B	33,34,96
If Renal Colic:		
IV hydration, bedrest, analgesia (meperidine), and antibiotics. Initial conservative management is successful in 70% of cases.	III/B	96
Epidural anesthesia may facilitate the passage of the stone.	—/GPP	—
Continued symptoms, or obstruction, especially in a single kidney, require cystoscopy for stone removal by ureteroscopy or passage of a ureteric stent, or nephrostomy.	III/B	96
Definitive removal of obstructing calculus by ureteroscopic holmium laser lithotripsy.	III/B	97
For Recurrent Stone Formers:		
In case of persistent gross hypercalciuria, increase fluid intake and give thiazide diuretics.	III/B	98,99
In case of cystinuria or recurrent uric acid calculi, maintain high diuresis and alkalinize the urine with potassium citrate.		

GPP, good practice point; KUB, kidneys, ureter, bladder (plain abdominal radiography); MRU, magnetic resonance urography.

Diabetic Nephropathy (See also Chapter 44)

Although only 5% to 10% of pregnant women with pregestational DM have diabetic nephropathy, this is the most common chronic renal disorder in pregnancy. It also represents the highest risk subgroup among pregnant women with DM. When the renal function is only minimally diminished, pregnancy does not have any negative impact on kidney function.[101] Conversely, women with diabetic nephropathy and moderate to severe renal impairment (serum creatinine > 1.4 mg/dL) have a 45% chance of an accelerated decline in renal function, significantly higher than in nonpregnant controls.[102] The prognosis is especially worse if hypertension coexists. The data on the impact of pregnancy on renal function in cases of moderate to severe renal impairment are based almost exclusively on studies conducted on type 1 DM cases, with only limited data from type 2 DM.

Pregnancies in women with diabetic nephropathy are complicated by an overall rate of hypertension of more than 60% and superimposed preeclampsia in 41% of cases.[103] In class F diabetics, the rate of preeclampsia is 50%, and even 60% in association with chronic hypertension. Besides chronic hypertension, other risk factors independently associated with the development of preeclampsia are an elevated glycosylated hemoglobin in the first trimester and the pre-pregnancy duration of DM.[104] Effective antihypertensive treatment is essential because, even in women with advanced diabetic disease, blood pressure control can considerably

slow the deterioration of maternal renal function.[105] The target diastolic blood pressure is 90 mm Hg or less, lower than that usually recommended for nondiabetic pregnant women with chronic hypertension.[106] In all cases of diabetic nephropathy, proteinuria will increase in pregnancy, peaking in the third trimester, and decreasing postpartum.[103] The increase during pregnancy is dramatic in 58% of cases.[107] However, increased protein excretion, in the absence of preeclampsia, does not influence pregnancy outcome or the rate of change in creatinine clearance.[107]

Although pregnancy in women with diabetic nephropathy and moderate renal function impairment appears to accelerate the progression of their disease, fetal prognosis remains generally favorable in the absence of uncontrolled hypertension.[108] With severely impaired renal function, early delivery between 32 and 36 weeks frequently becomes necessary for fetal concerns or superimposed preeclampsia or to prevent further deterioration of maternal renal function. The mainstay of management before conception and during pregnancy is adequate glycemic and blood pressure control. However, even with normoglycemia throughout pregnancy, the risk of preterm delivery remains high (22%–30%). Other pregnancy complications are fetal growth restriction in 16% of cases and more frequent bacteriuria.[103] The willingness to expectantly manage women with increasing proteinuria without other signs of preeclampsia may at least in part explain the current fetal survival rate of 95%.[103]

Diabetic Nephropathy (See also Chapter 44)

Management Options	Evidence Quality and Recommendation	References
Adequate glycemic control.	III/B	103
Control hypertension to ≤150/90 mm Hg.	III/B	103,105,106
In cases with severe renal failure, consider early delivery (32–36 wk gestation).	—/GPP	—

GPP, good practice point.

Lupus Nephritis (See also Chapter 43)

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disorder that predominantly affects young women, without impact on their fertility.[109] Renal involvement (lupus nephritis) occurs in 50% of SLE cases and, in pregnancy, is one of the most serious complications of lupus. Possible manifestations include hematuria, proteinuria, elevated serum creatinine, hyperuricemia, thrombocytopenia, and hypertension. Women with active lupus nephritis at conception, especially in association with proteinuria, hypertension, and antiphospholipid antibodies, have an increased risk of fetal loss (≤50%), fetal growth restriction, preterm delivery, preeclampsia, and perinatal and maternal mortality.[110] Severe lupus nephritis with manifestations early in pregnancy may justify termination of pregnancy because this clinical context is not only associated with poor fetal outcome but also life-threatening for the mother. In contrast, women with absent antiphospholipid antibodies, normal or near-normal renal function, proteinuria lower than 500 mg/24 hr, controlled hypertension, and SLE in remission for at least 6 months before conception can expect better fetal and maternal outcomes.[110,111]

The risk of preeclampsia in pregnancies complicated by lupus nephritis is 15%.[111] Differentiating an exacerbation of lupus nephropathy from preeclampsia during the second half of pregnancy is often a diagnostic challenge. Hypocomplementemia (C3 and C4 fractions) and an increase in baseline anti-DNA antibodies favor the diagnosis of lupus flare,[112] although some degree of complement activation may also be present in preeclampsia.[113] Clinical features that may also be discriminatory are the presence of hematuria and red cell casts in the urine sediment in active lupus nephritis, as well as extrarenal manifestations affecting the skin and joints.

Treatment with corticosteroids usually improves the complement level and decreases proteinuria, but the very high doses needed to control the disease activity have been associated with a sharp increase in fetal loss rate. Antepartum fetal surveillance should be utilized. When the response to corticosteroids is suboptimal, it may be necessary to add hydroxychloroquine or even cytotoxic drugs, such as cyclophosphamide, azathioprine, or cyclosporine.[114] Cyclophosphamide should be avoided in the first trimester because of possible teratogenicity.[115] Additional treatment includes antihypertensive medication and, in the presence of antiphospholipid antibodies, prophylaxis with low-dose aspirin and heparin. In a series of 70 pregnancies with lupus, the presence of antiphospholipid antibodies increased the rate of adverse fetal outcome to 76%, compared with 13% in antibody-negative pregnancies (OR 17.8).[111] Results of one randomized trial indicated that administration of low-dose aspirin plus heparin in patients with antiphospholipid antibodies improves the rate of live birth in comparison with treatment with low-dose aspirin alone.[116] Lupus nephritis may flare postpartum, especially when the histologic type is active diffuse proliferative glomerulonephritis,[117] but the consensus is not to use prophylactic steroids peripartum unless there are signs of disease activity.[111]

SUMMARY OF MANAGEMENT OPTIONS
Lupus Nephropathy (See also Chapter 43)

Management Options	Evidence Quality and Recommendation	References
Severe lupus nephritis (SCr > 1.4 mg/dL, proteinuria > 500 mg/24 hr, hypertension) with manifestations early in pregnancy may justify termination of pregnancy.	III/B	110,111
Advise increased risk of adverse pregnancy outcome, if active lupus at conception, SCr > 1.36 mg/dL, BP > 140/90 mm Hg, antiphospholipid antibodies.	III/B	110,111
Corticosteroids, hydroxychloroquine, azathioprine, cyclophosphamide (avoid in first trimester), cyclosporine to be used to treat lupus nephritis flare as necessary.	III/B	111,114
Antihypertensive medication as needed.	III/B	110,111
Prophylaxis with heparin and low-dose aspirin if antiphospholipid antibodies are present.	Ib/A	111,116
Advise increased risk of postpartum lupus flare, but no need for prophylactic increase in immunosuppression	III/B	111,117

BP, blood pressure; SCr, serum creatinine.

CHRONIC DIALYSIS AND PREGNANCY

Maternal and Fetal Risks and Management Options

Women with ESRD have reduced fertility, but improvements in renal replacement therapy have increased the likelihood of spontaneous conception, especially with hemodyalisis.[118,119] The available data do not permit comparative statistical interpretations on outcomes between peritoneal dialysis and hemodialysis; however, there does not appear to be any obvious superiority of one modality over the other, and there is no compelling argument for changing dialysis modality in pregnancy.[120] When starting dialysis during pregnancy, the usual criteria for choosing the dialysis modality can be used, with the recommendation of catheter placement higher in the abdomen if the peritoneal modality is elected. Chan and coworkers[121] reported less preeclampsia and higher infant birth weight in pregnancies managed with peritoneal dialysis compared with hemodialysis, but the rate of preterm delivery was higher.

The outcome of pregnancies occurring in women on dialysis has improved in recent years but the prognosis remains limited. The various maternal and fetal complications should temper any optimism and raise questions about the advisability of pregnancy in dialysis patients. Only 60% of pregnancies result in a live infant,[119] with a 85% rate of preterm delivery.[122]

The management of pregnancy for women with ESRD requires knowledge of the pregnancy-related physiologic changes and a willingness to balance maternal benefit and fetal well-being. Gestational reduction in serum sodium concentration necessitates a concomitant reduction in dialysate sodium concentration to around 135 mmol/L, and the gestational reduction in serum bicarbonate concentration should be matched with a low bicarbonate concentration in dialysate.[123] The requirement for calcium and vitamin D supplements is also likely to change as pregnancy progresses, and plasma levels of calcium and phosphate need to be monitored and adjusted accordingly.

Aggressive dialysis can lead to maternal hypovolemia/hypotension and result in fetal hypoxia. Slow rate ultrafiltration, increased frequency of hemodialysis to almost daily sessions, and limitation in the ultrafiltration volume per session limit the risk of hypotension, extracellular volume contraction, and compromised uteroplacental blood flow.[121] Pregnancy outcomes are improved when the sessions are prolonged to 4 hours, occur six times a week, the fluid removal is limited to 400 mL per session, and the predialysis serum creatinine level is maintained at 4.5 mg/dL.[122,124] In those women who had been on dialysis less than 6 years and in those who still produce more than 50 mL of urine daily, fluid balance is easier to manage, and the likelihood of a successful pregnancy increases.[125]

The exchange volumes also have to be decreased in peritoneal dialysis (from 2 L to 1.5 L), and the exchange frequency increased. Because more frequent exchanges increase the risk of peritonitis, it may be necessary to use a combination of daytime with nighttime continuous cycling peritoneal dialysis.

The disadvantages of almost daily hemodialysis may include hypercalcemia, alkalosis, and hypokalemia. If worsening alkalosis is noted, an individually formulated dialysate solution with less bicarbonate may be required, and for hypokalemia, a higher concentration of potassium in the dialysate or potassium supplements. Conversely, an increased dialysis frequency will allow for a more liberal diet and greater protein intake, improving the nutritional status. The protein supply is calculated based on pregravid weight and is recommended to be about 1.8 g/kg/day.[119] Water-soluble vitamins are dialyzed off, and it is important to ensure their

supplementation. Vitamin C supplementation is necessary at 170 mg/day and folic acid at 2 mg/day, amounts that may not be present in prenatal vitamin formulations.

Electronic fetal monitoring for viable pregnancies immediately after the dialysis session is important because of the acute fluid shifts that may occur. Increased fetal heart rate after hemodialysis may be an indication of excessive fluid removal with fetal hypovolemia.[126] Uterine contractions frequently occur during and after dialysis but usually resolve and do not require any treatment. Significant changes in amniotic fluid volume have also been reported during hemodialysis.[127]

In ESRD, anemia occurs with almost 100% incidence[128] and the hematocrit will decrease even further when the patient with renal insufficiency conceives.[120] Serum iron, ferritin, and hemoglobin levels need to be monitored monthly, and when the hemoglobin level decreases below 8 g/dL (hematocrit < 25%), erythropoietin (EPO) treatment is indicated to maintain the hemoglobin above 10 g/dL and transferrin saturation above 30%. The dose of EPO needs to be 50% to 100% higher in pregnancy because of relative resistance to EPO. EPO is administered intravenously or subcutaneously and can also be administered at the time of hemodialysis. It does not cross the placenta and there are no reports of teratogenicity or polycythemia in the infant.[122] Rarely, maternal thrombogenic activity may be increased, causing clotting of the dialyzer. Other rare adverse effects may be hyperkalemia, hyperphosphatemia, seizures, and severe hypertension. EPO is contraindicated in women with uncontrolled hypertension. The development of hypertension is more likely when the hematocrit increases rapidly. A rise in hemoglobin of greater than 1 g/dL in 2 weeks requires EPO dose reduction. Adjustments in antihypertensive medication and reduction in EPO dose allowing the hematocrit to decrease slightly will correct the situation.[129] The treatment with EPO frequently has to be supported by 200 mg iron intravenously weekly. With intravenous iron, the rise in hemoglobin concentration is significantly faster than after orally administered iron.[130]

For women on dialysis, pregnancy should not be continued beyond 38 weeks' gestation, and even early delivery at 34 to 36 weeks' gestation with documentation of fetal lung maturity may be advisable.[125] Surveillance of fetal growth and umbilical artery Doppler recordings during pregnancy is common practice. The reported rate of cesarean delivery is about 50%. After cesarean delivery, peritoneal dialysis may be resumed with small 1-L exchange volumes 24 hours after surgery, gradually building back up to 2 L by day 3 after delivery.[131] If there is leakage, hemodialysis may be used instead for 2 weeks. Infants of women on dialysis are born with BUN and creatinine levels equal to the mother's and will experience osmotic diuresis after birth. Without careful monitoring and replacement, they may develop volume contraction and electrolyte abnormalities.[132] Fetuses exposed to hypercalcemia are at risk for hypocalcemia at birth and tetany. Fetal osmotic diuresis caused by high BUN levels is also responsible for the more than 50% rate of polyhydramnios in patients with ESRD.[133]

SUMMARY OF MANAGEMENT OPTIONS
Chronic Dialysis

Management Options	Evidence Quality and Recommendation	References
Advise on increased risk of adverse pregnancy outcome and limited prognosis, raising questions about the advisability of pregnancy.	III/B	119,122
When starting dialysis during pregnancy, the usual criteria for choosing the dialysis modality (peritoneal vs hemodialysis) can be used.	III/B	120
Dialysis regime to mimic physiologic renal changes of pregnancy (lower sodium and bicarbonate concentration in dialysate). Adjust potassium, calcium and phosphate binders according to serum chemistry.	III/B	119,120, 122,123
After first trimester, increase the dialysis regime to almost daily (20–24 hr/wk) to keep predialysis BUN < 50 mg/dL or SCr < 4.5 mg/dL, and limit fluid removal to 400 mL/session.	III/B	119,120, 122,124
Monitor serum iron, ferritin, and Hb monthly, and when Hb decreases below 8 g/dL (hematocrit < 25%), give EPO and iron (may need IV iron) to keep Hb > 10 g/dL. A rise in Hb > 1 g/dL in 2 wk requires EPO dose reduction.	III/B	120,122, 128,129
Fetal surveillance • Fetal monitoring after each dialysis session. • Serial recording of fetal growth and umbilical artery Doppler. • Vigilance for polyhydramnios	—/GPP	—

Management Options	Evidence Quality and Recommendation	References
Consider delivery at 34–36 wk gestation with documentation of fetal lung maturity; pregnancy should not be continued beyond 38 wk gestation.	III/B	125

RENAL TRANSPLANT PATIENTS AND PREGNANCY (See Also Chapter 53)

Maternal and Fetal Risks and Management Options

Current consensus opinion is that pregnancy can be relatively safely undertaken by 1 year after transplant if the woman has had no rejections, the immunosuppressive medication dosing is stable, allograft function is adequate (serum creatinine < 1.5 mg/dL and urinary protein excretion < 500 mg/day), and there are no infections that could affect the fetus.[134] About 1 in 20 women of childbearing age who have a functioning kidney transplant will become pregnant, and for those that go beyond the first trimester, fetal survival is 95%.[135]

Pregnancies in renal transplant patients are more likely to be complicated by preterm delivery (55%) and fetal growth restriction (20%).[135] As for all renal disease, obstetric and maternal outcome is worse in the presence of hypertension, recurrent UTIs, proteinuria greater than 500 mg/day, and renal impairment (serum creatinine > 1.5 mg/dL). According to data from the European Dialysis and Transplant Association Registry,[136] if serum creatinine is greater than 1.5 mg/dL, fetal survival is only 75%.

The rate of maternal complications in renal transplant recipients is up to 70%, including worsening of renal function, worsening hypertension, and infectious morbidity.[135] Although the deterioration in renal function cannot be categorically attributed to pregnancy,[137] graft loss can be expected in up to 11% of pregnancies within 2 years of delivery, according to the North American National Transplantation Pregnancy Registry.[138] Long-term maternal renal function correlates with serum creatinine level measured within 3 months before conception. The majority of controlled studies have shown that pregnancy has no influence on renal function if serum creatinine is less than 1.5 mg/dL,[137] but a serum creatinine level in excess of 2.3 mg/dL should be regarded as a contraindication to pregnancy because in the United Kingdom Transplant Pregnancy Registry experience,[139] all transplant recipients with such prepregnancy creatinine levels had progression of renal impairment and required renal replacement therapy within 2 years of delivery.

About one third of pregnancies in renal allograft recipients will develop worsening hypertension, often representing superimposed preeclampsia.[135] The differential diagnosis of preeclampsia from allograft dysfunction or postrenal obstruction may be very challenging because worsening proteinuria, increased uric acid level, and hypertension can occur with many causes of renal deterioration. Biopsy may be necessary to distinguish severe preeclampsia that may require delivery from acute rejection that can be treated with high-dose methylprednisolone as the first-line treatment.

The most frequent intercurrent infections in pregnant renal transplant patients are UTIs (40% risk).[136] Other infections that may be encountered include *Pneumocystis carinii* pneumonia, toxoplasmosis, cytomegalovirus, and herpesvirus infections.[68] Monthly urine cultures are recommended and even asymptomatic bacteriuria should be treated for 2 weeks followed by suppressive therapy.[140] Urethral instrumentation should be minimized during pregnancy and peripartum. Prophylactic antibiotics are indicated before any type of surgery and for vaginal delivery. Live vaccines are contraindicated in immunosuppressed patients, and if necessary, vaccination should ideally be given prior to transplantation.

During pregnancy, the allograft should be followed with monthly ultrasound examinations and a technetium renal scan each trimester, in addition to serum BUN, creatinine, and electrolytes every other week. The pelvic transplant kidney may have some baseline pyelectasis, not necessarily indicative of obstruction. But pelvicaliceal distention is concerning and, if detected preconceptionally, contraindicates pregnancy. Even a small rise in serum creatinine level or oliguria may indicate allograft rejection, the same as renal enlargement, tenderness, and fever. The rate of 2% to 11% allograft rejection episodes in pregnancy[138] would suggest a need for monitoring immunosuppressive levels. In practice, though, prednisone, azathioprine, or tacrolimus dosage alterations are only rarely necessary during pregnancy,[141] and in spite of conflicting opinions, most experts suggest that it is unnecessary to increase the dose of cyclosporine to prevent rejection in pregnancy.[142]

Antepartum exposure to immunosuppressive drugs is frequently associated with low birth weight. The rate of low birth weight may be higher in women requiring cyclosporine

(46%) than in women receiving prednisone and azathioprine (39%), although the two groups are not comparable as clinical condition.[138] Cyclosporine is otherwise well tolerated in pregnancy, and a meta-analysis of 15 studies suggested no increased risk of teratogenesis.[143] Several reports have raised the possibility of autoimmune disorders developing later in life in exposed children, underscoring concerns for still undefined long-term consequences.[144]

Prolonged administration of corticosteroids has been associated with preterm birth, and in utero first-trimester exposure may also increase the risk of facial midline fusion defects by approximately threefold. No definite pattern of teratogenesis has been detected with the use of azathioprine in a prospective, controlled, international study including 189 women who took azathioprine during pregnancy.[145] Although azathioprine crosses the placenta, the immature fetal liver lacks the enzyme inosinate pyrophosphorylase needed for conversion of azathioprine to its active metabolite 6-mercaptopurine, and consequently, the fetus is relatively protected from the effects of the drug. Significant problems attributable to the drug have been reported only rarely, as long as the used dose is low enough to maintain maternal white count greater than $7500/mm^3$.[146] Dose reductions in azathioprine may also be necessary to correct maternal liver toxicity when occuring.[147] Cyclosporine has also been associated with maternal liver toxicity, diabetes, tremor, convulsions, and HUS.

A series of 100 pregnancies in which the mother was treated with tacrolimus revealed a side effect profile similar to that of cyclosporine.[148] The incidence of hypertension, including pregnancy-induced hypertension, was lower with tacrolimus- than with cyclosporine-receiving patients (27% vs. 67%), but the incidence of DM was higher (27% vs. 6%).[148]

Because cyclosporine and tacrolimus may be associated with serious adverse effects, particularly nephrotoxicity, new, highly effective immunosuppressive drugs have been introduced, such as mycophenolate mofetil. Mycophenolate mofetil has fewer nephrotoxic effects, but its administration in pregnancy is unadvisable because of documented teratogenicity in animals and humans (18%–26% rate of congenital anomalies based on registry data: www.fda.gov/medwatch/safety/2007/safety07.htm#CellCept2). The reported malformations after first-trimester exposure demonstrate clustering of similar defects and include microtia, micrognathia, cleft lip and palate, hypoplastic nails and shortened fingers, diaphragmatic hernia, and heart defects. If a kidney transplant patient taking mycophenolate mofetil plans a pregnancy, she should consider switching to cyclosporine for a period of time.[149]

The use of sirolimus in pregnancy may be contraindicated because only limited data are available and the animal studies have suggested teratogenicity.[150] There is also very limited experience in human pregnancy with monoclonal antibodies against lymphocytes (OKT3) or antithymocyte globulin (ATG) to recommend their use in pregnancy. Other chemotherapeutics with immunosuppressive activity such as cyclophosphamide, methotrexate, chlorambucil, and leflunomide are better avoided in pregnancy.

Although the available information is often controversial, the Consensus Conference Report published in 2005[144] did not view breast-feeding as absolutely contraindicated in immunosuppressed transplant recipients. Immunosuppressants are excreted in breast milk at drug concentrations similar to maternal blood concentrations, but the dose absorbed by the infant is very small,[79] and the additional exposure for a few weeks postpartum is unlikely to be harmful compared with the in utero exposure over the previous 9 months.

In the absence of complications, pregnancies after transplantation can be delivered at term, with cesarean delivery reserved for usual obstetric indications.[151] The renal allograft is placed extraperitoneally and is not expected to obstruct the birth canal during labor.[136] Cesarean delivery is eventually necessary in 50% of women with renal transplants because of the higher rate of obstetric complications.[137] At cesarean delivery, care should be taken to identify the graft; the ureter may be superior to the uterine artery and may enter the bladder over the lower uterine segment. Cesarean delivery is preferred in combined pancreas-kidney recipients, because the effect of vaginal delivery on a pancreas graft placed in the pelvis is still unknown.

SUMMARY OF MANAGEMENT OPTIONS
Renal Transplant (See also Chapter 53)

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Advise that pregnancy can be undertaken 1 yr post-transplantation if the woman had no rejections, the immunosuppressive medication dosing is stable, allograft function is adequate (serum creatinine < 1.5 mg/dL and urinary protein excretion < 500 mg/day), and there are no infections that could affect the fetus.	III/B	134,137
Pelvicaliceal distension detected preconceptionally contraindicates pregnancy.	—/GPP	—
SCr > 2.3 mg/dL contraindicates pregnancy because of universal progression of renal impairment and requirement for renal replacement therapy within 2 yr of delivery.	III/B	139

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Keep maintenance immunosuppression the same as before pregnancy, despite dilutional fall in cyclosporine level	III/B	141,142,148
The use of sirolimus, mycophenolate mofetil, OKT3, ATG, cyclophosphamide, methotrexate, chlorambucil, and leflunomide is better avoided in pregnancy.	III/B	149,150
Monitor BUN, SCr, electrolytes every other wk. Monitor allograft with monthly US and technetium renal scan each trimester.	—/GPP	—
Monthly urine cultures. Treat asymptomatic bacteriuria for 2 wk followed by suppressive therapy.	III/B	140
Screen for and differentiate preeclampsia, allograft dysfunction, or postrenal obstruction. Biopsy may be necessary to distinguish severe preeclampsia from acute rejection	III/B	135
Vigilance for preterm labor.	III/B	135
Fetal assessment		
• Detailed anomaly scan at ~20 wk.	III/B	149
• Serial monitoring of growth and umbilical artery Doppler.	III/B	135
Labor and Delivery		
Prophylactic antibiotics for any type of surgery and vaginal delivery.	—/GPP	—
In the absence of complications, deliver at term, with cesarean delivery reserved for usual obstetric indications.	III/B	151
Temporary stress dose corticosteroids to cover delivery.	—/GPP	—
Cesarean delivery is preferred in combined pancreas-kidney recipients.	—/GPP	—
Postnatal		
No good evidence that limited (≤4 wk) breast-feeding while taking immunosuppressants is harmful.	III/B	79,144

ATG, antithymocyte globulin; BUN, blood urea nitrogen; GPP, good practice point; SCr, serum creatinine; US, ultrasound.

Spine and Joint Disorders

DARREN TRAVIS HERZOG and RALPH B. BLASIER

INTRODUCTION

During pregnancy, maternal anatomic changes present mechanical challenges to the musculoskeletal system. Hormonal changes occur that modify the connective tissues and their response to mechanical stress. Complaints of musculoskeletal discomfort during pregnancy are common[1,2] and may be temporarily disabling.[3] These problems usually do resolve spontaneously with completion of pregnancy, but occasionally, they may remain as chronic disorders. Some musculoskeletal conditions that exist prior to pregnancy may affect the course of the pregnancy.

LOW BACK AND PELVIC PAIN

General Considerations

In 2003, Wu and coworkers[3] published a meta-analysis of English-language papers concerning "pregnancy-related pelvic girdle pain (PPP)" and "pregnancy-related low back pain (PLBP)," considered together to be "lumbopelvic pain." They found 761 papers, of which 106 contained sufficient material for analysis. They concluded that about 45% of women have lumbopelvic pain during pregnancy and 25% of women have lumbopelvic pain after pregnancy. They also concluded that about 25% of women have severe lumbopelvic pain during pregnancy, with severe disability in 8%.

The many terms used in the literature such as "sacroiliac joint dysfunction," "pelvic girdle relaxation," "pelvic insufficiency," and even "sacroiliac joint pain" allude to an unjustified knowledge of pain mechanisms and describe a mixed group of patients. Albert and colleagues[4] proposed a more clear delineation between the subtle differences in the types of pregnancy-related pelvic joint pain. In their prospective epidemiologic cohort study of 1460 women, they found a total incidence of 20.1%. This total was subdivided into four groups based on objective findings and symptoms: pelvic girdle syndrome 6%, symphysiolysis 2.3%, one-sided sacroiliac syndrome 5.5%, and double-sided sacroiliac syndrome 6.3%.

Hormonal Considerations

Relaxin is a polypeptide hormone. In the human female, production sites for relaxin are the corpus luteum, the deciduas, and the chorion. The known target organs for relaxin are the uterine cervix, the myometrium, the endometrium, and the decidua. Unproven probable target organs are the pubic symphysis and the sacroiliac joints.[5] It has been taught that relaxin relaxes connective tissue, and a side effect of this instability may be pelvic pain.[6] Mens and associates in a 2009 meta-analysis[7] concluded that in the last months of pregnancy and in the first month after delivery, motion in the pelvic joints (sacroiliac and symphseal areas) is larger in women with pelvic girdle pain and/or low back pain than pelvic joint motion in pain-free controls. Other studies have called into question whether circulating relaxin levels do actually correlate with onset or severity of PPP or PLBP.[5] Björklund and coworkers[8] evaluated symphyseal distention, circulating relaxin levels, and pelvic pain in 68 patients. The patients' pain ranged from little–to–no pain to severe pain. They concluded that severe pelvic pain during pregnancy was strongly associated with an increased symphyseal distention, but relaxin levels were not associated with the degree of symphyseal distention or pelvic pain. The best conclusion is that the relationship between hormone levels and joint pain in pregnancy is unclear.

Mechanical Explanations for Back and Pelvic Pain in Pregnancy

Load on the spine is increased by general weight gain and the weight of the uterus, fetus, and breasts. Theories of increasing lumbar lordosis occurring in response to the more anterior center of mass and increased shear stress across the motion segments of the lumbar spine have long been entertained. The contribution of abdominal musculature to support of the spine may be diminished, and postural adjustments in response to increased loads are required.

Radicular symptoms are commonly noted in pregnancy.[9] This may be caused by direct pressure of the uterus on nerve roots and lumbar and sacral plexi. Bushnell[10] is credited with describing the "parietal neuralgia of pregnancy" as mechanical pressure on nerve roots by ligamentous structures of an increasingly lordotic spine. With descent of the fetus into the pelvis in late pregnancy, radicular symptoms attributed to pressure on the lumbosacral plexus may be experienced.

Ostgaard and colleagues[11] provided a biomechanical analysis, which demonstrates that the flexion moment caused by

the more anterior center of increasing mass of the fetus and uterus can be accommodated by large increases in extensor muscle forces and consequential lumbar spine compression forces. Extension of the upper trunk, head, and neck can partially offset the increase in flexion moment by moving the new center of gravity closer to the spine. Ostgaard and colleagues[11] analyzed biomechanical factors and low back pain in 855 pregnant women and found that lumbar lordosis did not increase during gestation. However, a correlation has been identified between back pain and prepartum lumbar lordosis, suggesting that women with increased lumbar lordosis for any reason prior to pregnancy may be at higher risk for back pain while pregnant. However, in two separate prospective studies, no correlation was found between spinal configuration and complaints of back pain.[11,12]

If lordosis does not increase during pregnancy, then hip joint extension, rather than lumbar spine extension, may be a major mechanism used by pregnant women to cope with the increased flexion moment produced by pregnancy. If so, back pain in pregnancy ought to occur more often in women with intrinsic limitation of hip extension, and women with hip flexion contracture ought to have a greater tendency toward back pain with pregnancy. However, these hypotheses are unproved.

Peripheral joint laxity, followed throughout pregnancy in the prospective back pain study by Ostgaard and colleagues[11] of biomechanical factors, was measured by the presence of *striae distensae*, by serial measurement of ulnar deviation angle of the fourth finger to a defined force, and by the Bishop score (a 1–10 scale of cervix "ripeness"). Peripheral laxity was seen to significantly increase from weeks 12 through 20 in primiparous women. Laxity in multiparous women was the same at 12 weeks as that in primigravidas at 36 weeks and did not change during pregnancy. The correlation between increased peripheral laxity and increased abdominal sagittal diameter was strong. These data suggest that an increase in laxity after an initial pregnancy does not return to normal.[11] All persons lose stature (total height) with physical exertion. Control individuals and pregnant women without back pain regain stature after exertion faster than pregnant women with symptoms of back pain.[13]

A presumed common inheritable disorder called *benign joint hypermobility syndrome* has been recognized in the medical literature since 1967. At times linked to entities such as fibromyalgia, osteogenesis imperfecta, and Ehlers-Danlos and Marfan's syndromes, several investigations suggest that the underlying pathophysiology for this ill-defined condition may relate to altered collagen synthesis. Grahame and associates[14] have attempted to establish specific clinical diagnostic criteria for this constellation of joint-related symptoms. Their "revised Brighton criteria" for diagnosis include major and minor articular and extra-articular symptoms or physical examination findings. Relative to spine and joint symptoms in pregnancy, an underlying hypermobility syndrome may add risk to affected individuals.

Lumbar Disk Disease

The association of lumbar disk disease and pregnancy has been suggested by several authors. Relaxin may weaken the annulus of the intervertebral disks.[15] No prospective, controlled studies have related lumbar disk disease to

pregnancy, yet the prevalence of symptomatic lumbar disk herniation may be on the rise owing to the increasing age of patients who are becoming pregnant.[16] Thus, the potential for disk herniation and lumbar nerve root compression, with radicular pain and definite neurologic loss, should be considered in the evaluation of the pregnant patient with back pain. Magnetic resonance imaging (MRI), as well as electromyographic studies, may be helpful in diagnosis and management. Initial treatment of the pregnant patient with a documented herniated disk may involve conservative approaches such as bedrest, heat therapy, and lumbrosacral bracing. Progressive paralysis or loss of bowel and bladder control secures the diagnosis of cauda equina syndrome, and this requires urgent imaging studies, usually with MRI, and urgent surgical decompression. Unless decompression of the affected nerve roots is accomplished fairly quickly, the loss of bowel and bladder control becomes permanent. Pregnancy at any stage is not a contraindication to undergoing an MRI, regional or general anesthesia, and surgical diskectomy, if necessary.[17–20]

Vascular Congestion and Night Backache

Back pain in pregnancy is common in the evening. It has been proposed that this pain is due to increased venous flow through lumbar veins, the vertebral venous plexus, paraspinal veins, and azygous veins that occurs at night in response to redistribution of an already large extracellular and venous fluid volume. This may be worsened owinge to mechanical vena caval compression by the gravid uterus in a supine patient. Edema and increased pressure occur, which causes pain.

Sacroiliac Pain and Osteitis Condensans Illii

Inflammatory changes in the sacroiliac joints have been suggested as a cause for sacroiliac pain. "Osteitis condensans illii," as described by Wells,[21] is a "fairly uniform area of increased density in the lower iliac bone, adjacent to the sacroiliac joint, unilateral or bilateral." This finding is most common in women, particularly those who have been pregnant. Of the 67 patients reported by Wells, all were females, 80% had been pregnant, and 30 patients had had low back pain. Shipp and Haggart in 1950[22] suggested that the motion and/or strain associated with pregnancy on the sacroiliac ligaments may explain that osteitis condensans illii is found most often in postpartum women. However, Wells[21] concluded, probably incorrectly, that there is little relationship between back pain and oteitis condensans illii and that the association with pregnancy is due to some unknown mechanism.

Risk Factors

Borg-Stein and coworkers in a 2005 review article[23] summarized risk factors for PLBP. Risk factors for back pain during pregnancy include increasing parity, older maternal age (except one study that said younger maternal age), and back pain during a previous pregnancy.[23] Risk factors for postpartum low back pain include early onset of severe pain during the pregnancy and inability to reduce maternal body

weight to prepregnancy levels. Risk factors did not include maternal height, weight, weight gain, or weight of the baby.

Other investigators found that risk factors for pelvic girdle syndrome included history of previous low back pain, history of trauma to the back or pelvis, multiparity, higher maternal body weight, and self-reported on-the-job stress. Risk factors for symphysiolysis included multiparity, higher maternal body weight, and smoking. Risk factors for one-sided sacroiliac syndrome included maternal professional education or vocational training, self-reported stress, history of previous low back pain, history of trauma to the back or pelvis, and history of salpingitis. Risk factors for double-sided sacroiliac syndrome included history of previous low back pain, history of trauma to the back or pelvis, multiparity, poor relationship with the spouse, and low job satisfaction.[24]

General Low Back and Pelvic Pain—Management Options

Evaluation

History and physical examination can give some insight into pain mechanisms and direct the management of back and pelvic pain. Extraskeletal causes for backache must be considered. Obstetric complications and urologic disorders may present with symptoms ranging from vaginal discharge, flank pain, nausea, vomiting, and dysuria. Atypical presentations of refractory pain may indicate more significant and rare pathology such as disk herniation, infection, or tumor. Although complaints of back pain are common, vigilance must be maintained if serious diagnoses are not to be missed.

A history of pain at night, a radicular pain distribution, paresthesias, and bowel or bladder dysfunction may herald radiculopathy from nerve root irritation by lumbar disk disease. Differentiation from similar symptoms related to direct fetal pressure on nerve roots, such as paresthesias, in the distribution of the ilioinguinal and iliofemoral nerves and even of quadriceps weakness and giving-way episodes, is necessary.

A number of physical examination signs may help locate the anatomic site of the pain generator. Straight-leg raise testing (Lasègue's sign) is performed with the patient supine, noting the presence and distribution of pain and the angle of lower limb elevation at which pain occurs as the examiner raises the straight leg from the examining table by flexion at the hip only. In the normal patient, the angle between the leg and the examining table should reach 70 degrees or more without pain, and the maneuver should not cause any pain beyond hamstring discomfort with stretching. A positive test reproduces the patient's radicular pain and suggests nerve root compression.

Posterior superior iliac spine pressure in the standing patient may reproduce sacroiliac pain. Sacrospinous and sacrotuberous ligament tenderness by direct pressure during vaginal examination suggests a pelvic contribution to the patient's pain. Symphyseal pain is reproduced by direct pressure over the pubic symphysis.

The femoral compression test, or "posterior shea," or "thigh thrust" test, is performed with the patient supine and the hip in 90 degrees of flexion. Axial pressure is applied to the femur. The test is positive if pain is produced in the sacral area or ipsilateral buttock. If positive, the test suggests a sacroiliac source of pain on the positive side(s).

The iliac or ventral gapping test involves lateral opening pressure against the medial aspect of the anterosuperior iliac spine, that is, the pelvis of the supine patient is pressed apart. The iliac compression or dorsal gapping test involves compressive or closing pressure against the lateral iliac wings of the patient in a lateral decubitus or supine position. Pain provoked in either right or left sacral area and/or buttock area denotes a positive test. If positive, the test suggests a sacroiliac source of pain on the positive side(s).

The Patrick test is performed on the supine patient by flexing, abducting, externally rotating, then extending the hip, placing the ankle of the side being tested across the thigh of the opposite leg. This is also named the FABERE (flexion, abduction, external rotation, and extension) test. The examiner places one hand on the contralateral pelvis to stabilize it. The test is positive if pain is provoked in the sacroiliac area with the pelvis stabilized. If positive, the test suggests a sacroiliac source of pain on the ipsilateral side(s).

Pain provoked in the groin with rotation of the lower limb suggests the hip joint itself is a source of the pain, whereas posterior pelvic or symphyseal pain indicates sacral or symphyseal causes. Limitation of extension (flexion contracture) may be associated with increased lumbar lordosis, likely of long duration (before pregnancy), and predisposing to low back pain with pregnancy.

Radiographic evaluation, undesirable during pregnancy, may be warranted if pain cannot be explained by the common hormonal, mechanical, and vascular mechanisms, especially if neoplasm or infection is being considered. No harm to the fetus has been demonstrated with fetal exposure of less than 5 rads, a dose greater than that incurred in a routine spine radiography series. MRI may be helpful in diagnosis of tumor and infection or herniated vertebral disk.[20] It is generally agreed now that MRI does not have any deleterious effects on mother or fetus.[17] Mass lesions impinging on nerve roots, such as disk herniations, can be safely evaluated with electromyographic and nerve conduction studies, although these are not highly sensitive and depend strongly upon operator skill and technique.

Treatment

The majority of complaints regarding back and pelvic pain during pregnancy require only symptomatic care. Lumbar disk disease, urologic disorders, venous thrombosis, or other vascular or visceral causes for back pain must be considered in refractory or atypical cases.

The institution of either an individualized physiotherapy or a stretching and/or stabilizing exercise program may be a cost-effective and useful option to alleviate the intensity of pelvic pain in both the pre- and the postpartum periods.[24–26]

In a randomized, controlled trial of 81 postpartum women with pelvic girdle pain, Stuge and colleagues[24] sought to establish whether a program of specific stabilizing exercises would reduce pain, increase functional status, and improve quality of life. The women were assigned randomly to one of two groups for 20 weeks, one received physical therapy with the addition of specific stabilizing exercises and the other received a traditional physical therapy regimen. The study group received specific training, which included

stretching and strengthening of the abdominal musculature, the lumbar multifidus, gluteus maximus, latissimus dorsi, erector spinae, quadratus lumborum, hip adductors, and hip abductors. The participants were required to exercise for 30 to 60 minutes a day, three times a week for 18 to 20 weeks. At 1-year follow up, the study group had significant improvements in pain, functional status, and health-related quality of life in comparison with the control group. This study alludes to the probable importance of the musculature surrounding and stabilizing the pelvic girdle, specifically the abdominal musculature, which has been shown in previous studies to play a pivotal role in the stability of the sacroiliac joints.[27,28]

A subsequent study looking at the role of three different regimens of physical therapy instituted during gestation showed no significant difference regarding pain and activity between the groups during pregnancy or at postpartum follow-up.[25] However, in all groups, there was a reduction in pain and an increase in activity ability between gestational week 38 and at 12 months postpartum. The results of this study are obscured by the fact that the home exercise group was not required to record the exercise sessions, which were performed and merely relied on patient compliance. The authors concluded that most pelvic pain will improve with time and recommended patient education and a sacroiliac belt.

Exercise may also play a role in altering the relationship between flexibility of the spine and low back pain during pregnancy. The reason for this may be that as weight gain during pregnancy increases, some instability of the sacroiliac joint must result.[29]

Waller and associates in a 2009 meta-analysis[30] concluded that there is evidence that therapeutic aqua exercise is beneficial to patients with PLBP, but the clinical trials available for inclusion into the meta-analysis were not of good quality. The utility of "water gymnastics" for reduction in PLBP was confirmed in another meta-analysis.[2]

Stuber and Smith,[31] in a 2008 meta-analysis of papers evaluating chiropractic care for PLBP, found that every paper reported positive results. However, they also found that none of the included papers had randomization and a control group and all seemed subject to bias.

Intradermal injection of sterile water has been found to provide analgesia for low back pain in pregnancy.[32–34] However, the pain relief lasts only approximately 2 hours, so this modality is reserved for pain during labor. Acupuncture has been found to decrease pregnancy-related pelvic and low back pain.[2]

SUMMARY OF MANAGEMENT OPTIONS
Back and Pelvic Pain—General

Management Options	Evidence Quality and Recommendation	References
Evaluation		
Consider extraskeletal causes for backache (obstetric complications and urologic disorders).	Ib/A	3
Atypical presentation or pain refractory to the usual care may indicate more significant, rare pathology (disk herniation, infection, tumor).	Ib/A	3
Differentiation from similar symptoms from direct fetal pressure on nerve roots (paresthesias in the distribution of the ilioinguinal and iliofemoral nerves and even of quadriceps weakness) is necessary.	IV/C	9,10
Radiographic evaluation, although undesirable during pregnancy, may be warranted if insidious causes for pain are suspected.	III/B IV/C	17–20
MRI may be particularly helpful in the diagnosis of tumor, infection, or disk herniation.	III/B IV/C	17–20
Mass lesions compressing nerve roots, such as disk herniations, can be initially evaluated with electromyographic and nerve conduction studies without radiation.	GPP	
Treatment		
Physiotherapy for strengthening and/or stretching, aqua therapy, acupuncture, chiropractic manipulation, and subdermal injection of sterile water have all been found to be beneficial in the symptomatic treatment of back and pelvic pain.	Ia/A II/B III/B IV/C	2,24–26, 29–34
For mild to moderate pain, general comfort measures including rest, activity modification, and physical therapy, including massage and pelvic and low back exercises, as well as general back care are helpful.	II/B IV/C	24,26,29
For night pain, the use of a "maternity cushion" may give relief.	Ia/A	2

Management Options	Evidence Quality and Recommendation	References
Elastic compression stockings worn throughout the day may, by limiting lower extremity edema, diminish the fluid shifts and venous engorgement that occur at night.	GPP	
Analgesic options are limited, and NSAIDs should be avoided for potential adverse fetal effects.	GPP	
Persistent pain, including diskogenic pain, not responsive to rest may benefit from lumbar epidural steroids.	GPP	
TENS may be helpful.	GPP	
Acute loss of bowel and bladder function or acute paralysis indicates a need for decompressive surgery during pregnancy.	III/B, IV/C	17–20
Treatment with a trochanteric belt or girdle provides relief, particularly for women with posterior pelvic pain.	Ia/A	2
Sacroiliac injection with corticosteroids and local anesthetic may be indicated in severe cases.	GPP	

GPP, good practice point; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal anti-inflammatory drugs; TENS, transcutaneous electrical nerve stimulation.

SPONDYLOLYSIS AND SPONDYLOLISTHESIS

Spondylolysis is a bony insufficiency at the pars interarticularis of the spine. The condition can cause instability and pain. Spondylolisthesis is the slipping forward of one vertebra on another. This can result from a spondylolytic defect or from degenerative change in the facet joints.[15] Depending on the cause and the nature of the defect, the disorder is classified into five different types. Dysplastic and isthmic spondylolisthesis represent congenital and developmental disorders, which have a high familial incidence. These slips are more common in males than females (2:1), although females have a higher chance of progression. These slips most commonly occur at the L5–S1 level. The condition probably develops or presents in the first 2 decades of life, with the diagnosis most often being made in adolescence.

Risks

Degenerative spondylolisthesis usually occurs at the L4–5 level and presents later in life and more commonly in women than in men (4:1). Sanderson and Fraser[15] found, in a review of radiographs of 949 women, that those who had borne children had a significantly higher incidence of degenerative spondylolisthesis than those who had not. Proposed explanations for their findings include the generalized increase in laxity of pregnancy and residual relative joint relaxation and the effects of relaxin on the collagen of the facet joint capsules and of the annulus of the intervertebral disk. Women have generally greater joint laxity than men. Possibly, compromised abdominal musculature in parous women may allow perpetually increased sheer and rotatory stresses at the L4–5 joints.[15]

Management Options

The management of spondylolysis and spondylolisthesis during pregnancy differs little from that in the nonpregnant patient. Symptomatic relief can be obtained by rest and immobilization. The choice of analgesics is limited in pregnancy and should not include aspirin or nonsteroidal anti-inflammatory agents. In the event that significant neurologic impairment is detected, consultation should be obtained emergently.

SCOLIOSIS

Scoliosis is a three-dimensional deformity of the spine, most prominently manifested by curvature in the coronal plane. The disorder is usually idiopathic, commonly familial, and presents and progresses most dramatically during the adolescent growth spurt. Spinal curvature may also be due to congenital defects in the vertebral bodies, spinal cord disorders, intracranial pathology, or muscle spasm and back pain. Scoliosis is more common in females than in males.

Risks

The influence of pregnancy on preexisting scoliosis, particularly with regard to curve progression, has been controversial. An increase in curve progression during pregnancy has been demonstrated in scoliosis patients in small series. In particular, those treated with bracing who have multiple pregnancies before age 23, those with curves greater than 25 degrees, and patients who already had ongoing curve progression at the time of the pregnancy have been found to have increases in their curves during pregnancy.[35] Subsequent reviews have not found the same associations.[35,36]

Betz and coworkers[36] retrospectively reviewed 355 women with idiopathic scoliosis who had reached skeletal maturity. Two groups, 175 who had had at least one pregnancy and 180 who had never been pregnant, were compared. No effects on curve progression during pregnancy were demonstrated with regard to age of the patient at the time of pregnancy, ongoing progression of the curve at the time of pregnancy, or the number of pregnancies. Those having severe back pain during pregnancy (12%) may be slightly higher in unfused patients with scoliosis than in nonscoliotic

patients. In patients who had undergone posterior spinal fusion, no progression of the unfused portion of the curve was demonstrated. In these patients, no problems during the pregnancy were attributed to the scoliosis.

In 159 deliveries of women who had scoliosis without a spinal fusion, spinal anesthesia could not be administered in 2 patients because of the scoliosis and cesarean section was necessary in 12 (7.4%) for reasons unrelated to the scoliosis.[36] In patients who had undergone posterior fusion, 2 patients had minor problems during delivery related to the fusion. In 1, spinal anesthesia could not be administered, and in the other, proper positioning was difficult. The incidence of complications or deformity in the newborn was not increased.

Postpartum back pain in scoliotic women or women with scoliosis who had not been pregnant was no greater than in the general population. As in other series, potential for progression of curves greater than 30 degrees during adulthood at a general rate of 1 degree per year was seen. However, increased progression, especially of the 6 to 8 degrees per pregnancy previously reported, was not found. They recommend that for women of childbearing age with curves greater than 30 degrees, radiographs should be done soon after each delivery to minimize the potential for fetal exposure.[36]

A more recent, long-term, case-control study looked at various outcomes after treatment for adolescent idiopathic scoliosis.[37] In a period between 1968 and 1977, 136 women who were surgically treated with distraction and/or fusion using Harrington rods and 111 who were treated by bracing were followed for 22 years. These women were compared with age-matched controls and displayed no significant difference in regard to the number of children born, rates of low back pain, or necessity to undergo cesarean section during first pregnancy. There was no correlation between progression of spinal curvature and number of pregnancies or between this progression and age at first pregnancy. They did find that the rate of vacuum extractions was greater in the surgically treated group (16%) than in the control group (5%) and the brace-treated group (8%). In addition, there was a significant difference in sexual function between the surgically treated group and the control group, with the surgically treated group reporting more limitation of sexual function owing to back-related issues, 33% versus 15%, respectively. There was no significant difference in sexual function between the surgically treated group and the brace-treated group. The patients reported that pain was not a predominant factor in limiting their sexual activity but was more related to physical difficulty and self-consciousness about appearance.

Management Options

Prepregnancy and Prenatal

The affected patient should be counseled that no significant increase in the rate or incidence of curve progression during pregnancy has been demonstrated in large series of pregnant scoliosis patients compared with nonpregnant ones.[35,36] In patients who had undergone posterior spinal fusion, no progression of the unfused portion of the curve is seen in the majority.

Labor and Delivery

In patients who have undergone posterior fusion, 1.5% have minor problems during delivery related to the fusion.[36] In one report, spinal anesthesia could not be administered, and in another, proper positioning for delivery was difficult.[36] More recent reports have presented successful ultrasound-guided spinal anesthesia after spinal fusion.[38] Overall, fewer than 3% of deliveries in women who had undergone posterior spinal fusion for scoliosis had problems requiring cesarean section. The indications for operative delivery were unrelated to the fusion or the scoliosis. The incidence of complications or deformity in the newborn was not increased in patients who had undergone posterior fusion for scoliosis.

The risk of cardiorespiratory complications during pregnancy should be considered in patients with severe kyphoscoliotic deformity. Involvement of the respiratory team, with possible use of nasal intermittent positive-pressure ventilation, may be of benefit for a successful outcome for both mother and child.

Postpartum

Scoliotic women show no increase in postpartum back pain compared with women with scoliosis who had not been pregnant. Therefore, no specific postpartum recommendations are offered. In general, for women with curves greater than 30 degrees, radiographs should be done every 2 years up to age 25 and every 5 years thereafter. Appropriate radiographic and clinical evaluation by a surgeon who manages scoliosis should be considered in the months following delivery, taking the opportunity to have a radiograph when pregnancy is unlikely.

PELVIC ARTHROPATHY AND RUPTURE OF THE PUBIC SYMPHYSIS

Pelvic arthropathy usually occurs in two recognizable syndromes, though there may be overlap between them:

- Abnormal mobility of the pelvic joints may lead to pain and a waddling gait.
- After a difficult delivery, there may be a rupture of the symphysis.

Pelvic Arthropathy

The weight and position of the developing fetus increases the stress on the lumbosacral junction and the sacroiliac joints. In patients with a more sagittal than oblique orientation of these joints, there is less inherent stability and there may be a predisposition to pelvic laxity. The ligaments of the pubic symphysis and the sacroiliac joints relax during the first half of pregnancy. Excessive relaxation of the ligaments of the pelvis may cause symptoms at about the sixth or seventh month, consisting of pain with walking, turning in bed, or other exertion. There may be a unilateral limp or even a bilateral waddling gait. The pain may rarely be so severe that standing or walking is precluded. Asymmetrical sacroiliac laxity (right different from left) is much more strongly associated with pelvic pain than is the absolute amount of laxity.[28,39,40]

In some cases, symptoms appear only during labor, due to excessive loosening of the symphysis and sacroiliac joints.

Separation of the pubic symphysis during pregnancy is common, varying between 0 and 35 mm (average 7–8 mm). Separation over 8 to 9 mm is considered pathologic. Rupture of the ligaments of the pubic symphysis may occur spontaneously during labor or as a result of forceps delivery. Patients often complain of prelabor pain in the pubis and sacroiliac joints. During and after labor, the patient may complain of pain over the symphysis and sacroiliac joints, radiating down the thighs and often exacerbated by leg movement.

Commonly, there is tenderness over the greater trochanters, and severe pain can be elicited in the pubic symphysis when the greater trochanters are compressed toward the midline. The lower limbs may be externally rotated, and the patient may be unable to walk normally for weeks or months. The diagnosis is made with a history of pregnancy, pain at the pubic symphysis or the sacroiliac joints, tenderness at the pubic symphysis or the sacroiliac joints, and excessive laxity of the ligaments. A gap may be felt at the symphysis externally or by vaginal examination. Relaxation of the symphysis can be ascertained by placing the examiner's fingers on the superior edges of the pubic bones and noting vertical translation during walking. A prevaginal examination of the symphysis can be made while an assistant pulls down on one of the patient's ankles while pushing up on the other.

Ultrasonography has been used to confirm the diagnosis, with symptomatic patients having a symphyseal gap of 20 mm (range 10–35 mm) and asymptomatic controls 4.8 mm (range 4.3–5.1 mm).[41,42] MRI has been used to diagnose postpartum pubic and pelvic pain, but its clinical benefit has not been established.[43,44]

Management Options

Treatment is generally by rest, with or without a pelvic band or girdle. Some investigators report treatment with early injection of steroid or local anesthetic or use of oral anti-inflammatories.[39–41] A limited number of reports mention pelvic arthropathy with onset 1 to 2 days after delivery, characterized by pain and tenderness at the symphysis, but without swelling or bruising and without widening or abnormal mobility of the symphysis.[40] Symptoms abate within a week or 2 with rest and analgesics. It has been speculated that this is caused by swelling and pressure within the fibrous confines of a relatively normal pubic symphysis.

Rupture of the Pubic Symphysis

Separation of the pubic symphysis in association with labor and delivery is rare and is sometimes unrecognized when it does occur. Some widening of the pubic symphysis has been noted as being necessary for normal delivery and some widening normally does occur. Rarely, the separation is greater than 10 mm, and this is usually asymptomatic. The pubic symphysis consists of a thick fibrocartilagenous disk between two thin layers of hyaline cartilage covering the articular surfaces of the bone. It is held together by four ligaments: the anterior pubic (strong), the superior and inferior arcuate, and the posterior pubic (weak).

Occasionally, actual rupture of the pubic symphysis may occur. The onset of pain may be abrupt and may even be accompanied by an audible "crack."[45] Associated factors may include hard labor, precipitous labor, difficult forceps

delivery, cephalopelvic disproportion, abnormal presentation, multiparity, forceful abduction of the thighs, or previous pelvic trauma.[46–49] Estimates of incidence range between 1 in 500 and 1 in 30,000.[50,51] The incidence appears to be decreasing over time, because many difficult vaginal deliveries are being replaced by cesarean section.[50] Separations of as much as 120 mm have been reported, and the sacroiliac joints become affected with more than 40 mm of separation.[50]

Management Options

Treatment may begin with tight pelvic binding and/or rest in the lateral decubitus position. Symptoms may last as little as 2 days, typically 8 weeks, or up to 8 months.[50] For inadequate reduction, recurrent diastasis, or persistent symptoms, external skeletal fixation, and open reduction and internal fixation are the treatment options available to maintain stability while the ligaments heal.[45] Pin tract infections in association with external fixation pins are common and are usually readily manageable. Internal fixation by plate and screws or cerclage wire has been reported with good results.[45] In addition, concurrent open reduction and internal fixation at the time of cesarean delivery has been described.[52] Advantages of this option include a definitive treatment that would ensure stability, facilitating pain relief and earlier mobilization. This approach may help avoid rare but potential complications associated with conservative management. Using a pelvic binder or sling may require several weeks of bedrest, thus placing the patient at increased risk of decubitus ulcers, pulmonary and urogenital infections, venous thromboembolism, muscle atrophy, and joint stiffness. There is some concern that if the symphysis has been fixed by a plate and screws, the plate and screws should be removed before the next pregnancy. However, there is a report of two normal vaginal deliveries with symphyseal plate and screws remaining in situ.[53]

Complications of separation of the pubic symphysis include nonunion (failure to heal with reduction), pubic degenerative joint disease, osteitis pubis, and hemorrhage. The separation may occur in association with a connecting vaginal laceration, and there have been reports of these being complicated by suppurative arthritis, abscess of the vulva, and abscess of the space of Retzius.[50] Some investigators report irrigation and immediate closure of such a connecting vaginal laceration, under the belief that lack of a cortical fracture, unexposed bone ends, and coverage of the bone by articular cartilage may decrease the chance of a resulting wound infection.[54]

A previous symphyseal rupture has been found to increase the risk of a recurrence, especially with subsequent vaginal delivery.[49,55] Thus, it may be reasonable to offer cesarean delivery to patients who sustained a severe symphyseal disruption during a prior vaginal delivery.

POSTPARTUM OSTEITIS PUBIS

Osteitis pubis is a self-limited, apparently noninfective, osteonecrosis that begins at the pubic symphysis and extends into the pubic bones. It is rarely associated with pregnancy, either antepartum or postpartum. It is similar to pelvic arthropathy in its presentation, with accompanying pubic tenderness and pain that may prevent ambulation. It

is differentiated from pelvic arthropathy and symphyseal disruption by radiographic rarefaction of the pubic bones, without symphyseal widening. It is differentiated from septic symphysitis by its lack of fever, leukocytosis, and radiographic bony sequestrum. Steroids and nonsteroidal anti-inflammatories have been recommended for treatment.[56] Treatment of symptomatic osteitis pubis with intravenous pamidronate has been reported.[57]

SEPTIC PUBIC SYMPHYSITIS AND SACROILITIS

Osteomyelitis in or adjacent to the pubic symphysis has rarely been reported in association with pregnancy. Fever is not universal, though leukocyte count, erythrocyte sedimentation rate, and C-reactive protein levels are usually elevated. Surgical drainage and antibiotics should be curative.[58,59]

STRESS FRACTURES OF THE PUBIC BONE

Stress fracture of the body of the pubic bone has rarely been reported during pregnancy, unrelated to athletics or physical training. In the few cases reported, no underlying pathologic process has been found. The cause is thought to be due to ligament laxity, muscle imbalance, and increased load. Pain is usually insidious in onset. There is tenderness at the fracture. Radiography is diagnostic but not usually until some healing has occurred. MRI has been suggested to diagnose pelvic stress fractures immediately.[60,61] Management is usually directed toward symptomatic relief.

PELVIC TRAUMA AND PREGNANCY

In a study of 34 women who had had a displaced pelvic ring fracture, all of whom had at least one full-term pregnancy after healing, only 2 required elective cesarean section, and the need for the cesarean section was determined at the first presentation by pelvimetry.[62] Of these 34 women, 17 had healed with displacement of the fracture involving the birth canal. Of 8 who had had previous traumatic pubic symphyseal disruption, 2 had recurrence of pain during pregnancy. Recently, orthopedic surgical exposure and fixation techniques have improved to the point at which restoration of the preinjury pelvic size and shape is closely approached, but sometimes that goal is not met. In cases in which the pelvic inlet, the mid pelvis, and/or the outlet measurements are less than 9.5 cm, consideration should be given to cesarean delivery.

TRANSIENT OSTEOPOROSIS OF THE HIP

Transient osteoporosis of the hip is a rare condition. It has been defined by multiple case reports over the last half century.[63] It is characterized by a gradually developing pain in the hip with weight-bearing.[64] Symptoms begin in the third (or late second) trimester. The pain is predominantly in the anterior thigh and groin. The patient often presents with an antalgic gait and functional disability on the affected side. For unknown reasons, the left hip is affected more often than the right, though both may be affected.[63] The pain is relieved by rest. There is no associated history of trauma or illness. Musculoskeletal examination is normal, except for discomfort at the extremes of hip motion and a slight decrease in total range of hip motion.[64] Joints other than the hip may become involved, and the process may regress at one joint and progress at another. Other areas affected may include knee, ankle, foot, ribs, shoulders, and spine.

Radiographic osteopenia can occur, beginning 2 to 4 weeks after onset of symptoms. Radiographically, the joint space is preserved.[63,64] The indistinctness of the subchondral cortical bone on radiographs may be striking. MRI of the involved joint reveals a joint effusion and diffuse signal abnormalities in the marrow, suggestive of marrow edema (decreased signal on T1-weighted images and increased signal on T2-weighted images). This is in contrast to the findings of avascular necrosis, which on MRI, may typically show a focal lesion often in the anterosuperior region of the femoral head and decreased signal intensity on both T1- and T2-weighted images. The differential diagnosis includes joint infection, rheumatoid arthritis, pigmented villinodular synovitis, and osteonecrosis. Radionucleide bone scanning shows an increased uptake in the affected femoral head and often the acetabulum. One report of a case followed by serial dual-energy x-ray absorptiometry (DEXA) over a period of 4 years showed a loss of 20% of bone mineral density (compared with age-matched controls) that resolved rapidly in the first year and returned to the normal range after cessation of lactation.[63]

The cause of transient osteoporosis of the hip is unknown. Some hypothesize that the cause may be neurovascular and perhaps related to reflex sympathetic dystrophy.[64] However, lack of trauma; lack of the characteristic burning, pulsing pain; lack of changes in skin color, temperature, and moisture; and failure to respond to sympathetic blockade all militate against this explanation.[65,66] Some authors have speculated about other causes, including abnormalities in local blood flow, viral infection, rheumatic and other inflammatory conditions, and metabolic abnormalities, but none of these explanations has been convincingly upheld.[67] Other investigators have speculated that mechanical compression of the obturator nerve in pregnancy may be a causative factor, but animal experimentation has failed to produce hip osteoporosis by this mechanism.[68] It appears that by an unknown stimulus, intense bone resorption is initiated in the femoral head.[63,69] Later, during resolution, osteoid is laid down and mineralized. Between resorption and remineralization, the bone is weak and susceptible to microtrauma, thus explaining the pain with weight-bearing. If the microtrauma accumulates faster than it can be repaired, a pathologic fracture may ensue. For this reason, weight-bearing should be limited until resolution of osteopenia.

Management Options

The condition is self-limiting, usually resolving spontaneously in 6 to 8 months. Treatment is conservative, including protection from weight-bearing, maintenance of joint motion, and analgesic medications.[65] Bone and synovial biopsies are not necessary. In cases in which joint aspiration has been performed, the effusion is sterile and the joint fluid is normal. Some cases report associated pathologic fracture of the pubic rami or the femoral neck. In a series by Guerra and Steinberg,[66] the authors report two patients with transient osteoporosis in their third trimester of pregnancy.

They both sustained a subcapital femoral neck fracture after a fall, which was treated with simultaneous pinning and birth by cesarean section. One of these patients went on to have two successful pregnancies with no recurrence of the transient osteoporosis. The authors advised restricted weight-bearing until confirmatory radiographs show the reestablishment of bone mass.

Various treatments have been used, including limitation of weight-bearing by wheelchairs, crutches, or canes. Corticosteroids, phenylbutazone, and calcitonin have been tried without beneficial effect.[65] After delivery, symptoms completely resolve over 3 to 9 months.

AVASCULAR NECROSIS OF THE HIP

Avascular necrosis is not an uncommon disorder. Incidence in the United States has been estimated to be approximately 15,000 new cases annually. However, avascular necrosis during pregnancy has only rarely been reported, and thus, it is difficult to demonstrate a causal relationship between the two.[66,69] Traditionally, the risk factors most commonly associated with nontraumatic avascular necrosis of the hip have included systemic administration of steroids, excessive alcohol consumption, collagen vascular diseases, renal transplantation, and pregnancy, among others. Despite this diverse spectrum of conditions, the most widely accepted precipitating event is a mechanical interruption of the circulation to the femoral head.

It is not entirely clear that there is any difference between pregnancy-related transient osteoporosis of the hip and pregnancy-related avascular necrosis of the hip. Some authors have defined aseptic necrosis of the femoral head during pregnancy as an entity separate from transient osteoporosis of the hip in pregnancy,[66] but the clinical presentation is very similar to transient osteoporosis. Symptoms begin in the third trimester; the hip is painful with weight-bearing; the pain is relieved by rest; there is no associated history of trauma or illness; and the musculoskeletal examination is normal, except for discomfort at the extremes of hip motion and a slight decrease in total range of hip motion. Radiographs show osteoporotic changes, and radionucleide bone scanning shows an increased uptake in the affected femoral head.[66] Unlike nonpregnancy-related aseptic necrosis of the hip, which often mandates operative treatment and often leads to predictable degenerative joint disease, it has been observed that aseptic necrosis of the hip in pregnancy gives good results with conservative treatment, consisting of reduction in weight-bearing. However, the optimum treatment of avascular necrosis in the pregnant patient remains controversial. Accepted surgical treatment options include osteotomy, use of a nonvascularized structural graft, electrical stimulation, core decompression, and use of a vascularized structural graft.[69]

One radiographic finding that may differentiate aseptic necrosis of the femoral head during pregnancy from transient osteoporosis of the hip has been a "crescent sign," with subchondral lucency or subchondral collapse of the weight-bearing dome of the femoral head. Actual bone necrosis, dead osteocytes, or empty osteocyte lacunae have not been well documented. The crescent sign of the femoral head radiographically resembles other proven cases of aseptic necrosis that occur without pregnancy, and this has been the basis for calling the osteoporotic hip with a crescent sign in pregnancy, "aseptic necrosis during pregnancy." However, the crescent sign might as well be a pathologic fracture in osteoporotic bone, making the distinction between these two entities questionable.

With MRI, avascular necrosis typically shows focal lesions in the anterolateral femoral head with decreased signal intensity on both T1- and T2-weighted images. There may frequently be a double-density signal surrounding the lesion. In a series by Montella and colleagues,[69] the authors followed 13 women who developed hip pain during pregnancy and were later diagnosed with avascular necrosis. Eleven of these women were treated with a free vascularized fibular graft. They differentiated necrosis from transient osteoporosis based on the presentation, radiographic characteristics, and natural history. Specifically, the diagnosis was made based on MRI findings of the double-density signal as well as radiographic features, including the crescent sign, progression, and collapse of the femoral head. All 13 of their patients had severe, debilitating symptoms that worsened over 12 months. They also found that there were significant demographic differences in women who have osteonecrosis associated with pregnancy compared with nonpregnant women of childbearing age who have an idiopathic avascular necrosis. The pregnancy-associated form was more likely to be found in older primigravid women with a smaller body frame who gain a relatively larger amount of weight during their pregnancy.

The diagnosis of avascular necrosis is frequently delayed, and thus, the practitioner should have a high clinical suspicion. The use of MRI may be efficacious in earlier diagnosis and a better prognosis. The incidence of this disease in pregnancy may be increasing as more women delay childbearing.

HIP ARTHROPLASTY

Historically, hip joint replacement has not been an option in women of childbearing age, because this operation was typically reserved for patients with limited physical activities and a relatively short expected life span. However, there are a few rare indications for hip joint replacement in the young, such as avascular necrosis of the hip, severe rheumatoid disease, post-traumatic arthritis, or certain aggressive tumorous conditions. With the advent of more durable bearing materials with superior wear characteristics, as well as hip resurfacing designs, younger patients are being more readily considered for hip joint replacement. There have been reports of completely normal impregnation, labor, and delivery in girls who had had a prior total hip replacement.[70] Sierra and associates conducted a survey of 343 women, all of child bearing age with a total of 420 total hip arthroplasties.[70] Of these women, 13.7% had a successful pregnancy after their procedure. The authors concluded that childbirth is not affected by the presence of hip arthroplasty implants, nor is a pregnancy after hip arthroplasty associated with decreased survival of the prosthesis. Previous smaller studies corroborate these findings in the use of both total hip prostheses and bipolar designs.[71,72]

Women who have had a previous total hip replacement may have increased pain during their pregnancy in the respective hip with an increased risk of continued pain

postpartum. Persistence of pain in the groin and joint should be investigated to determine whether it is related to implant loosening, wear, or osteolysis, which may necessitate revision. Although the need for revision may increase in these situations, it is not likely attributed to the evolution and completion of pregnancy, but more likely directly related to the age at which the primary arthroplasty was done.

A prosthetic hip does not have as much inherent joint stability as a biologic hip. Dislocation during positioning is a theoretical concern. However, hip flexion as long as it is accompanied by abduction ought to be relatively safe. The dangerous positions are hip flexion with internal rotation and/or adduction and, to a lesser extent, hip extension with external rotation and/or adduction. Neither of these positions would be likely to occur during delivery, with or without stirrups, or squatting with a birthing chair.

Other preexisting hip conditions, such as severe slipped capital femoral epiphysis, especially bilateral or hip fusion, may make positioning for delivery challenging. They do not otherwise preclude vaginal delivery.

SUMMARY OF MANAGEMENT OPTIONS
Back and Pelvic Pain—Specific Conditions

Management Options	Evidence Quality and Recommendation	References
Scoliosis		
Prepregnancy and Prenatal		
Curvature does not usually worsen.	III/B	35,36
Compromise of respiratory function may occur in some (see Chapter 37).		
Labor and Delivery		
Regional analgesia may not be possible.	IV/C	36
Positioning for delivery may have to be individualized.	IV/C	36
For respiratory compromise, see Chapter 37.		
Pelvic Arthropathy		
Rest, with or without a pelvic band or girdle.	GPP	
Analgesia and anti-inflammatory drugs.	III/B	48
If this fails, consider injection of steroids and local anesthetic.	III/B	48
Rupture of the Pubic Symphysis		
Treatment is generally nonsurgical, and complete recovery is to be expected.	GPP	
Steroids and anti-inflammatory drugs.	IV/C	56
Treatment may begin with tight pelvic binding and rest in the lateral decubitus position.	IV/C	50
Symptoms may last as little as 2 days, typically 8 wk, or reportedly up to 8 mo.	IV/C	50
For inadequate reduction, recurrent diastasis, or persistent symptoms, external skeletal fixation is the treatment of choice to maintain stability while the ligaments heal.	IV/C	45,52
Internal fixation by plate and screws or metallic cerclage wire is considered in extreme cases.	IV/C	52,53
Pelvic Problems		
Postpartum Osteitis Pubis		
Needs to be differentiated	GPP	
• From pelvic arthropathy and symphyseal disruption by w-ray.		
• From septic symphysitis by lack of fever, leukocytosis, and radiographic bony sequestrum.		

Management Options	Evidence Quality and Recommendation	References
Steroids and NSAIDs recommended for treatment.	IV/C	56
Treatment with intravenous pamidronate has been reported.	III/B	57
Septic Pubic Symphysitis and Sacroilitis		
A rare condition in pregnancy; surgical drainage and antibiotics should be curative.	III/B	58,59
Stress Fractures of the Pubic Bone		
Radiography is diagnostic, but often after some healing; MRI may give earlier diagnosis. Management is symptomatic relief.	III/B	60,61
Pelvic Trauma and Pregnancy		
Manage as for nonpregnancy. Critical issue is the degree to which pelvic anatomy is distorted and cesarean delivery indicated.	III/B	62
Maternal Pelvic Osteotomy		
If this has been performed before skeletal maturity, there is greater risk of smaller pelvis and greater need for cesarean delivery.	III/B	73
Acetabular rotational osteotomy after skeletal maturation appears to have no effect on pelvic dimensions and need for cesarean delivery.	III/B	74
Hip Problems		
Transient Osteoporosis—Conservative Approach		
Limit weight-bearing.	IV/C	65,66
Encourage movement.	IV/C	65
Analgesia.	IV/C	65
Avascular Necrosis		
Manage as for transient osteoporosis.	GPP	
Hip Arthroplasty		
Usually no significant problem encountered nor special management required.	IV/C	70
Normal birthing position can be used.	GPP	
Avoid flexion to more than 90 degrees and internal rotation or adduction of the hips, which can provoke dislocation.	GPP	

GPP, good practice point; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal anti-inflammatory drugs.

MATERNAL PELVIC OSTEOTOMY

Historically, pelvic osteotomy was reserved for young patients, predominantly female, for the treatment of developmental dysplasia of the hip. When the osteotomies were done at a young age, the pelvis would remodel during growth to a normal size and shape. When the osteotomies were done at an older age, the pelvis might not remodel to a normal size and shape. Loder[73] compiled a series of 40 pelvic osteotomies in 37 patients done for developmental dysplasia of the hips. He was able to follow 30 patients to skeletal maturity. At skeletal maturity, the mid-pelvis and/or outlet measurements were less than 9.5 cm in 6 of the 30 cases, and these tended to be those in whom the osteotomy had been done at an older age.

Recently, the use of pelvic osteotomies has been expanded to patients after skeletal maturity, typically in the childbearing years. Such osteotomies are for the purpose of delaying or avoiding the need for a hip replacement later in life. These osteotomies are typically rotational osteotomies at the acetabulum for the purpose of correcting slight residual hip dysplasia or redirecting a slightly arthritic joint. Masui and colleagues[74] studied 21 patients who had had successful pregnancy and childbirth after rotational acetabular osteotomy. They conceded that rotational acetabular osteotomy caused no substantial difference in the bony birth canal before or after surgery. Fortunately, in case of osteotomy, the treating orthopedic surgeon would most likely have large numbers of the patient's radiographs, so new radiation exposure for pelvimetry might not be needed.

Skin Disease

GEORGE KROUMPOUZOS

INTRODUCTION

Skin problems in pregnancy can be categorized as follows[1]:
- Physiologic skin changes of pregnancy.
- Preexisting skin diseases and tumors affected by pregnancy.
- Pruritus in pregnancy.
- Specific dermatoses of pregnancy.

Prompt recognition and correct classification of the skin problem are essential for treatment, when necessary. The pregnant woman should be counseled about the nature of her skin condition, possible maternal or fetal risks associated with it, and management options.

PHYSIOLOGIC SKIN CHANGES OF PREGNANCY

The skin undergoes changes during pregnancy that are caused by the profound endocrine and metabolic alterations during the gestational period. The physiologic skin changes of pregnancy include pigmentary changes such as hyperpigmentation and melasma, vascular changes such as spider angiomas (Fig. 51–1), palmar erythema, nonpitting edema, and varicosities, stretch marks (*striae gravidarum*) (Fig. 51–2), as well as mucosal, hair (Fig. 51–3), nail, and glandular changes.[1–3] These changes are not associated with any risks for the mother or fetus and are expected to resolve postpartum.

The types of pigmentation seen in pregnancy are summarized in Table 51–1. The most common pigmentary changes of pregnancy are hyperpigmentation and melasma (Fig. 51–4). Uncommon pigmentary patterns, such as pseudoacanthosis nigricans (Fig. 51–5) and dermal melanocytosis (Fig. 51–6), can also be seen.[4–8] Furthermore, postinflammatory hyperpigmentation secondary to specific dermatoses of pregnancy (Fig. 51–7) is particularly common

in skin of color. A mild form of localized or generalized hyperpigmentation occurs to some extent in up to 90% of pregnant women[1,3] and shows accentuation of the areolae, nipples, genital skin, axillae, and inner thighs. The most familiar examples are darkening of the *linea alba* (*linea nigra*) (see Fig. 51–2) and periareolar skin (*secondary areolae*).

Melasma (*chloasma* or *mask of pregnancy*) is a type of facial melanosis reported in up to 70% of pregnant women[2] and one third of nonpregnant women taking an oral contraceptive.[9] Although the malar pattern is common, the entire central face is affected in most patients (*centrofacial pattern*) (see Fig. 51–4) and, less often, the ramus of the mandible (*mandibular pattern*).[10] Melasma results from melanin deposition in the epidermis (70%, accentuated by Wood's lamp examination), dermal macrophages (10%–15%), or both (20%). This type of melanosis is thought to be associated with the hormonal changes of gestation and worsens with exposure to ultraviolet and visible light.[10,11] Melasma usually resolves postpartum but may recur in subsequent pregnancies or with the use of oral contraceptives. The dermal type of melasma is less responsive to treatment than the epidermal. Mild gestational melasma can be treated with azelaic acid, which is safe during pregnancy. Persistent melasma can be treated postpartum with topical hydroquinone 2% to 4% and a broad-spectrum sunscreen, with[12] or without a topical retinoid and mild topical steroid. Melasma, whether caused by pregnancy or oral contraceptives,[3] is resistant to treatment in 30% of patients. Combination therapies, including laser treatment[13,14] and chemical peels,[15] may be effective to some extent in resistant cases.

The physiologic vascular, connective tissue, mucosal, glandular, hair, and nail changes of pregnancy are summarized in the Summary of Management Options box. The oral pyogenic granuloma of pregnancy (*granuloma gravidarum* or *pregnancy epulis*) is discussed under "Skin Tumors."

FIGURE 51–1
Spider angioma (telangiectasia) on the arm.

FIGURE 51–2
Stretchmarks (striae gravidarum) on the lateral aspects of the abdomen and hyperpigmentation of the linea alba, causing development of the linea nigra.

FIGURE 51–3
Telogen effluvium, which developed in the immediate postpartum period, with typical temporal recession and thinning.

FIGURE 51–4
Melasma of the entire central face.
FIGURE 51–5
Pseudoacanthosis nigricans may develop in skin of color during pregnancy and manifests itself as hyperpigmented velvety plaques on the axillae (as shown) and neck.

TABLE 51–1

Patterns of Pigmentation in Pregnancy

Common Hypermelanoses
Hyperpigmentation
Melasma

Uncommon Hypermelanoses
Pseudoacanthosis nigricans
Dermal melanocytosis
Vulvar melanosis
Verrucous areolar pigmentation
Localized reticulate pigmentation

Darkening of Preexisting Pigmentation
Acanthosis nigricans
Pigmentary demarcation lines

Darkening of Benign Skin Lesions
Scars
Melanocytic nevi
Skin tags, seborrheic keratoses

Postinflammatory Hyperpigmentation
Secondary to specific dermatoses of pregnancy (see specific section in text)

Jaundice (see specific section in text)

FIGURE 51–6
Grayish-brown ill-defined patches of dermal melanocytosis may develop in pregnancy and persist in the postpartum period.

FIGURE 51–7
Extensive postinflammatory hyperpigmentation secondary to pruritic urticarial papules and plaques of pregnancy in an Asian female.

SUMMARY OF MANAGEMENT OPTIONS
Physiologic Skin Changes of Pregnancy

Management Options	Evidence Quality and Recommendation	References
Pigmentation		
Follow-up for spontaneous resolution in postpartum period.	—/GPP	—
Sun protection is mandatory in all cases.	—/GPP	—
For persistent cases postpartum, consider:		
• Hydroquinone 2%–4% cream with or without tretinoin and mild topical steroids.	IV/C	12
• Combination therapies including laser treatment (Er:YAG, Q-switched ruby, or Q-switched Nd:YAG).	IIa/B	13,14
• Combination therapies, including chemical peels (glycolic acid and Jessner's solution).	IIb/B	15
Spider Nervus (see Fig. 51–1)		
Reassure (occurs in 67% of white women, in the second to fifth mo; resolves within 3 mo postpartum); persistent lesions can be treated with fine-needle electrocautery, cryotherapy, or laser.	—/GPP	—
Palmar Erythema		
Reassure (occurs in 70% of white and 30% of African American women).	—/GPP	—
Varicosities		
Explain (occurs in 40% of women; thrombosis in < 10%); recommend leg elevation, compression stockings.	—/GPP	—
To treat symptomatic hemorrhoids, recommend stool softeners, hot sitz baths, topical anesthetics, suppositories, laxatives.		
Nonpitting Edema		
Reassure; exclude preeclampsia. Recommend leg elevation; compression stockings, diuretics if severe.	—/GPP	—

SUMMARY OF MANAGEMENT OPTIONS
Physiologic Skin Changes of Pregnancy—cont'd

Management Options	Evidence Quality and Recommendation	References
Striae Gravidarum (see Fig. 51–2)		
Reassure (occurs in 90% of white women; less common in other groups; less apparent postpartum but may never disappear); prescribe antipruritics, topical steroids if itchy; laser can improve the color changes.	—/GPP	—
Pyogenic Granuloma (*Granuloma Gravidarum*)		
Reassure (occurs in 2% of pregnant women at second to fifth mo; typically on the gingivae; postpartum shrinkage).	—/GPP	—
Recommend good dental hygiene; excision if excessive discomfort or bleeding		
Gum Hyperemia/Gingivitis		
Seen in most pregnant women in the third trimester; resolves postpartum.	—/GPP	—
Reassure; recommend good dental hygiene.		
Hair Changes (see Fig. 51–3)		
Mild hursutism regresses within 6 mo postpartum.	—/GPP	—
Postpartum hair shedding (telogen effluvium) lasts 1–5 mo.		
Frontoparietal hair recession and diffuse thinning also reported.		
Exclude pathologic androgen production if hirsutism.		
Follow-up postpartum hair changes.		
Glandular Changes		
Reassure (enlargement of sebaceous glands of the areolae); axillary sweating can be controlled with aluminum chloride solution (20%).	—/GPP	—
Nail Changes		
Reassure (start in the first trimester; onycholysis, subungual hyperkeratosis, transverse grooving, brittleness).	—/GPP	—

PREEXISTING SKIN DISEASES AND TUMORS AFFECTED BY PREGNANCY

The pregnant woman is susceptible to aggravation or, less often, to improvement of skin diseases and tumors.[16] The conditions that may improve during pregnancy are listed in Table 51–2.

Inflammatory Skin Diseases
ATOPIC DERMATITIS (ECZEMA)

Eczema is the most common pregnancy dermatosis, accounting for 36% of total cases.[17] Atopic dermatitis is more likely to worsen than remit in pregnancy, although remission has

been reported in up to 24% of cases.[17] There is a personal history of atopy in 27% of pregnant females with atopic dermatitis, a family history of atopy in 50% of cases, and infantile eczema in 19% of the offspring.[17] Some studies indicate that atopic dermatitis may start before the third trimester in up to 75% cases.[17] There have been no adverse effects on the fetal outcome. Maternal smoking may be implicated in the development of atopic eczema during pregnancy and lactation.[18] The effect of breast-feeding on atopic eczema has been debated. Gestational atopic eczema is treated with moisturizers and low- to mid-potency topical steroids. A short course of oral steroid may be required for severe eczema. Systemic antibiotics, such as erythromycin base or penicillin, are necessary in superinfected eczema. Systemic antihistamines, such as diphenhydramine, are often required for severe pruritus. Ultraviolet B (UVB) light is a safe adjunct in treating chronic eczema. Irritant hand dermatitis and nipple eczema are often seen postpartum.[1] Nipple eczema can show painful fissures and be complicated with bacterial infection, most commonly from *Staphylococcus aureus*.

ACNE VULGARIS

The effect of pregnancy on acne vulgaris is unpredictable. Some patients may develop acne for the first time during pregnancy, and acne conglobata may worsen during pregnancy. In one study, pregnancy affected acne in approximately 70% of women, with 41% reporting improvement and 29% worsening in pregnancy.[19] Comedonal acne can be treated with topical keratolytic agents, such as benzoyl peroxide, whereas inflammatory acne can be treated with azelaic acid, topical erythromycin, topical clindamycin phosphate, or oral erythromycin base. All these medications are safe to use during gestation.[19]

Urticaria may worsen in pregnancy, whereas **hidradenitis suppurativa** and **Fox-Fordyce disease** may remit during gestation as a result of reduced apocrine gland activity (see Table 51–2).[1]

CHRONIC PLAQUE PSORIASIS

Chronic plaque psoriasis is the most common type of psoriasis to develop or exacerbate during pregnancy.[20] It is more likely to improve (40%–63%) than worsen (14%) during gestation; it commonly flares, however, within 4 months of delivery. Psoriatic arthritis may develop or worsen during pregnancy and often starts postpartum or perimenopausally (30%–45%).[21] Topical steroids and topical calcipotriene as well as topical anthralin and topical tacrolimus appear to be safe treatment options for localized psoriasis in pregnancy.[22] UVB is the safest treatment for severe psoriasis that has not responded to topical medications. A short course of cyclosporine can be administered for psoriasis that has not responded to UVB.

GENERALIZED PUSTULAR PSORIASIS/ IMPETIGO HERPETIFORMIS

A very rare variant of generalized pustular psoriasis develops in pregnancy, often associated with hypocalcemia[23] or low serum levels of vitamin D.[24] When compared with nonpregnant women with various forms of psoriasis, pregnant women with impetigo herpetiformis rarely have a personal or family history of psoriasis, develop the eruption strictly during pregnancy, and improve postpartum. The eruption usually starts in the third trimester. It often persists until delivery and occasionally runs a protracted course postpartum. It can exacerbate with the use of oral contraceptives.[25] Impetigo herpetiformis is manifested as grouped discrete sterile pustules at the periphery of erythematous patches (Fig. 51–8A). The lesions start in the major flexures and extend centrifugally onto the trunk and around the umbilicus, usually sparing the face, hands, and feet. The lesions may become crusted (see Fig. 51–8B) or vegetative, and the mucous membranes may show erosive or circinate lesions. Postinflammatory hyperpigmentation commonly develops; nail changes secondary to subungual pustules are exceptionally seen.

Skin histopathology shows features of pustular psoriasis, and direct immunofluorescence is negative. The laboratory workup reveals leukocytosis, elevated erythrocyte sedimentation rate, and occasionally, hypocalcemia or decreased serum vitamin D levels. Impetigo herpetiformis is thought to be an outbreak of psoriasis probably triggered by a metabolic milieu, such as pregnancy or hypocalcemia.[1] The latter is known to exacerbate generalized pustular psoriasis and can develop secondary to hypoalbuminemia in pregnancy. A report that showed reduced levels of an inhibitor of skin elastase in a patient with impetigo herpetiformis warrants further investigation.[26] Furthermore, one report raised speculation that infections during pregnancy may trigger a flare
FIGURE 51–8
A, Early impetigo herpetiformis: discrete group sterile papules at the periphery of erythematous patch. *B,* Generalized advanced lesions of impetigo herpetiformis show crusting or vegetations. (*A* and *B,* Photographs courtesy of Aleksandr Itkin, MD.)

of pustular psoriasis in an individual with psoriatic tendency.[27]

Impetigo herpetiformis can be treated with systemic steroids at daily doses up to 60 mg/day of prednisone. Calcium and vitamin D replacement therapy should be undertaken if necessary and can lead to remission of the eruption.[23] A severe case was treated with cyclosporine.[28] Impetigo herpetiformis has been treated postpartum with oral retinoids[29] or PUVA[30] (psoralens with ultraviolet A light). Systemic antibiotics should be administered in superinfected cases. The eruption commonly resolves postpartum but recurs in each successive pregnancy with earlier onset and increased morbidity.[25,31] There are serious risks for the mother and fetus. Maternal risks include tetany, seizures, delirium, and exceptionally, death from cardiac or renal failure. Fetal risks[25] such as stillbirth, neonatal birth, and fetal abnormalities may result from placental insufficiency, which often complicates impetigo herpetiformis, and have been reported even when the skin disease was well controlled.[31] Maternal and fetal monitoring is of utmost importance. In severe cases, termination of pregnancy is warranted, the timing of which depends on the maternal and fetal status. The eruption resolves promptly afterward.

Infections

Pregnancy can affect the vast majority of common infections, causing an increase in the prevalence or exacerbation of candida vaginitis, *Trichomonas*, *Pityrosporum* folliculitis, and papillomavirus infections.[1,16] Other infections, such as recurrent genital herpes simplex virus infection, are not exacerbated in pregnancy but are of critical interest because they significantly increase fetal morbidity and mortality[32] (see Chapter 30). Disseminated infections are more likely to occur during gestation and may have devastating effects for the fetus. Viral exanthems can have significant maternal and/or fetal risks for complications; their management options are summarized in Chapters 29 and 32.

The prevalence of candida vaginitis increases during pregnancy. The infection has been reported in 17% to 50% of pregnant women[33]; of those, 10% to 40% are asymptomatic.[34] *Candida albicans* has been associated with intraamniotic infection.[35] The organism can be cultured from up to 50% of neonates born to infected mothers.[16] Neonatal candidiasis can result from passage of the infant through an infected birth canal and congenital candidiasis from an ascending infection in utero. The latter is characterized by generalized skin lesions that appear within 12 hours of delivery.[16] *Trichomonas* infection is seen in 12% to 27% of pregnant women.[36] An association with preterm delivery and low birth weight[37] has been debated.[38] *Pityrosporum* folliculitis and tinea versicolor (Fig. 51–9), both caused by yeasts of the *Malassezia* species, occur with greater frequency in pregnant women.[39] Papillomavirus infections may worsen during gestation, and condylomata acuminata can show accelerated growth, blocking the birth canal.[16]

Early studies showed exacerbation of leprosy during pregnancy or within the first 6 months of lactation,[40] a finding that was debated by one study.[41] Leprosy reactions are triggered by pregnancy: type 1 (reversal) reaction occurs maximally postpartum,[42] when the cell-mediated immunity

FIGURE 51–9
Hyperpigmented minimally scaly patches on the chest in a pregnant female with tinea versicolor.

returns to prepregnancy levels, and type 2 reaction (*erythema nodosum leprosum*) throughout pregnancy and lactation.[43] The increased incidence of erythema nodosum leprosum in pregnant women has been associated with early loss of nerve function secondary to "silent neuritis."[44] Multidrug therapy of rifampin, dapsone, and clofazimine is the treatment of choice during pregnancy. Leprosy reactions should be treated with oral steroids and not thalidomide, which is contraindicated in pregnancy. Patients with leprosy should be counseled about the effects of pregnancy on the disease before they become pregnant, and pregnancies should be planned when the disease is well controlled. Leprosy has been associated with increased fetal mortality and low birth weight.[40] Approximately 20% of children born to mothers with leprosy will develop the disease by puberty.

Autoimmune Disorders

SYSTEMIC LUPUS ERYTHEMATOSUS (See also Chapter 43)

Chronic discoid lupus is not affected by pregnancy. The data as to whether flares of systemic lupus erythematosus (SLE) are more common during pregnancy are conflicting.[45–47] The discrepancy among previous studies is due to methodologic differences,[48] including the definition of lupus flare, and the fact that several typical manifestations of active SLE, such as facial erythema (Fig. 51–10), alopecia, fatigue, edema, anemia, musculoskeletal pain, mild proteinuria, and elevated erythrocyte sedimentation rate, are common findings in pregnancy. In most studies, the frequency of flare during pregnancy was higher than 57%.[48] Pregnancy is well tolerated by mothers in remission for at least 3 months before conception, but if conception occurs during the active stage of disease, 50% of gravidas will worsen during pregnancy and might experience life-threatening progression of the renal disease.[45] When SLE first appears during pregnancy, it may show severe manifestations but usually remits postpartum. Cutaneous flares and arthralgias are the

Malar erythema in a butterfly distribution in a pregnant woman with systemic lupus erythematosus. (Photograph courtesy of Cameron Thomas, Campbell Kennedy, and Phillipa Kyle.)

most common manifestations of SLE in pregnancy. Flares are not more severe during than outside of pregnancy and can be treated with oral steroids. Yet, steroids do not prevent flares and should not be prescribed prophylactically.

The effects of lupus on fetal outcome correlate with the severity of maternal lupus, active disease at the time of conception or first presentation of SLE during pregnancy, and presence of anticardiolipin antibody or lupus anticoagulant. Preterm delivery occurs in 16% to 37% of pregnancies, and spontaneous abortion rates are two to four times normal. Other risks include fetal death, intrauterine growth restriction (IUGR), and preeclampsia.[48] These obstetric complications have been associated with uteroplacental hypoperfusion, defective placentation, and chronic inflammation. The antiphospholipid syndrome[49] may complicate SLE, but many patients have primary antiphospholipid syndrome without lupus. It presents with manifestations that can worsen or lead to its initial diagnosis during gestation, such as recurrent miscarriage, thrombosis, livedo reticularis, migraine, stroke, and thrombocytopenia. Treatment with low-molecular-weight heparin or aspirin and close antenatal surveillance for maternal and fetal complications is warranted.

NEONATAL LUPUS (See also Chapter 43)

Neonatal lupus[50] can develop owing to transplacental passage of maternal anti-Ro (SS-A) and, less commonly, anti-La (SS-B) or anti-U1-RNP antibody. The risk is 5% if anti-Ro–positive, and the incidence is 1.6% of all lupus pregnancies. An association with human leukocyte antigen (HLA) DR2 and DR3 positivity in the mother has been reported.[50] The female-to-male ratio is 3 : 1.[50] Neonatal lupus is characterized by a transient skin eruption and systemic manifestations, including congenital heart block (15%–30%), cytopenias, hepatosplenomegaly, and pericarditis/myocarditis. The eruption becomes manifest several weeks into postnatal life and resolves by 6 to 8 months of age, coincident with the clearance of maternal autoantibody from the infant's circulation. The skin lesions frequently affect the face and scalp, with a predilection for the eyelids. Other sun-exposed areas may be also affected; occasionally, the eruption becomes generalized. The lesions are papulosquamous or annular/polycyclic, indistinguishable from subacute cutaneous lupus of the adult. Skin histopathology shows interface dermatitis and superficial dermal mononuclear cell infiltrate. Immunofluorescence shows a particulate pattern of immunoglobulin G (IgG) in the epidermis.

Congenital heart block carries a substantial neonatal morbidity and mortality and can be detected in utero at 18 to 20 weeks' gestation.[50] Twenty-two percent of affected infants die in the perinatal period, and 62% of the infants require a pacemaker.[50] The risk of bearing a second child with heart block is 25%, rising to 50% after two or more affected infants. The maternal and fetal anti-Ro, anti-La, and anti-U1-RNP status should be determined, and the newborn should be screened for heart block. Survivors of neonatal lupus may be at increased risk of developing connective tissue disease in adulthood.

DERMATOMYOSITIS/POLYMYOSITIS

Dermatomyositis/polymyositis may show a flare of the heliotrope rash, worsening of proximal muscle weakness, or subcutaneous calcification in approximately half of the affected individuals.[51] When the disease is in remission during pregnancy, there are no maternal or fetal risks involved. Nevertheless, when the disease starts or relapses during gestation, it can be detrimental to the mother and/or fetus. High doses of oral steroids may be required to control the disease. Fetal demise owing to abortion, stillbirth, or neonatal death has been reported in over half of the cases of active disease, and prenatal surveillance is crucial. An assisted vaginal delivery may be required in case of active myositis during labor. If the disease is diagnosed in the first trimester, the option of therapeutic abortion should be offered to the mother because of the high risk of maternal and/or fetal complications.

SYSTEMIC SCLEROSIS (See also Chapter 43)

The course of scleroderma is not significantly altered by pregnancy. Gravidas with limited scleroderma without systemic disease do better than those with diffuse scleroderma.[52] Women with early (<4 yr) diffuse scleroderma are at high risk for hypertension, renal failure, premature delivery, and small full-term infants. The risk of hypertension and renal failure is greatest during the third trimester and postpartum period. Nevertheless, renal crisis during gestation is less common than previously thought. Successful pregnancy is now reported in 70% to 80% of patients.[52] The skin disease usually does not progress during pregnancy, whereas reflux esophagitis and articular disease worsen. Raynaud's phenomenon usually improves secondary to gestational vasodilation and increased blood flow.

BULLOUS DISORDERS

Pemphigus vulgaris, vegetans, or foliaceus may present or worsen during gestation.[53] Linear IgA disease may improve in pregnancy and relapse postpartum.[54] Pemphigus vulgaris is rare during pregnancy; it usually worsens in the first or second trimester. Skin immunofluorescence studies are required to differentiate pemphigus from herpes gestationis (see "Herpes Gestationis," later). Neonatal pemphigus can develop from transplacental transfer of IgG antibodies. Most neonates require no therapy because the blisters heal spontaneously within 2 to 3 weeks. A recent review of 49 pregnancies complicated by pemphigus vulgaris showed 5 stillbirths and 1 death in the early neonatal period (perinatal mortality 12%).[55] Of the 44 live births, 20 (45%) of neonates had pemphigus lesions of birth.[55] Stillborn infants have been found to have skin lesions and immunofluorescence findings consistent with pemphigus. Pemphigus during pregnancy can be controlled with high doses of oral steroids.

Metabolic Disorders

PORPHYRIA

Porphyria cutanea tarda, acute intermittent porphyria, and variegate porphyria can present problems in pregnancy because they are adversely affected by estrogen. Patients with porphyria cutanea tarda demonstrate bullous lesions, skin fragility, and milia on sun-exposed areas, such as the dorsa of the hands and forearms. Other skin changes include facial hypertrichosis, periorbital hyperpigmentation, scarring alopecia, and dystrophic calcification with ulceration. Reports of porphyria cutanea tarda and pregnancy have been scarce in the literature; these reports have provided conflicting results.[56] Symptomatic exacerbation of the disease has been often reported during the first trimester followed by improvement later in pregnancy. These changes parallel a rise in serum estrogen and porphyrin excretion in the first trimester and a fall in serum iron levels and urinary porphyrins later in gestation. Nevertheless, some authors reported exacerbation of the disease with oral contraceptives and not in pregnancy. The fetal prognosis is not usually affected by this disorder. Lists of drugs that are safe and unsafe for porphyria patients have been published.[57] Management of porphyria cutanea tarda during pregnancy includes sun protection, avoidance of alcohol and iron, and repeated phlebotomies in retractable cases. Chloroquine is contraindicated in pregnancy because of its teratogenicity. The newborn should be assessed and screened for porphyria cutanea tarda in the immediate postpartum period, both for genetic counseling and to avoid inducing factors in the child.

ACRODERMATITIS ENTEROPATHICA

Acrodermatitis enteropathica is a rare autosomal disorder of zinc deficiency characterized by dermatitis, diarrhea, and alopecia. The skin lesions are vesiculobullous and eczematous and are distributed on the extremities and periorificial sites, such as the mouth, anus, and genital areas. The disease usually flares during gestation, because serum levels decrease early in pregnancy.[58] This decline is not attributed to fetal demands only, because acrodermatitis enteropathica can also flare with oral contraceptive use. The skin lesions in pregnancy need to be differentiated from pemphigoid gestationis and impetigo herpetiformis. Most often, having first appeared in childhood, the skin disease reappears during pregnancy, worsens until delivery, and clears postpartum.[57] The disorder usually has no effect on fetal outcome. Fetal malformations and neonatal death have been reported in a few cases of untreated maternal disease.

Connective Tissue Disorders

EHLERS-DANLOS SYNDROMES I TO X

Ehlers-Danlos syndromes I to X are a group of inherited disorders of collagen metabolism that manifest with skin fragility, easy bruising, joint hypermobility, and skin hyperelasticity. Women with Ehlers-Danlos syndromes type I (classic or gravis) and IV (ecchymotic or arterial) are particularly likely to develop complications during pregnancy. The risks include premature rupture of the membranes; postpartum bleeding; rupture of major vessels (especially in type IV), including the aorta and pulmonary artery; poor wound healing and dehiscence; uterine lacerations; bladder and uterine prolapse; and abdominal hernias.[59] The reported maternal mortality in type IV disease is 20% to 25%. The risks are such that women with Ehlers-Danlos syndromes types I or IV should be counseled against pregnancy. A favorable outcome of pregnancy, however, has been reported for types II (mitis) and X (fibronectin abnormality).[2]

PSEUDOXANTHOMA ELASTICUM

Gestation may worsen the vascular complications of pseudoxanthoma elasticum. The main complication is massive hematemesis from gastrointestinal (particularly gastric) bleeding, but repeated epistaxis and congestive heart failure with ventricular arrhythmia have been also reported.[60] Hypertension is frequent and should be treated aggressively. An increased risk of first-trimester miscarriage and IUGR secondary to placental insufficiency has been reported.

Skin Tumors

MISCELLANEOUS LESIONS

Most benign skin tumors can appear for the first time, increase in number, or enlarge during gestation as a result of the effects of high estrogen levels on vascular and soft tissues. The most common lesions that change during pregnancy are melanocytic nevi, seborrheic keratoses, and skin tags. Melanocytic nevi may develop, enlarge, or darken during pregnancy (Fig. 51–11). The pigmentary changes observed in melanocytic nevi during pregnancy are thought to be due to the melanogenic effects of high estrogen levels and increased levels of melanocyte-stimulating hormone. An increase in estrogen and progesterone receptors in melanocytic nevi in pregnancy has been demonstrated. A mild degree of histopathologic atypia has been reported in a few studies. The pregnant woman should be advised that there is no evidence that pregnancy induces malignant transformation of preexisting nevi. Studies that used dermoscopic analysis of nevi showed that the pigment network becomes thicker and more prominent and the globules darker during

FIGURE 51–11
Melanocytic nevus that became darker and developed a mild border irregularity during gestation.

FIGURE 51–13
Keloid that developed during pregnancy without previous trauma.
FIGURE 51–12
Pyogenic granuloma of pregnancy (granuloma gravidarum), typically seen on the gingivae, can also develop on extramucosal sites.

pregnancy.[61] These features, however, return to their original condition within 1 year after delivery. Seborrheic keratoses may also enlarge or darken during gestation. Skin tags (*molluscum fibrosum gravidarum*) usually appear during the later months of pregnancy and may partially or completely disappear postpartum. In all these cases, the pregnant woman needs to be reassured that these skin lesions are common during pregnancy and may improve postpartum.

Vascular tumors may also be affected or present during pregnancy. The pyogenic granuloma of pregnancy (*granuloma gravidarum*, *pregnancy tumor*, or *pregnancy epulis*) is a benign proliferation of capillaries within the gingivae that appears between the second and the fifth months of pregnancy. The prevalence of granuloma gravidarum is estimated to approach 2% of all pregnancies. It may be caused by trauma to inflamed mucosa and presents as a vascular deep-red or purple nodule between the teeth or on the buccal or lingual surface of the marginal gingiva. Occasionally, pyogenic granulomas can develop on the lip or extramucosal sites (Fig. 51–12). Typical histopathologic features of a pyogenic granuloma are seen in all cases. Spontaneous shrinkage of the tumor usually occurs postpartum, and most cases do not require treatment. Surgical excision, however, is necessary in cases of excessive

bleeding. An increased frequency of other vascular tumors, such as hemangioma, hemangioendothelioma, glomus tumor, and glomangioma, has been reported in pregnancy. Large hemangiomas that exceptionally cause arteriovenous shunt and high-output cardiac failure in pregnancy partially regress postpartum, tending to enlarge again in subsequent pregnancies.

Dermatofibromata, dermatofibrosarcomata protuberans, leiomyomata, and keloids may develop or enlarge during pregnancy (Fig. 51–13). Desmoid tumors often develop in the rectus abdominis muscle. Neurofibromas may enlarge or arise de novo during gestation, often complicated with massive hemorrhage within the tumor. These lesions may partially resolve postpartum.

NEUROFIBROMATOSIS

Women with neurofibromatosis are at high risk for vascular complications during pregnancy such as hypertension and renal artery rupture.[62] A higher prevalence of maternal and fetal risks, such as first-trimester spontaneous abortion, stillbirth, IUGR, and perinatal complications, has been reported in neurofibromatosis.[63]

MALIGNANT MELANOMA

Malignant melanoma has an incidence of 2.8 cases per 1000 births and accounts for 8% of malignant neoplasms during pregnancy. Several studies have shown that melanomas that develop during pregnancy are thicker than melanomas in nonpregnant women.[64,65] This finding may be due to a delay in the diagnosis of melanoma during gestation, possibly because of a shared misconception by the patient and/or her physician that darkening and changing of a nevus is normal in pregnancy. Despite initial concerns, several epidemiologic studies evaluating the effect of pregnancy status at diagnosis have showed that the 5-year survival rate is not affected after controlling for other factors.[66–68] The protective effect of female gender on prognosis of melanoma has been attributed to the inhibitory effect of estrogens on melanoma cell lines through type II estrogen receptors and the fact that melanoma cells lack type I estrogen receptors. In the largest study to date, the major prognostic determinants of survival in pregnant women with localized melanoma were tumor thickness (Breslow scale) and ulceration status.[68]

Surgery is the treatment of choice in patients with early melanoma. Correct staging is crucial, and sentinel lymph node biopsy using preoperative intradermal injection of technetium-99m-sulfur colloid is considered safe during pregnancy[69] and should be performed as indicated. For pregnant women with advanced melanoma, the prognosis, risks, and benefits from systemic therapy should be discussed, and a special consideration should be given to gestational age at presentation and consequences of delayed treatment on overall survival. Systemic chemotherapy during the second and third trimesters does not usually cause fetal abnormalities, except in the case of alkylating agents.[70] Nevertheless, given that the effectiveness of chemotherapy in advanced melanoma is at present limited, systemic chemotherapy should not be given in pregnancy in other than exceptional circumstances. In some cases, termination of pregnancy in early gestation may be the least damaging course of action to allow systemic therapy to be offered.

Although placental and/or fetal metastasis is extraordinarily rare (19 cases),[69] melanoma is the most common type of malignancy to metastasize to the placenta and fetus, representing 30% of placental metastases and 58% of fetal metastases. Maternal and fetal death invariably occurs; 80% of maternal deaths occur within 3 months of delivery. When a gravida is diagnosed with melanoma, the placenta should be sent for histologic examination. Some authors suggested that blood from both the mother and the umbilical cord be examined cytologically. The effectiveness of systemic treatment in preventing metastases to the placenta and fetus has not been adequately studied.[70]

There are currently no standard guidelines for patients who desire a pregnancy after the diagnosis and treatment of melanoma. Based on the fact that 50% of recurrences develop by 3 years in patients with thick lesions, Mackie[70] suggested that women who have melanoma should not become pregnant nor should they take oral contraceptive or postmenopausal hormonal replacement therapy for 2 years after initial treatment unless there are exceptional circumstances. Nevertheless, pregnancy subsequent to a diagnosis of melanoma was associated with a nonsignificant decrease in mortality,[68] and there is no evidence to support an increased risk of melanoma recurrence with oral contraceptive use. The recommendation of other authors about how long to wait before becoming pregnant after a diagnosis of melanoma is on case-by-case basis, depending on tumor thickness and stage, age of the patient, and desire to become pregnant.[69]

FIGURE 51–14 Minimal residual skin lesions of sarcoidosis on the knee in a pregnant female who showed severe generalized skin sarcoidosis before gestation.

Miscellaneous Skin Disorders

A variety of skin disorders have been reported to start or flare during pregnancy, but large series are missing for most of them. Autoimmune progesterone dermatitis, a condition caused by hypersensitivity to progesterone and characterized by recurrent cyclic skin lesions that appear during the luteal phase of the menstrual cycle, has been reported to improve or flare during pregnancy. The improvement may be due to increased cortisol levels and/or the gradual increase in sex hormone levels during gestation with subsequent hormonal desensitization in some patients. Sarcoidosis of the skin is one of the most studied and has been shown to improve in pregnancy. Figure 51–14 demonstrates minimal residual skin lesions of sarcoidosis in a pregnant female who demonstrated generalized skin sarcoidosis before gestation. Exacerbation or new onset of erythema nodosum (adversely affected by estrogen), keratosis pilaris, erythema multiforme, bowenoid papulosis, mycosis fungoides, Langerhans cell histiocytosis, mastocytosis, erythrokeratodermia variabilis, hereditary angioedema, tuberous sclerosis, Marfan's syndrome, and hereditary hemorrhagic telangiectasia during pregnancy have been reported. The serious maternal risks related to vascular complications of tuberous sclerosis, Marfan's syndrome, and hereditary hemorrhagic telangiectasia should be promptly assessed. The management of the rest of the aforementioned conditions should be individualized.

SUMMARY OF MANAGEMENT OPTIONS
Preexisting Skin Disorders

Management Options	Evidence Quality and Recommendation	References
Atopic Dermatitis (Eczema)	IV/C	19
Emollients.		
Low- or mid-potency topical steroids.		
Oral antihistamines.		
UVB.		
Short-course oral steroid for severe disease.		

Management Options	Evidence Quality and Recommendation	References
Acne Vulgaris		
Comedonal Acne	IV/C	19
May treat with benzoyl peroxide.		
Inflammatory Acne	IV/C	19
Treat with:		
• Azelaic acid.		
• Topical erythromycin or clindamycin.		
• Oral erythromycin base.		
Psoriasis		
Chronic Plaque Psoriasis		
Treat with:		
• Topical steroids, calcipotriene, anthralin, tacrolimus.	IV/C	22
• UVB.	—/GPP	—
• Short-course cyclosporine.	—/GPP	—
Generalized Postular Psoriasis		
Monitor maternal BP, cardiac and renal function.	—/GPP	—
Institute fetal monitoring, vigilance for IUGR.	IV/C	25
Prescribe high-dose oral steroids as first-line therapy.	—/GPP	—
UVB and cyclosporine are second-line therapies.	IV/C	28
Give calcium and vitamin D if necessary.	IV/C	23
Prescribe systemic antibiotics if superinfection.	—/GPP	—
Infections (See Chapters 30–32 and Table 51–3)		
Autoimmune Disorders		
Systemic Lupus Erythematosus		
Give oral steroids for skin and joint exacerbation.	IV/C	48
Neonatal Lupus		
Perform skin biopsy if diagnosis uncertain.		
Screen fetus/newborn for heart block.		
Assess maternal/fetal anti-Ro, anti-La, anti-RNP.		
Test ECG, liver function, platelets in newborn.		
Give topical steroids, UV protection for skin rash.		
See Chapter 37 for discussion congenital heart block.		
Dermatomyositis/Polymyositis	III/B	51
Prescribe oral steroids; second line: methotrexate.		
Be vigilant for IUGR and preterm labor.		
Consider assisted vaginal delivery.		
Systemic Sclerosis		
Monitor for hypertension and renal failure.		
Be vigilant for preterm delivery and small-for-dates infants.		
Bullous Disorders—Pemphigus	III/B	53,54
Prescribe oral steroids.		
Institute vigilance for miscarriage/fetal death.		55
Institute vigilance for neonatal lesions.		55

SUMMARY OF MANAGEMENT OPTIONS		
Preexisting Skin Disorders—cont'd		
Management Options	**Evidence Quality and Recommendation**	**References**
Metabolic and Connective Tissue Disorders		
Porphyria Cutanea Tarda		
Be vigilant for exacerbation. Avoid sun, iron, and alcohol. Consider venesection.	IV/C	56
Avoid chloroquine in first trimester. Avoid drugs that cause exacerbation.	IV/C	57
Acrodermatitis Enteropathica		
Offer zinc supplementation.		
Screen carefully for fetal malformations.		
Ehlers-Danlos Syndromes I and IV	III/B	59
Counsel against conception prepregnancy.		
Maintain vigilance for rupture of major vessels, postpartum hemorrhage, wound dehiscence.		
Maintain vigilance for uterine or bladder prolapse.		
Be vigilant for preterm delivery.		
Provide IV access and cross-match blood for delivery.		
Avoid excessive trauma at operative delivery.		
Use nonabsorbable sutures for cesarean section.		
Consider termination of pregnancy if no response to therapy.		
Pseudoxanthoma Elasticum	IV/C	60
Institute vigilance for GI bleeding, hypertension.		
Institute vigilance for first-trimester miscarriage, IUGR.		
Skin Tumors		
Malignant Melanoma		
Make decisions about conception subsequent to a melanoma diagnosis on a case-by-case basis.	IIa/B	68
Perform prompt excision and staging for definitive management.	IIa/B	68
Chemotherapy may be used after first trimester with low risk of fetal anomaly.	IV/C	70
Perform biopsy of placenta for metastasis (very rare).	IV/C	69,70
Neurofibromatosis		
Monitor for hypertension and vascular complications.	IV/C	62
Monitor fetal growth and health.	IV/C	63

BP, blood pressure; ECG, electrocardiogram; GI, gastrointestinal; GPP, good practice point; IUGR, intrauterine growth restriction; UV, ultraviolet; UVB, ultraviolet light B.

PRURITUS IN PREGNANCY

Pruritus has been reported in up to 17% of pregnancies. As shown in Table 51–3, a broad differential diagnosis needs to be considered, and the constellation of clinical and laboratory findings is the most helpful approach to establishing a diagnosis and reaching management decisions. In summary, a patient with pruritus in pregnancy should be evaluated as follows:

- A detailed history, past medical history, obstetric history, and physical examination are imperative for determining the cause of pruritus. The laboratory workup should be directed by the clinical findings. The constellation of

TABLE 51–3

Etiology of Pruritus in Pregnancy

Common Causes

Uncommon Causes
Systemic causes of pruritus (lymphoma; liver, thyroid, or renal disease)
Viral hepatitis
Hyperbilirubinemic states
Hyperemesis gravidarum

clinical and laboratory data will help identify pruritic skin diseases that are not specifically related to pregnancy, such as scabies, or systemic disorders with skin manifestations (see the previous section).

- In the patient with pruritus and no eruption, one should consider systemic causes of pruritus such as lymphoma and liver, renal, and thyroid disease.
- In the patient with pruritus, jaundice, and no eruption, one should consider hepatitides, obstetric cholestasis, hyperbilirubinemic states, and other liver diseases.
- In the patient with pruritus and eruption, one should consider specific dermatoses of pregnancy (see the following section), allergic reactions, drug eruptions, and urticarial lesions of hepatitis B.
- In the patient with pruritus, no jaundice, no eruption, no systemic disease, and no specific pregnancy dermatosis, one should consider intrahepatic cholestasis of pregnancy, pruritus associated with striae gravidarum, and hyperemesis gravidarum complicated with cholestasis.

Obstetric Cholestasis (Intrahepatic Cholestasis of Pregnancy) (See also Chapter 47)

Generalized pruritus without a skin rash often results from obstetric cholestasis, the most common pregnancy-induced liver disorder. The condition manifests itself with jaundice (*intrahepatic jaundice of pregnancy*) or without (*pruritus gravidarum*). Viral hepatitis is the most common cause of jaundice in pregnancy, with obstetric cholestasis second. Obstetric cholestasis is very common in South Asia (0.8%–1.46%), South America (9.2%–15.6%), especially Chile and Bolivia, and Scandinavia (1.5% in Sweden).[71] The incidence of obstetric cholestasis is lower in the rest of Europe (0.1%–1.5%), the United States, Canada, and Australia. This geographic variation is thought to be due to environmental and/or dietary factors. Obstetric cholestasis recurs in 60% to 70% of subsequent pregnancies.[72] Oral contraceptives can cause a recurrence of pruritus and cholestasis. In half of the cases, there is a family history of this condition or an association with multiple-gestation pregnancy.[71] Obstetric

cholestasis may occur more frequently and at an earlier gestational age in pregnant women who are positive for hepatitis C virus.

Obstetric cholestasis manifests itself in 80% of cases after the 30th week of pregnancy,[71] although initial presentation as early as 6 weeks' gestation has been reported. The pruritus, which may precede the liver function abnormalities of the condition, affects the palms and soles and extends to the legs and abdomen. Excoriations due to scratching are invariably seen. Obstetric cholestasis is occasionally preceded by a urinary tract infection. Mild nausea and discomfort in the upper right quadrant may accompany the pruritus. Mild jaundice (20%) usually develops 2 to 4 weeks after the onset of itching and may be associated with subclinical steatorrhea and increased risk of hemorrhage.[72] Up to 50% of patients develop darker urine and light-colored stools. The symptoms and biochemical abnormalities of obstetric cholestasis usually resolve within 2 to 4 weeks postpartum. An increased risk of cholelithiasis has been debated.

Elevated serum bile acids, especially postprandial elevations, are the most sensitive marker of obstetric cholestasis[71] and correlate with the severity of the pruritus. The serum bile acid profile shows characteristically an increased cholic-to-chenodeoxycholic ratio and a decreased glycine-to-taurine ratio. Mild abnormalities on liver function tests are commonly found, namely elevated cholesterol, transaminases, alkaline phosphatase, γ-glutamyltranspeptidase, and lipids. The conjugated bilirubin is mildly to moderately elevated (2–5 mg/dL) in jaundiced patients. Other authors showed an increase in low-density lipoprotein (LDL) levels as early as the 16th week of gestation and increased glutathione S-transferase. Malabsorption of fat may cause vitamin K deficiency, resulting in a prolonged prothrombin time. Skin biopsy is unnecessary because there are no primary skin lesions. Liver biopsy is not indicated, but if performed, shows centrilobular cholestasis, bile thrombi within dilated canaliculi, and minimal inflammatory changes.

Hormonal, immunologic, genetic, environmental, and probably alimentary factors may play a role in the etiology of obstetric cholestasis.[71] It has been suggested that the relative decrease in hepatic blood flow during gestation causes decreased elimination of toxins and estrogens. Some D-ring estrogens, in particular glucuronides like estradiol-17β-D-glucuronide, interfere with bile acid secretion and increase biliary cholesterol secretion. Progestins inhibit hepatic glucuronyltransferase, thus reducing the clearance of estrogens and amplifying their effects.[73] Monosulfated or disulfated progesterone metabolites, in particular the 3α-, 5α-isomers, are substantially increased in obstetric cholestasis secondary to decreased biliary and fecal excretion. The increased serum levels of sulfated progesterone metabolites may saturate the maximal transport capacity of membrane transport proteins of the hepatocyte. The interaction between the high levels of sex steroids produced in pregnancy and the genetically determined dysfunction of biliary canalicular ABC transporters can contribute to the development of cholestasis. An immunologic study showed a predominance of T helper-1 (Th-1) cytokines (cell-mediated immunity) and decreased maternal-fetal lymphocyte reaction in obstetric cholestasis. Another study showed increased natural killer cells and decreased T cells in the decidual parietalis and oversecretion of interferon-γ.

Genetic factors have been suggested by experimental data, the existence of familial cases, and geographic variation of obstetric cholestasis. Mutations in the canalicular transporters ABCB4 (multidrug resistance 3 gene [MDR3]) and MDR-associated protein 2 (MRP2) have been found in several families with intrahepatic cholestasis of pregnancy, and associations with these genes' polymorphisms have been reported.[73] A high prevalence of the HLA haplotype Aw31B8 has been reported. A higher incidence of obstetric cholestasis has been observed in mothers of patients with progressive familial intrahepatic cholestasis (PFIC) or benign recurrent intrahepatic cholestasis. Patients with PFIC type 3 show mutations of the MDR3 gene, which encodes the canalicular phosphatidylcholine translocase, a biliary transport protein. In a family of PFIC type 3 patients, six women with a history of obstetric cholestasis were heterozygous for the familial mutation in the MDR3 gene.[74] Environmental factors, as indicated by the geographic variation of obstetric cholestasis and its higher incidence during the winter, and alimentary factors have been implicated in the pathogenesis of obstetric cholestasis.[71] The importance of these factors, however, has been debated.

Fetal risks in obstetric cholestasis include fetal distress (22%–33%), stillbirth (0.4%–4.1%), preterm delivery (44%), and meconium staining (25%–45%).[73] Acute onset of fetal compromise (22%) and intrauterine demise (2%) have been well-documented complications.[75] Untreated intrahepatic cholestasis is associated with increased perinatal mortality (11%–20%).[75] A twofold increase in neonatal respiratory distress syndrome has been reported.[75] Malabsorption of vitamin K increases the risk of intracranial hemorrhage. Early onset of pruritus and high levels of serum bile acids have been associated with preterm delivery and define a subgroup of patients at risk for poor neonatal outcome.[76] The pathogenesis of fetal complications is associated with decreased fetal elimination of toxic bile acids, which can cause vasoconstriction of human placental chorionic veins. Furthermore, a higher incidence of meconium passage has been reported in stillbirths in obstetric cholestasis. Meconium can cause acute umbilical vein obstruction. The incidence of meconium passage was increased with the infusion of cholic acid in animal studies.[77] Experimental data indicate that raised levels of bile acid taurocholate in the fetal serum in cholestasis of pregnancy may cause fetal dysrhythmia and sudden intrauterine fetal death.[77]

The risk of serious fetal complications in obstetric cholestasis makes intensive fetal surveillance mandatory.[78–80] Some obstetricians recommend nonstress tests or biophysical assessment, although no test reliably predicts the risk of fetal demise. Obstetric management should weigh the risk of preterm delivery against the risk of sudden death in utero and should be individualized. Glantz and coworkers[81] showed no increase in fetal risk with bile acid levels less than 40 μmol/L and suggested that these patients be managed expectantly. Because the majority of intrauterine fetal deaths in singleton pregnancies complicated by cholestasis occur after 37 weeks' gestation, delivery has been recommended no later than 37 to 38 weeks' gestation.[80,82,83] Delivery around 36 weeks or earlier, if lung maturity is achieved and cervix favorable, should be considered for severe cases with jaundice, progressive elevations in serum bile acids, and suspected fetal distress.[84] Most authors advocate starting treatment with ursodeoxycholic acid (UDCA), which has been shown to decrease fetal risks, in all patients with intrahepatic cholestasis as soon as the diagnosis is established.

Mild cholestasis can be treated symptomatically with topical antipruritics and emollients; oral antihistamines are rarely effective. Epomediol and silymarin have been helpful in mild cases.[71] Treatment with activated charcoal or benzodiazepines has met limited success. Phenobarbital has shown minimal effect on the pruritus of obstetric cholestasis and variable effects on the biochemical abnormalities of the condition.[83] UVB has been variably effective in controlling the pruritus.[68,75] The glutathione precursor S-adenosylmethionine has shown some relief of pruritus but does not effectively correct the biochemical abnormalities of cholestasis. Two controlled trials showed that UDCA was superior to S-adenosylmethionine in correcting the biochemical abnormalities of the disease[85,86]; relief of pruritus was more effectively achieved with UDCA in one of these trials.[85] Dexamethasone (12 mg/day) suppression of fetoplacental estrogen production was effective in improving the symptoms and biochemical abnormalities of cholestasis in an uncontrolled trial,[72] but a randomized, controlled trial showed that dexamethasone produced no alleviation of pruritus or reduction of alanine aminotransferase and was less effective than UDCA in reducing bile acids and bilirubin.[87]

Cholestyramine decreases the enterohepatic circulation of bile acids. It needs to be administered (≤18 g/day) for several days before a clear benefit for pruritus can be obtained and does not improve the biochemical abnormalities of obstetric cholestasis.[88] Furthermore, it has the disadvantage of precipitating vitamin K and should be administered in conjunction with weekly vitamin K supplementation.[71] A case of severe fetal intracranial hemorrhage during treatment with cholestyramine for obstetric cholestasis has been reported. Vitamin K and cholestyramine should be given at different times of the day so that cholestyramine does not interfere with vitamin K absorption. A decrease in pruritus has been reported in approximately half of the patients studied (uncontrolled), but recurrence of itching was common after the first week of treatment. Patients with high serum bile acids may not respond to cholestyramine,[88] and several patients who did not respond to cholestyramine subsequently responded to other agents, such as UDCA and dexamethasone. It may be concluded that cholestyramine can be effective only in mild to moderate obstetric cholestasis.

UDCA, a naturally occurring hydrophilic bile acid, protects against injury to bile ducts by hydrophobic bile acids and stimulates the excretion of these and other hepatotoxic compounds as well as sulfated progesterone metabolites. The medication restores the ability of the placenta to carry out bile acid transfer and reduces bile acid levels in colostrum, cord blood, and amniotic fluid.[73] It also normalizes the cholic-to-chenodeoxycholic and glycine-to-taurine ratios of the serum bile acid pool. Experimental evidence indicates that UDCA improves impaired hepatocellular secretion by mainly posttranscriptional stimulation of canalicular expression of transporters like the MRP or the bile salt export pump (ABCB11). A meta-analysis of four randomized, controlled trials indicated that UDCA, when administered in doses between 450 and 1200 mg daily, was highly effective

in controlling the pruritus and liver dysfunction associated with obstetric cholestasis.[72] A dose of 12 to 15 mg/kg/day has been used in most trials,[72] although some authors reported administration of high-dose (1.5–2 g/day) UDCA with no adverse reactions. The results of this meta-analysis[72] were confirmed by a subsequent retrospective, nonrandomized study[89] over a 12-year observation period, which also showed a greated proportion of deliveries at term in patients treated with UDCA. All children whose mothers were treated with UDCA were healthy in a 12-year follow-up period. A randomized, placebo-controlled trial showed that UDCA has shown a synergistic effect with *S*-adenosylmethionine in reducing the biochemical abnormalities of cholestasis.[90] A synergistic effect on improving pruritus and biochemical abnormalities was also shown in a randomized, prospective trial that compared UDCA with intravenous *S*-adenosylmethionine. The trial, however, showed that the combined therapy had no additive effect on pruritus compared with UDCA monotherapy.[91] Compared with cholestyramine, UDCA is safer, works faster, has a more sustained and profound effect on pruritus, and shows higher efficacy in improving the biochemical abnormalities of obstetric cholestasis.[92] Babies were delivered significantly closer to term by patients treated with UDCA than by those treated with cholestyramine. UDCA has been safe for both mother and fetus and may decrease the fetal mortality associated with obstetric cholestasis.[93] Some authors suggested that it has a cardioprotective effect on the fetus against the possible toxic effect of bile acid. Data that are available support the use of UDCA as a first-line agent and cholestyramine as a second-line agent in the treatment of moderate to severe obstetric cholestasis.

SUMMARY OF MANAGEMENT OPTIONS
Pruritus in Pregnancy

Management Options	Evidence Quality and Recommendation	References
Establish the Diagnosis		
Consider: • **Specific systemic diseases** with skin involvement (see previous sections). • **No eruption**: other systemic diseases with pruritus (lymphoma; liver, renal, thyroid disease). • **No eruption and jaundice**: hepatitides, obstetric cholestasis, hyperbilirubinemic states, and other liver diseases. • **Eruption**: specific dermatoses of pregnancy (see following section), allergic reactions, drug eruptions, and urticarial lesions of hepatitis B. • **No eruption/jaundice/systemic disease or dermatosis**: obstetric cholestasis, pruritus associated with striae gravidarum, and hyperemesis gravidarum complicated with cholestasis.	—/GPP	—
Management depends on cause—see "Obstetric Cholestasis," later.		
Obstetric Cholestasis		
Maternal Treatment		
Symptomatic in mild cases (antihistamines, topical medications, UVB).	—/GPP	—
First line: ursodeoxycholic acid.	Ia/A	72
Second line: cholestyramine plus vitamin K.	Ib/A	92
Consider ursodeoxycholic acid plus S-adenosylmethionine (synergistic effect) in severe cases.	Ib/A	90,91
Oral contraceptives with low-estrogen or progesterone-only products can be started postpartum once LFTs normalize.	—/GPP	—
Management of Fetal Risks		
Initiate fetal surveillance as soon as diagnosis of cholestasis is established (typically not before the 30th wk).	IIa/B	78–80
Initiate maternal treatment with ursodeoxycholic acid.	Ib/A	92,93

SUMMARY OF MANAGEMENT OPTIONS		
Pruritus in Pregnancy—cont'd		
Management Options	**Evidence Quality and Recommendation**	**References**
Monitor LFTs and bile acids every 2–4 wk.	III/B	80
Perform elective delivery at 37–38 wk.	III/B	82,83
Perform elective delivery at 36–37 wk if fetal lung maturity and favorable cervix.	IIb/B	84

GPP, good practice point; LFTs, liver function tests; UVB, ultraviolet light B.

SPECIFIC DERMATOSES OF PREGNANCY

Specific dermatoses of pregnancy are encountered predominantly during gestation or in the puerperium and include only those skin diseases that result directly from the state of gestation or the products of conception. The classification of specific dermatoses of pregnancy into herpes gestationis, pruritic urticarial papules and plaques of pregnancy (PUPPP), prurigo gestationis, and pruritic folliculitis of pregnancy that was proposed by Holmes and Black[94] was accepted by most authors. A reclassification[95] that included prurigo gestationis and pruritic folliculitis of pregnancy under the proposed "atopic eruption of pregnancy" was debated.[96]

Pemphigoid (Herpes) Gestationis

Pemphigoid (herpes) gestationis is a rare autoimmune bullous disease of pregnancy and the puerperium. It has been rarely associated with choriocarcinoma and molar pregnancy.[97] The disease is more prevalent in white females and occurs in approximately 1 in 50,000 pregnancies.[98] Pemphigoid (herpes) gestationis usually starts in the second or third trimester, with an average onset at 21 weeks' gestation, although initial onset in the immediate postpartum period occurs in about 20% of cases.[98,99] Pemphigoid (herpes) gestationis starts with severely pruritic urticarial abdominal lesions in half of the cases (Fig. 51–15A). The lesions do not spare the umbilicus. A generalized bullous eruption rapidly

ensues (see Fig. 51–15B), which may affect the palms and soles; facial and mucosal involvement is rare. Bullous lesions arise in both inflamed and clinically normal skin and, unless superinfected, heal without scarring. Annular patterns of new vesicles tend to develop at the periphery of the polycyclic lesions.

A flare at the time of delivery, preceded by a period of quiescence in late pregnancy, is typically seen (75%).[97] The disease spontaneously resolves in the postpartum period, although a protracted course and "conversion" to bullous pemphigoid have been reported. Cases with overlapping features of pemphigoid (herpes) gestationis and bullous pemphigoid have been described. Herpes gestationis often recurs in subsequent pregnancies, usually appearing at an earlier gestational age and more severely. Nevertheless, skip pregnancies occur (8%).[98,99] The postpartum duration of herpes gestationis may increase with the number of involved pregnancies. Recurrence with menses or ovulation or subsequent use of oral contraceptives has been reported.[99] The effects of breast-feeding and prolactin on prolonging the duration of pemphigoid gestationis deserve further clarification. The data previously discussed underscore the importance of hormonal factors in the pathogenesis of the disease.

Histopathology of early urticarial lesions shows a spongiotic epidermis, marked papillary dermal edema, and a mild perivascular infiltrate of lymphocytes, histiocytes, and characteristically, many eosinophils. Focal necrosis of the basal keratinocytes leads to subepidermal blister formation. Direct
FIGURE 51–15

immunofluorescence of perilesional skin shows linear C3 along the basement membrane zone.[1] In salt-split skin specimens, the antibody binds to the roof of the vesicle. Concomitant IgG deposition is detected in about 25% to 30% of patients. However, IgG is always positive when indirect complement-added immunofluorescence is used.[1] Deposition of IgG1 has been found in virtually all patients studied with monoclonal antibodies. Linear deposition of C3 and IgG1 has also been seen in the skin of neonates of affected mothers and in the basement membrane zone of amniotic epithelium.[91]

The antibody in pemphigoid gestationis belongs to the IgG1 subclass and is believed to activate complement through the classical pathway. Other studies, however, showed predominance of non–complement-fixing IgG4 subclass.[100] The major pathogenic antigen is the bullous pemphigoid 180-kd hemidesmosomal glycoprotein.[101] Reactivity against both the 180-kd and the 240-kd bullous pemphigoid antigens is detected in 10% of cases—the reactivity against the 240-kd antigen is thought to develop later during the disease process as a secondary response to basal keratinocyte injury[97] (*epitope spreading*). Serum antibody levels and eosinophilia do not correlate with the severity of disease. Antibody titers and immunofluorescence for C3 may remain positive even after clearance of the skin lesions or in subsequent disease-free pregnancies. The available enzyme-linked immunosorbent assays (ELISAs) have greater specificity and specificity for pemphigoid gestationis than indirect immunofluorescence. The major antigenic epitopes (A1, A2, A.25, and A3) are located in the noncollagenous domain (NC16A) of the transmembrane 180-kd antigen[102]; epitopes outside the NC16A domain have been also reported. Autoantibodies and autoimmune T lymphocytes from herpes gestationis patients recognize the NC16A2 (MCW-1) epitope[102]; these T cells express a Th-1 cytokine profile. Several authors postulate that an immunologic insult occurs against class II placental antigens of paternal haplotype, and the antibody then cross-reacts with a maternal skin basement membrane epitope.[103] This hypothesis is strengthened by a recent study that showed that the pemphigoid gestationis autoantigen is localized to the hemidesmosomes of amniotic epithelium, cultured extravillous trophoblast cells, and cells in the amniotic fluid, and its ectodomain in the amniotic fluid is structurally similar to the ectodomain produced by cultured keratinocytes.[104]

The association of pemphigoid gestationis with alleles of HLA-DR3 (61%–80%), HLA-DR4 (52%), or both (43%–50%)[105] and with the C4 null allele indicates that genetic factors may play an important role in the pathogenesis of the disease. Nonetheless, the finding of anti-HLA antibodies in all patients with herpes gestationis is considered an epiphenomenon in the disease process.[97] A change in partner has been occasionally associated with the onset of the disease,[99] and an increased prevalence of HLA-DR2 among husbands has been associated with herpes gestationis among their wives, particularly females positive for HLA-DR3/DR4. Yet, an association between change in consort and development of pemphigoid gestationis has not been consistently found,[98] and skip pregnancies despite having the same partner[98,99] would argue against this association. The role of paternal factors is intriguing but not yet entirely understood.

The differential diagnosis of pemphigoid gestationis includes drug eruptions, erythema multiforme, allergic contact dermatitis, PUPPP, and preexisting bullous disease with exacerbation during gestation, such as bullous pemphigoid. A careful history and clinical examination are usually sufficient to rule out allergic contact dermatitis, drug eruptions, and preexisting bullous disease with flare during pregnancy. Of note, bullous pemphigoid has not been reported during gestation, usually affects the elderly, and is equally common among males and females. The lesions in bullous pemphigoid are more prominent on the lower abdomen and thighs and do not cluster around the umbilicus. Erythema multiforme can be differentiated by histopathologic and immunofluorescence studies. PUPPP is the most common specific dermatosis of pregnancy that needs to be differentiated from herpes gestationis. Interestingly, PUPPP can manifest with urticarial and/or vesicular lesions almost indistinguishable from those of herpes gestationis. The two diseases, however, can be distinguished by direct immunofluorescence, which is negative in PUPPP.

Pemphigoid gestationis is associated with no maternal risks other than an increased risk of Graves' disease. Neonatal vesiculobullous lesions occur in 10% of cases[106] secondary to passive transplacental transfer of herpes gestationis antibody. The eruption is usually mild and resolves spontaneously in a few weeks as the maternal antibodies disappear from the infant's blood. The clinical course of neonatal pemphigoid gestationis is explained by the fact that the plasma elimination half-life of anti-BP 180 antibody has been shown by ELISA to be approximately 15 days. Lesions in the neonate resolve without treatment before antibody titers normalize, which indicates that factors other than the pathogenic antibody may be involved in the pathogenesis of the eruption in the nonate. Superinfection of bullous lesions warrants prompt treatment with systemic antibiotics. Monitoring for evidence of adrenal insufficiency is necessary for infants of mothers treated with oral steroids. Although an association with small–for–gestational age infants and preterm delivery has been reported,[107] no increase in fetal morbidity or mortality has been documented, with the exception of one case of fetal cerebral hemorrhage and one case of convulsions in the neonate. The fetal complications may not be altered by the use of systemic steroids[72] and are thought to be due to low-grade placental insufficiency.[103] A recent retrospective study showed that onset of pemphigoid gestationis in the first or second trimester and presence of blisters may be associated with adverse pregnancy outcomes, including prematurity and low birth weight, whereas systemic steroid treatment and autoantibody titers do not affect pregnancy outcomes.[108]

Early urticarial lesions may respond to topical steroids with or without an oral antihistamine, but most cases require oral steroids. Even though doses of prednisone up to 180 mg daily have been reported, most patients respond to lower doses (20–40 mg daily). The dose should be tapered 7 to 10 days after control is achieved. Most patients can be maintained on 5 to 10 mg of prednisone daily. The dosage should be increased at the time of delivery to control postpartum exacerbation. Plasmapheresis or chemical oophorectomy with goserelin have been used in recalcitrant herpes gestationis with some success.[97] Plasmapheresis can be considered for patients who do not respond to high doses of

oral steroids or when oral steroids are contraindicated. High-dose intravenous immune globulin, alone or combined with cyclosporine, has been used to treat herpes gestationis with some success.[109] Early delivery may be warranted in refractory cases. Intractable cases may respond to postpartum administration of cyclophosphamide, pyridoxine, gold, methotrexate, dapsone, rituximab or combination of minocycline with nicotinamide.[1,97] Nevertheless, these agents have not been consistently effective, and their use is limited to patients who are not breast-feeding.

Pruritic Urticarial Papules and Plaques of Pregnancy (Polymorphic Eruption of Pregnancy)

PUPPP is the most common specific dermatosis of pregnancy, affecting approximately 1 in 240 pregnancies.[94] The term *PUPPP* was coined by Lawley and colleagues,[110] who reported a specific self-limited pruritic urticarial eruption in seven pregnant women. PUPPP occurs predominantly in primigravidas in the third trimester, with a mean onset at 35 weeks' gestation, and occasionally postpartum.[94,111] Persistence of PUPPP months to years postpartum has been reported. PUPPP has been associated with predominance of male fetuses (55%) in recent studies.[112] Familial occurrence and recurrence in subsequent pregnancies, with menses, or with oral contraceptive use are uncommon. The lesions start in the abdominal striae in two thirds of the cases, and characteristically show periumbilical sparing (Fig. 51–16A and B).[1] The eruption is polymorphous, showing urticarial and at times vesicular, purpuric, polycyclic, or targetoid lesions[111] (see Fig. 51–16C). Lesions can spread over the trunk and

extremities, usually sparing the palms and soles. Involvement of the face and dyshidrosis-like lesions on the extremities are unusual. When generalized, PUPPP may resemble a toxic erythema (see Fig. 51–16D) or resolving atopic eczema. On resolution of PUPPP, extensive postinflammatory hyperpigmentation can be seen, especially in skin of color (see Fig. 51–7).

PUPPP is a clinical diagnosis because it lacks pathognomonic histopathologic features and laboratory abnormalities. The histopathology shows spongiotic dermatitis, a perivascular or upper dermal inflammatory cell infiltrate with variable numbers of eosinophils, and occasionally, mild epidermal changes such as parakeratosis, acanthosis, and exocytosis.[1] Results from immunofluorescence and serology studies are negative. Differentiation from the urticarial prebullous phase of herpes gestationis requires immunofluorescence studies (positive in herpes gestationis). Mild PUPPP requires symptomatic treatment with antipruritic topical medications, topical steroids, and oral antihistamines. Rarely, a short course of oral prednisone may be necessary. UVB can be effective (anecdotal).[1]

The pathogenesis of PUPPP has not been fully elucidated. The clinical presentation and immunohistologic profile suggest a delayed hypersensitivity reaction. No immunologic or hormonal abnormalities have been found, with the exception of a decrease in serum cortisol in one study.[17] It has been postulated that rapid abdominal wall distention in primigravidas may trigger an inflammatory process. This hypothesis was proposed by Cohen and associates,[113] who first reported an association with twin pregnancy and excessive maternal and fetal weight gains. The author's meta-analysis[72] of 282 PUPPP cases revealed 29 multiple gestation pregnancies (11.7%). This prevalence is at least 10-fold
FIGURE 51–16

(*A–D*, Photographs courtesy of Helen Raynham, MD.)

higher than the prevalence of multiple gestation in the United States (1%).[72] The association of PUPPP with multiple-gestation pregnancy is also supported by other studies.[114,115] Furthermore, multiple gestation is characterized by higher estrogen and progesterone levels, and progesterone has been shown to aggravate the inflammatory process at the tissue level. Interestingly, increased progesterone receptor immunoreactivity has been detected in skin lesions of PUPPP.[116]

Immunohistochemical studies showed an infiltrate composed predominantly of T-helper lymphocytes.[117] Activated T cells (HLA-DR+, CD25+, LFA-1+) were found in the dermis associated with increased numbers of CD1a+, CD54+ ([intercellular adhesion molecule-1 [ICAM]+-1+) dendritic cells, and CD1a+ epidermal Langerhans cells in skin lesions, compared with unaffected skin. This immunohistologic profile may imply a delayed hypersensitivity reaction to an unknown antigen. Fetal DNA was detected in skin lesions of PUPPP by Aractingi and coworkers.[118] The authors suggested that fetal cells can migrate to maternal skin and cause PUPPP because pregnancy is associated with peripheral blood chimerism, particularly during the third trimester. The importance of microchimerism in the pathogenesis of PUPPP awaits further clarification.

PUPPP has not been traditionally associated with any maternal or fetal risks.[119] Two recent studies showed an association with cesarean section, which should be discussed with the pregnant female.[112,115] Early delivery in refractory cases is not indicated because there are no maternal or fetal risks.

Prurigo of Pregnancy

Prurigo of pregnancy affects between 1 in 300 and 1 in 450 pregnant females.[94] The condition usually begins at about 25 to 30 weeks' gestation and manifests itself with grouped excoriated or crusted pruritic papules over the extensor surfaces of the extremities (Fig. 51–17) and occasionally on the abdomen and elsewhere.[1] The lesions may be nodular, reminiscent of prurigo nodularis. Prurigo of pregnancy commonly resolves in the immediate postpartum period but may occasionally persist for up to 3 months. On resolution of the lesions, postinflammatory hyperpigmentation develops. Recurrence in subsequent pregnancies is variable. Serology may show an elevated IgE.[17] Results of immunofluorescence studies are negative and the histopathology nonspecific. Although Spangler and colleagues[120] reported a dismal fetal outcome in their series, fetal or maternal risks have not been confirmed by any other studies. The differential diagnosis includes other specific dermatoses of pregnancy, pruritic dermatoses unrelated to pregnancy, drug eruptions, arthropod bites, and infestations such as scabies. The treatment is symptomatic with moderately potent topical steroids, if necessary intralesional or under occlusion, and oral antihistamines.[1]

The pathogenesis of prurigo of pregnancy has not been adequately studied. Although its clinical presentation is indistinguishable from that of prurigo nodularis in nonpregnant women, a flare of prurigo nodularis during pregnancy has not been reported. Prurigo of pregnancy has been associated with a family history of obstetric cholestasis. Vaughan Jones and associates[17] postulated that prurigo of pregnancy

and obstetric cholestasis are closely related conditions, being distinguished only by the absence of primary lesions in obstetric cholestasis. The authors reported an association with personal or family history of atopic dermatitis and elevation of serum IgE and suggested that prurigo of pregnancy may be the result of obstetric cholestasis in women with an atopic predisposition. Furthermore, they more recently suggested that prurigo of pregnancy be classified under "atopic eruption of pregnancy."[95] Nevertheless, many patients with prurigo of pregnancy fulfilled only minor criteria of atopy in the study,[95] and IgE was not measured by the authors in a control group of pregnant women without the eruption. The regulation of IgE in pregnancy is complex and warrants further investigation. The classification of prurigo of pregnancy under "atopic eruption of pregnancy" has been debated.[96]

Pruritic Folliculitis of Pregnancy

Pruritic folliculitis of pregnancy is a rare specific dermatosis of pregnancy first described by Zoberman and Farmer.[121] In two of the original six cases, pruritic folliculitis of pregnancy had occurred in previous pregnancies. Since the original description, 26 cases have been reported.[122] Decreased awareness of the condition and the fact that many cases may be misdiagnosed as infectious folliculitis[123] or PUPPP may have contributed to an underestimate of its true prevalence. The lesions are pruritic follicular erythematous papules and

A, Pruritic folliculitis of pregnancy: typical follicular erythematous or pigmented papules on the abdomen. *B*, Follicular acneform pustules and papules on the upper back in pruritic folliculitis of pregnancy. *C*, Follicular erythematous papules on the lower extremities are seen less often in pruritic folliculitis of pregnancy.

pustules that predominate on the trunk (Fig. 51–18*A* and *B*).[124] Lesions on the extremities are seen less often (see Fig. 51–18*C*). The eruption develops during the second or third trimester and clears spontaneously at delivery or in the post-partum period. The histopathology is that of a sterile folliculitis. Results of immunofluorescence and serology tests are negative. The differential diagnosis includes infectious folliculitis and specific dermatoses of pregnancy. An infectious folliculitis can be ruled out with special stains and cultures from the pustules. The largest series of pruritic folliculitis of pregnancy patients showed a decreased birth weight and a male-to-female ratio of 2 : 1.[17] Preterm delivery was reported in one case. No other maternal or fetal risks have been documented.

The patient should be reassured that the eruption resolves after delivery and has not been associated with substantial fetal risks. Symptomatic pruritic folliculitis of pregnancy can be treated with low- or mid-potency topical steroids, benzoyl peroxide, and UVB therapy.[1] The pathogenesis of pruritic folliculitis of pregnancy remains elusive. No immunologic or hormonal abnormalities have been found, and associations with increased serum levels of androgens or obstetric cholestasis seem to have veen coincidental. It has been suggested that pruritic folliculitis of pregnancy may be a form of hormonally induced acne, similar to the monomorphic type of acne that develops after the administration of systemic steroids or progestogens.[94] This intriguing hypothesis has not been supported by any data. Other authors have considered pruritic folliculitis of pregnancy to be a variant of PUPPP.[125] Although follicular lesions have been reported in PUPPP, the clinical presentation and histopathology of pruritic folliculitis of pregnancy differ from those of PUPPP. A more recent study classified pruritic folliculitis of pregnancy under "atopic eruption of pregnancy," but this was based on only one case (patient with family history of atopy).[95] For the time being, pruritic folliculitis of pregnancy can be considered a specific dermatosis of pregnancy.[96,126]

SUMMARY OF MANAGEMENT OPTIONS
Rashes in Pregnancy

Management Options	Evidence Quality and Recommendation	References
Establish the Cause—Two Possibilities:		
Preexisting skin conditions.	—/GPP	—
Dermatoses of pregnancy.	—/GPP	—
Pemphigoid (Herpes) Gestationis		
Perform skin immunofluorescence to confirm the diagnosis.	III/B	17
Give topical steroids with or without an oral antihistamine (e.g., diphenhydramine) for early urticarial lesions.	IV/C	97
Give oral steroids in most cases.	III/B	17
Perform plasmapheresis if oral steroids fail.	IV/C	97
Cyclosporine with IVIG may be beneficial.	IV/C	109
Immunosuppressants postpartum in non–breast-feeding mothers can be considered.	IV/C	97

Management Options	Evidence Quality and Recommendation	References
Maintain fetal surveillance (growth and health).	III/B	107,108
Maintain vigilance for neonatal herpes gestations.	IV/C	106
Polymorphic Eruption of Pregnancy		
Perform skin biopsy if herpes gestation is a consideration.	III/B	17
Reassure that there are no fetal risks.	IIb/B	119
Discuss possible association with cesarean section.	IIa/B	112,115
Prescribe topical steroids and/or antipruritic medications with or without an oral antihistamine.	III/B	17
Give oral steroids in severe cases.	III/B	17
UVB can be tried.	IV/C	1
Prurigo of Pregnancy		
Reassure that there are no fetal risks.	III/B	17
Give topical steroids with or without an oral antihistamine.	III/B	17
Give oral steroids in severe cases.	III/B	17
Pruritic Folliculitis of Pregnancy		
Perform cultures and special stains to rule out infectious folliculitides.	III/B	17
Reassure that there are no fetal risks.	III/B	17
Topical benzoyl peroxide, low- or mid-potency topical steroids, and UVB can be tried.	III/B	17

GPP, good practice point; IVIG, intravenous immunoglobulin; UVB, ultraviolet light B.

and VERONICA L. SCHIMP

INTRODUCTION

Cancer is the second leading cause of death in women of reproductive age, and fortunately, a rare cause of maternal mortality.[1,2] Between birth and 39 years of age, 1 in 52 females has invasive cancer, and approximately 3500 women between the ages of 15 and 34 years die annually of cancer in the United States.[1] It is estimated between 1 in 1000 and 1 in 1500 women will be affected by cancer while pregnant each year. The predominant malignancies associated with pregnancy are cervical cancer, breast cancer, melanoma, hematologic cancer, thyroid cancer, and colorectal cancer (Table 52–1).[3] It should be noted that preinvasive cervical cancer is often included in these numbers and that the incidence of invasive cervical cancer is likely lower than estimated.[4] No convincing data show that pregnancy adversely influences the biology, natural history, prognosis, or treatment of maternal cancer.[5]

The evaluation and treatment of pregnant women with cancer are similar to those in nonpregnant women. Both maternal and fetal outcomes should be considered when planning therapy during pregnancy. One major dilemma encountered in the treatment of pregnant women with cancer is the timing of therapeutic intervention with regard to fetal growth, development, and viability. For most malignancies, the presence of the cancer does not adversely affect the fetus. The major risk to fetal survival and normal development is the toxic effect of the various treatment modalities. Conversely, continuation of pregnancy has not been associated with accelerated tumor growth for most malignancies; therefore, elective abortion often appears to have no therapeutic advantage to the mother. Intuitively, however, any cancer left untreated has an opportunity to grow and metastasize. The therapeutic challenge for the medical team is to weigh the need to immediately intervene owing to maternal indications against the need to delay therapy for fetal well-being.

RADIATION

Radiation therapy is an effective treatment modality for a variety of cancers encountered during pregnancy. In addition, many diagnostic procedures, such as regular x-rays, radioisotope scans, and computed tomography, used in the pretreatment evaluation of malignancies are associated with radiation exposure to the mother and, potentially, to the fetus.[6] The effects of radiation on tissues are the result of multiple cellular events that include mitotic delay, cytogenetic abnormalities, mutagenesis, and apoptotic cell death.

The effects of radiation on the fetus depend on the dose of radiation delivered (total dose, field size, and distance) as well as the stage of gestation during which exposure occurred. The dose to the embryo or fetus depends on several factors. These include the teletherapy machine used and its leakage, the target dose, the size of the radiation fields, the distance from the edge of the field to the embryo or fetus, and the use of wedges, lead blocks, compensators, and other scattering objects. Factors that decrease the radiation dose to the embryo or fetus include less leakage, a lower target dose, smaller irradiation fields, greater distance between the edges of the radiation fields and the embryo or fetus, and avoidance of wedges and other scattering objects. Advances in the field of radiation oncology and new technologies have focused on optimizing the dose to the target tissue and minimizing the leakage of radiation to the surrounding organs. A distance of more than 30 cm between the edges of the radiation fields and the embryo or fetus yields a fetal exposure of only 4 to 20 cGy. Lead shielding can further reduce exposure.[7]

Before and during implantation, the embryo is a multicellular organism that is mostly sensitive to the lethal effects of radiation.[8,9] Exposure to high-energy radiation at that stage may induce cytogenetic abnormalities that will result in an abortion.[10–12] An all-or-nothing phenomenon occurs during the first 10 days after conception.

The teratogenic effects of radiation are a significant risk if the fetus is exposed during organogenesis, which usually lasts for 10 days to 7 weeks after conception. The congenital malformations that are most frequently described with exposure to high-dose radiation involve the central nervous system, skeleton, and genitals. Microcephaly is the most common malformation reported.[13] Other malformations

include eye abnormalities, such as microphthalmia, retinal changes, and cataracts. Growth retardation and abortion can also occur during this period.

Later in gestation, the fetal organs, except for the central nervous system, become more resistant to the teratogenic effects of radiation. Exposure to high-dose radiation at that stage mainly results in growth retardation and neurophysiologic and behavioral changes that may become obvious in infancy or childhood. Data show that central nervous system malformations and growth retardation have occurred after acute exposure to more than 50 rad and until 25 weeks after conception.[13] Fetal exposure to less than 5 rad has not been associated with such effects. In utero exposure to radiation may result in an increased risk of leukemia in childhood.[13–16] This effect, however, is a subject of debate among investigators. Although some have suggested that radiation therapy may be compatible with pregnancy under strict conditions,[17] ample evidence exists that radiation therapy delivered to the abdomen and pelvis results in fetal exposure to dangerous radiation doses.

CHEMOTHERAPY

Chemotherapy is an essential part of the treatment of many malignancies, such as breast and ovarian cancers, lymphomas, and leukemias, that can occur during pregnancy.[18–23] Before the initiation of treatment with an antineoplastic agent in a pregnant woman, the potential benefits to the mother should be weighed against the potential risks to the mother and fetus. When cure is a realistic goal, appropriate treatment should be initiated as needed, without modifications that may adversely affect maternal outcome.

The physiologic changes that accompany pregnancy may alter the pharmacokinetics of various drugs, including many chemotherapeutic agents. For water-soluble drugs, the increase in plasma volume and decrease in albumin concentration may lead to a decreased concentration of the drug

after bolus administration; however, its half-life will be longer. Conversely, an increase in the activity of the hepatic oxidases and an increase in glomerular filtration may lead to an increase in the hepatic or renal clearance of some agents. As with other substances, the transfer of antineoplastic agents to the fetus through the placenta is controlled by the molecular weight, lipid solubility, and protein binding of the agents. For example, the highly protein-bound nature of vinca alkaloids makes transplacental passage to the fetus inefficient.

The timing of fetal exposure to the chemotherapeutic agents is one of the most important determinants of pregnancy outcome. In the first trimester, exposure to chemotherapy can result in congenital malformations or abortion.[18,24,25] The risk of congenital malformations has been reported to be as high as 17%. The folic acid antagonists aminopterin and methotrexate, when used in the first trimester, seem to be more teratogenic than other antineoplastic agents. Taking into account a background risk of 3% for congenital malformations, the use of cytotoxic drugs during organogenesis is associated with a risk as high as 17%. Excluding folate antagonists, the risk is estimated at 6%.[26] Syndromes of congenital anomalies that include cranial anomalies, cleft palate, anencephaly, and micrognathia have been associated with the use of aminopterin. Similarly, the use of alkylating agents and procarbazine has led to skull abnormalities known as "cloverleaf skull," or oxycephaly.[27–32] First-trimester use of alkylating agents and procarbazine is also associated with an increased risk of fetal malformations.[33] Second- and third-trimester exposure to chemotherapy does not seem to result in an increased risk of congenital malformations except for microcephaly. However, chemotherapy given at those stages has been associated with other complications including spontaneous abortion, low birth weight, intrauterine growth retardation, premature birth, mental retardation, and impaired learning behavior. The alkylating agents cyclophosphamide, cisplatin, and carboplatin seem to be relatively safe to be administered at that stage. Some authors have suggested that cisplatin may be preferable in pregnancy to carboplatin, because carboplatin is more myelosuppressive and less protein-bound and thus possibly more prone to transplacental transfer.[26] However, there are a number of reports regarding the use of carboplatin with normal neonatal outcome; in some of these, it was used in combination with paclitaxel, another commonly used chemotherapy drug.[34] No fetal problems were reported in at least 11 case reports using taxanes alone or in combination regimens for lung, ovarian, and breast cancer.[35]

Myelosuppression is a side effect common to many chemotherapeutic agents. Maternal thrombocytopenia or leukopenia at the time of delivery can result in significant complications including massive hemorrhage and serious infections. Therefore, the timing of delivery should be well planned in a woman who is receiving chemotherapy. Unwanted toxicities to the mother and fetus at the time of delivery commonly result in the discontinuation of chemotherapy administration 3 to 4 weeks preceding delivery.[36] Rarely is chemotherapy indicated after 35 weeks' gestation.

CERVICAL CANCER

Cervical cancer is diagnosed in pregnancy with a frequency of 10 to 1000 cases per 100,000 pregnancies.[37] The wide variability in the incidence reported in the literature seems to be caused by the inclusion of patients with postpartum cancer, carcinoma in situ, and preinvasive disease. A recent cancer registry study[5] reported cervical cancer as the most common gynecologic malignancy to occur during pregnancy and represented 15% of all cancers during pregnancy. It is estimated that between 1% and 3% of patients with cervical cancer are pregnant at the time of diagnosis.[38] The mean age of pregnant patients at the time of diagnosis of cervical cancer is 31.6 years (range 31–36.5 yr).[39] As in nonpregnant patients, the most common histologic type is squamous cell carcinoma, which accounts for more than 80% of all cervical cancers.[40] More than 70% of patients have early-stage disease, which includes FIGO (International Federation of Gynecology and Obstetrics) stages I to IIA lesions.[40–43] Diagnosis may be made at an earlier stage in pregnancy because pregnant women are seen frequently by health care providers and undergo routine examinations and Pap smears. One third of pregnant patients who are diagnosed with cervical cancer are asymptomatic, with diagnosis made at the time of an abnormal Pap smear result. The interpretation of Pap smears obtained during pregnancy can be problematic, because several common physiologic changes associated with the gravid state can lead to false-positive results.[44–46] For example, eversion of the transformation zone and exposure of columnar cells to the acid pH of the vagina cause squamous metaplasia that may be falsely interpreted as dysplasia. The changes seen with Arias-Stella reaction can resemble those of endocervical adenocarcinoma.[47,48] In one study of gravid hysterectomy specimens, Arias-Stella reaction was reported in 9% of specimens examined.[49] Another cause of false-positive Pap smear is related to the presence of trophoblastic cells that may be misinterpreted as dysplastic cells in the cytologic specimen. It is essential to inform the cytopathologist interpreting the Pap smear that the patient is pregnant.

Historically, it was believed that pregnancy had an adverse effect on the natural history of cervical cancer. Multiple studies have shown that there is no difference in survival between pregnant and nonpregnant cervical cancer patients when matched by age, stage, and year of diagnosis.[5,38–40,43,48,50–52] In addition, the decision for a vaginal delivery versus a cesarean delivery depends on the stage of disease

at the time of diagnosis.[44] Microinvasive or early invasion is not a contraindication to vaginal delivery.[44,53] However, gross tumor present at the time of delivery may have a higher likelihood of peripartum complications and potentially higher risk of locoregional recurrence and death.[54,55]

Management Options

Colposcopy is a safe and reliable method for evaluation pregnant patients with abnormal cervical cytologic findings.[56–60] The interpretation of colposcopy during pregnancy is more difficult owing to increased cervical volume, stromal edema, glandular hyperplasia, and increased vascularization.[4] Colposcopy-direct biopsy may be performed during any trimester, although most colposcopists suggest delaying biopsy until the second trimester. The main complication associated with cervical biopsy during pregnancy is bleeding; however, this usually can be controlled with the application of Monsel's solution and pressure. Endocervical biopsy must be avoided during pregnancy because of the risk of premature rupture of the membranes, preterm labor, and uncontrollable bleeding.[55] Many investigators estimate that without colposcopic findings suggestive of cancer, the likelihood of invasive cancer or progression to invasive cancer is low and that carcinoma in situ lesions may be treated conservatively until the postpartum period with periodic control colposcopy antenatally.[61] During pregnancy, diagnostic cervical conization is reserved for selected indications including (1) the diagnosis of minimal stromal invasion on a colposcopically directed biopsy and (2) persistent cytologic abnormalities suspicious of invasive cancer on Pap smear.[44] Fortunately, eversion of the squamocolumnar junction during pregnancy improves access to the endocervix and decreases the necessary volume of tissue to be removed if conization is performed. The risks of immediate and delayed bleeding after conization are 8.9% and 3.7%, respectively.[51] An estimated blood loss of 500 mL has been reported to occur during conization procedures performed during pregnancy.[44] Other infrequent complications include premature labor, chorioamnionitis, and fetal loss.[62]

Pregnant women who are diagnosed with invasive cervical cancer should be counseled extensively about treatment options as well as the effect of the treatment on the mother and fetus. Many factors should be considered in treatment planning, including gestational age, tumor size and stage, and the patient's desire to preserve the pregnancy. Few studies have evaluated the effect of delaying definitive therapy until fetal maturity is reached.[63–70] In these reports, treatment delays ranging from 21 to 212 days to allow for fetal maturity did not result in decreased maternal survival. At last follow-up, 96% of the patients were alive without disease. However, the numbers of patients in these series are small and definitive conclusions should be drawn cautiously. Two intervention options have been described in case reports for patients diagnosed with cervical cancer greater than FIGO stage IA and who desire pregnancy preservation. One is a surgical excision option, which involves an abdominal radical trachelectomy during pregnancy; it is hazardous and associated with significant risk of surgical complication and pregnancy loss.[71] Alternatively, neoadjuvant chemotherapy during pregnancy has been used with the intent to stabilize or reduce the cervical tumor.[67] Cesarean delivery followed by definitive treatment would be performed after fetal maturity. For patients with more advanced disease and at less than 20 weeks' gestation, termination of pregnancy is an option so that definitive management is not delayed.[38,44,72] The choice of treatment modality for pregnant patients with invasive cervical cancer is based on the same principles that are used in the nonpregnant state. Patients with early-stage disease can be treated surgically with radical hysterectomy and bilateral pelvic lymphadenectomy.[63,64,73,74] Depending on the time of diagnosis, surgery can be done early in gestation with termination of the pregnancy or at cesarean delivery. Except for increased blood loss, there is no significant increase in other perioperative complications compared with nonpregnant patients, and the cure rates are comparable.[64] Radiation therapy with chemosensitization is used to treat advanced disease that is not amenable to surgical management. When radiation is administered in the first trimester, spontaneous abortion usually occurs at a cumulative dose of 30 to 50 Gy. Treatment in the second trimester results in abortion at a higher cumulative radiation dose and less reliably. If spontaneous abortion did not occur by the end of the external radiation therapy, surgical evacuation should be performed before brachytherapy.[75] For patients who are treated after delivery, most radiotherapists wait a few weeks for uterine involution before starting treatment. Tumor stage is an important predictor of survival in cervical cancer. The outcome of patients with early-stage disease is excellent, with 5-year survival rates exceeding 90%.[40] In one report, the survival rate was worse and risk of recurrence was higher in women who were diagnosed postpartum than in those diagnosed during pregnancy.[65] One uncommon site of tumor recurrence when cervical cancer occurs in pregnancy is the episiotomy incision line.[76–78] It is believed that tumor cells can implant at the site of the episiotomy incision after vaginal delivery.

SUMMARY OF MANAGEMENT OPTIONS
Cervical Cancer

Management Options	Evidence Quality and Recommendation	References
Diagnosis		
Physical examination and cervical smear at first prenatal visit in high risk and those without smear in previous 3 yr.	III/B	56–61
Colposcopy and directed biopsies for suspicious lesions, though measures are needed to deal with increased bleeding risk.	III/B	51,55–61

Management Options	Evidence Quality and Recommendation	References
Cone biopsy when microinvasion suspected on directed biopsies; loop excision may be associated with increased preterm births.	III/B	55,62
Treatment		
Cervical Intraepithelial Neoplasia		
Follow-up with colposcopy during pregnancy.	III/B	59,61
Microinvasive Cancer		
After careful maternal counseling, consider delaying definitive therapy until fetal maturity is reached (enhance with steroids) and delivery is completed.	III/B	51–53, 63–70,74
Invasive Cancer		
Use same therapy guidelines as for nonpregnant patient:		
• Before 20 wk: consider termination and immediate therapy.	III/B	38,44,63, 64,71–74
• After 20 wk: consider awaiting fetal maturity (enhance with steroids), then deliver and implement therapy postnatally.	III/B	63,64,73, 74,78
Elective cesarean hysterectomy can be considered with early-stage disease.	III/B	53
Careful patient counseling required with either presentation.	III/B	63,64,73, 74,78
Prognosis		
Impact of cervical cancer during pregnancy does not appear to influence outcomes. However, some studies suggest a worse prognosis when diagnosed after pregnancy.	III/B	65,68
Reports of recurrences in episiotomy sites after vaginal birth.	III/B	63,78

OVARIAN CANCER

Ovarian cancer occurs in between 10 and 40 per 100,000 pregnancies and is the fifth most common malignancy diagnosed during pregnancy.[37,79] Most ovarian masses are diagnosed incidentally at the time of obstetric ultrasound. They are frequently nonmalignant and are found on histologic examination to be functional ovarian cysts (41%), endometriomas (24%), dermoid (18%), serous cystadenoma (6%), mucinous cystadenoma (3%), paraovarian cyst (3%), and borderline serous tumor (5%).[80] The risk of malignant or borderline ovarian neoplasm discovered during pregnancy ranges from 2% to 5% compared with 20% outside of pregnancy.[81–83] The histologic distribution of ovarian cancers diagnosed in pregnancy is different from that seen in the general population, partly because pregnant women are relatively young and have a higher incidence of germ cell tumors. Germ cell tumors account for 6% to 40% of malignant neoplasm complicating pregnancy; conversely, epithelial malignancies account for 49% to 75% and gonadal stromal tumors for 9% to 16%.[84–89] The distribution of subtypes of germ cell tumors diagnosed during pregnancy has varied among published series. Whereas some indicate that dysgerminomas are the most common subtype,[82,86,87] others indicate that malignant teratomas[84,85] and endodermal sinus tumors[90] are more common. Most ovarian malignancies

diagnosed in pregnancy are stage I, as would be expected with germ cell tumors.

Management Options

Management of an adnexal mass during pregnancy depends on the ultrasonographic characteristics of the mass and the gestational age. Some authors recommend to proceed with surgical exploration early in the second trimester for lesions that are larger than 6 cm, have a significant solid component, are bilateral, or persist after 14 weeks' gestation.[91,92] However, others encourage conservative management secondary to the low risk of malignancy and acute complications.[93] The serum cancer antigen 125 (CA-125) level can be elevated in normal pregnancies, especially in the first trimester, and low-level elevations are typically not associated with pregnancy.[93,94] Ovarian neoplasms, even when benign, are associated with increased risk of complications during pregnancy. Adnexal torsion is reported in up to 25% of patients.[95–97] Other complications include rupture and hemorrhage.[93,98] The risk of pregnancy loss or preterm labor is increased if surgery is performed for one of these acute complications.

Unilateral salpingo-oophorectomy with staging biopsy is the recommended surgery for stage I germ cell tumors.

Patients with stage IA dysgerminomas and stage IA grade 1 immature teratomas do not require further adjuvant therapy. The remaining germ cell tumors behave more aggressively and usually require adjuvant chemotherapy even in early stages. Treatment of advanced germ cell tumors of any histologic subtype includes surgery and chemotherapy. In anecdotal reports of pregnant patients with malignant ovarian germ cell tumors treated with combination chemotherapy (bleomycin, etoposide, cisplatin and vinblastine), good maternal and fetal outcomes were achieved.[99–101] Patients with early-stage epithelial ovarian carcinomas can be treated successfully with conservative surgery, including salpingo-oophorectomy and staging biopsy. Advanced-stage disease presents a management problem. Tumor debulking surgery is often extensive and may result in adverse pregnancy outcome. This surgery may be performed after vaginal delivery or at the same time as the cesarean section. Platinum-based chemotherapy is usually used postoperatively. Few case reports describe successful treatment of advanced ovarian cancer in pregnancy with surgery and chemotherapy.[16,21,26,34–36,92] Gonadal stromal tumors are uncommon in pregnancy. They are often confined to the ovary and have an indolent course. Treatment involves unilateral salpingo-oophorectomy.

SUMMARY OF MANAGEMENT OPTIONS
Ovarian Cancer

Management Options	Evidence Quality and Recommendation	References
Diagnosis		
Often diagnosed as a chance finding during an obstetric ultrasound examination.	III/B	80,91,92
CA-125 levels are unhelpful because they can be raised in normal pregnancy.	III/B	93,94
MRI helpful.	IV/C	89
Treatment		
Surgical exploration ideally performed in second trimester.	III/B	84–86
Pregnancy preservation and conservative surgery with unilateral salpingo-oophorectomy and staging biopsies are possible in most early-stage ovarian cancers (uncommon).	III/B	84–86
Chemotherapy, if needed, has risks (see earlier and Chapter 39).	III/B	16,21,24–32
Salvage of the pregnancy may not be possible with advanced disease.	III/B	16,21,26,34–36, 84–86,92

MRI, magnetic resonance imaging.

OTHER GYNECOLOGIC MALIGNANCIES

Vulvar carcinoma in pregnancy is extremely rare. The most common histologic varieties are invasive squamous cell carcinoma and melanoma.[102] Radical excision of the primary lesion with inguinofemoral node dissection is the treatment of choice for stage I and II tumors.[103] The timing of treatment and mode of delivery are usually dependent on the time of diagnosis during pregnancy. The current recommendation is to proceed with definitive surgical treatment before 36 weeks' gestation.[102,104,105] If wounds have healed, then cesarean is indicated only for obstetric indications.

Human papillomavirus–related intraepithelial neoplasia might be treated with laser vaporization, surgical excision, or observation. Although the use of imiquimod has been described during pregnancy,[106] the application of podophylline or imiquimod is contraindicated.

Few cases of endometrial carcinoma have been reported during pregnancy.[107–109] Surprisingly, some were associated with a viable fetus.[84,85] The remaining cases were diagnosed at the time of dilation and curettage performed for miscarriage or postpartum bleeding. This highlights the importance of evaluation of abnormal postpartum bleeding despite the protective effects of pregnancy.[110]

Management Options	Evidence Quality and Recommendation	References
Vulval Carcinoma		
Histologic varieties most commonly encountered are invasive squamous cell carcinomas and melanomas.	III/B	102–105
Radical excision of the primary lesion and inguinal femoral node dissection is the treatment of choice for stages I and II squamous cell cancer.	III/B	102–105
Timing of treatment and mode of delivery are usually dependent on the time of diagnosis during pregnancy. It has been recommended to proceed with definitive surgical treatment at any time during pregnancy up to 36 wk' gestation. Patients can be allowed to deliver vaginally, provided the wounds have healed.	III/B	102–105
Endometrial Carcinoma		
Endometrial cancers rarely occur during pregnancy. Surprisingly, 30% were associated with a viable fetus. The remaining cases were diagnosed at the time of dilation and curettage performed for irregular bleeding.	III/B	107–110

BREAST CANCER

Pregnancy-associated breast cancer is usually defined as carcinoma that is diagnosed during pregnancy or within 1 year postpartum.[111,112] It is second only to cervical cancer as one of the most common types of pregnancy-associated cancers.[37] Approximately 15% of breast cancers occur in women of childbearing age and 3% of breast cancers occur in pregnancy. The incidence is approximately 10 to 40 per 100,000 pregnancies.[37,113] Pregnancy-associated breast cancer usually presents as advanced disease; the largest proportion of stages II to IV breast cancers are reported among women diagnosed during pregnancy or less than 2 years postpartum.[114] Between 53% and 74% of pregnant women who are diagnosed with breast cancer have evidence of lymph node metastases. A delay in diagnosis has been reported as a potential cause for the advance stage at diagnosis. The estimated delay in the diagnosis of breast during pregnancy is between 1 and 6 months or more.[111] Physiologic changes that affect the breast during gestation make clinical examination difficult and inaccurate. In addition, physicians may be reluctant to perform breast biopsy during pregnancy and lactation because of the increased risk of bleeding, infection, and milk fistulas. Traditionally, it was believed that pregnancy adversely affected the outcome of patients with breast cancer. Earlier reports had shown poor survival in women with pregnancy-associated breast cancer.[115–118] In at least one series, pregnancy was found to be an independent adverse prognostic factor in multivariate analysis; however, it is unclear whether delay in treatment may have contributed to the poorer survival.[115] In contrast, there are data that show identical survival rates in pregnant women and nonpregnant cohorts when matched for disease stage.[5,72,119–121] The 5-year survival rate for pregnant women with stage I disease have been reported to be 90%.[122] In an analysis of selected studies,

an expert panel concluded that the worse prognosis in pregnant women with breast cancer is probably caused by the advanced stages of the cancer at diagnosis or a less standardized therapy.[123]

Management Options

Pregnant women should have a baseline breast examination at the first prenatal visit. Diagnostic mammography can be performed safely during pregnancy when clinically indicated; however, it should not be done routinely because of concern about fetal irradiation. A bilateral mammogram performed with modern equipment yields less than 500 µGy to the human embryo, which is well below the 100-mGy toxic level.[7] The mammogram may have limited diagnostic utility because of the hyperemia and edema that affect the mammary tissues and contribute to the generalized radiographic density of the breasts. Mammography is one of the most intensely studied imaging procedures during pregnancy and the only imaging procedure to rule out microcalcifications and should be used if it is necessary.[123] Ultrasound is accurate in differentiating between cystic and solid masses. The detection of a mass necessitates prompt evaluation with fine-needle aspiration or surgical biopsy. An experienced cytologist should evaluate the cells obtained from aspirates because hyperproliferative physiologic changes in the mammary tissue may be mistaken for malignancy. Because atypical cytomorphologic findings are encountered during gestation and lactation, some authors describe a core biopsy as a more sensitive and specific method for evaluating a suspicious, palpable mass.[124] The increased risk of complications associated with breast biopsy during pregnancy should not deter the surgeon from performing these procedures when clinically indicated.[111]

As in the nonpregnant patient, staging of breast cancer during pregnancy involves a complete physical examination, blood testing, and chest x-ray with abdominal shielding. Evaluation of the liver can be safely performed using ultrasound.[125] A radionuclide bone scan can cause significant fetal exposure to radiation. Because of lower yield in early-stage disease, bone scans should be limited to patients with more advanced disease. Magnetic resonance imaging (MRI) during pregnancy is generally considered safe for the mother and fetus; it is being used with increasing frequency to diagnose bone, liver, and brain metastases. MRI has been used to evaluate many obstetric and fetal conditions without any evidence of harmful effects.[126] One advantage of this imaging modality is its avoidance of exposure of the fetus to ionizing radiation. However, gadolinium is known to cross the placenta and was associated with fetal abnormalities in animal models, especially during the first trimester.[127]

Mastectomy with axillary lymph node dissection has been the most common breast surgery for stages I, II and some stage III breast cancers when the patient wants to continue the pregnancy.[128,129] A major advantage of mastectomy is the elimination of the need for breast radiation therapy. The indications for axillary lymph node dissection are similar in the pregnant and the nonpregnant patients with breast cancer. Lumpectomy with axillary lymph node dissection is feasible and safe in pregnant woman with breast cancer[130,131] and is reported to have no adverse impact on locoregional recurrence rates.[132] Owing to the reduction in short- as well as long-term morbidity, there has an increasing interest in sentinel node biopsy. The use of radiocolloid injections during sentinel node localization procedures does not appear to significantly increase the risk of prenatal death, fetal malformation, or mental impairment.[133] A recent review of a prospectively collected database revealed that sentinel lymph node biopsy could be performed safely during pregnancy.[113] Sixty percent of the population had combined sentinel node localization procedures (technetium-99m and blue dye) with 90% achieving successful pregnancy and delivery. The most common reported reason for unsuccessful pregnancy was first-trimester voluntary termination of pregnancy.[113] Alternatively, blue-staining alone can be used and appears to be of little risk to the fetus. More data are needed regarding the use of sentinel node biopsy as a standard in pregnant women with localized disease.[134]

The standard breast radiation therapy course of approximately 5000 cGy exposes the fetus to a radiation dose that varies according to gestational age and the associated anatomic changes. Early in pregnancy, when the uterus is still in the pelvis, fetal exposure may be as low as 10 cGy. However, in late pregnancy, when the fetus moves up into the mother's abdomen, fetal exposure can reach 200 cGy. Conversely, for some women diagnosed with early breast cancer in the third trimester, delaying treatment until after parturition is an acceptable option with minimal maternal risks and obvious fetal benefit.[135,136]

Adjuvant chemotherapy is indicated in patients with specific high risk factors including those with lymph node metastases. During organogenesis in the first trimester, the risks of teratogenicity and fetal malformation should be weighed carefully against the potential benefits. Chemotherapy administration during the second and third trimesters appears to be feasible. Many agents with known activity

in breast cancer have been safely administered during pregnancy for the treatment of other cancers.[137–140] However, some agents may offer a potentially excessive risk of fetal toxicity.[141,142] Antimicrotubule agents paclitaxel, docetaxel, and vinorelbine display a high activity against breast cancer and have a favorable toxicity profile when administered during pregnancy.[36] The transplacental transfer of chemotherapy agents varies greatly, and it is commonly recommended that chemotherapy administration be discontinued 3 weeks preceding delivery.[36] Chemotherapy during pregnancy may also result in maternal complications, including sepsis and hemorrhage, with unplanned labor and delivery.

Breast cancer in young patients (≤35 yr) overexpress HER-2 in up to 35% of cases.[143] The HER-2 targeting agent trastuzumab has been used for the treatment of advanced breast cancer in pregnant patients. Although assigned a category B pregnancy risk on the basis of trials in monkeys, fetal effects vary based on gestational age and length of exposure. Its use has been associated with uteroplacental complications.[144] Lapatinib, a tyrosine kinase inhibitor, has been reported in only one patient who unexpectedly became pregnant during a phase I trial. There were no reported adverse events during the pregnancy or delivery.[145] Hormonal therapy with tamoxifen is contraindicated during pregnancy because of its teratogenic effect and the risk of severe fetal malformations.[146] There are no published reports of the use of aromatase inhibitors for the treatment of breast cancer during pregnancy. Animal studies have reported that aromatase is needed during embryo and fetal development. The inhibition of aromatase during the prenatal period may interfere with the development of fetal gonadocytes and sexual differentiation of the brain and significantly impair the pregnancy outcome.[147,148] Advanced-stage disease requires both chemotherapy and radiation therapy. The prognosis is poor, and maternal survival is limited. Management of these patients during pregnancy presents ethical and medical dilemmas and should be planned on an individual basis.

Published literature does not support the routine recommendation of therapeutic abortion in pregnant patients with breast cancer.[111,149] Many authors showed that survival is not improved by pregnancy termination for maternal indications.[150–152] In some cases, therapeutic abortion may be strongly recommended because of potential fetal damage from the proposed chemotherapy or radiation treatments. In early pregnancy, treatment is greatly simplified with therapeutic abortion.[111] Subsequent pregnancy in women who have been treated for breast cancer does not seem to confer a worse prognosis than that in patients who did not become pregnant. Interestingly, few population-based studies have shown that a subsequent pregnancy results in an improvement in survival, with favorable relative risks of 0.2 (range 0.1–0.5)[112] to 0.8 (range 0.3–2.3).[135,136] However, it is difficult to draw definite conclusions from available studies because of the small number of patients reported and the associated selection bias. Because recurrence is most likely to occur in the first 2 years, most investigators recommend delaying conception for 2 to 3 years after treatment. A recent publication has even suggested that premenopausal women with localized disease and good prognosis are unlikely to have a reduced survival if conception is delayed only 6 months after treatment.[153]

SUMMARY OF MANAGEMENT OPTIONS
Breast Cancer and Pregnancy

Management Options	Evidence Quality and Recommendation	References
Diagnosis		
Physiologic changes of pregnancy reduce the sensitivity of physical examination and mammography.	IV/C	111,123
Fine-needle aspiration of any suspicious lesion.	IV/C	111,124
Open biopsy if the results of needle biopsy are equivocal.	IV/C	111,124
Treatment		
Mastectomy with lymph node dissection is the preferred treatment for early cancers. Indications for lymph node dissection are similar in the pregnant and the nonpregnant patients.	III/B	129
Sentinal node localization procedures appear safe during pregnancy.	III/B	113,133,134
Adjuvant chemotherapy may be indicated for some patients with high risk cancers. Both maternal benefits and potential risks to the fetus should be weighed carefully.	III,IV/B,C	111,129
If diagnosis is made late in pregnancy and chemotherapy or radiation treatment is indicated, consider delaying therapy until after delivery.	IIb/B	128,135,136
Routine therapeutic abortions are not indicated.	III/B	111,122,149
Termination of pregnancy may be considered in patients with advanced disease if chemotherapy and/or radiation treatment is indicated in early pregnancy.	IIa/B	136
Recommend delaying conception for 2–3 yr after treatment.	IIa/B	111,136,153

PLACENTAL METASTASES

Metastasis of maternal malignancy into the placenta is rare and poorly understood. Malignant melanoma is the most common maternal malignancy associated with placental metastasis; it accounts for nearly one third of reported cases.[151,154] Next in frequency are hematopoietic malignancies and breast carcinoma.[151,155,156] Fetal metastasis is extremely rare, even when the maternal surface of the placenta contains evidence of metastatic tumor. The low incidence of fetal metastasis has been attributed to two factors: inherent resistance of the trophoblast to tumor invasion and possible immune rejection by the fetal immune system.[155] Interestingly, after delivery, some infants with metastatic melanoma have complete tumor regression and long-term survival. Comprehensive understanding of maternal cancers with metastasis to the placenta or fetus would benefit from a registry of malignancies associated with pregnancy.[156,157]

Pregnancy after Transplantation

VINCENT T. ARMENTI, MICHAEL J. MORITZ, and JOHN M. DAVISON

INTRODUCTION

Transplantation is now an accepted therapeutic option for patients with end-stage organ failure. The first successful human kidney transplant took place in 1954.[1] However, it was not until the 1960s that immunosuppression became available and not until the 1980s, with the introduction of cyclosporine, that consistently acceptable graft and patient survival was achieved. With the restoration of organ function, patients experience an overall improvement in their health, increased libido, and return of fertility.

The first post-transplant pregnancy occurred in March 1958 and was reported in 1963.[2] It occurred in a patient who had received a kidney from her identical twin.[2] This pregnancy resulted in cesarean delivery of a healthy boy. As transplantation has progressed, with improvements in surgical techniques and medical therapy and advances in immunosuppression, pregnancies have been reported in recipients of each organ type. Most outcomes reported are in kidney transplant recipients. Issues that must be considered include maternal graft function and maternal health, the effect of pregnancy on graft function, and the effect of the medications and graft function on the developing fetus. There is also concern about the long-term effects of pregnancy on graft function. Finally, there is the question of whether more subtle and long-term effects, although not apparent at birth, might affect the growth and development of the offspring of these recipients or future generations.

ORGAN TRANSPLANTATION

Patients with end-stage renal disease who are receiving or will soon need dialysis are candidates for renal transplantation. Common indications for renal transplantation are glomerulonephritis, diabetes, polycystic kidney disease, and hypertension. In 2008, in the United States, 16,514 kidney transplants were performed.[3] The 1-year graft survival rate was 90% for deceased donor kidneys and 98% for living donor kidneys.[4] Recent technical advances that allow laparoscopic removal of living donor kidneys have helped to make living donation more acceptable, removing disincentives.[5] Standard requirements for donor-recipient pairs for kidney transplantation are ABO compatibility and a negative pretransplant cross-match (i.e., absence of preformed antidonor antibodies). Efforts to increase the number of kidney transplants include the use of methods to use ABO-incompatible donor treatment protocols to alter antidonor antibodies and exchange programs.

Patients with type 1 diabetes and concomitant end-stage renal disease are candidates for simultaneous kidney-pancreas transplantation. These patients may opt for a kidney transplant first, especially if they have a living donor, and later undergo a pancreas transplant. In 2008, there were 836 pancreas-kidney transplants performed in the United States,[3] with a 1-year graft survival rate of 95% for simultaneous pancreas-kidney allografts.[4]

Patients with end-stage liver disease are candidates for liver transplantation. The first successful human liver transplant was performed in 1967.[1] Of candidates for liver transplantation, 95% have chronic liver disease (i.e., cirrhosis) and 5% have fulminant hepatic failure, a disorder that progresses rapidly. Chronic diseases that require transplantation include cirrhosis as a result of hepatitis C, hepatitis B, alcohol use, biliary cirrhosis, and primary sclerosing cholangitis. In children, the most common cause of liver failure is biliary atresia. Complications of end-stage liver disease that suggest the need for transplantation include ascites, encephalopathy, and bleeding as a result of esophageal varices. In 2008, in the United States,[3] 6318 liver transplants were performed, with a 1-year graft survival rate of 88% for deceased donor liver transplantation.[4] Living donation, in which part of an adult liver is donated, is now an option for both adult and pediatric recipients; 249 living related liver transplants were performed in the United States in 2008.[3]

Cardiomyopathy and coronary artery disease are the most common indications for heart transplantation. Peripartum cardiomyopathy is a rare indication for heart transplantation. On average, these adults are older than patients in other organ groups, which is likely part of the reason why fewer pregnancies have been reported. In the United States, 2163 heart transplants were performed in 2008,[3] with a 1-year graft survival rate of 85%.[4] Fewer heart-lung and liver-kidney transplants are performed, and few pregnancies have been reported in these recipients.

Patients with end-stage lung disease and an anticipated survival of less than 2 years without transplantation

are candidates for lung transplantation. Three common indications are emphysema or chronic obstructive pulmonary disease, including α_1-antitrypsin deficiency, primary pulmonary hypertension, and cystic fibrosis. The 1-year graft survival rate is lower than the groups discussed, at 76%,[4] with 1478 transplants performed in the United States in 2008.[3] Living donation has been an option, although none were performed in the United States in 2008 and the number has declined over the last several years.

The majority of patients who receive an intestinal transplant (70%) have had the diagnosis of short gut syndrome. This type of transplant may be performed in conjunction with a liver in up to 71% of the cases.[4] In 2008, 185 transplants were performed with a 1-year graft survival rate of 73%.[3,4]

SUCCESS OF TRANSPLANTATION

Medication regimens to maintain graft survival and prevent rejection have been evolving since the 1960s. In general, these can be divided into the following three categories:

- Induction regimens are used in the first week after transplantation. These include agents such as antilymphocyte sera and interleukin-2–receptor blockade antibodies.
- Antirejection regimens are used to treat episodes of rejection. They typically include high-dose, short-term treatments with either corticosteroids or antilymphocyte sera.
- Maintenance regimens are initiated soon after transplantation to prevent acute rejection episodes and provide long-term immunosuppression. The goal of this treatment is to minimize acute rejection episodes and toxicity. Combination therapies are used to balance benefits against side effects and toxicities.

A major goal of therapy is to avoid acute rejection episodes, which affect graft survival. Different organs show different effects of acute rejection, but the result can be chronic rejection, which has no effective treatment and ultimately leads to graft loss.

Maintenance regimens in the early 1960s included azathioprine and prednisone. In the 1980s, the mainstay of immunosuppression was cyclosporine, either in combination with azathioprine and prednisone or with prednisone alone. Tacrolimus (Prograf), introduced in the 1990s, has a mechanism very similar to that of cyclosporine, but is more potent and with different side effects. Mycophenolate mofetil (CellCept, MMF) was introduced in the mid-1990s. A few years later, mycophenolic acid (Myfortic, MPA), an enteric-coated capsule with less gastrointestinal side effects than MMF, was introduced. These agents have essentially replaced azathioprine and, in most cases, are used as an adjunct. Sirolimus was introduced in 2000 and has a different mechanism of action and the added advantage of not being nephrotoxic. In standard combination regimens, two drugs of the same class are not used together (e.g., cyclosporine and tacrolimus). Table 53–1 summarizes the current agents and their mechanisms of action and side effects, including agents used for induction and rejection.[6] The U.S. Food and Drug Administration (FDA) categories for these drugs are shown in Table 53–2, including information on published reproductive or clinical outcome data.[7]

RISKS OF TRANSPLANTATION

Immunosuppressive Agents and Teratology

Corticosteroids

In animal studies, corticosteroids have caused cleft palate, although this has not been seen in humans.[8] Clinically, these agents are associated with an increased risk of premature rupture of the membranes and adrenal insufficiency in newborns.[9] Prednisone has been used for more than 45 years for maintenance therapy, and intravenous methylprednisolone is used for induction and treatment of rejection. At current doses, it is considered an adjunctive drug. More recently, given the many side effects, steroid withdrawal and steroid avoidance regimens have become common.

Azathioprine

Azathioprine (1.5–3 mg/kg/day), a primary drug used for immunosuppression before the introduction of cyclosporine, is now an adjunctive agent at doses of 0.5 to 1.5 mg/kg/day. Clinical data do not support early concerns about teratogenicity in animal studies, nor has a predominant structural malformation pattern been identified. It is listed as a category D agent, and reviews show occasional attributable newborn problems, including thymic atrophy, leukopenia, anemia, thrombocytopenia, chromosomal aberrations, sepsis, and reduced immunoglobulin levels.[10,11]

Cyclosporine

As the first calcineurin inhibitor, cyclosporine became the mainstay of immunosuppression and remains a commonly used agent. Cyclosporine was originally available as Sandimmune, which was later reformulated as Neoral. The two formulations are not bioequivalent and should not be interchanged. Generic versions are available. It is usually used with one or two adjunctive agents. Maternal problems include hypertension and nephrotoxicity. Although fetal toxicity and abnormality were reported in animal studies, these occurred at dosages higher than those used clinically.[12,13] Some early clinical reports suggested a greater risk of fetal growth restriction, not borne out by later studies.[14] The magnitude of teratogenic risk appears minimal, and no predominant pattern of newborn malformations is evident.

Tacrolimus (Prograf)

Tacrolimus, approved for use in the United States in 1995, is more potent than cyclosporine. In animal studies, fetal resorption occurred at doses higher than those used clinically.[15] Transient neonatal hyperkalemia has been reported,[16] as has a higher incidence of maternal diabetes. Tacrolimus is usually used with an adjunctive agent.

Mycophenolate Mofetil/Mycophenolic Acid

The mycophenolate drugs, first approved for use in 1995, are typically used in combination with a calcineurin inhibitor. In contrast to the calcineurin inhibitors, there is greater concern about the potential risk of teratogenicity with MMF/MPA, based on reproductive toxicity studies in animals. Developmental toxicity in rats and rabbits included malformations and intrauterine growth restriction. Death occurred at dosages that appeared to be within the recommended clinical dosages based on body surface area.[17,18]

TABLE 53–1
Immunosuppressive Drugs

DRUG	USES	EFFECTS	SIDE EFFECTS	COMMENTS
Cyclosporine (Sandimmune, others), cyclosporine modified, USP (Neoral, Gengraf)	Maintenance	Inhibitor of helper T-cell function	Nephrotoxicity, hypertension, tremor, hirsutism	Relatively selective for alloimmune responses; synergistic nephrotoxicity with tacrolimus
Tacrolimus (Prograf)	Maintenance	Inhibitor of helper T-cell function	Nephrotoxicity, neurotoxicity, diabetes	
Corticosteroids (oral prednisone, IV methylprednisolone)	Maintenance, antirejection, induction	Inhibits all leukocytes; high doses cause lymphocytolysis	Cushingoid facies, diabetes, excessive weight gain, aseptic necrosis of joints	Many troublesome side effects; nonspecific immunosuppressant
Azathioprine	Maintenance	Inhibits clonal proliferation of T cells	Leukopenia	Nonspecific
Antithymocyte globulin, antilymphocyte globulin	Antirejection, induction	Depletes T cells	Fevers, chills	Polyclonal serum made in rabbits, horses; Maximum duration of therapy 2 wk
Mycophenolate mofetil (CellCept)	Maintenance	Inhibits lymphocyte proliferation	Diarrhea, leukopenia	More lymphocyte-selective than azathioprine
Mycophenolic acid (Myfortic)	Maintenance	Inhibits lymphocyte proliferation	Leukopenia	More lymphocyte-selective than azathioprine
Sirolimus (Rapamune)	Maintenance	Inhibits helper T cells	Anemia, thrombocytopenia, hyperlipidemia	Site of action distinct from other drugs
Basiliximab (Simulect)	Induction	Inhibits interleukin-2–mediated activation of lymphocytes	Possible anaphylactoid reaction	Immunosuppressive chimeric monoclonal antibody
Daclizumab (Zenapax)	Induction	Inhibits interleukin-2–mediated activation of lymphocytes		Chimeric humanized monoclonal antibody
Muromonab-CD3 (OKT3)	Antirejection, induction	Disables or depletes all T cells	First dose can cause fever, chills, or bronchospasm as a result of cytokine release	Murine monoclonal, maximum duration of therapy 2 wk

Liveborn with birth defects (N)	5*	1*	0	2
Incidence of birth defects (%)	19	20	0	40

* Includes one neonatal death.

From Coscia LA, Constantinescu S, Moritz MJ, et al: Report from the National Transplantation Pregnancy Registry (NTPR): Outcomes of pregnancy after transplantation. In Cecka JM, Terasaki PI (eds): Clinical Transplants 2008. Los Angeles, UCLA Terasaki Foundation Laboratory, 2009, pp 89–105.

Clinical data have demonstrated a particular pattern of malformation noted in the National Transplantation Pregnancy Registry (NTPR) database, with additional reports of problems in newborns with exposure to MMF.[19–31] In 2007, the package inserts of MMF and MPA included a change from pregnancy category C to category D.[17,18] These package inserts state that females of childbearing potential must use contraception while taking MMF or MPA, because use during pregnancy is associated with increased rates of pregnancy loss and congenital malformations. This is also the recommendation of the European Best Practice Guidelines.[32] In addition to the NTPR data, in postmarketing data collected by Roche Laboratories, Inc., between 1995 and 2007, among the 77 women exposed to systemic MMF during pregnancy, 25 had spontaneous abortions and 14 had a malformed infant or fetus. Six of these 14 had ear abnormalities. Table 53–3 lists the structural birth defects in transplant recipient offspring with exposure to MMF during pregnancy.[33] Women using MMF or MPA at any time during pregnancy are encouraged to enroll in the NTPR.

Sirolimus

Sirolimus, approved for use in the United States in 1999, is an antiproliferative agent of its own class. It is used in combination with cyclosporine or tacrolimus or with prednisone alone (European and U.S. labeling). There are concerns about its use in pregnancy. Teratogenicity has not been noted in animal studies, although decreased fetal weight and delayed ossification have been reported.[34] When it was used with cyclosporine in pregnant animals, resorption and fetal mortality rates were increased, suggesting increased toxicity; however, there are insufficient data on clinical outcome.[19,35–37] Data remain limited with regard to sirolimus exposure during pregnancy.

Other agents used for short-term induction or rejection have a minor role in pregnancy. In a small series of patients, muromonab-CD3 (OKT3)[7] and corticosteroids were used for rejection in pregnancy (discussed later).

Maternal Risks

Transplant recipients have varying degrees of post-transplant recovery. One difficulty in assessing pregnancy risk in this population overall is that many of the conclusions have been derived only from experience in kidney transplant recipients. In 1976, a management plan was suggested in a detailed case report of a renal transplant recipient during pregnancy.[38] Based on this information and a survey of literature at the time, the following criteria were derived for counseling renal recipients who are contemplating pregnancy:

- Good general health for at least 2 years after the transplant.
- Stature compatible with good obstetric outcome.
- No proteinuria.
- No significant hypertension.
- No evidence of renal rejection.
- No evidence of renal obstruction on excretory urogram or ultrasound.
- Stable renal function.
- Stable immunosuppressive therapy.

Most of these guidelines still apply, although recipients can safely become pregnant sooner than 2 years post-transplant.[39] Drug-treated hypertension is now much more prevalent.[40] It has been more difficult to identify criteria for recipients of other organs, but good, stable graft function would seem to be essential for pregnancy to be well tolerated. The appropriate interval after transplant and the features of good, stable graft function for each group of organ recipients are harder to define. For renal recipients, graft function can be assessed by measuring the serum creatinine level or creatinine clearance. Studies in both clinical and animal models in the nontransplant population have assessed the effect of pregnancy on renal function. Renal function is unaffected if the kidney is stable.[41] In the transplant population, this finding is supported by well-designed case-control studies showing that pregnancy does not cause deterioration of graft function when prepregnancy graft function is stable.[42–46] Factors that must be considered in nonrenal recipients are the nephrotoxic effect of calcineurin inhibitors on native kidney function and the increased likelihood of hypertension. Thus, nonrenal recipients who receive calcineurin inhibitor therapy often have baseline renal impairment.

These guidelines have been revised and published as Consensus Guidelines through the American Society of Transplantation (AST).[39] The European Best Practice Guidelines[32] are also available for clinicians.

Literature surveys from the azathioprine era of the 1970s and 1980s attest to thousands of successful post-transplant pregnancies in renal transplant recipients. The spontaneous abortion rate was approximately 14%, and the therapeutic abortion rate was approximately 20%. Of pregnancies that continued beyond the first trimester, more than 90% were successful. Renal impairment occurred in approximately 15% of women, and hypertension complicated approximately 30% of pregnancies. Preterm delivery was common, affecting 45% to 60% of pregnancies, with fetal growth restriction occurring in approximately 20%.[47,48]

Initial reports of cyclosporine exposure during pregnancy raised concern because a higher rate of fetal growth restriction, which may have been related to higher doses, was

Estimates based on literature from 1991 to 2007, with all pregnancies attaining at least 24 wk' gestation (unpublished data from Dr. John Davison).

noted.[14] Also apparent was a higher incidence of hypertension than was previously noted in the azathioprine era.[40] With the advent of cyclosporine, it was suggested that this drug might not be optimal for use in pregnancy and that patients should be switched back to azathioprine-based regimens because of the longer experience with these drugs. Given the need to provide more consistent and effective surveillance for the transplant community, the NTPR was established in 1991 with the goal of maintaining an ongoing database to assess the safety of pregnancy in female transplant recipients as well as pregnancies fathered by male transplant recipients.[33,49] A pregnancy registry was established in the United Kingdom in 1997[50] but discontinued in 2002, although there has been an updated publication reporting the pregnancy outcomes in the United Kingdom.[51] This report depicts outcomes similar to those of the NTPR.

After the introduction of cyclosporine, case and individual transplant center reports and registry data reported successful pregnancies in female transplant recipients while highlighting potential risks to mothers and newborns. Most conclusions came from data on renal recipients, but information is accruing from other organ recipients, with differences evident among the groups.

Overall, compared with the general population, female transplant recipients are at greater risk for preeclampsia and hypertension during pregnancy. A higher percentage of cesarean deliveries are reported as well. The balance between graft function and management of immunosuppression during pregnancy is crucial. Fortunately, in organ recipients, the incidence of rejection during pregnancy does not appear to be higher than that in the nonpregnant population, and similarly, graft loss within 2 years of delivery does not appear to be affected by pregnancy. When irreversible and unpredictable graft events occur, they more often happen in patients with impaired prepregnancy graft function. Many recipients have had successful successive pregnancies, and some have had successful outcomes with multiple gestations and in vitro fertilization.[52–55] An overview of the literature in renal transplant recipients is summarized in Table 53–4.

Current data for each organ recipient group reported to the NTPR are summarized in Tables 53–5 to 53–9.[33] High incidences of preterm delivery and low birth weight are reported and are more apparent among pancreas-kidney recipients and less apparent in liver and heart recipients. Pancreas-kidney recipients usually tolerate pregnancy without gestational diabetes. Most infectious complications

involve the urinary tract. Rejection during pregnancy is associated with poorer outcomes for the newborn and for graft survival (Tables 53–10 and 53–11). Rejection should be biopsy-proven, if possible; treatment is with steroids, antilymphocyte sera, or adjustment of baseline immunosuppression.

Fetal Risks

Two large reports on the two primary calcineurin inhibitors, cyclosporine and tacrolimus, examined the overall prevalence of malformations in newborns. In the offspring of cyclosporine-treated recipients, the malformation rate was 4.1% (14 of 339 births), based on a meta-analysis.[56] NTPR data on the offspring of cyclosporine-treated liver or kidney recipients showed malformations in 3% to 5% of a total of 425 liveborn infants.[57] The types of malformations varied among different systems, with no predominant type noted. In a report of patients treated with tacrolimus during pregnancy (84 women, 100 pregnancies), 4 of 71 liveborn infants analyzed (5.6%) had evidence of structural malformations, but no specific pattern was evident.[58] Transplant recipients, on average, delivered 1 month early, with birth weights of 2160 to 2600 g reported. Differences were seen among organ recipient groups. Genetic considerations must be taken into account. They may contribute to organ failure in

the mother and must be considered in the assessment of risk to the newborn. Table 53–12 summarizes the incidence of malformations reported to the NTPR in transplant recipients receiving the newer immunosuppressants, but prior to reports of additional birth defects with MMF.[59] Of additional concern is the potential for more subtle effects that may not be apparent at birth, but may affect long-term growth and development as well as in the next generation.[60] Clinical reports noted that children of recipients are developing well, although there is concern that alterations in T-cell subpopulations may affect vaccinations or long-term immunity.[61,62] A large series of 175 newborns of cyclosporine-treated kidney recipients reported to the NTPR showed no evidence of an increased incidence of developmental delays over that expected, given the high percentage of premature offspring in this group.[63]

Childhood transplant recipients who subsequently become pregnant in adulthood are of increasing relevance (Table 53–13).[64] The risk of malformations in newborns of these patients is not increased, but a small percentage of recipients have graft rejection, dysfunction, or even loss within 2 years of delivery. Consistent features of obstetric outcomes are higher incidences of prematurity and low birth weight, depending on the type of organ transplant.

These rates are always higher than in the general population.

MANAGEMENT OPTIONS

Prepregnancy and Prenatal

Recommendations for the management of pregnancy after transplantation have been published.[65–83] Transplantation restores fertility, and patients must be advised about appropriate birth control. For all organ recipients, an interval from transplant to conception is advisable to allow establishment of stable graft function and reduction of immunosuppression to maintenance levels, with concomitant reduction of the risk of more serious post-transplant infections. NTPR data showed a higher incidence of pregnancy termination and peripartum rejection with transplant-to-conception intervals of less than 6 months compared with longer intervals in cyclosporine-treated kidney recipients. Waiting at least 6 months, and preferably 1 year, from transplant seems advisable.[39,82,83] It is important to note whether the recipient has been rejection-free (and for how long) as well as the level and stability of graft function.

The potential teratogenicity of MMF/MPA amplifies the dilemma between protecting the transplanted organ from rejection versus fetal risk. The risk to the fetus of a kidney recipient from MMF/MPA of a significant malformation is based on a small experience with varying other immunosuppressants and comorbidities. It is not currently known to what degree this risk is generalizable to other organ

recipients. Conversely, the benefit of a lower risk of rejection to the recipient of a regimen including MMF/MPA varies by organ, other immunosuppressants in the regimen, recipient factors, and so on. Further, there are no data available on the risks of switching patients to alternative regimens that have a presumed lower risk of malformations of the newborn. Currently, the most popular regimens at the time of hospital discharge for kidney recipients are cyclosporine or tacrolimus plus MMF/MPA, with or without prednisone. Thus, for each recipient contemplating pregnancy, an individual decision must be made. One must weigh the risks to the transplanted organ of switching immunosuppressants, because organ function directly affects fertility and the ability to safely carry a pregnancy. This must be weighed against the risk of continuing the prepregnancy immunosuppressive regimen, which could harm the fetus. At this time, such decisions are best made preconception with the involvement of the patient, her partner, and the transplant team.

A significant percentage of recipients have hypertension and may be receiving a combination of antihypertensive medications. Angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists are contraindicated during pregnancy, although some controversy exists with regard to the timing of greatest exposure risk.[39,84] If dosage adjustments or changes to hypertensive agents are needed, these changes can be made in anticipation of pregnancy. In addition to hypertension and preeclampsia, attention should be focused on other comorbid conditions that are likely to occur, including infections and gestational diabetes.

Rejection, although not common, must be considered in the face of graft dysfunction. The etiology of graft dysfunction in any solid organ recipient must be investigated. There are special clinical considerations for each organ group. In the renal transplant group, the group with the most data, the usual pattern for the serum creatinine level is a slight decrease in early pregnancy, with a return to baseline postpartum. Increases during pregnancy and postpartum should be evaluated. Pancreas-kidney recipients usually can tolerate pregnancy without problems with glucose control, but additional comorbid conditions caused by cardiovascular disease must be considered. Lung recipients appear to have a higher

incidence of peripartum problems in terms of both graft function and patient survival.

Infectious complications during pregnancy are most often urinary tract infections; therefore, monthly urine culture should be performed. Occasionally, more serious yeast infections, pneumonia, sepsis, or unspecified viral infections complicate pregnancy. Cytomegalovirus is usually asymptomatic and is detected by serologic, antigen, or viral monitoring. If a primary infection occurs during pregnancy, there is a risk of transmission with fetal sequelae, but the effectiveness of treating the mother's infection in preventing or ameliorating fetal sequelae is uncertain.

The rate of hepatitis C transmission from mother to child in the nontransplant population is 5%.[85] Recipients with acute hepatitis B infection may transmit it to their offspring. Administration of hepatitis B immune globulin and hepatitis B virus vaccine to the newborn within a few hours of birth usually prevents transmission. Estimates of the incidence of acute infection with toxoplasmosis are 0.2% to 1%, with most cases undiagnosed and asymptomatic. Congenital toxoplasmosis can have severe consequences, and the diagnosis is dependent on culture, direct antigen detection, or serologic tests.[86]

Scrutiny for hypertensive changes and preeclampsia is essential, although the diagnosis of preeclampsia may be difficult because serum uric acid levels and urinary protein excretion may be well above expected normal ranges without preeclampsia, as a result of drug nephrotoxicity or the renal allograft. Other complications include HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome, ureteral obstruction, and complications of cesarean delivery. Peripartum ultrasound assessment to exclude urinary obstruction is warranted if the serum creatinine level increases.

Unless obvious immunosuppressive toxicity or rejection occurs, it is best to maintain baseline immunosuppressive dosing. Blood concentrations are likely to decrease during pregnancy, given the increased maternal volume of distribution as well as fetal metabolism of drugs. Some recipients are noncompliant, choosing to stop taking medications during pregnancy for fear that the medication will harm the fetus. Reports to the registry show that, in most pregnancies, immunosuppressive doses have been kept the same or increased during pregnancy. Regardless of dosing during pregnancy, many changes that occur peripartum mandate that postpartum immunosuppressive dosing should be directed by blood level, when possible.

Significant unexplained deterioration in graft function should be assessed with biopsy. For heart recipients to avoid x-ray exposure, biopsy can be done with echocardiographic guidance.[73] If the diagnosis of acute rejection is made, appropriate antirejection treatment is necessary. Given the risk of rejection and preeclampsia, more frequent monitoring is warranted from midpregnancy onward, including blood pressure measurements, assessment of graft function, and measurement of immunosuppressive drug levels.

In liver recipients, worsening liver function with chronic rejection or hepatitis C has been noted, with further deterioration in subsequent pregnancies.[87] Whether such deterioration is time-linked or pregnancy-induced requires further study. Recipients with stable graft function have tolerated subsequent pregnancies. Data to support this observation have been noted in each recipient group but are more easily quantified among kidney recipients.

Labor and Delivery

A high incidence of cesarean section is reported in all organ recipient groups. Cesarean delivery should be performed for obstetric indications only. Immunosuppression must not be interrupted during labor and delivery.

Postnatal

Most oral maintenance agents are easily absorbed, and treatment can usually be resumed shortly after cesarean delivery. When oral treatment cannot be resumed, intravenous formulations are available for most, but not all, agents. Immunosuppressive drug levels should be monitored and dosage adjusted appropriately, which may affect blood pressure, renal function, and other toxicities. One must be aware of postpartum depression among transplant recipients, because medications may be missed or not taken; therefore, close monitoring is required for several months postpartum.

Breast-feeding is controversial. Although exposure of the newborn to an immunosuppressive drug may be detrimental, a newly emerging view is that the benefits of breast-feeding outweigh the minimal risk. Further study of potential long-term effects is needed.

SUMMARY OF MANAGEMENT OPTIONS
Pregnancy after Transplantation

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Patients should defer conception for at least 1 yr after transplantation, with adequate contraception.	IIb/B	39,47,79, 82,83,92
Assessment of graft function:	III/B	47,70,92
• Recent biopsy.	III/B	93
• Proteinuria.	III/B	93
• Hepatitis B and C status.	IV/C	69
• Cytomegalovirus, toxoplasmosis, and herpes simplex status.	IV/C	69,70

Management Options	Evidence Quality and Recommendation	References
Maintenance immunosuppression options: • Azathioprine. • Cyclosporine. • Tacrolimus. • Corticosteroids. • Mycophenolate mofetil. • Mycophenolic acid. • Sirolimus.	IV/C	7,19,33,40, 56,58,65,67, 69,73,94,95, 99
The effect of comorbid conditions (e.g., diabetes, hypertension) should be considered and their management optimized; nonrenal recipients should have their baseline kidney function assessed.	III/B	39,41,47,96
Vaccinations should be given, if needed (e.g., rubella).	IV/C	47,69
Explore the etiology of the original disease; discuss genetic issues, if relevant.	IV/C	47,97
Discuss the effect of pregnancy on renal allograft function.	IIa/B	42–47
Discuss the risks of intrauterine growth restriction, prematurity, and low birth weight.	III/B	33,40,47, 48,80
Prenatal		
Accurate early diagnosis and dating of pregnancy.	IV/C	47
Clinical and laboratory monitoring of the functional status of transplanted organs and immunosuppressive drug levels: • Every 4 wk until 32 wk. • Every 2 wk until 36 wk. • Then weekly, until delivery.	III/B	47,69,70, 73,98,100
Monthly urine culture.	IV/C	47,69,71
Surveillance for rejection, with biopsy considered if it is suspected.	III/B	47,60,69,87
Surveillance for bacterial or viral infection (e.g., cytomegalovirus, toxoplasmosis, hepatitis).	IV/C	47,69,70
Fetal surveillance.	IV/C	47,70,79
Monitoring for hypertension and nephropathy.	IV/C	40,47,69,72, 96
Surveillance for preeclampsia.	IV/C	47,70
Screening for gestational diabetes.	IV/C	47
Labor and Delivery		
Vaginal delivery is optimal; cesarean delivery is used for obstetric reasons.	IV/C	47,71
For kidney recipients, episiotomy is performed on the side opposite the allograft.	GPP	
For heart, lung, or heart-lung recipients: • Vigilance for poor or absent cough reflex and the need for airway protection. • Unpredictable response to vasoactive medications. • Judicious use of intravenous fluids.	GPP	
Postnatal		
Monitor immunosuppressive drug levels for at least 1 mo postpartum, especially if dosages were adjusted during pregnancy.	III/B	69,73,94,98

Trauma

RENEE A. BOBROWSKI

INCIDENCE AND RISKS

General

Trauma occurs in 6% to 7% of all pregnancies and is the leading cause of nonobstetric maternal death.[1,2] Nationwide in 2002, almost 17,000 pregnant women sustained an injury requiring hospitalization, with nearly half the women younger than age 25.[3] For trauma admissions not resulting in delivery, motor vehicle accidents (MVAs) were most common, followed by falls; the reverse is seen with patients requiring delivery at the time of trauma admission. Poisoning, overexertion injuries, assault, and penetrating trauma were next most frequent. MVAs occur with equal frequency across trimesters, whereas falls are most frequent between 20 and 30 weeks, and trauma secondary to abuse and interpersonal violence increases with advancing gestation.[4]

Most injuries during pregnancy are minor, but 2% to 8% of victims have a life-threatening injury and require admission to an intensive care unit.[5] Maternal mortality from trauma approximates 10%, but it is the same as nonpregnant patients when matched for injury severity.[6] Trauma places the mother and fetus at increased risk, and fetal loss occurs in at least 40% of critically injured gravidas. High injury severity and Glascow Coma scores, increasing fluid requirement during resuscitation, and maternal acidosis and hypoxia appear to predict an increase in fetal loss.[5–9] The rate of adverse pregnancy outcome, however, is approximately 4%, even when maternal injuries are minor.[10] Because 90% of all trauma in pregnant women is minor, more fetuses die as a result of lesser injuries than as a result of catastrophic trauma.

Women injured during pregnancy but not requiring delivery at the time of their injury nevertheless appear to be at increased risk for adverse outcome. An increased risk for preterm delivery, low birth weight, and abruption has been reported when injured pregnant women are followed for the duration of their pregnancy.[11–13] Several mechanisms have been proposed. Trauma may be a marker for lifestyle risks that adversely affect pregnancy outcomes. The traumatic event may also result in uteroplacental injury causing uteroplacental insufficiency and/or chronic abruption.[11,12] Thus, ongoing surveillance for the remainder of the pregnancy has been suggested by several authors.[11,12]

The obstetrician must be prepared to work in concert with the trauma team to evaluate and treat an injured pregnant woman (Fig. 54–1). The presence of a fetus may be extremely unnerving to even the most experienced emergency team, and obstetric consultation can be invaluable. Simulation training is ideal for low-frequency, high-acuity events occurring in medicine. Simulated scenarios provide a great opportunity for obstetric and trauma personnel to develop protocols for obstetric trauma and improve communication and teamwork under noncritical circumstances. Simulation as a training tool in medicine provides many opportunities to improve provider knowledge and skills, refine clinical protocols, educate staff and students, and ultimately, improve patient care. The most important component of simulation training, however, is postscenario debriefing to allow participants discuss, analyze, and synthesize their actions.

The basic principles of trauma management apply to injured pregnant women, and maternal resuscitation is the first priority under all circumstances. It is imperative to understand the physiologic changes of pregnancy and the implications for managing gravid trauma patients. Among the many physiologic changes that occur during pregnancy, some assume greater importance in trauma. Understanding a pregnant woman's response to injury will facilitate her care from the moment of arrival in the emergency department. Table 54–1 outlines changes pertinent to the care of gravid trauma victims and their clinical implications. Once the maternal condition is stable, diagnostic evaluation, fetal assessment, and treatment can proceed.

MANAGEMENT OPTIONS—GENERAL

Prehospital Care

Most emergency medical services (EMS) personnel find their anxiety increases upon arrival at the scene of an injured pregnant woman. Thus, familiarity with prehospital procedures is beneficial for hospital staff in providing guidance to those at the scene. EMS should follow standard Advance Trauma Life Support (ATLS) protocols for extrication and spinal immobilization.

A left lateral tilt of 15 degrees should be performed for all women greater than 20 weeks' gestation. If a spine injury is suspected or documented, a rolled towel or blanket can be placed beneath the spine board at the level of the hips without risking neurologic compromise. If a patient in the

TABLE 54–1

Clinical Implications of the Physiologic Changes of Pregnancy in the Patient with Traumatic Injury

PHYSIOLOGIC CHANGE	CLINICAL IMPLICATION
Blood volume increases 50%.	Clinical signs of hypovolemia may not occur until 1500–2000 mL blood loss.
	Aggressive volume replacement is needed.
Systemic vascular resistance decreases.	Misinterpreted as hemodynamic instability.
Heart rate increases 15–20 beats/min.	Misinterpreted as early decompensation.
Respiratory rate and tidal volume increase.	Normal Pco_2 = 27–32 mm Hg.
Minute ventilation and oxygen consumption increase.	More susceptible to hypoxemia with apnea.
Diaphragm is elevated 4 cm cephalad.	Perform thoracostomy one to two interspaces higher than normal.
Gastrointestinal motility decreases.	Aspiration risk increases.
Distended abdomen occurs with advancing gestation.	Sensitivity of peritoneal signs decreases.
Uterine enlargement occurs.	Protects bowel with lower abdominal penetrating trauma.
Uterine blood flow increases to 600 mL/min	Risk of hemorrhage and retroperitoneal bleeding increases
Bladder becomes intra-abdominal after 12 wk.	More susceptible to injury.
Renal blood flow increases 50%.	Serum blood urea nitrogen and creatinine levels = 4 and 0.6–8 mg/dL, respectively.
Hypomotility of the renal collecting system occurs.	Ureteral dilation and mild hydronephrosis (right > left).
White blood cell count may increase.	Nonspecific for injury.
Levels of fibrinogen and Factors VII, VIII, IX, and X increase.	Hypercoaguable state; risk of thrombosis increases.

Pco_2, carbon dioxide pressure.

third trimester is having difficulty lying flat with a left lateral tilt, 30 degrees of reverse Trendelenberg and the tilt may provide some comfort.

Early establishment of an airway in the field is the best option if there is any concern for airway stablility or patency. Practice management guidelines for prehospital fluid resuscitation in the general population have been established by the Eastern Association for the Surgery of Trauma (EAST) Workgroup and can be summarized as follows[14]: The benefit of venous access and fluid resuscitation in the field is not supported in the literature and may be harmful to some critically injured patients. Attempting access at the scene also delays transport and attempts en route are equally successful if indicated. Fluids should be administered to patients with penetrating trauma and altered mental status or lack of a radial pulse and patients with traumatic brain injury to maintain systolic blood pressure greater than 90mm Hg. Small boluses (250 mL) of hypertonic saline are equivalent to large boluses (1000 mL) of standard solutions.[14] Guidelines for transfer of an injured pregnant patient to a level I trauma center (in addition to accepted guidelines for nonpregnant patients) include maternal heart rate greater than 110, chest pain, loss of consciousness, and third-trimester gestation.[15]

Basic Management Principles for Minor Injury during Pregnancy

Patients with minor injuries should receive routine medical treatment and obstetric assessment based upon gestational age and clinical findings. A recent prospective study of a standardized protocol for minor trauma patients demonstrated that extensive evaluation does not appear to be required.[16] Over 300 pregnant women with minor trauma (Index-Injury Severity Score [ISS] = 0) at 23 + 6 weeks or more were prospectively evaluated. Falls were the most common mechanism of injury (48%). All patients had reassuring fetal testing prior to discharge. Pregnancy outcome data was available for 80% of women in the study. Nineteen percent had a low–birth weight infant or preterm delivery.

One patient had an abruption but it occurred 5 weeks after her injury, which is lower than the rate previously reported with minor trauma. No single clinical or laboratory risk factor predicted an adverse outcome. The authors recommend that Kleihauer-Betke (KB), fibrinogen, and coagulation studies not be performed for minor trauma and that a thorough but brief clinical examination is adequate. This study also raises the issue of an increased risk for long-term adverse outcomes as previously discussed,[11–13] even though this is a lower risk group of patients.[16]

Basic Principles of Trauma Resuscitation for Moderate to Severe Injury during Pregnancy

Emergency department evaluation and treatment of the injured gravida should proceed in a timely and organized fashion. Each member of the trauma team is assigned specific tasks to avoid confusion and duplication of services. The management of gravidas with moderate to severe injuries can be divided into steps, some that are performed simultaneously:

- Primary survey.
- Resuscitation.
- Secondary survey.
- Laboratory and diagnostic studies.
- Definitive treatment.

The management scheme is summarized in Figure 54–2.

Primary Survey

The standard ATLS protocol for the primary survey focuses on identifying life-threatening injuries and initiating resuscitative measures. Details of the event, the mechanism of injury, resuscitation attempts in the field, and the patient's medical history should be obtained from the transporting paramedics. The components of the primary survey include the ABCs of resuscitation (airway, breathing, and circulation), an initial physical examination with adequate exposure to identify injuries, and a brief neurologic assessment.

The highest priority is to establish that the patient has an adequate airway. This can be accomplished in many cases by talking to the patient. A patient who can speak in complete sentences, in a normal voice, and can respond appropriately has a patent airway as well as adequate oxygenation and brain perfusion. If there is evidence of airway compromise, endotracheal intubation should be performed without delay.

Once the airway is deemed adequate, breathing is assessed. The chest should be examined for expansion, breath sounds, crepitus, subcutaneous emphysema, and open wounds. Supplemental oxygen, 100% by mask, is administered to all patients until respiratory assessment is completed. Pulse oximetry objectively confirms normal oxygen saturation unless the patient has hypotension, peripheral vasoconstriction, or severe anemia. If there is evidence of maternal hypoxia, arterial blood gas analysis should be obtained while the patient breathes room air if possible. A maternal arterial oxygen pressure (PaO_2) of 60 mm Hg or greater is needed to ensure adequate fetal oxygenation. Oxygen can be weaned based on the clinical assessment and the patient's condition. When a nasogastric tube is required for gastric decompression, it should be placed after adequate ventilation is established.

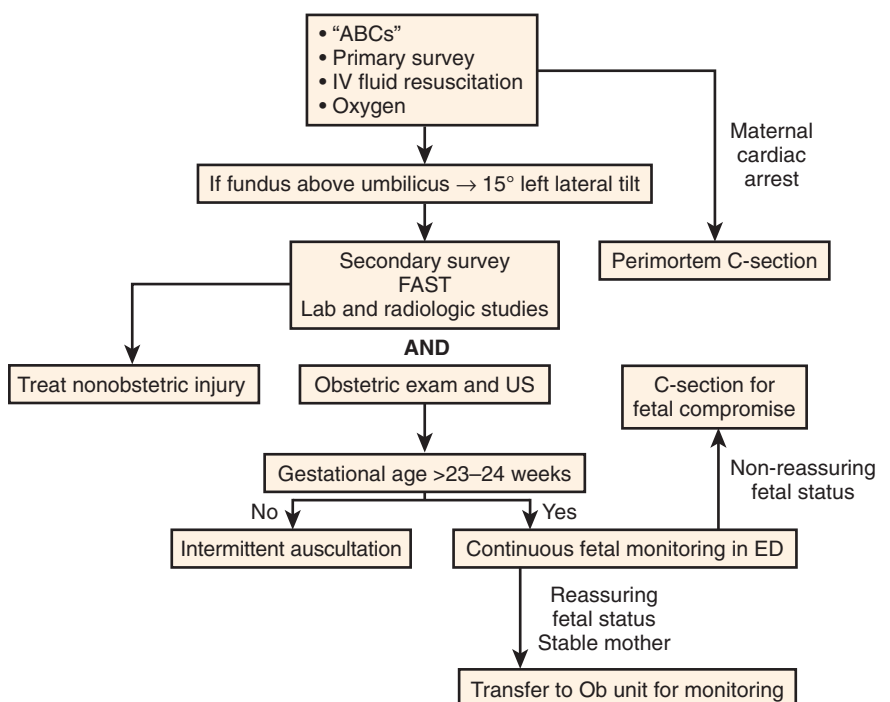
Endotracheal intubation and mechanical ventilation are indicated for a patient who cannot maintain adequate ventilation and/or oxygenation. Indications for intubation and mechanical ventilation include airway obstruction, inability


FIGURE 54–2
Initial resuscitation of the pregnant trauma patient.

to protect the airway, hypoxia, coma, shock, flail chest, open chest wounds, and ineffective ventilation. Intubation should not be delayed with the expectation that a patient's respiratory status will quickly and spontaneously improve. Oxygen consumption increases by 20% and functional residual capacity decreases in pregnancy, resulting in rapid development of maternal hypoxia during respiratory compromise. The failed intubation rate during pregnancy is 1 : 300, or sevenfold higher than for the nonpregnant patient.[17] Thus, early intubation under controlled conditions is preferable to an emergent procedure in a profoundly hypoxic gravida. Blood gas analysis can be helpful in the decision-making process, but clinical judgment is equally important. There are several important modifications for intubation of the pregnant patient. Adequate preoxygenation and prompt reoxygenation afterward are important, given the respiratory changes of pregnancy. Lower esophageal sphincter tone is decreased during pregnancy, and rapid-sequence induction with cricoid pressure should be performed. Postintubation chest radiography is mandatory to confirm proper tube placement.

Circulation is the third component of the ABCs that requires immediate assessment. The hemodynamic changes of pregnancy can result in a misleading impression of maternal stability. Blood volume increases 50% during pregnancy, and gravid women tolerate a greater degree of acute blood loss before hemodynamic compromise occurs. Pulse rate and blood pressure may not change until 30% to 35% of blood volume has been lost.[18] Tachycardia and hypotension are absent in a pregnant woman during the early phase of shock, and hemodynamic instability does not occur until 1500 to 2000 mL of blood loss.[19] A gravida with tachycardia and hypotension will need aggressive resuscitation with fluids and blood products. Any pregnant patient beyond 20 weeks' gestation lying supine should have a 15-degree left lateral tilt. This positioning maximizes cardiac output by reducing uterine pressure on the inferior vena cava and allowing adequate venous return. Failure to tilt the patient results in a 30% decrease in maternal cardiac output.

The physical examination during the primary survey should be thorough and efficient. In patients with moderate to severe injuries, all clothing must be removed to allow adequate visualization and assessment of injuries. Obvious hemorrhage should be controlled with direct pressure to the wound. A rapid neurologic assessment is included, and the initial examination includes determination of orientation and responsiveness, pupillary reaction, motor response, and the Glasgow Coma Scale.

Concurrent with the initial evaluation of a moderately to severely injured patient, intravenous access must be established. A large-bore (14–16-gauge) peripheral catheter is preferred because it allows the quickest infusion of fluids and blood products. The number of peripheral catheters placed should increase as injury severity increases; patients with moderate injuries should have two secure catheters in place. Central venous access is required when peripheral access cannot be established because of absent veins, hypotension, or large surface area burns. Subclavian line placement in hypotensive trauma patients, however, carries a 12% complication rate, including pneumothorax, hemothorax, thrombosis, and infection.[20] In addition, the infusion ports of a double- or triple-lumen central venous catheter are generally

18 gauge, and the maximum flow rate is slower than with a large-bore peripheral intravenous line. Another option for central access is placement of a large-bore (8.5-Fr) central catheter; if needed, this line can be converted over a guidewire to a triple-lumen catheter after resuscitation.

Crystalloid (lactated Ringer's solution) is the fluid of choice for initial resuscitation for many physicians. Replacement should be at a rate of 3 : 1 crystalloid to blood lost. Others use colloid or plasma expanders. If the patient remains hypotensive despite infusion of 2 to 3 L of crystalloid, transfusion of packed red blood cells should begin. In the emergency setting, type O-negative blood is administered until blood type and cross-match are obtained. A warming device helps to prevent hypothermia as a result of rapid infusion of crystalloid and blood products. Coagulation products should be administered based on abnormal laboratory parameters.

Military antishock trousers are controversial in the management of traumatic shock. They have not been well studied nor widely used in pregnant women. In the injured gravida, the lower extremity compartments can be inflated, but this may increase bleeding from injured pelvic structures. Generally, the abdominal compartment should not be inflated in the second and third trimesters, because it can compromise venous return and precipitate or exacerbate respiratory compromise from increased intra-abdominal pressure. Military antishock trousers are recommended for an injured pregnant woman only when major pelvic fractures are accompanied by uncontrollable hemorrhage.[21,22]

Resuscitation

The goal of the resuscitation phase is to monitor the patient's response to initial treatment and optimize intravascular volume and oxygen delivery. Adequate maternal resuscitation is of paramount importance to fetal survival. Blood pressure and pulse rate are assessed frequently, although these parameters are not reliable in detecting early shock in the gravida.[6] Measurement of central venous pressure has been used in the acute setting, but absolute values should be viewed with great caution because central venous pressure is lowered by pregnancy. A pulmonary artery catheter is rarely indicated during initial resuscitation attempts. Vasopressors are contraindicated in hemorrhagic shock unless the patient has cardiogenic shock from cardiac contusion or spinal cord injury with neurogenic shock.[22]

A urinary catheter is diagnostic and therapeutic; it allows accurate measurement of urine output, assessment for hematuria, and complete bladder drainage. The kidney is sensitive to the effects of hypotension, and urine output decreases as the kidney attempts to conserve fluid and maintain intravascular volume. An output of 30 mL/hr or more indicates adequate renal perfusion. Evidence of blood at the urethral meatus or difficulty in passing a catheter suggests bladder or urethral injury. If no urine is obtained through the catheter, bladder rupture must be considered. This condition is most commonly associated with a pelvic fracture. Gross or microscopic hematuria mandates evaluation to exclude urinary tract injury.

If an injured patient in shock is unresponsive to aggressive resuscitative measures, immediate operative intervention must be considered. A number of causes of refractory shock in the seriously injured pregnant woman should be

eliminated, however, before proceeding to the operating room. Volume replacement may be inadequate, particularly in the third trimester, when blood volume is at its peak. Concealed hemorrhage associated with abruptio placentae can result in maternal shock, and amniotic fluid embolism is a rare but potential cause of cardiovascular collapse. Additional causes of persistent shock include tension pneumothorax, cardiac tamponade, neurogenic shock, uncorrected hypothermia, significant electrolyte and acid-base disturbances, and hypoxia.[18]

Secondary Survey

The secondary survey is performed once there is evidence of response to resuscitation efforts and the maternal condition is stabilized. Ongoing assessment of vital signs and a complete physical examination should be conducted in an ordered fashion. Particular attention must be given to sites of bleeding, injured limbs, and entrance and exit wounds in cases of penetrating trauma. Head injuries account for nearly 50% of deaths in trauma patients, and a complete neurologic assessment should be performed and compared with the initial examination.[23] The most common underlying etiologies of central nervous system impairment in a trauma patient include alcohol intoxication, diabetic ketoacidosis, narcotic and barbiturate overdose, hypovolemic shock, and cerebrovascular accidents. All neck injuries should be presumed to be life-threatening until excluded by appropriate evaluation. Tension and open pneumothorax, flail chest, and massive hemothorax are thoracic injuries that require rapid diagnosis and treatment. A chest tube should be placed one to two interspaces higher in pregnant patients because the diaphragm is elevated.[4] Abdominal injury may also occur with penetrating thoracic trauma secondary to the high diaphragm. An abdominal examination should be conducted, although the absence of findings does not exclude an acute intra-abdominal process. A rectal examination performed in patients with moderate to severe injuries evaluates for gastrointestinal bleeding and documents sphincter tone.

A complete obstetric examination is included in the secondary survey. Fundal height should be measured and fetal heart tones auscultated. A mark can be placed at the level of the fundus to provide a baseline in the case of increasing fundal height due to a concealed abruption. Uterine tone and the presence of contractions and tenderness are assessed. Pelvic examination should be performed on all gravidas unless contraindicated by their injuries. A sterile speculum examination assists in identifying membrane rupture or genitourinary bleeding. Contraindications to the pelvic examination include unstable spine, pelvic, and femur fractures because positioning may risk additional injury. Examination may be possible after orthopedic consultation. AmniSure (AmniSure International LLC) can accurately diagnose rupture of membranes, and speculum examination is not required. Digital examination can be performed if there is no vaginal bleeding or, in the presence of bleeding, once placenta previa has been excluded by ultrasonographic examination.

Fetal assessment begins with estimating gestational age by last menstrual period, fundal height, and ultrasonography. If the gestational age is uncertain, ultrasonographic measurements can quickly approximate dating of the pregnancy. When the potential for fetal survival must be determined

urgently, a biparietal diameter of 54 mm or greater measured by ultrasonography has been suggested as more predictive than estimated fetal weight.[24] Fetal heart tones can be auscultated intermittently by Doppler in a previable fetus.

Continuous fetal heart rate monitoring of a viable fetus should be instituted in the emergency room as soon as possible, once initial resuscitation of the mother has begun. Fetal well-being is an excellent indicator of adequate maternal resuscitation. Changes in the fetal heart rate pattern may be the first sign of maternal compromise and generally occur before changes in maternal vital signs. Fetal tachycardia, bradycardia, late decelerations, and decreased beat-to-beat variability can indicate deterioration in fetal status. The tocodynamometer is helpful in detecting contractions that an injured patient may not perceive. Obstetric staff must be immediately available to interpret the fetal heart rate tracing while the patient is in the emergency department or other nonobstetric unit.

A variety of laboratory studies and diagnostic modalities are available to assist in evaluating and managing an injured gravida. The study or combination of studies performed should be tailored to the clinical situation as discussed in the following sections.

Laboratory Studies in the Gravid Trauma Victim

Complete laboratory evaluation must be initiated quickly for patients with moderate to severe injuries. Suggested studies are listed in Table 54–2. Additional tests should be ordered as dictated by the patient's condition and the clinical situation.

Pregnant women have a physiologic anemia because plasma volume increases to a greater degree than red cell volume. Nevertheless, the hemoglobin level during pregnancy is normally 10 g/dL or higher. An initial hemoglobin level less than 8 g/dL has been associated with ongoing hemorrhage and an increased mortality rate in nonpregnant trauma patients.[25] A normal hemoglobin level, however, does not exclude excessive bleeding because several hours may be required for equilibration to occur. Activated partial thromboplastin time (aPTT) and prothrombin time (PT) are unaffected by pregnancy. Fibrinogen increases during pregnancy, and a low-normal fibrinogen level (200–250 mg/dL) suggests a consumptive coagulopathy.[26]

TABLE 54–2

Suggested Laboratory Studies for Patients with Moderate to Severe Traumatic Injury

Complete blood count and platelet count
Coagulation profile
Type and cross-match

Serum glucose
Aspartate aminotransferase and alanine aminotransferase
Amylase
Lipase
Arterial blood gas analysis
Urinalysis
Urine and blood toxicology screens
Kleihauer-Betke stain

Serum chemistry values provide additional information. Although electrolyte levels are usually normal in healthy gravidas, a decreased bicarbonate level is correlated with fetal demise in pregnant trauma patients. Determining a baseline creatinine level is helpful in case renal complications develop. Elevation of the aspartate aminotransferase (AST) or alanine aminotransferase (ALT) level above 130 IU/L is associated with a sixfold increase in the risk of intra-abdominal injury and is an indication to pursue diagnostic imaging in the stable nonpregnant patient.[27] Lactate may have decreased sensitivity due to increased renal clearance in the pregnant patient.

The KB stain determines the presence of fetal blood cells in the maternal circulation as well as the degree of fetomaternal hemorrhage (FMH). Fetal cells and ghost maternal cells are counted after acid elution and staining of the maternal blood sample. A normal maternal blood volume of 5000 mL is commonly assumed. The laboratory reports the ratio of fetal to maternal cells, and the volume of FMH is calculated:

$$\frac{\text{Fetal cells}}{\text{Maternal cells}} \times \text{Maternal blood volume}$$

Alcohol and illicit substance use is common in trauma patients, and urine and blood toxicology screens should be performed. The results of testing provide information that is important for both medical and legal reasons. The physiologic effects of illicit substances can alter a patient's response to the stress of trauma. Alcohol lowers sympathetic response, whereas cocaine can cause sympathetic stimulation or paradoxical depression. Cocaine use has been associated with placental abruption and should be considered in the gravid trauma patient with an adverse fetal outcome. Organic pathology should be excluded in patients with neurologic compromise, but their condition may reflect the effects of an illicit substance.

Diagnostic Studies in the Gravid Trauma Victim

Diagnostic studies are pursued once initial resuscitation is complete and the mother and fetus are stable. Radiographic screening of patients with moderate to severe injuries consists of cervical spine, chest, and pelvis films. Cervical spine films exclude C-spine injury in most patients with blunt trauma. Chest x-ray can detect hemothorax, pneumothorax, or ruptured diaphragm, but there are several limitations in pregnant trauma patients that should be kept in mind. A small pneumothorax may not be evident on initial chest film owing to the reduced inspiratory effort and decreased lung volume. The sensitivity of a chest x-ray in diagnosis of aortic injury is also decreased and transesophageal echocardiography or computed tomography (CT) scan of the chest is the modality of choice to exclude thoracic aortic injury or pericardial tamponade.[4] A plain film of the abdomen should be obtained if abdominal injury or a foreign body is suspected.

Radiation exposure is always a consideration when caring for the pregnant patient, but necessary tests should not be omitted because the patient is pregnant. Fetal risk is negligible if maternal exposure is limited to less than 5 rad (5000 mrad).[28] Abdominal shielding and avoiding duplication of studies minimizes fetal exposure. A review of a large

group of pregnant trauma patients found all patients had less than 5 rads of exposure with their trauma evaluation.[29] Radiation exposure to the fetus from specific radiologic studies is outlined elsewhere in this text.

Intra-abdominal injury must be excluded, as in the non-pregnant patient. Clinical examination of the abdomen in nonpregnant patients with blunt trauma detects only 60% of intra-abdominal injuries. During pregnancy, signs and symptoms of an acute intra-abdominal process are often further obscured as the uterus stretches the peritoneum, decreasing the afferent sensory fibers of the peritoneum per square centimeter. Pain may also be referred to an atypical location owing to displacement of organs.[4] The diagnostic modalities available to exclude abdominal injury when the patient does not require emergent laparotomy include diagnostic peritoneal lavage (DPL), CT scan, and focused abdominal sonography in trauma (FAST). Although not established in the trauma literature, magnetic resonance imaging (MRI) may be useful in evaluation of the pregnant trauma patient. Each examination has its advantages, disadvantages, and limitations, as detailed below.

DPL is highly sensitive and accurately detects 94% to 98% of intra-abdominal injuries.[30,31] Traditional indications for DPL include equivocal findings on physical examination, unexplained hypotension, an unresponsive patient, and spinal cord injury. DPL can be performed in a pregnant patient without compromising safety and accuracy.[32,33] Although FAST and CT scan have become the more commonly used modalities, DPL is still useful for evaluation of unstable blunt trauma or an indeterminate FAST study. DPL is more accurate than CT for early diagnosis of hollow visceral and mesenteric injury, but does not reliably exclude retroperitoneal injury. DPL also cannot assess the specific site of bleeding or the extent of injury. Previous laparotomy, massive obesity, and advanced third-trimester pregnancy are relative contraindications to DPL, although no gestational age cutoff has been defined.[34] The complication rate for DPL is 1% in nonpregnant patients and does not appear to be increased during pregnancy.[32–34]

The standard technique for DPL is modified somewhat for the pregnant patient. Location of the incision is dependent on the stage of gestation. During the first trimester, a standard infraumbilical incision may be used. As pregnancy advances, however, the incision must be supraumbilical and above the uterine fundus, and an open technique is employed. A positive DPL is an indication for exploratory laparotomy.[31]

CT scanning is recommended when a patient with blunt trauma is hemodynamically stable but has unreliable or equivocal findings on physical examination or multiple injuries. It is the diagnostic modality of choice for nonoperative management of solid viscus injuries and has the advantage of detecting clinically unsuspected injuries. Its negative predictive value is excellent. Disadvantages of CT include a lower sensitivity for hollow viscus injury, possible dye reactions, and lack of portability, which requires patients to be moved from the resuscitation area of the emergency department.

MRI has not been described for the pregnant trauma patient but might be an option in a stable mother requiring further evaluation. The CT is typically a faster study to

perform and more accessible in many emergency departments, and thus, remains the standard. Discussion among the radiologist, trauma surgeon, and obstetrician regarding the utility of MRI for specific trauma patients may be considered.

FAST has become the diagnostic study of choice in many centers for hemodynamically stable patients.[35,36] It is noninvasive, can be performed at the bedside in the emergency room, and can be repeated easily if the results are equivocal. The examination focuses on identifying fluid in the pericardium, pleural cavity, pararenal retroperitoneum, and peritoneal cavity. The sensitivity of FAST to detect intraperitoneal fluid is 73% to 88%, and its accuracy is 96% to 99%.[31] FAST appears to decrease the need for both DPL and CT scan, allowing more selective and cost-effective use of these modalities.[35] The sensitivity and specificity of FAST in pregnant blunt trauma victims is similar to those in nonpregnant patients (80%–83% sensitivity), making it a safe and effective screening examination.[37,38]

An evidence-based algorithm incorporating hemodynamic status and the findings on physical examination was developed by the EAST Practice Management Guidelines Work Group.[31] FAST is considered the diagnostic examination of choice for patients who are hemodynamically unstable, with DPL as an alternative to exclude hemoperitoneum. Patients who are hemodynamically stable, with a reliable physical examination, undergo serial examinations or diagnostic testing, depending on the findings on initial clinical examination. Patients with an unreliable physical examination should undergo FAST or CT scan, depending on institution and physician preference, with subsequent management determined by results.

Definitive Treatment

Definitive treatment is instituted according to the type and severity of injuries as well as the clinical condition. A patient with hemorrhagic shock and obvious intra-abdominal injury is unlikely to remain in the emergency department longer than necessary and will have undergone minimal diagnostic evaluation before operative intervention. In a patient who is hemodynamically stable, adequate time is available to assess the full extent of injuries. Once diagnostic studies have been completed and interpreted, a treatment plan can be devised in consultation with appropriate specialty services.

Trauma victims are frequently transported to the nearest hospital. However, not all institutions are equipped to care for a patient with major injuries, and transfer to a tertiary care center may be necessary for definitive therapy. Maternal stability and fetal well-being must be ensured before land or air transport. A patient should not be transferred if there is any sign of hemodynamic compromise, ongoing hemorrhage, severe uncorrected anemia, non-reassuring fetal status, or danger of delivery en route. Personnel equipped to handle obstetric emergencies should always accompany a pregnant patient during transport.

Tetanus immunization is the first of several general treatment issues. Tetanus occurs almost exclusively in patients who have been inadequately immunized. Preventing tetanus after injury entails ensuring adequate immunity and local wound care, with elimination of necrotic tissue and foreign bodies. Tetanus toxoid (0.5 mL intramuscularly) is administered when a patient has been appropriately immunized but the most recent booster was longer than 5 years ago. Previously unimmunized patients require both tetanus immune globulin (500 U intramuscularly) and the first of three doses of tetanus toxoid. The immune globulin and toxoid must be injected into different sites to ensure adequate protection.

The second issue is the extremely high risk of deep venous thrombosis (DVT) in patients with moderate to severe injuries. Blood transfusion, surgery, femur or tibia fracture, and spinal cord injury are associated with an increased risk of DVT.[39] Young patients with injuries are at high risk, and DVT has been reported to occur in 46% of trauma victims younger than 30 years of age.[39] Pregnant women who suffer a fracture injury have been noted to be at a ninefold increased risk for thrombosis.[40] The American College of Chest Physicians[41] recommends DVT prophylaxis for trauma patients with an identifiable risk factor of which the hypercoaguable state of pregnancy is included. Low-molecular-weight heparin (LMWH) prophylaxis should be administered if the patient has no contraindications to heparin therapy. If LMWH is contraindicated, mechanical prophylaxis (graduated compression stockings, intermittent pneumatic compression devices, or the venous foot pump) should be instituted. An inferior vena caval filter is not recommended for prophylaxis.[41]

Guidelines for stress ulcer prophylaxis have been developed by The EAST Practice Committee.[42] Level 1 recommendations for prophylaxis include all patients with mechanical ventilation, coagulopathy, traumatic brain injury, and a major burn. Prophylaxis is also recommended for all intensive care unit patients with multitrauma, sepsis, or acute renal failure (level 2) as well as an ISS greater than 15 or high-dose steroid administration (level 3). No difference is noted in effectiveness of H_2 antagonists, proton pump inhibitors (PPIs), and cytoprotective agents (level 1). Tolerance has been noted to develop in H_2 antagonists but has not been observed with PPIs. The duration of prophylaxis is less clear but it may be continued throughout the time of mechanical ventilation or intensive care unit stay or until enteral feeding is tolerated.[42]

Damage Control Surgery for the Critically Injured Patient

Damage control surgery is defined as rapid termination of an operation after control of life-threatening hemorrhage and intestinal spillage. It creates a stable anatomic environment to prevent progression to an unsalvageable metabolic state. It is a staged approach to the patient with multiple injuries. If the patient declines owing to hypothermia, acidosis, hypotension, or coagulopathy, only problems that require immediate intervention are addressed in the operating room, with return to the intensive care unit for ongoing resuscitation and stabilization. Pregnancy does not influence the decision for damage control surgery, and there are limited data with regard to its use in the pregnant trauma patient. Nevertheless, delivery of the term or near-term fetus should be considered part of the approach in a woman in extremis.[4]

SUMMARY OF MANAGEMENT OPTIONS
Trauma in Pregnancy—General Management

Management Options	Evidence Quality and Recommendation	References
Overall Primary Survey: Identify and Treat Life-Threatening Injury		
Use a multidisciplinary team approach.	—/GPP	—
Assess airway.	IV/C	18

BLUNT TRAUMA

Incidence

MVAs are responsible for 60% to 75% of cases of blunt trauma, making it the most common mechanism of injury and the leading cause of fetal death related to maternal trauma.[6,43] Higher crash severity, severe maternal injury, and lack of restraints are associated with a higher risk of adverse fetal outcome.[44] Although most injuries are minor, each year in the United States, an estimated 1300 to 3900 women experience a fetal loss as a result of an MVA.[45] Obstetric complications associated with blunt trauma include abruptio

placentae, preterm labor, uterine rupture, FMH, direct fetal injury, and fetal demise. The incidence of abruptio placentae, direct fetal injury, and fetal death in non–life-threatening blunt abdominal trauma is fortunately low (1.6%, 0.8%, and 1.6%, respectively), but the fetus is nevertheless at risk, even when maternal injuries are minor.[46] The incidence of preterm delivery associated with noncatastrophic blunt trauma is also infrequent, at 0.86%.[47]

Falls are the second most common form of blunt trauma, but direct abdominal assault is occurring with increasing frequency in pregnant women. The prevalence of physical abuse of pregnant women is 6% to 31%. Morbidity and adverse outcomes of pregnancy appear to be more common with direct assaults than with MVAs, including a high risk of uterine rupture.[15,48,49] Women sustaining an assault during pregnancy are also at increased risk for long-term sequelae of abruption, preterm delivery, and low birth weight.[49] Physical abuse is often a repetitive event that may prompt multiple emergency room visits. It is important to ask specific questions about abusive relationships because women frequently do not volunteer such information. As the only health care provider many patients sees regularly during pregnancy, the obstetrician has the best opportunity to offer assistance to victims of abuse.

General Management

The trauma team may have performed a primary survey and begun resuscitation efforts of a woman with blunt trauma before an obstetrician arrives. This approach is appropriate because maternal stabilization is always the priority. The obstetric consultant should assume co-management responsibilities for the mother and fetus once notified of the patient's admission to the emergency department.

Injury patterns associated with MVAs vary depending on whether the victim was restrained, the type of safety belt system in use, and the patient's place in the vehicle. On average, 30% of pregnant women involved in an MVA are unrestrained.[27,28,50] Unbelted individuals usually sustain injuries to the head, face, chest, abdomen, and pelvis when they hit the interior of the car or are ejected. An unbelted pregnant woman is nearly three times more likely to suffer a fetal death compared with a belted gravida.[51] A lap belt prevents ejection from the vehicle, but hollow viscus and lumbar spine injuries are common. Those wearing a shoulder harness without the lap component often have cervical spine, clavicular, chest, liver, and spleen injuries. A three-point lap-shoulder system offers optimal protection, but injuries do occur and include rib, sternum, and clavicular fractures. Air bag deployment may cause face, arm, and chest abrasions, and chemical keratitis has been reported.

Fractures, dislocations, and sprains have been reported to be the most common type of injury in women hospitalized for traumatic injury, with falls being the leading mechanism of injury.[40] Pelvic fractures are the least common type of injury but are associated with the worst outcomes.[40] Detailed information on pelvic fracture during pregnancy is found in a review of 101 cases.[52] Mechanisms of injury included automobile-pedestrian accidents, MVAs, and falls. Overall maternal mortality was 9%, and fetal mortality was 35%. Pelvic fractures in the third trimester were associated with an 18% incidence of fetal skull fracture. As reported by other authors, increasing severity of maternal injury increases both maternal and fetal mortality rates. The trimester of pregnancy during which the injury occurred did not influence fetal death. Repair of the pelvic fracture usually is not performed during pregnancy, and 75% of women deliver vaginally. Mode of delivery should be individualized with consideration for cesarean delivery for pubi rami fractures adjacent to urethra/bladder, severe lateral compression fractures, and acute pelvic fractures with marked displacement.[52]

Abdominal injuries are common in victims of blunt trauma. Specific injuries sustained during pregnancy change with advancing gestation. By 12 weeks, the bladder has become an intra-abdominal organ and thus is more susceptible to injury. As the uterus enlarges and rises out of the pelvis, risk of direct injury to the uterus increases. Life-threatening retroperitoneal hemorrhage occurs more frequently during pregnancy, when pelvic blood flow is markedly increased.[53] Bowel injuries, however, tend to occur less often because the small intestine is compressed into the upper abdomen.

Accurate and timely diagnosis of intra-abdominal injury requiring surgical intervention is one of the challenges in blunt trauma. Findings on initial physical examination of the abdomen may be normal despite visceral injury. Serial examinations are, therefore, important to detect deterioration in the patient's condition. Splenic injury and retroperitoneal bleeds are the most common injuries from blunt abdominal trauma in pregnancy and occur more frequently than in nonpregnant patients.[10] Rib fractures are frequently associated with liver and spleen injuries, and pelvic fractures are associated with genitourinary injuries and retroperitoneal hemorrhage. The choice of diagnostic studies is best made in concert with the trauma team.

Abruptio Placentae

Abruptio placentae occurs in 1% to 5% of gravidas with minor injuries and 6% to 37% of those with major injuries.[19,46,47,53–55] The largest prospective study of minor trauma in pregnancy, however, noted a much lower rate of abruption than prior studies and the single case was remote from the time of injury.[16] It is the most common cause of fetal death when the mother survives blunt trauma. Placental abruption cannot be predicted based on placental location, severity of maternal injury, or vehicle damage (in the case of an MVA), and it can occur without obvious injury to the mother.[8,10,56,57] A small series reported an increased incidence of abruption in patients involved in MVAs at speeds of 30 mph and greater and those with a higher ISS.[9]

When a gravida is involved in an MVA, intrauterine pressure at the time of impact is estimated to be 10 times greater than the forces generated with labor.[58] Although the uterus is considered more elastic than the placenta, recent models indicate that their mechanical properties are similar and there is overlap. The uteroplacental interface appears to fail at a lower strain than either the uterus or the placenta.[45] Increased intrauterine pressure generated on impact may propagate placental separation, with subsequent formation of a retroplacental hematoma.[58]

Placental abruption usually occurs soon after the traumatic event. Classic signs and symptoms include vaginal bleeding, abdominal pain, and fundal tenderness as well as

uterine irritability, high-frequency contractions, and increased tone. Back pain and vaginal bleeding may be the most prominent symptoms in women with separation of a posterior placenta.[59] The absence of vaginal bleeding, however, does not exclude the diagnosis. Bleeding can be concealed within the uterus and may be detected only by increasing fundal height, fetal heart rate abnormalities, or maternal hypovolemia. A hypertonic uterus and evidence of fetal compromise are highly suggestive of abruptio placentae. Cardiotocographic monitoring is the most sensitive method of surveillance after a traumatic event and is discussed later in this section.[10,15,47]

Management of a patient with abruptio placentae after traumatic injury is similar to that of an uninjured gravida with this complication. As soon as abruption is suspected, intravenous access must be established. A urinary catheter allows accurate measurement of output. Complete blood and platelet counts, fibrinogen level, aPTT, and PT should be obtained and repeated every 4 to 6 hours to detect disseminated intravascular coagulation. D-Dimer and fibrin split products are often elevated in placental abruption but have not been shown to be a useful screen.[47] A minimum of 2 units of packed red blood cells must be immediately available in the blood bank. Fresh frozen plasma and packed red blood cells should be administered based on abnormal laboratory findings and estimates of ongoing hemorrhage. Obstetric management depends on the maternal condition, fetal status, and severity of abruption. If there are signs of maternal hypovolemia or shock, fluid resuscitation and administration of blood products should begin promptly. Disseminated intravascular coagulation is not an indication to proceed with cesarean section, and abdominal delivery only increases the risk of bleeding complications.

Fetal status and the severity of abruption direct the clinical course once the mother is stable. When the fetus is alive, gestational age and plans for intervention must be established quickly. Hysterotomy offers no benefit to either mother or fetus if a previable fetus shows signs of compromise. Continuous fetal monitoring and close observation are reasonable approaches for a preterm gestation when the heart rate pattern is reassuring. Corticosteroids should be administered to minimize the complications of prematurity if the gestational age is 24 to 34 weeks. As always, the risks of prematurity must be weighed against the risks of continuing the pregnancy. Delivery is generally indicated in a term pregnancy with abruptio placentae, but cesarean delivery is unnecessary if the fetal and maternal status are reassuring. If the fetus has died, induction of labor and vaginal delivery are the safest method of delivery for the mother.

Preterm Labor

Preterm labor requiring tocolysis has been reported in 11% to 28% of gravidas who have blunt trauma.[47,48,60] Delivery before 34 weeks' gestation, however, is uncommon and experienced by only 0.86% of gravidas with blunt trauma.[47] Extravasation of blood into the myometrium is a stimulus for uterine contractions associated with traumatic events. Uterine muscle injury can also cause release of lysosomal enzymes, generation of prostaglandins, and subsequent uterine activity.

When uterine contractions occur after blunt trauma, it may be difficult to determine whether they represent placental abruption or isolated preterm labor. Tocolysis is discouraged by those who believe that uterine activity is an indication of the former. Uterine contractions developing after blunt trauma abate without treatment in 90% of gravidas.[19] Successful tocolysis has been reported after blunt trauma,[60] but close observation is prudent in many cases, given the high rate of spontaneous resolution of contractions. Regardless of whether pharmacologic inhibition of labor is used, fetal heart rate and uterine contractions should be monitored continuously during observation of the patient.

If a tocolytic is administered, the agent should be selected with an awareness of its potential complications. β-Mimetics (ritodrine, terbutaline) are relatively contraindicated in patients at risk for hemorrhage because drug-induced tachycardia may mask early signs of hypovolemia. Magnesium sulfate has fewer cardiac side effects than the β-mimetics. However, patients with renal dysfunction are at increased risk for toxicity because magnesium is excreted through the kidneys. Indomethacin may be used to inhibit preterm labor, although nonsteroidal anti-inflammatory agents, such as indomethacin, may be contraindicated in severely injured patients because the drug can adversely affect platelet and renal function. In addition, it can cause transient premature closure of the fetal ductus arteriosus and oligohydramnios. Calcium channel blockers (e.g., nifedipine) have also been used successfully as an oral tocolytic. This class of drugs may cause maternal hypotension, however, and may imitate early shock in a gravid trauma patient.

Uterine Rupture

Uterine rupture usually occurs as a result of direct abdominal trauma during the late second and third trimesters. It occurs in 0.6% to 1% of gravidas who have blunt trauma and is most frequently associated with maternal pelvic fracture.[61–63] When the uterus ruptures, the site is often fundal.[64] A scarred uterus has a greater propensity to rupture than an unscarred uterus. It is much more devastating for the fetus than for the mother, with a 10% maternal mortality rate but a fetal mortality rate of nearly 100%.[60]

The diagnosis of uterine rupture can be difficult. Signs and symptoms may be limited to vague abdominal pain. Uterine tenderness, a non-reassuring fetal heart rate pattern, absence of the presenting part, palpable fetal parts outside the uterus, fetal demise, and maternal shock are more dramatic presentations. When fetal death occurs after a serious accident, uterine rupture must be considered. Rupture of the uterus may first be suspected when induction of labor is unsuccessful. DPL results are generally positive when the uterus has ruptured and major vessels have been damaged.

If uterine rupture is suspected, exploratory laparotomy should be performed to control maternal hemorrhage. Ideally, a trauma surgeon will be in attendance to explore the abdomen for additional injuries. A vertical abdominal incision allows maximum exposure, particularly if surgical repair of intra-abdominal injuries is required. Conservation of fertility is always a consideration because a patient's wishes may be unknown or uncertain at the time of the accident. However, uterine repair should be undertaken only if the patient is hemodynamically stable and hemorrhage can

be controlled. When the uterus is extensively damaged and repair is impossible or the patient is in hemorrhagic shock, hysterectomy is indicated.

If the uterus is to be repaired, the site of rupture should be assessed after delivery of the fetus and once hemostasis is achieved. Necrotic tissue along the rupture site may be excised to allow reapproximation of well-vascularized tissue. The uterine defect can then be repaired in layers. The risk of uterine rupture in future pregnancies is certainly present, but not prohibitive. It would seem prudent to offer elective cesarean delivery in subsequent pregnancies, especially if the rupture site was fundal or the damage was extensive.

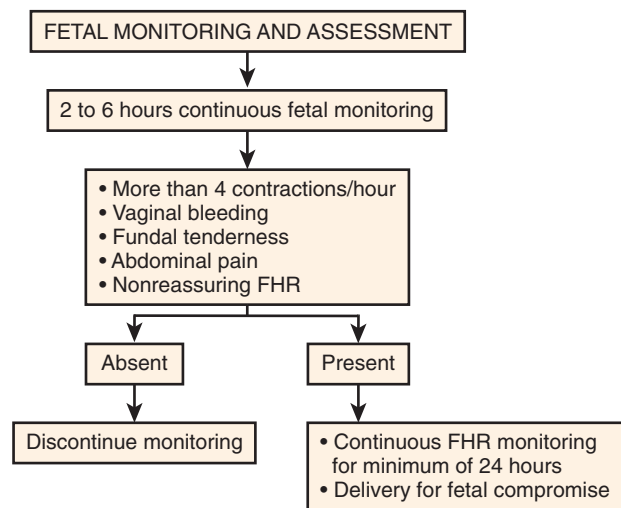
Fetal Injury

The exact incidence of fetal injury as a result of maternal trauma is unknown. An incidence of 0.49% has been noted in gravidas with noncatastrophic trauma.[47] Fetal skull fractures, long bone fractures, intracranial hemorrhage, and soft tissue injury have been reported. Skull fracture or head injury is most commonly described and is associated with maternal pelvic fracture late in gestation, when the fetal head is engaged.[52]

The management of fetal injuries must be individualized, and experience is limited. Delivery may be delayed in a very premature gestation if the fetus is alive and without signs of distress. Serial ultrasonography and frequent assessment of fetal well-being may be beneficial until maturity is reached. If pregnancy is advanced or delivery is indicated for fetal compromise, a pediatrician, or neonatologist if available, should be in attendance for delivery. Accurate and unbiased documentation is always important, given the medicolegal ramifications of fetal injury.

Fetal Assessment

The prediction of adverse fetal outcome after a traumatic event has been a controversial subject. Cardiotocographic monitoring is currently the most sensitive method of immediate fetal surveillance and is more sensitive than ultrasound in detecting abruption.[19,61,65] Risk factors for fetal death include ISS, severe abdominal injury, hypotension, hemorrhagic shock, disseminated intravascular coagulation (DIC) with or without abruption, and gestational age less than 23 weeks.[66–70] Because almost all patients who have placental abruption after trauma manifest signs soon after the event, it is important to institute fetal heart rate and uterine activity monitoring in the emergency department as soon as the mother is stable. Delayed abruption several days after an accident is described, but the few patients reported were not monitored immediately after the event and early signs may have been overlooked.[71,72]

Uterine activity appears to be the most sensitive indicator for the risk of abruption after blunt trauma.[15,23,47,73] The presence of six to eight or more contractions per hour identifies a patient who is at risk for adverse pregnancy outcome.[10,15,47] Approximately 14% of women who had contractions every 2 to 5 minutes immediately after blunt trauma subsequently had abruption. No patient with fewer than eight contractions per hour had abruption.[10] Similarly, a second study showed that when uterine contractions, tenderness, or vaginal bleeding were present, 19% of patients had obstetric


complications compared with 0.9% who did not have these symptoms.[15]

Although obstetric ultrasonographic examination can be helpful in fetal assessment, normal findings do not exclude or reduce the risk of abruption. The sensitivity of ultrasonography in predicting abruption in blunt trauma patients is only 40%.[10,19] Findings suggestive of an abruption include retro- or preplacental hematoma, increased placental thickness and echogenicity, and subchorionic or marginal fluid collection. Ultrasonography is useful to exclude placenta previa, document fetal viability, establish gestational age, estimate fetal weight, measure amniotic fluid volume, and assess fetal well-being.

Guidelines for monitoring pregnant trauma victims have been suggested and are outlined in Figure 54–3. If a patient does not have uterine tenderness, contractions, or vaginal bleeding on presentation, 2 to 6 hours of cardiotocographic monitoring is sufficient.[15,47,48,60,61] Patients may be released home if they do not have symptoms, the fetal heart rate pattern is reassuring, and maternal injuries have been appropriately evaluated and treated. These patients are not at increased risk for adverse pregnancy outcome compared with uninjured control subjects.[10] They should be instructed about the symptoms and signs of preterm labor and abruption as well as indications to return to the hospital.

Approximately 52% of gravidas have uterine tenderness, irritability, or contractions or vaginal bleeding after blunt trauma.[48] These patients require additional observation and continuous fetal monitoring; a minimum of 24 hours has been recommended, even if symptoms resolve.[47] A more recent study also recommends at least 24 hours of fetal monitoring if the maternal heart rate is greater than 110 beats/min, the ISS is greater than 9, the fetal heart rate is less than 120 beats/min or greater than 160 beats/min, or there is evidence of placental abruption, and for victims of ejections or motorcycle or pedestrian collisions.[74] The hospital stay should be extended as maternal and fetal conditions dictate. Seriously injured patients who require surgery or transfer to the intensive care unit present a challenge to

the obstetrician. If the fetus is viable, continuous monitoring should be used; obstetrics personnel must be readily available to evaluate the fetal heart rate tracing.

Fetomaternal Hemorrhage

The KB remains controversial and no study has clearly demonstrated usefulness in predicting adverse maternal or fetal outcome in pregnant trauma victims. Although routine testing of all gravid blunt trauma victims has been suggested, the clinical utility of this approach is uncertain.[48] Earlier studies reported that FMH occurs in a significant number of gravidas who are victims of blunt trauma, with an incidence of 8.7% to 30% in gravid trauma patients versus 1.8% to 8% of pregnant controls.[10,15,48,73,75] Another study, however, found no difference in the incidence of a positive KB in pregnant trauma patients (2.6%) versus low risk gravidas undergoing a diabetes screen (5.1%).[76] Patients evaluated in the study of minor trauma had a similar low incidence of a positive KB (2.8%).[16] The KB does not correlate with the occurrence of placental abruption or fetal distress,[16,47,73] but a positive KB has been suggested to predict preterm labor.[77] The KB predicted obstetric complications in only 27% of pregnant trauma patients in one study,[73] and the sensitivity for adverse outcome was only 4% to 18% in another series.[16] Although no clinical signs reliably predict FMH, an increased incidence has been noted in women who have an anterior placenta or uterine tenderness.[10,15]

Most fetuses with FMH have a normal outcome, but anemia, supraventricular tachycardia, and fetal demise are recognized complications.[10,75] No classification for degree of FMH has been established, but a number of studies have attempted to clarify the amount of FMH that predicts adverse fetal outcome. A transfused volume of greater than 20 mL/kg fetal weight has been suggested as the threshold at which adverse perinatal outome is observed.[78] Most recently, the transfused blood volume corrected for fetoplacental weight was shown to best correlate with fetal hemoglobin levels. A KB greater than 2.5% or transfused volume corrected for fetoplacental weight greater than 43 mL/kg was associated with adverse fetal outcome.[79] Middle cerebral artery (MCA) blood flow velocity reliably predicts fetal anemia in isoimmunized pregnancies, but its accuracy in the acute anemia of FMH is less certain. Too few data exist to use the MCA in isolation because severe acute anemia may not be detected.[79] Nevertheless, an elevated peak systolic velocity of the MCA would be very suggestive of fetal anemia.

The importance of KB testing in the pregnant trauma patient remains identification of a large volume of fetomaternal transfusion in the Rh-negative woman. Massive FMH occasionally occurs, so all Rh-negative gravidas should undergo KB testing after any trauma to ensure an adequate dosage of Rhogam is administered. Repeat testing 24 to 48 hours after the initial positive result may be considered to evaluate for ongoing FMH and ensure adequate Rhogam coverage.

Isoimmunization can occur very early in pregnancy because the Rh antigen is present on fetal red blood cells 34 days after conception. The amount of fetal blood required to stimulate maternal antibody formation may be as little as 0.01 mL. The KB test, however, is not sensitive enough to detect such a small amount of fetal blood in the maternal circulation. Because an undetectable amount of fetal blood can lead to sensitization in early pregnancy, all unsensitized Rh-negative women who suffer trauma should receive Rh immune globulin.[47,61]

The amount of immune globulin administered depends on the volume of FMH as calculated from the KB stain results. Anti-D immunoglobulin (300 μg or 1500 IU) administered within 72 hours of the event protects against maternal antibody formation for transfusion of up to 15 mL fetal red blood cells (30 mL whole blood). If KB testing is unavailable, 300 μg is adequate in most women and can be administered empirically.[15,19]

SUMMARY OF MANAGEMENT OPTIONS
Blunt Trauma

Management Options	Evidence Quality and Recommendation	References
General Management		
Perform general trauma resuscitation.	—/GPP	—
Obtain FHR monitoring and fetal ultrasound.	III/B	47
Abruptio Placentae		
Assess maternal condition.	III/B	59
Assess fetal condition with FHR.	IIa/B	10,15
	III/B	47

Preterm Labor		
Be alert for evolving abruption.	—/GPP	—
Consider tocolysis.	III/B	47,48
See Chapters 61 and 62 for detailed discussion.	—/—	—

Management Options	Evidence Quality and Recommendation	References
Uterine Rupture		
Exploratory laparotomy when suspected.	III/B	33
Use a midline incision for adequate exposure.		
Perform uterine repair if the patient is hemodynamically stable.		
Perform cesarean hysterectomy if the patient has uncontrollable hemorrhage or excessive uterine damage.		
Fetal Injury		
Individualize management, because experience is limited; gestation and fetal condition will influence the management; ultrasound evaluation may help.	—/GPP	—
Fetomaternal Hemorrhage		
Perform KB test: if positive, confirms significant fetomaternal hemorrhage; if negative, does not exclude a small bleed.	III/B	47
Give Rh immune globulin to all Rh-negative women in accordance with local guidelines; increased doses required with positive KB test.	III/B	47
	IV/C	61
Fetal Assessment		
FHR monitoring is the most sensitive assessment of immediate fetal condition.	III/B	19
	IV/C	61
Normal obstetric ultrasound does not exclude fetal risk (e.g., abruption); confirms viability, approximate weight, and presentation; excludes placenta previa.	IIa/B	10
	III/B	66,67
Clinical risk factors for adverse fetal outcome are severity of injury, shock, disseminated intravascular coagulation, and gestation <23 wk.	III/B	15,47,48
Guidelines for fetal monitoring:	III/B	15,47,48
• No uterine tenderness, contractions or bleeding.	III/B	15,47,48
• 2–6-Hr continuous FHR monitoring.	IV/C	61
• Uterine tenderness, contractions or bleeding: minimum of 24-hr continuous FHR monitoring.		

FHR, fetal heart rate; GPP, good practice point; KB, Kleihauer-Betke.

Seat Belts and Airbags

Passenger restraint systems have saved thousands of lives. The use of lap-shoulder belts reduces the likelihood of fatal injury by 45% and the likelihood of moderate to critical injury by 50%.[80] Safety belts minimize injuries by limiting passenger contact with the interior of the vehicle, preventing ejection, and spreading the force of deceleration over a larger area.

The leading cause of fetal death in MVAs is maternal death, and the most common cause of maternal death is ejection from the vehicle.[81] Maternal mortality rate is 33% when the woman is ejected from the vehicle versus only 5% when she is not. When the mother is ejected, the fetal mortality rate is 47% compared with 11% when the mother remains in the vehicle. The rate of fetal death is decreased by seat belt use because seat belts prevent ejection, thereby decreasing maternal mortality.[81]

The shoulder harness reduces the risk of maternal head injury by preventing jackknifing of the mother's torso over the lap belt and increasing the area over which deceleration forces dissipate. Decreasing force over the abdomen reduced the fetal mortality rate in animal studies from 50% with a lap belt alone to 12% with the three-point restraint system.[82] Crash simulation with a pregnant crash dummy also provides

evidence that the three-point restraint system decreases the likelihood of injury.[83]

Although air bags have augmented the reduction in rates of injury and death, they do not offer protection in lateral collisions and do not prevent ejection. Combined lap-shoulder restraint systems must continue to be worn for optimal crash protection. Air bags should not be disconnected during pregnancy and do not appear to worsen fetal outcomes.[44] Peak uterine strain has been shown to be reduced by half in computer simulations of air bag deployment.[84]

Despite the benefits of safety belts, pregnant women often hesitate to use them; 30% of gravidas either do not wear a safety belt or wear it incorrectly.[44,50,85] The perception of increased risk of fetal injury with seat belt use is a major factor contributing to the reluctance of pregnant women to use restraint systems. Unfortunately, only 42% to 55% of gravidas receive information on the use of restraint systems during pregnancy.[50,86,87] Women should be instructed to place the lap portion of the belt under the abdomen and across both the anterior and the superior iliac spines. The belt should be snug, but comfortable. The shoulder restraint should cross the shoulder without rubbing the neck and should be positioned between the breasts. It is helpful to remind pregnant women that women wearing seatbelts at the time of an MVA are not at significantly greater risk for adverse fetal outcomes than pregnant women not in an MVA.[51]

PENETRATING TRAUMA

Incidence

Pregnant women are the victims of penetrating trauma with increasing frequency, particularly in inner-city areas. Gunshot and stab wounds are the most common, but injury occurs by other mechanisms as well and may be self-inflicted.[88] Pregnant women have also been victims in terror-related multiple-casualty incidents and frequently sustain significant injuries.[89]

Mortality in nonpregnant victims with penetrating injury increases with the number of organs injured, but visceral injury and mortality are lower during pregnancy. The mother usually fares much better than the fetus when the injury is caused by a gunshot or stab wound.[22,90] Maternal mortality is 0% to 9% for gunshot wounds during pregnancy, whereas perinatal mortality is 41% to 71%.[90] When the mother is stabbed, fetal injury and fetal death occur in 93% and 50% of cases, respectively.[91]

Fetal survival is affected by several factors, including the severity of fetal and maternal injury, the presence and extent of placental hemorrhage, and gestational age at delivery. Although direct fetal injury is responsible for most perinatal deaths, some deaths results from premature delivery, with its attendant complications.[92] Women in terror-related incidents have a high likelihood of requiring emergent delivery for fetal compromise with bradycardia, uterine rupture, and placental abruption cited in a recent review.[89]

General Management

Maternal injury patterns change with advancing gestation. Penetrating trauma in the first trimester causes wounds similar to those in nonpregnant victims. As the uterus enlarges and occupies more space in the abdominal cavity, it is more likely to be injured than any other intra-abdominal organ. The uterus offers relative protection to other abdominal organs by the third trimester. Hence, bowel injury is less common when a pregnant woman has a penetrating injury to the lower abdomen, but the small bowel is at high risk for injury when entry is in the upper abdomen. Multiple bowel wounds are more common in pregnant victims than in their nonpregnant counterparts because the intestine is compressed in the upper abdomen with advancing gestation.

As with other forms of trauma, the emergency team, trauma surgeon, and obstetrician must coordinate the care of a pregnant woman. Maternal resuscitation and hemodynamic stability are a priority, and the leading cause of early death from gunshot wounds is hypovolemia as a result of major vessel injury. The injured woman must be thoroughly examined and each entrance and exit wound noted. If exploratory laparotomy is indicated, a midline vertical incision offers optimal exposure to the abdomen.

DPL may be used to identify intra-abdominal injury requiring laparotomy, but it has several limitations in patients with penetrating injuries.[6] First, the findings may be negative in nonpregnant victims, despite hollow viscus injury, because bleeding is usually minimal. Second, the leukocyte response to bowel injury may be delayed, causing a false-negative finding. Finally, the accuracy of DPL in pregnant women with stab wounds is unknown. Although a positive finding would be expected when uterine vessels are injured, the size of a uterine wound and the depth of penetration cannot be ascertained.

FAST was prospectively evaluated in 75 patients with penetrating abdominal trauma and was shown to be useful as the initial diagnostic test.[93] It is not, however, as reliable as in blunt trauma, and a negative result requires additional testing. In addition, it has not been studied in pregnant victims of penetrating trauma, and its accuracy is unknown in this setting.

An indication for exploratory laparotomy, however, is not an indication to empty the uterus. Abdominal delivery concurrent with exploratory laparotomy increases operative time and blood loss. A patient may undergo induction of labor and vaginal delivery postoperatively without increased risk of morbidity.[94] The only indication for hysterotomy is to provide adequate surgical exposure for repair of maternal injuries. Cesarean hysterectomy is indicated when damage to the uterus is extensive or uterine injury is associated with uncontrollable hemorrhage. Specific guidelines for treating pregnant women with gunshot and stab wounds are discussed later, but these guidelines should be individualized based on obstetric and surgical needs.

Gunshot Wounds

The size of the entrance wound does not predict the internal damage caused by a bullet. If no exit wound is found, radiographic studies are performed to localize the bullet. A flat plate and lateral film usually suffice. A number of management options exist for intra-abdominal bullet wounds and

include exploratory laparotomy with or without cesarean delivery, DPL, laparoscopy, contrast CT, wound exploration, and observation.

Surgical exploration has been considered standard practice for managing bullet wounds of the abdomen and flank. However, careful observation of a wounded gravida has been suggested as an alternative in the following situation[95]:

- The mother is hemodynamically stable.
- The bullet has entered below the uterine fundus.
- The bullet can be localized to within the uterus.
- No maternal genitourinary or gastrointestinal injury has occurred.

The fetus should be free of injury or compromise, or dead, if the mother is managed conservatively.[96,97] Broad-spectrum antibiotic coverage is prudent, at least initially. This conservative approach should be considered only in trauma centers in which experienced surgeons manage trauma care. With this approach, it has been suggested that fewer than 20% of gravidas require surgical intervention for visceral wounds.[95]

Although nonoperative management has been reported, this approach has not been prospectively tested in gravidas with penetrating injuries. Radiologic studies may give a false impression of the location of the bullet in the uterus when significant maternal injury has occurred.[98] DPL can be performed to exclude intra-abdominal hemorrhage. Exploratory laparotomy, however, is the most reliable means for detecting intra-abdominal injury should doubt exist. The ultimate decision about the need for operative intervention rests with the surgical team.

The decision to deliver the fetus is based on gestational age, fetal status, and exposure required for surgical exploration and repair of maternal injuries. If a near-term fetus is alive and the uterus injured, cesarean delivery with uterine repair is reasonable. When a viable fetus is alive but remote from term, suggested indications for delivery include evidence of fetal hemorrhage, uteroplacental insufficiency, and infection.[90]

Although fetal injury can occur when a bullet enters the mother's lower abdomen, the risks of prematurity may outweigh the risk of delaying repair of fetal injuries. Although obstetric ultrasonography and radiography may be helpful, the diagnosis of in utero injuries can be difficult. Neonatal and pediatric surgical consultation is invaluable in planning care.

If the fetus has died, vaginal delivery is preferred if there is no evidence of uterine hemorrhage. Options include awaiting spontaneous labor and induction of labor with prostaglandins or oxytocin once maternal injuries have been addressed. If laparotomy is required and the uterus prevents exposure for repair of maternal injuries, evacuation of the dead fetus is indicated.

Stab Wounds

When a patient has a stab wound, attempts should be made to determine the object used and its length. The longer the object, the more likely it is that the peritoneum was penetrated when the abdomen was wounded. The risk of intestinal injury in nonpregnant stabbing victims is less than that with gunshot injuries because bowel tends to move away

from a penetrating object (sliding effect). This effect explains, in part, the lower mortality rate with stab wounds than with gunshot wounds. The sliding effect may be less during pregnancy because bowel is compressed into the upper abdomen with advancing gestation.

Traditionally, all abdominal stab wounds have been regarded as an indication for exploratory laparotomy, but nonoperative management has been considered for some patients.[88] Two of the most important factors in assessing the need for laparotomy in injured gravidas are peritoneal penetration and location of the entrance wound. A wound can be probed, and a fistulogram may assist in determining whether the peritoneal cavity has been entered. If a conservative approach is chosen, the patient must be closely monitored and exploration undertaken without delay if the mother has signs of hemorrhage or evidence of sepsis. Contraindications to observation include

- Penetration of the peritoneal cavity.
- Entry above the fundus.
- Hemodynamic instability of the mother.
- Fetal compromise at a viable gestational age.

The final decision for operative intervention should, as with gunshot wounds, be made by the surgical consultant.

A lower abdominal stab wound with adequate force is likely to damage the uterus as well as the fetus. Management options include observation or laparotomy/uterine repair with or without delivery of the fetus.[99] No outcome data are available comparing repair of a uterine wound with no repair. The risks of infection and uterine rupture associated with each approach are unknown, given the limited number of patients with these injuries. Indications for delivery are the same as those for gravidas with a gunshot wound.

Based on reported cases of stab wounds to the pregnant uterus, Sakala and Kort[91] proposed the following management plan: A nonperforating injury of the uterus may be repaired without disturbing the pregnancy. Perforating injuries, however, carry a much higher rate of fetal injury. A fetus at or near term should be considered for cesarean delivery and uterine repair. If the fetus is premature, alive, and not compromised, the uterus may be repaired, with vaginal delivery anticipated. When the fetus has died, both perforating and nonperforating injuries should be repaired and the fetus delivered vaginally. The injured uterus maintains its ability to labor and deliver an infant.[100] Antibiotic prophylaxis seems reasonable in these cases, although no data are available to support this recommendation.

Stab wounds to the upper abdomen are three times more frequent than lower abdominal wounds. Upper abdominal wounds that penetrate the peritoneum require surgical exploration because of the high likelihood of small bowel injury. If doubt exists, exploratory laparotomy is the safest approach to exclude intra-abdominal injury. When the peritoneum of the upper abdomen has been penetrated, laceration of the diaphragm must be excluded because it can result in bowel herniation, strangulation, and sepsis. After diaphragm repair, labor and second-stage Valsalva efforts should be avoided and cesarean delivery should be performed, presumably to avoid increasing intra-abdominal pressure.[91]

SUMMARY OF MANAGEMENT OPTIONS
Penetrating Trauma

Management Options	Evidence Quality and Recommendation	References
General Management		
See earlier box on "Blunt Trauma."	—/—	—
Examine patient for entrance and exit wounds.	IV/C	22
	III/B	90
Exploratory Laparotomy		
Use a midline vertical incision.	IV/C	22
	III/B	90
Uterine evacuation is not mandatory.	IV/C	22
	III/B	90
Cesarean hysterectomy may be necessary if the patient has uncontrollable hemorrhage or excessive uterine damage.	IV/C	22
	III/B	90
Gunshot Wounds		
Obtain flat plate and lateral radiographs if no exit wound is visible.	IV/C	96
Perform surgical exploration if:		
• Signs of intra-abdominal injury.	III/B	94
• Positive peritoneal lavage.	III/B	6
• Persistent unexplained shock.	—/GPP	—
Consider conservative management if:		
• The mother is hemodynamically stable.	IV/C	95,96
• The bullet entered below the uterine fundus.	III/B	94
• The bullet can be localized to the uterus.	III/B	94
• The fetus is without injury or dead.	III/B	94
• The mother has no genitourinary or gastrointestinal injury.	III/B	94
Deliver fetus if:		
• Evidence of fetal hemorrhage.	IV/C	95
• Uteroplacental insufficiency.	IV/C	95
• Infection.	—/GPP	—
Stab Wounds		
Determine peritoneal penetration; options:		
• Probe wound.	—/GPP	—
• Fistulogram.	IV/C	91
• Diagnostic peritoneal lavage.	III/B	6
Perform surgical exploration if:		
• Peritoneal penetration.	IV/C	91
• Entry above the uterine fundus.	—/GPP	—
• Hemodynamically unstable mother.	IV/C	99
• Fetal compromise at viable gestation.	IV/C	91
Consider conservative management if:		
• No peritoneal penetration.	IV/C	91
• Entry below the uterine fundus.	IV/C	91
• Guidelines for delivery of the fetus are the same as for gunshot wounds (see "Gunshot Wounds," earlier).	IV/C	91

Management Options	Evidence Quality and Recommendation	References
Assess uterine injury with lower abdominal stab wound; options:		
• Observation.	IV/C	91
• Uterine repair with delivery.	IV/C	91
• Uterine repair and fetus remains in utero.	IV/C	91

GPP, good practice point.

ACUTE SPINAL CORD INJURY

The initial management of a pregnant patient with a spinal cord injury includes general resuscitation measures, stabilization of the neck, and airway maintenance. Initiation of high-dose methylprednisolone (30 mg/kg) within 8 hours of the injury followed by 5.4 mg/kg for 23 hours improves motor and sensory function at 6 months.[101] Evaluation for additional injuries should be performed and fetal monitoring instituted as soon as possible given the potential hemodynamic sequelae of cord injury. Neurogenic shock, cardiovascular instability, and autonomic hyperreflexia can develop following complete cord transection. Long-term issues of the patient with a spinal cord injury are beyond the scope of this chapter.

Neurogenic shock develops due to the blockade of sympathetic function associated with the cord injury. Parasympathetic symptoms dominate and include hypotension, bradycardia, decreased cardiac output, and hypothermia, all of which can lead to fetal distress. Fluid replacement and inotropic agents such as dobutamine may be required to maintain hemodynamic stability. This therapy should be guided by central vascular monitoring. Neurogenic shock lasts from 1 to 3 weeks, and its resolution may be signaled by the onset of autonomic hyperreflexia.

Autonomic hyperreflexia develops in 85% of patients with a cord injury above T5-6. It is due to unregulated sympathetic discharge and is triggered by a stimulus below the level of the lesion (full bladder or rectum, labor). Paroxysmal release of catecholamines causes tachycardia, hypertension, flushing, headache, sweating, and feelings of anxiety. Treatment in the laboring patient includes regional anesthesia; labetolol or hydralazine may also be used but with caution to avoid hypotension.

BURNS

Incidence

Fortunately, most burns sustained during pregnancy are minor, and more severe burns are uncommon. Most burns occur in the home and result from a house fire, hot water, flammable liquids, or gases. Pregnant women account for 0.4% to 7% of all patients who are hospitalized with major burns.[102–106]

Maternal survival is dependent on the percentage of total body surface area (TBSA) burned.[105,107,108] When 20% to 39% of TBSA has been burned, 97% to 100% of gravidas survive. The mortality rate for 40% to 59% TBSA burns ranges from 27% to 50%. Burns exceeding 60% TBSA are associated with very high death rates.[104,105,108–111] Survival in pregnant women with burn injuries is comparable with that in their nonpregnant counterparts, when matched for burn severity.[107] Concurrent inhalation injury is associated with increased maternal and fetal mortality.[112]

Fetal survival is also affected by the percentage of maternal TBSA involved. The fetal mortality rate is negligible when the burn affects less than 20% of maternal TBSA. When 20% to 39% of the mother's TBSA is involved, the fetal loss rate ranges from 11% to 27%. The fetal mortality rate increases to 45% to 53% with burns that affect 40% to 59% of maternal TBSA. When a pregnant woman has a burn that involves greater than 60% of TBSA, fetal loss approaches 100%.[104,105,108–111]

Classification of Burns

The depth of a burn is classified by a system that characterizes the need for surgical treatment. A *superficial burn* is confined to the epidermis with pink or red painful skin. *Superficial partial-thickness burns* involve the epidermis and superficial dermis. Adequate epithelial cells remain and allow skin to regenerate. Clinically, blistering, erythema, and pain characterize superficial partial-thickness burns. *Deep partial-thickness lesions* are characterized by blisters, pale white appearance, and no pain. *Full-thickness burns* destroy all dermal elements and regeneration is not possible without grafting. The burned area appears charred and leathery, without blisters; thrombosed superficial vessels may be visible and pain is absent.

Burn size, or the percentage of TBSA, can be estimated by the "rule of nines" and refined with a Lund-Browder or Berkow chart. This system was devised for nonpregnant patients, however, and does not account for the presumed increase in abdominal surface area with advancing gestation.

Burn severity is defined as minor, moderate, or major. A minor burn is a superficial burn, a partial-thickness burn that covers less than 10% of TBSA, or a full-thickness burn that covers less than 2% of TBSA. Moderate burns are those of 10% to 20% TBSA, 2% to 5% full-thickness burn, high-voltage injury, suspected inhalation injury, circumferential burn, and coexisting medical problems that predispose to infection. Moderate burns require hospital admission for management. Major burns include any burn covering more than 20% TBSA; full-thickness burns covering more than 5% of TBSA; burns of the face, eyes, ears, hands, feet, genitalia, or skin over major joints; high-voltage burn, including

lightning strike; inhalation injury; patients with other significant injury; and patients requiring special social, emotional, or long-term rehabilitation. Major burns mandate referral to a burn center.[113]

Management of Minor Burns

Minor burns may be treated on an outpatient basis if the burn does not affect an area of critical function (e.g., hand, across a joint) or an area in which cosmesis is a concern (e.g., face). Superficial burns do not require specific treatment beyond keeping the area clean and protected. A mild analgesic may be prescribed. A narcotic, such as oxycodone, may be required for pain control in patients with partial-thickness burns. The burned area should be cleansed with sterile saline and devitalized tissue removed. Large blisters may be incised and débrided. Blisters should not be aspirated because bacteria can be introduced into a closed space. A number of biosynthetic dressings are commercially available and can be used to protect the burned area. Patients with partial-thickness burns should be reevaluated in 24 hours. At this time, the wound is evaluated and the dressing changed. Complete healing can be expected in 2 to 3 weeks, with no adverse effects on the pregnancy.

Management of Major Burns

The basic principles of resuscitation also apply to the patient with a major burn injury. Fluid resuscitation is the most important initial treatment and is commonly required for burns covering greater than 20% TBSA. Venous access should be established with a 14- to 16-gauge catheter placed through unburned skin, when possible. Immediate removal of clothing prevents continued burning by smoldering synthetic fabric. All skin surfaces must be examined, burned areas assessed for depth and surface area involved, and additional injuries excluded. Diligent wound care is critical to preventing infectious complications. Inhalation injury should be suspected and 100% oxygen given by face mask. Arterial blood gas analysis and carbon monoxide level measurements are standard. An intravenous narcotic should be administered, as needed, for pain control.

The systemic response to a major burn is a massive release of vasoactive mediators that cause a decrease in plasma and blood volumes, shifting intravascular fluid to intracellular and interstitial compartments. Thus, the goal of fluid resuscitation is to correct hypovolemia during the initial 24 to 48 hours. Hypovolemic shock develops in a patient with burns covering more than 15% to 20% of TBSA if fluid resuscitation is not instituted promptly.[114] Hypovolemia in the pregnant patient can also lead to decreased placental perfusion and fetal compromise. Therefore, proper resuscitation is critical for both mother and fetus.

The essential component of fluid resuscitation is crystalloid (normal saline or lactated Ringer's solution). Edema formation at the burn site is most rapid during the initial 6 to 8 hours after a burn, and fluid is administered at a rate to compensate for the intravascular loss. The amount of fluid that a patient requires during the first 24 hours after a burn injury can be estimated with one of several formulas. The Parkland formula estimates fluid requirements during the first 24 hours as 4 mL/kg/% TBSA burned. One half of the total fluid required is administered during the first 8 hours after the burn (not after admission), and the remaining half is administered over the next 16 hours. The Brooke and Evans formulas are also used to estimate fluid requirements, but differ in their administration of colloid and free water in addition to crystalloid. Inhalation injury also increases the amount of fluid required during initial resuscitation. A new multifactorial formula has been recently published that may offer a better guide to initial fluid resuscitation.[115]

The standard formulas, however, may not be as accurate for a major burn in pregnancy because they appear to underestimate the amount of fluid required for adequate resuscitation. A case report of a gravida with 38% TBSA burn and inhalation injury required twice the amount of fluid estimated by the Parkland formula.[116] Fluid administration is adjusted to maintain urinary output of 0.5 mL/kg/hr or 30 to 50 mL/hr. Over-resuscitation must be avoided because compartment syndromes can develop as edema accumulates beneath the inelastic burned skin of deep burns (eschar). Most patients remain tachycardic despite adequate fluid resuscitation, and because pregnant women have a mild baseline increase in heart rate, this may not be a reliable clinical measure. Serum electrolytes must be closely monitored during and after resuscitation, with imbalances corrected on an ongoing basis.

Carbon Monoxide Poisoning

Carbon monoxide (CO) poisoning can occur whenever carbonaceous material is released as a result of incomplete combustion. The affinity of CO for hemoglobin is more than 200 times that of oxygen, and it readily displaces oxygen from hemoglobin.[117] CO causes a left shift of the oxyhemoglobin dissociation curve and increases the affinity of hemoglobin for the remaining bound oxygen. Tissue oxygenation decreases as less oxygen is released from hemoglobin in the periphery. Signs and symptoms of CO poisoning correlate with the blood level. A CO level of less than 10% is unlikely to cause symptoms, whereas levels of 10% to 20% cause a mild headache and palpitations. Once the level reaches 20% to 40%, dizziness, agitation, confusion, and incoordination become apparent. Patients with a CO level of greater than 40% are at risk for progressive dyspnea, lethargy, coma, and death.

CO readily crosses the placenta and may cause fetal malformations, hypoxia, neurologic dysfunction, low birth weight, and death in utero. CO levels rise more slowly in the fetus than in the mother and continue to increase for up to 24 hours after the maternal level has reached a steady state. Once fetal CO reaches a steady state, the concentration is 10% to 15% higher than the mother's concentration. Likewise, the fetus requires a much longer time for elimination than the mother does. The maternal half-life of CO in a sheep model was 2.5 hours compared with 7 hours in the fetus.[117]

The blood level determines the urgency of treatment for CO poisoning. Observation is sufficient if the CO level is less than 10%. When the level is 10% to 20%, treatment with 100% inspired oxygen is indicated. High-concentration oxygen administered with a tight-fitting face mask decreases the half-life of carboxyhemoglobin in adults from 2 to 3 hours in room air to 45 minutes.[117] Similarly, 100% oxygen decreases the half-life of carboxyhemoglobin

in the fetus from 7 hours to 2 to 3 hours, but it is still longer than that in the mother. Based on mathematical calculations, a pregnant woman with CO poisoning should receive 100% oxygen for up to five times longer than needed to reduce her own level to normal (<5%).[117,118] This extended period of treatment allows for the longer elimination time required by the fetus.

Hyperbaric oxygen therapy is used for nonpregnant patients with a CO level greater than 25% or with neurologic changes, regardless of the blood level. It has been used to treat pregnant women with CO poisoning, with no adverse fetal effect. Therapy has been recommended for pregnant women with a maternal CO level of more than 20%; neurologic changes, regardless of the CO level; or signs of fetal compromise.[119] However, hyperbaric oxygen therapy in patients with a major burn presents a number of logistic problems, and care must be individualized.

Inhalation Injury

Inhalation injury occurs as a result of exposure to smoke particles and chemicals. Patients who are burned in a closed space are at increased risk, and the incidence increases with burn severity. Two thirds of patients with burns affecting more than 70% of TBSA have concurrent inhalation injury.[114] Singed nasal hair, facial burns, inflamed oropharyngeal mucosa, carbonaceous sputum, and a CO level greater than 15% suggest injury. Laryngeal edema should be suspected in a patient with hoarseness, stridor, or cough. Intubation may be required to maintain a patent airway. The initial chest radiograph, however, may not show the severity of injury. If the diagnosis of inhalation injury is in doubt, laryngobronchoscopy can be performed. Treatment includes warm humidified oxygen, bronchodilators, pulmonary toilet, nebulized heparin, and therapeutic bronchoscopy. Mechanical ventilation is required if respiratory failure occurs.

Additional Complications of Burns

Patients with major burns are at risk for many complications, including pulmonary edema, pneumonia, septic shock, electrolyte disturbances, ileus, nutritional deficiencies, and scar formation. Sepsis is the major cause of death in patients with burns, emphasizing the importance of sterile technique.[108] Topical antimicrobial agents delay bacterial colonization of the wounded area. Three have established efficacy in the treatment of major burns: 11.1% mafenide acetate, 1% silver sulfadiazine, and 0.5% silver nitrate. Silver sulfadiazine must be used with caution, and long-term use is relatively contraindicated in pregnant women because of the theoretical risk of kernicterus in the newborn. Iodine-containing solutions are frequently used for wound care, but their use must be limited during pregnancy because of the absorption of the iodine and the risk of fetal thyroid dysfunction.[108] All patients with a burn affecting greater than 10% of TBSA should receive tetanus toxoid with immunoglobulin if their previous immunization status is uncertain

Circumferential burns of the thorax or abdomen may cause respiratory compromise or vena caval compression in pregnant victims. Early escharotomy improves respiratory excursion and relieves increased intra-abdominal pressure. Scar formation can be physically limiting, but successful

pregnancies have been reported in patients with significant abdominal scarring after burn injuries. Surgical release and grafting can be performed in a scar that becomes restrictive with advancing pregnancy, and uninvolved expanded abdominal skin has been used as a flap to reconstruct a scar after delivery.[120,121]

Clinically significant thromboembolism is an infrequent complication in patients with a major burn. Nevertheless, prophylaxis has been suggested for patients with additional risk factors, including lower extremity trauma, extensive burns, morbid obesity, prolonged bed rest, and central venous lines.[41] Although data on thromboembolism in pregnant burn victims are not available, the hypercoaguable state of pregnancy is a risk factor for which heparin prophylaxis seems reasonable, providing no contraindications.[112,116]

Obstetric Complications of Burns

Obstetric complications associated with major burns include spontaneous abortion, premature labor, and fetal death in utero. The first week after injury seems to be the period of highest risk, and medical complications often precede obstetric complications. The physiologic response to burns includes hypovolemia, hypoxia, acidosis, electrolyte imbalance, and sepsis. Each of these, alone or in combination, can lead to uterine activity or fetal compromise.[122] Septicemia is the most common cause of spontaneous abortion in women with burns.[102]

An increased incidence of premature labor has been associated with burns affecting more than 30% to 35% of TBSA.[122] Prostaglandins and leukotrienes are released from macrophages, neutrophils, and platelets at the burn site. Prostaglandin F_2, a uterine stimulant, is produced by scalded skin. Because prostaglandins are associated with uterine activity, pregnant women who have a burn injury should be monitored for uterine contractions. Tocolytic agents, particularly β-mimetics, must be used very cautiously, and only after the mother is clinically stable and the fetal heart rate tracing is reassuring.

Intervention on behalf of a viable fetus may be required in a gravida with a major burn. The following recommendations are based on combined experiences of various authors caring for pregnant burn victims: Delivery is suggested when a significant medical complication develops in a woman with moderate burns, because fetal survival in this group appears to be influenced by maternal complications. Likewise, early obstetric intervention has been advocated for a gravely ill woman who has complications that jeopardize the fetus and any woman with extensive burns who is beyond 32 weeks' gestation.[103,107] Fetal death occurs most commonly during the first week after a major burn and is a likely event when a gravida has severe to critical burns.[122,123] Delivery after maternal stabilization is recommended for women at 26 weeks' gestation and beyond with burns affecting greater than 40% to 50% of TBSA.[105,110,111,123] This recommendation is based on older literature, and the gestational age for intervention should be adjusted based on institutional neonatal survival at the limits of viability and on patient and family wishes. Cesarean delivery is reserved for obstetric indications, and vaginal delivery has been accomplished, even in women with perineal burns. If abdominal delivery is indicated, the incision may be performed through burned skin without increasing morbidity.

SUMMARY OF MANAGEMENT OPTIONS
Burns

Management Options	Evidence Quality and Recommendation	References
Minor Burns		
Treat as outpatient if burn does not cover area of critical function or cosmetic importance.	—/GPP	—
Superficial burn:		
• Analgesia.	—/GPP	—
• Keep burned area clean and protected.	—/GPP	—
Partial full-thickness burn:		
• Clean, débride and irrigate.	—/GPP	—
• Bacitracin ointment.	—/GPP	—
• Nonadherent dressing.	—/GPP	—
• Adequate analgesia.	—/GPP	—
• Reevaluate in 24 hr.	—/GPP	—
Major Burns		
Perform resuscitation.		
See "General Management" (earlier)	—/—	—
Manage fluid balance:	IV/C	114,115
• Adequate fluid administration (Parkland, Brooke, or Evans formula).		
• Monitor urinary output to maintain 0.5 mL/kg/hr.		
Examine entire body surface: assess depth of burn and surface area involved.	IIa/B	105,109
Obtain arterial blood gas analysis and carbon monoxide level.	IV/C	117
Wound care:		
• Sterile technique.	—/GPP	—
• Topical antimicrobial agent.	—/GPP	—
• Silver sulfadiazine relatively contraindicated in late pregnancy.	—/GPP	—
• Surgery for débridement, prevention of cicatrization.	—/GPP	—
• Cicatrized abdominal wounds may require release in pregnancy.	IV/C	120
• Minimal use of iodine-containing topical cleansing solutions.	IV/C	108
Carbon monoxide poisoning:		
• 100% inspired oxygen by face mask if CO level ≥10%.	IV/C	117
• Treat five times longer than required to lower maternal level <5%.	IV/C	117
• Hyperbaric oxygen therapy if:	IV/C	119
• Maternal CO level >20%.		
• Neurologic changes occur (regardless of CO level).		
• Signs of fetal compromise are noted.		
Inhalation injury:	IV/C	114
• Intubation if laryngeal edema develops.		
• Warm humidified oxygen.		
• Pulmonary toilet.		
• Mechanical ventilation as indicated.		
• Therapeutic bronchoscopy.		

Management Options	Evidence Quality and Recommendation	References
Preterm labor: • Cautious use of tocolysis if preterm labor. • Steroids if preterm delivery likely.	III/B	122
Consider delivery of the fetus if: • Significant medical complications in a gravida with a moderate to severe burn injury. • Complications occur in a gravely ill woman. • Extensive burns at > 32 wk' gestation. • >40%–50% of the total body surface area is burned.	IIa/B	105,109

CO, carbon dioxide; GPP, good practice point.

ELECTRICAL INJURY

Incidence

Reports of electrical injuries in pregnant women are exceedingly uncommon. A total of 21 pregnant women with electrical injury and 13 gravidas struck by lightning have been reported.[124,125] Although one study reported no maternal deaths from conductive and lightning injuries, the fetal mortality rate was 73%[124] and 50% in a second series,[126] respectively. The fetal death rate was only 6%, however, in 31 women who were followed prospectively after predominantly household electrical injuries.[125] Minor injuries are less likely to be reported than catastrophic events, however, and the true incidence of electrical injury in pregnancy is probably underestimated. Most victims of electrical injury have multisystem trauma and should be transferred to an experienced center for optimal care.

Management Options

The direct effects of the current and the heat it generates cause physical damage, as does trauma as a result of electrical injury. Electrical injury can be thermal, conductive, or caused by lightning; conductive injuries are the most common. The type of current, its path through the body, and its voltage also affect the type of injury. Cardiac and respiratory arrest are the main causes of death after injury from domestic alternating current and lightning. The current passing through the body can cause cardiac dysrhythmia, asystole, respiratory arrest, muscle contraction, tetany, skeletal fractures, and neurologic injury. Continuous cardiac monitoring is recommended for patients who have loss of consciousness, cardiac dysrhythmia, abnormal findings on 12-lead electrocardiogram, abnormal mental status or physical examination findings, or burns or tissue damage expected to cause hemodynamic instability or electrolyte abnormalities.[127] Fractures may be caused by a fall occurring with the shock, and cervical spine injury as a result of muscular contraction must be excluded. Rhabdomyolysis can cause renal failure if adequate intravenous hydration is not maintained until myoglobinuria resolves. Tissue necrosis may be extensive, and antibiotic prophylaxis with penicillin decreases the risk of muscle and fascial infection. Surgical consultation may be required for wound care, débridement, and fasciotomy. Most victims of electrical injury have multisystem trauma and require transfer to an experienced center for optimal care.

Resistance to current varies among tissues of the body. Amniotic fluid, the uteroplacental circulation, fetal skin, nerves, and blood offer low resistance to electrical current flow; much higher resistance is found in tendon, fat, and bone.[124,128] As a result, the fetus is very vulnerable to electrical injury. When the current takes a hand-to-foot path through the mother, it presumably passes through the uterus.[125,128] The current path may, therefore, be an important factor in fetal outcome and may account for the difference in mortality rates among reported cases.[124,125]

The severity of maternal injury is not predictive of fetal outcome, and minor exposure can have a profound fetal effect. Significantly less current is required to produce injury in the fetus than in the mother.[124] In cases of fetal demise, cardiac arrest appears to have been the cause of death. This observation is consistent with maternal reports of sudden cessation of fetal movement after the injury. Intrauterine growth restriction and oligohydramnios have been reported in fetuses surviving maternal electrical injury.[124,128] An animal model also showed growth restriction in 71% of rabbit fetuses subjected to electrically induced thermal injury of the placenta.[129]

The paucity of data makes it difficult to offer management recommendations for a gravida who has an electrical injury. Care of the mother should follow established guidelines. Fetal cardiac activity should be confirmed after electrical injury. If the fetus is alive and viable, continuous cardiotocographic monitoring should be started at the time of initial maternal evaluation. Monitoring for 4 hours is suggested when minor mechanical trauma (e.g., fall to the floor) is associated with electrical injury. Twenty-four hours of maternal and fetal monitoring has been recommended if the results of maternal electrocardiogram are abnormal, maternal loss of consciousness occurred, or there is a history of maternal cardiovascular disease.[127] Monitoring for oligohydramnios and fetal growth restriction throughout the rest of the pregnancy is also recommended for the surviving fetus.[128]

SUMMARY OF MANAGEMENT OPTIONS
Electrical Injury

Management Options	Evidence Quality and Recommendation	References
Maternal Resuscitation		
Manage multisystem trauma in cooperation with subspecialists (see earlier).	—/—	—
Obtain continuous cardiac monitoring with:	III/B	127
• Loss of consciousness.		
• Cardiac dysrhythmia.		
• Abnormal 12-lead electrocardiogram reading.		
• Abnormal mental status or physical examination findings.		
• Burn or tissue damage is expected to cause hemodynamic instability or electrolyte abnormalities.		
Provide adequate intravenous hydration if rhabdomyolysis develops.	III/B	124,125
Provide antibiotic prophylaxis.	III/B	124,125
Provide wound and burn care.	III/B	124,125
Obstetric Management		
Confirm the presence of FHR.	—/GPP	—
Maternal injury does not correlate with fetal injury.	III/B	124
Obtain continuous cardiotocographic monitoring for 4 hr:	III/B	128
• Minor mechanical trauma.		
Obtain continuous cardiotocographic monitoring for 24 hr:	III/B	128
• Abnormal maternal electrocardiogram reading.		
• Maternal loss of consciousness.		
• History of maternal cardiac disease.		
Consider surveillance for oligohydramnios and fetal growth restriction if the fetus survives the event.	III/B	124,128

FHR, fetal heart rate; GPP, good practice point.

PERIMORTEM CESAREAN SECTION

Incidence

The concept of perimortem and postmortem cesarean delivery dates back thousands of years. Fortunately, it is an uncommon occurrence, and the exact incidence is difficult to calculate. It is important to distinguish emergency cesarean section in the emergency department from perimortem cesarean section. Emergency cesarean section is performed for maternal or fetal distress but maternal vitals are present. Perimortem cesarean section is performed concurrent to the mother's cardiopulmonary arrest.

Management Options

The decision to perform perimortem cesarean delivery in an attempt to save the fetus is based on gestational age and the duration of cardiac arrest. The operation is not performed in anticipation of cardiopulmonary arrest, but only once cardiovascular collapse has occurred.

One of the most important questions is the effect of cesarean delivery on the efficiency of cardiopulmonary resuscitation (CPR). Even under optimal conditions, CPR generates a cardiac output that is only 30% of normal.[130] Ten percent of maternal cardiac output is shunted to the uterus, and left lateral tilt as recommended to decrease vena caval compression further reduces the effectiveness of chest compressions. Oxygen consumption increases during pregnancy and predisposes pregnant women to rapid desaturation with hypoventilation. It is presumed that delivery of the fetus allows more efficient CPR by relieving vena caval obstruction and increasing blood volume by autotransfusion.

The sooner the infant is delivered after a maternal arrest, the better the chance of intact neurologic survival. Optimal neonatal outcome is achieved when delivery occurs less than 5 minutes from the arrest. There are no documented cases of intact fetal survival beyond 35 minutes from the onset of

cardiac arrest in the mother.[130] Therefore, it seems reasonable to proceed with delivery up to 35 minutes after maternal collapse, although the risk for neonatal compromise is high. If more than 4 minutes have passed, but signs of fetal life are present, proceed with delivery. If the duration of arrest is unknown, proceeding with delivery is also reasonable, although fetal survival becomes unlikely beyond 20 minutes, particularly with catastrophic maternal trauma.

Once maternal cardiopulmonary arrest has occurred and the decision is made to intervene on behalf of the fetus, the following steps are suggested: Initiate delivery 4 minutes after maternal arrest if resuscitation is unsuccessful, with the intention to deliver the fetus 5 minutes after the arrest.[130] Intervention at a gestational age of 24 weeks or more is recommended by the EAST Practice Group.[131] CPR is continued throughout the procedure to offer every chance for maternal survival. Do not waste precious time preparing a sterile field or instrument tray or attempting to perform an ultrasound examination. Each surgeon should approach the abdominal incision in their most efficient fashion. A low transverse uterine incision offers the advantages of less blood loss and quicker closure than with a classic incision.

SUMMARY OF MANAGEMENT OPTIONS
Perimortem Cesarean Section

Management Options	Evidence Quality and Recommendation	References
Perform when maternal cardiopulmonary arrest occurs, not in anticipation of it.	IV/C	130
Initiate delivery 4 min after arrest if maternal resuscitation is unsuccessful: the goal is delivery 5 min after arrest.	IV/C	130
Continue cardiopulmonary resuscitation during delivery.	IV/C	130
Use time efficiently: • Do not prepare a sterile field or a full instrument table. • Use the quickest incision possible. • Consider a low transverse uterine incision.	IV/C	130
Proceed with delivery if >4 min have passed since maternal arrest but signs of fetal life are still present.	IV/C	130

Psychiatric Illness

ROGER F. HASKETT

INTRODUCTION

Recognition of psychiatric illness during pregnancy and the postnatal period is vitally important for the health of the mother and infant. Psychiatric disorders, such as depression, are commonly associated with impaired functioning that can significantly interfere with a pregnant woman's ability to care for herself, including participating in optimal prenatal care and maintaining an appropriate diet, as well as increasing the risk of using substances such as tobacco and alcohol. Women with psychiatric and substance use disorders during pregnancy are reported to have at least twice the risk of inadequate prenatal care compared with women without these diagnoses.[1] This association with inadequate prenatal care persists after controlling for other known risk factors and is associated with more adverse pregnancy outcomes and decreased use of pediatric care after birth. These findings are consistent with studies of patients in other primary care settings, noting that depressed individuals are much less likely to comply with treatment recommendations. In addition, the presence of mood or anxiety disorders during pregnancy is a strong predictor of psychiatric illness and disability in the postpartum period.

In obstetrics and gynecology practices, the prevalence of psychiatric disorders, including substance abuse disorders, is reported to range from 20% to 48%; this number is even higher in clinics serving low-income women.[2] In particular, the prevalence of major depression in these settings is reported to be as high as 22%.[2] This high prevalence should not be unexpected, considering that adult women suffer from depression and anxiety disorders at rates two to three times higher than men and that the increased prevalence tends to be most prominent following puberty and throughout the reproductive years.[2] When detected, it will be noted that the onset of these psychiatric disorders may predate pregnancy, occur during pregnancy, or most commonly, appear during the postpartum period.

In addition to appropriately administering specific treatments,[3] successful management of psychiatric illness in pregnancy and the postpartum period requires effective collaboration between the obstetrician, the pediatrician, the psychiatrist, and other mental health professionals as well as the participation of relatives and other key social supports.

PREVALENCE OF PSYCHIATRIC ILLNESSES IN PREGNANCY

Recognition of the high frequency of psychiatric symptoms in obstetric and gynecology practices has followed the recent development of screening tools for use in these settings. One study in a university-based obstetric clinic providing prenatal care for low-income minority women reported that 38% of women screened positive for psychiatric disorders including substance abuse.[4] One in five pregnant women screened positive for alcohol or other substance abuse, and more than half of the women who screened positive for a psychiatric disorder (21%) met criteria for a depressive disorder, including 4%, with major depression. Other identified diagnoses were anxiety disorder (5%) and eating disorder (5%). Women with psychiatric disorders were more likely to have public insurance, an unexpected pregnancy, and a previous history of psychiatric treatment. More significantly, they tended to be more likely to have received inadequate prenatal care and to be referred to child protective services. Another study of 766 women attending gynecologic practices in Sweden[5] found that 30% met criteria for a psychiatric disorder, although these investigators deleted the screening questions for alcohol abuse. Overall, 27% of women screened positive for a depressive disorder, including 10% for major depression, and 12% were positive for an anxiety disorder. Of more concern was the finding that only one out of five women with a psychiatric diagnosis was receiving any treatment, either medication or psychotherapy.

The PRIME-MD Patient Health Questionnaire (PHQ) was the screening instrument used in these studies to assess current psychiatric disorders. The PHQ is a four-page self-report measure that assesses eight common psychiatric diagnoses, including mood, anxiety, eating, alcohol, and somatoform disorders. Although developed in other primary care settings,[6] the validity and utility of the PHQ has been assessed in a multisite sample of 3000 patients attending obstetric/gynecology outpatient clinics or office practices.[7] In addition to assessing the eight psychiatric diagnoses, the PHQ screens for disorders that are more common among or restricted to women, such as premenstrual syndrome,

postpartum and menopausal mood disorders, and post-traumatic stress disorder. Information about reproductive history, psychosocial stressors, and severity of impairment is also included. In the validation study, 20% of women met criteria for a psychiatric diagnosis; the majority were unrecognized prior to reviewing the questionnaire. Most physicians and nurse practitioners (89%) reported that the diagnostic information provided by the PHQ was "very" or "somewhat" useful in management or treatment planning.[8]

MAJOR DEPRESSION

General

In 2008, the Global Burden of Disease study, 2004 update,[9] again reported that unipolar major depression was the most common cause of disease burden in women aged 15 to 44. This heavy burden of depression-related disability in women results not only from the high prevalence of depression but also from a clinical course that is characterized by early onset, recurrence, chronicity, and co-morbidity.[9] Typically, major depression is found to be 1.5 to 3 times more prevalent in women than in men. This higher prevalence of depression among women has been detected throughout the world using a variety of epidemiologic study designs.[2] Similar gender differences have been found for chronic minor depression or dysthymia and recurrent minor depression. The gender difference in prevalence appears at age 11 to 14 and is consistently found through midlife.[10,11] There does not appear to be a gender difference in the course of depression. The higher prevalence of depression among women is due to a higher risk of first onset, not to a differential risk of recurrence or chronicity of depression.[12] In addition, although limited, research has not found an effect of pregnancy on the onset or recurrence of major depression.[13] Pregnancy does not protect against depression, as was once believed, nor does it appear to increase the risk of depression compared with that in nonpregnant controls. In a review of depression in pregnancy, the prevalence rates were reported as 7.4%, 12.8%, and 12.0% for each trimester of pregnancy.[13] An emerging consensus holds that significant distress and impairment are also associated with the presence of "minor depression," or depressive symptoms that do not reach a level of severity to meet criteria for major depression. When depressive symptoms were monitored through pregnancy, the prevalence of major depression was 12.3% and minor depression was 18.1%, with major depression having a later onset and longer duration than minor depression.[14]

Diagnosis

Depression during pregnancy may be difficult to detect because many symptoms characteristic of depression, such as sleep and appetite disturbance, low energy, and diminished libido, are common in pregnant women who are not depressed. Although five of nine symptoms (Table 55–1) must be present over the same 2-week period to meet criteria for major depression, one of the symptoms must be either (1) depressed mood most of the day and nearly every day or (2) markedly diminished interest or pleasure in activities,

---

TABLE 55–1

Diagnostic Criteria for Major Depression

1. Depressed mood most of the day, nearly every day*
2. Markedly diminished interest or pleasure in activities*
3. Major change in appetite or weight
4. Decrease or increase in sleep
5. Psychomotor agitation or retardation
6. Fatigue or loss of energy
7. Feelings of worthlessness or excessive or inappropriate guilt
8. Diminished ability to think or concentrate; indecisiveness
9. Recurrent thoughts of death or suicide

* Must be present to establish diagnosis.

---

often referred to as *anhedonia*. Using these symptoms in a two-question case-finding instrument is an effective means for identifying major depression. A positive response to either of the questions (1) "During the past month, have you often been bothered by feeling down, depressed, or hopeless?" or (2) "During the past month, have you often been bothered by little interest or pleasure in doing things?" had a sensitivity of 96% and a specificity of 57%; a negative response made a diagnosis of major depression very unlikely.[15] In women who give a positive response to either question, additional inquiry should be made about the presence of the other seven features of depression—such as change in sleep or appetite, physical agitation, fatigue, worthlessness or guilt, poor concentration, and suicidal thinking. In pregnant women, the most useful confirming symptoms are anhedonia, guilt, hopelessness, and suicidal thinking.

Many pregnant women do not seek treatment; identification of their depression is dependent on adequate screening by their obstetrician during antenatal visits. Risk factors for depression in pregnancy include a personal and family history of mood disorder, marital conflict, younger age, and limited social support with greater numbers of children. In a study of 3472 women at 10 obstetric clinics who were screened for depression during a prenatal visit,[16] 20% were found to have elevated depressive symptom scores (Center for Epidemiologic Studies—Depression [CES-D] ≥ 16), but fewer than 1 in 7 of these women was receiving treatment for depression. Among the 28% of women who were positive on the lifetime depression screen items ("You had 2 weeks or more when nearly every day you felt sad, blue, or depressed or in which you lost interest in things like work"), nearly one half (42.6%) reported increased depressive symptoms during pregnancy. Women having a prior history of depression were nearly five times more likely to have elevated depressive symptoms during pregnancy than women without this history. Other factors predicting elevated depression scores were a self-rating of poor overall health, greater alcohol use problems, smoking, being unmarried, being unemployed, and lower educational attainment. Other studies have reported low levels of spousal support and conflicts with spouse/partner as predicting depression during pregnancy.[14,17]

Maternal and Fetal Risks

Several literature reviews and cohort studies note the association between depressive symptoms during pregnancy and poor neonatal outcomes, such as low birth weight, increased risk of premature delivery, and maternal preeclampsia.[18–21] In a study of African American women, who have twice the risk of spontaneous preterm birth relative to white women, an association was found between elevated maternal depressive symptoms and spontaneous preterm birth.[22] In addition, there have been reports linking developmental delays, antisocial behavior, and criminality in individuals whose mothers were depressed during pregnancy.[23,24] Pregnant women with depression may have decreased appetite and inadequate weight gain during pregnancy and are more likely to use tobacco, alcohol, or illicit drugs.[25] In addition, depression during pregnancy is a strong predictor of postpartum depression.

Management Options

Screening for depression is feasible, and when using self-report instruments, does not require clinical staff. In the Marcus and coworkers study,[16] 90% of women approached were willing to be screened; in the study by Scholle and colleagues,[26] 82% of screened women agreed to a clinical research review of their results. Identification of risk factors for depression in pregnancy can increase the efficiency of screening; for example, women with a past history of depressive illness should be specifically targeted for appropriate screening.

Standard treatments for depression with demonstrated efficacy include psychotherapy, antidepressant medications, and electroconvulsive therapy (ECT).[27] Selection of a specific intervention will be influenced by the severity of depression and level of impairment, specific information related to use of the intervention in pregnancy, and the woman's preferences.[28–30] Nonpharmacologic treatments such as interpersonal psychotherapy have been adapted successfully for use during pregnancy[31] and are sometimes preferred by women concerned about exposing the fetus to antidepressant medications.

When considering pharmacologic treatments for depression in pregnancy, the risks to the developing fetus can be divided into risks of physical malformations (*teratogenesis*), risks of neonatal toxicity or withdrawal syndromes following delivery, and risks of long-term behavioral effects (*behavioral teratogenesis*). Although the U.S. Food and Drug Administration established a system to advise physicians about the safety of medications in pregnancy, these categories should be used with caution. The majority of psychotropic medications are categorized as category C, which indicates "human studies are lacking … risk cannot be ruled out." No psychotropic medications are in category A, indicating that they are safe for use in pregnancy, because ethical concerns do not permit the randomized studies needed to generate the data for this classification. Clinicians should note that medications in category B should not be assumed to be safer than those in category C because, although the former indicates that there is no evidence of risk in humans, this may be the result of an absence of human studies.

On review of the literature, there is no evidence that tricyclic or selective serotonin-reuptake inhibitor/serotonin and norepinephrine-reuptake inhibitor (SSRI/SNRI) antidepressants are associated with an increased risk of major malformations.[32] Maternal use of antidepressants during early pregnancy was not associated with increased risks of most categories of birth defects, and when associations have been observed, the specific defects are rare and absolute risks are small.[33] Although reports have been inconsistent and generated from small numbers of women, fluoxetine, paroxetine, and sertraline have been linked to transient neonatal difficulties for some women taking these medications in late pregnancy.[33] There are limited data assessing behavioral teratogenesis or neurologic and behavioral developmental outcomes following prenatal exposure of the developing brain to tricyclic and SSRI antidepressants.[34,35] Fortunately, the studies that have been published were unable to detect any differences between children exposed to antidepressants in utero and unexposed children at ages varying from 4 months to 7 years.[36]

The treatment of depression during pregnancy raises the following issues, which must be addressed by the treating physician and the patient:

- Risk of exposing the fetus to antidepressant medication.
- Risk of untreated depression in the mother.
- Risk of relapse of depression in the mother following antidepressant withdrawal.[37]

Obstetricians may encounter these issues in two possible circumstances: a pregnant woman who is recently diagnosed with depression or a woman who is not currently depressed or pregnant and who seeks consultation before conception. In women who present with a new onset or recurrence of depression during pregnancy, the choice of antidepressant treatment will be influenced by the severity of the current episode and any prior episodes of depression. In milder forms of depression, interpersonal or cognitive behavioral psychotherapy alone may be an appropriate treatment. Alternatively, in women who have failed psychotherapy alone or who have severe symptoms, such as weight loss or suicidality, or marked functional impairment, antidepressant medication is likely to be strongly recommended. In these latter women, the risks to the pregnancy associated with their depressive illness will usually exceed the known risks of exposure to an antidepressant medication.[38] Many of the women who seek consultation about antidepressant treatment prior to conception will have suffered prior episodes of depression and may be taking maintenance treatment. In these circumstances, the decision to continue or withdraw antidepressant medications prior to conception will be influenced by the risk for relapse of depression, including the severity and frequency of prior episodes of depression. Up to 68% of women who discontinue an antidepressant during pregnancy will suffer a depressive relapse,[37] although assessing a specific woman's prognosis should focus on the number of prior episodes and the time to relapse after previous attempts at antidepressant discontinuation. Women with a history of rapid and severe relapses following antidepressant discontinuation are likely to be most appropriately treated by continuing medication throughout pregnancy. These risk-benefit discussions with the mother should be documented in the medical record and, if possible, should occur with the father present.

ANXIETY DISORDERS

General

Studies of women in the general population have reported that the 12-month prevalence of anxiety disorders is 4.3% for generalized anxiety disorder (GAD), 3.2% for panic disorder, and 1.8% for obsessive-compulsive disorder (OCD).[39] The prevalence of post-traumatic stress disorder (PTSD) in a cohort of economically disadvantaged pregnant women was 7.7%, with these women being five times more likely to have a major depressive disorder and three times more likely to have a GAD.[40] Unfortunately, in contrast to depression, the systematic data on the frequency and course of anxiety disorders during pregnancy are limited. Some of the difficulty in characterizing anxiety disorders in pregnancy results from the frequent overlap of depressive and anxiety symptoms and from the past convention of subsuming all combined presentations under a depressive diagnosis. Surveys that distinguish between anxiety and depressive disorders, however, find a prevalence of anxiety disorders in obstetrics and gynecology practices that ranges from 5% to 12%.[41] Little is known about the influence of pregnancy on the course of anxiety disorders, although a small number of retrospective accounts and case reports have suggested that symptoms of anxiety and panic disorder decrease and symptoms of OCD increase during pregnancy.[42]

Diagnosis

Anxiety is frequently free-floating, although it may focus on specific pregnancy fears, and is accompanied by symptoms of autonomic arousal. In women with panic disorder, chronic feelings of elevated anxiety are interspersed by the abrupt onset of episodes of pronounced fear, sometimes described as a fear of dying, going crazy, or losing control, which is associated with prominent physical symptoms of distress. These include shortness of breath, dizziness, unsteady feelings or faintness, palpitations or tachycardia, chest pain or discomfort, trembling or shaking, sweating, hot flashes or chills, choking, nausea or abdominal distress, numbness or paresthesias, as well as depersonalization (feeling separated from their body) or derealization (familiar surroundings feel unfamiliar). Episodes of panic usually begin to ease within 30 minutes but may be followed by a lingering period of increased anxiety and impaired function. Women with OCD describe recurrent thoughts that are unpleasant and out of character, often involving personally unacceptable aspects of aggression or sexuality, or repetitive compulsive behavioral rituals that are experienced as unreasonable; attempts to resist are followed by increased and incapacitating anxiety.

Maternal and Fetal Risks

There is some evidence for a deleterious effect of increased maternal stress and anxiety on birth weight and preterm

birth.[43,44] Other obstetric complications associated with increased maternal anxiety include preeclampsia, increased analgesic use,[45] and increased rate of cesarean section.[46] Adverse effects on the fetus include increased uterine artery resistance, as well as changes in fetal hemodynamics and autonomic reactivity.[47,48]

Management Options

Nonpharmacologic treatments are often effective in decreasing anxiety symptoms and include cognitive behavioral therapy and relaxation techniques. Pharmacologic treatment of anxiety disorders during pregnancy is indicated in women who have severe symptoms and are unresponsive to

psychotherapy. Use of SSRI antidepressants is favored, owing to their demonstrated effectiveness in anxiety disorders and accumulating evidence for their safety in pregnancy. Epidemiologic studies in the 1970s and 1980s suggested an increased frequency of oral clefts as well as signs of toxicity in neonates born to women taking high doses of benzodiazepines in late pregnancy. More recent meta-analyses and case-control studies have concluded that first-trimester exposure to benzodiazepines is associated with minimal risk, although these medications should be used cautiously and at the lowest effective dose.[49] Abrupt withdrawal of benzodiazepines during pregnancy is not recommended. There are insufficient data to determine the safety of buspirone during pregnancy.

BIPOLAR DISORDER

General

The prevalence of mania and bipolar disorder is about 1% and, in contrast to depression, there is no significant gender difference. Despite this, there appears to be a relationship between childbirth and the first episode of mania in women with bipolar illness, as noted by reports that childbirth predated the first episode of mania in 1 of 4 women with this illness.[50,51] A population-based cohort study found that women with a history of bipolar disorder are at particular risk of postpartum psychiatric readmissions.[52] Epidemiologic studies also note a marked excess of postpartum psychosis after the first child compared with subsequent pregnancies, suggesting that there is a particular change occurring at the first delivery that is less evident at other births.[52] Overall, the risk of relapse of mania after delivery is estimated to be between 1 in 3 and 1 in 4. Diagnostic and management issues associated with depressive episodes occurring during the course of a bipolar disorder are similar to those for unipolar depressive episodes, described previously.

Diagnosis

The essential criterion for the diagnosis of mania is the presence of abnormally and persistently elevated, expansive, or

irritable mood for at least 1 week. This must be accompanied by at least three of the following clinical features: inflated self-esteem or grandiosity, decreased need for sleep, increased talkativeness or pressure to keep talking, flight of ideas or subjective experience of racing thoughts, distractibility, increase in goal-directed activity (socially, at work or school, or sexually) or psychomotor agitation, disinhibited behavior, and excessive involvement in pleasurable activities with high potential for painful consequences (engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments). The overall severity must lead to marked functional impairment or need for hospitalization. Women with bipolar illness may also present with less severe forms of mania, diagnosed as *hypomania*, which are of shorter duration and usually associated with less functional impairment. Although the euphoric or irritable mood changes are usually evident in a patient being followed longitudinally, the most informative diagnostic feature of mania, especially during the assessment of current and past episodes in a new patient, is persistently decreased need for sleep without daytime fatigue or lowered energy.

Maternal and Fetal Risks

Risks to the mother and fetus result from the impulsive, disinhibited, or high risk behavior that is seen in mania, as

well as from the commonly associated substance abuse and dependence. In addition, women with untreated mania or hypomania are unlikely to participate in appropriate prenatal care or maintain an adequate diet.

Management Options

Treatment considerations should address two separate groups of women:
- Those presenting with mania during pregnancy.
- Women with an established diagnosis of bipolar disorder requesting advice about a planned or recently confirmed pregnancy.

In the former, the risks to the mother and fetus from untreated mania are prominent, and the risks of failure to treat must be balanced against the risks of effective pharmacologic treatment.[53] Admission to a psychiatric facility is necessary if there is a high risk of imminent harm to the mother or fetus and the woman has reduced insight and is unwilling to cooperate with appropriate outpatient treatment. Medication choices for mania in pregnancy should include lithium carbonate, despite early reports about the risk of Ebstein's anomaly and other cardiovascular abnormalities in infants exposed to lithium during the first trimester.[54] Subsequent studies of lithium in pregnancy suggest a more modest teratogenic relationship, with a risk of cardiovascular abnormalities that is 10 to 20 times higher in exposed children than the normal population, but with an actual occurrence rate that is low (0.05%–0.1%).[55,56] It is recommended that fetuses who have first-trimester exposure to lithium should be screened for cardiovascular abnormalities by ultrasound in the mid trimester. Despite these concerns, the risk of lithium for mania must be balanced against the increased teratogenic potential of the anticonvulsants that are the other established pharmacologic treatment for this disorder.[57] Valproate and carbamazepine have been linked to neural tube defects in 2% to 5% of exposed babies; there are insufficient data to assess the risks with the newer, more novel anticonvulsants. It does appear, however, that teratogenic risk is increased by the use of combinations of anticonvulsants and high plasma levels. In addition, a third class of

medications is now under consideration for the treatment of mania, the atypical antipsychotics. Olanzapine was the first approved for this indication and has been followed by others in the class. Although, currently, there are limited safety data available, which limits use of these drugs in pregnancy, studies of small numbers of women taking olanzapine during pregnancy have not revealed any teratogenicity. Finally, ECT should also be considered as an alternative to psychotropic medication exposure. It has demonstrated effectiveness for treatment of mania and depression, and reviews support the relative safety of ECT during pregnancy, provided that specific modifications are made to the anesthetic procedure.[58]

Ideally, a woman with well-controlled bipolar illness will address the specific management of pregnancy prior to conception.[59] Unfortunately, the rate of unplanned pregnancy in women with bipolar illness is even higher than the 50% seen in the general population. In these women, pregnancy will commonly be at an advanced gestational age when diagnosed. As neural tube closure usually occurs by the end of the fourth week and development of the heart by the end of the eighth week, the period of risk for major organ malformation may have passed by the time many women taking maintenance psychotropic medication have confirmed pregnancy. This is particularly important information for women considering a rapid discontinuation of medications once pregnancy is detected. Studies have shown a 50% recurrence rate within 2 to 10 weeks of discontinuation of lithium in patients with bipolar illness, and this is increased if medication is discontinued abruptly.[60] Considering the lack of data of a clear safety advantage for a specific mood stabilizer and the risks of relapse following a change in treatment, there is little support for switching a woman from one mood stabilizer to another once pregnancy is detected.[60] If the decision is made to continue medication during pregnancy, the minimum effective dose should be used. In women who are planning pregnancy and report only occasional episodes of moderately severe mania or hypomania, medication discontinuation before conception may be a supportable option, provided that the taper occurs over 2 to 4 weeks minimum and there is close collaboration between the obstetrician and the psychiatrist.

SCHIZOPHRENIA

General

Pregnancy in women with schizophrenia occurs under very different circumstances today compared with a few decades ago.[61] The first and most influential change resulted from the release of patients to the community instead of confining them to institutions, providing them with increased opportunities to meet partners. Despite this, although the fertility rates for women with schizophrenia have increased, its occurrence remains between 30% and 80% of the general population.[62] Because effective utilization of birth control practices is limited in women with schizophrenia, one important contributing factor for this decrease in fertility is the high prevalence of hyperprolactinemia in patients taking the older class of antipsychotic medications. More recently, the treatment of schizophrenia has seen an increased utilization of a new generation of atypical antipsychotics that are much less likely to produce elevated prolactin levels. As a result, it is very likely that the frequency of pregnancy in women with schizophrenia will increase.

Diagnosis

The diagnostic criteria for schizophrenia require the presence of at least two of the following over a 1-month period: delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and affective flattening or markedly decreased volition. These features should be associated with prominent social and occupational dysfunction of at least 6 months' duration. The diagnostic evaluation should focus on the chronic and persistent features of the illness because the clinician may have difficulty during a cross-sectional assessment in differentiating psychosis in schizophrenia from psychotic symptoms in a patient with mood disorder. Particular presentations that may

have diagnostic challenges are the delusional denial of the pregnancy or the incorporation of the pregnancy into established delusional systems.

Maternal and Fetal Risks

Prenatal care might not be appropriately sought or maintained by these women, especially in cases in which the pregnancy was not planned and in women with prominent volitional deficits. Individuals with this illness are also noted to have great difficulty maintaining healthy lifestyle choices for diet, exercise, and avoidance of alcohol and tobacco. All of these factors are associated with worse outcomes from pregnancy. The use of older antipsychotic medications conveys some increased risk of teratogenicity, although further examination of these data linked the low-potency phenothiazines, such as chlorpromazine, with an increased risk of malformations. The depot antipsychotics are not recommended during pregnancy because they have been associated with an increased risk of extrapyramidal side effects in the neonate (see Chapter 34).

Management Options

Although it may be desired by the patient, discontinuation of psychotropic medication during pregnancy in women with schizophrenia is associated with a markedly increased risk of relapse. Considering that treatment of relapse is likely to require higher doses of medication than maintenance treatment, one alternative is to attempt reduction to the lowest effective dosage of medication, especially during the first trimester. Although low doses of the more potent older antipsychotics, such as haloperidol, are preferred for the treatment of schizophrenia in pregnancy, the new atypical antipsychotics are commonly being continued in pregnancy, despite the limited amount of safety data currently available. Any indication of psychotic relapse should be managed by

prompt admission to a psychiatric facility for restabilization. A key aspect of management during pregnancy is to evaluate the options for the mother and child after delivery. Assessment of the woman's capacity to provide appropriate care for the infant should begin during the pregnancy; this should include review of the stability of the illness, the woman's adherence to outpatient care, and the quality of psychosocial supports.

SUBSTANCE ABUSE AND DEPENDENCY
(see also Chapter 33)

General

Considering that substance abuse and dependence are chronic relapsing disorders, women with these diagnoses are at particular risk when they become pregnant. Identification of prenatal substance use, including alcohol and nicotine, is a critical public health issue in the care of pregnant women.[63] In 1992, the National Pregnancy and Health Survey reported an estimated prevalence among U.S. women during pregnancy of alcohol (18.8%) and illicit drug use (5.5%). Another report of prospectively screened newborns in an urban population noted that 44% of infants tested positive for opiates, cocaine, or cannabis. Although many women report spontaneously quitting substance use on learning of the pregnancy, maintenance of abstinence is problematic without participation in treatment programs.[64] A key strategy in the accurate identification of affected women is the use of self-report screening instruments. These tend to identify much higher rates of substance use than those detected by maternal interview alone. For example, one report contrasted the 65% to 70% correct identification of prenatal drinkers using a questionnaire with the 20% having documentation of alcohol use in the obstetric record.

Diagnosis

One of the strongest risk factors for substance abuse is the presence of other psychiatric disorders. Depression, mania, and schizophrenia are all associated with an increased prevalence of substance use and abuse. Other risk factors identified for frequent drinking in pregnancy were being unmarried, smoking, age 25 years or older, and having a college education, although the applicability of these findings to other populations requires further study.[65] Interviewing individuals who are aware of the mother's behavior, such as the spouse/partner and other relatives, can be informative, although the presence of substance abuse in these individuals may decrease the reliability of their responses. Urine screening of the mother has been controversial, although with the mother's consent, it may be a useful strategy for identifying mothers who should be referred for treatment.

Maternal and Fetal Risks

The legality of substances does not lessen their serious implications for the health of the fetus; legal substances are probably associated with more widespread use.[66] The fetal consequences of maternal smoking are well established. These include intrauterine growth restriction, low birth weight, and developmental delays. Fetal alcohol syndrome (FAS) is associated with alcohol consumption during pregnancy. The three critical features are growth deficiency, facial phenotype, and brain damage dysfunction. A preclinical study showed that alcohol blocked N-methyl-D-aspartate receptors and excessively activated γ-aminobutyric acid (GABA) receptors, leading to extensive neuron degeneration. The damage was dependent on the rapidity of dose administration and the duration of blood alcohol level elevation.[67] This suggests that peak levels during a drinking episode are most critical to developing FAS. Maternal use of benzodiazepines and barbiturates is known to be associated

with neonatal withdrawal syndromes, but of more concern is the recent report suggesting that these substances may delete neurons from the developing brain through a mechanism similar to that proposed for alcohol. Considering their relatively common use in pregnant women and infants, there is an urgent need for more systematic examination of these risks.

Maternal use of illicit substances is associated with significant risk of adverse effects on the fetus.[68] Cannabis use during pregnancy has been associated with effects on the exposed infant's cognitive development and behavior, with at least one report linking hyperactivity, inattentiveness, and impulsivity at age 10 with first- and third-trimester exposure to cannabis.[69] Prenatal cocaine use is reported to be associated with a dose-dependent decrease in head circumference and head weight.[70] There has been a report of increased frequency of cardiovascular and musculoskeletal anomalies in infants exposed to methyl-enedioxymethamphetamine (Ecstasy) during pregnancy,[71] but further study is needed. Opiate withdrawal is the primary risk for infants born to opiate-dependent mothers and is characterized by autonomic dysfunction as well as gastrointestinal and respiratory symptoms.

Management Options

The key to management of substance abuse is detection. The use of screening instruments is valuable; questionnaires such as CAGE (cut down, annoyed by criticism, guilty about drinking, eye opener) or T-ACE (tolerance, annoyed, cut down, eye opener; Table 55–2) are commonly used for the detection of alcohol misuse.[72] Although the literature suggests that six drinks daily can cause overt FAS, the safe level has not been identified and the comparative risks for binge drinking and daily drinking are not clear. Risk-drinking (enough to *potentially* damage the offspring) has been defined as an average of more than one drink (0.5 oz) per day, or less if massed (binges of > five drinks per episode).[73] In the

---

TABLE 55–2
T-ACE Screening Tool for Pregnancy Risk-Drinking*

Tolerance
"How many drinks can you hold?"
(A positive answer, scored a 2, is at least a six-pack of beer, a bottle of wine, or six mixed drinks. This suggests tolerance of alcohol and very likely a history of at least moderate to heavy alcohol intake.)

Annoyed
"Have people annoyed you by criticizing your drinking?"

Cut Down
"Have you felt you ought to cut down on your drinking?"

Eye Opener
"Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover?"

* The first question is scored 0 or 2 points. The last 3 questions are scored 1 point if answered affirmatively. A total score of 2 or more is considered positive for risk-drinking.
From Sokol RJ, Delaney-Black V, Nordstrom B: Fetal alcohol spectrum disorder. JAMA 2003;290:2996–2999.

United States, a conservative position has been adopted that essentially recommends total abstinence during pregnancy.

Unfortunately, there are few screening tools for detection of the use of other substances. When diagnosed, a comprehensive treatment program is indicated, with individual and group therapy, behavioral incentives, and in some situations, pharmacologic agents such as methadone. These interventions have demonstrated positive effects on both maternal and neonatal outcomes.

The Summary of Management Options for this section is found in Chapter 33.

POSTPARTUM DEPRESSION CONDITIONS
General

The psychiatric diagnostic system (i.e., *Diagnostic and Statistical Manual for Mental Disorders*, 4th ed. [DSM-IV]) does not recognize postpartum disorders as discrete diagnoses but permits "postpartum onset" to be used as a specifier for episodes of illness appearing within 4 weeks of childbirth. There is continued debate about this relatively brief interval for the definition of postpartum illness. Most epidemiologic studies use a 3-month period, which captures the peak prevalence of psychiatric illness and hospitalization after childbirth, and other researchers and clinicians are extending their focus to the events occurring during the first postnatal year.[74] Postpartum mood changes include three distinct clinical syndromes: postpartum blues, postpartum depression, and postpartum psychosis, although a single cross-sectional evaluation of all three may be indistinguishable. Fortunately, the prevalence of these three disorders varies inversely to their severity.

Postpartum "Blues"
General

Although not actually listed in *DSM-IV* as a psychiatric disorder, this well-recognized, common disorder occurs in 25% to 80% of women following delivery. Sadness may be prominent, but the syndrome is commonly characterized by emotional lability, bursting into tears without apparent cause; increased anxiety; insomnia; and negative thinking. Symptoms usually appear within the first postpartum week and, in the majority of women, peak around day 5 postpartum and resolve within 2 weeks. Given the timing and self-limiting nature of this syndrome, there have been many reports and hypotheses linking its pathophysiology to the rapid and profound changes occurring at parturition, but so far none has achieved wide support.

Diagnosis

The key to the diagnosis of this state is its time course.[75] Distinguishing between postpartum blues and postpartum depression has great clinical significance. Persistence of depressive symptoms past the second week postpartum should result in a careful reassessment of the original diagnosis. In addition, prominent insomnia and mood lability in a woman with risk factors for postpartum psychosis, even if it occurs in the first 2 weeks after childbirth, should prompt an urgent psychiatric consultation.

Maternal and Fetal Risks

Generally, this syndrome is not associated with significant functional impairment of the mother and does not significantly increase risks to the infant.

Management Options

Provide support and education about the typically self-limiting nature of this condition, but monitor for progression and development of postpartum depression.

Postpartum Depression

General

The prevalence of postpartum depression is 10% to 15%; it occurs in 1 of every 7 to 10 women after delivery, making it the most common complication of childbirth.[76] Women with a past history of depression have an elevated risk of postpartum depression, estimated to range from 25% to 50%.[76] Although the psychiatric diagnostic system focuses on depression appearing up to 4 weeks after delivery, a significant body of data emphasizes the importance of depression having an onset up to 1 year after childbirth. Owing to its temporal association, the cause of postpartum depression is commonly attributed to the rapid and profound hormonal changes occurring after delivery. Other factors that increase the risk of postpartum depression are also seen in women suffering from depression unrelated to childbirth, such as past and family history of depressive episodes, poor marital relationship, low social support, stressful life events, and low socioeconomic status.[17,76]

Diagnosis

The clinical features and diagnostic process for postpartum depression are similar to those for women suffering from depression at other times. The first step is to identify a period of persistent depressed mood or anhedonia lasting at least 2 weeks. Several screening instruments have been utilized for this purpose. The most commonly reported instrument in the literature is the Edinburgh Postnatal Depression Scale (EPDS), a 10-item self-report instrument designed to assess the presence of depressive symptoms in women after childbirth.[77] Each symptom item is scored from 0 to 3 according to severity. A score greater than 9 on the EPDS should be followed by a brief focused interview to determine the presence of a depressive diagnosis. Other instruments include a 2-question case-finding instrument assessing the presence of depressed mood or anhedonia.[15] A positive response to either of the two items suggests that a diagnosis of depression should be explored.

In women who were screened during the second trimester of pregnancy and again during the postpartum year, the two independently predictive risk factors for postpartum depression were high depressive symptoms during pregnancy and a past personal history of depressive disorder.[78] Another study of first-time, otherwise-healthy mothers found that women reporting high levels of depressive symptomatology at 2 months' postpartum had an increased risk of high levels of depressive symptoms continuing through the first year postpartum.[79] This emphasizes the persistence of depressive symptoms with associated impairment of function and reinforces the importance of identifying depressed mothers soon after childbirth, preferably with routine use of screening instruments, and referring for appropriate interventions.[80]

Considering that bipolar illness can present with an episode of depression, it is essential to ask the depressed woman about the features of past hypomania or mania, particularly when psychotic features are present. This can be done by asking about the past occurrence of at least 3 to 4 days of a markedly decreased need for sleep (i.e., feeling rested after 3 to 4 hours sleep per night, without daytime fatigue or decreased energy). A positive response to this question or one about periods of persistently elevated or irritable mood that others thought were abnormal indicates that further evaluation for possible bipolar disorder is indicated and psychiatric referral is recommended.

Maternal and Fetal Risks

Although the overall risk of suicide in postpartum women is low, those who develop a severe psychiatric illness in the first year after childbirth are at a significantly increased risk. In one study, the long-term risk of suicide in women admitted to a psychiatric hospital in the first year after childbirth was increased 17 times.[81] In these women, the risk of completed suicide during the first postpartum year was markedly increased to 70 times greater than the age-specific mortality rate. A report from the United Kingdom noted that suicide was the leading cause of maternal death during the first year after childbirth.[82]

Adverse effects of maternal depression on infant development have been widely reported,[83–85] including reports of an association between maternal depression and an increased risk of sudden infant death syndrome.[86] Children of depressed

parents are at high risk for anxiety and depressive disorder in childhood, depression in adolescence, and alcohol dependence as adults.[87] Children of depressed mothers are also less likely to benefit from appropriate parental prevention practices.[88] Depressed mothers reported a three times greater risk of serious emotional problems in their children and more functional disability.[89]

Homicide is the leading cause of infant deaths due to injury, 9 per 100,000 live births from 1988 to 1991.[90] This study revealed that children born to young unmarried and poorly educated mothers were several times more likely to be killed. In this group of mothers, the most important risk factors were maternal age younger than 17 years and birth of the second or subsequent child before age 19; these accounted for 17% of the infant deaths. Five percent of homicides occurred on the first day of the infant's life; 95% of these infants were not born in a hospital compared with 8% of all infants killed during the first year of life who were not born in a hospital. Infants killed immediately after birth appeared to be the result of unwanted or disguised pregnancies. Identification of adolescents who have hidden their pregnancies and provision of appropriate prenatal care are particularly important. Maternal depression may play a role in the deaths occurring after the first day of life. The combination of depressed mood, low self-esteem, pessimism, and hopelessness may reach delusional levels in some mothers, leading them to believe that their babies and themselves are better off dead.[91] In addition, reports suggest that infants of depressed mothers are more irritable, are less easily consoled, and have disrupted sleep and wake cycles, all increasing their risks of being abused.

Management Options

Women receiving a diagnosis of depression after childbirth are commonly treated with antidepressant medication.[92] Uncontrolled studies have reported improvement in postpartum depression after treatment with antidepressants such as sertraline, fluvoxamine, and venlafaxine. Unfortunately, only one placebo-controlled trial of antidepressants in postpartum depression has been published.[93] This study compared antidepressant medication (fluoxetine) with psychotherapy (cognitive-behavioral therapy [CBT]). Results indicated that fluoxetine was more effective than placebo. With regard to the role of psychotherapy, six sessions of CBT were more effective than one session, but the addition of multiple CBT sessions to fluoxetine did not provide any additional benefit.[93] As concluded in the Cochrane Review on the use of antidepressants for postnatal depression,[94] more trials are needed to determine the role of antidepressants in treating women with postnatal depression.

Women with postpartum depression appear abnormally sensitive to the withdrawal of high levels of gonadal steroids following parturition. A preliminary placebo-controlled study showed that transdermal estrogen was an effective treatment for women with severe postpartum depression,[95] although more research is needed to assess the safety of estrogen in the postpartum period.

Owing to the reluctance of some postpartum women to take medication, psychotherapy has been studied as an alternative to antidepressant medication as well as an adjunct to medication. In addition to the study noted previously, several randomized, controlled trials have shown that individual psychotherapy is an effective treatment for postpartum depression.[96] There was greater improvement of maternal mood and social functioning in women receiving interpersonal psychotherapy than in women in the waiting-list control group.[97] Other studies have shown the benefit of including the partner in the psychotherapy sessions, although the results from group therapy are mixed.[98]

The Cochrane Review by Dennis and Hodnett[99] on "psychosocial and psychological interventions for treating postpartum depression" included nine trials and 956 women. Both psychosocial (e.g., peer support, nondirective counseling) and psychological (e.g., CBT and interpersonal psychotherapy) interventions appeared to reduce the symptoms of postpartum depression.

Many women who express reluctance to take medication after childbirth identify concern about the possible adverse effects on breast-feeding infants. Because all antidepressants are excreted in breast milk, many studies have evaluated the serum levels of antidepressants in breast-feeding infants. With few exceptions, these reports have found that the serum levels of antidepressants in infants were either very low or undetectable.[100,101] Reports of adverse effects in breast-fed infants of mothers taking antidepressants have included increased crying, colic, and decreased sleep in three infants whose mothers were taking fluoxetine and who were found to have serum levels of fluoxetine and its metabolite that were in the adult therapeutic range.[100,101] Citalopram, sertraline, and doxepin have been identified in case reports with either adverse effects or elevated serum levels.[100,101] It should be noted that most reports were of one or two cases, methodologies varied, and with the exception of one study, the follow-up was brief.

Postpartum Psychosis

General

Postpartum psychosis is the most severe postpartum mood disorder; fortunately, it is rare, affecting 1 to 2 women per 1000 births. Current literature generally reflects the view that postpartum psychosis, in the majority of cases, is a presentation of bipolar disorder following childbirth.[102] Women with a history of bipolar disorder have a 100-fold higher risk of developing postpartum psychosis than women without bipolar disorder.[103] In addition, women with bipolar disorder and a family history of postpartum psychosis have a rate of postpartum episodes twice that seen in women with bipolar disorder and no family history.[104]

Diagnosis

Symptoms of insomnia, prominent mood lability, restlessness, sadness, and irritability appear within 2 weeks of childbirth, followed by the development of psychotic features, such as delusions, hallucinations, and thought disorder. Insomnia is an early and common symptom and is found in 42% to 100% of women with psychosis.[105] The presence of perplexity and confusion are also noted to be common, unlike in nonpuerperal manic episodes. Some researchers have commented on the role of sleep loss in the precipitation of mania generally[106]; this may be of particular importance following childbirth.[107] Studies of sleep in the later stages of pregnancy show prominent sleep disruption, with prolonged sleep latency, more awakenings, decreased total sleep time, and suppression of stage 4 sleep; recovery of stage 4 sleep and reduction in REM sleep occur in the early postpartum period.[108,109] More important, a prospective study of sleep in pregnancy revealed a differential effect depending on the presence of a past history of mood disorders. In addition, sleep disruption during late pregnancy and the early postpartum period appears to be more pronounced in first-time mothers than in multiparous women. This may be relevant for the observed increase in the risk of postpartum psychosis after the first child compared with after later births.

Maternal and Fetal Risks

In almost all instances, women with postpartum psychosis are unable to provide adequate care for themselves or their child and require additional support and supervision. Thoughts of harming the infant are common in women with postpartum psychosis; sometimes, they act on their thoughts. Postpartum women who commit infanticide or suicide more commonly present with depressed mood than with mania.

Management Options

Early identification of sleep impairment is important in the management of women with a history of bipolar disorder or postpartum psychosis. Prevention of sleep loss in vulnerable women by daytime delivery and reduction of nocturnal stimulation may be appropriate. Prompt treatment of decreased sleep in these women, with a high-potency benzodiazepine such as clonazepam or a sedating antipsychotic, is essential. Owing to the high risk of recurrence, prophylactic treatment of women with a history of postpartum psychosis or bipolar disorder is often considered, although there is no consensus about the optimal time to begin prophylaxis. Many patients prefer to defer starting prophylactic medication until immediately after delivery.

Established postpartum psychosis requires admission to a psychiatric hospital. Mother and baby units are optimal but are relatively uncommon in the United States. Because there are no adequately controlled studies of psychopharmacologic treatment of postpartum psychosis, the standard treatments for a psychotic manic or depressed episode are used, including new-generation antipsychotics, lithium, valproate, and antidepressants. If an antidepressant is used, a mood stabilizer such as lithium or valproate should be given in combination. There are numerous reports that ECT is effective in the treatment of postpartum psychosis, but there are no controlled studies of this strategy. A small open-label pilot study of 17β-estradiol in the treatment of postpartum psychosis found encouraging results but requires further investigation.[110]

Abdominal Pain

KASSAM MAHOMED

INTRODUCTION AND OVERVIEW

Abdominal pain during pregnancy presents unique clinical challenges; the differential diagnosis during pregnancy is extensive. The pain may result from three sources:

- Physiologic effects of pregnancy.
- Pathologic conditions related to pregnancy.
- Pathologic conditions unrelated to pregnancy.

The clinical presentation and natural history of many abdominal disorders are altered during pregnancy; the diagnostic evaluation is altered and constrained by pregnancy; and finally, the interests of both the mother and the fetus must be considered in pain management.

The initial step in management of abdominal pain is to establish a diagnosis by a detailed history, a thorough physical examination, and specific investigations as summarized in Tables 56–1 to 56–5.

Abdominal assessment during pregnancy is modified by displacement of abdominal viscera by the enlarging gravid uterus, because of which, abdominal masses may also be missed on physical examination.

Physiologic changes in laboratory values during pregnancy that are relevant to interpreting laboratory results include mild leukocytosis, dilutional anemia, increased alkaline phosphatase levels, hyponatremia, hypercoagulability, and fasting hypoglycemia with postprandial hyperglycemia.

DIAGNOSTIC IMAGING IN PREGNANCY

Fetal safety during diagnostic imaging is a concern in pregnancy. Ultrasonography in pregnancy is not associated with adverse maternal or perinatal outcome, impaired physical or neurologic development or an increase in childhood malignancy.[1] Guidelines for computed tomography (CT) and magnetic resonance imaging (MRI) during pregnancy and lactation have recently been published.[2] Radiation dosage is the most important risk factor and is worse in earlier gestation. Exposure of more than 15 rads during the second and third trimester, or more than 5 rads in the first trimester, should be of concern because of the associated increased risk of miscarriage, chromosomal and fetal abnormalities, as well as the increased likelihood of malignancies in childhood.[3] Diagnostic studies with the most radiation exposure, such as intravenous pyelogram (IVP) and barium enema, typically expose the fetus to less than 1 rad.[4]

Sigmoidoscopy, especially flexible sigmoidoscopy, seems to be relatively safe in pregnancy; it does not induce labor and should be considered in medically stable patients with important indications, as opposed to routine screening.[5] Informed consent, however, should be routine in all cases.

PHYSIOLOGIC CONDITIONS IN PREGNANCY (Table 56–1)

Round Ligament Pain

Round ligament pain occurs in 10% to 30% of pregnancies and most commonly occurs toward the end of the first trimester and in the second trimester. It is more common in multigravidae than primigravidae and is said to be due to stretching of the round ligaments, but there is no documented evidence for this. The pain, which is usually described as "cramplike" or "stabbing" and is made worse by movement, is in the lower quadrant and can radiate to the groin. It is often associated with some tenderness over the area of the round ligaments.

Risks

The main risk is failure or delay in diagnosis of a significant pathologic condition (see later discussion).

Management Options

Management is conservative and includes reassurance, reducing physical activity, avoiding movements or postures that exacerbate the symptoms, and in some cases, administering analgesics. Failure to respond to conservative measures or worsening of symptoms is an indication for further investigation.

Severe Uterine Torsion

Mild asymptomatic axial rotation of the uterus (<40 degrees), usually to the right, is observed in the majority of pregnancies.[6] Torsion of the gravid uterus is a rare obstetric complication in humans, but has been reported in association with malpresentation and with uterine leiomyomata; it has also

+, present; –, absent; ±, may be present.

been reported following an external cephalic version.[7] The features of pain, shock, intestinal complaints, urinary symptoms, bleeding, and obstructed labor are related to the degree of torsion and can be acute, subacute, chronic, or intermittent.[8]

Risks

Maternal vasovagal shock and possible fetal asphyxia (both acute and chronic) are the main risks of severe uterine torsion.

Management Options

Conservative measures such as bedrest, analgesia, and altering the position of the mother can be used to try to produce a spontaneous correction of the torsion. Often laparotomy is performed for detorsion of the uterus, hoping the pregnancy will continue. If the fetus is viable, cesarean section is performed following detorsion of the uterus.[7,8]

Braxton Hicks Contractions

Many women experience Braxton Hicks contractions in the latter half of pregnancy.[9] They are irregular in frequency and inconsistent in intensity. Although in the majority of women these contractions are painless, some women find them painful.

Risks

The main danger is to mistake the uterine activity of true preterm labor for Braxton Hicks contractions.

Management Options (See also Chapters 60 and 61)

A careful history and examination should be performed to exclude genuine labor. Absence of a "show" or membrane rupture together with a high presenting part would be reassuring. Cervical ultrasound and fetal fibronectin testing

ideally in combination have a very high negative predictive value and would rule out the possibility of threatened preterm labor.[10] In the presence of a positive test, however, a vaginal examination, perhaps repeated in 4 hours, may be the only satisfactory way to assess the significance of these uterine contractions. Once the diagnosis is made, reassurance is all that is necessary.

Miscellaneous Nonpathologic Causes of Discomfort

Heartburn, excessive vomiting, and constipation are common causes of mild discomfort or pain, especially during early pregnancy. A full discussion of the risks and management of hyperemesis gravidarum is given in Chapter 47.

During the third trimester, heartburn may affect up to 80% of women. The reasons for the increase in symptoms in pregnancy are not well understood, but may be due to the effect of pregnancy hormones on the lower esophageal sphincter and gastric clearance.

Risks

The main risk is to miss a pathologic cause for the pain.

Management Options

Heartburn may be helped by reassurance, avoidance of bending, and lying flat in bed. Numerous interventions have been used to relieve these symptoms including advice on diet and lifestyle, antacids, antihistamines, and proton pump inhibitors. The use of these in pregnancy appears to be safe.[11,12] If vomiting is excessive and not relieved by reassurance and dietary adjustments, hospital admission may be required, especially if there is dehydration.

Constipation may be relieved by increasing dietary fiber and avoiding iron unless absolutely necessary. In severe cases, laxatives may be tried.[13]

Abdominal Pregnancy
General

Advanced abdominal pregnancy is a rare event. In the United States, it has been estimated that there are 10.9 abdominal pregnancies per 100,000 births and 9.2 abdominal pregnancies per 1000 ectopic gestations.[14]

It is more commonly seen in patients of low socioeconomic status, in developing countries, and in those patients with a history of infertility or a previous history of pelvic infection.

Advanced abdominal pregnancy has been divided into
- Primary abdominal pregnancy, in which the tubes and ovaries are normal, and there is no evidence of uteroplacental fistula. The pregnancy is related exclusively to the peritoneal surface very early in pregnancy.
- Secondary abdominal pregnancy occurs after tubal abortion or rupture, with subsequent implantation of the conceptus on a nearby peritoneal surface.

Diagnosis

Advanced abdominal pregnancy can have dramatic and catastrophic consequences for the fetus and the mother. Difficult to diagnose preoperatively, it presents special challenges to the physician. Preoperative diagnosis allows time for thoughtful preparation of the patient, family, and medical team; diagnosis requires a high index of suspicion. Abdominal pain is present in 80% of cases, often noticed in early

pregnancy, and varies from mild discomfort to severe and unbearable pain. Fetal movements may be painful or absent with fetal death. In 30% of cases, vaginal bleeding is reported in early pregnancy. Examination reveals abdominal tenderness, with easily palpable fetal parts.

Abnormal lie occurs in 15% to 20% of cases. Vaginal examination often reveals a closed, uneffaced cervix occasionally displaced anteriorly. Absence of palpable uterine contractions to oxytocin stimulation or to induction of labor by prostaglandins is one of the most helpful clinical clues to the diagnosis.[15] Even with a high index of suspicion, confirmation of the diagnosis is not always easy.

Ultrasound scan may reveal one or more of the following features: the fetal head is located outside the uterus; the fetal body is outside the uterus, as is the ectopic placenta; failure to demonstrate a uterine wall between the fetus and the urinary bladder; and recognition of a close approximation of fetal parts and the maternal abdominal wall. An unusual echographic appearance of the placenta should prompt a more thorough investigation to confirm the diagnosis.[16]

MRI can safely produce images in different planes without the use of ionizing radiation. This method seems to be a very sensitive diagnostic tool where facilities exist.

Risks

Perinatal mortality rate is reported to be greater than 50%. If there is reduced liquor volume, there is an increased incidence of fetal malformation, pressure deformities, and pulmonary hypoplasia. Maternal mortality rate depends on availability and accessibility of services but has been reported as 5 per 1000 cases.[14]

Management Options

Management is based on an empirical approach derived from a review of cases[15–17] rather than evidence from controlled trials.

Timing and the nature of the intervention will depend on the gestation and viability of the fetus at the time of diagnosis. If the fetus is dead, surgery is indicated. Waiting for a few weeks to allow atrophy of the placental vessels will possibly decrease intraoperative complications. If the fetus is alive but nonviable (before 24 wk), immediate surgery is thought to be indicated. If the pregnancy is 24 or more weeks, a conservative approach may be contemplated to allow time for further development of the fetus. This approach requires thorough and careful counseling of the parents. There are no data that define the risks for the conservative versus surgical options at either gestation.

NATURE OF THE INTERVENTION

Preoperative preparations should include having several units of blood available and, if possible, carrying out the delivery with a general, vascular, or genitourinary surgeon. A midline vertical incision is always advisable to improve access. The amniotic sac should be carefully incised in an avascular area free of placenta. Removal of the fetus should be done in a way to minimize manipulation of the placenta and surrounding membranes and the likelihood of bleeding.

MANAGEMENT OF THE PLACENTA

If the blood supply to the placenta can be safely secured, complete removal of the placenta usually results in an uncomplicated postoperative recovery, and if removal of the placenta is straightforward, this should be the optimal approach.

If the placenta cannot be removed safely, other options include ligating the cord close to the placenta and leaving it in situ or ligating the placental blood supply and removing the pelvic organ upon which implantation has occurred (e.g., hysterectomy or salpingo-oophorectomy).

Partial removal of the placenta when its whole blood supply cannot be ligated may result in massive hemorrhage, shock, and death. This is not recommended. In such situations, it is best that the placenta be left in situ. However, this option is often accompanied by ileus, peritonitis, abscess formation, and prolonged hospital stay.

One possible option would also be to leave the placenta in situ with later use of methotrexate to increase the rate of absorption/destruction of the retained placental tissue. However, this leads to rapid destruction of the placenta with accelerated accumulation of necrotic placental tissue, which often becomes infected. This is, therefore, not a recommended method of treatment.[15,17]

SUMMARY OF MANAGEMENT OPTIONS
Abdominal Pregnancy

Management Options	Evidence Quality and Recommendation	References
Dead Fetus		
Delivery by laparotomy, possibly with a delay to reduce complication rates.	IV/C	15–17
Live Fetus before 24 Weeks		
Deliver by laparotomy.	—/GPP	—

Management Options	Evidence Quality and Recommendation	References
Live Fetus after 24 Weeks	IV/C	15–17
Consider a conservative approach after careful counseling. Possibly undertaken as inpatient.	—/GPP	—
Perform laparotomy and deliver if oligohydramnios and/or compressional deformities.	—/GPP	—
Guidelines for laparotomy and delivery:	IV/C	15–17
• Ideally perform jointly with general/vascular surgeon.		
• Have several units of blood available.		
• Make midline vertical incision in abdomen.		
• Incise sac away from placenta.		
• Avoid placental manipulation during delivery.		
• If blood supply to placenta can be secured, remove placenta completely.		
• If blood supply to placenta cannot be secured, ligate cord only (greater postoperative morbidity).		

GPP, good practice point.

PATHOLOGIC CONDITIONS UNRELATED TO PREGNANCY (Table 56–4)

Gastrointestinal Tract

Acute Appendicitis

GENERAL

Acute appendicitis is the most common nonobstetric cause of an acute abdomen during pregnancy complicating about 1 in 1000 pregnancies,[18] the same frequency as in nonpregnant women.[19] The incidences are approximately 30%, 45%, and 25% in the first, second, and third trimesters, respectively.[20] An infected appendix appears to be more likely to rupture during pregnancy, especially in the third trimester, possibly because of delay in diagnosis and intervention. The incidence among teenagers is higher than in older age groups.[21]

DIAGNOSIS

The diagnosis is challenging because the typical symptoms—anorexia, nausea, and vomiting—mimic normal pregnancy, and the anatomic location of the appendix during pregnancy can be different from that in the nonpregnant patient. Conventional teaching maintains that appendicitis pain "migrates" upward with the growing uterus. However, ine review of cases over a 10-year period showed that pain in the right lower quadrant of the abdomen is the most common presenting symptom in pregnancy, regardless of gestational age.[18] Appendicitis should always be considered when a pregnant woman presents with persistent abdominal pain and tenderness, nausea, vomiting, and fever. Rebound tenderness and muscle guarding are valuable signs in the diagnosis of appendicitis, but because of the laxity of the abdominal wall, these signs are found less frequently in pregnant women.[21] In several publications, features significantly associated with the diagnosis of acute appendicitis included nausea, vomiting, and peritonism.[22,23]

Normal pregnant women may have mild leukocytosis, but serial white blood cell counts can prove helpful when evaluating patients over several hours.[19] Pyelonephritis is the most common differential diagnosis of abdominal pain that mimics acute appendicitis in pregnancy.[20] Ultrasound, CT scan, and MR imaging have all been used to assist in the diagnosis of acute appendicitis.[22,24,25] A systematic review of studies in individuals 14 years of age and older compared the reported overall accuracy for the diagnosis of appendicitis using CT scan with ultrasound. CT had an overall sensitivity of 0.94 (95% confidence interval [CI] 0.91–0.95), a specificity of 0.95 (95% CI 0.93–0.96), a positive likelihood ratio of 13.3 (95% CI 9.9–17.9), and a negative likelihood ratio of 0.09 (95% CI 0.07–0.12). Ultrasonography had an overall sensitivity of 0.86 (95% CI 0.83–0.88), a specificity of 0.81 (95% CI 0.78–0.84), a positive likelihood ratio of 5.8 (95% CI 3.5–9.5), and a negative likelihood ratio of 0.19 (95% CI 0.13–0.27).[26] In one review of cases over 5-year period, ultrasound was positive in over a third whereas MRI was positive in all cases of acute appendicitis.[24] In patients without appendicitis, a normal appendix was visualized in fewer than 2% with ultrasound but in 87% of cases with MRI. In another review, in 5 out of 19 (25%) patients who had confirmed acute appendicitis the ultrasound was normal.[27]

RISKS

Similarity with normal symptoms in pregnancy can lead to a delay in the diagnosis. Maternal morbidity following appendectomy is low, except when perforation has occurred. Pregnancy complications are frequent, especially when surgery is delayed or performed in the first or second trimester. In one review of 56 women who underwent

appendectomy in various trimesters, spontaneous miscarriage occurred in 33% if in the first trimester, and preterm labor in 14% patients operated on in the second trimester.[28] No pregnancy complications were observed in women who underwent appendectomy in the third trimester.

Reluctance to operate in a pregnant woman causes further delay and thus increases the risk of perforation, peritonitis, and septicemia as well as a substantial risk of miscarriage, preterm labor, and fetal demise. The interval between onset of symptoms and surgery has been reported to be the only predictive variable, with a longer interval being associated with appendix perforation. In one study, there was a significant difference in the rate of preterm labor (5.1% vs, 1.3%) and the rate of fetal mortality (25% vs, 1.7%) between patients with and without perforation of the appendix.[29]

MANAGEMENT OPTIONS

Despite the difficulty in making the diagnosis, surgery should not be delayed when the clinical suspicion is high. Laparoscopy appears to be well tolerated in pregnancy,[22,25,27,30] but larger multicenter prospective trials are required to make firm recommendations concerning its use in pregnancy. Use of ultrasound to guide first trocar insertion to prevent injury to the uterus may be a useful adjunct to improve safety.[31]

The decision to proceed with a laparoscopic approach or to perform a laparotomy will depend on the skill and experience of the surgeon as well as clinical factors such as the size of the gravid uterus.

If laparotomy is being performed, the incision site needs to be individualized. In the first trimester, because the appendix remains in its usual location and the uterus does not obstruct access to it, a low transverse or McBurney incision can be used. In the second and third trimesters, a right paramedian incision over the area of maximal tenderness allows better access to the appendix and the option of extending the incision if needed. It is thought preferable to extend the incision to gain adequate exposure rather than to extensively compress or manipulate the pregnant uterus. There are, however, no studies that address this issue.

Postoperatively, vigilance should be maintained for signs of preterm labor, monitoring for contractions and cervical dilation. The value of perioperative use of tocolysis is uncertain. The main concern with using tocolysis is the risk of potential fluid overload and adult respiratory distress syndrome.[32] However, many have used prophylactic tocolysis successfully.[33] There are no reported trials to resolve this issue.[33,34]

SUMMARY OF MANAGEMENT OPTIONS

Appendicitis

Management Options	Evidence Quality and Recommendation	References
Diagnosis is not easy; risks to mother and fetus greatly increased with perforation.	III/B	29
Laparoscopy can be performed safely especially before 20 wk.	IV/C	22,25,27,30
Use of ultrasound scan to guide trocar is a useful adjunct for safety.	III/B	31
Laparotomy performed with right paramedian incision at site of maximal tenderness.	—/GPP	—
There is conflicting evidence for the use of prophylactic tocolysis postoperatively for 2–3 days.	III/B	32–34
Administer postoperative antibiotics.	—/GPP	—

GPP, good practice point.

Intestinal Obstruction

Acute intestinal obstruction is the second most common nonobstetric abdominal emergency complicating pregnancy. It occurs in 1 in 1500 pregnancies. Its incidence as a cause of acute abdominal pain requiring surgery in pregnancy is increasing.[35] This trend is attributed to a number of factors, including a rising number of surgical procedures performed in young women[36] and an increased number of pregnancies occurring in older women.[37,38] Obstruction most likely occurs in the third trimester because of the added mechanical effects of the enlarged gravid uterus.[39]

Clinical presentation is similar to that in the nonpregnant state, with colicky abdominal pain, vomiting, and constipation. Abdominal distention and high-pitched bowel sounds are found. If the diagnosis is suspected, there should be no delay in requesting an erect abdominal x-ray to demonstrate dilated loops of bowel with fluid levels.

RISKS

Like appendicitis, delay in diagnosis is common and is often the explanation for the morbidity and fatality that accompany intestinal obstruction in pregnancy. High maternal and fetal mortality rates of 10% to 20% and 30% to 50%, respectively, are reported, especially if the obstruction is complicated by strangulation or perforation or by fluid and electrolyte imbalance.[35,37]

MANAGEMENT OPTIONS

If there are no signs of strangulation, conservative management with intravenous fluids and nasogastric aspiration may be tried for a few hours.[35–37] However, where there is any doubt, early surgery after correcting fluid and electrolyte imbalance would be the safest option in view of the high complication rate. A vertical midline incision is usually necessary, and occasionally, the definitive surgical procedure may have to be preceded by cesarean section if access becomes a problem and fetal maturity is assured. Use of perioperative tocolysis to prevent preterm labor is of uncertain benefit.[31–33]

SUMMARY OF MANAGEMENT OPTIONS

Intestinal Obstruction

Management Options	Evidence Quality and Recommendation	References
Once diagnosis is made, conservative vs. surgical approach are the options: • *Conservative* (nasogastric suction and IV fluids) may be considered for a few hours if no strangulation/perforation is present. • *Surgical* approach (laparotomy and surgical correction of obstruction) always indicated if strangulation/perforation, though some would advocate early surgery for all cases.	IV/C	35,37

SUMMARY OF MANAGEMENT OPTIONS
Intestinal Obstruction—cont'd

Management Options	Evidence Quality and Recommendation	References
If surgical option chosen:	IV/C	35,37
• Obstetrician and surgeon should operate together.		
• Make adequate vertical incision.		
• Cesarean section may be necessary for adequate surgical field in late pregnancy.		
Give careful attention to fluid and electrolyte balance.	—/GPP	—
Use of tocolysis for 2–3 days after surgery is controversial.	III/B	32–34

GPP, good practice point.

Acute Cholecystitis and Cholelithiasis

Physiologic changes of the biliary system in pregnancy including decreased gallbladder motility and delayed emptying results in an increase in gallbladder disease in pregnancy. In a prospective study of 3254 women having serial ultrasound examination during pregnancy, stones or sludge were present in 5% and 8% of women by the second and third trimesters, respectively, and 10% of women by 4 to 6 weeks postpartum.[40] Spontaneous regression of sludge and stones was common in the postpartum period. Twenty-eight women (0.8%) underwent cholecystectomy within the first year postpartum. The paper also reported that higher body mass index and serum leptin levels were independent predictors of the risk of gallbladder disease.

In another large ultrasound study in Chile, 12% of pregnant women versus 1.3% of nonpregnant control subjects had gallstones.[41] Most gallstones are asymptomatic in pregnancy, but when symptoms occur, they are the same as in nonpregnant women. The obstruction may result in gallbladder distention and acute cholecystitis. When inflammation occurs, it may be aseptic or bacterial. In a audit of over 6500 cases of biliary disease during pregnancy and in the first year postpartum, in the United States, 76% had uncomplicated cholelithiasis, 16% had pancreatitis, 9% had acute cholecystitis, and 8% had cholangitis.[42]

DIAGNOSIS

Pain is located in the epigastrium and right upper quadrant and can vary in severity. It may be sudden in onset and become intermittent. Colicky pain is often a result of a stone obstructing the common bile duct. There may be nausea, vomiting, pyrexia, tachycardia, and right subcostal tenderness. The tenderness on deep palpation under the right costal margin on deep exhalation is known as positive Murphy's sign. Leukocytosis is common. Serum liver function tests and amylase may be mildly abnormal. The differential diagnosis includes viral hepatitis, pneumonia, appendicitis, acute fatty liver of pregnancy, and shingles. Ultrasound scan of the gallbladder and the common bile duct will demonstrate gallstones in more than 90% of cases.[43] Cholangiography is contraindicated in pregnancy.

It is important to differentiate cholecystitis from the hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome and severe preeclampsia, which are associated with great risk to the mother and fetus (see Chapter 35). Abnormal renal function, raised serum uric acid levels, and low platelet counts will help to make the correct diagnosis of HELLP syndrome.

RISKS

Spontaneous rupture of the gallbladder may occur. There is a possible risk of miscarriage and preterm delivery when surgery is required during pregnancy.

MANAGEMENT OPTIONS

Management is similar to that in the nonpregnant woman. Cholecystectomy is not indicated when asymptomatic gallstones are present. Initially, and particularly in the first and third trimesters, conservative treatment should be advocated.[44–46] This approach includes analgesia (avoid morphine), intravenous fluids, and nasogastric suction. Antibiotics may be used.

Recurrent attacks, failure to respond to conservative treatment, suspected perforation, empyema of the gallbladder, peritonitis, and doubt about the diagnosis are indications for surgery.

If symptomatic, it is safer to operate in the second trimester when the risk of preterm labor is lowest, although more aggressive surgical options have now become more acceptable during all trimesters because of advances in maternal and fetal monitoring and advances in laparoscopic surgery.[47,48] Laparoscopic cholecystectomy has been performed during pregnancy and is thought to be safe if performed by a skilled laparoscopic surgeon and has not been associated with fetal mortality.[49,50]

Use of perioperative tocolysis to prevent preterm labor in a continuing pregnancy is debatable, as has been noted previously.[31–33]

SUMMARY OF MANAGEMENT OPTIONS
Cholecystitis

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Consider cholecystectomy prior to conception with symptomatic gallstones.	—/GPP	—
Prenatal		
Conservative approach first:	III/B	44–46
• Bedrest.		
• Analgesia/sedation.		
• IV fluids		
• Nasogastric suction.		
• Antibiotics (e.g., amoxicillin, cephalosporine, or co-amoxiclav).		
• Dietary adjustment after attack has subsided (e.g., avoiding fatty foods).		
Cholecystectomy can be performed in pregnancy if required and can be performed laparoscopically.	III/B	47–50

GPP, good practice point.

Inflammatory Bowel Disease

Chapter 47 provides a detailed discussion of risks and management options.

Gastroesophageal Reflux and Peptic Ulcer Disease

Chapter 47 provides a detailed discussion of risks and management options.

Acute Pancreatitis

Acute pancreatitis is an uncommon complication of pregnancy, and its incidence has been reported to range from 1 in 1000[51] to 1 in 3333 in a recent 10-year audit in the United States.[52] Most cases tend to be associated with gallbladder disease, and more than half (56%) occur in the second trimester.[53] Cases that are biliary in origin have a better outcome than nonbiliary cases.[52] Gallstones probably cause obstruction of the sphincter of Oddi. Preexisting genetic abnormalities in lipid metabolism may be worsened during pregnancy and may also cause gestational hyperlipidemic pancreatitis.[51] In these, a third are reported to develop pancreatitis in their first pregnancy and are associated with a worse outcome. Management may include expectant or surgical. In the 10-year audit, it was noted that patients with gallbladder disease who received surgical or endoscopic treatment during pregnancy had lower preterm delivery rates and recurrences than those that were managed expectantly.[52]

Typical symptoms include fever and often sudden midepigastric pain, which may localize to the left upper quadrant and often radiates into the left flank. Anorexia, nausea,

and vomiting are common. There may be mild pyrexia with varying degree of abdominal tenderness. Ultrasonography will demonstrate gallstones in more than 70% of cases. Raised serum amylase and lipase concentrations will confirm the diagnosis.[54] False-negative results may occasionally occur with hemorrhagic pancreatitis with massive necrosis or when the blood is taken 24 to 72 hours after the attack. A CT scan may be used for severe cases to delineate areas of pancreatic necrosis.[54] Endoscopic retrograde cholangiopancreatography (ERCP) may be used as a diagnostic tool and has been safely performed during pregnancy,[55] but needs further evaluation.

RISKS

There is increased perinatal mortality and morbidity. An acute episode may be associated with preterm labor and its associated risks.[54] This is especially so with hyperlipidemic pancreatitis.[51]

MANAGEMENT OPTIONS

The recommended treatment is similar to that for the nonpregnant patient and includes intravenous fluids, nil orally, gastric acid suppression, analgesia, and possibly nasogastric suction.[52] Because conservative treatment is associated with a high recurrence rate,[52] especially if associated with gallbladder disease, early surgical intervention is appropriate as soon as inflammation has subsided. This may be cholecystectomy or endoscopic sphincterotomy. Some have, however, recommended early aggressive surgical intervention.[54,56]

SUMMARY OF MANAGEMENT OPTIONS
Acute Pancreatitis

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Discuss specific measures in women with risk factors:	—/GPP	—
• Cholecystectomy in women with known gallstones and previous attacks of cholecystitis or pancreatitis. Various strategies in women with alcohol abuse (see Chapter 33). Change treatment in women taking thiazide diuretics		
Prenatal		
Prevent and treat shock with IV fluids and monitoring of electrolyte, calcium, and glucose concentrations.	IV/C	52
Provide analgesia.	—/GPP	—
Administer prophylactic antibiotics	IV/C	52
Suppression of pancreatic activity (no randomized, controlled trials).	—/GPP	—
Prompt recognition and treatment of surgical complications:	—/GPP	—
• Laparotomy usually performed with cholecystectomy if conservative measures fail.	IV/C	52,54,56
• Cholecystectomy can be an early option when pancreatitis occurs with gallstones in first or second trimester.	IV/C	52,54,56
Postnatal		
Cholecystectomy possible if pancreatitis with gallstones successfully treated conservatively in pregnancy.	IV/C	54,56

Urinary Tract Pathology

Chapter 49 provides detailed discussions of risks and management options.

Liver Disease

Acute Fatty Liver of Pregnancy

Chapter 47 provides a detailed discussion of risks and management options.

Severe Preeclampsia and Eclampsia

Chapters 35 and 78 provide detailed discussions of risks and management options.

MISCELLANEOUS CAUSES (Table 56–5)

Rectus Hematoma

Bleeding into the rectus muscle and subsequent hematoma formation following rupture of a branch of the inferior epigastric vessels may occur following a bout of coughing or direct trauma, usually in late pregnancy. A large unilateral painful swelling may be confused with an ovarian cyst, degenerating fibroid, uterine rupture, or placental abruption. However, its superficial location in the abdominal wall should enable accurate diagnosis.

Management Options

If diagnosed early, treatment consists of analgesia and bedrest. If, however, diagnosis is made only at the time of surgery, the hematoma can be evacuated and hemostasis secured.

Sickle Cell Crisis

Chapter 38 provides a detailed discussion of risks and management options.

Porphyria

Chapter 51 provides a detailed discussion of risks and management options

Malaria

Chapter 32 provides a detailed discussion of risks and management options

Arteriovenous Hemorrhage

Miscellaneous, very rare conditions resulting in intra-abdominal hemorrhage can cause abdominal pain in pregnancy. These conditions include rupture of the utero-ovarian veins, rupture of aneurysms (splenic, hepatic, renal, aortic), and spontaneous rupture of the uterine vein.[57] In addition

HbS, hemoglobin S.

to the abdominal pain, rapidly progressing shock is a feature.

Risks

The main risks of these conditions are maternal and fetal demise.

Management Options

Speed of action is imperative in these cases, and even then, death may not be avoided. In all conditions, the principles of management are the same: namely, surgical control of the hemorrhage, correction of shock, and specific measures for specific problems (such as splenectomy with splenic rupture or insertion of a graft with aortic rupture). If the patient survives long enough for such definitive measures to be considered, practical assistance from a general or vascular surgeon is mandatory.

Tuberculosis

Chapter 32 provides a detailed discussion of risks and management options.

Psychological Causes

About 1% of laparoscopies performed for abdominal pain in pregnancy reveal no cause for the pain.[58] Many of these patients have psychological stress that affects the irritable bowel syndrome. Pregnant women with idiopathic abdominal pain are often single, are smokers, and have financial problems.[58] This diagnosis should, however, be made only after exclusion of all possible organic causes and requires comprehensive diagnostic evaluation. This would possibly

avoid unnecessary surgical intervention. Reporting a high number of ailments during antenatal care may be an indication for psychosocial support.[59] Domestic violence should also be considered in these cases (see Chapter 3).

PROCEDURE

LAPAROSCOPY IN PREGNANCY

Indications

Laparoscopy has become an increasingly popular option for many conditions. The common indications in pregnancy have been acute appendicitis and cholecystectomy, which though initially reserved for the second trimester, are now being more widely and safely being performed in any of the three trimesters as surgeons become more aggressive in their management approach. Other indication includes ovarian cyst complications in early pregnancy.

Procedure

In pregnancy, patients should be counseled adequately regarding the risks from the procedure. In late pregnancy, ultrasound-guided Vers needle insertion has been shown to reduce injury to the uterus.[31] An experienced anesthetist would be recommended to ensure that respiration is not compromised by the pneumoperitoneum.

Complications

Lachman and associates[60] reviewed the literature on the subject and cautioned on the lack of adequate data

on the possible harmful effect of intra-abdominal pressure as a result of the pneumoperitoneum as well as any possible effect of carbon dioxide absorption on the fetus. The long-term consequences have also been questioned in another review article.[61] In terms of short-term risks of miscarriage and preterm labor, the numbers studied to date are too small to be reassured and caution would still need to be exercised.

PROCEDURE

LAPAROTOMY IN PREGNANCY

Indications

The indications for laparotomy in pregnancy are discussed in the different sections of this chapter. In general, they are the same as in the nonpregnant patient. Obstetricians arguably are more comfortable with the idea of operating on a pregnant woman than are general surgeons. They are also often more familiar with the alterations in disease presentation and differential diagnosis in pregnancy than are general surgeons. For these reasons, it is advisable that obstetricians do not simply turn the care of their patients over to surgical specialists for diagnosis and treatment, but rather, remain actively involved in their patients' management throughout the period of evaluation, treatment, and postoperative care.[62]

Procedure

Anesthetic Considerations

The choice of the anesthesia for surgery during pregnancy depends on the operation proposed, the skill of the anesthesiologist, and the preference of the surgeon and the patient, Although it has been suggested that chronic exposure of operating room personnel to anesthetic agents leads to an increased rate of miscarriage, the hazard associated with acute general anesthetic administration to the patient is not well characterized. It seems that the risk is very small. It is probably more important that meticulous attention is paid to maintenance of maternal homeostasis. The fetus is totally dependent on adequate maternal oxygenation and uterine perfusion. Any compromise of maternal oxygenation will potentially affect the fetus. Both conduction or regional anesthesia and general anesthesia can be used in pregnancy with safety for both the mother and the fetus.

Operation

Abdominal incisions in pregnancy are the same as those used in nonpregnant patients. McBurney and low transverse incisions are best limited to the first trimester. Later in pregnancy, the enlarged uterus so completely fills the lower abdomen that access to organs other than the anterior, lower uterine segment (as for cesarean section) is extremely difficult. It is generally advisable to make an incision that can be extended if

necessary, rather than attempting to use a small and poorly placed incision and being forced to manipulate the uterus in an attempt to accomplish the operation. Midline or paramedian incisions work well. Healing in pregnancy is generally without complications, though there may be some skin scar spreading as the abdomen enlarges through pregnancy and keloid formation in some women. If labor occurs shortly after surgery, the fresh incision may inhibit maternal expulsive efforts during the second stage, necessitating an assisted delivery.

Complications

There is an increased risk of miscarriage in association with laparotomy performed during early pregnancy.[64] This risk exists especially in the first trimester and is considerably reduced on planned procedures carried out in the second trimester. Preterm delivery and technical difficulty are problems encountered when laparotomy is carried out during the third trimester. However, although the risks of laparotomy in pregnancy should not be underestimated, the risks to the mother and baby of the condition for which the surgery is required are usually greater than the risks of the operation itself, and if surgery is indicated, it should not be unduly delayed.

Nonmalignant Gynecology

KASSAM MAHOMED

INTRODUCTION

This chapter discusses the significance of a number of gynecologic problems in association with pregnancy that are not covered elsewhere in the book. For malignant gynecologic problems, see Chapter 52. Nonmalignant topics discussed elsewhere include infection (see Chapter 31), female circumcision (see Chapter 71), previous pelvic floor surgery, and previous third-degree tear (see Chapter 71).

OVARIAN CYSTS IN PREGNANCY (See Chapters 52 and 56)

Introduction

With wider routine ultrasound scanning during the first trimester, the discovery of an ovarian cyst has become relatively common. In a retrospective audit, 4.8% of women having a scan before 10 weeks had an ovarian cyst of 3 cm or more.[1] Larger ovarian cysts that are 6 cm or more are estimated to occur in 0.5 to 2 per 1000 pregnancies.[2] Most unilocular and anechoic ovarian cysts with thin borders that are seen during the first trimester are corpus luteum cysts. These cysts are not usually present after the end of the first trimester. The majority are asymptomatic, and most resolve spontaneously.[3] Thus, further evaluation and management of cysts in early pregnancy are usually left until the second trimester.[4]

If cysts are noted after 16 weeks' gestation, pathology needs to be excluded. They may present with torsion or pain or on routine ultrasound scanning. In a recent review of such cases, 20% were functional cysts, 50% were serous cysts, 10% were mucinous cysts, and 35% were dermoid cysts.[5]

Risks

The major risk of ovarian cysts in pregnancy is to the mother, namely pain from torsion, rupture, or hemorrhage into cyst. If the cyst is large enough in the third trimester, it may predispose to malpresentation or obstructed labor.[6] Fetal risks include miscarriage and preterm delivery.[7]

Management Options

Prepregnancy

Surgical treatment is indicated for cysts that are detected before pregnancy, if they are larger than 5 cm, contain echogenic material, or are symtomatic.[8] Aspiration of cysts, either laparoscopically or ultrasonically, with cytologic examination of the fluid, is not favored because cystadenomas or cystadenocarcinomas may be misdiagnosed.[9] However, in one long-term follow-up of patients who had aspiration of simple cysts because they were not suitable for surgery, the main risk was recurrence (75%).[10] No patient developed ovarian malignancy.

Prenatal

Familiarity with the natural history and ultrasound scan features of common adnexal lesions, such as simple cysts, hemorrhagic cysts, endometriomas, mature cystic teratomas, and ovarian conditions specific to pregnancy, may permit stratification of patients into management protocols. More than 90% of cysts that occur in pregnancy are non-neoplastic.[5] Corpus luteum cysts usually begin to regress after 12 weeks.[11] Ultrasound scanning may help to identify those patients in whom conservative management is appropriate. Asymptomatic ovarian cysts with benign sonographic features may be followed closely by serial scanning into the second trimester, when surgery can be planned, if necessary.[12,13] However, if the cyst is not enlarging, conservative management may be preferred. Surgery, even in the second trimester, may result in preterm delivery.[7]

If ultrasound examination of an ovarian cyst larger than 5 cm shows echogenic features, surgery may be indicated.[12] The risk of surgical interventions needs to be balanced against the potential risks of nonintervention, which may include torsion, rupture, and hemorrhage. Laparoscopic management is now the preferred management option if the cyst is not too large.[14,15]

Torsion of ovarian cysts is treated by surgery.[16] If intervention is necessary, laparoscopy is the preferred method.

The use of tocolysis to reduce the risk of preterm delivery is controversial, and there are no reported trials to help to resolve this issue.[17] Aspiration of the cyst is not well evaluated and is not generally recommended.[9] The role of

progesterone in women considered to be at risk of preterm birth for "other reasons" is uncertain. Two randomized trials to date indicate no benefit in terms of preterm birth less than 37 weeks' gestation.[18] However, the combined sample size of these two trials is significantly underpowered to detect all but large differences in these outcomes.

Labor and Delivery

If an ovarian cyst causes obstruction in labor, delivery is by cesarean section. The ovarian mass is managed in the usual manner at the same time.[19] Aspiration is generally not recommended.[9]

PROCEDURE

OVARIAN CYSTECTOMY IN PREGNANCY

Indications

Cystectomy is performed in patients with a symptomatic cyst (e.g., torsion, hemorrhage, rupture) and in those with an asymptomatic cyst that is recognized ultrasonically but does not regress by 16 weeks. Other indications include echogenic material that suggests a dermoid or has a septate or multilocular appearance.

Gestation

The procedure should be performed ideally at 18 to 20 weeks' gestation. A cyst noted earlier in gestation may be corpus luteum.

Description

Preoperative and perioperative measures include the use of appropriate antithromboprophylaxis.

Anesthesia

A general anesthetic agent is traditionally used, though regional anesthesia is an alternative.

Incision

If laparotomy is being performed, the type of skin incision will depend on the size of the cyst, although in the majority, a lower transverse skin incision would be adequate.

Method

The ovary with the cyst is usually very mobile, unless the cyst is associated with infection, endometriosis, or malignancy. The principles are the same whether performed via laparotomy or laparoscopy. The ovary and cyst are gently grasped at the antimesenteric border near each pole of the ovary (Fig. 57–1A).

The ovarian capsule only (not the cyst) is incised along the antimesenteric border, between the two forceps (taking care not to puncture the cysts; see Fig. 57–1B).

The handle of the scalpel or dissecting scissor blades are used to bluntly dissect the capsule away from the cyst, using grasping forceps on the margin of the capsule as counteraction (see Fig. 57–1C). The blunt

FIGURE 57–1
Ovarian cystectomy.
dissection is continued close to the cyst, including along the mesenteric aspect. The cyst can then be removed and sent for histologic evaluation.

Hemostasis

Spot diathermy is applied to bleeding points arising from the mesenteric aspect of the ovary.

Repair of the Ovary

Usually, the cut edges of the ovary are everted and repaired with either polyglactic (Vicryl) or polyglycolic

(Dexon) (2/0 or 3/0) (see Fig. 57–1*D*). If hemostasis is satisfactory, and especially with laparoscopy, the ovarian base may be left open unsutured. Careful tissue handling is required, and microsurgical technique (i.e., forceps) is preferred to gross handling (see Fig. 57–1*E*).

Postoperative Management

Narcotic analgesia is used. The use of prophylactic tocolysis is debatable.[17] The histology report should be followed up.

Complications

Complications are miscarriage, preterm labor, and tubal adhesions of the fimbria to the incision in the ovarian capsule, which may impair future fertility. If the lesion appears benign, ovarian cystectomy rather than oophorectomy is probably the treatment of choice, because malignancy is rare. In young women, it is probably better to repeat the laparotomy to remove the ovary later rather than remove an ovary for what may be a benign condition.

SUMMARY OF MANAGEMENT OPTIONS
Ovarian Cysts

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Treat symptomatic cysts, sonolucent cysts, and echogenic cysts ≥8 cm in diameter.	III/B	8
Prenatal		
Aspiration of cysts is not recommended.	IV/C	9
Corpus luteum cysts regress by 12 wk.	IV/C	11
Remove cysts that are symptomatic.	—/GPP	8
Laparoscopy is the preferred method of surgical management whenever possible.	III/B	9,14,15
Surgery is best performed in the second trimester.	III/B	12,13
If cysts are asymptomatic with benign features, conservative management is acceptable.	III/B	12,13
Use of tocolysis to prevent miscarriage or preterm labor is debatable.	III/B	17
There is no evidence that progesterone is of benefit to prevent preterm labor.	Ib/A	18
Labor and Delivery		
For cysts impacted in the pouch of Douglas, perform LSCS and ovarian cystectomy rather than cyst aspiration.	IV/C	19

GPP, good practice point.

FIBROIDS (See also Chapter 56)

Introduction

In a review of over 15,000 women with singleton pregnancies undergoing routine second-trimester ultrasound scan, fibroids of 1 cm or more were found in 2.7% of cases.[20] Others have noted 4% of pregnant women having uterine fibroids on routine scanning,[21] and the proportion of women with fibroids increases with age, especially in African American women compared with white women.[22]

Risks

It is widely believed that fibroids increase in size during pregnancy; however, only about 25% of fibroids enlarge during pregnancy.[23,24] In those that enlarge, most of the growth occurs in the first trimester, with little if any further increase in size during the second and third trimesters.[23,24] Larger fibroids (>5 cm in diameter) are more likely to grow, whereas smaller fibroids are more likely to remain stable in size.[25] The mean increase in fibroid volume during pregnancy is 12%, and very few fibroids increase by more than 25%.[23,24] Larger fibroids may undergo hemorrhagic infarction and can cause varying severity of pain, which is often localized to the region of the fibroid. There may be associated nausea, vomiting, and mild pyrexia and mild leucocytosis.[25] Classically, this complication occurs at approximately 20 to 22 weeks' gestation.

There are no well-designed studies that provide adequate data on fibroids and pregnancy outcome. Risks of fibroids in pregnancy probably relate to their number, size, and position. Large submucosal and intramural fibroids that distort

the uterine cavity are associated with miscarriage.[26] Antepartum hemorrhage and placental abruption are reported to occur, especially with retroplacental fibroids.[26,27] Other complications include preterm labor and preterm birth,[26] malpresentation (mainly breech presentation),[26,28] and dysfunctional and obstructed labor.[28] Studies have also reported that uterine fibroids are associated with an increased risk of cesarean delivery,[21,26–28] especially when the fibroids are located in the lower uterine segment. This is probably related to the increased risk of malpresentation, dysfunctional and obstructed labor, and placental abruption. Some have reported an increased risk of postpartum hemorrhage, especially if the fibroids are large and retroplacental.[26,29]

Management Options

Prepregnancy

Prepregnancy myomectomy may improve the chances of a successful pregnancy in women with recurrent miscarriages, particularly those in whom no other cause has been found apart from the presence of fibroids.[30] Because most complications of pregnancy are associated with larger submucosal fibroids, removal before pregnancy should be considered in these cases also,[31] usually hysteroscopically, with or without the use of gonadotropin-releasing hormone analogue.[32]

Intramural or subserosal fibroids should be removed only if they are large, distorting the uterine cavity, or are symptomatic and are better performed laparoscopically rather than by open myomectomy.[33] Careful patient counseling[34] is important because hysterectomy may become necessary if excessive bleeding occurs. Preoperative gonadotropin-releasing hormone analogue therapy may reduce the risk of hemorrhage.[32] The appropriate interval from surgery to conception is not known.

Prenatal

Most fibroids are asymptomatic during pregnancy and are diagnosed on routine ultrasound examination. If degeneration occurs and causes pain, analgesia is necessary. Application of local heat or ice packs to the abdomen may provide relief.[35]

Myomectomy has generally been contraindicated during pregnancy.[36] However, several case series have been reported of myomectomy being performed in the first and second trimesters.[37–40] The most common indication would be intractable pain. In a series of 106 pregnant women with uterine fibroids, surgical intervention for recurrent pain, or for rapidly growing fibroid (defined as doubling in size over 8 wk), or if a fibroid larger than 5 cm was located in the lower uterine segment, prenatal surgery was not associated with any increased risk of miscarriage or preterm birth.[41] Despite this reassuring publication, antepartum myomectomy should be avoided if possible until further data are available. A subserosal fibroid that becomes impacted in the pouch of Douglas and interferes with micturition may be managed conservatively by catheterization. The patient should be encouraged to spend time resting prone in the head-down position.[42]

If a fibroid (usually a lower segment fibroid) causes an abnormal lie of the fetus after 36 weeks' gestation, elective cesarean section at 38 to 39 weeks' gestation is advised.[28]

Labor and Delivery

Management during labor of a patient with a fibroid depends on whether the fibroid is obstructing delivery. Cesarean delivery is indicated when a lower segment fibroid causes an abnormal lie at 38 weeks' gestation or is larger than 6 cm at 38 weeks' gestation and is palpable below the fetal head, either abdominally or vaginally.[34] Fibroids are usually soft and "drawn" or "pressed" out of the way during labor. Specific management points for the operation include

- Cross-matched blood should be available.
- Thromboprophylaxis should be undertaken.
- Regional anesthesia is normally used.
- A midline subumbilical incision is advisable if the fibroid is large or if a classic cesarean section is anticipated. However, if the fibroid is small or posterior, a routine lower transverse incision may be performed.
- The type of incision used depends on the observed site of the fibroid. If the lower segment is well formed around the fibroid and a transverse lower segment incision can be made, allowing a 2- to 3-cm margin with the fibroid, a lower segment approach is used. If access through the lower segment with a 2- to 3-cm margin is not possible, a classic cesarean section should be performed, again ensuring a 2- to 3-cm safety margin with the fibroid.

Myomectomy at the time of cesarean delivery may be required if the fibroid makes it impossible to satisfactorily close the uterine incision. Performing an elective myomectomy at the time of cesarean delivery is associated with high risk for postpartum hemorrhage and hysterectomy[42] and should be strongly discouraged, even though this has been reported to have been performed safely.[43] Following delivery, even without any intraoperative problems, postpartum hemorrhage due to poor uterine contractility should be anticipated. Adequate oxytocic therapy should be prescribed and blood transfusion anticipated.[29,31,44]

Pregnancy after Previous Myomectomy

The increased risk of uterine rupture during labor in patients with prior myomectomy is well described.[45] An incidence of zero to 1 in 40 has been reported, mainly from early descriptive studies, and appears to depend on whether the endometrial cavity had been opened.[46,47] The risk of rupture may be higher with laparoscopic myomectomy, which may be related to the efficacy of laparoscopic suturing.[48,49] However, a literature review of pregnancy outcome following laparoscopic myomectomy noted a rupture rate of only 1 in 211 cases.[50]

Until more reassuring data become available, standard advice would be to perform elective cesarean section if the endometrial cavity had been entered during the myomectomy or a large number of fibroids had been removed. However, if the myomectomy was performed for subserosal fibroids only, there is less risk of uterine rupture during labor. In this case, conservative management is usually advised, although labor should be managed as in a patient with a previous cesarean delivery.

Another concern for women who have had a myomectomy is the association with placenta accrete, and a careful search for invasive placentation is warranted.[51]

SUMMARY OF MANAGEMENT OPTIONS
Fibroids

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Remove endometrial or submucosal fibroids hysteroscopically, with or without the use of a gonadotropin-releasing hormone analogue, if the patient has a history of subfertility.	III/B	30–32
Most women with fibroids have no problem conceiving and the pregnancy is usually uneventful.	Ia/A	33
Consider myomectomy for other fibroids if they are symptomatic, and only after careful counseling.	Ia/A	33,34
Prenatal		
Red degeneration is treated with bedrest, analgesics, local heat, and ice.	IV/C	35
Need to remove a pedunculated serosal fibroid for severe symptoms is rare. Avoid surgery if possible.	IV/C	36
Consider elective LSCS if: • Lower segment or cervical fibroids cause unstable lie or failure of engagement of the fetal head. • The patient had a previous myomectomy for intramural fibroids.	IV/C	28
Labor and Delivery		
Perform an LSCS if a fibroid leads to obstructed labor or if endometrial cavity opened during previous myomectomy.	IV/C	34,48,49
Be vigilant for postpartum hemorrhage.	IV/C	29,31,44
Avoid myomectomy at LSCS.	IV/C	42
For cesarean delivery, consider a classic or upper segment approach if access through the lower segment with 2 to 3 cm normal tissue is not possible.	IV/C	28
Beware of invasive placentation if previous myomectomy.	IV/C	51

SUBFERTILITY

Introduction

One in six couples of reproductive age needs specialist help because of inability to conceive (primary infertility) or inability to conceive the number of children they wanted (secondary infertility).[52] This figure is increasing because both women and men are delaying having children until after the age of 35 years.[53] In one study, the probability of pregnancy was twice as high for women aged 19 to 26 years compared with women aged 35 to 39 years. Controlling for age of the woman, fertility was significantly reduced for men older than 35 years.[54] The number of couples seeking assisted reproductive technology (ART) has tripled between 1992 and 2004.[55]

A male factor is the dominant cause of subfertility in 20% to 25% of couples.[56,57] Female causes of subfertility include problems with ovulation, defects in sperm-mucus interaction, and tuboperitoneal disorders. In 25% to 30% of couples who undergo evaluation, inability to conceive is unexplained.[56] Endometriosis causes subfertility in approximately 5% of women through any of these mechanisms.

. Whereas tubal causes of subfertilty have decreased, others female factor, male factors, and multiple causes have become more common.[55] In couples without a clear indication for in vitro fertilization (IVF), one study has also shown that, although the cumulative probability of pregnancy was highest for early treatment with IVF, over time, conservative treatment or frequent intercourse approached the same cumulative probability; thus, emphasizing that benefit must be weighed against cost and potential harm and that couples should continue to be encouraged to maintain regular intercourse.[58]

Treatments to assist conception include use of ovulation-inducing agents, tubal or ovarian microsurgery, and various forms of ART.

Risks Associated with Pregnancies Conceived Using Fertility Treatments

Ovarian Hyperstimulation

Ovarian stimulation is associated with a risk of theca-lutein cysts in the ovary; these cysts are more common with

gonadotropin (6%) than with clomiphene therapy (3%).[59] Ovarian hyperstimulation syndrome (OHSS) is a potentially life-threatening complication of ovulation induction. Its most severe form is associated with massive ovarian enlargement and multiple cysts, ascites, pleural effusions, hemoconcentration, and hypoalbuminemia. It may result in oliguria and renal failure, hypovolemic shock, thromboembolic episodes, adult respiratory distress syndrome, and rarely, death.[60] Mild OHSS occurs in about 25% of cases, and the severe form occurs in 0.5% to 5% of cases.[61]

Miscarriage

In a large U.S. database, it was noted that the spontaneous miscarriage rate among ART pregnancies was 14.7%, similar to that after normally conceived pregnancies. The increased rate is related to oocyte or embryo quality. Pregnancies conceived with frozen and thawed embryos have a higher miscarriage rate than fresh embryos.[62]

Chromosomal Abnormality

There does not appear to be an increase in the prevalence of karyotype abnormalities in offspring of IVF-conceived pregnancies. However, this may be so with the use of sperm from subfertile men, and the intracytoplasmic sperm injection (ICSI) procedure itself may increase the risk of chromosomal and gene abnormalities in children conceived by ART.[63]

Ectopic Pregnancy

In a large review of 94,118 ART pregnancies, 2.1% were ectopic. The figures were 2% among pregnancies conceived with IVF and 3.6% with zygote intrafallopian transfer (ZIFT).[64]

Multiple Pregnancy

A world collaborative report on IVF pregnancies cites a twin pregnancy rate of 27% and a triplet pregnancy rate of 3%. ART is estimated to account for just over 1% of all births and 18% of all multiple births.[65]

Preterm Birth and Small for Gestational Age and Perinatal Mortality

The 2006 result of the Canadian ART Register[66] have confirmed that clinical pregnancy and live birth rates continue to increase, but multiple birth rates have only slightly decreased despite the recommendation of only one embryo transfer.[67] Although multiple pregnancy remains the principal cause of adverse outcome after ART,[68] a meta-analysis of 15 studies comprising 12,283 IVF and 1.9 million spontaneously conceived singletons, IVF singleton pregnancies were also associated with significantly higher odds of each of the perinatal outcomes examined: perinatal mortality (odds ratio [OR] 2.2; 95% confidence interval [CI] 1.6–3.0), preterm delivery (OR 2.0; 95% CI 1.7–2.2), low birth weight (OR 1.8; 95% CI 1.4–2.2), and small for gestational age (OR 1.6; 95% CI 1.3–2.0).[69] These poor outcomes have also been confirmed in a large case-controlled study.[70] It is possible that these adverse outcomes could be attributable to the factors leading to infertility, rather than to factors related to the reproductive technology.

Cerebral Palsy

An increased risk of cerebral palsy has been reported (OR 2.2; 95% CI 1.7–2.8), but most of the increase may be related to the high risk of multiple pregnancy and of preterm birth.[71]

Intraventricular Hemorrhage

There was a significantly increased risk of grade III/IV intraventricular hemorrhage in infants of IVF pregnancies from a single study,[72] and more information is needed on this issue.

Long-Term Health Implications

There do not appear to be any long-term health implications for children conceived by IVF or ICSI. However, more long-term follow-up is required to fully establish the truth of this statement.[73]

Placenta Previa

There was a sixfold higher risk of placenta previa in singleton pregnancies conceived by assisted fertilization compared with naturally conceived pregnancies. The authors of that report suggest that the increased risk may be caused by factors related to the reproductive technology.[74]

Other Obstetric Complications

Other obstetric complications include gestational diabetes and preeclampsia. In a case-control study, pregnant women with polycystic ovary syndrome (PCOS) had a much higher incidence of pregnancy-induced hypertension (31.8%) than women without PCOS (3.7%).[75] However, confounding factors such as the cause of infertility were not consistently ascertained and adjusted for when interpreting pregnancy outcome data. For example, PCOS is a common cause of infertility and is associated with insulin resistance, which plays a major role in development of gestational diabetes.[76]

Effect of Medical Adjuncts in Assisted Reproductive Technologies on the Fetus

One important outcome of the increase in pregnancies conceived by ART is the number of women who are taking medical adjuvant treatment in the early stages of pregnancy. Table 57–1 reviews the present state of knowledge of such adjuncts in assisting conception.[77] In summary, very few have any evidence to support their use in clinical practice other than as part of a randomized trial. Furthermore, and of greater concern, the impact of most of these treatments on the first-trimester fetus is not known.

Management Options

Prepregnancy

When a couple seeks treatment for infertility, the woman must undergo an assessment that includes a thorough history and examination to ensure that she does not have a medical problem that must be treated or controlled before conception to minimize subsequent risks during pregnancy. All women with infertility should be tested for rubella. Those who are not immune should be vaccinated at least 3 months before pregnancy.[78] Couples considering IVF should be

TABLE 57–1

Medical Interventions in In Vitro Fertilization

INTERVENTION	COMMENT ON EVIDENCE	EVIDENCE GRADE
Investigations		
Measuring uterine natural killer cells	There is no robust evidence that this is clinically useful in predicting the outcome of IVF treatment.	B
Routine testing for antiphospholipid antibodies	There is no evidence that this is of benefit.	A
Testing for thrombophilias	This is justified in patients with a history of repeated implantation failure.	C
Testing for thyroid and ovarian autoantibodies	There is no evidence that this is of benefit.	B
Alloimmune testing	There is no evidence that this is of benefit.	C
Treatments		
IVIG for recurrent failed IVF cycles	There is no evidence for the use of IVIG as adjunctive therapy for recurrent failed IVF cycles	A
TNF-α immune therapy in women undergoing IVF	There are a lack of studies investigating the role and the safety of TNF-α immune therapy in women undergoing IVF; thus, there is no indication for its use.	C
Peri-implantation steroids in ART cycles	There is no evidence to support the use of this treatment.	A
Peri-implantation steroid administration in women undergoing IVF alone	There is limited evidence that peri-implantation steroid administration may improve pregnancy rates in women undergoing IVF alone. These results need to be confirmed in a suitably powered, RCT designed specifically to address this issue.	GPP
NTG or sildenafil citrate	Neither NTG nor sildenafil citrate has beneficial effects on IVF outcome and should not be used.	A
Uterine relaxants (β_2-adrenergic antagonists, progesterone)	These should not be used because their effect is unknown.	GPP
Aspirin	There is no evidence that this is of benefit and should not be prescribed.	A
LMWH alone and in combination with LDA	There is no evidence that this is of benefit.	C
Pragmatic treatment with LMWH and LDA	This should be used only in women with antiphospholipid syndrome and in those with antiphospholipid antibodies and repeated implantation failure.	C
Growth hormone adjuvant therapy	There is no evidence that this is of benefit.	A
Luteal phase estradiol supplementation	There is no evidence that this is of benefit in all patients.	A
	Estradiol supplementation should be used only in recipients of donated oocytes and in patients with hypogonadotrophic hypogonadism.	C

ART, assisted reproductive technology; GPP, good practice point; IVF, in vitro fertilization; IVIG, intravenous immunoglobulin; LDA, low-dose aspirin; LMWH, low-molecular-weight heparin; NTG, nitroglycerin; RCT, randomized, controlled trial; TNF-α, tumor necrosis factor-α.
From Nando LG, Granne I, Stewart J: Medical adjuncts in IVF: Evidence for clinical practice. Hum Fertil 2009;12:1–13.

informed of the increased risks of complications discussed previously and should include provision of genetic counseling.[79]

For all women contemplating pregnancy, folic acid supplementation should be initiated.[80]

Preventive strategies for OHSS attempt to identify women who are at increased risk (using ultrasound and serum estradiol measurements). The lowest possible dose of gonadotropin is used to reduce the granulosa and luteal mass. In patients with a large number of follicles (>20) and an increasing serum estradiol level, the most widely used and most cost-effective approach is to withhold gonadotropin stimulation (coasting) while continuing down-regulation.[81] Other methods include early unilateral ovarian follicular aspiration; administration of glucocorticoids, macromolecules, and progesterone; cryopreservation of all embryos; and electrocautery or laser vaporization of one or both ovaries.[82] Surgical resection of the ovary causes regression of symptoms much faster than pharmacotherapy and should be considered in severe cases that do not respond well to initial management.[83]

Prenatal

The first, and probably most important, management step is to confirm that the missed period is associated with at least one viable intrauterine pregnancy and to identify whether there is a multiple pregnancy, and if present, to determine the chorionicity (see Chapter 59). The prenatal management of multiple pregnancy is discussed in Chapter 59.

All caregivers should recognize the likelihood of anxiety and the need for supportive counseling in patients who conceive after IVF.[84] Ideally, the number of people caring for these patients should be restricted, especially so that consistent information and advice can be given to the couple, who may be anxious. The couple may believe that their only difficulty was in conceiving and that once this goal has been achieved, the pregnancy is not at additional risk.[84]

Vigilance for ectopic pregnancy should be maintained in women with a history of tubal disease.[85]

If pregnancy is associated with the use of hyperstimulatory drugs, corpus luteum cysts are commonly seen until 12

weeks.[86] Surgical therapy or aspiration should be avoided. Sometimes, the need for stimulation of ovulation is associated with an endocrine dysfunction, such as a progesterone defect, in early pregnancy. Use of progesterone has become widely prescribed based on biologic plausibility and reports of successful treatment,[84] though not on any controlled trials.[87]

First-trimester screening (nuchal translucency and biochemistry) should be offered to all women; few patients will need second-trimester screening and invasive testing.[88]

Women with PCOS should be screened for gestational diabetes during pregnancy, with frequent surveillance of blood pressure.[76]

Ultrasound is frequently performed to evaluate fetal growth and well-being, especially to allay the anxiety of the couple.[84]

Labor and Delivery

These pregnancies have an increased rate of operative deliveries, especially cesarean section. Continuous fetal heart monitoring is advisable and may be demanded by the patient. Use of fetal blood sampling for any non-reassuring fetal heart rate pattern may avoid unnecessary cesarean section.

Postnatal

Contraception is not usually an issue in these couples, but it must be discussed. The usual contraindications to the use of intrauterine devices in women with a recent history of tubal disease apply. Contraceptives that may delay the return of ovulation (such as progesterone-only preparations) should be avoided in couples who may want another pregnancy soon.

SUMMARY OF MANAGEMENT OPTIONS
Subfertility

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Check for underlying medical disease (e.g., hypertension, diabetes, renal disease, *Chlamydia* infection).	—/GPP	—
Counsel women undergoing assisted reproduction about the rates of multiple pregnancy and other specific risks.	III/B	65
Use pre- and postconceptual folate supplementation.	Ia/A	78
Ensure that the patient is immune to rubella.	III/B	76
Follow protocols to avoid hyperstimulation and multiple pregnancy.	III/B	66,67,79
If the male partner has obstructive azoospermia, the couple should be screened for cystic fibrosis carrier status. Males should also be screened for Y chromosome deletions.	IV/C	62
Prenatal		
Check the viability and number of intrauterine pregnancies and chorionicity if multiple.	III/B	65,66
Diagnose ectopic pregnancy early.	IV/C	83
First-trimester screening should be offered to all women.	IIa/B	86
Screen for hypertension and gestational diabetes in women with polycystic ovary syndrome.	IV/C	75
Check fetal growth and development in pregnancies achieved through an ART.	III/B	70,82
Provide reassurance and counseling.	IIb/B	82
Labor and Delivery		
Provide continuous fetal heart rate monitoring for psychological reasons.	IIb/B	82
Postnatal		
Contraception is not usually an issue.	—/GPP	—
Avoid IUCD use in patients with a history of tubal disease.	—/GPP	—
Avoid progestogens in patients with a history of ovulatory disorders.	—/GPP	—

GPP, good practice point.

OTHER GYNECOLOGIC DISEASES AND PROBLEMS

Congenital Disorders

Some women have congenital abnormalities of the genital tract that affect pregnancy or labor and delivery. Most uterine abnormalities are diagnosed by ultrasound scan and/or hysterosalpingogram. Bicornuate uterus, uterus didelphys, and septate uterus constitute 80% of cases.[89] These conditions are associated with preterm delivery (29%), spontaneous first-trimester miscarriage (24%), ectopic pregnancy (3%), fetal malpresentation (23%), and a high cesarean delivery rate (28%).[89]

Whereas there is overall evidence of benefit from cerclage with short cervix in women at risk of preterm delivery, there are insufficient data for the subgroup of women with congenital abnormality.[90] Progesterone therapy may have a role, but its use to prevent preterm labor awaits evaluation.[18] In women with repeated miscarriages, hysteroscopic metroplasty in the treatment of septate uterus has improved fetal survival rates.[91]

The other disorder of the lower tract is a vaginal septum. A septum that is fenestrated superiorly may obstruct labor. This complication can usually be managed acutely simply by dividing the septum in the second stage under epidural or pudendal anesthesia. Hemostatic measures are not usually required.

Cervical Stenosis or Incompetence as a Result of Previous Cone Biopsy

Cone biopsy may affect conception because the destruction of mucus-producing glands might cause cervical stenosis or incompetence. The overall rate of normal-term vaginal delivery is reported as 46.6% and is inversely proportional to the cone size. The incidence of both spontaneous mid-trimester miscarriage and preterm birth is increased in direct proportion to cone size. Cervical stenosis necessitating cesarean delivery is associated with small rather than large cones.[92] The role of cervical cerclage is uncertain.[90]

Pregnancy after Previous Endometrial Ablative Therapy

Endometrial ablation by numerous methods is used in women with dysfunctional menstrual bleeding and usually is performed only in women who do not wish to retain reproductive capacity. A few women may become pregnant after endometrial ablation (0.7% in one series[93]), and 45 pregnancies have now been reported in the English literature. A large number ended with an ectopic pregnancy or a miscarriage or were terminated (62%). Nine of the 17 that continued beyond 20 weeks' gestation reached 38 weeks with good outcome. Only 1 term pregnancy was complicated by placenta increta and resulted in cesarean hysterectomy.

Vulval Varicosity

Vulval varicosities are common during pregnancy, especially in multipara. This familial condition may be noted in the first pregnancy, but varicosities develop earlier and are larger as the number of pregnancies increases. They cause discomfort, heaviness in the pubic region, and sometimes pruritus or even pain, which is most often relieved by lying flat. They usually disappear completely postpartum. Bedrest and support may provide symptomatic relief. They are also significantly relieved by sclerosing agents.[94]

SUMMARY OF MANAGEMENT OPTIONS
Other Gynecologic Diseases and Problems

Management Options	Evidence Quality and Recommendation	References
Congenital Anatomic Defects		
Evaluate and treat prepregnancy.	IV/C	87
Evaluate prenatally and plan delivery.	IV/C	87
Divide vaginal septa.	IV/C	89
Cervical Stenosis or Incompetence		
Evaluate prenatally and plan delivery.	IV/C	90
Cervical suture may be of benefit	Ia/A	88
Be vigilant for dystocia in labor and the need for LSCS.	—/GPP	—
Endometrial Resection		
Counsel risk of ectopic pregnancy, miscarriage, preterm delivery, and intrauterine growth restriction.	III/B	91
Vulval Varicosity		
Provide symptomatic treatment prenatally (bedrest, support).	—/GPP	—
Sclerosing therapy may be used.	IV/C	92
Avoid trauma during delivery.	—/GPP	—

GPP, good practice point.

Bleeding in Late Pregnancy

OSRIC B. NAVTI and JUSTIN C. KONJE

INTRODUCTION

Vaginal bleeding in late pregnancy, or antepartum hemorrhage (APH), is defined as bleeding from the genital tract after 20 weeks' gestation. This type of bleeding complicates 2% to 5% of all pregnancies[1] and has various causes (Table 58–1). There is no identifiable cause in almost half of cases. Bleeding from the placental bed is the most common identifiable cause.

MANAGEMENT OF BLEEDING IN LATE PREGNANCY

APH is often unpredictable, and the patient's condition may deteriorate rapidly before, during, or after presentation. The initial management is the same regardless of etiology and starts with general measures to treat or prevent deterioration, followed by specific treatment measures. The general measures discussed in this chapter apply to all cases of APH, but they may be modified depending on the severity of bleeding. The specific measures depend on the diagnosis and are discussed under the various causes of bleeding.

INITIAL ASSESSMENT AND MANAGEMENT (Fig. 58–1)

Management of the patient with APH must be in a hospital with adequate facilities for transfusion, cesarean delivery, neonatal resuscitation, and intensive care. In the patient with significant vaginal bleeding, immediate transfer to a hospital by ambulance is recommended. Initial management includes a history, evaluation of the patient's general condition, and initiation of testing and treatment.

History

The history must include the amount, character, and duration of bleeding. It is also important to ascertain whether there is any associated pain or regular uterine contractions. The history should identify initiating factors, such as trauma or coitus, a history of ruptured membranes, or previous vaginal bleeding. The gestational age as determined ideally by early ultrasound scan should be documented and note taken of fetal movements and the placental site recorded in previous scans. Additional information includes details of previous bleeding episodes, past obstetric history, and cervical smear histories.

Physical Examination

Physical examination should assess both the maternal and the fetal condition, including
- Maternal pulse, blood pressure, and respiratory rate.
- Clinical evidence of shock (restlessness; cold, clammy extremities; poor skin perfusion; piloerection response).
- Abdominal examination to determine whether the uterine fundus is compatible with the estimated gestational age and to assess the presence of tenderness, the number and viability of fetuses, the presence of uterine contractions, and the lie and presentation of the fetus or fetuses.
- Vaginal examination. Traditionally, digital and speculum examinations are considered inadvisable unless placenta previa has been excluded. However, despite this conventional guidance, in practice, experienced clinicians can undertake careful vaginal examinations when they are certain that the fetal head is engaged, making the diagnosis of placenta previa unlikely. However, in most cases, only an inspection of the vulva to quickly assess the amount of blood loss and to determine whether bleeding has stopped or is continuing is necessary. When placenta previa has been excluded, a speculum examination can then be performed.

Testing and Immediate Management

Initial management comprises
- Insertion of an intravenous line with a wide-bore cannula (preferably 14–16 Fr). A second line may be needed in cases in which bleeding is severe.
- Obtaining blood for immediate hemoglobin or hematocrit estimation, complete blood count and typing, and holding of serum for potential cross-matching. If bleeding is continuing or is heavy, then at least 4 units of blood must be cross-matched. When placental abruption is suspected, a coagulation profile and measurement of urea and electrolytes should be performed. Another test that may be performed is the Kleihauer-Betke test on maternal blood.

● Administration of intravenous fluids if bleeding is continuing or severe while waiting for cross-matched blood. Colloids are the most suitable fluids. Consideration should be given to transfusing O-negative blood or type-specific blood if cross-matching is delayed.

● Performing an ultrasound scan to exclude placenta previa if a scan has not been done previously or to exclude a major abruption with placental separation. However, a scan should be performed only if maternal and fetal conditions are stable.

Subsequent management is determined by the fetal and maternal condition, the severity of the bleeding, and the gestational age of the fetus. Options include immediate delivery versus expectant management. These are discussed under the various types of APH. The flow charts in Figures 58–1 and 58–2 outline the steps in management.

TABLE 58–1
Causes of Bleeding in Late Pregnancy

Genital tumor	0.5
Genital infection	0.5
Hematuria	0.5
Others	0.5

PLACENTA PREVIA

In placenta previa, the placenta is inserted partially or entirely into the lower uterine segment. Although clinical acumen remains vitally important in suspecting and managing placenta previa, the definitive diagnosis of most low-lying placentas is now achieved with ultrasound imaging. Clinical suspicion should always be raised in women with painless vaginal bleeding with a high presenting part or abnormal lie irrespective of previous ultrasound imaging. Four grades have traditionally been defined (Fig. 58–3). Figures 58–4 and 58–5 show two of these grades. If the placenta overlies the cervical os, it is considered as major previa.

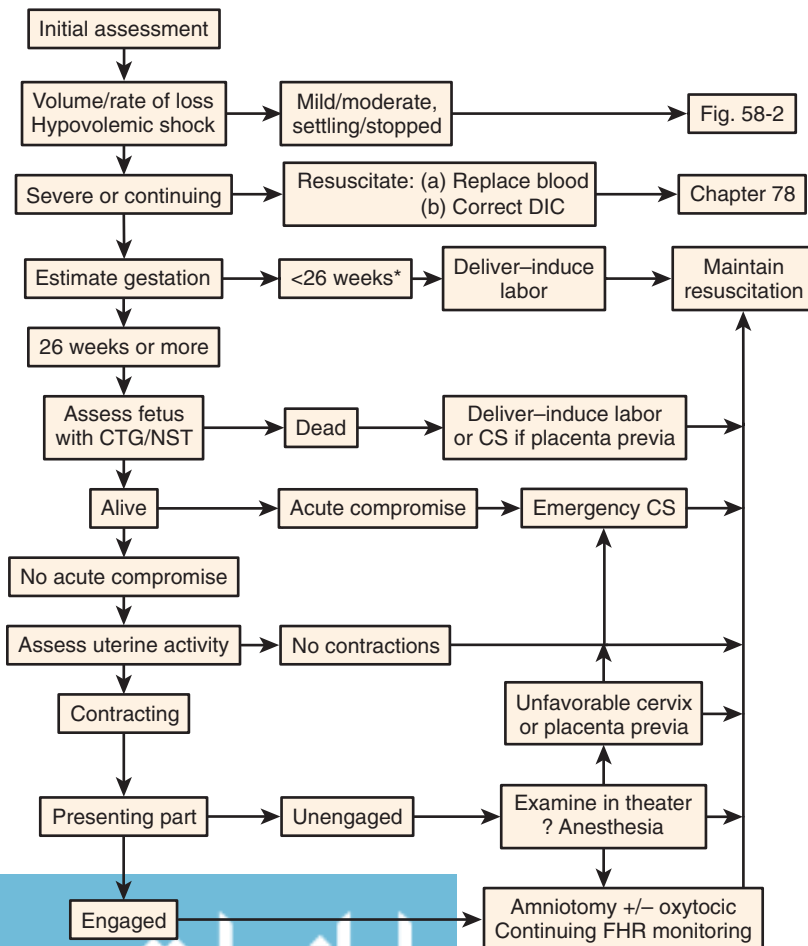
Several publications have described the diagnosis and outcome of placenta previa on the basis of localization using


FIGURE 58–1
Management of bleeding in late pregnancy. Initial assessment and management of severe bleeding. *The gestation after which survival rates are considered high enough to influence the mode of deliver of the preterm fetus varies in different centers from 24-28 wk. CS, cesarean section; CTG, cardiotocography; DIC, disseminated intravascular coagulation; FHR, fetal heart rate; NST, nonstress test.

Grades of placenta previa: I. The placenta is in the lower segment, but the lower edge does not reach the internal os. II. The lower edge of the low-lying placenta reaches, but does not cover, the internal os. III. The placenta covers the internal os asymmetrically. IV. The placenta covers the internal os symmetrically.

FIGURE 58–4
Grade II posterior placenta previa. The placenta extends to the cervical
os, but does not cover it.
FIGURE 58–5
Grade IV placenta previa. The placenta covers the os symmetrically.

transvaginal ultrasound (TVUS) recording of the exact rela-
tionship of the placental edge to the internal cervical os. The
increased prognostic value of TVUS diagnosis has rendered
the imprecise terminology of the previous classifications
obsolete.[2] TVUS is the gold standard in the localization of
a low-lying placenta. It is significantly more accurate than
transabdominal scanning and its safety is well established.[3]
A reasonable antenatal imaging policy is to perform a TVUS
on all women in whom a low-lying placenta is suspected
from their transabdominal scan (at ~20–24 wk) in order to
reduce the number of women requiring follow-up scans.[4]

Placenta previa occurs in 2.8 of 1000 singleton pregnan-
cies and 3.9 of 1000 twin pregnancies[5] and presents a sig-
nificant clinical problem because patients are at risk for
significant hemorrhage needing blood transfusions and
preterm delivery. They may need to be admitted to the
hospital for long periods of observation with significant
impact on family life. Cesarean hysterectomies may be
required in cases of intractable postpartum hemorrhage
with an incidence of 5.3%[6] with a three- to fourfold
increase in perinatal mortality compared with normal
pregnancies.[7,8]

The etiology of placenta previa is unknown, but various
associations have been identified. These include older age,
multiparity, multiple gestation, previous cesarean delivery,
previous uterine curettage, and chronic hypertension.[9]
Other risk factors include cigarette smoking, drug abuse
(especially cocaine), a history of abortion, previous placenta
previa, and assisted conception.[10]

A single cesarean delivery increases the risk by 0.65%,
two increase the risk by 1.5%, three increase the risk by
2.2%, and four or more increase the risk by 10%.[11] A recur-
rence risk of 4% to 8% after one pregnancy affected by
placenta previa has been reported.[12] The association with
abortion (spontaneous or induced) is greater with an increas-
ing number of previous abortions.[13,14]

Placenta accreta and placenta percreta are discussed in
Chapter 75.

Maternal Risks

- **Maternal mortality**: The U.K. CEMACH (Confidential
  Enquiry into Maternal and Child Health) reports have
  demonstrated an impressive decline in deaths from obstet-
  ric hemorrhage over the last 50 years. Maternal mortality
  as a result of hemorrhage decreased from 29 cases in
  1952–1954 to 3 in 2003–2005.[15] Possible reasons for this
  are
- **Postpartum hemorrhage** is believed to be caused by inad-
  equate occlusion of the sinuses in the lower segment
  after delivery.
- **Anesthetic and surgical complications** may occur, espe-
  cially in women with major placenta previa who have
  emergency cesarean delivery with suboptimal preparation
  for surgery.
- **Air embolism** occurs when the sinuses in the placental
  bed are torn.
- **Ascending infection** of the raw placental bed causes post-
  partum sepsis.
- **Placenta accreta** occurs in up to 15% of women with
  placenta previa.
- **The risk of recurrence** is approximately 4% to 8% after
  one previous placenta previa.

Fetal Risks

The fetal risks of placenta previa include
- **Perinatal mortality**: Cotton and colleagues[16] reported a
  perinatal mortality rate of 100% at less than 27 weeks,
  19.7% at 27 to 32 weeks, 6.4% at 33 to 36 weeks, and
  2.6% after 36 weeks in 1980. In recent years, the overall
  perinatal mortality rate has dropped from 126 per 1000
  to 42 to 81 per 1000[17] as a result of conservative manage-
  ment and improved neonatal care. In women with pla-
  centa previa the odds ratio for having a preterm delivery,
  need for neonatal intensive care and low birth weight are
  27.7, 3.4, and 7.4 respectively.[18]
- **Fetal growth restriction** may occur in up to 16% of cases.
  The incidence is higher in patients with multiple episodes
  of APH.[19]
- **Major congenital malformations** are twice as common in
  women with placenta previa. The most common malfor-
  mations are those of the central nervous system, cardio-
  vascular, respiratory, and gastrointestinal systems.[20]

- **Unexpected fetal death** can occur secondary to vasa previa (VP) or severe maternal hemorrhage.
- **Other risks** include fetal malpresentation, fetal anemia, umbilical cord prolapse, and compression.[13]

Presentation

Placenta previa characteristically causes unprovoked painless vaginal bleeding. Occasionally, it is caused by sexual intercourse. Threatened second-trimester miscarriage may precede placenta previa,[21] although bleeding may be minor—and in some cases unreported. The initial episode of bleeding has a modal incidence at approximately 34 weeks and occurs before 36 weeks in more than 50% of cases. It occurs after 40 weeks in only 2% of cases.[17]

The absence of pain is often considered a significant distinguishing factor between placenta previa and placental abruption, but 10% of women with placenta previa have coexisting abruption.[13] These patients and those who seek care for the first time while in labor and are therefore experiencing painful uterine contractions (25% of women with placenta previa[22]) may present a diagnostic problem.

Because ultrasound scanning is performed in early pregnancy in most centers, some patients with a low-lying placenta may be identified before 20 weeks' gestation, but the diagnosis of placenta previa cannot be made because the lower segment has not formed at this time.

Abdominal findings in placenta previa include malpresentation, which is either breech or transverse in 35% of cases[16]; slight, but consistent, deviation of the presenting part from the midline; and difficulty with palpating the presenting part.

Diagnosis

Various approaches have been used to diagnose placenta previa.

Vaginal Examination

Digital vaginal examination may cause hemorrhage. Because local causes are likely to be benign, speculum examination is probably best deferred until ultrasonography has excluded the diagnosis. If digital vaginal examination is necessary because of excessive bleeding, it should be performed only in an operating room, with full preparation for cesarean delivery (see later).

Placental Localization

Diagnostic ultrasound scanning is safe, accurate, and noninvasive and is the diagnostic method of choice. Routine placental localization is considered part of the anomaly scan at 20 to 22 weeks' gestation in many centers. Unfortunately, the earlier the scan is performed, the more likely the placenta is to be found in the lower pole of the uterus. For example, approximately 28% of placentas in women who undergo transabdominal scanning before 24 weeks are "low," but by 24 weeks, this number drops to 18%, and only 3% are low-lying by term.[23] Conversely, a false-negative scan for a low placenta is found in as many as 7% of patients at 20 weeks.[24] These results are more common when the placenta is posterior, the bladder is overfilled, the fetal head obscures the margin of the placenta, or the operator does

not scan the lateral uterine wall.[25] A low-lying placenta is more common in early pregnancy because the lower segment does not exist. The apparent placental migration is caused by enlargement of the upper segment and formation of the lower segment. Many apparently low placentas are found above the lower segment. Comeau and associates[26] and Ruparelia and Chapman[27] showed that the more advanced the pregnancy, the more accurate the diagnosis of placenta previa based on scanning findings.

TVUS is now well recognized as the preferred method for accurately localizing the placenta. Sixty percent of women may have a reclassification of placental localization following transvaginal scans. Sonographers are encouraged to report the actual distance from the placental edge to the internal os at TVUS, using millimeters away from the os or millimeters of overlap. A placental edge exactly reaching the os is described as 0 mm. When the placental edge reaches or overlaps the internal os on TVUS between 18 and 24 weeks' gestation (incidence 1%–2%), a follow-up scan for placental localization in the third trimester is recommended. Overlap of more than 15 mm is associated with an increased likelihood of placenta previa at term. When the placental edge lies between 20 mm away from the internal os and 20 mm overlap after 26 weeks' gestation, ultrasound repeats should be guided by clinical features such as bleeding, gestational age, and actual distance from the internal os because continued change in placental location is likely. Overlap of more than 20 mm at any time is highly predictive of the need for cesarean section.[28] Although no randomized, controlled trials have been conducted exploring whether this is of benefit, case studies advocate localization of the placenta at the routine anomaly scan. Practitioners must recognize the limitations of this practice, and whenever possible, TVUS should be used to investigate placental localization when the placenta is thought to be low lying.

Because there are no randomized, controlled trials of the maternal and fetal effects of routine localization versus no localization, current practice must be governed by large cohort case studies. It is assumed that when there is a low-lying placenta, education of patients and carers enhances the chance of better maternal and fetal outcome, but this is not always the case. Whether these patients should be admitted routinely at a later gestation is debatable. Most units do not routinely admit these patients, but repeat the scans at 32 to 34 weeks' gestation. Dashe and coworkers[29] observed that in 34% of cases, placenta previa that was diagnosed at 20 to 23 weeks was still present at delivery, whereas 73% of those present at 32 to 35 weeks persisted at delivery. A policy of routine scanning will reduce the false-positive rate, but at the expense of increasing workload and patient anxiety. Unfortunately, none of the studies reported the proportion of patients with low-lying placenta diagnosed at 32 to 34 weeks who had bleeding later in gestation. For units that do not routinely scan for placental site at 20 weeks, this 32- to 34-week scanning is indicated only in patients with an indication such as abnormal presentation, vaginal bleeding, or a chance finding when ultrasound was undertaken in late pregnancy for other reasons. In these cases, a transvaginal approach is recommended because it has a better diagnostic accuracy, especially with posterior placenta previa.[30,31] This approach is safe and well tolerated. Placenta previa is

diagnosed on TVUS when the placental edge is less than 20 mm from the internal os.

The findings on placenta previa can be summarized as follows:

- Routine location of the placental site at the 20-week transabdominal ultrasound has a low positive predictive value for placenta previa later in pregnancy.
- TVUS is more accurate than transabdominal in diagnosing placenta previa.
- Transperineal or translabial ultrasound (using a transabdominal probe) can also improve upon the diagnostic accuracy of transabdominal ultrasound and may be a useful alternative when TVUS is not available.[32]
- Recent guidance from the Royal College of Obstetricians and Gynaecologists (RCOG) recommends that patients with a previous cesarean section and an anterior placenta previa should have color-flow Doppler as the investigation of choice pending further evidence about magnetic resonance imaging (MRI) between 32 and 36 weeks.[33] MRI may also be beneficial in defining the degree of myometrial invasion, if any. It has the advantage of being a more objective test.
- There is no evidence that either of these interventions or rescanning "at-risk" patients in the third trimester reduces adverse maternal or fetal outcomes from placenta previa, and randomized trials addressing these issues are needed.

Management Options (See Fig. 58–2)

General management options were discussed earlier (see Fig. 58–1). Specific measures include immediate delivery and expectant management.

Immediate Delivery

If bleeding continues, but is neither profuse nor life-threatening and the gestation is more than 34 weeks, delivery is preferred after resuscitation is initiated. The mode of delivery depends on the grade of placenta previa and the state of the cervix. Occasionally, placental localization leads to inaccurate grading of placenta previa. In addition, some units do not have facilities for emergency placental localization. Options include immediate cesarean section and examination in an operating room, with or without anesthesia ("double setup"). Cesarean section is the only option in patients with profuse, life-threatening bleeding.

PROCEDURE

EXAMINATION IN AN OPERATING ROOM (DOUBLE SETUP)

This procedure is fast becoming obsolete with the advent of all the ancillary diagnostic tools for placenta previa. It is, however, considered important to continue to describe this setting because these tools are not universally available. Examination in an operating room provides the most accurate assessment of the relationship between the lower edge of the placenta and the cervical os. It should be done only when delivery will be undertaken. This approach is contraindicated by active, profuse hemorrhage mandating immediate delivery; fetal malposition or malpresentation precluding vaginal delivery; and fetal heart rate abnormality.

Preparation

Before this procedure is undertaken, cross-matched blood must be available. An anesthetist must be present, a midwife or operating room nurse must be scrubbed and gowned, and a cesarean section tray prepared. A second obstetrician should be scrubbed and ready to operate. The procedure must be performed by an experienced obstetrician, and a pediatrician must be present. Opinions vary as to whether the procedure should be carried out under general anesthesia. A survey of anesthetic management of cesarean section for placenta previa in the United Kingdom showed that 86% of anesthetists were willing to use regional anesthesia for a minor degree of placenta previa, but only 15% were prepared to offer these techniques for all degrees of placenta previa.[34] One advantage of general anesthesia is proper relaxation of the patient, which makes examination easier and allows rapid progression to cesarean section, if necessary. The main disadvantage is the need to wake the patient from anesthesia before inducing labor if vaginal delivery is possible. In addition, if cesarean section becomes necessary, a second anesthetic increases the risks. Performing the procedure under epidural anesthesia is an alternative, but this approach causes peripheral vasodilation and may worsen the effects of hypovolemia if hemorrhage is severe. A compromise appears to be drawing the drugs for induction of general anesthesia and preparing the anesthetic machine and instruments before the procedure. With such precautions, and in experienced hands, the interval between examination and delivery can be short.

Procedure

The patient is placed in the lithotomy position and draped with sterile towels after the vulva, but not the vagina, is cleaned. The bladder is catheterized, and two fingers are gently introduced into the vagina, with care taken to avoid the cervical os. Each vaginal fornix is palpated in turn to feel whether there is placenta between the presenting part and the finger. If placental tissue is present, a sensation of "bogginess" is felt. If the four fornices are empty, the index finger is gently introduced into the cervical os and the surroundings felt for the placental edge. If the cervix is closed, it should not be forced open and cesarean section should be performed. If the cervix admits a finger and no placental tissue is felt, the fetal membranes should be ruptured. An organized blood clot in the cervix may be mistaken for placental tissue. Persistent bright red bleeding after membrane rupture is an indication for cesarean delivery. If the placental edge is felt anteriorly but does not extend to the os and no bleeding is provoked, the decision may be made to rupture the membranes in preparation for vaginal delivery. If brisk vaginal bleeding occurs at any stage during the procedure, the procedure should be abandoned immediately and cesarean section performed.

Expectant Management

The major concern in caring for asymptomatic women with placenta previa is the possibility that the women may bleed suddenly and heavily, requiring speedy delivery. For that reason, the traditional management has involved admitting women with placenta previa even if asymptomatic from about 34 weeks' gestation until delivery. Attempts have been made to predict which women are more likely to bleed. Observational studies so far suggest that women with raised α-fetoprotein levels at 15 to 20 weeks and placentas that encroach on the cervical os, are thick inferiorly, or show turbulent flow at their lower margin on ultrasound are most associated with APH.[35] A review of the evidence from the Cochrane Database[36] to assess the impact of any clinical intervention applied specifically because of a perceived likelihood that a pregnant woman might have placenta previa found three randomized, controlled trials. These included 114 women in total. Both tested interventions (home vs. hospitalization and cervical cerclage vs. no cerclage) were associated with reduced lengths of stay in hospital antenatally: weighted mean difference (WMD) respectively −18.50 days (95% confidence interval [CI] −26.83 to −10.17), −4.80 days (95% CI −6.37 to −3.23). Otherwise, there was little evidence of any clear advantage or disadvantage to a policy of home versus hospital care. The 1 woman who had a hemorrhage severe enough to require immediate transfusion and delivery was in the home care group. Cervical cerclage may reduce the risk of delivery before 34 weeks (relative risk [RR] 0.45; 95% CI 0.23–0.87), the birth of a baby weighing less than 2 kg (RR 0.34; 95% CI 0.14–0.83), or having a low 5-minute Apgar score (RR 0.19; 95% CI 0.04–1.00). In general, these possible benefits were more evident in the trial of lower methodologic quality. The authors of the review concluded that there are insufficient data from trials to recommend any change in clinical practice. Available data should, however, encourage further work to address the safety of more conservative policies of hospitalization for women with suspected placenta previa and the possible value of insertion of a cervical suture.[36]

Severe hemorrhage (causing maternal hypovolemia) was originally considered a contraindication to expectant management.[37] However, in one study in which approximately 20% of the women lost more than 500 mL blood, half were managed expectantly, with a mean gain in gestation of 16.8 days.[38] Crenshaw and colleagues[39] managed only 43% to 46% of patients successfully with an aggressive expectant approach, whereas Cotton and associates[16] successfully managed 66% of women expectantly with an aggressive approach.

During expectant management, preterm labor is a problem. Brenner and colleagues[40] found that 40% of women with placenta previa had rupture of the membranes, spontaneous labor, or other problems that resulted in delivery before 37 weeks' gestation. Inhibiting contractions in those with preterm labor seems logical, but some consider APH a contraindication to the use of tocolytics.[41] When vaginal bleeding and uterine contractions occur, placental abruption, which is widely considered a contraindication to tocolysis, cannot be excluded. In addition, placental abruption may coexist with placenta previa in 10% of cases. Further, tocolytics cause maternal tachycardia and palpitations, features that may be confused with hypovolemia. Sampson and coworkers[42] advocate the use of tocolytics in cases of placenta previa and uterine contractions after 21 weeks and reported a reduction in the perinatal mortality rate from 126 to 41 per 1000. Besinger and colleagues[43] conducted a prospective trial on 112 women with acute vaginal bleeding and known placenta previa and gave tocolysis to the 72 women with significant uterine activity. This resulted in a prolongation of pregnancy (39.2 days vs. 26.9 days; $P < .02$) and an increase in birth weight (2.52 kg vs. 2.124 kg; $P < .03$) compared with the 40 women who were not given tocolysis. A retrospective review by Towers and associates[44] on the use of tocolysis for third-trimester bleeding including 76 of 105 women with placenta previa suggested no increased mortality or morbidity associated with tocolytic use in a tertiary setting. Prophylactic terbutaline to prevent bleeding has, however, not been found to be of benefit in women with placenta previa.

The perinatal mortality rate is also directly related to the total amount of blood lost antepartum. Liberal use of blood transfusions may nullify this effect.[16] There is no limit to the number of blood transfusions a patient can have. To optimize the oxygen supply to the fetus and protect the mother against anticipated blood loss, the aim of transfusion is to maintain hemoglobin of at least 10 g/dL or hematocrit of 30%.

Despite expectant management, 20% of women with placenta previa are delivered earlier than 32 weeks. These cases account for 73% of perinatal deaths.[16] These premature deliveries are a major problem, and although cervical cerclage has been advocated, it is not normally used. Neonatal mortality and morbidity rates are reduced in this group by maternal corticosteroid administration.

The main disadvantages of continuous hospitalization are the cost and the psychological effect of separation on families. For many families, hospitalization means prolonged separation, and in some extreme cases, the break up of marriages. Advantages include easy access to resuscitation and prompt delivery and ensuring bedrest (which may decrease the occurrence of hemorrhage) and limitation of activities. Outpatient management of placenta previa may be appropriate for stable women with home support, close proximity to hospital, and easy access to transportation and telephone. For women who are managed as inpatients, 2 units of cross-matched blood should be readily available, especially if they have had bleeds.

Method of Delivery

The need for cesarean delivery is dictated by the ultrasound findings as well as clinical judgment. Five studies have examined the likelihood of cesarean section for placenta previa based on placental edge–to–os distance on the last scan prior to delivery. The scans were performed between 35 and 36 weeks' gestation, and a distance of more than 20 mm away from the os was associated with a high likelihood of vaginal delivery (range 63%–90%). When the fetal head is engaged, the pregnancy may be allowed to continue beyond 37 to 38 weeks and vaginal delivery anticipated. In these patients, amniotomy followed by oxytocin (Syntocinon) administration can be considered. Where the placental edge is between 0 and 20 mm from the os, the rates of cesarean delivery was 40% to 90%. A placental edge less than 20 mm from the internal os, especially with a posterior or thick (>1 cm), is

likely to need delivery by cesarean section. Where the placenta overlaps the cervical os on a third-trimester scan, a cesarean section is invariably required.

In those with major placenta previa, emergency or elective cesarean delivery is commonly used. Elective delivery is ideal because emergency delivery has a negative effect on perinatal mortality and morbidity rates, independent of gestational age. Cotton and colleagues[16] found that 27.7% of infants delivered emergently had anemia compared with 2.9% delivered electively. Cesarean section for placenta previa poses several problems. It should never be left to an inexperienced obstetrician. The RCOG in the United Kingdom recommends that such cesarean sections be performed by senior obstetricians ("consultants" in the United Kingdom). Anesthetists are divided in their opinions regarding the safest method of anesthesia for cesarean section in placenta previa.[34] There is increasing evidence of the safety of regional anesthesia, especially with regards to maternal hemodynamics.[45] However, when prolonged surgery is anticipated, as in women with prenatal diagnosis suggestive of placenta accreta, general anesthesia may be preferable. Regional anesthesia may also be converted to general anesthesia when the clinical situation dictates. Ideally, cross-matched blood should be available on the delivery suite prior to cesarean sections for placenta previa. Cell salvage may be considered in cases at high risk of massive hemorrhage.

Yamada and coworkers[46] suggested some benefit from autologous transfusion of placenta previa women, but further studies are required to establish its benefit.

PROCEDURE

There is increasing evidence to support the safety of regional anesthesia in cesarean sections for placenta previa. The choice of anesthetic technique is usually made by the anesthetist in consultation with the obstetrician and the mother. An experienced obstetrician and anesthetist must be present at the delivery. Because patients and their partners may experience severe anxiety in the presence of profuse bleeding during cesarean delivery, careful consideration should be given to the decision to allow partners in the operating room.

A transverse incision of the lower segment of the uterus is commonly used, provided there is a lower segment. When the lower segment is nonexistent or is very vascular, some obstetricians advocate a classic or De Lee's incision. Scott,[47] however, believes that such incisions are rarely justified because of their consequences and long-term disadvantages. When difficulties occur with transverse incisions of the lower segment, the incision may be converted to an inverted T-, J-, or U-shaped incision.

If the incision in the uterus is transverse and the placenta is anterior, two approaches are available: going through the placenta or defining its edge and going through the membranes above or below the placenta. The former approach requires speed and may cause significant fetal blood loss.[48] The latter approach, however, may be associated with undue delay in the

delivery of the fetus, more troublesome bleeding from a partially separated placenta, and resultant fetal blood loss and anoxia. Myerscough[48] advises against cutting or tearing through the placenta because of the inevitable fetal blood loss that occurs as fetal vessels are torn. Because the lower segment is less muscular, contraction and retraction cause inadequate occlusion of the sinuses of the placental bed, and intraoperative hemorrhage is not uncommon.[49] When hemostasis is difficult, bleeding sinuses can be oversewn with atraumatic sutures.[47] If this approach is unsuccessful, uterine balloon tamponade or uterine packing may be considered. However, if the pack is left in situ during closure of the uterus, bleeding may continue but remain concealed for some time. Intramyometrial injection of prostaglandin $F_{2\alpha}$ is useful in these cases.[48] When bleeding is uncontrollable, ligation of the internal iliac artery or even hysterectomy may be necessary as a last resort.

Placenta Previa and Placenta Accreta

There is a well-recognized association between previous cesarean section, placenta previa, and placenta accreta. The increasing incidence of cesarean section deliveries and advanced maternal age has led to a rise in the incidence of placenta accreta, which is 1 in 2500.[50] The risk of placenta accreta increases dramatically in the presence of placenta previa and previous cesarean section, with a risk of 25% for one prior cesarean section and 40% for two previous cesarean sections.[51,52] Placenta accreta is associated with significant risk of massive obstetric hemorrhage, sometimes necessitating hysterectomy. Antenatal diagnosis by ultrasound may be beneficial in allowing preparation for delivery by a multidisciplinary team of obstetricians, anesthetists, radiologists, and surgeons in an appropriate setting. Color-flow Doppler studies on ultrasound[53] and MRI[54] are helpful in making an antenatal diagnosis. In all cases of placenta accreta, increta, or percreta, the risk of hemorrhage, transfusion, and hysterectomy should be discussed with the patient as part of the consent procedure. There are numerous case reports of placenta accreta and its management. Options have included clamping and leaving the placenta in situ at the end of cesarean section in association with prophylactic or therapeutic uterine artery ligation or internal iliac artery ligation at time of initial surgery. Others have been treated with methotrexate following the cesarean section with successful pregnancies being reported subsequently.[55]

PLACENTAL ABRUPTION

Placental abruption is defined as premature separation of a normally situated placenta. The reported incidence varies from 0.49% to 1.8%.[56] The wide variation in reported incidence is believed to be caused by variations in diagnosis. Fox[57] found evidence of abruption in 4.5% of placentas examined routinely, suggesting that small episodes of placental abruption are more common than those diagnosed clinically. Placental abruption is concealed in 20% to 35% of cases and revealed in 65% to 80% of cases.[31,58] The concealed type is more dangerous, with more severe

TABLE 58–2
Grading of Placental Abruption

GRADE	DESCRIPTION
0	Asymptomatic patient with a small retroplacental clot.
1	Vaginal bleeding; uterine tetany and tenderness may be present; no signs of maternal shock or fetal distress.
2	External vaginal bleeding possible; no signs of maternal shock; signs of fetal distress.
3	External bleeding possible; marked uterine tetany, yielding a boardlike consistency on palpation; persistent abdominal pain, with maternal shock and fetal demise; coagulopathy may be evident in 30% of cases.

From Sher G, Statland BE: Abruptio placentae with coagulopathy. A rational basis for management. Clin Obstet Gynecol 1985;28:15–23.

complications. Four grades of placental abruption have been described (Table 58–2). The most severe type (grade 3) occurs in approximately 0.2% of pregnancies.[31]

The etiology of placental abruption is unknown in most cases. In a few, however, the cause is obvious, such as in direct trauma to the uterus. Various risk factors are associated with placental abruption. The risk of recurrence in subsequent pregnancies is significant, varying from 6%[56] to 16.7%.[59,60] It is more common in older women, but this increase has been attributed to parity and is independent of age.[61] Cigarette smoking increases the incidence of placental abruption.[62] Naeye[63] reported an incidence of 1.69% in non-smokers, 2.46% in smokers, and 1.87% in smokers who had quit. In the smokers, evidence of decidual necrosis at the edge of the placenta was found. This finding may represent the effect of smoking on uteroplacental blood flow[64,65] and decidual integrity.

Other etiologic factors include sudden decompression of the uterus after membrane rupture in patients with polyhydramnios and multiple pregnancy, external cephalic version,[65] placental abnormalities (especially circumvallate placenta),[66,67] abdominal trauma,[68] and increased levels of α-fetoprotein.[69,70] Although maternal hypertension is considered a risk factor, there is no consensus on whether hypertension precedes abruption or vice versa. Naeye[63] found no evidence of placental abruption in patients with hypertension, but Abdella and associates[71] observed that the incidence of placental abruption in patients with preeclampsia was twice that in those without preeclampsia. In a meta-analysis, Ananth and colleagues[72] concluded that chronic hypertension was associated with a threefold increased risk of abruption compared with normotensive patients, whereas the odds ratio for patients with preeclampsia was 1.73. The suggestion that folic acid deficiency may have an etiologic role in placental abruption has not been confirmed. Large prospective studies have not shown an association between placental abruption and folate supplementation.[73,74] More recently, hyperhomocysteinemia and protein C deficiency[75] and other thrombophilias were reported to be more common in women with placental abruption.[76]

There has recently been some evidence suggestive of a genetic influence in the pathogenesis of placental abruption. A review and meta-analysis by Zdoukopoulos and coworkers[77] found a positive association for the F5 Arg506Gln and

F2 G20210A polymorphisms. However, considering the multifactorial etiology of abruption and the relatively small numbers of studies and participants, this review provided only the first clues of possible genetic causes, and larger case-control studies that include gene-gene and gene-environment interactions may help to further elucidate the genetics of placental abruption.

Maternal Risks

- The maternal mortality rate is approximately 1%. In the last CEMACH study in the United Kingdom (2003–2005),[15] two maternal deaths were caused by placental abruption. The maternal mortality rate decreased from 8% in 1919 to less than 1% in 1995.[69] Although severe hemorrhage is usually the major cause of other complications that lead to mortality, disseminated intravascular coagulation may cause severe hemorrhage, renal failure, and death.
- The recurrence rate is generally reported as 6% to 17% after one episode and increases to 25% after two episodes. Approximately 7% of women with abruption severe enough to kill the fetus have the same outcome in subsequent pregnancies, and 30% of all future pregnancies of women who have a placental abruption do not produce a living child.[1]
- Hypovolemic shock. Blood loss may be underestimated in placental abruption because concealed bleeding into the myometrium may be difficult to quantify.
- Acute renal failure can result from hypovolemia or disseminated intravascular coagulation.
- Disseminated intravascular coagulation.
- Postpartum hemorrhage can result from coagulation failure or from a couvelaire uterus, in which severe bleeding occurs into the myometrium and impairs the ability to contract.
- Fetomaternal hemorrhage can lead to severe Rh sensitization in Rh-negative patients. All Rh-negative patients must undergo a Kleihauer-Betke test and have anti-D immunoglobulin administered to prevent immunization.

Fetal Risks

Fetal risks include

- In a review of 7,508,655 singleton births delivered in 1995 and 1996 in the United States,[78] placental abruption was recorded in 6.5 per 1000 births. The perinatal mortality was 119 per 1000 births to mothers with abruption compared with 8.2 per 1000 among all other births. The high mortality to mothers with abruption was due, in part, to its strong association with preterm delivery. Babies in the lowest percentile of weight (<1% adjusted for gestational age) were almost nine times as likely to be born to mothers with abruption than those in the heaviest (≥90%) birth weight percentiles. The risk of abruption declined with increasing weight percentiles. Fifty-five percent of the excess perinatal deaths in deliveries linked with placental abruption were due to early gestational age alone. In contrast, the fetal size at delivery contributed only 9% to the perinatal mortality associated with abruption despite the strong predictive value of poor fetal growth as a risk factor for abruption.[78] The fact that babies born to

mothers with placental abruption are smaller at most gestational ages than those born without suggests that factors other than prematurity contribute to the increase in perinatal mortality. The association with fetal growth restriction is so strong that growth restriction in itself can serve as a marker for abruption risk. The chronic processes underlying abruption may also contribute to the risk of preterm delivery. More than 50% of the perinatal deaths are stillbirths.[12] Of the infants delivered alive, Abdella and associates[71] reported a 16% mortality rate within 4 weeks, with most infants weighing less than 2500 g. Paterson[61] reported survival rates varying from 23% at 28 to 32 weeks to 87.6% at 37 to 40 weeks. However, survival rates today are probably higher than these figures suggest because they were reported before the advances that have occurred in modern neonatal care. For example, in Norway, the rate decreased from 2.5 per 1000 to 0.9 per 1000 between 1967 and 1991.[60] The higher incidence of fetal malformations[69] and intrauterine growth restriction[1] also contribute to the high perinatal mortality rate. For babies weighing more than 2500 g, the reported survival rate is 98%.[79] In the presence of associated complications, such as hypertension, the fetal mortality rate increases threefold.[71]

- Fetal growth restriction is reported in up to 80% of infants born before 36 weeks' gestation.
- The rate of congenital malformations may be as high as 4.4% (twice that in the general population[80]). The rate of major malformations is increased threefold. Most involve the central nervous system, and these can occur at five times the normal incidence.[69]
- The neonatal hematologic findings may be abnormal. Anemia results from significant fetal bleeding.

Diagnosis

The diagnosis is usually made on clinical grounds, but ultrasonography is helpful in some cases (e.g., when there is a large retroplacental hematoma, although this is uncommon, even in severe cases). The symptoms and signs are diagnostic in moderate to severe cases. In mild forms, the diagnosis may not be obvious until after delivery, when a retroplacental clot is identified.

Placental abruption causes vaginal bleeding, abdominal pain, uterine contractions, and tenderness. Vaginal bleeding occurs in no more than 70% to 80% of cases.[31] This bleeding is characteristically dark and nonclotting. It occurs after 36 weeks' gestation in approximately 50% of cases.[81] In a study of 193 cases, Paterson[61] found that 18% occurred before 32 weeks, 40% occurred between 34 and 37 weeks, and 42% occurred after 37 weeks. Because labor is the most common factor precipitating placental separation,[12] nearly 50% of patients with placental abruption are in established labor. Uterine contractions may be difficult to distinguish from the abdominal pain of abruption. When this distinction is possible, the contractions are characteristically very frequent, often with more than five occurring in 10 minutes.[82]

Although abdominal pain is common, it is not invariable and is less common in posteriorly sited placentas. This is evidenced by unsuspected, or silent, abruption described by Notelovitz and colleagues[83] and the higher pathologic incidence of placental abruption reported by Fox.[57] Pain probably indicates extravasation of blood into the myometrium. In severe cases (grade 3), the pain is sharp, severe, and sudden in onset. In addition, some patients may have nausea, anxiety, thirst, restlessness, and a feeling of faintness, whereas others report absent or reduced fetal movements.

If blood loss is significant, the patient may have signs of shock (tachycardia predominates and blood pressure is poorly correlated with blood volume). Hypertension may mask true hypovolemia, but increasing abdominal girth or fundal height suggests significant concealed hemorrhage. The uterus is typically described as "woody hard" in severe placental abruption. In such cases, the fetus is difficult to palpate, and a continuous fetal heart rate monitor or real-time ultrasonography must be used to identify the fetal heart beat. The fetus may be "distressed," with fetal heart rate abnormalities, or may be dead. Fetal distress occurs in grade 1 to 2 abruption, but in grade 3 abruption, fetal death is inevitable, by definition.[84] In severe cases complicated by disseminated intravascular coagulation, there may be no clotting in the vaginal blood, which is dark. The incidence of coagulopathy is 35% to 38%,[59,85] and it occurs mainly in the severe forms.

Typically, blood clots are found in the vagina, except if the blood is nonclotting. Serous fluid from a retroplacental clot may be confused with liquor. The cervix may be dilating because 50% of patients are in labor. If the membranes are ruptured, blood-stained liquor is seen.

Ultrasonography is not a sensitive method of diagnosing placental abruption, but it is useful in excluding coincident placenta previa, which is present in 10% of cases. When the retroplacental clot is large, ultrasonography identifies it as hyperechogenic or isoechogenic compared with the placenta. This echogenicity may be misinterpreted as a thick placenta.[86] Resolving retroplacental clots appear hyperechogenic within 1 week and sonolucent within 2 weeks. Although ultrasonography is not an accurate diagnostic tool, it is useful in monitoring cases managed expectantly, and Rivera-Alxima and associates[87] used it to determine the time of delivery. The size of the hematoma, its location, change in size over time, and fetal growth are monitored by ultrasound scan. The Kleihauer-Betke test may be useful in making the diagnosis when a patient has abdominal pain without vaginal bleeding and in cases of unsuspected (silent) abruption.

The differential diagnosis of placental abruption includes conditions that can be broadly classified into two groups. These are other causes of vaginal bleeding and causes of abdominal pain. The former groups are discussed elsewhere in this chapter.

Management Options (See Fig. 58–2)

Once the diagnosis of placental abruption has been made, management depends on its severity, associated complications, the condition of the mother and the fetus, and gestational age. Management is divided into general and specific measures. For management, Sher and Statland[88] divided placental abruption into three degrees of severity. These are summarized in Table 58–2.

The general management options were discussed earlier (see Fig. 58–1). Specific measures to be considered are

- Immediate delivery.
- Expectant management.
- Management of complications.

Immediate Delivery

The need for immediate delivery depends on the severity of abruption and whether the fetus is alive or dead. If the fetus is dead, vaginal delivery is the goal. Maternal resuscitation is emphasized because fetal death is common in severe placental abruption, often with coagulopathy. Once resuscitation has been initiated, the fetal membranes should be ruptured to hasten the onset of labor. This approach is effective in most cases, but in a few, augmentation with oxytocin is needed. This drug must be administered cautiously because uterine rupture may be caused by an overstimulated uterus. Barron[89] reported that membrane rupture should be reserved for dead fetuses and patients who are in advanced labor.

If the fetus is alive, the decision as to how best to achieve delivery is not always easy. In addition, the outlook for the fetus is poor not only in terms of immediate survival but also because studies show that as many as 15.4% of liveborn infants do not survive.[71] However, when the mortality rate associated with vaginal delivery is compared with that of cesarean section in nonrandomized, controlled trials (52% vs. 16%, Okonofua and Olatubosun[90]; 20% vs. 15%, Hurd and coworkers[82]), cesarean delivery has advantages. Hibbard[12] stated that many of the poor results associated with cesarean section are largely the result of indecision and delay in the last quarter of pregnancy. He stated that cesarean delivery must be considered when the fetus is alive, particularly if there is evidence of fetal distress. However, coagulopathy adds considerable maternal risk, and the likelihood of injury or death may be increased by surgery.

If the decision is made to deliver and the fetus is alive, the degree of abruption and the state of the fetus are important determining factors. When abruption is severe, cesarean section must be performed once resuscitation has started. Delivery should be performed promptly, especially because most postadmission fetal deaths occur in fetuses delivered more than 2 hours after admission.

In mild to moderate cases of abruption, the mode of delivery is determined by the condition of the fetus, its presentation, and the state of the cervix. Abnormal fetal heart rate patterns are an indication for immediate cesarean delivery. However, if the decision is made to deliver vaginally, continuous fetal monitoring must be available to identify early abnormal fetal heart rate patterns. Golditch and Boyce,[73] Lunan,[79] and Okonofua and Olatubosun[90] showed that the perinatal mortality rate is higher with vaginal delivery in the absence of electronic fetal monitoring. Prostaglandins are used to ripen the cervix in women with mild abruption, but the danger of inducing tetanic contractions must be remembered. When feasible, amniotomy often hastens delivery, but when it is not possible, oxytocin can be used. However, vigilance must be maintained for the development of hyperstimulation.

Expectant Management

The goal of expectant management is to prolong pregnancy, with the hope of improving fetal maturity and survival. Expectant management is usually considered in cases of mild placental abruption occurring before 37 weeks' gestation.

Vaginal bleeding is slight, abdominal pain is mild and usually localized, and the patient is cardiovascularly stable. Once conservative management has been chosen, the fetal condition must be monitored closely. No evidence supports the routine admission of patients who are being managed expectantly, especially when there is no evidence of maternal or fetal compromise or uterine contractions. Fetal growth restriction is a common finding in association with placental abruption. The timing of delivery depends on the finding of further vaginal bleeding, the fetal condition, gestational age, and the availability of neonatal care facilities. If bleeding episodes are recurrent, induction at 37 to 38 weeks is usually undertaken if fetal indices of health (e.g., biophysical parameters and growth) are satisfactory. When the initial episode is small and self-limiting and there is no acute (abnormal cardiotocographic findings or biophysical profile score) or chronic (growth restriction, oligohydramnios, or abnormal umbilical artery Doppler recording) fetal compromise, no evidence supports the induction of labor. Despite this lack of evidence, induction of labor at term is often advocated in such patients using the speculative argument that undetected damage might have occurred to the integrity and function of the placenta, and in the face of uncertainty, delivery at term confers more advantages.

If the initial ultrasound scan showed a retroplacental clot, the clot may be monitored by serial ultrasound scans. If the fetal condition deteriorates, delivery is expedited, with the speed and urgency determined by whether fetal compromise is acute or chronic.

Some cases of mild abruption may be complicated by labor. In such cases, it is difficult to establish which came first. Many consider tocolytics contraindicated in the presence of placental abruption because they may worsen abruption.[41] Tocolytics are controversial in the management of abruption and are considered only in patients who are hemodynamically stable with no evidence of fetal compromise and who might benefit from corticosteroids or prolongation of pregnancy. Towers and associates[44] conducted a review on the use of tocolytics in patients with placental abruption and first bleeding at mean of 28.9 weeks. They showed that this resulted in a mean increase in time from bleeding until delivery of 18.9 days. The neonatal mortality rate was 51 deaths per 1000 live births and all the deaths were related to complications of prematurity. An ongoing randomized, double-blind trial of magnesium sulfate tocolysis versus intravenous saline for suspected placental abruption by Stanford University investigators may provide further evidence.[91]

Management of Complications

The major complications of placental abruption are hemorrhagic shock, disseminated intravascular coagulation, ischemic necrosis of the distal organs (especially the kidneys and brain), and postpartum hemorrhage (see Chapter 78).

Rh Isoimmunization

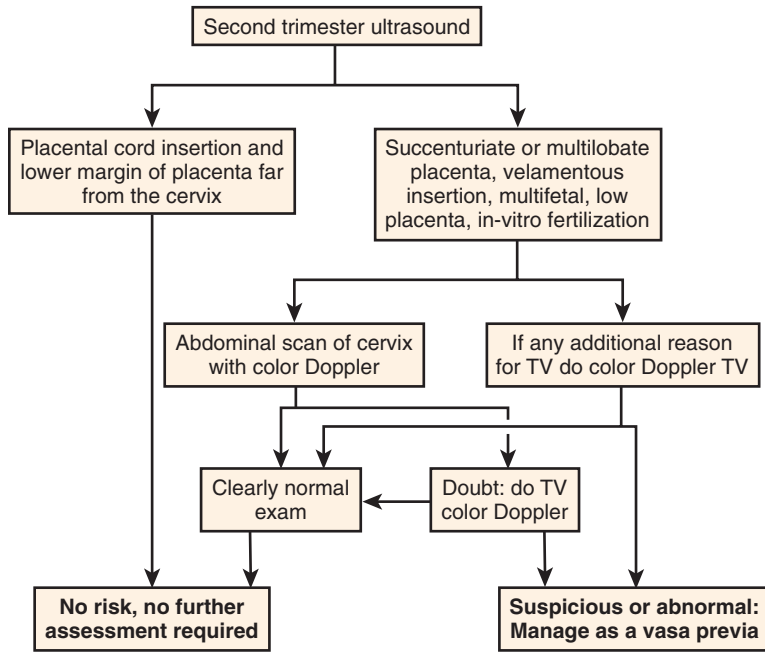
Fetomaternal hemorrhage is a risk in association with all forms of placental bleeding but the risk is arguably higher during abruption.[59] All Rh-negative women with abruption must undergo a Kleihauer-Betke test and receive an appropriate dose of anti-D immunoglobulin to prevent immunization. Repeated doses depend on the amount of fetomaternal


FIGURE 58–6
Proposed diagnostic algorithm for second trimester detection of vasa previa.
(From Derbala Y, Grochal F, Jeanty P: Vasa previa. J Prenat Med 2007;1:2–13.)

hemorrhage as determined by the Kleihauer-Betke test. This treatment must be given within 72 hours of the onset of abruption. When management is expectant in a patient with intermittent recurrent bleeding, regular Kleihauer-Betke testing and assays of anti-D immunoglobulin levels can be performed to guide further anti-D administration. Collaboration with the hematologist and blood bank is advisable to determine the correct dose when the Kleihauer-Betke test result is positive.

VASA PREVIA

VP is a characterized by fetal or placental vessels coursing over the cervix beneath the presenting part. These vessels are vulnerable to laceration and compression during pregnancy because they are unprotected by Wharton's jelly or placental tissue. The reported incidence is 1 per 2500 deliveries.[92] The incidence is reported to be 1 in 300 in vitro fertilization (IVF) pregnancies,[93,94] and this has been attributed to the increased proportion of placental morphologic alterations seen in assisted conceptions.[95,96] The patients usually present in labor, classically with bleeding at the time of artificial rupture of membranes; however, presentation after spontaneous rupture of membranes has been reported in several cases reports.[92] Type 1 VP occurs with a single-lobed placenta with velamentous insertion of the cord (VCI) whereas type 2 VP occurs when vessels join the placenta to an accessory lobe.

Risks

Fetal exsanguination after rupture may cause fetal death with fetal and neonatal mortality rates of up to 75% being reported in the past.[97] The presenting fetal pole may also exert direct pressure on the exposed blood vessels causing

death by asphyxiation. The main risk to the mother is bleeding, but often maternal blood loss is mild and therefore not life-threatening.

Management Options

VP typically presents with painless vaginal bleeding at the time of spontaneous or artificial rupture of membranes. Fetal heart rate abnormalities quickly follow, leading to emergency cesarean section delivery for fetal distress. The neonate is usually severely anemic and hypovolemic requiring rapid life-saving blood transfusion and fluid replacement.[98]

Ultrasound scan is the mainstay of antenatal diagnosis of VP. Figure 58–6 shows an algorithm for the antenatal diagnosis of VP. The first reported diagnosis of VP on ultrasound was by Gianopolous and colleagues in 1987.[99] It was, however, only in 1996 that the first case of VP was diagnosed at the time of routine second-trimester anomaly scan.[98] The chances of VP being present are minimal when the umbilical cord inserts into the placental mass or in the absence of a succenturate or bilobed placenta.[100] Determining placental cord insertion during the anomaly scan is reported to take less than a minute and can be easily incorporated into the allocated scanning time with no additional skills required.[101] The ultrasound technique for ruling out VP is based on

- Assessment of placental cord insertion.
- Assessment of placental appearance and location.
- Consideration of other risk factors.

The umbilical cord inserts into the placental mass centrally or paracentrally in 90% of pregnancies. In 10%, the insertion is marginal with 1% being VCI. When the site of cord insertion into the placental mass is clearly identified, the possibility of VP type 1 is extremely low and no further

action is required.[100] In contrast, when the insertion site cannot be identified, efforts should be made to exclude VCI because this group has a higher risk of having VP (6%). It is imperative to scan the area above the internal os using a transvaginal approach with color Doppler when a VCI cannot clearly be demonstrated in the upper uterine segment. Some authors have proposed a transperineal approach, but the use of color Doppler is critical.[102]

Placenta previa and marginal placenta are risk factors for VP, and when present, it is important to check for vessels near the cervix. Other risk factors for VP pregnancies include IVF, multiple pregnancies (10% of VP occur in twins), and patients presenting with APH.

When the presentation is with vaginal bleeding or bleeding during labor and VP is suspected, direct visualization of the vessels with an amnioscope may be possible, or alternatively, a blood test is performed to determine the presence of fetal hemoglobin in the vaginal loss.[97] The use of amnioscopes in modern obstetrics practice is, however, not common.

When the diagnosis is made antenatally and cesarean section delivery appropriately scheduled, infant survival rates of up to 97% have been reported compared with 44% survival when the condition was undiagnosed.[103] Even when the infant survives an undiagnosed VP, the study demonstrated an often complicated postnatal course with over 50% requiring a blood transfusion and registering poor Apgar scores. Reported methods for the diagnosis in symptomatic cases include the palpation of velamentous vessels through the dilated cervix.

UNCLASSIFIED BLEEDING

The exact cause of APH is unknown in approximately 47% of patients. The reported incidence varies from 38% to 74%.[102,104] The cause of bleeding may become apparent later, but in most cases, no cause is identified.[58] When causes are identified, they include marginal sinus rupture (60%), "show" (20%), cervicitis (18%), trauma (5%), vulvovaricosities (2%), genital tumors, hematuria, genital infections, and VP (0.5% each). Although this group of causes is referred to as "unclassified bleeding," it invariably includes unrecognized cases of minor abruption or placenta previa. Marginal sinus rupture is the most common source of bleeding in APH of unknown cause.[66]

Risks

The risks of unclassified bleeding depend on the cause. More serious causes are discussed in the relevant sections earlier and in Chapters 40, 49, 56, 57, and 78. This type of bleeding is associated with a higher perinatal mortality rate (3.5%–15.7%).[104–106] This rate is higher than that associated with placenta previa (4.2%–8.1%), suggesting some degree of placental dysfunction. Preterm labor is more common in these patients and is a contributor to the higher perinatal mortality rate.

Diagnosis

There are usually no signs and symptoms diagnostic of either placenta previa or placental abruption. In most cases,

bleeding is mild and resolves spontaneously. Approximately 60% of cases occur after 37 weeks, and of these, 15% of patients are delivered within 10 days of the initial hemorrhage.[104] When marginal bleeding occurs with clot formation, serum separated from the clot may be confused with liquor after spontaneous rupture of fetal membranes.[107]

The diagnosis of unclassified bleeding is often made after placental abruption and placenta previa are excluded. An ultrasound scan is necessary to exclude placenta previa because minor grades may present in a similar manner.

Speculum examination should be performed in patients with unclassified bleeding, although opinions differ about the timing of this examination. Some argue that it should be delayed until bleeding has stopped, whereas others advocate immediate examination once placenta previa has been excluded. Those advocating immediate examination do so because they want to exclude advanced labor and local causes of bleeding. Those advocating delayed examination do so because of the belief that a delay does not affect management and that other local causes of bleeding are usually benign and need no immediate action. No controlled trials have compared these different types of management.

Management Options

If placenta previa and abruption have been excluded, further management depends on gestational age, the nature of the bleeding (severity and persistence or recurrence), the state of the fetus (abnormal fetal heart rate patterns), and the presumed cause of bleeding.

Options for further management include delivery and an expectant approach. At or beyond 37 weeks' gestation, when bleeding is recurrent or significant or associated fetal factors (e.g., growth restriction, abnormal heart rate patterns) are present, delivery is the management option of choice. Vaginal delivery is not contraindicated if there is no fetal compromise. Before 37 weeks' gestation, if bleeding is recurrent and significant, delivery may be justified. The mode of delivery is determined by the state of the fetus, its lie, and other associated factors, such as the state of the cervix.

If expectant management is chosen, the patient may be monitored at home or in the hospital. Most units monitor patients in the hospital until bleeding has stopped for at least 24 hours. Watson,[104] in a retrospective review, showed no significant advantage in admitting patients to the hospital. A randomized, controlled trial comparing inpatient versus outpatient care in these cases is needed, especially with the current emphasis on community-based care for pregnancy. Regardless of where the patient is managed, fetal surveillance should be implemented because of the increased risk of perinatal death (discussed earlier). When awaiting the spontaneous onset of labor is the practice,[106] the perinatal mortality rate is not increased. Some advocate elective delivery usually by labor induction at 38 weeks[106] because any bleeding carries a theoretical risk of causing placental separation.[108] However, there is no evidence to support this theoretical risk. Thus, the authors recommend awaiting the spontaneous onset of labor if fetal growth and welfare are satisfactory and use induction only when there is evidence of fetal compromise.

SUMMARY OF MANAGEMENT OPTIONS
Bleeding in Late Pregnancy

INTRODUCTION

Multiple pregnancy rates vary worldwide, from a low of 6.7 per 1000 births in Japan to 40 per 1000 births in Nigeria. The frequency of twin births in tertiary centers ranges from 1 in 25 to 1 in 100, reflecting the hospital referral population rather than the true population rate. The incidence of monozygous twinning is relatively constant at 3.5 per 1000 births.[1] Dizygous twinning rates and higher-order birth rates vary widely and are affected by age, parity, racial background, and the use of assisted reproductive techniques. This chapter discusses the general and obstetric risks associated with multiple pregnancy. Problems specific to multiple pregnancy are discussed in Chapter 23.

RISKS

Multiple pregnancy is associated with more maternal and fetal risks than singleton pregnancy.

Maternal Risks (Table 59–1)

Increased Symptoms of Early Pregnancy

Nausea and vomiting are three times more common in multiple than in singleton pregnancies,[2,3] with higher levels of pregnancy hormones implicated.[4]

Increased Risk of Miscarriage

Both threatened and actual miscarriage are more common in multiple pregnancy,[2] with the rate of missed abortion approximately twice as high as the 2% rate seen in singletons at 10 to 14 weeks' gestation.[5]

Vanishing Twin Syndrome

Twins and higher-order multiple gestations are more often conceived than born. During the first trimester, arrest of development and subsequent reabsorption of one or more of the fetuses may occur. This event can be seen ultrasonographically and is known as the "vanishing twin" phenomenon.[6] First-trimester vaginal bleeding may be related to this syndrome. Whereas the prognosis for the remaining fetus after loss of a co-twin at this early stage of pregnancy is generally considered to be good,[6] more recent reports suggest an increase in the risk of low birth weight in the surviving twin.[7–9]

Minor Disorders of Pregnancy

The extra weight carried with a multiple pregnancy exaggerates the minor symptoms of pregnancy. Backache, breathlessness, difficulty walking (especially toward the end of pregnancy), and pressure problems (e.g., varicose veins) are more common in multiple pregnancy.

Anemia

Anemia is thought to be more frequent in multiple than in singleton pregnancy. However, the greater increase in blood volume compared with the red cell mass decreases the hemoglobin concentration, producing a more pronounced decrease in hemoglobin than in seen in singleton pregnancy.[10] Mean corpuscular hemoglobin concentration, used as a measure of anemia, does not differ in multiple versus singleton pregnancy. In a retrospective case-control study comparing hemoglobin concentration in twin and singleton gestations matched for parity, no statistically significant differences in third-trimester hemoglobin levels were identified between the two groups.[11] The lower levels identified in the first and second trimesters of pregnancy in twins compared with singletons reflected lower values in multiparous women with a twin pregnancy. Fetal demands in a multiple pregnancy are greater, particularly for folate, and megaloblastic anemia has been reported.

Preterm Labor and Delivery

Preterm birth (birth <37 wk) occurs in over 50% of all twin pregnancies,[12–15] with approximately 10% of these births occurring prior to 32 weeks' gestation.[12,14] The mean duration of pregnancy decreases as the number of fetuses in utero increases. The risks to the mother of a preterm birth relate to the need for hospitalization and the possible use of tocolytic therapy, with potential side effects. Preterm prelabor rupture of the membranes occurs more frequently in multiple gestations and is often followed by preterm labor and birth.

Hypertension

The incidences of pregnancy-induced hypertension, pre-eclampsia, and eclampsia are all increased in multiple

</table>

pregnancy.[2,16,17] A primigravid woman with a twin pregnancy has a 5 times greater risk of severe preeclampsia than one with a singleton pregnancy, and for a multigravid woman, the risk is 10 times greater.[18] Some report a higher risk of hypertension with monozygotic twins,[19] but others do not.[20,21]

Antepartum Hemorrhage

Antepartum hemorrhage as a result of either placenta previa[22] or placental abruption[23–25] is increased in multiple gestations.

Hydramnios

Hydramnios is suspected clinically in up to 12% of multiple pregnancies[26] and is associated with an increased risk of preterm labor.[27] Acute polyhydramnios may occur, particularly with monochorionic twins, often with significant abdominal discomfort for the mother. This is often associated with twin-twin transfusion syndrome (TTTS) (see Chapter 23).

Possible Need for Prenatal Hospitalization

With the increased risk of threatened preterm labor, hypertension, fetal growth restriction, and minor disorders of pregnancy, women with a multiple pregnancy often require hospital admission, sometimes for prolonged periods, during the prenatal period. For the mother, prolonged separation from her family is often a disruptive and stressful experience. Specific complications of twinning, such as TTTS or single fetal death, may require hospitalization.

Single Fetal Death in Twins

The risk of single fetal death in a multiple pregnancy is 2% to 6%. Psychological trauma may be considerable and is enhanced by concerns about the health of the surviving fetus or fetuses. The mother who experiences fetal death of one twin during the antepartum period must adjust to a future without one of the twins while developing a bond with the surviving twin. The mother also must adjust to the additional

risk of death and morbidity from cerebral and renal lesions for the surviving twin (see Chapter 23).

Risk of Operative Vaginal Birth

Compared with a vaginal singleton birth, there is an increased likelihood of operative delivery for one or both twins, with the associated maternal risks of trauma, infection, and hemorrhage.

Increased Likelihood of Cesarean Birth

Twins are more frequently born by cesarean section than are singletons, either as an elective procedure or as an emergency procedure before or after the birth of the first twin. Presentation and gestational age influence this likelihood.[28]

Postpartum Hemorrhage

The risk of postpartum hemorrhage is greater in multiple pregnancy because of the increased placental site, uterine overdistention, and a greater tendency to uterine atony.[29,30]

Postnatal Problems

Learning to cope with the demands of two or more infants can be stressful. A higher percentage of depression is reported in mothers of twins.[31] Given the increased perinatal mortality rate among higher-order multiple pregnancies, the problems of coping with the loss of one or more infants may be an added burden in the postnatal period.

Maternal Mortality

Women with a multiple pregnancy have a twofold increase in the risk of death compared with women with a singleton gestation.[32]

Fetal Risks (Table 59–2)

Stillbirth and Neonatal Death

Multiple pregnancy contributes approximately 10% of total perinatal mortality,[14,33] being up to 10 times greater than in

singletons.[26,34,35] If late abortion, late neonatal death, and infant death are included the mortality, the risk is further doubled. Cause-specific perinatal mortality in twins is higher for every major cause of death, and at all weeks of gestation, compared with singletons.[36]

Higher mortality rates are reported for monochorionic compared with dichorionic twins,[37–39] although not in all studies.[40] For dichorionic twins, the risk of death increased throughout gestation, whereas the risk for monochorionic twins reached a maximum at 28 weeks' gestation and then remained constant.[40] In a review of 1051 twin pairs, factors associated with one or both twins dying in utero related to monochorionicity (odds ratio [OR] 2.0; 95% confidence interval [CI] 1.2–3.4) and discordant birth weight (OR 4.3; 95% CI 2.5–7.3), after correcting for gestational age at birth.[41]

Single Fetal Death in Twins

See Chapter 23.

Preterm Labor and Birth

Preterm birth (<37 completed wk) is the major contributor to the poor perinatal outcomes observed in multiple pregnancy. The preterm birth rate in twin pregnancy is consistently reported to be above 50%,[13–15,33] the risk increasing to in excess of 80% among triplet pregnancies.[14,42,43]

The median gestational age at birth for monochorionic twins is 36 weeks compared with 37 weeks for dichorionic twins. However, 9.2% of monochorionic twins are born before 32 weeks' gestation compared with 5.5% of dichorionic twins (Fig. 59–1).[5]

Intrauterine Growth Restriction

The incidence of small–for–gestational age infants (birth weight < 10th percentile for gestational age standards in pregnancy) is common in multiple pregnancy, with up to 50% of infants having birth weight below 2500 g.[14] These infants are at increased risk for perinatal mortality and morbidity.[44–47]

(From Sebire N, Thornton S, Hughes K, et al: The prevalence and consequence of missed abortion in twin pregnancies at 10–14 weeks of gestation. Br J Obstet Gynaecol 1997;104:847–848.)

Fetal Problems Specific to Multiple Pregnancy

Major congenital abnormalities are more common in multiple pregnancies than in singletons, with rates reported as 4.9%.[48] Several fetal problems are specific to multiple pregnancy, including conjoined twins (discussed later), twin reversed arterial perfusion sequence, monoamniotic twins, and TTTS (see Chapter 23).

Conjoined Twins

Conjoined twins is a congenital abnormality that occurs only in multiple pregnancy and affects 1 in 200 monozygotic twins.[49]

Cord Accident

Preterm birth, preterm prelabor rupture of the membranes, hydramnios, malposition, and malpresentation are more likely to increase the risk of a cord accident in multiple pregnancies than in singleton pregnancies.

Chorionicity

Chorionicity has an important effect on pregnancy outcome. Two thirds of monozygous twins are monochorionic and are at increased risk for mortality and morbidity compared with dichorionic twins. Risk factors include increased risk of TTTS, congenital anomalies, single fetal death in utero, and acute hydramnios (see Chapter 23).

Hydramnios

Hydramnios may occur in one gestational sac in both TTTS and the "stuck twin" phenomenon (see Chapter 23). It may be caused by fetal anomalies such as upper gastrointestinal tract atresias, congenital heart anomalies, or hydrops fetalis. In some cases of gross hydramnios in both sacs, no causal factor is evident. Hydramnios is a major cause of preterm birth and the associated perinatal mortality rate is high.[27]

Risk of Asphyxia

The risk of mortality as a result of asphyxia in a twin is four to five times than in a singleton.[50] Important risk factors include the increased occurrence of intrauterine growth restriction, cord prolapse, and hydramnios.

Operative Vaginal Birth, Especially for the Second Twin

The likelihood of operative birth is increased, especially for the second twin, who may require internal podalic version. Operative birth is associated with an increased risk of birth trauma, low Apgar scores, and hyperbilirubinemia compared with a normal vaginal birth.

Twin Entrapment

Twin entrapment is rare and reported to occur in 1 in 817 twin pregnancies.[51] The risk of fetal death of the first twin is high, as is the risk of fetal hypoxia in both twins. Twin entrapment is associated with monoamniotic twins.

Cerebral Palsy

The prevalence of cerebral palsy in triplets is 47 times greater and in twins 8 times greater than in singletons.[52] Lower gestational age at birth is associated with a greater risk of cerebral palsy.[53]

MANAGEMENT OPTIONS

Prepregnancy

The rate of multiple pregnancy for women undergoing ovulation induction is increased to 20 to 40%. For clomiphene, the twinning rate is 9% to 14%.[54] Appropriate counseling about this increased risk should be provided to women who are offered this treatment. The risk of multiple pregnancy from assisted reproductive techniques correlates with the number of embryos or zygotes transferred, increasing from 1.4% with single embryo transfer to 17.9% with two embryos, and 24.1% after transfer of four embryos.[55] Similarly, after gamete intrafallopian transfer, the rate of multiple pregnancy is 18.7% after transfer of two oocytes and 25.8% after transfer of three oocytes.[55] The rate of multiple pregnancy at 20 weeks' gestation after zygote intrafallopian transfer with three zygotes is 27%.[56]

The best way to reduce the risk of multiple pregnancy is to reduce the number of embryos, zygotes, or oocytes transferred after full discussion of the risks (of multiple pregnancy) and benefits (of high successful pregnancy rates) with the couple. Three randomized, controlled trials compared single versus double embryo transfer,[57–59] and another compared double embryo transfer with transfer of four embryos.[60] When single embryo transfer was compared with double embryo transfer, fewer women became pregnant (relative risk [RR] 0.69; 95% CI 0.51–0.93), but the risks of twin pregnancy (RR 0.12; 95% CI 0.03–0.48) and low birth weight (RR 0.17; 95% CI 0.04–0.79) were markedly reduced.[61] No statistically significant differences were identified for outcomes relating to singleton pregnancy, pregnancy loss at less than 20 weeks' gestation, extrauterine pregnancy, or preterm birth at less than 37 weeks.[61] When the transfer of two embryos was compared with the transfer of four embryos, no statistically significant differences were seen in the number of women who became pregnant with a multiple or singleton pregnancy or the risk of pregnancy loss.[60] In view of the risks associated with multiple pregnancy, the Royal College of Obstetricians and Gynaecologists (RCOG) has issued guidelines indicating that consideration should be given to transferring only a single embryo.[62]

Periconceptual folate supplementation is recommended as a general measure for all women to reduce the risk of neural tube defects.[63]

Prenatal

Overall Care

Regular prenatal attendance for pregnancy care is accepted practice. The variation in visit frequency, the health care provider, and screening program seen in practice are of unproven value. Specialized multidisciplinary twin clinics have been advocated, and some nonrandomized cohort data suggest that perinatal outcome can be improved by intensive preterm birth education, continuity of care providers, and individualized care.[64–66] Prospective randomized data are lacking.

Frequent prenatal visits permit extra vigilance in the early detection of pregnancy-induced hypertension.[67] Routine screening for gestational diabetes is often performed, with some reports suggesting an increased risk in twins[68] and

others suggesting no increased risk.[69] Antepartum hemorrhage can be neither predicted nor prevented by additional prenatal visits or any other strategy. In addition, iron and folate supplementation is frequently advised from the beginning of the second trimester for women with multiple pregnancy, although the evidence to support this practice is limited.[10,11]

Diagnosis of Chorionicity by Early Ultrasound

Amnionicity and chorionicity can be determined by ultrasound.[70] This knowledge may be useful in predicting which pregnancies are at greater risk for TTTS, and for monoamniotic twins, cord entanglement, or to differentiate TTTS from a twin pregnancy complicated by growth restriction. Similarly, this knowledge may be useful in the management of twin pregnancy when one twin has a major congenital malformation and selective termination is considered or in the management of pregnancy after a single fetal death.[71] Screening for amnionicity and chorionicity is best performed in the first trimester, although it is not always easy, even for a skilled ultrasonographer.[72]

Monochorionic twins are the same sex and have one placental mass, with a thin dividing membrane (two amnions, no chorions) and a T insertion.[41,73] Because the dividing membrane is so thin, it is often difficult to identify, and the pregnancy may be misidentified as monoamniotic. Visualization of the dividing membrane is facilitated by searching over the fetal chin or away from the fetal body and around the limbs. A dichorionic placenta essentially eliminates the diagnosis of TTTS.

The dividing membrane is thicker in dichorionic twins (containing two layers of amnion and two layers of chorion). Measuring the membrane thickness by ultrasound, using a cutoff of 2 mm to characterize a dichorionic or monochorionic placenta,[74] has been described as a good, but suboptimal, test for determining chorionicity.[72] High interobserver and intraobserver variation, together with differences related to gestational age and sampling site, lead to suboptimal accuracy of the determination of chorionicity.[73] Ultrasonic detection of the lambda sign[69] (an echogenic V-shaped chorionic projection of tissue between the dividing membranes in dichorionic placentation) is reported as more reliable, especially if the scan is performed at 10 to 14 weeks' gestation (Fig. 59–2).[75] As gestational age increases, the lambda sign is more difficult to see, and after 20 weeks, it may disappear. The lambda sign is also known as the "twin peak" sign.[76] Given the prognostic value for later risks of pregnancy, attempting to establish the chorionicity of the placenta between 10 and 14 weeks' gestation may be appropriate.

Accuracy rates for determining chorionicity with first-trimester ultrasound, determined by subsequent pathologic examination, are reported as up to 96% with transabdominal sonography[77] and up to 100% with transvaginal sonography.[32]

No prospective clinical studies show that knowledge of chorionicity should alter subsequent clinical management or whether pregnancy outcome can be improved by changes in clinical care. Despite this, many practitioners increase antenatal surveillance in women with a monochorionic pregnancy.

TABLE 59–3

Nuchal Translucency Screening

The use of nuchal translucency screening for aneuploidy in singleton gestation is widespread, and it has been used to screen women with twin pregnancy. In a study of 448 women with twin pregnancy, nuchal translucency was measured for each fetus and combined with maternal age to derive a risk estimate.[78] The detected nuchal translucency was greater than the 95th percentile for gestational age (using crown-rump length derived from singletons) in 7.3% of fetuses, including 88% of those with trisomy 21. These findings suggest that in dichorionic twin pregnancies, the sensitivity and false-positive rate of fetal nuchal translucency as a screening tool for trisomy 21 are similar to those reported for singleton pregnancies.[78] In monochorionic twin pregnancies, the false-positive rate of screening is higher than that reported in singleton pregnancies, and discordance in nuchal translucency measurements raise the possibility of early-onset TTTS.[79] The incorporation of nasal bone assessment has more limited sensitivity in screening for chromosomal anomalies and is technically more difficult to achieve in multiple pregnancies.[80]

Pregnancy Reduction

Couples who are faced with the dilemma of a triplet or higher-order multiple pregnancy have several options. Termination of the entire pregnancy generally is not acceptable to women, particularly those with a history of infertility. Attempting to continue the pregnancy with all of the fetuses is associated with inherent problems related to preterm birth, survival, and long-term morbidity. Reduction in the number of fetuses by selective termination has been advocated in an attempt to reduce the risk of adverse obstetric and perinatal outcomes.[81] The procedure is described in Chapter 23. Many prospective, nonrandomized studies have compared pregnancy outcome after multifetal pregnancy reduction in twins conceived spontaneously or after assisted reproduction[82–84] with multifetal pregnancy reduction in expectantly managed triplet pregnancies.[84–87] A systematic review assessed the effects of multifetal pregnancy reduction on fetal loss, preterm birth, and perinatal and infant mortality and morbidity rates in women with triplet and higher-order multiple pregnancies.[88,89] When pregnancy was reduced to twins, the reported outcomes appeared comparable with those in twins conceived spontaneously or those conceived with assisted reproductive techniques (Table 59–3).[88,89] Counseling these women is further complicated by the varying preterm delivery rates and their consequences (Table 59–4). No randomized, controlled trials have assessed multifetal reduction. The available nonrandomized studies provide limited insight into the benefits and risks associated with fetal reduction procedures.[88,89] Although a randomized, controlled trial would provide the most reliable evidence, selective termination may not be acceptable to couples, particularly those with a history of infertility, and consequently, recruitment to such a trial may be exceptionally difficult.

Fetal Anomaly Scanning

Given the increased risk of congenital abnormalities, an anomaly scan of each fetus by an ultrasonographer with appropriate expertise is suggested, usually between 18 and

20 weeks' gestation. In centers offering routine ultrasound scanning at this stage of pregnancy, undetected multiple pregnancy should be diagnosed. Early diagnosis allows appropriate counseling and planning for future care and has been reported to reduce perinatal loss related to twin pregnancy.[90] Conjoined twins can be diagnosed if an ultrasound scan is performed at this stage.

In one series, prenatal ultrasonography, including cardiac screening limited to the four-chamber view, resulted in the detection of up to 39% of all major congenital anomalies in twins.[91] However, none of the cardiac lesions was detected. Of major noncardiac anomalies, 55% were detected, as were 69% of major anomalies that could alter prenatal management.[91] In a retrospective study of 245 women with twin pregnancy, ultrasound screening for fetal anomalies identified a 4.9% prevalence of congenital malformations.[48] For the detection of each individual anomaly, sensitivity was 82%, specificity was 100%, positive predictive value was 100%, and negative predictive value was 98%.[48]

Conjoined Twins

Conjoined twins are usually diagnosed antenatally.[92] Determination of the conjoined site permits multidisciplinary discussion before birth as to the prognosis and the possibility of surgical correction and allows full involvement of the parents. Unless birth is necessary for other reasons, preterm cesarean section is recommended. The use of one course of steroids to stimulate fetal lung maturity is advisable. Some test for fetal lung maturity before birth. Many obstetricians recommend elective cesarean delivery at 38 weeks; however, this procedure can be difficult technically. Some recommend a classic incision, although this increases the maternal risks, particularly of uterine scar rupture in subsequent pregnancy. At delivery, two neonatal teams should be available, with the neonatal surgical team and operating room on standby.

Preterm Labor

Preterm labor and subsequent birth presents the greatest risk for fetal morbidity and mortality. Maternal counseling as to the signs and symptoms of preterm labor may be of value.

If uterine activity is noted, the woman should go to the hospital promptly.

It is difficult to predict which patients will have preterm labor. Cervical assessment by either digital[93–95] or ultrasound examination[96–99] has been suggested as a useful way to evaluate the risk of preterm delivery. How frequently such an assessment should be made (e.g., weekly, every 2 weeks, monthly) is uncertain, and whether such assessment is more beneficial than harmful is not known. Cervical assessment allows calculation of the cervical score (cervical length [in centimeters] – cervical dilation [in centimeters]). A cervical score of 2 or less at or before 34 weeks' gestation has a positive predictive value of 75% for preterm birth,[94] with other authors reporting that a cervical score of 0 or less has a positive predictive value of 75% for preterm birth.[95] As part of a study of the prediction of preterm delivery, cervical length was prospectively assessed by ultrasound in 147 women with a twin pregnancy.[96] A short cervix (<25 mm) was consistently associated with spontaneous preterm birth at less than 32 weeks' gestation (OR 6.9; 95% CI 2.0–24.2), less than 35 weeks' gestation (OR 3.2; 95% CI 2.3–7.9), and less than 37 weeks' gestation (OR 2.8; 95% CI 1.1–7.7).[96]

The presence of fetal fibronectin in cervical secretions has been used to predict preterm birth.[96,99] In multiple pregnancy, a positive fetal fibronectin test result at 28 to 30 weeks was associated with preterm birth before 32 weeks' gestation.[96] A positive fetal fibronectin test result at 28 weeks' gestation predicted birth before 35 weeks, with sensitivity, specificity, positive predictive value, and negative predictive value of 50.0%, 92.0%, 62.5%, and 87.3%, respectively.[99] The ability of fetal fibronectin to predict very preterm birth requires ongoing prospective evaluation to determine whether such prediction can lead to effective interventions that would reduce the risk of preterm birth.

If cervical change is noted, hospital admission is the most generally accepted management. Routine hospital admission and subsequent rest, however, seem to offer little benefit in delaying labor.[100,101] It is unknown whether prophylactic tocolysis is of value in this identifiable group at high risk for preterm birth.

Several prenatal interventions have been tried to reduce the risk of preterm birth in multiple pregnancies and have been evaluated by randomized clinical trials. These include prophylactic cervical cerclage,[102,103] prophylactic β-mimetic agents,[104–106] prophylactic progesterone therapy,[107–109] bedrest in the hospital,[100,110] and home uterine activity monitoring.[111,112] However, none of these haa proved to be of value in reducing the incidence of preterm birth and the associated high perinatal mortality rate in multiple pregnancy.

Prophylactic cervical cerclage in twin pregnancy does not show benefit when the results of randomized trials are reviewed.[113] It seems prudent to reserve the insertion of a cervical suture for women with evidence of cervical incompetence. Prophylactic tocolytic agents are occasionally used in multiple pregnancy. Systematic review of randomized trials of prophylactic β-mimetics does not show a benefit in the incidence of preterm labor,[114] and their use cannot be recommended.

Prophylactic progesterone has been advocated as a treatment for women at risk for preterm birth from multiple pregnancy. Two randomized trials have been identified evaluating the use of 17α-hydroxyprogesterone caproate in women with a twin pregnancy,[108,109] and a single trial involving women with a triplet pregnancy.[107] To date, there is little evidence to support its use, with no demonstrated benefit in either the risk of preterm birth or the neonatal health outcomes.[115,116]

Admission of women with an uncomplicated twin pregnancy to the hospital for rest does not reduce the risk of preterm birth. The Cochrane Systematic Review of randomized trials of routine hospitalization for rest shows an increased likelihood of preterm birth in women who were admitted compared with control subjects who continued normal activity at home.[100] Hospital admission for rest in an uncomplicated twin pregnancy should be considered only if the woman requests admission. Women may request hospital admission for several reasons, including discomfort, difficulty coping at home, or living a significant distance from the hospital.

The value of hospital admission for rest in triplet or higher-order multiple pregnancy is uncertain. Only two small randomized studies have been conducted, with no demonstrable benefit.[110,117]

Home uterine activity monitoring (HUAM) has been suggested to permit the diagnosis of preterm labor at an early stage, allowing successful tocolysis and fewer preterm births. A small randomized trial of 45 women reported these benefits.[112] However, in subgroup analysis of the 844 twin gestations in a multicenter trial comparing HUAM with weekly or daily nursing contact, HUAM did not reduce the risk of preterm birth.[111] HUAM, when combined with daily nursing contact, did result in more unscheduled visits and increased use of tocolytics.

A course of prenatal corticosteroids should be given to improve fetal outcome in women with multiple pregnancy who are considered at increased risk for preterm birth at less than 34 weeks, if birth is planned, or if there is a high risk of birth within the next 48 hours.[118] Whether a larger dose of corticosteroids than that given in singleton pregnancies would be more beneficial in twin gestations has been suggested but not adequately assessed.[118] For women who

remain undelivered after 7 days following corticosteroids, repeat doses may be recommended, because they have been shown to reduce the occurrence and severity of neonatal lung disease and other serious health problems in the early neonatal period.[119] However, these benefits are associated with a reduction in some measures of weight and head circumference at birth, and there is still insufficient evidence on the longer-term benefits and risks.[119,120]

Fetal Assessment

Fetal assessment during pregnancy includes regular ultrasound to determine fetal growth and well-being. The recommended frequency of scanning varies (e.g., from every 2 wk from 24 wk' gestation to every 3–4 wk from 20 wk' gestation). Umbilical artery Doppler improves pregnancy outcome in high risk pregnancy and is often included as part of routine fetal assessment.[121] Some centers suggest obtaining biophysical profiles from 30 weeks' gestation, although the evidence to support this strategy is not strong.

The use of umbilical artery Doppler studies in the assessment of twin pregnancy was evaluated in three randomized, controlled trials.[122–124] Giles and colleagues[122] randomly allocated 526 women with a twin pregnancy at 25 weeks' gestation to biometry only or to biometry and umbilical artery Doppler waveform at 25, 30, and 35 weeks' gestation. This study of close antenatal surveillance identified a lower than expected fetal mortality rate from 25 weeks' gestation in both the biometry alone and the combined biometry and Doppler groups.

Maternal Education and Support

During the prenatal period, the couple will need specific information and support to help prepare for the birth and care of theïr infants.[125] The most likely mode of birth, care in labor, and the use of analgesia, especially epidural, should be discussed.[126] Many countries have multiple pregnancy support groups. The opportunity to contact a local group during the prenatal period, attend meetings, and make personal contact with other families who have had a multiple birth is recommended.

Labor and Delivery

Birth in a hospital is accepted practice,[127] with many advising birth in a tertiary unit, when possible. Induction of labor may be indicated for complications such as preeclampsia or growth restriction. The benefit of elective birth at 37 weeks' gestation to reduce the risk of antepartum stillbirth as a result of intrauterine growth restriction is controversial.

Retrospective data suggest that the lowest rate of perinatal mortality and morbidity in twin pregnancies occurs at 36 to 38 weeks' gestation, with the risk of adverse outcome increasing as gestation advances.[36,128–131] The recent Cochrane Systematic Review of the role of elective birth in twin pregnancy from 37 weeks' gestation[132] identified a single small randomized, controlled trial from Japan assessing elective birth with continued expectant management.[133] This study identified no statistically significant differences. However, the sample size was underpowered to detect meaningful differences, and insufficient data are available to support the practice of elective birth from 37 weeks' gestation in women with an

otherwise uncomplicated twin pregnancy. A multicenter randomized, controlled trial is in progress, coordinated by the Maternal Perinatal Clinical Trials Unit at the University of Adelaide, to assess the optimal timing of birth in women with twin pregnancy at term.[134]

Intrapartum blood loss is greater in multiple pregnancy, as is the risk of postpartum hemorrhage. An intravenous access line should be inserted early in labor and blood obtained to estimate maternal hemoglobin or hematocrit and to hold serum for cross-matching, if needed later.

For a vaginal birth, both twins should be monitored continuously.[127] Initially, only external fetal monitoring will be possible. When feasible, a scalp electrode should be placed on the first twin, with continuation of external monitoring of the second twin. The use of a twin fetal heart rate monitor allows simultaneous recording of the two fetal heart rate tracings. If continuous monitoring of the second twin is impossible, some recommend cesarean section because of the higher risk of fetal asphyxia in twins, which may go undetected without adequate monitoring.

Epidural analgesia is widely used, providing the mother with adequate pain relief, and minimizes the risk that she will push before full dilation occurs.[127] In addition, adequate analgesia is provided in the event that operative birth, internal podalic version of the second twin, or cesarean delivery is needed. The widespread use of epidural anesthesia often negates the need for emergency general anesthesia with the complications discussed earlier, although it may still be needed for emergency cesarean section for fetal distress.

The optimal mode of birth in multiple pregnancy is controversial.[135] For triplets and higher-order multiple gestations, the most frequent mode of delivery is cesarean section,[136–138] although no randomized studies are available to support this mode of birth over vaginal birth. Reports suggest that the risk of lower Apgar scores in higher-order multiple gestations is reduced with cesarean delivery[42,139]; in addition, there are fewer perinatal deaths.[42]

Neonatal respiratory disease was more common in twins born by cesarean section at 36 to 38 weeks than in those born vaginally at 38 to 40 weeks.[140] Another report suggested higher perinatal mortality rates with cesarean delivery, primarily as a result of respiratory distress syndrome.[141] This has led to the suggested role of prophylactic corticosteroid administration prior to elective cesarean section.[142]

The Cochrane Systematic Review of the mode of birth for the second twin[143] identified a single randomized trial[144] comparing planned vaginal birth with planned cesarean birth for the second, nonvertex twin. This study highlighted the need for further evidence from randomized, controlled trials to inform practice. To provide more reliable information about the optimal mode of birth for women with twin pregnancy, a randomized, controlled trial (Twin Birth Study) is in progress, coordinated by the University of Toronto's Centre for Mother, Infant, and Child Research.[145]

Based on the literature on twin pregnancy, some recommendations can be made. The mode of birth is often affected by the presentation of the twins, which may be divided into the following three groups:

- First twin vertex, second twin vertex.
- First twin vertex, second twin nonvertex.
- First twin nonvertex.

First Twin Vertex, Second Twin Vertex

The most common presentation of twins is vertex-vertex. In this case, most obstetricians recommend vaginal birth,[146–149] and the literature supports vaginal birth, even of very low–birth weight infants (<1500 g).[147,150,151]

First Twin Vertex, Second Twin Nonvertex

For twins presenting as first twin vertex, second twin non-vertex, opinion is divided as to the optimal mode of birth. Some recommend elective cesarean delivery, reporting reduced neonatal mortality and morbidity rates for the second twin.[146,152] Others suggest that there is no increase in neonatal risk associated with vaginal birth of the second twin weighing 1500 g or more, either as breech presentation after internal podalic version if the fetus does not have a longitudinal lie or as cephalic presentation after external cephalic version.[153–158] The only randomized study found no difference in neonatal outcome in 60 nonvertex second twins at 35 weeks' gestation or more. Study subjects were randomly allocated to either vaginal delivery or cesarean section.[144,159] Assessment of whether vaginal breech delivery is appropriate is necessary using the standard criteria for singleton birth. These include exclusion of cephalopelvic disproportion, estimated fetal weight of less than approximately 3500 g, and the finding of a flexed fetal head on ultrasound.

For a nonvertex second twin of very low birth weight (<1500 g), the mode of birth is controversial. Some reports recommend cesarean delivery to minimize birth trauma to the preterm infant,[147,153,155,158,160] whereas others show no neonatal benefit and emphasize that vaginal delivery has reduced risks for the mother.[151] No randomized studies have compared vaginal and cesarean birth in these infants.

First Twin Nonvertex

When the first twin is nonvertex, cesarean delivery is often preferred[135,148] and advised,[147] although no series suggests that vaginal birth is inappropriate. It is likely that this approach is influenced by the data on the optimum mode of delivery in singleton breech presentations (see Chapter 63). By following such a policy, the risk of twin entrapment by interlocking chins or heads can be avoided.

PROCEDURE

TWIN BIRTH

For a vaginal twin birth, at least one experienced obstetrician, anesthetist, pediatrician, and neonatal nurse should be in attendance. Depending on gestational age (e.g., if preterm) and circumstances (e.g., operative birth, abnormal cardiotocographic findings), a double pediatric team (two pediatricians and two neonatal nurses) may be appropriate. For higher-order multiple births, one pediatric team should be present for each infant. Some recommend having a nurse scrubbed and the operating room prepared for emergency cesarean section.

For a vaginal birth, delivery of the first twin should be as for a singleton. After the birth of the first twin, an experienced obstetrician assesses the lie and presentation of the second twin. This assessment can be

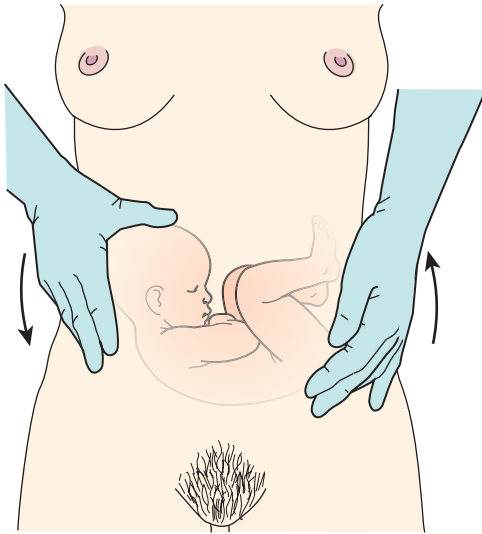
FIGURE 59–3
Modified external version for delivery of the second twin.


FIGURE 59–4
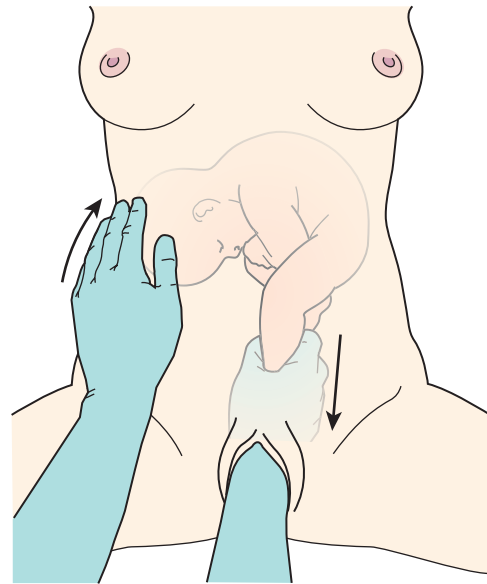
Internal podalic version.
done by vaginal examination, abdominal palpation, or transabdominal ultrasound examination. The lie should be corrected to longitudinal by external version or internal podalic version.[161] External version (Fig. 59–3) gently turns the fetus so that the vertex lies above the pelvic brim. Amniotomy can be performed if there are uterine contractions (discussed later), and then delivery is completed. Version is more likely to be successful with epidural anesthesia and when the twins are of similar weight (difference of <500 g).[156]

In two series, external version was less likely than breech extraction to result in a vaginal birth.[158,162] Emergency cesarean section and complications such as cord prolapse and fetal distress were more frequent in the external version group. Although these were not randomized studies, in view of these findings, internal podalic version, if necessary, and breech delivery are recommended by some obstetricians if the lie is nonlongitudinal or the breech is presenting. However, others prefer to use external cephalic version and perform amniotomy once the lie is longitudinal and there are regular uterine contractions. They advocate cesarean delivery if the lie remains nonlongitudinal. Oxytocin (Syntocinon) infusion is mandatory if there is uterine inertia, and it is normal practice in many units to have an infusion ready at the onset of the second stage of labor. Once there are contractions and the lie is longitudinal, amniotomy is performed and birth proceeds with maternal effort during contractions. A scalp electrode can be applied after amniotomy to permit continuous fetal heart rate monitoring, or an external monitor can be used. Most authors advise continuous monitoring of the second twin throughout the second stage of labor, given the increased risk of intrapartum asphyxia. The risk of fetal distress and acidosis is increased if the twin-twin delivery interval exceeds 30 minutes.[163] If fetal distress develops and birth cannot be achieved safely, or if the second twin does not


descend into the pelvis, emergency cesarean delivery is necessary.

After birth of the second infant, active management of the third stage of labor is recommended with an oxytocic agent.[164] To prevent uterine atony, in many units, an oxytocin infusion is continued for 3 to 4 hours.

Internal podalic version with vaginal breech delivery remains an option for birth of the second twin when a nonlongitudinal lie persists and the membranes are intact (Fig. 59–4). This approach involves the following steps:
- Use adequate analgesia, usually epidural, but possibly a general anesthetic.
- Place the patient in the lithotomy position.
- Provide continuous fetal heart rate monitoring.

- Use aseptic technique, and catheterize the patient.
- Ensure that a pediatrician is present.
- Determine the lie of the second twin by abdominal palpation, internal examination, or transabdominal ultrasound examination.
- Locate a fetal foot. Confirm that the structure is a foot rather than a wrist by palpating the heel.
- Perform an amniotomy.
- Grasp the foot, and pull down into the vagina. Grasp both feet, if possible.
- With maternal effort during contractions, deliver the fetus as an assisted breech.

Complications

Complications include
- Fetal anoxia.
- Difficulty with delivery of the head with breech presentation.
- Fetal trauma as a result of breech delivery (e.g., dislocated hips).
- Inadvertent delivery of a hand with shoulder presentation.
- Placental abruption.
- Cord accident.
- Endometritis.
- Maternal trauma (e.g., ruptured uterus).

Twin Entrapment

Twin entrapment may occur if the first twin is delivered as a breech and the second twin is cephalic and the head of the second twin enters the pelvis before the head of the leading twin. Some maintain that the risk of twin entrapment can be avoided by performing elective cesarean section if the first twin is breech and the second twin is cephalic. In an emergency, an attempt may be made to separate the locked twins by passing a hand vaginally between the chins of the fetuses and pushing the second twin upward. If this attempt fails, emergency cesarean section is necessary. Alternatively, an attempt may be made to push back the first twin, presenting as a breech, and allow the "second" twin, presenting cephalically, to deliver first. Again, if this attempt fails, emergency cesarean delivery is necessary.

During cesarean section, the head of the first twin is maneuvered upward, enabling birth of the second twin's head and body. The "first" twin may then be delivered. Some recommend having a second obstetrician available to manipulate the infants vaginally, if necessary.

If the first twin is already dead, rather than cesarean birth, there is the option of decapitation of the first twin, vaginal delivery of the second twin, and delivery of the head of the first twin. Such a destructive procedure should be performed under general anesthesia to protect the mother from seeing it. Many believe that this option should not be used in modern obstetrics, and some would argue that abdominal delivery may be associated with a lower incidence of perinatal asphyxia for the second twin.

Complications

In twin entrapment, the risk of fetal death of the first twin is high, as is the risk of fetal hypoxia for both twins. Maternal risks relate to the need for emergency cesarean section, endometritis, and the possible need for general anesthesia.

Postnatal

After the birth of twins, the mother may require a prolonged hospital stay. Breast-feeding should be encouraged, and additional support is important. The provision of adequate contraception is necessary and should be discussed. Coordinated support to help the parents care for their infants should be available.[125]

Before discharge, if extra help is not available at home, additional community support may need to be arranged. Maintaining contact with the local multiple birth support group during the puerperium is important.

SUMMARY OF MANAGEMENT OPTIONS		
Multiple Pregnancy		
Management Options	**Evidence Quality and Recommendation**	**References**
Prepregnancy		
Counsel women who are undergoing assisted conception techniques about the risks of multiple pregnancy.	III/B	56
No data are available to indicate the "ideal" number of embryos or oocytes to replace. But, there is guidance encouraging the consideration of single embryo replacement.	Ia/A	61
Supplement folate pre- and periconception.	Ia/A	63
Prenatal		
Specialized twin clinics may lessen adverse outcomes. Little evidence supports other forms of prenatal care.	III/B	64–66
Document zygosity or chorionicity at 10–14 wk. But no prospective data are available on whether this documentation improves outcome.	III/B	75

Management Options	Evidence Quality and Recommendation	References
Maintain increased surveillance if twins are monozygous or monochorionic.	IIb/B	165
Monochorionic twins are at increased risk for adverse outcome. But no prospective data are available on whether increased surveillance improves outcome.		
Supplement iron and folate from the second trimester.	IIb/B	11
Screen for hypertension.	IIa/B	67
There is conflicting evidence of the value of screening for gestational diabetes.	IIa/B	68,69
Nuchal translucency measurement of each fetus identifies fetuses at risk for trisomy 21, cardiothoracic abnormalities, and twin-twin transfusion syndrome.	III/B	78
Obtain routine anomaly ultrasound scan at 18–20 wk.	III/B	48
Conjoined twins: • Obtain careful ultrasonographic evaluation of anatomy. • Provide interdisciplinary discussion of therapeutic options.	III/B	92
Be vigilant for early symptoms of preterm labor; prompt self-referral if suspected.	Ib/A	112
Obtain possible ultrasound assessment of cervical changes and fetal fibronectin as part of preterm delivery screening.	IIa/B	96
Provide prenatal corticosteroids if preterm birth before 34 wk is possible.	Ia/A	118
There is no evidence that hospitalization prevents preterm labor and delivery.	Ia/A	100
There is no evidence that prophylactic cervical cerclage prevents preterm labor and delivery.	Ia/A	113
Obtain regular fetal ultrasound assessment of growth and umbilical artery Doppler.	Ib/A	122
Hospitalize at the woman's request or if complications are detected.	Ia/A	100
Consider therapeutic amniocentesis (repeated if necessary) for extreme hydramnios and maternal distress.	IIb/B	166
Provide prenatal education about the possible modes of delivery, analgesia, and care in labor.	IV/C	126
Labor and Delivery		
Arrange for hospital delivery.	III/B	127
Have experienced obstetrician and other health professionals on stand by.	III/B	127
Await spontaneous labor if no complications occur.	Ia/A	132
Have pediatrician, neonatal nurse, and anesthetist available at delivery, with one pediatrician per infant present if preterm or operative delivery or fetal problems are anticipated.	GPP	—
Maintain continuous monitoring of all fetuses during labor.	III/B	127
Provide IV access.	GPP	—
Epidural analgesia recommended.	III/B	127
Aim for vaginal delivery unless the leading twin has a nonlongitudinal lie.	III/B	140,151
Some advocate elective cesarean delivery if the first twin is not cephalic.	III/B	140,151
Arrange for vaginal delivery of the first twin, if appropriate.	III/B	151
Consider synthetic oxytocin infusion for uterine inertia, especially after the first twin is delivered.	GPP	—
If the second twin has a longitudinal lie, perform amniotomy and deliver.	III/B	161

SUMMARY OF MANAGEMENT OPTIONS
Multiple Pregnancy—cont'd

Management Options	Evidence Quality and Recommendation	References
If an infant has a nonlongitudinal lie, convert to a longitudinal lie by external version or internal podalic version.	III/B	161
Infuse oxytocin prophylactically after delivery to reduce the risk of postpartum hemorrhage.	Ia/A	163
Some advocate elective cesarean delivery for triplets and higher-order births.	IIb/B	141
Postnatal		
Provide extra support while in the hospital to assist with infant care.	GPP	—
Offer longer in-patient stay.	GPP	—
Arrange support at home.	GPP	—
Provide adequate contraceptive advice.	GPP	—

GPP, good practice point.

INTRODUCTION

Preterm birth is associated with significant perinatal morbidity and mortality rates. Adverse outcomes from preterm birth include cerebral palsy, developmental delay, chronic lung disease, and visual and hearing loss. About 40% of preterm births follow idiopathic preterm labor, 35% follow preterm prelabor rupture of membranes, and the remainder are iatrogenic because of obstetric or medical indications.[1] The early detection of preterm labor or preterm rupture of membranes in traditional antenatal care is often problematic because symptoms or signs may vary only a little from the normal physiologic symptoms and signs of pregnancy. The criteria for diagnosis of preterm labor, defined by the onset of increasingly frequent and painful uterine contractions with progressive effacement and dilation of the cervix, can be assessed most accurately once contractions occur at least once every 10 minutes, there is 80% cervical effacement, and the cervix is at least 3 cm dilated.[2,3] However, the patient may frequently present with relatively mild symptoms and signs suggestive of labor, which may be features of normal pregnancy.[4] Using lower thresholds for contraction frequency and cervical change will, therefore, affect the sensitivity and positive predictive value of clinical assessment for detection of preterm labor.

Prediction of preterm birth would ideally involve a screening test with high sensitivity and high negative predictive value. It should also enable effective intervention if the test gives a positive result. Until recently, the screening tools and interventions that were available did not enable obstetricians to decrease the incidence of preterm birth and, therefore, did not satisfy the requirements of an optimal screening test. However, in 2007, Fonseca and associates[5] published a randomized, controlled trial suggesting that effective screening by measuring cervical length at 23 weeks' gestation and therapeutic intervention with progestins to 34 weeks could reduce the risk of preterm delivery by 42%, which may translate into improved neonatal outcomes. A wide variety of screening tools have been evaluated in research, and those most extensively evaluated fall into four groups:

- Monitoring of uterine activity.
- Assessment of cervical length.
- Measurement of cervical fetal fibronectin.
- Presence of bacterial vaginosis in early pregnancy.

Other forms of screening have been looked at in small series and include estimation of estriol, interleukins, ferritin, and corticotropin-releasing hormone, but findings in relation to these measures have not been consistently associated with preterm labor. This chapter reviews the four major areas of screening and evaluates their effectiveness in screening for preterm labor and preterm rupture of membranes.

MONITORING UTERINE ACTIVITY

If the onset of increasingly frequent and painful uterine contractions precedes effacement and dilation of the cervix, then assessment of uterine activity may identify pregnancies at risk of preterm delivery at an early stage of preterm labor, allowing effective intervention.

The simplest method for assessing uterine activity relies on teaching the patient to palpate and record her own contractions. Increased uterine activity appears to precede a clinical diagnosis of preterm labor by less than 24 hours.[6] Most obstetricians using this technique would therefore advise the patient to monitor her own contractions for an hour twice a day. Although this technique has the advantage that it does not involve any expensive equipment, it is completely subjective and has been shown to have poor sensitivity, with 89% of women palpating less than 50% of their contractions.[7] In addition, the process of monitoring is time-consuming, is generally limited to high risk groups, and potentially increases patient anxiety, which is itself associated with an increased risk of preterm delivery. This issue applies equally to other forms of uterine activity monitoring; indeed, these techniques require intense patient support through a process of education, analysis of results, and encouragement to continue monitoring on a regular basis, and it has frequently been suggested that it is this support that leads to an improvement in outcome more often than the process of monitoring itself.[8]

A more objective approach to uterine activity monitoring involves tocography, monitoring activity indirectly via a pressure transducer attached to a recording device and placed against the maternal abdominal wall. Early studies with this technique demonstrated that normal uterine activity increases with advancing gestation and is more pronounced at night. Uterine activity was monitored in a series of 109 low risk pregnancies that delivered at term; the 95th

percentile was 1.3 contractions per hour at 21 to 24 weeks, 2.9 contractions per hour at 28 to 32 weeks, and 4.9 contractions per hour at 38 to 40 weeks.[9] It was found that 96% of recordings had fewer than 4 contractions per hour, and this threshold is often used to define a risk of preterm labor. An early case-control study recruited 76 women at high risk of preterm labor to assess whether daily ambulatory home uterine monitoring could facilitate an early diagnosis of preterm labor and compared them with 76 matched control subjects.[10] The rates of threatened preterm labor were similar in the study and control groups (51% vs. 45%), but the cervix was significantly less effaced and dilated and there were no cases of ruptured membranes at the time of diagnosis in the monitored group. Consequently, all cases were considered suitable for long-term tocolytic therapy, and the preterm delivery rate was lower in the monitored group (22%) than in the control group (41%).

Although this initial series appeared to give encouraging results, there are several problems with this technique. Few studies have validated the instrumentation used in home monitoring. Those that have been performed suggest that patients are readily able to use the machines, that home machines appear to be of similar sensitivity as hospital machines, and that they detect more than 90% of contractions recorded by an intrauterine pressure catheter during normal term labor.[11–13] However, the sensitivity and specificity of the tocometer vary according to its position, the tension on the belt, and the thickness of the maternal abdominal wall, so the amplitude of the waveform seen on a tocogram cannot be related to the strength of uterine activity. Data interpretation is also subject to observational error, with one study finding that the results were interpreted reliably in only 70% of cases by a single observer.[14]

Perhaps more important, monitoring uterine activity does not lend itself to screening a low risk population; the equipment is relatively expensive, monitoring is time-consuming, studies need to be repeated regularly for many weeks of pregnancy, and data analysis requires a skilled health care professional. The technique is, therefore, suitable only for pregnancies deemed to be at high risk for preterm labor. Many randomized, controlled trials have evaluated the use of home uterine activity monitoring in such high risk pregnancies. The first six were reviewed qualitatively by the U.S. Preventative Services Task Force.[15] They concluded that there was insufficient evidence to recommend for or against home uterine activity monitoring as a screening test for preterm labor in high risk pregnancies, but recommendations against its use could be made on other grounds, including cost and inconvenience. In response to these recommendations, Colton and associates[16] conducted a meta-analysis of the same six studies, but accessed previously unpublished data from the study groups and defined four outcome measures: incidence of preterm birth, incidence of preterm labor with a cervical dilation of over 2 cm at diagnosis, neonatal admission to intensive care, and mean birth weight.[8,17–22] The meta-analysis, presenting data from six studies on a total of only 697 pregnancies, concluded that home uterine monitoring in singleton pregnancies was associated with a 24% reduction in preterm birth, a 52% reduction in "late presentation" with cervical dilation greater than 2 cm, and a significant mean increase in birth weight of 126 g. There was, however, no difference in the admission

rate to neonatal intensive care.[16] This analysis was controversial. Grimes and coworkers[23] analyzed the methodology of four of the six studies. They demonstrated that the included studies were of poor scientific rigor. Their combined crude relative risk for preterm birth was 0.9—a small improvement in outcome, which could easily have resulted from any one of the methodologic shortcomings. One of the criticisms of early trials of home uterine monitoring was that the increased level of support that the monitored patients received may have been responsible for any improvement seen in the outcome. Three trials addressed this possibility, one using a sham monitor but offering all patients nursing support,[24] the second offering monitoring without any nursing support,[25] and the third randomly assigning patients to both nursing support and home monitoring.[26] The first of these studies randomized 1992 women, 1165 of whom used home monitoring devices, but only 842 (72.3%) of them completed the study, suggesting that there may be difficulties with compliance when home monitoring devices are used for wider indications.[24] The study concluded that there was no evidence that either home uterine activity monitoring or daily nursing contact improved early diagnosis of preterm labor or reduced the rates of preterm birth or neonatal morbidity.[24] In contrast, the second, smaller study ($N = 218$), which also had a significant dropout rate in monitoring (15% did not complete the monitoring), found that the diagnosis of preterm labor could be made significantly earlier and that this affected the outcome, measured in terms of the interval between the diagnosis of labor and delivery, and was independent of nursing support.[25] However, the third study, which randomly assigned 2422 women to combinations of nurse contact and home monitoring, concluded that neither daily contact nor home monitoring improved pregnancy outcome beyond that seen with weekly nurse contact.[26]

Because little evidence indicates that home uterine monitoring is a useful screening tool for preterm labor, the number of studies examining its role has dropped significantly since the year 2000. During this time, interest in other markers for preterm delivery, such as sonographic assessment of the cervix and measurement of fetal fibronectin, has grown. Consequently, the recent data sets that review home uterine monitoring are often acquired in trials primarily designed to assess other screening tests or a combination of screening tools. Although most of the original trials defined preterm delivery before 37 completed weeks as their endpoint, more recent data sets are concerned with delivery before 34 weeks' gestation. Morrison and colleagues[27] assessed 85 asymptomatic women at high risk of preterm labor with both serial fetal fibronectin measurement and home uterine monitoring. They reported that 14 (16.5%) of the 85 women delivered before 34 weeks and the sensitivity and specificity of fetal fibronectin and home uterine monitoring alone were 43% and 89% (fetal fibronectin) and 64% and 85% (home uterine monitoring alone). When the two tests were combined, the specificity improved substantially but the sensitivity of a double-positive result was poor (3 of 14 cases [21%]), so they are not usefully combined in this manner.

A study of home uterine monitoring to assess the risk of preterm labor in 306 high-risk singleton pregnancies was reported in 2002.[28] These patients were also seen regularly at the hospital for serial assessment of fetal fibronectin and

for sonographic assessment of the cervix. All three investigations had a low sensitivity and poor positive predictive value for preterm delivery. The authors concluded that, although the likelihood of preterm delivery is associated with an increased frequency of uterine contractions, assessment of uterine activity is not clinically useful for predicting preterm delivery.

CERVICAL SCREENING

Ultrasound assessment of the cervix in normal pregnancy shows that cervical effacement starts around 32 weeks. In pregnancies affected by preterm labor, the process may begin between 16 and 24 weeks. Effacement begins at the internal os and can be visualized as cervical shortening and funneling, a process that occurs before dilation of the external cervical os. Ultrasound assessment potentially allows changes other than cervical dilation to be assessed with a higher degree of accuracy, and using a transvaginal route, assessment is possible in almost all cases.[29,30]

Ultrasound assessment of the cervix has been used in a variety of situations to improve the accuracy of a diagnosis of preterm labor and to predict the likelihood of a woman going into preterm labor. Screening has been studied in both high and low risk populations, and because the prevalence of preterm labor varies in these groups, these data sets are considered separately. A variety of techniques have been used to assess the cervix with ultrasound, and the multitude of studies describing the use of this test are heterogeneous in design, assessing the cervix at different stages of pregnancy, using either single or serial examinations, and choosing varying gestational ages at delivery to report the sensitivity and specificity of the test. A meta-analysis of antenatal transvaginal ultrasound assessment of the cervix identified 46 studies involving 31,577 pregnancies describing the effectiveness of this screening technique.[31] The review concluded that assessment of both cervical length and funneling, either alone or in combination, appeared to be useful in predicting spontaneous preterm birth in asymptomatic women, although there were less data available to assess the usefulness of this technique in symptomatic patients.

Digital Measurement of the Cervix

Sonek and associates[32] compared digital and transvaginal assessment of the cervix in 83 gravidas—56 from a population considered at-risk for preterm delivery and 27 with no risk factors. Analyzing the at-risk cohort, the authors found that in the second trimester, 87% of cervical length measurements by digital examination were less than those by transvaginal sonography, and 13% were greater. A similar association was seen in the third trimester. Linear regression analysis was used to evaluate the strength of association—the r-value was only 0.49. The authors concluded that digital assessment of the cervix is subjective and does not correlate well with transvaginal assessment.

Ultrasound Measurement of the Cervix

One of the problems with comparison of studies measuring cervical change is a lack of standardization of the

investigational technique. Most sonographers assess the cervix using a transvaginal scan, but transabdominal and transperineal routes can also be used. The cervix may be curved, and there may evidence of funneling; it is important to establish a method that allows for these differences in a consistent manner. The cervix is a dynamic structure, and measurements are affected by factors such as bladder filling and abdominal pressure.

A standardized technique for transvaginal cervical assessment has been described.[33] After the patient has emptied her bladder, a transvaginal probe (5–7 MHz) is introduced into the anterior fornix of the vagina, taking care to optimize image quality while avoiding undue pressure on the cervix that will distort anatomy. The whole length of the sonolucent endocervical mucosa is identified in a sagittal section, and the image is magnified so that this occupies 75% of the screen. Calipers are placed from the triangular echodense area marking the external os to the V-shaped indentation marking the internal os, and this distance is measured in a straight line. Three measurements are made over a period of 3 minutes to allow for any change in the state of the cervix, and the shortest measurement is reported. This technique allows clear views of the cervix and lower uterine segment and is acceptable to the majority of patients.

For women who do not find transvaginal sonography acceptable, or in circumstances in which vaginal examination ideally would be avoided (such as preterm prelabor rupture of membranes), alternative techniques such as transabdominal or transperineal/translabial assessment may be used. The limitations of these techniques, however, must be recognized. Transabdominal cervical assessment in 149 low risk singleton pregnancies at 23 weeks' gestation demonstrated that it was harder to visualize the cervix as it became shorter: a cervical length of less than 20 mm could be identified only 13% of the time, whereas a cervical length greater than 20 mm could be identified 51% of the time (X^2 4.52; P < .05). In addition, the cervix was significantly easier to visualize when the bladder was fuller, but this state is associated with an increase in the length of the cervix.[34] Given this finding, transabdominal assessment of cervical length should be abandoned in favor of transvaginal assessment.

Visualization can also be difficult using a transperineal/translabial approach, and there is some evidence that the "operator learning curve" with this technique is substantial, making it a less appropriate test for screening.[35] Many authors have reported a poor correlation between transvaginal and transperineal/translabial techniques, making interpretation of data more difficult.[35–37] Cervical length in a low risk population is normally distributed, with a mean length at 23 weeks' gestation of 35 to 38 mm; the 10th and 90th percentiles are approximately 25 mm and 45 mm, respectively.

Other cervical parameters have also been investigated. In many circumstances, a sagittal section of the entire length of the endocervical canal shows that it is in fact curved, and direct measurement from the internal to external os does not take this curvature into account. In these circumstances, cervical length would be undermeasured, and there would be a potential for false-positive screening results. To and coworkers[38] investigated this in a prospective series of 300 singleton pregnancies undergoing transvaginal cervical

assessment at 23 weeks' gestation. A curved cervix was seen in 48% of patients: in 51% of those with cervical length of 26 mm or more, 25% of those with cervical length of 16 to 25 mm, but 0% in those with cervical length of 15 mm or less. This group had previously defined that pregnancies with cervical length less than 15 mm should be considered to have a positive test result, and in these circumstances, the effect of cervical curvature would not be important.

Early studies of transvaginal cervical screening suggested that cervical funneling could also be reported and that this finding had an independent predictive role for preterm delivery.[39] Funneling can be assessed in a number of ways; subjectively, describing presence or absence, by measuring dilation at the internal os and the length of the endocervical canal that is involved, or by combining these features to give a cervical index.[40] In a series of 469 high risk pregnancies assessed longitudinally, funneling, determined in terms of width and length and the percentage of the cervix involved, was not found to give any additional information about risk if the cervical length was less than a screen-positive cutoff of 25 mm.[41] This was also the case in a series of 6819 low risk pregnancies screened at 23 weeks' gestation, in which funneling was defined as being present if the width at the internal cervical os was greater than 5 mm.[42] In this series, funneling appeared to be almost universally associated with a short cervix, and there was no apparent advantage to its inclusion as a screening criterion.

Cervical Assessment in Asymptomatic Patients at High Risk for Preterm Labor

Women with a previous history of preterm labor or preterm prelabor rupture of membranes together with women who have previously had cervical surgery or have a known uterine anomaly are considered to be at high risk of preterm labor. Other inclusion criteria have included extreme maternal age, in utero exposure to diethylstilbestrol, and maternal genetic anomalies such as Ehler-Danlos syndrome. The rationale for screening in this group is to allow early intervention that would prevent the onset of preterm delivery or preterm prelabor rupture of membranes.[43–45] It is not currently clear what the optimum gestation for screening is, what cervical cutoff should be used to define a screen-positive group, or whether serial scans would be more appropriate than a single scan.

There is a strong association between a short cervix and preterm delivery in high risk pregnancies. Cook and Ellwood[46] showed that cervical length less than 21 mm at less than 20 weeks' gestation was associated with 95% delivery by 34 weeks' gestation. Guzman and colleagues[40] examined 469 women at high risk of preterm delivery with singleton pregnancies serially (mean of three occasions) between 15 and 24 weeks' gestation. The cervix was 25 mm or less in length in 23.4% of women, including 76% of those delivering before 34 weeks' gestation. The negative predictive value of this cutoff was 96%. Similarly, Owen and associates[36] demonstrated that a single examination at 16 to 19 weeks' gestation with a cervix 25 mm or less in length increased the risk of preterm delivery by 35 weeks' gestation 3.3 times (95% confidence interval [CI] 2.1–5.0) and found that if serial examinations up to 24 weeks'

gestation were performed, a single cervical length of less than 25 mm increased the risk of preterm labor 4.5 times (95% CI 2.7–7.6). Only limited data are available about the value of serial screening beyond 24 weeks' gestation, but in one small study (N = 69) of high risk pregnancies examined every 2 weeks from 16 to 30 weeks' gestation, cervical length and funneling were found to be significant at evaluations performed at 20 to 24 weeks as well as 25 to 29 weeks.[47]

Cervical Assessment in Asymptomatic Patients at Low Risk for Preterm Labor

The rationale for screening in a general, low risk population is that a significant proportion of preterm deliveries occur in pregnancies with no historical risk factors. The apparent effectiveness of screening high risk populations has led many groups to examine screening in a low risk group, and evaluation of cervical length seems to be of similar predictive value in this setting.[48–52] Iams and coworkers[48] reported a multicenter study of 2915 pregnancies recruited through 10 university perinatal centres in the United States. Investigators used a clearly described method to assess cervical length; the process involved initial training, a period of standardization of technique, and continuing audit of the quality of examinations. Both cervical length and funneling were examined, but although funneling seemed to be equally predictive of outcome, the authors noted that determination of this sign was less consistent, with a prevalence of 0% to 12.7% across centers. The predictive value of cervical assessment was reported in terms of the proportion of spontaneous preterm deliveries that occurred before 35 weeks' gestation; this occurred in 126 (4.3%) of the pregnancies enrolled. The mean cervical length at 24 weeks was 34.0 mm ± 7.8 mm for nulliparous women and 36.1 mm ± 8.4 mm for parous women. Cervical length was noted to be "normally" distributed. A cervical length less than 20 mm was found in less than 5% of women, and this group included 23% of preterm births (sensitivity); the specificity, positive predictive, and negative predictive values were 97, 25.7, and 96.5, respectively. The relative risk of preterm labor associated with various cervical lengths was also reported. These data were calculated relative to the risk of preterm delivery in the top quartile rather than relative to the background population as a whole. This approach demonstrated that there is a significant association between the risk of preterm labor and a short cervix. It also demonstrated that there was a continuum of risk, and the authors suggested that this challenged the traditional concept that the cervix is either competent or incompetent and provided evidence that cervical competence should be considered as a continuous variable.

Four other studies have examined large (>500 pregnancies) groups of low risk singleton pregnancies.[49–52] Although they are not directly comparable with the study of Iams and coworkers described earlier,[48] a review of their results demonstrates similar findings, that is, the risk of spontaneous preterm birth is inversely related to cervical length (Table 60–1).

As detailed previously, until recently, there was little evidence to suggest that screening in a low risk population was

useful, because an effective intervention to improve pregnancy outcome had not yet been demonstrated.

Papiernik in 1970[53] was the first to use progesterone for the prevention of preterm birth. Ninety-nine women identified as being at risk of preterm birth via a risk scoring system were randomly assigned to either weekly injections of 17α-hydroxyprogesterone caproate or placebo. The preterm delivery rate in the intervention group was 4% compared with 18% in the placebo group. This initial study prompted multiple other studies aimed at determining the efficacy of progesterone in the prevention of preterm birth. These initial studies were summarized by two conflicting meta-analyses by Goldstein and colleagues[54] and Keirse.[55]

Interest in the efficacy of progesterone in preventing preterm birth was reignited in 2003 by da Fonseca and associates.[56] They randomized 157 asymptomatic, high risk (≥1 prior spontaneous preterm delivery, prophylactic cervical cerclage, or uterine malformation), singleton women to either progesterone (100 mg; $N = 72$) or placebo ($N = 70$) vaginal suppositories. They concluded that progesterone was effective in reducing the incidence of delivery prior to 37 (13.8% vs. 28.5%; $P = .03$) and 34 (2.8 vs. 18.6%; $P = .002$) weeks. However, they did not comment on perinatal outcomes.

Meis and coworkers[57] concluded that weekly intramuscular injections of 250 mg 17α-hydroxyprogesterone acetate from 16 to 20 weeks to 36 weeks in women at risk of preterm delivery based on historical factors significantly reduced the rate of spontaneous preterm delivery (<37 wk: 36.6% vs. 54.9%; relative risk [RR] 0.66; 95% CI 0.54–0.81) (<35 wk: 20.6 vs. 30.7%; RR 0.67; 95% CI 0.48–0.93) (<32 wk: 11.4 vs. 19.6%; RR 0.58; 95% CI 0.37–0.91) and was also associated with reduced rates of birth weight less than 2500 g (27.2% vs. 41.1%; RR 0.66; 95% CI 0.51–0.87), supplemental oxygen (14.9% vs. 23.8%; RR 0.62; 95% CI 0.42–0.82), and intraventricular haemorrhage (1.3% vs. 5.2%; RR 0.25; 95% CI 0.80–0.82).

However, O'Brien and colleagues[58] concluded that daily intravaginal progesterone gel (equivalent to 90 mg) in women at risk of preterm delivery based on historical factors did not reduce the rate of early preterm delivery (≤32 wk) or decrease perinatal mortality/morbidity rates.

In an attempt to clarify the role of progesterone in preventing preterm delivery, Dodd and associates[59] for the *Cochrane Collaboration* in 2006 performed a meta-analysis and concluded that intramuscular progesterone is associated with a reduction in the risk of preterm delivery (<37 wk: RR 0.68; 95% CI 0.56–0.82) and birth weight less than 250g (RR 0.63; 95% CI 0.49–0.81). Intravaginal progesterone is associated with a reduction in the risk of preterm birth (<37 wk: RR 0.49; 95% CI 0.25–0.96) (<34 wk: RR 0.15; 95% CI 0.04–0.64).

In 2007, Fonseca and associates[5] published a randomized, controlled trial suggesting that effective screening by measuring cervical length between 20 and 25 weeks' gestation and therapeutic intervention for those with a cervical length of 15 mm or less with progestins (200 mg intravaginal suppositories) to 34 weeks could reduce the risk of preterm delivery (<34 wk: 20.8% vs. 36.0%; RR 0.58; 95% CI 0.38–0.87). There was no statistically significant reduction in perinatal mortality or morbidity; however, the trial was not sufficiently powered to address these points.

Whereas there is sufficient evidence that cervical length assessment can accurately predict those women who are at risk of preterm delivery, evidence regarding intravaginal/intramuscular progesterone therapy preventing preterm delivery and especially improving perinatal outcomes is less clear-cut. Therefore, it is the opinion of the authors that a screening policy such as transvaginal assessment of cervical length should be offered to all women at the time of their routine anomaly ultrasound because this would facilitate identifying those women in need of close surveillance and potentially enable timely administration of corticosteroids. Further research is warranted as to whether progesterone therapy results in improved perinatal outcomes, and "at risk" women should be encouraged to enroll in future trials that address this question.

Cervical Assessment in Patients Symptomatic of Preterm Labor

Early diagnosis of preterm labor potentially allows early intervention to reduce the risk of preterm delivery or to optimize conditions for the premature neonate. The clinical diagnosis of labor is dependent on the presence of uterine activity with cervical effacement and dilation, and accurate cervical assessment is therefore important. Traditional digital examination tends to be imprecise, with large margins of inter- and intraoperator error. The rationale for using ultrasound to assess the cervix in women presenting with symptoms of preterm labor is that cervical assessment will be more precise, allowing earlier treatment of women with evidence of cervical change but reducing the proportion of women who are not in preterm labor and have unnecessary treatment.

Cervical effacement has many potential causes. This process may be biologic or may represent a mechanical weakness that is revealed as the uterus becomes distended. Alternatively, it may be secondary to the onset of uterine contraction or to inflammation and the release of local hormones in response to infection or hemorrhage. It is unlikely that a single form of therapy will resolve all the etiologies underlying cervical effacement and dilation, and this may explain why most randomized, controlled trials of cervical cerclage have not shown this to be an effective method of preventing preterm birth.

Cervical Screening in Twin Pregnancies

The incidence of preterm delivery is significantly higher in multiple pregnancies, with a consequent effect on perinatal mortality and morbidity rates in these infants. From 5% to 10% of twins deliver before 33 weeks' gestation, a sixfold increase over the rate of preterm delivery in singleton pregnancies by this gestation.[60] Despite this, fewer studies have assessed the use of cervical screening in twin pregnancies, and it is less clear whether ultrasound assessment is useful or at what week of gestation ultrasound should be performed.

A prospective cohort of 177 pregnancies was used to evaluate cervical length in normal twin pregnancies.[61] Of these 177, 28 (16.3%) pregnancies delivered before 34 weeks' gestation and were excluded from further analysis. In

the remainder, the mean cervical length decreased from 47 mm at 13 weeks' gestation to 32 mm at 32 weeks' gestation in a linear fashion. The rate of cervical shortening was 0.8 mm/wk.

Ong and coworkers[62] suggested that from a clinical perspective, it is not the estimation of risk per se that is important, but the prediction of preterm labor within a limited timeframe, allowing admission, preparative treatment (such as steroid therapy), and transfer to a unit with appropriate neonatal facilities. Cervical length was assessed every 2 weeks in 46 twin pregnancies between 24 weeks' gestation and delivery. Only data from pregnancies that labored spontaneously were subsequently included in the analysis. There was no difference in the rate of shortening between pregnancies delivering before and after 37 weeks' gestation. An absolute threshold for cervical length was, however, more useful: cervical lengths of less than 20 mm and less than 25 mm had relative risks of delivery within 1 week of 11.67 (95% CI 4.23–32.17) and 4.12 (95% CI 1.10–15.47), respectively. A similar longitudinal study of only 20 twin pregnancies suggested a difference in the rate of cervical shortening between women delivering preterm (<36 wk' gestation) and those delivering at term. After excluding 1 preterm delivery that had a short cervix at the time of the first scan (10 mm at 24 wk' gestation), the rate of shortening was found to be 2.9 mm/wk and 1.8 mm/wk in preterm and term pregnancies, respectively. This difference was not statistically significant, but this may have been due to the relatively low numbers enrolled.[63]

Skentou and colleagues[64] also examined various thresholds for cervical length to predict the risk of preterm delivery. This prospective study of 464 twin pregnancies involved a single transvaginal ultrasound assessment at 23 (22–24) weeks' gestation. This study included 313 (67.5%) dichorionic and 151 (32.5%) monochorionic twin pregnancies and found no significant difference in the rate of preterm delivery (defined as before 34 wk' gestation) in these two groups. A significant inverse relationship was found between cervical length and the risk of preterm birth (risk = 26.48 × cervical length − 1.688) such that thresholds of 15 mm, 20 mm, and 25 mm detected 17.6%, 39.1%, and 46.4% of twin pregnancies delivering before 34 weeks, respectively. The corresponding screen-positive rates were higher than those seen in singleton pregnancies: 2.1%, 4.7%, and 9.6%.

In addition to assessing cervical length, Guzman and associates[65] looked at cervical funneling and the effect of transfundal pressure during the examination. A series of 131 pregnancies were examined serially between 15 and 28 weeks' gestation. The effectiveness of assessments at 15 to 20, 21 to 24, and 25 to 28 weeks' gestation for the prediction of preterm delivery by 28, 30, 32, and 34 weeks' gestation were evaluated. Although the cervix was significantly shorter with transfundal pressure, this application did not improve the investigators' ability to predict preterm labor. A cervical length of less than 20 mm was found to be at least as good as any other characteristic at predicting spontaneous preterm delivery.

These data differ slightly from the findings of another group who investigated the associations between preterm delivery and a short cervix and cervical funneling in a series of 251 twin pregnancies, examined at 22 and 27 weeks' gestation.[66] A receiver operating characteristic curve showed

no clear best cutoff point for cervical length at 22 weeks' gestation, although a cutoff of 25 mm appeared best at 27 weeks' gestation. Using this cutoff at 22 weeks (for comparison with other data sets) gave a sensitivity of 38% and specificity of 97% for preterm delivery before 32 weeks' gestation. Cervical funneling, considered to be present when the lateral border of the funnel was more than 3 mm in length, was present in 12.4% of pregnancies at 22 weeks' gestation, and this finding had a sensitivity of 54% and a specificity of 89% as an indicator of preterm birth by 32 weeks' gestation. The authors concluded that cervical length and funneling both predict very preterm birth and that, although cervical length is the method of choice at 27 weeks' gestation, at 22 weeks the diagnostic characteristics of both parameters are close.

CERVICOVAGINAL FETAL FIBRONECTIN

Fetal fibronectin is a glycoprotein found in amniotic fluid, placental tissue, and the decidua basalis.[67] Although its specific function remains uncertain, it is thought to play a role in implantation and placental-uterine attachment. It is normally found in cervicovaginal secretions before 16 to 18 weeks' gestation, before fusion of the fetal membranes and the decidua is complete. Similarly, it is found at the end of pregnancy, prior to the onset of labor, but it is not normally present in cervicovaginal secretions between 22 and 37 weeks. It has been suggested that the presence of fetal fibronectin in cervicovaginal secretions in the later part of the second trimester and in the early part of the third trimester of pregnancy is due to disruption of the chorionic-decidual interface and is often secondary to infection.[68]

Initial studies establishing the presence of fetal fibronectin in cervicovaginal secretions involved extensive laboratory analysis that delayed the availability of results. An enzyme-linked immunosorbant assay containing the FDC-6 monoclonal antibody has been developed that can be used at the bedside, potentially making this test a much stronger clinical tool.[69] Intercourse/digital examination within 24 hours, vaginal bleeding, and the presence of ruptured membranes are associated with false-positive results. The use of lubricant jelly is associated with a false-negative result.

A large systematic review of 64 primary articles reporting the effectiveness of screening for preterm delivery by the detection of cervicovaginal fetal fibronectin in a total of 26,876 women was published in 2002.[70] There were two large subsets of women, asymptomatic and symptomatic of preterm labor. Among asymptomatic women, the likelihood ratio for predicting preterm delivery before 34 weeks was 4.01 (95% CI 2.93–5.49) with a likelihood ratio for negative results of 0.78 (95% CI 0.72–0.84). Among those women who were symptomatic, the likelihood ratio for positive results was 5.42 (95% CI 4.36–6.74) for predicting birth between 7 and 10 days of testing, with a corresponding negative likelihood ratio of 0.25 (95% CI 0.20–0.31).

Another meta-analysis in 2003, confined to reports in the English language, found that fetal fibronectin was useful in the prediction of delivery before 34 weeks, with an overall sensitivity of 53% and specificity of 89%.[71] The sensitivities for prediction of delivery within 7, 14, and 21 days were

71%, 67%, and 59%, respectively. The corresponding specificities were 89%, 89%, and 92%. Further analysis of studies in asymptomatic women who could be divided into low risk and high risk showed that for a single sampling of fibronectin, sensitivity for detection of delivery prior to 34 weeks was 41% (21%–59%) for low risk women with a specificity of 94% (91%–96%). For high risk women, the sensitivity was considerably lower at 23% (14%–32%) but with a comparable specificity of 94% (93%–96%). The studies of serial sampling of cervical fibronectin showed a higher sensitivity of prediction of delivery prior to 34 weeks with low risk and high risk groups showing a sensitivity of 68% (52%–83%) and 92% (62%–100%), respectively. Predictably, the specificities in each group of serial sampling were significantly reduced (there is an independent chance of a false-positive result every time the test is done, so the specificity falls as the number of samples, and hence false positives, increases). The few studies looking at multiple pregnancies have small numbers and result in sensitivities and specificities with such broad CIs that a meaningful conclusion cannot be drawn.

Subgroup analysis of symptomatic and asymptomatic pregnancies demonstrated that this test was most sensitive in women with symptoms of preterm labor, but its usefulness as a screening test for decisions about hospital admission and the administration of glucocorticoids is reduced by the fact that the specificity is significantly lower than in asymptomatic women. The authors concluded that fetal fibronectin is a reasonably effective marker in predicting preterm delivery in the short term, particularly if there are symptoms of preterm labor.

Combined Cervical Screening and Fibronectin

The combined use of ultrasound and fibronectin has been evaluated in only a few studies and in symptomatic women. Rizzo and coworkers[72] found that combining cervical sonography with fibronectin screening improved diagnostic accuracy and allowed better prediction of the admission to delivery time. Other investigators have found that fibronectin and cervical length had comparable ability to distinguish those at high and low risk of preterm delivery, but that their combination provides little added benefit.[73] Hincz and colleagues[74] proposed a two-step test only when the cervical length was in an immediate range of 21 to 31 mm. This form of testing had an overall sensitivity of 86% with a specificity of 90% for predicting delivery within 28 days. Similarly, Schmitz and associates[75] conducted a prospective, blinded, observational study to determine if the selective use of fetal fibronectin after ultrasound measurement of cervical length (<25 mm) predicts preterm delivery in symptomatic women better than either test alone. They found that the selective use of fetal fibronectin after cervical length measurement was more specific than cervical length measurement alone. The specificity of cervical length alone in predicting delivery less than 35 weeks and less than 7 days was 63% (95% CI 58–69%) and 61% (95% CI 56–67%), respectively. These values increased to 81% (95% CI 77–86%) and 79% (95% CI 74–83%), respectively, with sequential screening.

SCREENING FOR BACTERIAL VAGINOSIS IN EARLY PREGNANCY

Bacterial vaginosis (BV) is characterized by an overgrowth of a mixture of organisms (*Gardnerella vaginalis*, *Mobiluncus*, *Bacteroides* spp., and *Mycoplasma hominis*), is often asymptomatic, and may resolve spontaneously. Although the role of BV in preterm labor is poorly understood, several reports[76,77] found that the relative risk of preterm labor is doubled if the mother has BV. The hypothesis is that the organisms found in BV ascend into and colonize the chorionic-decidual space, resulting in preterm labor or preterm rupture of membranes. This increase in invasion of the genital tract may be due to the rise in pH, which is a key feature of BV, allowing vaginal bacteria to proliferate relatively unchecked. Two studies[78,79] suggest that infection in early pregnancy may be a greater risk factor than BV infection in the late second trimester and early third trimester of pregnancy.

Leitich and coworkers[80] performed a meta-analysis to evaluate the risk of preterm delivery associated with BV; 20,232 patients in 18 studies were included. They found that BV increased the risk of early delivery (<37 wk' gestation) with an odds ratio (OR) of 2.19 (95% CI 1.54–3.12). A subgroup analysis showed that if BV was identified prior to 16 weeks, then the risk of preterm birth was further increased with an OR of 7.55 (95% CI 1.80–31.65). Even at less than 20 weeks, a finding of BV was associated with an OR of 4.20 (95% CI 2.11–8.39) for preterm birth. This analysis found no particular association of BV with delivery prior to 34 weeks; however, few studies used that gestation time as an outcome and the studies that used early screening used less than 37 weeks as their criterion for preterm delivery. There is little evidence that screening for BV in specific subgroups, particularly in women with a prior preterm delivery and in multiple gestations, improves its sensitivity or specificity.

Despite this reasonably convincing evidence of a link between early infection with BV and preterm delivery, screening and subsequent treatment of BV remain controversial. The recent review of the *Cochrane Collaboration*[81] of 15 trials of 5888 women showed that antibiotic therapy successfully treated BV but failed to reduce the risk of preterm birth before 37 weeks, with OR 0.91 (95% CI 0.78–1.06); at 34 weeks, with OR 1.22 (95% CI 0.67–2.19); or 32 weeks, with OR 1.14 (95% CI 0.76–1.70). In those women who had a previous preterm birth, treatment of BV did not decrease the risk of a subsequent preterm birth (<37 wk), OR 0.83 (95% CI 0.59–1.17), but did decrease the risk of preterm premature rupture of membranes, OR 0.14 (95% CI 0.05–0.38) and the risk of delivering a low–birth weight neonate, OR 0.31 (95% CI 0.13–0.75). Screening and subsequent treatment at less than 20 weeks' gestation decreased the risk of preterm premature rupture of membranes, OR 0.14 (95% CI 0.04–0.44), decreased the risk of preterm birth before 37 weeks, OR 0.72 (95% CI 0.55–0.95), but did not decrease the risk of preterm birth before 34 weeks, OR 0.39 (95% CI 0.07–2.07). Carey and colleagues[82] failed to show oral metronidazole therapy to be useful in prevention of preterm labor in a mixed population.

At present, the role of screening for BV and then treating it is not clear in a low risk population. It possibly has benefit in a high risk population, but further controlled studies are required.

Editor's note: As this chapter was going to press, a report of a double-blind, placebo-controlled, randomized trial of the use of prophylactic progesterone to reduce the rate of preterm birth or stillbirth in twins appeared in the *Lancet*.[83] In the progesterone group, 24.7% of women delivered before 34 weeks or had a stillbirth, compared with 19.4% in the placebo group (OR 1.36; 95% CI 0.89–2.09). (There were 6 stillbirths in the progesterone group and 4 in the placebo group). The authors also performed a meta-analysis of all available studies on the use of progesterone in twin pregnancies. This confirmed that progesterone does not prevent early preterm birth in women with twin pregnancy (pooled OR 1.16, 95% CI 0.89–1.51).

SUMMARY OF MANAGEMENT OPTIONS
Screening for Spontaneous Preterm Labor and Delivery

Management Options	Evidence Quality and Recommendation	References
Uterine Activity Monitoring		
Self-monitoring applies to whole population but has a poor sensitivity.	IIb/B	7
Any improved outcome reported in monitored pregnancies may represent the benefits of increased education and support inherent in the studies.	Ib/A	8

Threatened and Actual Preterm Labor Including Mode of Delivery

JOHN M. SVIGOS, JODIE M. DODD, and
JEFFREY S. ROBINSON

INTRODUCTION, DEFINITION, AND INCIDENCE

Preterm birth is estimated to affect approximately 13 million births annually worldwide.[1] Preterm labor (PTL) is defined by the World Health Organization as the onset of labor after the gestation of viability (20–28 wk, depending on definition) and before 37 completed weeks or 259 days of pregnancy.[2] The onset of labor may be determined by documented uterine contractions (at least one every 10 min) and ruptured fetal membranes or documented cervical change with an estimated cervical length of less than 1 cm or cervical dilation of more than 2 cm. Threatened PTL is diagnosed when there are documented uterine contractions but no evidence of cervical change.

Despite these apparently clear definitions, and because of the need for early management of suspected PTL, it is common for clinicians to make the diagnosis before the just-discussed criteria are met. Hence, the reported incidence of threatened PTL is likely to be considerably greater than the real incidence of actual PTL (at least double). In the 1970s, O'Driscoll[3] suggested that the pregnant woman's own diagnosis of PTL based on her perception of uterine contractions may be incorrect in 80% of instances. In the 1980s, Kragt and Keirse[4] demonstrated that 33% of women presenting with contractions could be safely discharged home in 48 hours without requiring treatment. In the Overview of Role of Antibiotics in Curtailing Labour and Early Delivery (ORACLE) II study in 2001,[5] the difficulty in diagnosing PTL accurately was clearly demonstrated, with 63.5% of women enrolled in the study with threatened PTL delivering after 37 weeks' gestation.

The incidence of preterm birth in developed countries is reported to vary widely, ranging from 4.4% in Ireland to 12.7% in the United States. In South Australia in 2006,[6] the overall preterm delivery (PTD) rate was 8.2%, of which 53.6% occurred following the spontaneous onset of labor. Doubts have been expressed about the current estimates of PTD compared with previous years because they increasingly reflect the increased survival of extremely preterm, very low–birth weight infants who previously would have been regarded as "nonviable." Registration practices have also altered because of changes in the definition of viability in which, previously, babies that are now registered as PTDs would have been recorded in the past as mid-trimester miscarriages, thereby compounding any ascertainment bias already present. Approximately 50% of PTDs are a result of spontaneous PTL, 30% follow preterm premature rupture of the fetal membranes (PPROM), and the other 20% are indicated PTDs for maternal or fetal indications.[7] There are now studies from both Denmark[8] and Australia[9] reporting an increase in the occurrence of spontaneous PTD even among women considered to be of low risk, to 22% and 12% of all PTDs, respectively. Major components of this rise are likely to be the rise in multiple births secondary to the growing use of assisted reproductive techniques, increases in body mass index (the "epidemic" of obesity), and the rising incidence of sexually transmitted disease. In addition, a significant proportion of this increase is related to medically indicated iatrogenic PTDs. These are justified on the basis of a substantial decline in gestation specific stillbirth and neonatal mortality rates,[7] with the largest proportion of such births occurring between 34 weeks and 37 weeks (now referred to as "late preterm births"). In South Australia in 2006, 66.9% of PTDs occurred between 34 weeks and 37 weeks.[6] Recent long-term follow-up studies on this group of preterm infants have demonstrated poorer perinatal outcomes compared with babies born after 37 weeks' gestation, and this may lead to a reappraisal of policies involving early delivery.[7]

In westernized countries, PTL accounts for approximately 70% of neonatal mortality and almost 50% of all long-term neurologic morbidity, with an associated major economic impact on health budgets. Figures from the United States suggest that the annual cost associated with care of infants born preterm is in excess of $26 billion.[10]

Current management regimens can be directed only to the approximately 10% to 15% of our obstetric population who present with threatened or actual PTL, and our current failure to impact substantially on this cohort of women has in part been due to our lack of understanding of the etiology of PTL, which appears to be diverse, and in addition, our inability to prevent or reverse the final common pathway of the cytokine/prostaglandin cascade and uterine contractions. To emphasize the complexity of any attempts at

prevention, in Project 27/28 in the United Kingdom, all babies born between 27 and 28 weeks' gestation (3522) in 1 year were reported to The Confidential Enquiry into Still-births and Deaths in Infancy (CESDI).[11] A 2-year follow-up of 761 of these babies demonstrated that major placental bleeding (18%), pregnancy-induced hypertension (21%), prelabor rupture of the membranes (31%), clinical chorio-amnionitis (11%), idiopathic PTL (55 %), cervical incompetence (5%), bacteriuria (7%), and maternal smoking were the most important antecedents of the PTDs.[11]

As a consequence of this diverse etiology, we have a diversity of management regimens that are directed toward improving neonatal outcomes either by trying to prevent delivery before 37 weeks' gestation or by delaying delivery to optimize the available resources prior to PTD. However, in applying these management regimens, we must continue to be mindful of their efficacy (and, often, lack of it) and of the inherent risks to mother and baby of many of the treatments used.

MATERNAL RISKS

General Risks

Consideration of PTD makes it clear that many of its etiologic associations have their origins in maternal pathology and these carry risks for the mother as well as for the fetus.

If PPROM and "idiopathic" PTL are excluded, then the two most common maternal conditions associated with PTD are pregnancy-induced hypertension and antepartum hemorrhage. These may either precipitate PTL spontaneously or prompt the deliberate induction of PTL in order to resolve the maternal problem or deliver the fetus from an adverse environment. Induction of labor may of itself carry risks for the mother (see Chapter 66) and demands careful consideration.

Tocolytic Agents

β-Sympathomimetics

The Cochrane Systematic Review by Anotayanonth and coworkers[12] assessed 11 trials involving 1320 women comparing the use of β-sympathomimetic agents with that of placebo and demonstrated that β-sympathomimetics were significantly associated with withdrawal from treatment owing to the following adverse maternal effects: chest pain, dyspnea, tachycardia, palpitations, tremor, headaches, hypokalemia, hyperglycemia, nausea and/or vomiting, and nasal stuffiness. Gyetvai and colleagues in a systematic review[13] found the incidence of adverse maternal effects of sympathomimetics compared with no treatment or placebo to be palpitations (48% vs. 5%), tremor (39% vs. 4%), nausea (20% vs. 12%), headache (21% vs. 6%), and chest pain (10% vs. 1%). Rare but serious and potentially life-threatening adverse effects have also been reported. Pulmonary edema is an insidious problem, the frequency of which is difficult to estimate. It is thought to be more common with multiple pregnancies receiving concomitant corticosteroid therapy for fetal lung maturation. Combination with other tocolytic agents, unrecognized chorioamnionitis, and fluid overload are major contributory factors. Myocardial

ischemia due to diffuse myocardial micronecrosis may constitute an infrequent but serious maternal hazard, whereas underlying diabetes, thyrotoxicosis, or cardiac disease can accentuate the biochemical effects of hypokalemia and hyperglycemia seen with these agents. Although β-sympathomimetic agents have been the mainstay of tocolytic regimens in the management of PTL, other agents are now being used because they appear to have fewer adverse effects with comparable effectiveness. However, it must be stressed that none of these agents is without risk for the mother.

Nonsteroidal Anti-inflammatory Agents

Nonsteroidal anti-inflammatory drugs (NSAIDs) are inhibitors of the cyclooxygenase (COX) enzyme (prostaglandin synthetase), which plays an integral role in the initiation and maintenance of labor. The most common maternal side effects or complications of these drugs include peptic ulceration, gastrointestinal bleeding, thrombocytopenia, postpartum hemorrhage, renal function impairment, with depression, dizziness, psychosis, and headaches after long-term use. It has been shown that labor is associated with up-regulation of the expression of COX-2 (constitutive type isoform), but not COX-1, within the uterus, and it was anticipated that selective COX-2 agents might have fewer adverse effects than COX-1 agents. However, although a Cochrane Systematic Review by King and associates[14] demonstrated a low incidence of adverse drug reactions requiring cessation of treatment with nonselective COX antagonists compared with other types of tocolytic agents (relative risk [RR] 0.07; five trials with 355 women in total), a comparison of nonselective COX inhibitors versus any COX-2 inhibitor (two trials, 54 women in total) did not demonstrate any differences in maternal side effects (although the numbers are small).

Calcium Channel Blockers

Following the initial favorable report of Read and Wellby in 1986,[15] nifedipine and other calcium channel blockers have been increasingly used in the management of PTL. Although uncommon, there have been reports of pulmonary edema, maternal hypotension, and hepatotoxicity associated with the use of calcium channel blockers, whereas caution is advised if magnesium sulfate is being administered concurrently for eclampsia prophylaxis because there may be potentiation of the side effects described for both agents. The systematic review by King and coworkers,[16] of 12 randomized, controlled trials involving 1029 women, demonstrated a reduced requirement for women requiring calcium channel blockers to have treatment stopped because of adverse drug reactions compared with sympathomimetics (RR 0.14; 95% confidence interval [CI] 0.05–0.36).

Oxytocin Receptor Antagonist (Atosiban)

Atosiban has been compared with three different β-sympathomimetic agents in a large multicenter study[17] and was found to be associated with fewer adverse maternal effects such as chest pain, palpitations, tachycardia, hypotension, dyspnea, nausea, vomiting, and headache. There was only one case of pulmonary edema in the atosiban group compared with two in the β-sympathomimetic group. Atosiban has been licensed in Europe and the United Kingdom

for use as a tocolytic (although not in the United States), but its relatively high cost limits its use. In addition, the Cochrane Systematic Review by Papatsonis and colleagues[18] identified two randomized trials involving 651 women in which atosiban was compared with placebo. When compared with placebo, the use of atisoban was not associated with a reduction in the risk of PTD and, in one study, was associated with an increase in the risk of infant death to 12 months of age. When compared with β-sympathomimetic agents, atisoban was associated with a fewer maternal side effects requiring cessation of therapy (RR 0.04; 95% CI 0.02–0.11, four trials, 1035 women), but was associated with an increase in the likelihood of a birth weight less than 1500 g (RR 1.96; 95% CI 1.15–3.35, three trials, 575 infants).

Nitric Oxide Donors

The systematic review by Duckitt and Thornton[19] of five randomized, controlled trials involving 466 women in total demonstrated that these women being treated with nitric oxide (NO) donors were more than six times more likely to experience headache, without any evidence of improved efficacy against placebo or other tocolytics. From the available evidence, the authors were unable to support its use in the management of threatened or actual PTL.

Magnesium Sulfate

The Cochrane Systematic Review by Crowther and associates[20] of 2000 women in 23 trials failed to support its use as an effective tocolytic agent, but despite this lack of effectiveness, magnesium sulfate is still widely used in North America for this purpose. Elliott's study[21] of maternal side effects found that these occurred in 7% of patients and required cessation of treatment in 2% of patients. Cutaneous vasodilation, flushing, nausea, vomiting, palpitations, and headaches were the most common side effects reported, with maternal hypothermia, bone demineralization, and paralytic ileus being less common. Pulmonary edema and adult respiratory distress syndrome were reported to occur in 1% of patients. Hypermagnesemia can also lead to maternal respiratory depression and cardiac arrest. In view of these significant side effects and the lack of efficacy, the use of magnesium sulfate as a tocolytic agent cannot be supported.

Summary

It is important to be aware that, although tocolytic agents have been shown to reduce the proportion of births occurring up to 7 days after beginning treatment, there is no clear evidence of any benefit of their use on reducing perinatal or infant mortality or serious morbidity. This may be because by suppressing uterine activity, they are damaging the fetus by keeping it in an adverse intrauterine environment, thus negating any advantage of prolonging gestation. Accordingly, the current "green-top" guidelines of the Royal College of Obstetricians and Gynaecologists of the United Kingdom (Tocolytic Drugs for Women in Preterm Labour, Clinical Guideline No. 1[B] available at http://www.rcog.org.uk/files/rcog-corp/GT1BTocolyticDrug2002revised.pdf) state that "In the absence of clear evidence that tocolytic drugs improve outcome following preterm labour, it is reasonable not to use them. The women most likely to benefit from tocolysis

are those who are still very preterm, those needing transfer to a hospital that can provide neonatal intensive care or those who have not yet completed a full course of corticosteroids to promote fetal lung maturation. For these women, tocolytic drugs should be considered."

Maternal Risks Associated with the Mode of Delivery in Preterm Labor

Cesarean section as the preferred mode of PTD, particularly for the very preterm infant (<30–32 wk' gestation), is a practice that did not receive adequate scrutiny before it came into common use. With it came significant maternal morbidity related to a poorly formed lower uterine segment, increased operative hemorrhage, infection, and the potential for compromised future uterine function—all this without documented improvement in perinatal mortality and morbidity rates. A systematic review by Grant and coworkers[22] of six trials of elective versus selective cesarean delivery for infants less than 30 weeks' gestation not only demonstrated the difficulty of randomization of the mode of delivery in this clinical situation (with only 122 women recruited) but also concluded that decision-making on an individual basis taking into account parental preference was all that could be recommended from the available data. The use of classic cesarean section for gestations less than 30 weeks carries more risk of maternal morbidity than the lower segment approach, and unpublished data from a small series by Stacey and Steer (personal communication) would suggest that it confers no particular benefit for the fetus. In addition, there are considerable risks of maternal morbidity following classic cesarean section as well as significant implications for mode of birth in subsequent pregnancies.

Assessment of the impact of the psychological trauma experienced by the patient, her partner, and her family in relation to the management of threatened or actual PTL is difficult, and this short paragraph cannot do justice to the magnitude and importance of this problem. The physical restrictions imposed by the use of intravenous tocolytics, coupled with their often incapacitating side effects, the impersonality of the required multidisciplinary approach, the institutionalization (often with geographic dislocation) that is commonly necessary, added to the uncertainty of the perinatal outcome and the delayed maternal-infant bonding that are inherent in contemporary management of PTL, are probably the major conflicts experienced. These factors must be kept in mind as we attempt to further reduce the maternal risks associated with PTL.

FETAL AND NEONATAL RISKS
Risks of Associated Pathology

Compromised fetal well-being is often the precipitating factor in PTL. Hence, intrauterine fetal death, intrauterine growth restriction, major congenital fetal anomalies, intrauterine fetal infection, and complicated multiple pregnancy may all contribute to the perinatal mortality and morbidity associated with PTL.

Risks of Prematurity

Physicians and parents struggle with the type of care they might wish to be provided for extremely premature infants born in the 22nd through to the 25th weeks of gestation. In situations in which the infant is unlikely to survive, all parties may opt for "comfort care," which provides for an infant's basic needs but forgoes often-painful medical procedures. Gestational age is known to play a large role in an infant's survival, but assessment of gestational age is often difficult (particularly antenatally); in order to assist in decision-making, the recent work of Tyson and colleagues[23] for the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network is particularly valuable. They have observed 4000 extremely low–birth weight infants and constructed a web tool to predict disability and survival of these infants, taking into account not only gestational age but also the predicted sex of the infant, the estimated birth weight, singleton or multiple pregnancy, and the administration of maternal corticosteroids prior to birth. Most tertiary institutions already use their own center-based statistics when counseling parents, but this web tool may offer an extra refinement in this difficult area. These predictions must not be divorced from the urgency of any maternal condition that may require delivery to safeguard the mother's health (e.g., fulminating preeclampsia). Fetal intrapartum hypoxia and birth trauma associated with PTL, particularly involving the very low–birth weight infant, whether birth is by the abdominal or vaginal route, will contribute to the perinatal risk. The risks in the neonatal period are those of congenital malformations, the sequelae of intrauterine growth restriction, respiratory distress syndrome, necrotizing enterocolitis, intracranial hemorrhage, convulsions, and septicemia.

Risks of Medical Management of Preterm Labor

The fetal and neonatal risks associated with the medical management of PTL have not been accurately quantified, but they certainly require consideration in the overall management.

Risks of Tocolytic Agents

β-Sympathomimetic tocolytic agents cross the placenta and may cause fetal tachycardia and occasionally other adverse fetal cardiac effects that can be significant in an already compromised fetus.[24] The maternal hyperglycemia commonly associated with the use of these agents can result in neonatal hypoglycemia, whereas there is a suggestion that neonatal intraventricular hemorrhage may be associated with the use of these agents.[25] However, there are no substantial studies documenting long-term ill effects for the neonate, and there does not appear to be any difference in developmental outcome once all the confounding factors are considered.

Prostaglandin synthase inhibitors (NSAIDs) cross from the mother to the fetus, potentially resulting in prolonged bleeding time, cardiopulmonary effects (predominantly premature closure or constriction of the ductus arteriosus and [paradoxically] persistent fetal circulation after birth), renal dysfunction, and reduced renal output. Necrotizing enterocolitis and neonatal intraventricular hemorrhage have also been

recorded with these agents. Most studies have limited the use of these agents to short-term therapy (48–72 hr) before 32 to 34 weeks' gestation. It was hoped that the more specific prostaglandin synthetase inhibitors and COX-2 selective agents might have fewer fetal side effects, but the latest evaluation does not confirm this.[14]

Magnesium sulfate crosses the placenta and has the potential to compromise fetal cardiac activity, with reduced baseline variability on cardiotocography being a not uncommon occurrence, which in turn, may lead to unnecessary intervention. The neonate can exhibit hypotonia and hypocalcemia as a consequence of hypermagnesemia. The more controversial aspects of magnesium sulfate are related to its possible neuroprotective role because several observational studies appeared to indicate a reduction in cerebral palsy in very low–birth weight infants in association with its use.

The latest Cochrane Systematic Review by Doyle and associates[26] studied five trials of 6145 babies. Four trials specifically targeted women who were likely to give birth early and magnesium was being used for neuroprotection. Antenatal magnesium sulfate treatment had no overall significant effect on pediatric (fetal, neonatal, and later) mortality (RR 1.04; 95% CI 0.92–1.17). There was a significantly reduced risk for cerebral palsy (RR 0.68; 95% CI 0.54–0.87). This remained significant if the neuroprotective intent subgroup was considered in isolation (RR 0.71; 95% CI 0.55–0.91, four trials, 4446 infants) but was not significant in the other subgroups. Substantial gross motor dysfunction was the only other outcome to show a significant difference between magnesium and placebo overall (RR 0.61; 95% CI 0.44–0.85; four trials, 5980 infants). There was no significant effect of antenatal magnesium sulfate treatment on the combined rate of death or cerebral palsy overall (RR 0.94; 95% CI 0.78–1.12; five trials, 6145 infants). There were no substantial differences between treatment groups in maternal deaths (RR 1.25; 95% CI 0.51 to 3.07), cardiac arrest (RR 0.34; 95%CI 0.04 to 3.26), or respiratory arrest (RR 1.02; 95% CI 0.06–16.25) in four trials of 5411 women, but few women had these outcomes. Overall, significantly more women in the magnesium group ceased therapy because of side effects (RR 3.26; 95% CI 2.46–4.31), whereas there was significantly more maternal hypotension and tachycardia but no significant differences in maternal respiratory depression, postpartum hemorrhage, or cesarean births. The need for ongoing neonatal respiratory support was reduced in the magnesium group (borderline statistical significance: RR 0.94; 95% CI 0.89–1.00). There were no significant differences seen in any of the other secondary pediatric outcomes in all studies combined: intraventricular hemorrhage, periventricular leucomalacia, Apgar score less than 7 at 5 minutes, neonatal convulsions, neonatal hypotonia, and chronic lung disease. The authors have concluded that the evidence now supports a role for antenatal magnesium sulfate therapy in women at risk of PTD as a neuroprotective agent against cerebral palsy.[27] Further studies are required to clarify how magnesium works, who should receive magnesium sulfate, and how best it should be given. Studies are needed comparing the dose and timing of administration, whether maintenance therapy is required, and also whether the magnesium sulfate treatment should be repeated.

Calcium-channel blockers have not been adequately evaluated with regard to fetal or neonatal effects and the Cochrane

reviewers King and coworkers[16] recommended detailed assessment of different dosage regimens and formulations on maternal and neonatal outcomes. Some animal studies have demonstrated profound metabolic alterations in the fetus, but to date, these changes have not been confirmed in human neonates.[28]

More recent tocolytic agents such as *NO donors* have not been sufficiently assessed to date with regard to possible fetal and neonatal effects,[28] whereas one of the randomized trials assessing Atosiban reported an increased risk of infant death.[18]

Risks of Thyrotropin-Releasing Hormone

The maternal administration of thyrotropin-releasing hormone (TRH) in association with corticosteroids was thought, from preliminary studies, to enhance the development of fetal lung maturity. The findings of the Cochrane Review by Crowther and colleagues[29] involved three trials comprising 1969 infants in total and confirmed that all side effects monitored—ventilation requirements and low 5-minute Apgar scores—were increased in women given TRH, and in two studies, there were poorer outcomes at childhood follow up. Given these unfavorable results, the use of TRH is now discouraged.

Risks of Corticosteroids

The maternal administration of *corticosteroids* to enhance fetal lung maturity is beneficial for the preterm neonate, as confirmed by the systematic review by Roberts and Dalziel[30] of 21 studies involving 3885 women and 4269 infants that demonstrated an overall reduction in neonatal death (RR 0.69; 95% CI 0.58–0.81) and a significant reduction in respiratory distress syndrome (RR 0.66; 95% CI 0.59–0.73) with less respiratory support and neonatal intensive care admissions (RR 0.80; 95% CI 0.65–0.99). In addition, there was a reduction of neonatal cerebroventricular hemorrhage in 13 studies of 2872 infants (RR 0.54; 95% CI 0.43–0.69) and a reduction of necrotizing enterocolitis in 8 studies of 1675 infants (RR 0.46; 95% CI 0.29–0.74). The potential risk of an increase in maternal and neonatal infection was not confirmed, with no demonstrated increased risk to the mother of death, chorioamnionitis, or puerperal sepsis and a reduction in neonatal systemic infections in the first 48 hours of life in 5 studies of 1319 infants (RR 0.56; 95% CI 0.38–0.85). Because of concerns that these favorable effects of maternally administered corticosteroids may diminish as the post-treatment interval lengthens, some clinicians advocate administering steroids repeatedly to mothers who remain undelivered between 23 and 34 weeks' gestation, usually at weekly intervals.[31] However, concerns have been expressed regarding a body of evidence suggesting adverse fetal/neonatal consequences from the use of repeated doses. Two large trials, the NICHD trial of Wapner[32] and the Australasian Collaborative Trial of Repeat Doses of Steroids (ACTORDS) study of Crowther,[33] which were well-designed, prospective trials with both short- and long-term evaluations[34,35] meticulously conducted and appropriately analysed, unfortunately came to opposite conclusions. Wapner[35] concluded that administering four or more courses of maternal corticosteroids increases the incidence of cerebral palsy or fetal/neonatal death, whereas Crowther and colleagues[34] concluded that repeat courses improved neonatal outcome without affecting

neurodevelopment. In contrast to animal data, both groups found that repeat steroids were not associated with lower birth weight or smaller head circumference, and although the neurologic outcomes of the children in both groups were similar, Crowther and colleagues' study found a slightly increased incidence of behavioral problems such as attention deficit and emotional reactivity in the repeat steroids group.[34] Wapner,[35] however, found that 6 of the 248 (2.4%) children in the repeat steroids group had cerebral palsy compared with only 1 of the 238 in the single-course group, and 5 of those 6 children had been exposed to four steroid courses. The rates of cerebral palsy in Crowther and colleagues' study of 22 of 521 (4.2%) children in the repeat steroids group compared with 25 of 526 (4.8%) were both higher than in either group in the Wapner study. The studies differed in that in Crowther and colleagues' trial only 11.4 mg of betamethasone was used each week compared with Wapner's trial which used 24 mg each week. Moreover, in Crowther and colleagues' trial, 40% of women received only one repeat dose, 33% received only two or three repeat doses, and only 26% received four or more doses. More of the women in Wapner's study received four or more doses, but the relevance of this to the rate of cerebral palsy is unknown at this time.

The study by Murphy and associates (MACS [Multiple Courses of Antenatal Corticosteroids for Preterm Birth] trial)[36] assessed 1858 women who were randomized between 25 and 32 weeks' gestation, and those who remained undelivered 14 to 21 days after their initial dose of corticosteroids and were considered to remain at increased risk of PTD were randomized either to repeat doses of corticosteroids every 14 days or to placebo. The primary outcome was a composite of perinatal mortality, severe respiratory distress syndrome, intraventricular hemorrhage, periventricular leucomalacia, bronchopulmonary dysplasia, or necrotizing enterocolitis. There were no statistically significant differences between the two groups for the primary outcome, but the use of repeat doses of corticosteroids was associated with a reduction in fetal/neonatal growth parameters.

The Cochrane Systematic Review by Crowther and Harding,[37] which does not include the MACS trial, identified five other randomized trials involving 2000 women; these demonstrated that repeat corticosteroids were associated with a reduction in the occurrence of neonatal lung disease (RR 0.82; 95% CI 0.72–0.93) with no differences in mean birth weight.

At present, the American College of Obstetricians and Gynecologists (ACOG) recommends, in support of the National Institutes of Health (NIH) Consensus conference, that only one course of betamethasone (12 mg × 2 doses, 24 hr apart) should be given to women in PTL and that repeated or "rescue" doses should not be used. It seems likely that in the United States, this view will prevail given the results of Wapner's trial.[35] However, in Australia and New Zealand, particularly in the hospitals that participated in the ACTORDS trial, repeat corticosteroids are still given weekly to women at risk of PTD up to 32 weeks' gestation. It will be interesting to see if, in the future, differences in the incidence of cerebral palsy following PTD in the two countries will become apparent.

Corticosteroids can also be given as a "rescue" therapy when it is considered obvious that PTD will occur. Two trials have used corticosteroids in this manner.[38,39] Peltoniemi and

coworkers[39] raised concerns that the use of rescue treatment potentially disturbed respiratory adaptation at birth, increasing the need for ventilator support. In a subsequent trial, Garite and colleagues[38] demonstrated a reduction in the risk of respiratory morbidity in the babies of women with threatened PTL, who were given two 12-mg doses of betamethasone at 12-hourly intervals. However, in a subsequent editorial, Bonanno and Wapner[40] questioned how this might be used successfully in clinical practice, given our inability to predict who will deliver when threatened PTL occurs.

In addition, investigation is under way with regard to the different types of antenatal corticosteroids used to enhance fetal lung maturity. The Cochrane Systematic Review by Brownfoot and associates[41] identified 10 randomized trials in which dexamethasone was compared with betamethasone, involving 1161 infants. Dexamethasone was associated with a reduction in risk of intraventricular hemorrhage when compared with betamethasone (RR 0.44; 95% CI 0.21–0.91; four trials, 549 infants). There is only limited information available relating to other infant health outcomes including long-term health,[42] and at present, it is unclear whether there are advantages associated with different corticosteroid agents. We await the results of the A*STEROID study that has been designed to answer whether, compared with betamethasone, antenatal dexamethasone given to women at risk of PTD (<34 wk' gestation) reduces the risk of death or any neurosensory disability caused by impairments such as cerebral palsy, blindness, deafness, or developmental delay in their children at 2 years' corrected age.[43] Of interest is the preliminary paper by Mittendorf and coworkers[44] suggesting that when high magnesium exposures occur in PTL, betamethasone may be less effective in preventing neonatal intraventricular hemorrhage.

Risks of Antibiotics

The previous conclusion of the ORACLE II trial[5] that in the absence of overt intrauterine infection, the use of antibiotics in PTL with intact membranes does not contribute positively to the neonatal outcome has been reinforced by the more recent findings of the ORACLE Children Study II,[45] which demonstrated an increased risk of cerebral palsy in the children whose mothers had received erythromycin or co-amoxiclav 7 years previously compared with those women who did not receive either antibiotic (erythromycin 53 [3.3%] of 1611 vs. 27 [1.7%] of 1562; RR 1.93, 95% CI 1.21–3.09; co-amoxiclav 50 [3.2%] of 1587 vs. 30 [1.9%] of 1586; RR 1.69, 95% CI 1.07–2.67). Also, the number of children with cerebral palsy was greater when both antibiotics were given together (35 of 769 [4.55%]) compared with erythromycin alone (18 of 785 [2.29%]), co-amoxiclav alone (15 of 763 [1.97 %]) or placebo alone (12 of 735 [1.63%]). The mechanism of this effect is unclear, but if subclinical infection is provoking labor, treatment with relatively low doses of oral antibiotics might only suppress rather than eradicate intrauterine infection, allowing continued fetal exposure to a damaging environment with the association between perinatal infection and neurologic impairment being well established.

These findings do not mean that antibiotics are unsafe for use in pregnancy, and pregnant women showing overt signs of infection should be treated promptly with parenteral antibiotics because the serious risks to mother and baby of untreated infection has been reinforced by the 2007 CEMACH report, *Saving Mothers Lives*.[46]

MANAGEMENT OPTIONS
Prepregnancy Preventive Measures

Unfortunately, there is little evidence from randomized trials of there being any value to preventive programs against PTD, based on prospective risk scoring. Both hospital-based and local social interventions have been tried, but none has proved to be successful.[47] This failure is due to both a low sensitivity (generally < 50%) and a poor predictive value (17%–34%) of risk scoring systems, particularly in nulliparous women because past obstetric performance is reported to be one of the more consistent predictive factors.[48] Given that most of the preventive strategies are directed at "idiopathic" PTL, which constitutes only a minority of cases, they are inherently unlikely to make much of an impact, even less so when with the services of a perinatal pathologist, a significant proportion of women with "idiopathic" PTL can be demonstrated to have specific etiologic factors that are currently not treatable once they are established. However, such information may be of some value in planning care for women in their next pregnancy.[49]

It is, however, useful in prepregnancy counseling to estimate the likely recurrence risk of PTD. The most significant and consistently identified risk factor for PTD is a woman's history of previous PTD.[50] Estimates suggest the rate of recurrent PTD in this group of women to be 22.5%, a 2.5 times increased RR when compared with women with no previous PTD.[51] Ashmead and colleagues,[52] in their prospective study of PTDs without uterine anomalies or medical problems, reported that women with one previous PTD had a 15% chance and those with two previous PTDs a 41% chance of another PTD. For approximately 10% of these women, the PTD will occur at a similar gestational age.[31,53] There appears to be intergenerational effects related to PTD, with an increase in a woman's risk of PTD if she herself was born preterm, the risk being greater at earlier gestational ages,[54,55] although this effect has not been consistently demonstrated.[56] These statistics may be helpful in counseling women living in areas remote from a perinatal center by suggesting their relocation during the critical period of a subsequent pregnancy to enhance the neonatal outcome.

More general advice with regard to daily work activity (avoidance of heavy manual labor or mental stress if family economics permit) and attention to specific habits such as alcohol, smoking, and chemical dependency should be given because there is some evidence that these factors may play a role in PTD.[57]

Women with a low body mass index at conception and women with poor weight gain in pregnancy relative to their prepregnancy weight have an increased risk of PTD.[58] Women who are overweight or obese are recognized have an increased risk of medical complications of pregnancy, including gestational diabetes and hypertension.[59] Accordingly, obesity is associated with an increased risk of PTD at less than 34 weeks, which is largely related to elective or iatrogenic PTD rather than spontaneous PTD.[60,61]

Even after adjustment for other sociodemographic risk factors, there is a strong racial predisposition to PTD being

higher in black women than in other racial and ethnic groups.[62] This over-representation among black women is 2 to 3.5 times greater when compared with white women, with a tendency to an earlier average gestational age at birth.[63,64] There is, however, some evidence of accelerated maturity in babies born early to mothers of black African and south Asian race, which is to some extent protective (see Chapter 65). These findings indicate that whereas maternal medical and socioeconomic factors are most influential, racial differences and genetic predisposition make important contributions.[65]

While initiatives to try to deal with the aforementioned risk factors are being assessed, at the present time, specific prepregnancy measures for PTL and PTD might be considered for multiparous patients. Unfortunately, for nulliparous women, apart from those with known genital tract anomalies for which surgical correction might be possible, there does not appear to be any proven strategies to prevent PTL and PTD.

Prenatal Preventive Measures

Assessment of Risk

At the first prenatal visit, assessing the risk of PTD based on the history and clinical examination may be useful in identifying those women more likely to deliver preterm. The assessment of risk can be updated during the pregnancy if complications develop. An adaptation of the score devised by Creasy and associates,[66] which combines socioeconomic factors, previous medical history, daily habits, and aspects of the current pregnancy, is probably the most acceptable method but its predictive value is low (17%–34%) owing to the multifactorial nature of PTL. In all women, particularly those at risk of PTD, it is desirable that gestational age be confirmed by an ultrasound scan in the first trimester.

Patient Education

Education of the patient with a previous PTD about the signs and symptoms of PTL is a useful option to consider. The perception of contractions, menstrual-like cramps, pelvic pressure sensation, low dull backache, abdominal cramping with or without diarrhea, an increase or change in vaginal discharge, and a "show" may all prove to be significant but individually are not particularly predictive. Nevertheless, if these signs and symptoms of PTL are evident, then a thorough cervical assessment either digitally or by ultrasound should be performed.

Antenatal Care

In those women suspected of being at increased risk of PTL, more frequent antenatal assessment, particularly in the latter half of pregnancy, is a common option employed. The rationale is based on indirect evidence that absent or delayed institution of antenatal care is associated with an increased rate of PTD and low–birth weight infants.

It is possible that those patients sufficiently motivated to seek early and regular antenatal care may be intrinsically healthier and better motivated than those who do not seek early antenatal care. Antenatal care does provide the opportunity to detect and possibly treat some of the maternal and fetal conditions (e.g., anemia, hypertension, and bacteriuria) that are associated with PTD.

Bowes[67] best summarized the contributions of prenatal care by suggesting that success is related to the continuity of care, the time available for patients to talk about their problems, ready access to ancillary services, and a prenatal patient record that provides reminders of critical procedures and screening tests. Enhanced prenatal care may have the potential to become more effective as better predictive tests and more selective prophylactic measures are developed for PTD.

Prediction of Preterm Labor

Prediction of PTL (see Chapter 60) has dominated research efforts since the 1990s.

Outpatient and home monitoring of uterine contractions, regular cervical assessment both digitally and by ultrasound, biochemical markers such as placental corticotropin-releasing hormone (CRH) and its binding protein, salivary estriol, the inflammatory cytokines and prostaglandins, fetal fibronectin (fFN), cervical ferritin, and noninvasive cutaneous cardiovascular dynamics (CVD) have come and gone or have been reevaluated in the hope that a reliable predictor with high sensitivity and specificity can be found.

Strategies for Prevention of Preterm Labor and Preterm Birth—Primary Prevention Cervical Cerclage

Cervical incompetence is classically diagnosed by a history of painless cervical dilation that results in a second-trimester spontaneous miscarriage. The contemporary use of ultrasound in the early second trimester can recognize the asymptomatic cervical changes of shortening and funneling that are associated with an increased risk of PTD.[68] The etiology of the pregnancy loss or PTD may be mechanical in nature, or alternatively, it may be of an inflammatory or subclinical infection nature as a result of cervical dilation and possibly the loss of the mucous plug.

Hollier[69] reviewed four randomized trials evaluating the value of cervical cerclage in women with historical risk factors, and all failed to demonstrate a reduction in birth before 37 weeks' gestation. The largest of these trials was the Medical Research Council/Royal College of Obstetricians and Gynaecologists (MRC/RCOG) trial,[70] which evaluated the effectiveness of the McDonald suture and found a nonsignificant reduction in the rate of birth before 37 weeks (26% vs. 31%; $P = 0.07$) and a significant reduction in birth before 33 weeks (13% vs. 17%; $P = 0.03$). However, there was only a small and statistically insignificant improvement in miscarriage, stillbirth, and neonatal death (9% vs. 11%) whereas there was an increase in medical intervention and a doubling of the risk of puerperal pyrexia. It has been calculated from these four trials that 1 woman in 30 will benefit from a cervical cerclage.

Three randomized trials have been performed assessing the effectiveness of cervical cerclage in women with a short cervix detected on second-trimester ultrasound. The only trial to show benefit was the smallest trial by Althuisius and coworkers[71] of 30 women in total that had a "mixed" study group of women with historical risk factors as well as women identified in the second trimester to have a short cervix on

ultrasound. For women randomized before 24 weeks, the rate of PTD was significantly lower in the cerclage group (0/16 vs. 7/14; P = .002). The neonatal survival was similar but the compound morbidity was significantly lower in the cerclage group (RR 9.1; 95% CI 1.3–64.4).

The larger studies by Rust and colleagues[72] and To and associates,[73] although methodologically a little different, nevertheless failed to demonstrate any benefit from the placement of a cervical cerclage after ultrasound detection of cervical shortening.

The Cochrane review by Drakeley and coworkers,[74] evaluating elective cerclage compared with no cerclage, failed to reveal any difference in the risk of total pregnancy loss (RR 0.86; 95% CI 0.59–1.25), PTD before 37 weeks (RR 0.88; 95% CI 0.76–1.03) or 32 weeks (RR 1.29; 95% CI 0.67–2.49), with an increase in the risk of infection (RR 2.57; 95% CI 1.42–4.64) and minor maternal morbidity (RR 1.32; 95% CI 1.13–1.55) associated with cervical cerclage. On the basis of this information, the authors concluded that cerclage had a limited role in women considered to be at low to moderate risk of PTD.

A subsequent systematic review and individual patient data meta-analysis by Berghella and colleagues,[75] involving randomized trials in which women were identified with cervical shortening on transvaginal ultrasound and then allocated to cervical cerclage or no treatment, identified a small reduction in the risk of PTD less than 37 weeks' gestation (RR 0.84; 95% CI 0.71–0.99). Although there is currently insufficient information available to indicate that this prolongation in gestational age translates into improved infant health outcomes, nevertheless further scientific evaluation of the role of cervical cerclage in this group of high risk women is warranted.

Placement of a cervical suture is usually a vaginal procedure, but on rare occasions, it may have to be performed by the abdominal route, usually after two failed vaginal cerclages and/or significant shortening or damage of the vaginal cervix. This can be achieved at open operation or at laparoscopy and can be performed either prepregnancy or in the late first trimester.[76–78]

Treatment of Vaginal Infection

The presence of inflammation is associated with activation of the cytokine cascade, which in turn, may be associated with the release of prostaglandin, which is associated with the onset of uterine contractions and the process of cervical ripening leading to PTD.[79]

In both term labor and PTL, there is evidence of an increase in inflammatory markers, tumor necrosis factor-α (TNF-α), interleukin-1 (Il-1), Il-6, and down-regulation of the anti-inflammatory Il-10. These maternal inflammatory cytokines may alter enzyme expression, increasing prostaglandin production, and may then interact at the fetoplacental unit precipitating PTL and PTD.[80]

The epidemiologic associations with PTD discussed in relation to both personal and family history of PTD and racial disparities in its occurrence would support a genetic predisposition to PTD, and this has led to the identification of several gene polymorphisms altering cytokine expression and increasing the risk of PTD.[81,82]

In addition, alterations in vaginal microbial flora have been linked with inflammatory processes, with infection being implicated as a cause of PTD in up to 30% of affected women. The fetus may also play a role in these inflammatory-mediated causes of PTD through the fetal inflammatory response syndrome (FIRS).[83] As a result of this understanding of the likely pathophysiologic changes associated with PTD, identification and treatment of women with vaginal infection has promise as a potential means of reducing the incidence of PTL and PTD.

In women at high risk for PTD based on history and colonized with bacterial vaginosis (BV) during the index pregnancy, three randomized trials demonstrated that oral metronidazole therapy reduced the risk of PTD by 25% to 75%.[84–86] However, three trials of oral treatment of BV in a mixed group of women at both high and low risk of PTD, including the large trial by Carey and associates,[87] failed to detect any significant differences in the rate of birth at less than 37 weeks' gestation, at less than 35 weeks' gestation, or less than 32 weeks' gestation. Seven trials have evaluated the use of clindamycin treatment of BV (six using intravaginal cream, and one oral clindamycin), and six of the trials demonstrated an increase (rather than the anticipated decrease) in the rate of prematurity.[88–94] The seventh trial treated persistent BV after the initial treatment course and also treated any associated vaginal candidiasis and trichomoniasis. In this trial, there was a significantly lower rate of spontaneous PTD in the treatment group compared with the control group (3.0% vs, 5.3%; P < .01).[89]

From the evidence accumulated so far, it would appear that screening and treating low risk women with BV is not justified and may cause some harm. The argument for screening and treating high risk women with BV would appear to be more compelling, and some have argued that both timing of treatment and antibiotic used are critical variables. Moreover, although treatment of symptomatic women with metronidazole is appropriate simply to relieve symptoms,[95] two randomized trials have assessed the effect of antibiotic treatment of women with *Trichomonas* vaginitis (TV) on the rate of PTD; in both studies, it appeared that treatment of TV resulted in an increased risk of an adverse outcome.[96,97] The explanation for this is not clear but may be related to an alteration of the vaginal flora with the local release of cytokines and/or possibly a systemic maternal immune response to *Trichomonas*. Once again, there does not appear to be any justification for universal screening and treatment of asymptomatic women with TV. The recent work of Goldenberg and coworkers[98] demonstrated that 23% of neonates born between 23 and 32 weeks' gestation have positive blood cultures for genital mycoplasmas (*Ureaplasma urealyticum* and *Mycoplasma hominis*) and that these newborns had a higher frequency of neonatal systemic inflammatory response syndrome with higher serum concentrations of Il-6 and placental inflammation than those with negative cultures, which in turn may have some important long-term neonatal implications and thus is worthy of mention in trying to understand the implications of such infections.

There is accumulating evidence that these organisms are implicated in neonatal sepsis, pneumonia, meningitis, and cerebral damage, and although their presence in the genital tract of sexually active and normal pregnant women is common and they are possibly present as commensal

organisms, nevertheless, these microorganisms are frequently isolated from the amniotic fluid in women with PTL, PPROM, cervical incompetence, mid-trimester amniocentesis, and clinical chorioamnionitis. This raises the question as to how they gain access to the amniotic cavity, and once present, why they might induce a deleterious inflammatory response. Romero and Garite[99] highlight the fact that the detection of genital mycoplasmas is not part of current clinical practice, and in addition, the standard treatment for suspected neonatal sepsis does not include antibiotics that are effective against these microorganisms. Investigators are now beginning to address these areas.

The use of probiotics to prevent or treat urogenital infections (primarily BV) is a relatively novel method of treatment. A Cochrane review by Othman and associates[100] demonstrated a major reduction in vaginal infection associated with treatment (RR 0.19; 95% CI 0.08–0.48), although no information is currently available relating to the risk of PTD or other maternal and infant health outcomes.

Prophylactic antibiotic administration to prevent PTD in an unselected pregnant population has been associated with a reduction in the risk of PPROM (odds ratio [OR] 0.32; 95% CI 0.14–0.73), but currently, there is insufficient information available to recommend prophylactic antibiotics during pregnancy to prevent PTL and PTD whereas there is a possible increase in the risk of other infectious morbidities including an increase in the risk of neonatal sepsis (OR 8.07; 95% CI 1.36 to 47.77).[101]

Treatment of Periodontal Disease

The initial promising results of the treatment of periodontal disease in the prevention of PTD have not been consistently reproduced. Michalowicz and colleagues[102] and Ruma and associates[103] have recently questioned the previous suggestion that systemic inflammation due to periodontal disease can contribute to the causation of PTD.

Use of Progesterone

Many studies have examined the use of progesterone for the prevention of PTL, and whereas the presumed mechanism of action of progesterone is thought to be that of inducing uterine muscle quiescence, preliminary evidence suggests that progesterone may also modulate cytokine production and provide a protective antiapoptotic effect in human fetal membrane cells, both of which may be important in preventing PTL.

However, the etiology of PTD is heterogeneous, with many causal pathways leading to regular uterine contractions and cervical dilation, and therefore, it is unlikely that progesterone therapy will be a panacea for all women considered to be at increased risk of PTD.

The recent systematic review by Dodd and coworkers[104] identified 11 randomized trials evaluating the role of progesterone for women at increased risk of PTD. For women with a prior history of PTD,[105–107] progesterone was associated with reduction in the risk of PTD before 34 weeks' gestation (one study, 142 women; RR 0.15; 95% CI 0.04–0.64; number needed to treat [NNT] 7; 95% CI 4–17). Whereas there was a significant reduction in the risk of infant birth weight less than 2500 g (two studies, 501 infants, RR 0.64; 95% CI 0.49–0.83), no other differences were identified between the treatment groups for other neonatal outcomes. It must be

noted that the combined sample size of 1329 infants is not sufficiently powered to detect differences in neonatal morbidity.

A single trial was identified in which progesterone was administered to women with a short cervix detected on transvaginal ultrasound.[108] The use of progesterone was associated with a reduction in PTD before 34 weeks (250 women; RR 0.58; 95% CI 0.38–0.87; NNT 7; 95% CI 4–25). Although a significant reduction in the risk of neonatal sepsis was identified, the sample size is underpowered to reliably detect differences in neonatal outcomes.

It seems unlikely that progesterone will be of value in multiple pregnancies (see Chapter 59).

The value of progesterone in women who present with symptoms or signs of threatened PTL that is subsequently arrested is uncertain. Two randomized studies have been reported to date, with a combined sample size of 130 women.[109,110] Although there is a suggestion of a reduction in cervical length shortening detected by ultrasound following the use of progesterone, there is little other relevant information relating to maternal or infant health outcomes.

Currently, there is insufficient information to make reliable recommendations about the optimal dose of progesterone, the optimal route of administration, and the appropriate gestational age at which to start therapy. The information that is available suggests that the potential benefit is for women considered to be at increased risk of PTD (usually determined on the basis of a previous PTD) and the benefit is primarily in the reduction births before 34 weeks' gestation. However, there is currently little information available about neonatal and longer-term infant and childhood health outcomes; thus, it remains unclear whether any prolongation of pregnancy translates into improved health outcomes. Further research is required before progesterone can become a standard recommended form of management of women at risk of PTD, and the results of several trials ongoing at the time of writing are awaited with great interest. One is using vaginal progesterone in women with a history of prior PTD.[111] One in a high risk group using "natural" progesterone was started in 2006 but subsequently withdrawn (NCT00329316)[112]; however a study of 17 alpha-hydroxyprogesterone caproate in high risk women who present with a short cervix, registered in 2006, appears still to be ongoing.[113]

Strategies for Prevention of Preterm Labor and Preterm Birth—Use of Tocolytics as Maintenance Therapy after Primary Treatment

Dodd and associates[114] assessed 11 randomized, controlled trials of the administration of oral β-sympathomimetic drugs for prophylaxis after threatened PTL and found no difference for admission to a neonatal intensive care unit following maintenance therapy compared with placebo (RR 1.29, 95% CI 0.64–2.60) or with magnesium sulfate (RR 0.80; 95% CI 0.43–1.46). The rate of PTD at less than 37 weeks showed no significant difference (RR 1.08; 95% CI 0.88–1.32) when comparing ritodrine and terbutaline with placebo/no treatment. There were no differences with respect to perinatal mortality and morbidity.

A prospective, randomized, double-blind, multicenter study by Lyell and colleagues[115] using nifedipine versus placebo yielded similar results, with no improvement

demonstrated in prolonging pregnancy or improving neonatal outcome. The available evidence does not support the use of oral β-sympathomimetic drugs and other tocolytic drugs for maintenance therapy after threatened PTL.

Management of Women Presenting with Threatened or Actual Preterm Labor

Once the diagnosis of threatened or actual PTL is established, a careful clinical appraisal with appropriate investigations of maternal and fetal condition should be performed. Ultrasonography can be used to ascertain fetal number, estimate fetal weight, check fetal morphology and presentation, as well as estimate liquor volume and localize the placental site. In addition, ultrasound can be used to assess fetal well-being utilizing umbilical vessel Doppler assessment and fetal activity including fetal breathing movements, which were found in preliminary studies to be suppressed in women with PTL.[116]

Testing for an infective etiology is important in the initial assessment and includes culture of vaginal and cervical secretions and a midstream specimen of urine, a complete blood count (including a differential white cell count), and C-reactive protein estimation. Amniocentesis with Gram stain and culture and, more recently, Il-6 estimation may be considered if infection is suspected. In addition, fetal lung maturity using lecithin/sphingomyelin ratio or phosphatidyl glycerol can also be assessed concurrently. If indicated by abnormal fetal morphology, fetal karyotype determination should be considered.

However, not all obstetricians would perform amniocentesis in this context because of the possibility of inducing further uterine activity and because of a lack of robust data to guide management decisions based on the findings.

Determination of the presence or absence of PPROM by clinical and, if necessary, additional investigations is essential to the management of threatened or actual PTL. Although acknowledging that a positive fFN test in symptomatic women has only a 29.3% positive predictive value of delivery before 34 weeks' gestation, a large body of evidence now exists that confirms that a negative fFN test has a more than 95% predictive value that PTD will not occur before 34 weeks' gestation.[117] On a logical basis, it should be possible to use the information gained from fibronectin screening information to reduce unnecessary and potentially harmful and costly treatment and to avoid unnecessary maternal-fetal transfer to a tertiary level unit in women presenting with threatened PTL. However, there have been three randomized, controlled trials examining the impact of fFN testing on the management of threatened PTL that have not borne out this hypothesis. Plaut and coworkers[118] found that in women with a negative fFN test, the hospital stay was not significantly shorter when the result was known compared with when the result was not known (6.8 hr vs. 8.1 hr; P =.35). Lowe and colleagues[119] found no difference between similar groups in the number of hours spent in the labor and delivery suite, the number of women admitted to the antepartum service, the length of inpatient hospital stay, or the number of medical interventions. Grobman and associates[120] found no difference in the initial length of labor and delivery (4 hr vs. 3 hr), in hospital admission (28% vs. 26%), use of tocolysis (18% vs. 16%), cessation of work

(27% vs. 26%), or health care costs between the two groups. The Cochrane Systematic Review by Bergella and coworkers[121] identified five randomized, controlled trials assessing the value of knowing about the result of fFN tests in women presenting with symptoms or signs of PTL in a total of 474 women. Although the knowledge of fFN testing was associated with a reduction in risk of PTD less than 37 weeks' gestation (RR 0.54; 95% CI 0.34–0.87), no other differences were identified relating to maternal and infant health outcomes. Currently, there is insufficient information available to recommend the routine use of fFN testing in threatened PTL, although it still remains in use in some regionalized perinatal networks as an aid to the selective transfer of women with threatened PTL to tertiary perinatal centers.

Once gestational age is established, the generally poor immediate and long-term outcomes of infants born between 20 and 24 weeks require considerable discussion between the parents, the obstetrician, the neonatologist, and the midwife either before or shortly after the initiation of tocolytic therapy. In cases of extreme fetal immaturity, the parents may choose to allow delivery to occur rather than invoking risky, uncomfortable, and expensive delaying strategies of poor efficacy. However, caution must be exercised in agreeing to this strategy because fetal weight and gestational estimates are subject to significant variation between 20 and 24 weeks' gestation.

This dilemma is more pragmatically handled by transferring the patient to a tertiary perinatal center and allowing her to deliver vaginally without assistance ("intervention") with a neonatologist present at delivery to immediately assess the neonate's suitability for intensive support. Whether continuous electronic fetal monitoring should be used during such labors is in dispute. Knowledge of whether the fetal heart rate pattern is normal or not may be of some value in deciding on whether to carry out neonatal resuscitation; however, some members of the medical/midwifery/nursing team find it stressful to observe an abnormal fetal heart rate pattern without intervening. Accordingly, whether to carry out continuous intrapartum fetal monitoring should be discussed with the parents and the key members of the delivery care team.

The use of tocolytic therapy between 24 and 34 weeks' gestation is not only to facilitate the in utero transfer of the fetus to a tertiary referral center but also to allow sufficient time to enhance fetal lung maturity by the concomitant use of maternal corticosteroid therapy. Although the most widely tested tocolytics are the β-sympathomimetic agents, which are effective in delaying delivery, they have not been shown to improve perinatal outcome and have a relatively high frequency of undesirable maternal side effects, as previously described. Calcium channel blockers are now becoming the first-line tocolytics because they have the advantage of availability, cheaper cost, ease of administration, and fewer maternal side effects than β-sympathomimetics.[16] King and colleagues[122] assessed 12 randomized, controlled trials involving 1029 women; calcium channel blockers compared with other tocolytics (principally β-sympathomimetics) reduced the number of women giving birth within 7 days of treatment (RR 0.76; 95% CI 0.60–0.97) and prior to 34 weeks' gestation (RR 0.83; 95% CI 0.69–0.99). Currently, there is a lack of consensus with regard to regimens for the use of calcium channel blockers.

Maternal contraindications to its use include hypotension (systolic blood pressure <90 mm Hg), known allergy to nifedipine, cardiac disease (congestive cardiac failure, aortic stenosis), concurrent use of salbutamol, glyceryl trinitrate (GTN), other antihypertensive agents, hepatic dysfunction, and caution if magnesium sulfate is being administered because significant hypotension and neuromuscular blockade may result.

Fetal contraindications to its use include suspected intrauterine infection, urgent fetal distress, undiagnosed significant vaginal bleeding, severe intrauterine growth restriction, and the more apparent problems of lethal anomalies and intrauterine fetal death. In Australia, nifedipine for inhibition of PTL is an "off-label" use because it has not been approved by the Therapeutics Goods Agency for this indication.

With threatened or actual PTL, the South Australian Perinatal Practice Guidelines[123] recommend that a starting dose of 20 mg nifedipine be given and the tablet should be chewed or crushed to aid the speed of absorption. However, if this approach is used, careful and continuous maternal and fetal monitoring must be carried out. Sublingual administration of nifedipine has been associated with severe maternal hypotension and fetal distress,[124] and chewed tablets with severe maternal hypotension and fetal death.[125] If contractions persist, then a second dose of 20 mg of nifedipine is recommended, with the maximum dose in the first hour being 40 mg. Any further doses are not recommended until 3 hours after the second dose, with a maximum dose of 160 mg of nifedipine in 24 hours.

Maternal baseline observations should be taken initially in association with continuous electronic fetal monitoring, and the rate of observations can be tapered according to the clinical situation. Although cessation of nifedipine tocolysis is uncommon, owing to side effects the patient should be warned of the possibility of headache, tachycardia, palpitations, flushing, fatigue, dizziness, nausea, heartburn, constipation, and edema. Tocolytic therapy should be continued for 48 hours if possible to try to maximize the enhancement of fetal lung maturity by maternally administered corticosteroids in the form of betamethasone (two doses of 12 mg IM, 24 hr apart) or dexamethasone (6 mg every 12 hr for four doses).

If the initially selected tocolytic agent is unsuccessful in suppressing threatened PTL or is not tolerated, an alternative agent may be considered either alone or in combination with the original agent. However, any such strategy should be instituted only after a very careful appraisal of maternal and fetal well-being and, in particular, the exclusion of intrauterine infection, which is notorious for producing an apparent failure of tocolysis. As previously discussed, maintenance oral tocolytic therapy after 48 hours has not been found to prevent PTD or improve neonatal outcome and cannot be recommended, although it is still commonly employed.

The place of other maternally administered agents to enhance fetal outcome—TRH, magnesium sulfate, and repeated courses of maternally administered corticosteroids—have been discussed previously, whereas the prophylactic use of maternally administered vitamin K and phenobarbitone to reduce the incidence of neonatal periventricular hemorrhage has not been validated scientifically and cannot be recommended.[126,127]

The results of the ORACLE II Trial[5,45] and the recent meta-analysis by King and Flenady[128] would reinforce the view that adjunctive antibiotic therapy in threatened or actual PTL for the purpose of preventing PTD is not indicated; however, intrapartum intravenous penicillin prophylaxis for women colonized with group B streptococcus is appropriate, as is the aggressive treatment of proven/overt maternal infection.

Treatment of threatened and actual PTL after 34 weeks was formerly considered to be unnecessary; however, accumulating data suggest that singleton infants born at this late preterm stage, who constitute up to two thirds of all PTDs, are at increased risk for perinatal death compared with infants born at term.[129] In addition, these infants have increased morbidity including transient tachypnea, respiratory distress, hypoglycemia, and pulmonary hypertension. Recent cohort studies[130] also demonstrate poorer school performance and increased risks of cerebral palsy (RR 2.7; 95% CI 2.2–3.3), developmental delay (RR 1.6; 95% CI 1.4–1.8), schizophrenia (RR 1.6; 95% CI 1.4–1.8), and other disorders of psychological development, behavior, and emotion (RR 1.5; 95% CI 1.2–1.8) in these late preterm infants. Not only are these late preterm infants at increased risk of developmental, social, and neurocognitive problems but they also have a 40% increased risk for any medical disability (RR 1.4; 95% CI 1.3–1.5) in adulthood.[131] These findings are at variance with the conventional belief that 34 weeks is a critical physiological period in fetal maturity and now require us to carefully assess the maternal and fetal indications that necessitate obstetric assistance (intervention) at 34 to 37 weeks' gestation—preeclampsia, intrauterine growth restriction, diabetes, and other maternal medical conditions—and to determine the risk/benefit to the mother and her baby of delivery at this gestation compared with a more conservative approach with delivery after 37 weeks' gestation. Two studies[132,133] have indicated that 22.4% and 21%, respectively, of births between 34 and 36 weeks had no apparent indication for iatrogenic delivery and these infants had higher neonatal and infant mortality rates than infants who delivered at this gestation after spontaneous labor. Underreporting of indications may have accounted for this discrepancy; however, overintervention may also have occurred. A retrospective study by Merlino and associates[134] found that the majority of late PTDs at their tertiary center were not amenable to conservative management, with only an estimated 6% of late PTDs being potentially suitable for conservative treatment. The safety and efficacy of conservative management under these circumstances still remain to be determined.

The use of maternally administered "late" corticosteroid therapy, between 34 and 37 gestational weeks, has been promoted to reduce respiratory morbidity and admission to special care nurseries in these neonates following a number of recent comparative cohort studies.[135] This practice has been extended in an attempt to reduce transient tachypnea of the newborn for women undergoing elective or semielective cesarean section before 39 weeks' gestation.[136] Because of concerns about the potential long-term harmful effects on the baby of antenatal steroids, avoiding unnecessary delivery should always be considered as a better option before additional steroid treatment is given. Certainly, steroids should not be given simply to make it easier for the obstetrician or the mother to choose earlier delivery for social convenience.

Emergent (emergency) cerclage may have a limited place in an attempt to extend the gestational age of delivery in a selected number of women presenting with advanced cervical dilation in the second trimester. No randomized study has prospectively documented the benefits that emergent cerclage placement might impart. Although one prospective, nonrandomized study has suggested that increased gestational time can be gained,[137] the benefits of this increased latency remain unclear because many of these infants are delivered at the threshold of viability and suffer from the resultant sequelae of extreme prematurity. As a consequence, little published evidence exists to assist in counseling patients who present with cervical change documented by physical examination in the second trimester regarding the probability of a desirable outcome after placement of an emergent cervical suture. The present literature is mainly limited to series with small numbers of patients with variable entry criteria.

In the retrospective trials that have included only women with cervical change diagnosed by physical examination, a variety of surgical techniques have been attempted yet little assessment of the benefits of these techniques has been performed. Many of these studies have reported outcomes such as the number of days a pregnancy is prolonged rather than actual health outcomes.[138,139] In addition, the univariant statistical analyses that have been applied have not allowed an assessment of the factors that independently predict these health outcomes.[140]

In order to give patients an individualized probability of relevant outcomes, a number of workers have attempted to construct predictive scores/models upon which to base further management.[141] Parity, gestational age at presentation, degree of cervical dilation, and C-reactive protein levels/amniocentesis to detect infection are the consistent parameters evaluated in these scoring systems, but as previously mentioned, these parameters have not been prospectively validated.[142]

Labor and Delivery

Once PTD seems inevitable, the mode of delivery and the likely neonatal outcome should be discussed with the patient and her partner by a multidisciplinary team of an obstetrician, a neonatologist, an obstetric anesthetist, and a midwife.

In general, before 24 weeks' gestation, vaginal delivery should be anticipated with expert neonatal evaluation at delivery to determine whether active neonatal supportive care is warranted.[143]

Between 24 and 34 weeks' gestation, the management of labor should not differ significantly from that beyond 34 weeks, with vaginal birth being the anticipated outcome.

Although continuous electronic fetal monitoring and regional anesthesia have not been critically evaluated in the management of actual PTL, they are commonly employed. Once labor is established and if there are signs of intrauterine infection, maternal antibiotic therapy should be instituted because a reduction in maternal infectious morbidity has been demonstrated with antibiotic treatment.[144] The authors currently favor the use of intravenous ampicillin 2 g stat and 1 g every 4 hours, gentamicin 160 mg daily, and metronidazole 500 mg every 12 hours. This combination is undergoing further evaluation in light of evidence suggesting that β-lactam antibiotics may have deleterious effects on the neonate as a result of the sudden release of cytokines that may precipitate the fetal inflammatory response syndrome.

If the *group B streptococcus* status of the patient is unknown, appropriate parenteral antibiotics (penicillin or, in the case of allergy, lincomycin) should be administered during labor. Evaluation of the available randomized trials would suggest that "prophylactic" outlet forceps or "elective" episiotomy does not contribute significantly to the neonatal outcome and, hence, should be performed only for standard obstetric indications. It is generally agreed that ventouse delivery is relatively contra-indicated, particularly before 34 weeks' gestation, should an expedited vaginal birth be required.

In extremely preterm infants between 24 and 28 weeks' gestation, intact amniotic membranes may serve to protect such infants from the mechanical forces exerted upon the baby and the umbilical cord during vaginal birth, with evidence suggesting that the "en caul" method of delivery is associated with significantly higher arterial cord pH values in these infants.[145]

Delayed cord clamping has been found to confer an advantage to the neonate in a Cochrane Systematic Review by Rabe and coworkers[146] identifying a reduction in the need for infant transfusion for anemia (RR 2.01; 95% CI 1.24–3.27; three trials, 111 infants), a reduction in neonatal hypotension (RR 2.58; 95% CI 1.17–5.67; two trials, 58 infants), and a reduction in intraventricular hemorrhage (RR 1.74; 95% CI 1.08–2.81; five trials, 225 infants). The standard management of the third stage is recommended with PTD.

The attendance at the birth of a neonatologist/pediatrician with an assisting neonatal nurse or an accoucheur skilled in neonatal resuscitation is critical to the optimal outcome for a premature infant. From the neonatal perspective, the significantly higher risk of mortality and morbidity of infants born outside a tertiary perinatal center makes a compelling argument for maternal-fetal transport to such a center with a neonatal intensive care unit (level III, now designated as level 6 in most Australian states), particularly for women up to and including 32 weeks' gestation.[147]

In a well-organized perinatal network, women at 32 to 37 weeks' gestation may be allowed to deliver in an obstetric hospital with level II (now designated as level 4 or 5 in most Australian states) facilities with short-term ventilatory care capability. When transport is not possible (in some series, up to 50% of women), specifically trained and equipped obstetric and neonatal teams with appropriate nursing and medical personnel should attend the birth.[148] Their role is to supervise and, if necessary, deliver the neonate and then stabilize the mother and her premature infant prior to their respective transfer to the tertiary perinatal center if deemed necessary.[148]

Postnatal Management

Maternal Considerations

Encouragement of parent-infant bonding is a major consideration in postnatal management. Continuous access by the parents to the neonatal nursery should be encouraged to facilitate the bonding process and breast-feeding should be encouraged in a compassionate and pragmatic manner.

Continuing psychological support is important, utilizing the services of a domiciliary midwife, neonatal nurse, lactation consultant, social worker, and if indicated, a psychiatrist, more so if there is significant neonatal morbidity and/or neonatal death. An early postnatal evaluation of possible etiologic factors should be considered by the immediate perinatal team along with input where appropriate from a perinatal pathologist, obstetric physician, pediatric surgeon, geneticist, and ultrasonolographer in order to construct a coherent plan not only for the current neonate but also for further pregnancies.

Neonatal Considerations

Premature birth requires adaptation to extrauterine life while the different organ systems undergo continued structural and functional development and maturation. Thus, premature infants can be expected to have a variety of problems in the neonatal period with the risk of complications being proportional to the degree of prematurity. However, this statement may be modified by the observation that spontaneous PTL is probably adaptive in nature because the rate of neonatal respiratory distress syndrome in a comparative cohort study by Lee and colleagues[149] was greater in "indicated" rather than spontaneous PTD (OR 2.29; 95% CI 1.22–4.29).

Premature infants are likely to have difficulties in maintaining body temperature and in oral feeding as well as having a greater risk of infection. Lung maturity of premature infants is proportional to their gestational age and is the major cause of respiratory distress syndrome in these infants, whereas poorly developed respiratory control may lead to recurrent apnea. Congestive cardiac failure may occur as a result of patent ductus arteriosus associated with prematurity, for which there are medical and surgical options available for correction. Liver immaturity is likely to be associated with severe neonatal jaundice with the premature baby being more vulnerable to the neurotoxic effects of unconjugated bilirubin. Phototherapy reduces serum bilirubin levels in jaundiced preterm infants, but it is not clear whether aggressive or conservative phototherapy is optimal, particularly for extremely low–birth weight infants (<1000 g).

Morris and Tyson[150] allocated nearly 2000 infants weighing less than 1000 g to aggressive phototherapy, which aimed to achieve bilirubin levels around 7 mg/dL, or to conservative phototherapy, which aimed at a level around 10 mg/dL. All infants were tracked up to 2 years, and there was no significant difference in either survival or neurodevelopmental impairment between the two groups.

Small infants are often hyperglycemic because of immature intracellular feedback mechanisms, stress responses, or high-calorie feeding regimens. It has been postulated that insulin treatment may enhance survival rates and promote brain growth, but mixed findings and hypoglycemic episodes have confused its acceptance.

Beardsall and Dunger[151] have published the results of an international trial of early insulin therapy versus standard neonatal care; unfortunately, the results were disappointing because the early intervention group fared no better than those receiving conventional treatment and hypoglycemic episodes were more frequent. There is also an increased risk of intracranial hemorrhage and necrotizing enterocolitis in premature infants, and maternal corticosteroid administration has been associated with a significant reduction in these morbidities, as previously discussed.

In the extremely premature infant, chronic lung disease and retinopathy are more likely in the longer term. Similarly, cerebral palsy and developmental delay are more likely in preterm infants, and it is here that previously discussed strategies such as antenatal maternal magnesium sulfate administration may play a neuroprotective role.

Head cooling has been proposed as a method of improving outcomes in infants with hypoxic ischemic encephalopathy. The Cochrane review by Jacobs and associates[152] included eight randomized trials involving infants with asphyxia or hypoxic ischemic encephalopathy. Cooling reduced the risk of death or developmental disability at 18 months of age (RR 0.76; 95% CI 0.65–0.89; NNT 7; 95% CI 4–14). The reviewers cautioned that fewer than half the subjects known to have been entered into these trials have been included in the final reports (and therefore in the review), raising the possibility of bias.[152] Further studies of head cooling are in progress, such as that being conducted at Vanderbilt University, assessing the impact of head cooling in reducing neurologic morbidity in preterm infants.[153]

Maturity of organ systems, particularly the lung, is really the key factor determining the ultimate prognosis of the premature infant. Minimizing the incidence and severity of respiratory distress has been the major factor in the substantial improvement in neonatal morbidity and mortality rates since the 1980s.

Previously mentioned strategies of regionalization of perinatal care, selective use of tocolytic agents, and maternally administered corticosteroids to enhance fetal lung maturity have all been positive contributing factors. Similarly, the "prophylactic" use of exogenous surfactant as well as its use as "rescue" therapy in association with mechanical ventilation in established respiratory distress syndrome has been a major advance in reducing respiratory morbidity.[154]

In addition there have been efforts directed at improving the neurodevelopmental outcomes of preterm infants using high-dose docosahexaenoic acid (DHA) as in the randomized, controlled trial conducted by Makrides and coworkers[155] that demonstrated a statistically significant difference in the Bayley Mental Development Index at 18 months' corrected age in preterm infant females delivered between 23 and 33 weeks' gestation who were fed high-DHA (~1% total fatty acids) compared with infants fed standard DHA (~0.3% total fatty acids). The lack of responsiveness of boys to the intervention is unclear and may relate to the higher rate of endogenous synthesis of DHA from the precursor fatty acid α-linolenic acid in girls compared with boys. Further studies are required to establish the role of DHA in the routine management of preterm infants.

Although there has been a significant increase in neonatal survival rates at 24 to 27 weeks' gestation over the past decade, it appears that prematurity per se has a deleterious effect on neonatal growth and development that contributes to a poorer outcome. This must be taken into account when assessing survival and morbidity rates, particularly in very low–birth weight infants less than 24 weeks' gestation.

The NIH Newborn Research Network, previously mentioned, has recently compiled survival and neurodevelopmental outcomes based on the observation of 4000 infants in relation to gestational age, sex of the neonate, birth weight, singleton or multiple birth, and maternal administration of corticosteroids. This tool has enabled rationalization of care for the very preterm neonate because it must be emphasized that not every newborn infant can be salvaged, and on some occasions, survival may be accompanied by severe handicap either physical or psychological or both. Prolonging life in these circumstances may not be beneficial to the infant and may become unacceptably burdensome to the parents. In such cases, the parents may opt for "comfort care" soon after birth, or later, after detailed and extensive consultation and counseling, they may consider withdrawing life support.

In addition to these medical and ethical challenges confronting the neonatologist are the immediate and delayed financial costs of neonatal intensive care. Economic constraints may not unreasonably act as a brake to those who would seek to overcome all of the aforementioned medical and ethical challenges, resulting in a more restrained attitude of evidence-based medical practice in an environment of cost containment.

The final measure of the quality of a tertiary neonatal service is the dedication and commitment of its long-term follow-up program. All perinatal centers must be prepared to commit resources to maintain and upgrade this essential service so that early intervention of detected physical and psychological problems can be instituted to minimize their effects on the infant born preterm.

In addition, the follow-up program will provide valuable information to the obstetricians and maternal fetal medicine subspecialists that will allow them to promulgate relevant advice and provide appropriate support, reassurance, and counseling of the parents who will continue to bear the logistic, financial, physical, and psychological impact of the care for the infant who is born prematurely.

SUMMARY OF MANAGEMENT OPTIONS
Threatened and Actual Preterm Labor

Management Options	Evidence Quality and Recommendation	References
Prepregnancy (Previous Preterm Labor)		
Establish cause/precipitating factors.	III/B	46,48,51
Estimate risk of recurrence:	III/B	56
• Advise re: lifestyle, work, place of residence at critical phase of pregnancy.		
• Specific reference to diet, smoking, alcohol, recreational drugs, obesity.		
Prenatal—Assessment of Risk		
Take a careful history for presence of specific risks (e.g., previous preterm birth, race, intergenerational aspects, cervical trauma).	III/B	56–65
Value of formal risk scoring systems is not confirmed.		
Establish gestational age early and as accurately as possible (first-trimester scanning if required).	GPP	
Prenatal—Previous Preterm Labor and Delivery		
Provide general advice re: lifestyle, work, place of residence at critical phase of pregnancy.	III/B	57
• Specific reference to diet, smoking, alcohol, recreational drugs, obesity.		
If cervical incompetence, perform cerclage at 12–14 wk.	Ib/A	68–72
Patient education programs re: signs and symptoms of preterm labor have poor predictive value.		
Increased attendance and discussion for women at risk may be helpful for decisions on place, timing, and mode of delivery.	III/B	66
Prenatal—Strategies Needing Further Evaluation		
Screening (See Chapter 60)		
• Monitor uterine contractility.		
• Obtain regular cervical assessment—clinical and ultrasound.		
• Infective screening.		
• Biochemical screening.		
Prophylaxis		
Tocolytics offer no value.	Ib/A	13
Antibiotics (general) offer no value.	Ib/A	5

Management Options	Evidence Quality and Recommendation	References
Treatment of bacterial vaginosis in women at high risk of preterm labor may be of use.	Ib/A	85,86
Maternal corticosteroids should be considered, although there are concerns with repeated courses.	Ib/A	30,37
Presentation with Threatened or Actual Preterm Labor		
Initial assessment to determine if genuine preterm labor:	GPP	
Uterine activity:		
• Bleeding.		
• Membrane rupture.		
• Presenting part.		
• Engagement of presenting part.		
• Cervical status—clinical, ultrasound.		
• Gestational age.		
• Biochemical tests may be useful in excluding the diagnosis (e.g., fibronectin).	III/B	118–121
Search for cause or precipitating factor.	GPP	
Discuss prognosis with parents.	III/B	23
Maternal-fetal transfer to tertiary center.	III/B	147,148
Liaison with neonatologists/pediatricians.	GPP	
Tocolysis (depending on gestation, cause, contraindications including infection):		
• Calcium channel blockers are becoming more popular.	Ia/A	13
• β-Sympathomimetics are less popular owing to unacceptable side effects.	Ib/A	122
• Tocolytics are justified for at least 48 hr to allow fetal pulmonary maturation and other beneficial effects.	GPP	
Maternal Corticosteroids		
These are proven use up to 34 wk and are being evaluated for benefits between 34 and 37 wk.	Ia/A	30
TRH, Vitamin K, Phenobarbitone		
Use is not justified.	Ia/A	126,127
Antibiotic Therapy		
Not recommended as an adjunct to tocolysis.	Ia/A	128
Should be used if group B streptococcus is present or PPROM is confirmed.		
Emergent/Rescue Cerclage		
Only in the context of an RCT.	III/B	137–141
Maternal Magnesium Sulfate		
For neuroprotection of the preterm infant.		
Should now be considered—dosage and duration yet to be determined.		26
Labor and Delivery		
Use a multidisciplinary approach—obstetric, midwifery, neonatology/pediatric, anesthetic.	GPP	
Before 24 Wk		
Discuss with parents re: prognosis.	GPP	
Aim for vaginal delivery, experienced pediatrician/neonatologist in attendance.		
From 24 Wk		
Discussion with parents re: prognosis	GPP	

SUMMARY OF MANAGEMENT OPTIONS
Threatened and Actual Preterm Labor—cont'd

Management Options	Evidence Quality and Recommendation	References
If cephalic presentation, aim for vaginal delivery with usual indications for cesarean section.	GPP	
If breech, see Chapter 63.		
Provide continuous fetal heart rate monitoring.	GPP	
Regional anesthesia choice.	GPP	
Use assisted vaginal birth for standard obstetric indications.	GPP	
Prescribe antibiotics if clinically infected.	GPP	
Have an experienced pediatrician/neonatologist in attendance.	GPP	
Maternal		
• Encourage breast-feeding.	GPP	
• Provide psychological/social support.	GPP	
Neonate		
• Allow continuous access to neonatal unit.	GPP	
• Provide direct communication re: neonatal progress.	GPP	
Follow-up		
• Search for cause/precipitating factors.	GPP	
• Establish plan for future pregnancies.	GPP	
• Provide long-term follow-up of neonate.	GPP	

GPP, good practice point; RCT, randomized, controlled trial; TRH, thyrotropin-releasing hormone.

Acknowledgment

Prelabor Rupture of the Membranes

JOHN M. SVIGOS, JODIE M. DODD, and
JEFFREY S. ROBINSON

INTRODUCTION

Prelabor rupture of the membranes (PROM) is an obstetric conundrum. It is ill-defined with an obscure etiology; is often difficult to diagnose; is associated with significant maternal, fetal, and neonatal risks; and has management strategies that are often diverse and controversial. Some of this controversy relates to the currently low level of evidence. Although currently available systematic reviews and meta-analyses provide some guidance toward clinical care for both PROM and preterm prelabor rupture of the membranes (PPROM), further basic and clinical research will be necessary before we will be better able to define effective strategies for treatment and for primary prevention.

DEFINITION AND INCIDENCE

PROM is defined as rupture of the fetal membranes before the onset of contractions. There is then a "latent period" before the onset of spontaneous uterine activity. The length of the "latent period" varies, from an hour or two up to weeks. It is generally reported that PROM occurs in about 10% of all pregnancies, with the majority of cases occurring after 37 completed weeks of gestation.[1–5] If PROM occurs before 37 completed weeks of gestation, it is referred to as PPROM. PPROM occurs in approximately 2% of pregnancies overall, but in tertiary referral centers, it may occur in 5% or more of the obstetric population.[6]

RISKS

Maternal Risks

Significant maternal morbidity is associated with PROM, particularly preterm, and this morbidity can occur before, during, or after labor. Although the incidence of subclinical chorioamnionitis may be as high as 30% with PPROM,[7] serious systemic maternal infection is rare if treatment is initiated promptly. The use of a number of therapeutic agents, such as corticosteroids, antibiotics, and particularly β-sympathomimetic tocolytic agents, will pose additional maternal risk in the setting of PPROM, which must be considered in the overall management. Abruptio placentae is evident in 4% to 7% of women with PPROM, and hence,

vaginal bleeding in the presence of PROM must be regarded seriously and managed accordingly.[8–10] Psychosocial sequelae occur in association with PPROM because of the disruption created by the need for continuing observation, often involving hospitalization, together with the uncertain fetal/neonatal prognosis; this should be addressed on an individual basis within the overall management strategy. The intrapartum maternal consequences of PROM are predominantly related to the augmentation of labor. The latent phase of labor under these circumstances may be as long as 16 to 20 hours, and thus, unrealistic limits must not be set regarding the duration of labor when counseling the patient and the attendant staff. The increase in operative delivery associated with PROM inevitably increases maternal morbidity.[11] Pathologic examination of placentae associated with PROM demonstrates an increased incidence of marginal cord insertion and battledore placenta, which may account for the increased incidence of retained placenta in this setting. This, in turn, may be associated with the known increased incidence of primary and secondary postpartum hemorrhage. The latter complication is probably associated with the 10% incidence of endomyometritis that occurs with PROM.[12] After delivery, in addition to the previously discussed, there is an increased incidence of impaired maternal-infant bonding that contributes significantly to maternal psychological and lactation problems.

Fetal and Neonatal Risks

Prematurity is the most significant factor in the associated increased perinatal morbidity and mortality because delivery occurs within 7 days in over 80% of women who present with PPROM.[13,14] The duration of the latency period in PPROM is not only inversely related to gestational age but also shorter in the presence of oligohydramnios, cervical dilation, and fetal growth restriction.[15] Although the incidence of chorioamnionitis is 30%, the reported incidence of neonatal sepsis is only 2% to 4%.[16–18] Gestational age at the time of rupture of the membranes will have some influence on the incidence of neonatal sepsis, as will the length of the latent period. A growing body of epidemiologic data has demonstrated a relationship between intrauterine infection and the development of intraventricular hemorrhage, periventricular leukomalacia,

and the subsequent occurrence of cerebral palsy.[19] This damage is likely to be the result of the fetal inflammatory response syndrome[20] initiated by placental inflammation, rather than infection, and resulting from the local generation of arachidonic acid and preinflammatory cytokines: interleukin-1 (Il-1), Il-6, and tumor necrosis factor-α. The oligohydramnios resulting from PPROM, particularly if it is prolonged, may result in the neonatal "oligohydramnios tetrad" of flattened facies, limb positional deformities, pulmonary hypoplasia, and impaired fetal growth, all of which contribute to increased neonatal morbidity. Fetal hypoxia is more likely due to the greater possibility of cord prolapse, cord compression, and abruptio placentae associated with PROM, particularly with PPROM. Neonatal morbidity may also be increased owing to the mechanical difficulties that can be encountered at delivery by either the vaginal or the abdominal route as a result of an increased incidence of malpresentation and the reduced volume of surrounding amniotic fluid.

MANAGEMENT OPTIONS

Prepregnancy and Prenatal Prevention

Prepregnancy counseling has only a limited role in the management of PROM, particularly PPROM, because in the vast majority of cases, the cause is unknown.

The recurrence risk for PPROM has not been studied extensively but Naeye's original observation[21] of a recurrence rate of 21% to 32% was subsequently confirmed by Asrat and coworkers,[22] although Lee and associates[23] have since reported a lower recurrence rate of 16.7%.

A detailed examination of the etiologic associations of PPROM by Harger and colleagues[24] suggested that the only independent risk factor that might be amenable to prepregnancy intervention is cigarette smoking; the risk appears to be dose-related.

Other less constant associations that might be amenable to prepregnancy intervention include cocaine abuse[25] and intrauterine diethylstilbestrol (DES)-exposed women with congenital uterine anomalies (which is now becoming rare because DES use was discontinued in 1974).[26]

Nutritional deficiencies of ascorbic acid (vitamin C), copper, zinc, and iron have been variously suggested as increasing the incidence of PPROM,[27,28] but antioxidant therapy using vitamin C and vitamin E supplementation[29] has failed to demonstrate a reduced risk of PPROM (3.2% incidence in supplemented women vs. 2.4% with placebo; relative risk [RR] 1.34; 95% confidence interval [CI] 0.77–2.25). Indeed, there is some suggestion that such supplementation may be associated with an increased incidence of both PROM and PPROM.[30]

There is substantial direct and indirect evidence that reproductive tract infections and associated inflammatory changes are responsible for many instances of PPROM.[31] Group B streptococci, *Chlamydia*, gonorrhea, syphilis, *Mycoplasma hominis*, and *Ureaplasma urealyticum* have all been variously incriminated, but robust evidence that prophylactic treatment of these organisms is effective in reducing the incidence of PPROM is lacking.

The prophylactic antimicrobial treatment of bacterial vaginosis during pregnancy in high risk women has been evaluated in several randomized trials, with the evidence presented in a systematic review and meta-analysis.[32] Fifteen randomized trials involving 5888 women evaluated the role of antibiotics for treatment of bacterial vaginosis in pregnancy.[32] Treatment was associated with no difference in the risk of preterm birth prior to 37 or 34 weeks' gestation or in the risk of PPROM (odds ratio [OR] 0.88; 95% CI 0.61–1.28; 4 studies, 2579 women).[32] However, in a subgroup analysis of women who had experienced a prior preterm birth, treatment of bacterial vaginosis in a subsequent birth was associated with a significant reduction of the risk of PPROM (OR 0.14; 95% CI 0.05–0.38; 2 studies, 114 women).[32] In a recent meta-analysis that included nine studies relating to PPROM before 34 weeks, Hutzal and coworkers[33] reported that antibiotics were associated with prolongation of pregnancy. In addition, there was a reduction in neonatal infections and a trend toward a reduction in the incidence of sepsis with positive cultures. Importantly, there were fewer cases of intraventricular hemorrhage of all grades in the neonates. However, there remains uncertainty about the best antibiotic regimen to be adopted.[34] In light of this, prepregnancy vaginal microbial cultures would appear to be a useful investigation in women with a past history of PPROM, especially in the detection of group B streptococcus and bacterial vaginosis.

A population-based study of the race-specific risk for PPROM found that African American women were at higher risk than white women for the occurrence and recurrence of PPROM even after adjustment for known risk factors.[35] The implication from this study is that there may be genetic factors in addition to environmental factors contributing to the etiology of PPROM.

Antimicrobial treatment of the sexual partner is more controversial whereas the avoidance of coital activity during the course of further pregnancies would appear to be unnecessarily restrictive. If there is concern that infection might be introduced by the male partner, this risk may be reduced by the use of condoms.

Prenatal

Diagnosis and Further Assessment ("Expectant Management")

The diagnosis of PROM requires a judicious assessment of the history, clinical examination, and specialized testing. Whenever the history is suggestive of PROM, a sterile vaginal speculum examination should be performed. Visualization of amniotic fluid draining through the cervix provides the most reliable diagnosis and the opportunity to exclude cord prolapse, particularly with PPROM. In case of doubt, demonstration that vaginal fluid has an alkaline pH on Nitrazine yellow testing (the pH indicator turning black) is suggestive but not conclusive evidence of PROM. The normal vaginal pH is acidic and becomes neutral or alkaline owing to the presence of amniotic fluid. However, loss of acidity can be due to vaginal infection or the presence of urine or even bath water, and hence, although the sensitivity of the Nitrazine yellow test is 90%, there is a false-positive rate of 17%.[36,37] Ferning of vaginal fluid on microscopy is also a useful sign that the fluid is of amniotic origin, and this simple test, which is easy to perform, should be more widely

used in the diagnosis of PROM. However, both ferning and pH tests are less reliable at early gestational ages.

If the diagnosis of PROM is still in doubt, further investigations including the use of a modified vaginal pouch to collect amniotic fluid,[38] ultrasound evaluation of amniotic fluid volume, and intra-amniotic dye injections may be employed. Ultrasound evaluation of oligohydramnios is subjective unless there has been a recent large fluid loss, and intra-amniotic injection of dye is not without risk.[39,40] More recently, other tests have been evaluated in the diagnosis of ruptured membranes, with raised fetal fibronectin and raised insulin-like growth factor binding protein-1 having reported sensitivities of 94% and 75% and specificities of 97%, respectively.[41–43] A preliminary study of the Amnisure ROM immunoassay test measuring levels of placental α-microglobulin-1 in cervicovaginal secretions, when compared with the gold standard of clinical diagnosis, was found to have a sensitivity of 98.7%, a specificity of 87.5%, a positive predictive value of 98.1%, and a negative predictive value of 91.3%, which was superior to conventional clinical assessment of ruptured membranes. Further studies are awaited.[44]

Alternatively, if conservative management is deemed appropriate, a "wait and see" policy regarding diagnosis can be adopted. Repeatedly dry pads and a normal amniotic fluid volume on ultrasound examination make the diagnosis less likely. Digital vaginal examination is best avoided because this may introduce infection and possibly stimulate labor. A retrospective study reported that the latency interval between PROM and delivery in those who had a digital examination was significantly shorter than in those women who had only had a sterile speculum examination.[45]

The initial clinical assessment of the patient with PROM will determine further management. All efforts must be directed initially at the exclusion of overt chorioamnionitis, with attention to the detection of maternal tachycardia, pyrexia, uterine tenderness, purulent vaginal discharge, and fetal tachycardia. Thereafter, there should be an evaluation of the fetal gestational age from the history, clinical examination, and ultrasound assessment to determine the likelihood of abruptio placentae and preterm labor.

The subsequent management of the patient will depend very heavily on the particular combination of the previous findings; these management alternatives are discussed in the following sections.

Expectant management usually consists of hospitalization and continued clinical observation of the mother and the fetus. The role of bedrest is controversial but may aid diagnosis by allowing a pool of amniotic fluid to collect in the posterior fornix. Maternal activity appears to increase the rate of fluid leakage, possibly by dislodging the presenting part. Specialized assessment of continued fetal well-being can be employed using cardiotocography, biophysical profiles, and fetal growth estimates every 2 weeks. Abnormal biophysical profile scores have been shown to be markers of intrauterine infection, but in different studies, the true- and false-positive rates vary from 25% to 80% and 2% to 9%, respectively.[46] Fetal tachycardia detected on cardiotocography predicts 20% to 40% of cases of intrauterine infection with a false-positive rate of 3%. There is currently no consensus as to how frequently cardiotocography should be employed.[47,48]

The detection of covert chorioamnionitis using serial daily white blood cell differential counts and C-reactive protein estimates, in association with an initial and then weekly microbiologic cultures, has been advocated. The reported sensitivities and false-positive rates of leukocytosis in the detection of chorioamnionitis range from 29% to 47% and 5% to 18%, respectively, whereas the specificity of C-reactive protein is 38% to 55%.[49–52]

Ultrasound assessment of cervical length has been investigated as a possible predictor of microbial invasion of the amniotic cavity.[53] One study, using a cervical length of 24 mm, had a sensitivity of 76% and a specificity of 67%, performing better than amniotic fluid white cell count, maternal C-reactive protein, and white cell count.[53] The data evaluating weekly vaginal swabs do not show that this is beneficial, with positive genital tract cultures predicting only 53% of positive amniotic fluid cultures with a false-positive rate of 25%.[54] However, the detection of group B streptococcus will provide the opportunity for intrapartum antibiotic therapy.

The use of amniocentesis in clarifying the possibility of covert chorioamnionitis remains controversial and as yet remains to be adequately tested. Current evidence would suggest that infection is a cause rather than a consequence of ruptured membranes, and amniocentesis may detect subclinical infection. Microbiologic culture of amniotic fluid will direct the administration of antibiotics and/or delivery, depending on the gestation in infected cases, and expectant management for women with negative amniotic fluid cultures.[55] However, reported success rates in obtaining amniotic fluid in these circumstances vary from 45% to 97%. Another limitation is the lack of a gold standard for the diagnosis of occult/covert intrauterine infection versus colonization, which in turn, makes the interpretation of the Gram stain, amniotic fluid culture, leukocyte esterase testing, and gas liquid chromatography studies particularly difficult. Rapid amniotic fluid assays of cytokines such as Il-6, Il-8, and I,-18 in amniotic fluid, which may indicate intrauterine infection, have yet to be validated as markers for obstetric assistance and may prove to be no better than clinical indicators,[56] whereas the diagnostic and prognostic value of matrix metalloproteinase-8, amniotic fluid prostaglandin, activity of a lactate dehydrogenase isoform, and proteomic profiles also remain to be evaluated.[57–64]

General Management

Active management may be defined as the previously described expectant management plus the use of one or more of the following:
- Maternal corticosteroids.
- Tocolytic agents.
- Prophylactic antibiotics.

MATERNAL CORTICOSTEROIDS

In the contemporary management of PPROM, there is good evidence to recommend the use of maternal corticosteroids before 34 weeks' gestation to enhance fetal lung maturity.[65] A meta-analysis by Harding and colleagues[66] included 15 randomized, controlled trials involving more than 1400 women with PROM without clinical chorioamnionitis. Results demonstrated that antenatal corticosteroids reduced the risks of respiratory distress syndrome (RR 0.56; 95% CI 0.46–0.70), intraventricular hemorrhage (RR 0.47; 95% CI 0.31–0.70), and necrotizing enterocolitis (RR 0.21; 95% CI 0.05–0.82), without evidence of an increase in the risk of

infection in either the mother (RR 0.86; 95% CI 0.61–1.20) or the baby (RR 1.05; 95% CI 0.66–1.68).[66]

As discussed in Chapter 61, there is conflicting information with regard to the repeated use of corticosteroids in this group of women. However, the authors are committed to its use as per the findings of Crowther and associates,[67] in which repeat doses of corticosteroids were associated with demonstrated respiratory benefit, without compromise in neonatal and early childhood growth. In contrast, the Multiple Courses of Antenatal Corticosteroids for Preterm Birth (MACS) trial did not demonstrate improvement in neonatal respiratory outcomes following repeat doses of antenatal corticosteroids.[68] Given the conflicting results, some authors have cautioned about the use of repeat steroids,[69] expressing concerns that adverse fetal programming effects of repeated high dose steroids may not emerge until later childhood, or even adulthood (leading to conditions such as diabetes or hypertension). The Cochrane review,[70] last updated in May 2007, concluded that "further research is needed on other important health outcomes for the woman and baby, which should include child development."

TOCOLYTICS

There is no good evidence to support the use of tocolytics as prophylaxis against preterm delivery, with three randomized studies of 235 women with PPROM demonstrating no increase in the time to delivery following the use of tocolytic therapy.[71–73] It would seem logical that if maternal corticosteroids are advocated, therapeutic tocolysis for at least 48 hours is acceptable providing there is no evidence of overt chorioamnionitis. However, there is conflicting evidence to support this view, with a small randomized trial by Christensen and associates[74] demonstrating a prolongation of the latency interval, whereas more recent nonrandomized data suggest that aggressive tocolysis in PPROM does not increase latency or neonatal morbidity compared with limited tocolysis or no tocolysis all.[75] It is possible that tocolysis could have adverse effects, including delaying delivery from an infected environment, which will be discussed later. There appears to be consensus, however, that the use of tocolysis for maternal-fetal transport to a tertiary center in women with PPROM is appropriate, albeit on the basis of limited evidence.[76]

ANTIBIOTICS

There is better evidence to support the use of prophylactic antibiotics in women with PPROM. Twenty-two trials involving over 6000 women with PPROM were included in the Cochrane Review by Kenyon and coworkers[77] that demonstrated a reduction in chorioamnionitis (RR 0.57; 95% CI 0.37–0.86), a reduction in the number of babies born within 48 hours (RR 0.71; 95% CI 0.58–0.87) and 7 days (RR 0.80; 95% CI 0.71–0.90), a significant reduction in neonatal infection (RR 0.68; 95% CI 0.53–0.87), and a significant reduction in the number of babies born with an abnormal cerebral ultrasound scan prior to hospital discharge (RR 0.82; 95% CI 0.68–0.98). There was no significant reduction in perinatal mortality, although there was a trend for reduction in the treatment group.[77] There was a variation in the choice of antibiotics used and the duration of therapy in the studies examined in the meta-analysis.[77] Ten trials tested broadspectrum penicillins, either alone or in combination, 5 tested

macrolide antibiotics (erythromycin) either alone or in combination, and 1 trial tested clindamycin and gentamicin. The duration of treatment varied between two doses and treatment for 10 days. Any penicillin (except co-amoxiclav) or erythromycin versus placebo was associated with a reduction in the number of babies born within 48 hours with positive blood cultures. Co-amoxiclav versus placebo was associated with an increase in the number of babies born with necrotizing enterocolitis (RR 4.60; 95% CI 1.98–10.72).[77] It is speculated that this might have been because co-amoxiclav interfered with the establishment of normal neonatal gut flora, thus increasing the risk of invasion by pathogenic organisms.

The meta-analysis is dominated by the Overview of Role of Antibiotics in Curtailing Labour and Early Delivery (ORACLE) I trial that recommended the use of oral erythromycin (250 mg q6h for 10 days) as the prophylactic antibiotic of choice for women with PPROM. The ORACLE Children Study I[78] revealed that these early-improved outcomes did not make a substantial difference to the children's health and development (medical conditions, behavioral difficulties, and educational achievements) long term (7-year follow-up) compared with co-amoxiclav either alone or in combination. In contrast, the ORACLE Children Study II[79] suggested a small increased risk of functional impairment and cerebral palsy in the children of women who took these antibiotics 7 years earlier because of threatened preterm labor with intact membranes (and a bigger increase when the two antibiotics were used simultaneously).

OTHER MANAGEMENTS

Additional active management strategies have been or are continuing to be explored to determine their place in the management of women with PPROM. Transvaginal amnioinfusion during labor was examined by one randomized, controlled trial involving 66 women with PPROM; the results showed no significant difference between amnioinfusion and no amnioinfusion on cesarean section rates, low Apgar scores, and neonatal death.[80] Transbdominal amnioinfusion has also been assessed as a possible therapeutic option, but the risk of pulmonary hypoplasia does not appear to be reduced, although fetal survival was higher in the treated than in the control group (64.8% vs. 32.3%, $P < .001$).[81] Hence, at present, there is insufficient evidence to recommend transabdominal amnioinfusion as a strategy for preventing pulmonary hypoplasia in very early PPROM.

Studies have evaluated the use of an "amnio patch" for women with mid-trimester PPROM, particularly when it results from iatrogenic PPROM at the time of amniocentesis or with diagnostic or therapeutic fetoscopy.[82] A variety of fibrin sealants have been used with some success, but their application to spontaneous membrane rupture has not been adequately tested to determine whether this would be a helpful strategy in spontaneous cases.[83,84] Even more preliminary is a study in a similar group of women using a cervical cerclage with placement of a gelatin sponge, embolization, beads and a bioadhesive glue into the endocervical canal.[85] A nonrandomized evaluation in a small number of women suggested a neonatal survival rate of 21% in the treated group compared with 0% in the control group.[85]

Do these initiatives represent a return to the PPROM "Fence" (a barrier or sealant to close the defect in the

membranes) suggested but never adequately tested in the 1980s?[86] Further trials are required before such strategies can be regarded as more than experimental.

SPECIFIC MANAGEMENT

Aggressive management is employed when delivery is deemed necessary as a result of obstetric indications such as fetal distress, maternal sepsis, abruptio placentae, or if requested by the parents in the face of marked fetal immaturity (<24 wk) or demonstrated fetal maturity (>37 wk). This form of management involves induction and augmentation of labor, with an inevitable increase in operative delivery and its associated maternal morbidity.

The prospective, multicenter, randomized, controlled trial by Hannah and colleagues[87] (The Term PROM Trial) has enabled us to provide management options for women with PROM after 37 weeks' gestation, and similarly designed trials for women with PPROM at different gestational age groups are currently in progress. Generally, the recommended management of PROM has shifted from an expectant mode to a more active mode, with accurate assessment of fetal gestational age being crucial to the decision-making process. It is useful to consider prenatal strategies in relation to five gestational periods.

PPROM AT LESS THAN 24 COMPLETED GESTATIONAL WEEKS

The most appropriate management at this gestation is not clear and must be individualized, with the wishes of the parents being paramount. Aggressive management is indicated if active labor, abruptio placentae, or clinical evidence of maternal-fetal infection is present. It may also be requested by the parents if they fear delivery not only at this gestation but also at a later gestation (25–26 wk) when there is the possibility of survival but also a high likelihood of serious neonatal complications and long-term handicap. Expectant management is increasingly considered nowadays, but with reported neonatal survival rates of less than 30% at gestations less than 24 weeks even in the most optimistic studies[88,89] and with "normal" neonatal development in less than 30% of the survivors after a 12-month follow-up, extreme care must be taken to ensure that parental counseling by the obstetric/midwifery/neonatology team is thorough and cautious.

In view of the uncertainty of the neonatal outcome, an alternative management strategy has evolved for these women. After initial hospitalization, investigation, and observation for 72 hours, the patient may be managed at home, restricting her physical activity, taking her own temperature, and reporting weekly for prenatal evaluation and microbiologic and hematologic surveillance. The package, and each individual component, of these management options has yet to be tested in randomized trials, but clearly this approach, if safe, would have substantial psychosocial advantages. It would also have economic benefits for the health system, although it might impose greater costs for the woman and her family, depending on the circumstances (e.g., whether she is insured or has state health coverage).

PPROM AT 24 TO 30 COMPLETED GESTATIONAL WEEKS

At this gestation, the greatest risk to the fetus is still prematurity, and this risk currently outweighs any potential advantage in delivering a patient with covert intrauterine infection. As a consequence, expectant management is the favored option at this gestation. The use of amniocentesis to detect covert or occult intra-amniotic infection remains controversial at this gestation, particularly because fetal lung maturity is unlikely. It may be specifically indicated to clarify the situation in the patient with PPROM who has mild pyrexia, a significantly raised white cell count, or an elevated C-reactive protein.

A randomized study by Carlan and associates,[90] assessing hospital versus home management after 72 hours of PPROM at 26 to 31 weeks' gestation, suggested that home management was a safe regimen to adopt in terms of comparable latency periods, gestational age at delivery, and similar maternal and neonatal outcomes with regard to sepsis and respiratory distress, along with significant savings in maternal hospital bed days. However, only 18% of women with PPROM were eligible and agreed to randomization, owing to the rigorous requirements for entry into the trial, which included cephalic presentation, an adequate amniotic fluid volume on ultrasound assessment, and acceptance of advice and education about the signs and symptoms of chorioamnionitis, the need for twice-daily basal temperature measurement, and regular outpatient visits.

The randomized, controlled trial by Turnbull and coworkers[91] included 395 women, some with PPROM, to in-hospital versus outpatient management. Although there were no differences in clinical outcomes and costs, women preferred outpatient management. However, this study was underpowered to detect a difference in the clinical outcomes for women with PPROM suggested by earlier studies.[92,93] Larger randomized studies are required to determine the appropriate management of PPOM, but we consider it reasonable to keep a patient in the hospital for at least 48 hours before making a decision to recommend continued management at home. Following such a decision, management should be individualized, with rigorous selection on the basis of risk factors. Eligible women should be instructed to take their temperature every 12 hours and be aware of the symptoms associated with intrauterine infection.

Included in the prenatal management of PPROM at 24 to 31 weeks' gestation must be a discussion with the parents regarding the likely mode of delivery should expectant management not be appropriate. Based on the studies by Amon and colleagues[94] and Sanchez-Ramos and associates,[95] there has been a move away from almost-universal cesarean section to vaginal delivery, with resort to cesarean section for standard obstetric indications, including breech presentation.[96]

PPROM AT 30 TO 36 COMPLETED GESTATIONAL WEEKS

At most tertiary institutions, neonatal survival after 30 completed gestational weeks exceeds 95%, and thus, the risk from prematurity is similar to the risk to the neonate from sepsis. Although debate still occurs about the place of amniocentesis in the diagnosis of occult chorioamnionitis, the detection of fetal lung maturity would suggest that it is present in 58% of specimens obtained at this gestational age.[56] Testing for fetal lung maturity (L/S [lecithin-to-sphingomyelin] ratio) in women with PPROM has a positive predictive value of 68% with a negative predictive value of 79%. Specific situations of occult amniotic fluid infection

but fetal lung immaturity and fetal lung maturity but absent amniotic fluid infection must be managed on a clinical basis with its inherent limitations, as must be women with PPROM in whom amniocentesis has been unsuccessful. A large prospective, randomized trial is urgently required to evaluate the role of amniocentesis in women presenting with PPROM (especially at 30–34 wk) because preliminary findings by Blackwell and coworkers[97] suggest that amniocentesis may alter clinical management in up to 48% of cases. Whether this results in decreased neonatal morbidity remains unknown.

Although an expectant management policy is commonly employed at 34 to 36 completed weeks of gestation, this is by no means the standard approach, with many favoring induction of labor.[98] In a survey of practice among Australian and New Zealand obstetricians,[99] 49% indicated a preference for expectant management and 51% indicated a preference for delivery.

A retrospective study of 430 women with PPROM demonstrated that composite neonatal minor morbidity such as jaundice and transient tachypnea was significantly higher among pregnancies delivered at 34 weeks' gestation or less than among those delivered at 36 weeks.[100] Composite major neonatal morbidity including respiratory distress syndrome and intraventricular hemorrhage was significantly higher in neonates delivered at 33 weeks or less than in those delivering at 36 weeks' gestation. There were no differences in major morbidity rates for those neonates delivered after 34 weeks' gestation, which led the authors to conclude that expectant management after 34 weeks' gestation was of limited benefit.

In an earlier prospective, randomized study of 120 women with PPROM between 34 and 37 gestational weeks,[101] the expectantly managed group had a higher incidence of chorioamnionitis compared with the immediate delivery group (16% vs. 2%; $P < .05$), but the incidence of sepsis and respiratory distress was similar in both groups.[101] A retrospective series examining neonatal outcome with PPROM between 32 and 36 weeks demonstrated that the specific gestation for reduced morbidity was 34 weeks.[102] The incidence of respiratory distress syndrome was 22.5% at 33 weeks and 5.8% at 34 weeks in this study.

In a meta-analysis of three randomized trials comparing immediate delivery with expectant management for women with PPROM at 34 to 36 weeks' gestation, immediate delivery was associated with a reduction in the risk of chorioamnionitis (three studies, 260 women; RR 0.25; 95% CI 0.12–0.53).[103] There were no statistically significant differences identified for neonatal outcomes, including respiratory distress syndrome, sepsis, or perinatal mortality.[103] There are currently two larger ongoing randomized, controlled trials by Lacaze-Masmonteil and Chari in Canada[104] and Morris in Australia[105] comparing elective delivery versus expectant management in women with PPROM between 32 and 35 completed weeks' gestation, the results of which are awaited.

A cautionary note must be added regarding recent studies reminding us of the small but significantly increased risk of perinatal death in singleton infants born at late preterm compared with term gestation,[106–109] which suggests the potential for long-term neurobehavioral problems and medical and social consequences in infants intentionally delivered between 34 and 37 weeks' gestation. This information taken together with the recent work of Bastek and colleagues[110] and Cheng and associates[111] reinforces the need to better characterize the risks of short-term and long-term morbidity to infants who are delivered at late preterm gestations rather than assuming that 34 weeks' gestation represents the complete achievement of fetal "maturity."

PROM AFTER 36 WEEKS

In women with PROM after 36 completed gestational weeks, an expectant management policy may be justified initially because it can be anticipated that 75% to 80% of these women will labor spontaneously within 24 hours. The controversial aspects of management at this gestation center around the risks of maternal and neonatal sepsis as the latency period lengthens versus the risks of induction of labor and a possible increase in operative delivery. The key study by Hannah and colleagues,[87] in which 5041 women with PROM at term were randomly assigned to expectant management for up to 4 days or to induction of labor with intravenous oxytocin or vaginal prostaglandin E₂ gel, has helped clarify this controversy. The rates of neonatal infection were 2.0% for induction with oxytocin group, 3.0% for induction with prostaglandin group, 2.8% for the expectant management (including subsequent oxytocin) group, and 2.7% for the expectant management (with subsequent prostaglandin) group.[87] The rates of cesarean section ranged from 9.6% to 10.9% in the four groups.[87] Hence, in PROM after 36 completed weeks, similar frequency for neonatal sepsis and cesarean section occurred with expectant management and induction of labor. However, clinical chorioamnionitis was less likely to develop in the women in the induction with oxytocin group than those in the expectant management (±oxytocin) group (4% vs. 8.6%; $P < .001$) as was postpartum fever (1.9% vs. 3.6%; $P = .008$).[87] Further, it was found that women in this study viewed induction of labor more positively than expectant management, although it remains important to give women choices in their management.[87] If cost implications are to also be taken into account, an argument can be mounted for induction of labor with intravenous oxytocin for women presenting with PROM at 36 or more completed gestational weeks.

The Cochrane review assessing expectant management of PROM near term included 12 trials involving 6814 women.[112] Overall, there were no differences detected for mode of birth between planned induction and expectant groups (cesarean section: RR 0.94; 95% CI 0.82–1.08; or operative vaginal birth: RR 0.98; 95% CI 0.84–1.16).[112] Significantly fewer women in the planned induction versus the expectant group had chorioamnionitis (RR 0.30; 95% CI 0.56–0.97) or endometritis (RR 0.83; 95% CI 0.12–0.74).[112] No differences were identified for neonatal infection (RR 0.83; 95% CI 0.61–1.12), although fewer infants with planned induction went to neonatal intensive or special care compared with expectant management (RR 0.72; 95% CI 0.57–0.92).[112] The conclusions of the review were that because planned and expectant management may not be very different, women need to be given appropriate information and then be encouraged to make a choice that suits their preference and circumstances.

Special Circumstances

THE "HINDWATER" LEAK

This poorly defined clinical entity is of unknown frequency and is usually a diagnosis of exclusion. The natural history of this phenomenon and its maternal and neonatal consequences is unknown and awaits further evaluation.

RESEALED PROM

Once again, this is a poorly defined clinical entity that may encompass a number of women with a "hindwater" leak. Johnson and coworkers[113] studied 220 conservatively managed women with PPROM between 20 and 34 weeks' gestation, and identified 8 women (3.6%) in whom there was a cessation of leakage. Similarly, Carlan and colleagues[114] reported on 349 women with PPROM of whom 14 (4%) apparently resealed after initial confirmation of PPROM. In both studies, those women who resealed were of a younger age group, had PPROM at an earlier gestation, and had larger pockets of residual amniotic fluid at the initial ultrasound examination than women with PPROM who did not reseal. After resealing, the pregnancies all proceeded normally without an increased incidence of rerupture of the membranes. How resealing might occur, given that the fetal membranes are acellular, remains a matter of speculation.

MULTIPLE PREGNANCY AND PROM (See Also Chapter 59)

A multiple gestation with an overdistended uterus is an important risk factor for PPROM; the incidence is higher and occurs earlier in multiple pregnancies. Mercer and associates[115] compared 99 twin pregnancies with 99 well-matched singleton pregnancies, all complicated by PPROM, and found that PPROM at less than 26 weeks' gestation occurred more frequently in twins with an incidence of 18.2% (OR 2.1) compared with 0.52% in singletons (OR 2.71). Despite these differences, the etiology of PPROM appeared to be similar to singleton pregnancies, with infection being the main identifiable cause, although uterine overdistention may play a role. This study showed only a brief latency period in twins complicated by PPROM regardless of gestational age, with no difference in infant survival between the presenting and the nonpresenting twins but with a significant increase in respiratory morbidity in the nonpresenting infant. Not surprisingly, rupture of the membranes usually occurs in the presenting sac, but this is not invariable and can occur in the nonpresenting twin.

Novel management strategies such as delayed interval delivery[116] need to be considered in this situation and are discussed in Chapter 59.

Montgomery and coworkers[117] suggested that the natural history of PPROM in twin gestation parallels that in singleton pregnancy, and that similar management strategies are appropriate for both groups of women with PPROM, although the study by Andreani and colleagues[118] suggests that PROM in twins is associated with a lower risk of chorioamnionitis than in singletons.

Labor and Delivery

If labor occurs in the presence of PROM, both mother and fetus should be intensively monitored, and labor augmented

promptly if there is any delay in progress, because of the increased risk of maternal and fetal/neonatal infection. Labor may be suppressed to allow transfer to a tertiary center if PROM occurs in an institution without appropriate facilities for neonatal care. Vaginal delivery should generally be anticipated, with the need for cesarean section not differing substantially from other preterm deliveries with intact membranes. Once labor is established or is induced, maternal intravenous antibiotic therapy should be commenced, particularly if signs of intrauterine infection are present (e.g., maternal pyrexia, maternal tachycardia, fetal tachycardia, persistent uterine tenderness, offensive smelling vaginal discharge with an increased white cell count, and a C-reactive protein). A reduction in anticipated puerperal infections has been confirmed in most studies advocating this approach.

The authors currently favor a loading dose of 2 g of intravenous ampicillin with 1 g every 4 hours thereafter, together with gentamicin 5 mg/kg intravenously and metronidazole 500 mg intravenously every 12 hours.[119] In cases of known group B streptococcus colonization or status unknown or PROM greater than 18 hours, benzyl penicillin 3 g as an intravenous loading dose followed by 1.2 g intravenously every 4 hours is recommended. This regimen of intravenous penicillin, or in the case of penicillin allergy, lincomycin (600 mg, q8h intravenously), is currently employed in the United Kingdom, most of Europe, and Australia, and it is reported to reduce group B streptococcus sepsis by more than 90% in the neonate.[120]

A preliminary study by Chichester and associates[121] suggests that women with PROM and regular contractions sufficient to cause a second request for pain medication within 2 hours should be offered epidural analgesia because they are highly likely to deliver within 24 hours. Although regional analgesia has benefits for the fetus, there may be concerns about inserting an epidural block in the presence of overt maternal infection because of concerns that the mother might develop an epidural/spinal abscess.[121] At the time of delivery, in addition to an experienced obstetrician and midwife, the presence of a neonatologist with the back-up of an appropriate neonatal support team is essential to the optimization of the perinatal outcome.

Postnatal

With regard to women delivering after PROM, an awareness of the associated risks of endometritis, genital sepsis/septicemia, along with postpartum hemorrhage and thromboembolism, is essential for the effective management of such women. Active promotion of maternal infant bonding, particularly with PPROM, deserves special mention. Recently, reports suggest that induction of labor, preterm birth, operative delivery, and postpartum hemorrhage, which all commonly accompany PPROM, are associated with lower rates of breast-feeding with OR 0.56 (95% CI 0.47–0.67), 0.87 (95% CI 0.77–0.98), 0.80 (95% CI 0.69–0.92), 0.83 (95% CI 0.72–0.96), and 0.84 (95% CI 0.75–0.94), respectively.[122]

All infants born after PROM should be thoroughly screened for sepsis irrespective of the use of antepartum or intrapartum maternal antibiotic therapy. Screening investigations usually include neonatal blood culture, endotracheal aspirate culture, urinary latex particle agglutination testing,

and a complete blood picture including nucleated red blood cells.[123] Lumbar puncture and cerebrospinal fluid examination should be reserved for clinically septic neonates and for those infants with positive blood cultures. Initial antibiotic therapy using a combination of intravenous penicillin and gentamicin is usually employed empirically while awaiting the result of the screening investigations. Often the results are inconclusive or equivocal, and discontinuation of the antibiotic therapy may have to be based on clinical judgment.

Respiratory disease remains the greatest hazard encountered with PROM, with respiratory distress requiring mechanical ventilation a common sequela. This can be aggravated by pulmonary hypoplasia, which is usually only clinically significant if PPROM occurs before 25 weeks' gestation and/or with a latent period of more than 5 weeks before delivery.[124] The neonatal outcome of PPROM at later gestations is more optimistic than is reported for other causes of oligohydramnios. Common associations of prematurity including intracranial hemorrhage, jaundice, and

feeding difficulties must be attended to in the usual fashion by the neonatal care team.

Essential to the provision of comprehensive care of preterm or complicated term neonates is the requirement for long-term neonatal follow-up, particularly in view of preliminary data suggesting a higher risk of neurodevelopmental impairment in preterm infants delivered after prolonged PPROM than in those neonates born after spontaneous preterm labor with intact membranes[125] and the now more robust data previously mentioned with regard to late preterm delivery.[106–111]

As has been outlined in Chapter 61, a postdelivery evaluation of the circumstances of the delivery by the perinatal team not only may aid in the management of future pregnancies but also will provide instructive and constructive feedback to the parents who are required to deal with the day-to-day consequences of PROM, particularly PPROM, not only in the immediate and long term for themselves and their babies but also possibly for future pregnancies.

SUMMARY OF MANAGEMENT OPTIONS
Prelabor Rupture of Membranes

Management Options	Evidence Quality and Recommendation	References
Prepregnancy (Especially Previous PPROM)		
Counsel about recurrence risks (21%–32% for PROM and up to 34% for PTD).	III/B	11,23
Search for causes/precipitating factors has limited overall value.	—/GPP	—
Stress value of preventive measures, such as patient education and stop smoking.	III/B	24
Note conflicting data on value of vaginal bacteriologic screening and antimicrobial treatment of woman and partner.	Ib/A	32–34,126–128
Prenatal		
Prevention		
There are conflicting data on the value of vaginal bacteriologic screening and antimicrobial treatment of woman and partner.	Ib/A	32–34,126–128
Cervical ultrasound assessment with fetal fibronectin (and similar biochemical screening tests) in women with previous history of PROM may be of benefit.	III/B	53
Confirm Diagnosis		
Perform history and physical examination (especially sterile speculum) and collection of amniotic fluid; make repeated pad checks to confirm diagnosis.	—/GPP	—
Additional tests ("ferning," alkaline pH turning nitrazine yellow blue/black, presence of vernix or meconium) all have limitations, especially being unreliable/inappropriate at preterm gestations.	—/GPP	—
Presence of fetal fibronectin (and other biochemical markers) may be useful confirmatory test indicating the likelihood of ensuing preterm labor may allow intervention to reduce the likelihood of birth complications.	III/B	53
Intra-amniotic injection of dyes is not without risk and is not widely practiced.	IV/C	39,40
Ultrasound diagnosis of oligohydramnios is associated only with substantial fluid loss, which is usually clinically obvious.	—/GPP	—

Management Options	Evidence Quality and Recommendation	References
Prenatal Management		
General		
Maintain vigilance for chorioamnionitis.	IIb/B	55–64
Clinical: maternal fever, tachycardia, uterine pain/tenderness, purulent vaginal discharge, fetal tachycardia.		
Laboratory investigations (unreliable):		
• White blood cell count and differential.	—/GPP	—
• C-Reactive protein	—/GPP	—
• Amniotic fluid Gram stain, white cells, and culture (role of amniocentesis uncertain).	IIa/B	55–64
Biophysical testing (NST and/or BPS).	III/B	47,48
Value of pro-inflammatory cytokine testing is uncertain.	IIb/B	59,61–63
Delivery is indicated if chorioamnionitis is diagnosed or if fetal distress occurs (NST/BPS).	—/GPP	—
<24 Weeks with No Evidence of Chorioamnionitis or Fetal Distress		
Individualized management including parental input.	—/GPP	—
Careful counseling of parents needed.	—/GPP	—
If decision is to continue with pregnancy, implement surveillance for sepsis, possibly at home.	IIb/B	88,89
Mode of delivery is usually vaginal.	IV/C	92,93
24–31 Weeks with No Evidence of Chorioamnionitis or Fetal Distress		
The upper gestational age chosen will vary depending on local neonatal survival rates.	—/GPP	—
Expectant/conservative management (possibly at home after initial hospital assessment and exclusion of sepsis) is recommended.	Ib/A	90–93
Counsel parents re: prognosis.	—/GPP	—
Look for clinical evidence of chorioamnionitis.	IIb/B	89,90
Treatments:		
• Steroid use is variable.	Ib/A	65,67–69,129
• Tocolysis only for transfer to tertiary unit.	IV/C	65
• May give antibiotics (erythromycin not co-amoxiclav).	Ia/A	77
Assessment of fetal pulmonary lung maturity is a variable practice and of uncertain value	IIa/B	97
Aim for vaginal delivery if cephalic; ?cesarean section for breech presentation.	IV/C	96
31–36 Weeks with No Evidence of Chorioamnionitis or Fetal Distress		
Options used in practice:		
• Expectant/conservative (wait for 24–72 hr and if not in labor, consider induction).	—/GPP	—
• Aggressive (induce labor at presentation).		
After 36 Completed Weeks with No Evidence of Chorioamnionitis or Fetal Distress		
Discuss options with parents:		
• Expectant/conservative (wait for 24–72 hr and if not in labor, induce).		
• Aggressive (induce labor at presentation).	Ib/A	87,112
Special Circumstances		
Hindwater leak—poorly defined, difficult to diagnose.		
If definite proof of PROM (irrespective of whether cervical membranes intact), manage as PROM.	—/GPP	—

SUMMARY OF MANAGEMENT OPTIONS
Prelabor Rupture of Membranes—cont'd

Management Options	Evidence Quality and Recommendation	References
Cessation of PROM—manage normally.	Ia/A	113,122
Multiple pregnancy—manage as for singleton.	IIb/B	117,118
Labor and Delivery		
Continue observation for infection.	—/GPP	—
Use of maternal antibiotics prophylactically during labor remains controversial (except with group B Streptococcal colonization).	IIa/B	120
Cesarean section for normal obstetric indications.	—/GPP	—
Pediatrician should attend delivery.	—/GPP	—
Postnatal		
Maintain vigilance and screening for infection.	—/GPP	—
Neonatal screen for sepsis and appropriate care.	—/GPP	—
Long-term pediatric follow-up especially neurodevelopmental.	IIa/B	106–111,125

BPS, biophysical score; GPP, good practice point; NST, nonstress test; PPROM, preterm premature rupture of membranes; PROM, premature rupture of membranes; PTD, preterm delivery.

FUTURE DIRECTIONS

This review of the care of women and their babies when the amniotic membranes rupture before the onset of labor highlights the need for large well-designed trials of a range of management strategies. Where possible, these studies must be randomized with concealment of treatment options. It is likely that such studies will require collaboration between many centers in order to achieve sample sizes that would provide meaningful answers for incorporation into clinical practice guidelines.

Breech Presentation

ZOË PENN

INTRODUCTION

Many of the obstetric controversies surrounding breech presentation have been resolved since the turn of the Millenium. Antenatal external cephalic version (ECV) is now recommended for the term fetus and is deemed unnecessary for the preterm fetus, whereas delivery by elective cesarean section is recommended when the fetus is mature or labor commences at term. Vaginal delivery of the breech was the norm (and an essential manipulative skill to be acquired by all obstetricians) until the late 1950s, when cesarean section was first recommended on a routine basis to protect the fetus. This recommendation gained ground steadily, but it was not until shortly after the beginning of the third millennium that a trial was published that finally convinced most of the world's obstetricians that the policy was evidence-based.[1]

However, an important realization since the early 1980s has been that breech presentation may well be a bad prognostic variable in itself.[2] Any studies, clinical trials, or proposed clinical management must take this into account.

INCIDENCE

The incidence of breech presentation varies with gestational age, being approximately 14% at 29 to 32 weeks and 2.2 to 3.7% at term (depending on the use of ECV), giving an overall figure of 3% to 4%.[3,4]

ETIOLOGY

Although, in many cases, no specific underlying cause of breech presentation is apparent, in some cases, a cause can be identified (Table 63–1).

Preterm Labor

A major reason for breech presentation is the preterm onset of labor (probably the chance lie of a highly mobile fetus in relatively copious liquor); most of these babies are structurally normal. It remains unclear whether breech presentation per se predisposes to preterm labor.

Fetal Abnormality

Lamont and associates[5] found that 18% of preterm breech infants were congenitally abnormal. Collea and coworkers[6] quoted a 5% incidence of congenital abnormality in term breech fetuses, two and a half times higher than in their vertex counterparts (2.1%). Central nervous system abnormalities are the most commonly noted; approximately 50% of all babies with hydrocephalus and myelomeningocele present by the breech, as do 50% of those with Prader-Willi syndrome and trisomy. Despite the association of breech presentation with preterm labor, labor at term is still most common and 90% of abnormal breech babies weigh more than 2000 g.

Breech presentation is also associated with fetal growth restriction and with abnormalities of amniotic fluid volume (either oligo- or polyhydramnios). The association between fetal growth restriction and breech presentation is particularly marked in the preterm fetus. Breech fetuses tend to have reduced fetal-placental ratios, to be small for gestational age, and to have an increased head circumference regardless of the mode of delivery. This difference in weight persists at 18 months of age but disappears by 4 years.[7] Breech presentation has also been linked with relatively short umbilical cords.

Maternal Abnormality

Uterine size or shape may also influence presentation. The narrower cephalic pole of the fetus usually fits better than the breech into the narrower lower segment, and the breech and legs into the wider upper segment, especially if the legs of the fetus are flexed at the knee. However, if the knees are extended, the hips flexed, and the uterine space limited, the head and feet may lie alongside each other, making the cephalic pole of the fetus larger and thus encouraging a breech presentation. Uterine tone is greatest in nullipara, limiting the available space, and breech presentation is reported to be more common in nulliparous women. Conversely, the relaxed uterus of the grand multipara encourages an unstable lie, so that the fetus enters labor by chance in a breech presentation.

Other less benign conditions may alter the uterine capacity or the intrauterine shape. Uterine anomalies, such as bicornuate uterus, are associated with breech presentation. Placenta previa is well recognized in association with breech presentation, because this changes the intrauterine shape and prevents engagement of the head. Cornual implantation of the placenta, an otherwise benign condition, is also strongly associated with breech presentation; only 5% of

Preterm labor
Fetal abnormality (especially central nervous system)
Oligo- or polyhydramnios
Fetal growth restriction
Short umbilical cord
Extended legs in the fetus
Uterine abnormality (e.g., bicornuate uterus)
Placenta previa
Cornual placenta
Contracted pelvis
Multiple pregnancy
Maternal anticonvulsants
Maternal substance abuse

vertex-presenting fetuses have a cornual placenta in comparison with 73% of those presenting by the breech.

A contracted pelvis is also associated with breech presentation, probably by limiting uterine space in the lower segment.

Other Reasons for Breech Presentation

Women who have had a breech presentation at term are significantly more likely to have another in a subsequent pregnancy. This is usually associated with extended fetal legs and may indicate a genetic predisposition to this posture in the fetus.

Multiple pregnancy is strongly associated with breech presentation. The reader is referred to Chapter 59 for further discussion of management.

Medication with anticonvulsants in pregnancy also seems to be associated with breech presentation,[8] as does maternal alcohol abuse[9]; both substances have a profound influence on intrauterine fetal neurologic function. Fetal behavior in utero in fetuses with persistent breech presentation is also subtly different. They demonstrate more state transitions in fetal activity and heart rate patterns in utero than their cephalic presenting counterparts.[10]

RISKS AND SIGNIFICANCE

Although fetuses presenting by the breech have an increased perinatal mortality rate, it has proved difficult to separate and quantify the independent risks of the breech position itself and to distinguish the problems of the delivery from the problems of the fetus being abnormal. The perinatal mortality rate remains increased even when delivery is by cesarean section; this is true even after correction for gestational age, congenital defects, and birth weight.

Many retrospective reviews of breech presentation and trials of antepartum and intrapartum management compare the breech-presenting infant with the vertex-presenting infant, and because of its associated problems, the breech-presenting infant is more likely to perform unfavorably, regardless of the mode of delivery. There have only been a small number of randomized, controlled trials and meta-analyses studying the role of the mode of delivery of the term breech in relation to long-term outcome, and they have produced conflicting results.[6,11–14] (It should be noted that

functional and behavioral outcomes by mode of delivery need to be considered independently of perinatal mortality; see the later section on mode of delivery.)

Although breech presentation is an independent predictor for cerebral palsy,[15] some of the association of breech presentation with cerebral palsy can be accounted for by the excess of low birth weight in breech presentation, and the association is independent of the mode of delivery.[16]

Abnormalities of neuromotor development may also be manifest in breech-presenting fetuses, with subtle differences in in utero fetal behavioral states being evident.[16] Following birth, Bartlett and colleagues[17] compared 90 morphologically normal term breech-presenting singletons with birth weights greater than 2500 g and delivered by cesarean section with similar cephalically presenting infants, matched for gender and also delivered by cesarean. They collected data prospectively on neurologic status and motor performance over the first 18 months of life. They found that not only did breech-presenting infants have more open popliteal angles at birth (an unsurprising observation) but also they had significantly lower motor scores at 6 weeks and an excess of neurologic problems diagnosed at 18 months.

The risks to the mother are an increased rate of cesarean section with all its attendant complications. However, Lydon-Rochelle and associates,[18] using logistic regression, showed that among 265,000 nulliparous women undergoing cesarean section, there was no increased risk of maternal mortality compared with women delivering vaginally; similarly low rates of mortality have been reported in a number of other large population studies.[19,20] Several large population studies of maternal morbidity after elective caesarean section have shown morbidity to be mostly limited to postpartum fever, with the highest morbidity being associated with assisted vaginal delivery or intrapartum cesarean section.[21,22] The main risk seems to be of placenta previa and placenta accreta in a subsequent pregnancy, with a maternal mortality rate of up to 7% if these complications occur.[23] There is some evidence that breech presentation and cesarean section may reduce the subsequent pregnancy rate, probably because of the woman's decision not to reproduce again.[24] However, if these women do decide to have another child, vaginal delivery remains an option; one study in Dublin reported that 85% of those who had a trial of vaginal delivery in their second pregnancy after an elective caesarean section for breech presentation in their first pregnancy delivered vaginally.[25]

DIAGNOSIS

Three clinical types of breech presentation are recognized. This classification is useful in that it may indicate the cause of the presentation and the complications to be anticipated. As with most clinical classifications, there is overlap of the associated factors between the groups:

- The frank (or extended) breech indicates that the legs of the fetus are flexed at the hip and extended at the knee. This type accounts for 60% to 70% of all breech presentations at term. The risks of fetal-pelvic disproportion and of cord prolapse are lowest in this group.
- The complete (or flexed) breech indicates that the hips and knees are flexed so that the feet are presenting in the pelvis.

- The incomplete (or footling) breech indicates that one leg is flexed and the other extended.

The woman with a breech presentation, especially toward term, may complain of subcostal discomfort and of feeling the baby kick in the lower part of the uterus. On palpation, the hard round ballotable head is found at the fundus and the softer breech is at the lower pole. The fetal heart sounds are more commonly heard above the umbilicus. One diagnostic pitfall is the confusion of a deeply engaged head and a breech presentation. The examiner thinks that the shoulders are above the pelvic brim when, in fact, the breech is over the pelvis.

At vaginal examination, if the cervix is sufficiently dilated, the fetal ischial tuberosities and the sacrum provide the bony landmarks. The anus and the genitalia may also be felt but are less useful in diagnosis owing to their softness and compressibility. If the membranes are ruptured, the examining finger in the anus may produce meconium staining. The main diagnostic confusion is face presentation. Face presentation produces the characteristic bony landmarks of the malar eminences, mouth, and mentum that produce a bony triangle, whereas the ischial tuberosities and the sacrum are in line. The mouth, in contrast to the anus, has a firm unyielding margin of bone. Engagement of the breech implies that the bitrochanteric diameter has passed through the pelvic brim.

Approximately 45% of breech presentations are not diagnosed until after 38 weeks, and 10% to 30% remain undiagnosed until labor.[26] If there is any doubt about presentation, an ultrasound scan is mandatory if mistakes are to be avoided. Some clinicians even advocate routine late third trimester ultrasonography to determine presentation and ensure time for ECV (thus decreasing the need for cesarean section).[26]

THE PRETERM BREECH PRESENTATION

Techniques for optimizing the condition of preterm infants at birth have focused predominantly on the mode of delivery and led to an increase in the cesarean section rate of approximately threefold between 1995 and 2002, reflecting the increasingly aggressive management policies for extremely preterm infants.

Risks

General

The currently accepted definition of preterm birth—being born before 37 completed weeks of gestation—was first suggested by the World Health Organization in 1977 on purely epidemiologic grounds. However, in developed countries, the mortality and morbidity rates of babies delivered between 33 and 36 weeks inclusive is now very low, and not significantly influenced by mode of delivery, provided that cesarean section is undertaken for the usual clinical indications. Discussion is focused here on the gestation range of 26 to 32 weeks, when approximately 2% of women with viable fetuses will deliver. About 25% of babies delivered at these gestations are in breech presentation, probably due to the chance lie of a very mobile fetus in the relatively copious amniotic fluid. Thus, the overall incidence of very preterm (<33 wk) breech presentation at delivery is 0.5%.

The preterm baby in breech presentation shares many of the characteristics of the mature breech. The preterm breech also has a higher rate of congenital abnormality than its vertex-presenting counterpart, up to 18%.[27] This is associated with an increased antepartum stillbirth and neonatal death rate, regardless of mode of delivery.[3] It is probably even more true of the preterm than the term breech that poor outcome in survivors, including neurologic dysfunction, cannot be attributed solely to the fact of vaginal breech delivery but is often due to the abnormalities associated with breech presentation. The preterm breech shows other differences from the cephalic-presenting infant at the same gestation; it is more commonly small for gestational age and has a lower fetal-placental ratio. It also tends to have a larger head circumference for a given birth weight than babies delivered in vertex presentation, probably due to the lack of the compressive effect of the lower segment. It seems likely that in many cases, preterm birth and poor outcome are both determined by the same prenatal influences.

At Delivery

OCCIPITAL DIASTASIS AND CEREBELLAR INJURY

Experienced obstetricians have always recognized that cesarean section is not necessarily an atraumatic option for the fetus, and the preterm breech infant faces some formidable difficulties whichever route of delivery is employed. Wigglesworth and Husemeyer[28] emphasized the vulnerability of the occipital bone to damage during vaginal breech delivery, due to its impact on the maternal pubis during descent of the fetal head into the pelvis during the second stage. These forces tend to separate the squamous part of the occipital bone from the lateral part (occipital diastasis). This produces a ridge in the posterior fossa and, hence, bruising or laceration of the cerebellum. The squamous part of the occipital bone is forced anteriorly to distort the foramen magnum and produce pressure on the spinal cord. Cerebellar bruising can be present in the absence of occipital diastasis, and although the fracture may be easily diagnosable after delivery with a lateral skull x-ray, the cerebellar bruising alone will not be diagnosable unless the cerebellum is scanned routinely by the neonatologist using ultrasound. The injury is commonly not discovered at postmortem examination if traditional dissection techniques are used. The damage to the brain may not be clinically apparent until the age of approximately 2 years, when the child will manifest signs of clumsiness and poor coordination consequent upon its cerebellar damage (ataxic cerebral palsy).

INTRAVENTRICULAR AND PERIVENTRICULAR DAMAGE

In addition, the preterm infant is vulnerable to intraventricular and periventricular damage secondary to hemorrhage or ischemia, which can be due to hypoxic or acidotic insults in the antepartum, intrapartum, and/or neonatal periods. The preterm breech may be still more susceptible to these as a consequence of the peculiar circumstances surrounding delivery. However, avoiding vaginal delivery will not necessarily prevent intracranial bleeding. A review by Arpino and coworkers[29] showed that premature labor of itself can produce intracranial hemorrhage even if delivery is postponed or performed by cesarean section.

GENERALIZED TRAUMA AND NERVE INJURIES

A traumatic breech delivery in which there is widespread limb and body bruising can produce gross skeletal muscle damage that results in large quantities of hemoglobin and myoglobin being liberated, leading to severe jaundice and damage to the kidneys. This can also produce a form of "shock lung" in the neonate, manifesting as severe respiratory distress syndrome.

The premature breech infant is also susceptible to damage to internal organs, transection of the spinal cord, and other nerve palsies consequent on traction, especially the brachial plexus and fractures of long bones, in a way similar to that of its more mature counterpart. Because the widest diameter of the fetus is the biparietal diameter (BPD), and the discrepancy between the diameters of the head and the body is most pronounced in the preterm fetus, it is possible for the body and limbs of the baby to slip through a cervix that is still incompletely dilated and the head will be unable to follow. This "entrapment" of the aftercoming head is more likely in the mother who commences active pushing before full dilation has been confirmed and with a footling presentation. It is a particular problem in the preterm fetus because the subcutaneous fat has not yet been laid down and the liver is not of the large size reached in the mature fetus; hence, the abdominal circumference is relatively smaller than the head. Recommended management is usually to incise the cervix with scissors at 4 and 8 o'clock, but inevitably, there is delay in delivery and, therefore, an increase in the hypoxic stress to the fetus, together with a likely increase in traumatic morbidity to both mother and child. However, Robertson and colleagues,[30] after studying 132 consecutive preterm singleton breech deliveries, reported that there was no significant difference in the incidence of head entrapment by mode of delivery for breech infants at 28 to 36 weeks' gestation, and nor did there appear to be more adverse neonatal outcomes after entrapment.

Injuries are not confined to babies delivered vaginally in breech presentation. Any very low birth weight baby is susceptible to trauma from a difficult delivery through a poorly formed lower segment at cesarean section. If the presentation is breech, a limited uterine incision can impede the delivery of the head to the same degree as a difficult vaginal delivery and is analogous in every way to the entrapment of the aftercoming head that is such a feared complication of the premature breech delivered vaginally. To some extent, this can be avoided by performing an anterior vertical uterine incision (ideally DeLee's incision, but often in a very small uterus, it becomes a classic incision). However, this carries increased risks for the mother, particularly with respect to uterine rupture in a future pregnancy or labor, but occasionally, also in terms of poor healing and postpartum hemorrhage. The incidence of intraventricular hemorrhage in the fetus and neonate is in any case closely related to the occurrence of preterm labor of itself, independent of the mode of delivery.[29,31]

Management Options for the Preterm Breech in Labor

Most elective deliveries of the preterm breech when the woman is not in labor are for fetal or maternal indications, when the preferred route of delivery is cesarean section rather than induction of labor. Management controversies mainly center on the preterm breech presentation in labor, in which the immediate priorities are (1) the accurate diagnosis of preterm labor, (2) the confirmation of presentation, and (3) the exclusion of fetal abnormality.

It is evident that in up to 80% of cases in which the mother thinks she is in preterm labor, contractions cease spontaneously and the pregnancy continues. The definitive diagnosis of labor therefore rests on demonstrating progressive dilation of the cervix. Careful cervical assessment of all women in suspected premature labor is imperative to confirm or refute the diagnosis. The recent introduction of testing for fibronectin in the vaginal fluid may enable us to make a more secure diagnosis of labor; a negative test is about 97% reliable. In the presence of ruptured membranes, examination of the cervix should be done using full aseptic technique and the number of examinations limited to minimize the risk of introducing infection, causing chorioamnionitis. Vaginal examination can confirm the presentation and even reveal the presence of fetal abnormality (e.g., imperforate anus!). In view of the recognized association of fetal abnormality with premature breech presentation, all previous ultrasound examinations should be carefully reviewed. If possible, a further detailed ultrasound scan should be performed to identify any abnormalities previously overlooked and to check on placental position at the same time. An estimate of fetal weight may allow a more rational decision to be made about the optimum place and mode of delivery. Ultrasound fetal weight estimation is possible to ± 15% in skilled hands, although when performed by junior residents outside of normal hours, errors greater than 15% have been reported in over 40% of cases.[32] This has led some workers to suggest that the outcome for the infant is best predicted by accurate knowledge of gestational age.[26]

Administration of tocolytics may be appropriate in an effort to delay delivery long enough to administer steroids to promote surfactant production in the fetal lung prior to preterm delivery or to arrange delivery in a site with appropriate neonatal intensive care facilities. It is now clear that tocolytic therapy is ineffective in preventing premature delivery in the longer term and that its use beyond 48 to 72 hours is probably inappropriate.

The Optimum Mode of Delivery of the Preterm Breech

The preterm breech on the labor ward presents the obstetrician with a heterogeneous group of clinical problems. Some will present not in labor but with spontaneous rupture of the membranes; others will present at 7 cm dilation in strong labor with intact membranes and deliver after only a short interval. As with all preterm deliveries, preterm vaginal breech delivery is sometimes precipitate and may therefore occur in the absence of skilled medical attendants. It is important to realize that in common with all preterm labors, the antecedents are often pathologic, and therefore, a decision about the mode of delivery is uncontentious. If there has been, for example, a placental abruption or cord prolapse, clearly cesarean section is indicated.

However, if the clinical situation is of "the uncomplicated preterm breech in labor," that is, if fetal and maternal conditions are good and labor is progressing at a normal rate, it is necessary to decide whether a vaginal delivery is to be allowed or a cesarean section undertaken.

One of the first suggestions that cesarean section should be undertaken routinely for the delivery of the preterm breech was in 1977 when Goldenberg and Nelson[33] reviewed the outcome of 224 babies less than 1500 g delivered between 1965 and 1969. However, they compared three groups: babies delivered vaginally in breech presentation, babies delivered vaginally in vertex presentation, and babies (breech and cephalic) delivered by cesarean section. Such a comparison is confounded by the factors determining cesarean section, making it invalid. The authors also highlighted the noncomparability of the study groups in other respects. They reported that many fetuses below 1000 g were not monitored during labor because they were thought to be nonviable, or if they were monitored, when signs of fetal distress supervened, surgical intervention was often not performed as the fetus was thought to be "too small to live." This approach resulted in infants being delivered vaginally who happened to survive despite nonintervention being compared with infants who were thought to be viable and not "too small to live" and who were, therefore, delivered electively by cesarean section. Such a comparison, therefore, leads to the (potentially) erroneous conclusion that cesarean section improves the outcome for the preterm breech infant.

Further retrospective reviews of clinical practice were published over the next few years, some comparing the vertex with the breech,[34] some correctly comparing the vaginally delivered breech with the breech delivered by cesarean section, but then only stratifying by birth weight below and above 2500 g or in other similarly wide weight bands.[35] Further retrospective reviews of low–birth weight breech-presenting infants have given contradictory results on the optimum mode of delivery.[36–38] Wolf and associates[39] observed the natural experiment of two adjacent maternity units with different policies for the delivery of the preterm breech (26–31 wk). One unit chose to deliver most vaginally (17% cesarean section rate) and the other mainly by cesarean section (85% cesarean section rate). There were no significant differences in survival rates between the two units.

Further evidence of the noncomparability of the vaginally delivered and cesarean delivered breeches is reported in a paper by Jain and coworkers.[40] They noted that even within the weight range of 1000 to 1499 g, there was a marked difference in the average weight, with the babies delivered vaginally being significantly lighter and at a lower gestation than those delivered by cesarean section, a difference likely to account for any differences in survival. A recent study of 169 women with a breech presentation at 26 to 29 + 5 weeks' gestation reported no benefit for planned cesarean delivery in respect of neonatal death or morbidity or low arterial pH at delivery.[38]

In order to overcome the noncomparability of groups in these retrospective reviews of practice, there has been a series of attempts at using statistical techniques to determine the contribution that mode of delivery makes to outcome for the preterm breech, but these too have produced contradictory results.[41,42]

Thus, all currently existing evidence has major methodologic flaws that make it unreliable as a guide to clinical decision-making and have led to a number of calls for a randomized, controlled trial to settle the question of optimum mode of delivery. Despite this, there has only been one such randomized trial which has actually been completed. Viegas and colleagues[43] randomized 23 women, but unfortunately, their analysis was fundamentally flawed by inappropriate withdrawals, and no conclusions can be drawn from their results. Two other randomized trials of the optimum mode of delivery of the preterm infant (both vertex- and breech-presenting) have been initiated, but both were terminated prematurely and produced no interpretable results.[44,45] Lumley and associates[44] randomized only 4 subjects out of a possible 33 who were eligible over a 5-month period and terminated the trial after drawing the conclusion that clinicians were unwilling to randomize their management. Wallace and coworkers[45] aborted their randomized trial of the optimum mode of delivery of the preterm infant because they found that an unacceptably high proportion of the babies (63%) were above the 1500-g upper weight limit for the trial. They concluded that a more accurate way of estimating fetal weight prior to delivery was needed before a further attempt was feasible. The subjects they did randomize were analyzed according to the eventual mode of delivery, not according to the randomized mode of delivery, thereby invalidating the randomizing process. A prospective, randomized multicenter trial to determine the best mode of delivery for the preterm breech (26–32 wk) recruiting subjects in the United Kingdom was also abandoned.[46] The recruitment rate was disappointing, with only 10% of eligible subjects being randomized, despite large numbers of women consenting to take part in the trial antenatally and sufficient numbers of preterm breeches presenting for randomization. No definitive conclusion was reached. The authors concluded that the failure of the trial did not mean obstetricians were insisting on cesarean delivery; 30% of preterm breeches not entered in the trial were allowed to deliver vaginally. Instead, they concluded that obstetricians were reluctant to abandon individualized decisions about management even in the presence of a high degree of scientific uncertainty about the basis on which their decisions were being made. Also, some evidence suggested that if the clinician was unsure of the optimum mode of delivery, then women wished to make a choice for themselves and withdrew from randomization. It, therefore, appears likely that the optimal mode of delivery of the preterm breech will remain uncertain for the foreseeable future. At gestations above 32 weeks but below 37 weeks and when the fetus weighs 1500 to 2500 g, current evidence does not suggest any advantage to routine cesarean section. Under this gestation and weight but at more than 26 weeks' gestation, the optimal mode of delivery remains uncertain in the absence of any clinical feature specifically indicating cesarean section. The advantage, if any, that routine section confers on the fetus is likely to be small; otherwise, it would be obvious in the multiplicity of published data already available. What is certain is that if a policy of routine cesarean section for the preterm breech fetus is followed, a number of cesarean sections will be performed unnecessarily for the fetus that is congenitally abnormal, for the fetus that is over 1500 g and therefore

unlikely to benefit, for babies mistakenly thought to be in breech presentation (of which there were two in the U.K. study), and for some that will not actually be in established preterm labor and were destined to deliver at a later gestation. A policy of routine cesarean section will also expose the mother to a small but definite increased risk of maternal mortality and morbidity.

PROCEDURE

CONDUCT OF DELIVERY

Vaginal delivery of the preterm breech should be supervised by an experienced obstetrician. An effective epidural anesthetic is preferable to prevent the woman from pushing prior to full dilation, to allow manipulation of the breech or painless operative intervention with either forceps or rapid recourse to cesarean section. The anesthetist and pediatrician should be in attendance for the second stage. There is no clear evidence to favor the use of obstetric forceps to the aftercoming head; the pelvis will be relatively capacious for the premature neonate, and it will not be subject to the rapid compression-decompression forces applied to the head of the mature infant in breech presentation. There is some evidence that delivery with intact membranes is an advantage.[34] Should the cervix clamp down over the head or the body be delivered through an incompletely dilated cervix, the head should be flexed abdominally and the finger of the vaginal hand should be inserted into the mouth of the fetus to flex the head and facilitate delivery. If this is not possible, then scissors with the intracervical blade guarded by a finger should be introduced at 4 and 8 o'clock, and the cervix should be incised. The carefully flexed head should then deliver easily. The cervix is usually repaired easily provided analgesia is adequate.

If cesarean section is indicated, the abdominal incision used should be considered carefully. Although a Pfannenstiel or Joel-Cohen incision in the abdominal wall gives good access to the lower segment of the uterus, if a lower segment incision needs to be extended in an emergency (e.g., if the aftercoming head becomes entrapped), a vertical midline abdominal incision will be an advantage (it can be extended upward as far as is necessary to improve access). The advent of mass closure with nylon has reduced the morbidity of the midline approach so that it is now on a par with the Pfannenstiel, apart from the obvious cosmetic drawback of the midline scar. As well as providing improved access, it is also quicker. If a transverse uterine incision needs extending, a J shape is to be preferred to an inverted T. The DeLee or classic uterine incision appears to confer little benefit on the fetus in terms of reduced trauma, from 28 weeks onward (Patterson, Stacey, and Steer, unpublished data). Because of the maternal morbidity involved, it is probably unwise to use the classic approach to try to salvage the preterm baby if its viability seems doubtful.

THE BREECH PRESENTATION AT TERM

Management Options
Version of the Breech
SPONTANEOUS VERSION

The fact that breech presentation is uncommon at term implies that spontaneous version usually occurs in the weeks before term, and so breech presentation becomes progressively less common as the third trimester progresses. The incidence of spontaneous version after 32 weeks may be as high as 57%, and after 36 weeks' gestation is as high as 40% in multipara and 18% in nullipara, with the rate being higher in African women.[47,48] Spontaneous version is more likely in the breech with extended legs. Immediately prior to cesarean section solely for breech presentation at term, the presentation should be checked by ultrasound scanning, because the chances of spontaneous version even at this late stage are not insignificant.[48]

PROMOTION OF SPONTANEOUS VERSION

Techniques to promote spontaneous version have been investigated following Hofmeyr's postulate[49] that the combination of disengagement of the breech and postural change might promote spontaneous version between the diagnostic scan and a planned ECV. A variety of such techniques have been described. The Cochrane review[50] of five randomized or quasirandomized controlled trials including 392 women compared postural management of the breech with controls. There was no effect on the rate of noncephalic births, the rate of cesarean section, or the incidence of low Apgar scores. Therefore, although there is likely to be no significant adverse effects from postural management, there is currently no evidence to support its efficacy. There is also no evidence to support the use of moxibustion or acupuncture as techniques to promote spontaneous version.[51]

EXTERNAL CEPHALIC VERSION

ECV fell from favor in the mid-1970s. Prior to this time, it was performed without medication (except occasionally sedation), without tocolysis, and usually prior to 36 weeks' gestation. It was thought that because ECV was easier to perform prior to 36 weeks, it must therefore be safer. Without tocolysis, it was often unsuccessful after 36 weeks. Bradley-Watson in 1975[52] reported a 1% fetal mortality rate for ECV done prior to 36 weeks without tocolysis, which was considered unacceptably high. As a result, the use of ECV declined and was almost abandoned in most institutions because cesarean section was seen as a safer alternative. Another significant disadvantage of preterm ECV is that fetal bradycardia may precipitate immediate delivery by cesarean section, with the risk of ensuing respiratory distress syndrome. To avoid this, it was traditional to manage acute bradycardia by reversion of the fetus to breech, which did not always work and in any case defeated the objective of the ECV. In addition, spontaneous reversion to breech occurred quite often prior to delivery. Thus, the effectiveness of ECV was controversial.

A Cochrane review[53] included three randomized, controlled trials of the use of ECV before term involving 899 women and reported that it reduced noncephalic births and, if begun between 34 and 35 weeks, may have some benefit

in terms of reducing the rate of noncephalic presentations and cesarean sections, but the authors concluded that further trials are required to confirm this finding and to rule out increased rates of preterm birth or other adverse perinatal outcomes. There are no published data on the use of ECV in the management of the preterm breech in labor. The antecedents of the preterm breech in labor are often abnormal, and ECV is therefore less relevant as a management strategy.

Any consideration of the efficacy and safety of the technique of ECV should include a likelihood of spontaneous version, the effectiveness of ECV of producing a cephalic presentation at the time of birth, the risks to the mother and the baby, and the utility of cephalic presentation at birth to the mother and the baby (i.e., if some preexisting abnormality or fetal compromise determines the mode of delivery rather than the presentation itself and also if the prognosis of the baby is determined by its condition rather than the mode of delivery, correction of the breech presentation will then not alter the outcome for the fetus).

The advantage of performing ECV at term is that it allows time for spontaneous version to occur and the clarification of conditions that of themselves may require delivery by cesarean section. This will result in fewer unnecessary attempts being made. Also, should complications of ECV occur, prompt recourse to cesarean section will result in the birth of a relatively mature infant.

The 1996 Cochrane review of ECV at term[54] included five trials and concluded that version was associated with a significant reduction in noncephalic births (relative risk [RR] 0.38) and a reduction in cesarean section (RR 0.55), although there was no significant effect on the perinatal mortality rate. This review also concluded that there was insufficient evidence to assess any risks associated with ECV at term.

The implications of these data are that every 100 ECV attempts will prevent 34 breech births and 14 cesarean sections. A conservative estimate of the impact of performing ECV on 2% of the 750,000 pregnancies in the United Kingdom every year would be a reduction in the number of breech births by 5100 and a reduction in the number of cesarean sections by 2100.[54]

The impact of ECV on the rate of cesarean sections for breech presentation will depend on the success rate of ECV. There is a wide variation in the reported success rate. Trials performed in Africa on black African women have much higher success rates. This may be due to the tendency of late engagement of the presenting part in the pelvis in black African women.[55] Collaris and Oei[56] in a review of 44 studies of ECV described mean success rates of 59.2%, ranging between 35% and 100%. Of the successfully turned fetuses, 5.6% reverted to breech, and excluding patients lost to follow-up, in 80.7% of all pregnancies with successful version, birth was vaginal, although labors after successful version are associated with increased rates of obstetric intervention.[57–59] Nassar and colleagues[47] described a 30% reversion to breech but also that 4% of unsuccessful versions spontaneously converted to cephalic prior to delivery. Overall, a success rate of 40% for nulliparous women and 60% for multiparous women can usually be achieved.

Various methods of predicting the success of an attempted ECV have been devised. One study found that if the presenting part in a nullipara was engaged and there was difficulty in palpating the fetal head, no attempt at ECV was successful. Conversely, if the presenting part was not engaged in a multipara and the fetal head was easily palpable, 94% of attempts were successful.[60] Maternal weight, placental site, fetal size, and position of the fetal legs seem to make less difference to the chances of success. The quantity of amniotic fluid probably also has a bearing on the success of ECV, and a reduction in the rate of success has been observed in women with "borderline' amniotic fluid volumes (5–8 cm).[61]

Because of the observation that increased uterine tone decreases the chances of success of ECV, the use of tocolytics has been investigated. A variety of tocolytics have been used. The 2004 Cochrane review of six trials of routine tocolysis[62] showed that its use was associated with fewer failures and a reduction in the cesarean section rate (RR 0.85; 95% confidence interval [CI] 0.72–0.99). Use of fetal acoustic stimulation (FAS) when the fetal spine was in the midline was also associated with fewer failures of ECV (RR 0.17; 95% CI 0.05–0.60). Nitroglycerine was associated with significant side effects and was not found to be effective.

Marquette and associates[63] confirmed in a randomized trial the efficacy of ritodrine in improving the success of ECV in nulliparous women from 25% to 43%, but there was no benefit in parous women. Nor Azlin and coworkers[64] confirmed the benefit of ritodrine versus a placebo in reducing the rates of noncephalic presentations and reducing the cesarean section rate but showed the largest benefit in multiparous women (87% vs, 57%). Fernandez and colleagues[65] found terbutaline (0.25 mg subcutaneously) to be effective in reducing noncephalic presentations and reducing cesarean section in comparison with placebo for ECV. It has been suggested that tocolytics could be reserved for use when the first attempt at ECV has been unsuccessful. One randomized, controlled trial of tocolysis versus a placebo in 124 women with a previously unsuccessful attempt at ECV showed that it increased the success rate of a repeat attempt and reduced the rate of cesarean section.[66]

Other possible tocolytic agents studied are atosiban and nifedipine. A small retrospective review[67] and a small randomized, controlled trial[68] showed that atosiban was no more effective than ritodrine in reducing noncephalic presentations. Similarly, nifedipine was of equal efficacy to ritodrine in both a retrospective review[69] and a small randomized, controlled trial.[70] It may be that these agents are useful when there are contraindications to the use of β-sympathomimetic drugs.

Because one of the main reasons for the failure or abandonment of ECV is maternal discomfort, the use of epidural analgesia for the procedure has been suggested. A Cochrane review[62] included five randomized trials of the use of regional anesthesia to facilitate ECV. The two trials using epidural analgesia improved the success rate of ECV, increased the number of cephalic presentations at delivery, and reduced the cesarean section rate, but three trials using spinal analgesia showed no benefits. It is possible that the volume preload associated with the use of epidurals increases the amniotic fluid volume and this affected the success rates. The safety and efficacy of regional anesthesia to facilitate ECV remains in question.

Benefits to the Fetus of External Cephalic Version

It is clear that ECV reduces the incidence of breech presentation at term and of breech delivery, whether vaginal or by cesarean section. However, it would be a mistake to suppose that elective cesarean section eliminates all risks for the fetus: cesarean delivery of the preterm breech can still be traumatic,[72] and the risk of pulmonary hypertension of the newborn may be increased.[73]

Risks to the Fetus of External Cephalic Version

The risks to the fetus of ECV have been difficult to quantify because adverse effects are so rare that none of the randomized trials are large enough to clarify this issue. There are two systematic reviews of safety.[47,56] Collaris and Oei[56] identified 44 studies with a total of 7377 women from 1990 to 2002. Transient fetal heart rate abnormalities were reported in 5.7%, with pathologic cardiotocograms in only 0.37%. Vaginal bleeding occurred in 0.47%, but the incidence of confirmed placental abruption was only 0.2%. Fetomaternal transfusion was completely absent in 5 out of 7 series, with an overall mean incidence of 3.7%. Emergency caesarean section was performed in 0.43% of cases. Nassar and colleagues[47] looked only at the 11 studies that compared women who had had an external cephalic version from 36 weeks' gestation with a control group of women who had not had an ECV. They found a total of 2503 women. Relevant outcomes were rarely reported for the control group. They did not find an increase in antepartum fetal death, but numbers were small. There were no reported cases of uterine rupture, placental abruption, prelabor rupture of the membranes, or cord prolapse. The onset of labor within 24 hours and the incidence of nuchal cord was nonsignificantly higher among women who had had an ECV than in controls with a persisting breech.[47] It seems likely that adverse events associated with ECV are rare.[74]

ECV has been associated with demonstrable changes in the fetal circulation.[75] An 8% incidence of fetal bradycardia has been reported in association with ECV.[76] If an ECV (whether successful or not) produces a fetal bradycardia, it is possible that subsequent labor is more likely to be complicated by fetal heart rate abnormality and result in cesarean section.[76] Lau and associates[75] demonstrated changes in the fetal circulation, but not placental circulation, associated with attempted ECV. Isolated cases of cord presentation and even fetal demise have also been reported. Kouam[77] followed up 116 children born after ECV. Developmental screening at 2 to 5 years of age showed no developmental delay. Although the short-term neonatal outcomes reported in the randomized, controlled trials are essentially normal and compare favorably with control subjects, they are only surrogates for definitive follow-up studies of the effects of this procedure.

Benefits to the Mother of External Cephalic Version

Following a successful ECV, there will be a decrease in the number of cesarean sections and in the number of vaginal breech deliveries, which often entail episiotomy and forceps delivery. The risks to the mother of cesarean section have previously been described in Chapter 74. Cesarean section may compromise future reproductive function,[78] and there may be adverse emotional sequelae for the mother and the maternal-infant pair.[79]

Interestingly, although ECV has become much more widely since the 1980s and more pregnant women (and their clinicians) have become aware of the procedure, pregnant women may be becoming less inclined to take up the option of ECV and instead opt for planned cesarean section.[80]

The contraindications to the performance of ECV are outlined in Table 63–2. The absolute contraindications are uncontroversial. However, the relative contraindications are more debatable. It may be that uterine anomalies and excessive maternal body weight should be regarded as relative contraindications. An amniotic fluid volume of less than 2 cm in depth in any pocket, the fetal back lying anteriorly, a tense uterus, difficulty palpating the fetal head, an engaged breech, and nulliparity will decrease the chance of success.[81] Fetal abdominal circumference is related to the chances of success, whereas the BPD is not. Gestational age and estimated fetal weight, provided the attempt was after 37 weeks, had no relationship with the chances of success, because success rates were found to be the same at 37, 38, and 40 weeks.

TABLE 63–2

Indications and Contraindications for External Cephalic Version

Indications for ECV
Any breech presentation after 36 in nulliparas and 37 weeks' gestation in parous women
Suspected fetopelvic disproportion
Unengaged breech

Absolute Contraindications to ECV
Multiple pregnancy*
Antepartum hemorrhage within the last 7 days
Placenta previa
Ruptured membranes
Significant fetal abnormality
Need for cesarean section for other indications
Abnormal fetal heart rate pattern
Major uterine anomaly

Relative Contraindications to ECV
Previous cesarean section/scarred uterus
Intrauterine growth restriction/small–for–gestational age fetus with abnormal umbilical artery Doppler velocimetry
Oligohydramnios
Unstable lie
Severe proteinuric hypertension
Obesity
Rhesus isoimmunization
Evidence of macrosomia
(Grand multiparty)†
(Anterior placenta)
("Precious baby")
(Previous antepartum hemorrhage)
Any suspected fetal compromise: unreactive cardiotocogram

* Apart from the second twin after the vaginal delivery of the first. *Note*: If tocolysis is to be used, women with congenital or acquired heart disease, diabetes, or thyroid disease should be excluded because of possible adverse reactions.
† Entries in parentheses have been suggested by some authorities but have no clinical evidence to support them.
ECV, external cephalic version.

Although previous cesarean section is a relative contraindication to ECV, there is a small series of 36 women who had one previous cesarean section and underwent an ECV, of which 66% were successful, and of these, 76% had a vaginal birth. There were no maternal or neonatal complications.[82] Maternal Rh negativity is a relative contradiction. If ECV is used, a Kleihauer test should be done and an appropriate anti-D (RhoGAM) administered.

PROCEDURE

EXTERNAL CEPHALIC VERSION

Prerequisites

1. Gestational age of 36 weeks or more in the nullipara and 37 weeks or more in the parous woman.[81]
2. Recent ultrasound to confirm a normal fetus and an adequate liquor volume.
3. Reassuring fetal heart rate pattern.
4. Informed consent—in which the mother is specifically advised of the risks of provoking labor, ruptured membranes, and cord and placental accidents.
5. Facilities for the performance of a cesarean section.

Procedure

ECV may be performed in the labor room or the clinic room, if there is rapid access to delivery facilities. The woman is positioned either in steep or slight lateral tilt or in the Trendelenburg position. It is sometimes recommended that a Kleihauer test be performed before and after the procedure. Some also recommend placing an intravenous line and cross-matching blood for a possible cesarean section. If tocolysis is to be used, some practitioners perform an electrolyte and glucose estimation as well. A clinical pelvimetry should be judged as adequate. An ultrasound scan should be performed in order to assess the liquor volume, fetal attitude, and position of the fetal legs. The fetal heart rate pattern should be normal and reassuring prior to commencement. Some authorities recommend that a contraction stress test be performed prior to version. It has even been suggested that the maternal blood pressure be taken every 5 minutes throughout the procedure and that the maternal heart rate be monitored electronically. This is probably unnecessary if the mother appears well throughout but could be important if tocolysis is used.

If tocolysis is employed, this can be given in a variety of ways: 10 μg of hexaprenaline given intravenously over 1 minute, terbutaline 0.25 mg subcutaneously or in 5 mL of normal saline over 5 minutes intravenously; terbutaline 0.5 μg/min intravenously or terbutaline 0.5 μg/min intravenously over 15 to 20 minutes; ritodrine 0.2 mg/min intravenously for 20 minutes; nifedipine 10 mg orally; or atosiban intravenously 6.75 mg over 1 minute and at a rate of 18 mg/hr for 20 to 30 minutes. Some authors give the chosen tocolytic as a stat dose and commence the ECV almost immediately.

Others increase the dose steadily or wait until adequate uterine relaxation is achieved, all contractions have ceased, or there is softening of the uterus and easy palpation of fetal parts.

The ECV should be performed as one episode by one operator, and continuous pressure on the uterus should be limited to 5 minutes. Many recommend that uterine manipulation should continue for only 10 minutes, although waiting for the fetus to be active spontaneously (helping to dislodge it from the pelvis) and then applying pressure may be advantageous. Others have recommended stimulating the fetus to move using a vibroacoustic stimulator.[83] Mohamed and coworkers[84] reported that 55% are successful after 1 minute and only 15% require up to 5 minutes continuous pressure on the abdomen. The increased incidence of fetal heart rate abnormalities with failed ECV suggests that persistence in an attempt beyond these suggested times may be counterproductive. Mohamed and coworkers[84] also report that 73% were deemed by the obstetricians to be easy versions with 90% of women reporting little or no discomfort.

A forward or backward somersault can be performed: the forward somersault is the classically described maneuver. The technique involves placing the woman in a steep lateral tilt with her back against the wall behind the examination couch. A forward somersault is recommended if the fetal back is downward and a backward somersault if the fetal back is upward. If the breech is engaged, the breech must first be pushed out of the pelvis with the operator's right hand prior to correction of the presentation. There is a general consensus that vaginal disengagement should not be performed if the breech will not easily come out of the pelvis with abdominal pressure. If the fetal head is caught under the costal margin and this prevents the disengagement of the breech, the fetal head should be manipulated down and sideways prior to the disengagement of the breech and forward somersault. The actual version is accomplished using flexion of the fetal head and encouragement of a forward somersault by pressure on the uterus. Some practitioners pause as the breech is about to negotiate the transverse diameter of the uterus and apply acoustic stimulation. This may cause fetal kicking, which assists the version.[83] Women should be advised that ECV maybe painful but will be stopped if they wish.

After successful version, the attitude of the fetus should be maintained manually for a few minutes.

The fetal heart can be monitored continuously through the procedure or every 2 minutes. A repeat fetal heart rate tracing should be performed immediately after the ECV. If this is normal, the woman may go home. She should return within a few days so that the position of the fetus can be rechecked. Some practitioners perform a cesarean section if the breech presentation recurs, whereas others follow their protocol for selection for vaginal breech delivery. Still others continue to correct the presentation repeatedly. There is some evidence that the latter approach does result in more vertex presentations at delivery.

Current evidence indicates that ECV performed at term, and particularly with tocolysis, is a safe procedure for carefully selected women.

Assessment of the Fetus

Thorp and colleagues[85] showed that palpation only had a sensitivity of 28% and a specificity of 94% in the detection of breech presentation, using ultrasound scanning as the gold standard. Therefore, presentation of the fetus should be checked using ultrasound scanning. This should be possible in most cases even if the woman presents in labor.

X-Ray erect lateral pelvimetry (see later discussion) to investigate pelvic capacity has been traditional but has been increasingly abandoned partly because of a possible long-term increased incidence of myelodysplasia in the baby,[86] but mostly because of doubts about its usefulness. The presentation of the fetus can be confirmed at the same time. Radiologic exclusion of a nuchal arm, with an estimated incidence of 4%, has been suggested as a possible advantage, because this complication can produce delay and trauma during the second stage of labor.

As x-ray pelvimetry has been abandoned, assessment of the fetus using ultrasound has become mandatory. If ECV is contemplated, then placental site, adequacy of fetal growth, and liquor volume are the minimum information required from ultrasound examination. More detailed information about the fetus should be obtained if vaginal delivery is being contemplated. Ultrasound examination will provide an estimate of fetal weight, which is crucial to the management of breech delivery. However, it should always be remembered that estimation of fetal weight has, at best, an error of ±15%, which is ±600 g in the 4-kg fetus, and it may be less accurate in the breech-presenting fetus.[78,87] Placenta previa should also be excluded, as far as possible, prior to any decision about ECV or the mode of delivery. It has been suggested that prior to attempts at ECV or vaginal breech delivery, a nuchal cord should be excluded on ultrasound examination. Successful detection of a nuchal cord has been reported but is unlikely to be practicable on a routine basis.

The validity of ultrasound measurement of fetal size, especially the BPD, has long been debated. Bader and associates[88] performed ultrasound measurements in 450 fetuses in breech presentation and compared them with 1880 fetuses in cephalic presentation between 15 and 40 weeks' gestation. They found no difference between the BPD, the head circumference, and the cephalic index (cephalic index = BPD/occipital frontal distance × 100) in the two groups in uncomplicated pregnancy. However, in complicated pregnancies, the cephalic index was found to be lower in breech-presenting fetuses, indicating the dolichocephalic head shape that is commonly noted. Neck hyperextension (the star-gazing fetus) is an important condition that can cause spinal cord and brain injuries at delivery. Proposed etiologies are cord around the neck, fundal placenta, spasm of the fetal musculature, and fetal and uterine anomalies. It is of interest that most mammals other than humans deliver their young with the neck of the fetus in a hyperextended position. Flexion of the neck in the human fetus is probably an adaptation to the necessity of delivering a large brain in a large fetal skull through

a relatively small pelvis. Although the incidence of neck extension in the fetus has been quoted as 7.4%,[48] its significance is hard to ascertain. It is regarded as an unfavorable prognostic sign with regard to successful vaginal breech delivery, but few authors indicate how it is to be diagnosed antepartum. Rojansky and coworkers[89] have validated the ultrasound determination of fetal neck extension comparing ultrasound scans with the gold standard of x-rays and found a high correlation. They measured the craniospinal angle by obtaining a sagittal view of the fetus visualizing the orbital ridge and the occipital eminence along with the spine in the same plane. A line is drawn between the orbital ridge and the occipital eminence, and the angle formed with the second line, which passes through the cervical and thoracic vertebrae, is measured. Other adverse features if ECV or vaginal breech delivery is contemplated include intrauterine growth restriction and Rh isoimmunization.

Choice of Mode of Delivery—Vaginal Breech Delivery

It was not until the late 1950s that the increasing safety of cesarean section led to it becoming the preferred mode of delivery, and elective cesarean section began to be recommended on a routine basis to minimize perinatal morbidity and mortality. In the 50 years that followed, the controversy continued until the frequent calls for a randomized, controlled trial were finally answered.[1] Clinicians now have robust data on which to base their recommendations. These data strongly support the view that elective cesarean section is the safest option for the baby, at a marginally increased risk to the mother.[90,91]

Risks of Vaginal Breech Delivery for the Fetus

The risks and benefits of vaginal breech delivery are shown in Table 63–3.

SHORT-TERM NEONATAL/PERINATAL OUTCOME AND FOLLOW-UP

Many of the studies performed to assess the mortality and morbidity rates for fetuses undergoing vaginal breech

---

TABLE 63–3

Risks and Benefits of Vaginal Breech Delivery for the Fetus

Risks

Poor condition at birth
Intracranial hemorrhage
Medullary coning
Severance of the spinal cord
Brachial plexus injury
Occipital diastasis
Fracture of the long bones
Epiphyseal separation
Rupture of internal organs
Long-term neurologic damage
Genital damage in the male
Hypopituitarism
Damage to the mouth and pharynx

Benefits

Reduction in idiopathic pulmonary hypertension

delivery have been poor. They were mostly retrospective reviews of practice and often simply compared babies delivered vaginally by the breech and by the head. This approach does not compare like with like and is, therefore, invalid. However, because of the rise in the popularity of elective cesarean section for breech presentation, increasingly vaginal breech delivery was being performed only when the woman presented in advanced labor with an unexpected breech presentation. This situation increased the risk of a breech birth being attended by inadequately trained or experienced personnel. Moreover, there was no opportunity for prior assessment for suitability for vaginal breech delivery. Several studies have reported stringent selection criteria for vaginal breech delivery with cesarean section rates varying from 49% to 83%. Most of these have shown no difference in short-term outcomes for the fetus.[71,92–96] However, the evidence based on these retrospective reviews of practice is contradictory. Many report a higher 1-minute Apgar score and higher pH values in breech neonates delivered by cesarean section compared with those delivered vaginally. That the breech delivered vaginally has a lower pH than the cephalic infant or the breech infant delivered vaginally is not in doubt; it is what this difference means clinically that is difficult to ascertain.

Some specific conditions associated with breech presentation probably increase the chances of trauma during delivery. Fetal neck hyperextension, which can cause damage to the cervical spine, is a contraindication to vaginal birth. Flexed legs appear to increase the risk of cord prolapse to as much as 15% compared with 1.4% to 6% if the legs are extended (the risk of cord prolapse with a cephalic presentation is only 0.24%–0.5%). If the arms are caught across the back of the neck at delivery (nuchal arm), the risk of brachial plexus injury is about 8.5% at term, although 70% of these injuries have resolved fully by 3 months of age.

Until the Hannah and colleagues' trial,[1] there had been only two small randomized, controlled trials of the mode of delivery of the term breech. Collea and associates[13] randomized 208 women at term in labor to receive a cesarean section or a vaginal delivery. Despite this intention, 45% of the latter group was delivered by cesarean section. Although there are some caveats about their methodology, they showed no statistically significant differences in short-term neonatal outcome between babies delivered vaginally and babies delivered by cesarean section, by either intention to treat or actual mode of delivery. By contrast, they showed "striking and concerning differences in maternal outcome," with higher maternal morbidity rates associated with cesarean section. Gimovsky and coworkers[14] recruited 105 women with nonfrank breech presentation into their randomized, controlled trial. They also showed no statistically significant differences in short-term neonatal outcome. The two meta-analyses of the mode of delivery of the term breech did not significantly challenge these findings.[11,12] Hannah and colleagues[1] published the results of a multicenter, randomized, controlled trial of the optimum mode of delivery of the term breech in 2000. From 121 centers in 26 countries, 2088 women with a frank or complete breech were recruited. By the time the trial ended, 1041 women had been assigned to planned cesarean section, of whom 941 (90.4%) were actually delivered by cesarean section, and 1041 women had been assigned to planned vaginal delivery, of whom 591

(56.7%) were actually delivered vaginally. The trial was halted before the planned total had been recruited, on the advice of the data-monitoring group, because a highly significant difference had already emerged. Perinatal mortality, neonatal morbidity, and serious neonatal morbidity rates were significantly lower for the planned cesarean section group (1.6%) than for the planned vaginal birth group (5.0%) (RR 0.33), and there were no significant differences between the groups in terms of maternal mortality or serious maternal morbidity rates (3.9% vs. 3.2%).[1] These relative differences in outcome between planned cesarean section and vaginal breech delivery persist even when a variety of clinical differences between groups are taken into account: parity, type of breech, whether the fetus was larger or smaller than 3000 g, whether the pelvis had been assessed clinically or radiologically, whether labor was induced or augmented, the use of epidural anesthesia, presentation, the degree of experience of the clinician, and a variety of other clinical parameters that are usually held to be important predictors of the success and safety of attempted vaginal delivery. The only significant interaction was between the treatment group and the countries' reported perinatal mortality/morbidity rate (PNMMR) for the combined outcome of perinatal mortality, neonatal mortality, or serious neonatal morbidity rates. In countries with a low PNMMR (≤20 in 1000 births), the risk from planned cesarean section compared with planned vaginal birth was 0.4% versus 5.7%, whereas the rates in countries with a high PNMMR (>20 in 1000 births) were 2.9% versus 4.4%. The difference in the developed countries disappeared when just the outcome of perinatal or neonatal death was considered. Neonatal morbidity showed the greatest differences according to geography, with reductions in morbidity being much greater for countries with low PNMMRs than for those with high PNMMRs. It is not clear why this is the case. Possible explanations include incomplete ascertainment of poor neonatal condition in the first week of life or death before morbidity can be recognized. The observation might even be real, possibly because of high levels of experience with vaginal breech birth in countries with low cesarean section rates and high perinatal mortality rates—fewer women allocated to vaginal breech delivery in those countries ended up with a cesarean birth.[97] Overall, this study indicated that with a policy of planned cesarean section, for every additional 14 cesarean sections done, 1 baby will avoid death or serious morbidity. In countries with high a PNMMR as many as 39 additional cesarean sections would need to be done to avoid 1 dead or compromised baby, whereas in countries with a low PNMMR, the number of additional cesarean sections required may be as low as 7.

After the publication of the Term Breech Trial,[1] reservations were expressed about the generalizability of the results, but in general, the obstetric community have implemented the findings and the cesarean section rate rose rapidly to 90% to 95% in most of the developed world. Since then, a number of large population-based case series have been published, showing the impact of the trial. Reitberg and colleagues[98] published a series of 35,000 women with a breech presentation who were delivered in the Netherlands during a period of 33 months prior to the publication of the Term Breech Trial and 25 months after the publication. Over this period of time, the caesarean section rate rose from 49% to

80%. This was associated with a halving of the perinatal mortality rate and the rate of low Apgar scores and a three quarter reduction in birth trauma. The implication of these findings is that there are more than 60 Dutch children who are alive today who might not have been without the publication of the Term Breech Trial. A group in California demonstrated in a population base of 100,000 women with a breech presentation and a 95% cesarean section rate that the neonatal mortality rate was only 0.6 in 1000 and demonstrated that nulliparous women who delivered a breech vaginally had significantly increased rates of brachial plexus injury, neonatal death, birth trauma, and asphyxia.[99] Three further population-based studies in Scandinavia,[100–102] involving a total of 53,000 women, showed a risk of perinatal or infant death that was between 2.5 and 3.5 times higher in women who delivered a breech vaginally.

Further hospital-based cohort studies have been published[93,95,103–106] since the Term Breech Trial, but these have been relatively small and lack both its statistical power and the advantages of randomization. Given that units with disappointing results from vaginal breech delivery are unlikely to publish their results, these studies involving a total of less than 6000 cases need to be interpreted cautiously in the light of the results of other population-based studies including some 185,000 deliveries.

Vaginal delivery carries the risk of cord prolapse and extended arms at delivery as well as difficult delivery of the head. This risk may be approximately 1% to 2%.[15] Therefore, obstetric expertise should be maintained for dealing with unexpected breech presentations, and for the late-presenting (usually previously undiagnosed) breech in labor in whom cesarean section is logistically impossible; this may amount to 11% or more of all breech presentations.[71] How to achieve this maintenance of competence in an era of few vaginal breech deliveries and many trainees with restricted hours for teaching has not yet been fully established; training on sophisticated mannequins is probably the best approach.

LONG-TERM INFANT FOLLOW-UP

Those studies reviewing later-born (1970–1980) children reflect the impact of rising cesarean section rates and more modern obstetric care. They are still mostly retrospective reviews of practice.

In one case-controlled study, breech-delivered infants were compared with cephalic-delivered infants (matched for sex, birth weight, gestational age, maternal age, parity, and year of delivery) at 4 to 10 years of age. A slight excess of minor neurologic dysfunction was found in the breech group but was not statistically significant.[107]

In a population-based study, Danielian and associates[108] compared the long-term outcome of infants delivered in breech presentation at term by intended mode of delivery. They identified 1645 infants from the Grampian region in Scotland during the years 1981 to 1990 who had been delivered alive at term after breech presentation. Elective cesarean section was performed in 35.9% of cases, and 64.1% were intended vaginal deliveries. There were no significant differences in terms of severe handicap, developmental delay, or neurologic deficit up to school age. The 2-year follow-up results from the Term Breech Trial showed that

death or neurodevelopmental delay at age 2 years was similar between the two groups (RR 1.09; 95% CI 0.52–2.3).[109] The smaller number of perinatal deaths with planned cesarean section was balanced out by a greater number of babies with neurodevelopmental delay. This was unexpected, because there had been fewer babies in the planned cesarean section group with severe perinatal morbidity.

Another long-term follow-up of infants born by the breech either spontaneously or using the Bracht maneuver for delivery of the head reported that psychometric and intellectual development were superior in those infants delivered spontaneously.[110]

Despite the fact that many of the studies are of dubious quality, they are remarkably consistent in reporting minimal risk of long-term neurologic damage after careful selection for vaginal delivery and after correction for congenital anomalies. The major risk associated with mode of delivery remains that of perinatal mortality.

Risk of Breech Delivery for the Mother

The risks of breech delivery to the mother are shown in Table 63–4.

It may be the risks for the mother and the fetus in a subsequent pregnancy will turn out to be the most significant risk, rather than that associated with a primary cesarean section. The Dutch experience[98] has been used to calculate that 19 perinatal deaths will be avoided by performing 8500 extra primary caesarean sections, but that in subsequent pregnancies, this could result in as many as 4 maternal deaths and 9 perinatal deaths from complications of the uterine scar or repeat surgery.[111] It would seem to be appropriate to take into account a woman's planned family size when counseling her about mode of delivery for breech presentation.

Assessment for Vaginal Breech Delivery
(Table 63–5)

All the available literature stresses the importance of adhering to an appropriate protocol when assessing women for vaginal breech delivery. These protocols have produced elective cesarean section rates from 49% to 83%.

TABLE 63–4

Comparison of Risks to the Mother of Vaginal Breech Delivery and Cesarean Section

Risks of Vaginal Breech Delivery for the Mother
Perineal discomfort and morbidity
Difficult birth experience

Risks of Cesarean Section for the Mother
Short-term morbidity: increased postpartum pyrexia, increased need for blood transfusion
Increased maternal mortality rate
Reduction in future fertility
Difficult birth experience
Entering a subsequent pregnancy with a scar on the uterus and with increased risk of placenta previa/accreta

TABLE 63–5
Assessment for Vaginal Breech Delivery

Assessment of the Cause of Breech Presentation
Exclude:
- Placenta previa
- Multiple pregnancy
- Fibroids/pelvic tumors
- Oligohydramnios/polyhydramnios
- Hydrocephalus/anencephaly
- Other congenital abnormality

Assessment of Fetal Condition
Exclude:
- Intrauterine growth restriction
- Rhesus disease
- Fetal abnormality
- Other

Assessment of Fetal Weight and Attitude

Assessment of the Maternal Pelvis
Clinical pelvimetry (important for medicolegal reasons) (x-ray erect lateral pelvimetry no longer advocated)
Computed tomography scanning pelvimetry and magnetic resonance imaging may be unnecessary and unreliable

Assessment of Maternal Condition
Exclude significant maternal disease: diabetes, proteinuric hypertension, cardiac or renal disease

Assessment of Maternal and Parental Wishes

Close consultation with the mother and partner and counseling about the implications of the choice of vaginal breech delivery versus elective cesarean section are important. It is the responsibility of the obstetrician to explain the options and the evidence to the woman and her family in the clearest possible terms. Although cesarean section will be the recommended option for the great majority of women, especially in the developed world, some women when informed of the options will still wish to attempt a vaginal delivery, and their wishes should be respected.

ASSESSMENT OF PELVIC CAPACITY—CLINICAL

Clinical pelvimetry is a low-technology screening investigation that is probably of benefit only if there is gross contraction of the pelvis. A subjective assessment of the bony features of the pelvic cavity is made, including the sacral promontory, the curvature of the sacrum, whether the side walls are convergent or the ischial spines prominent, whether the sacrospinous ligaments will accommodate two fingers, whether the intertuberous diameter will accommodate the clenched fist, and whether the pubic arch is greater than 90 degrees. With regard to a clinical assessment of the size of the pelvis, a consideration of the woman's height alone is probably useful.[112]

ASSESSMENT OF PELVIC CAPACITY USING IMAGING

No prospective, randomized trials have ever been performed to assess the value of x-ray pelvimetry. There is no absolute level of pelvic contraction as assessed by x-ray below which vaginal delivery is impossible, and antenatal assessment of fetal weight is probably a more important determinant of the success of attempted vaginal delivery.[113] Studies of x-ray pelvimetry have been unable to show any value in selecting those women more likely to have a successful vaginal breech delivery or a satisfactory perinatal outcome.[114] In a subanalysis of the Term Breech Trial, the use of x-ray pelvimetry was not linked to improved success rates.

Computed tomography (CT) scanning for pelvimetry reduces the radiation dosage and is more accurate.[90] However, there is no good evidence that it will predict the outcome of a trial of vaginal breech delivery any better than standard pelvimetry.

One randomized, controlled trial of magnetic resonance (MR) pelvimetry has been performed.[115] Two hundred thirty-five women had MR pelvimetry and were then randomly assigned to two groups. In the study group, the results of the pelvimetry were disclosed to the clinicians who used them to decide on the optimal route of delivery. In the control group, the clinicians assigned the route of delivery after consideration of other clinical factors alone. The authors found that the overall cesarean section rate was the same, although the emergency cesarean section rates were lower in the MR group. There were no significant differences in the baby's condition at birth or in the early neonatal period between the two groups.

CRITERIA FOR SELECTION FOR VAGINAL BREECH DELIVERY

Various criteria have been proposed.[92,96] In summary, the fetus should be neither too small nor too big and should have a well-flexed head; the mother should have at least an average-capacity pelvis, judged clinically; and the mother and the baby should be in "good" condition.

An estimated fetal weight of 1500 to 3900 g is probably appropriate (for discussion of the delivery of the preterm breech, see previous section); however, the limits of fetal weight and gestation are contentious, with many different limits being suggested. In addition, clinical estimation of fetal weight is unreliable, and even when ultrasound is used, there is a margin of error of ±15%. The error of the estimation of weight is greater in the breech than in the vertex fetus.

It is probably wise to perform a clinical pelvimetry to exclude the obviously contracted pelvis, but x-ray pelvimetry should not be done because there is no clear evidence of its value. It is good practice and probably wise from the medicolegal point of view to explain this to the mother before labor.

Some authors would exclude the nulliparous woman with a breech from consideration of vaginal delivery, yet others consider the grand multiparous patient also at high risk. The evidence for either proposition is not compelling. The fetus should ideally be in frank or complete breech presentation (not a footling), and absence of detectable congenital abnormality should be confirmed using ultrasound.

It is commonly assumed that the undiagnosed breech in labor is at higher risk of complications than those that have been diagnosed prelabor and adequately assessed for suitability for trial of vaginal delivery. However, the experience of some authors[116,117] is that these women do well

and are more likely to deliver vaginally with no greater mortality or morbidity rates than those diagnosed and assessed prior to labor. They suggest that there are no grounds for delivering all undiagnosed breeches in labor by cesarean section.

<div style="text-align:center">**PROCEDURE**</div>

VAGINAL BREECH DELIVERY

Practical Considerations in the Conduct of Assisted Vaginal Breech Delivery

The essence of the assisted vaginal breech delivery is allowing as much spontaneous delivery by uterine action and maternal effort as possible. Operator intervention should be limited to the maneuvers described here, which are designed to correct any deviation from the normal mechanism of spontaneous delivery. The operator may make the delivery more complicated by injudicious traction that encourages displacement of the fetal limbs from their normal flexed position across the fetal body or by promoting hyperextension of the fetal head. Traction can also cause injury of itself. The fetal body should, at all times, be treated with the utmost care and grasped, if at all, by the bony parts. Some authors recommend using a towel to cover the baby to prevent friction injury, to improve grip without the need for too much squeezing, and to keep the baby warm. Within these limits, many procedures for the vaginal delivery of the breech have been described.

First Stage

Many authors suggest that spontaneous labor increases the chance of successful vaginal delivery, and that if delivery is required before the onset of spontaneous labor, elective cesarean section may be preferable to induction of labor. Other authorities would permit induction of labor.[113]

Labor should be conducted in a labor ward with all the facilities needed to perform a cesarean section, with a full anesthetic service and senior obstetric staff available. The woman should be instructed to arrive early in labor so that her progress and the condition of the fetus may be monitored. Similarly, if the membranes rupture, she should attend the hospital because of the risks of cord prolapse. Rupture of the membranes at any point during the labor should prompt immediate vaginal examination.

On presentation in labor, an intravenous line should be sited and blood taken for typing and to save serum. Because of the relatively high risk of cesarean section, oral intake should be avoided for the duration of the labor. After the usual assessment of the woman in labor, she should be told that continuous electronic fetal monitoring is advisable and that an epidural anesthetic may be preferable. The latter will make any manipulation in the second stage more comfortable and make any urge to push prior to full dilation easier

to resist. Bearing down prior to full dilation may push the relatively smaller breech through the incompletely dilated cervix and entrap the aftercoming head behind the cervix. Epidural anesthesia is not essential, and some obstetricians suggest that there is a higher chance of spontaneous vaginal delivery without one. Chadha and associates[118] reported that epidural analgesia was associated with a longer duration of the second stage, an increased need for augmentation of labor with oxytocin infusion, and a significantly higher cesarean section rate in the second stage of labor. There is little doubt that epidural anesthesia obtunds the urge to bear down. However, the counterargument is that if a baby does not deliver easily with an epidural in situ, it is better delivered by cesarean because there is likely to be mild relative disproportion. Because there is no clear scientific evidence to resolve this issue, it seems appropriate at the present time to allow the woman a major degree of personal choice in this respect. Whatever she chooses, however, an anesthetist should be in attendance during the second stage of labor in case rapid anesthesia should be required for an unexpectedly difficult delivery. The fear with the use of oxytocin in the presence of slow labor is that it will produce descent of the breech in the presence of fetal-pelvic disproportion; hence, the disproportion will be detected only when the head is entrapped above the pelvic brim and the body is already delivered. This leads many to suggest that there should be strict limits on the duration of first stage and that the use of oxytocin should be avoided.[95,113] The bitrochanteric diameter is usually smaller than the BPD, and if the former does not easily traverse the pelvis, neither will the latter. However, Collea and associates[13] demonstrated that the use of oxytocin in selected patients does not produce an excess rate of maternal or neonatal complications.

Failure to make expected progress in cervical dilation or for the breech to descend appropriately in the first 4 hours of labor or the appearance of cardiotocographic abnormalities should prompt careful consideration of whether cesarean section is advisable. Total labor duration should be similar to that in cephalic presentation, although descent of the breech may be slow. The progress of the labor should, therefore be plotted, on a partogram in the usual way. There is evidence that the use of the World Health Organization partogram in breech labor reduces the incidence of prolonged labor, reduces the incidence of cesarean section (at least in parous women), and improves the condition of the neonate at birth.[119] This probably reflects the importance of good progress in labor as a favorable prognostic variable for successful vaginal breech delivery.

Meconium staining of the liquor is common in breech labor, and its predictive value for asphyxia is poor. In early labor, it is often found on the glove at the end of a vaginal examination. Its passage when the breech is still high in the birth canal in first stage may indicate "fetal distress," and careful evaluation of the fetal heart rate pattern at this stage will be necessary. However, the passage of meconium in the second

stage is almost universal and is of no prognostic value. Cardiotocographic fetal heart rate abnormalities can be investigated using fetal blood sampling, preferably obtaining the blood from the region around the ischial tuberosity and avoiding the genitalia. Some authorities recommend that fetal blood sampling should not be attempted in breech presentation[113]; however, there is no evidence that an adequate sample of blood obtained in this way has a different pH than blood obtained from the fetal scalp, and so the usual criteria of acidosis could be applied.

Second Stage (Fig. 63–1)

Practical maneuvers to facilitate the delivery of the breech have been insufficiently evaluated and there is little good evidence to guide the clinician. The second stage should be supervised by an experienced obstetrician (see Fig. 63–1). The active second stage with vaginal breech delivery does not start until the cervix is fully dilated and the fetal anus is seen on the perineum without having to part the mother's labia. The woman should then be placed in the lithotomy position with her buttocks just over the end of the delivery couch. She should be cleaned and draped as for ventouse or forceps delivery. A lateral tilt using a wedge is probably advisable. It is best if the bladder and lower bowel are empty, and elective bladder catheterization is probably advisable, with an "in and out" catheter. If effective regional anesthesia is not in place, a pudendal block with perineal infiltration should be used. An episiotomy is generally advised and should be performed at this point. An episiotomy will nearly always be required if forceps are to be used to achieve delivery of the aftercoming head, if extensive manipulation of the fetus is anticipated, and in all nulliparas, but is not mandatory. The breech, legs, and abdomen should be allowed to deliver spontaneously to the level of the umbilicus; the only intervention recommended up to this stage is to correct the position to sacroanterior if it is not in this orientation already. At this point, the obstetrician should deliver the legs, if they are extended, by abduction of the thigh and flexion of the fetal knee (using finger pressure in the popliteal fossa), allowing the fetal thigh to pass lateral to the fetal body. A loop of umbilical cord should then be brought down to minimize traction and possible tearing with consequent loss of fetal blood. The prognostic significance of the absence of cord pulsation is controversial. Fetal condition is probably better assessed by noting fetal tone and color.

Delivery to this point should ideally have been achieved with one contraction and one maternal expulsive effort. Delivery of the rest of the body, to delivery of the mouth, should be achieved over the next one or two contractions. The duration of time that should be allowed to elapse between delivery just below the umbilicus to delivery of the mouth is 5 to 10 minutes. Arulkumaran and coworkers[120] examined two different ways of delivering the breech. They allowed spontaneous delivery to the hip with one contraction and maternal effort followed by an assisted delivery of the rest

A

B

C
of the body and head in the next contraction in one group of women; in another group, they assisted delivery to the shoulders with one contraction and then an assisted delivery of the head was performed with the next contraction. The former method produced babies with a smaller fall in fetal blood pH and in better condition at delivery, judged by the Apgar score and need for

ventilation. They hypothesized that this was due to exposure, stretching, and compression of the umbilical cord over a longer period of time during the delivery of the latter group, or possibly to premature separation of the placenta.

Once the legs and abdomen have emerged, the fetus should be allowed to hang from the vulva until the wing of the scapula is seen. The arms are often found folded over the fetal chest, flexed at the shoulder and elbow; in this case, no particular maneuver is required to effect their delivery. If injudicious traction is exerted in order to deliver the breech, the arms may become extended over the fetal head. In this case, Lovset's maneuver may be used to free the arm. This involves wrapping the fetus in a warm dry towel and grasping the body over the bony pelvis with the thumbs along the sacrum. The fetal back should then be turned through 180 degrees until the posterior arm comes to lie anteriorly. The elbow will appear below the symphysis pubis, and that arm and hand can be delivered by sweeping it across the fetal body. This maneuver is repeated in reverse to deliver the other arm. If these maneuvers fail, the traditional last resort is to induce deep anesthesia and push the body of the fetus well up, pass the hand along its ventral aspect, and bring down the most accessible arm. This may then allow completion of vaginal birth. However, having pushed the fetus up successfully, it may well be safer to proceed with cesarean section.[120]

The nuchal arm, in which the arm is flexed at the elbow and extended at the shoulder coming to lie behind the fetal head, may be dealt with by a modified Lovset maneuver: rotating the fetal back through 180 degrees in the direction of the trapped arm may draw the elbow forward toward the face and over the fetal head by friction on the birth canal and render it amenable to a traditional Lovset maneuver to deliver the arm. If this technique does not suffice to release the nuchal arm, it may be forcibly extracted by hooking the finger over it, in which case, it is almost always fractured.

The fetus should be allowed to hang from the vulva for a few seconds again until the nape of the neck is visible at the anterior vulva. This allows descent of the head into the pelvis, and at this point, the head may be delivered. Downward traction before spontaneous descent may result in hyperextension of the fetal head rather than flexion and descent; so again, operator interference can cause complications in the delivery. If the head negotiates the inlet of the pelvis easily, there is little danger that the progress of the head will be arrested in midcavity. If there is difficulty with the head in the midcavity, or the outlet, a properly performed Mauriceau-Smellie-Veit maneuver will overcome this (see later full description). Should the head fail to descend into the pelvis after the shoulders have delivered, the body of the fetus should be turned sideways and suprapubic pressure used to flex the head and push it into the pelvis in the occipitotransverse/oblique position. A vaginal finger in the mouth of the fetus may also tend to flex the head and help it to descend into the pelvis prior to delivery. McRobert's maneuver

can be used to facilitate delivery of the head if it is arrested at the inlet and suprapubic pressure and the Mauriceau-Smellie-Veit maneuver has failed. This involves a sharp flexion of the maternal thighs toward the maternal abdomen and abduction of the legs, in a way directly analogous to the management of shoulder dystocia in the vertex delivery.[121] Continued failure of the head to descend into the pelvis may be due to hydrocephalus; in which case, the head can be perforated through the foramen magnum (an epidural needle is a suitable instrument) and the cerebrospinal fluid drained. Such a maneuver should be performed only if the diagnosis has been confirmed by ultrasound and the fetus is already dead. Alternatively, the cervix may not be fully dilated; in which case, the cervix must be incised. This is done with round-ended scissors, and the incisions made at 4 and 8 o'clock to avoid the bladder and rectum and the main blood vessels (which supply the cervix at 3 and 9 o'clock). If there are locked twins, there is no choice but to do a cesarean section; the traditional technique of decapitating the first twin is no longer acceptable. If none of these causes is present, the operator must assume that cephalopelvic disproportion is present and there is then a strong case for the performance of a symphysiotomy.[122] With proper predelivery assessment and conduct of labor, this situation should arise only very rarely.

Performing a Symphysiotomy (Fig. 63–2)

The episiotomy should be enlarged. If the mother does not have epidural analgesia, the anterior, superior, and inferior aspects of the symphysis should be infiltrated with lidocaine 0.5%. The usual precautions to prevent intravenous injection should be taken. While waiting for the analgesia to take effect, an indwelling urinary catheter should be inserted. The suprapubic skin should then be cleaned with antiseptic solution. Following this, the index finger should be placed in the vagina and lateral pressure applied to the catheter to move the urethra away from the midline. A thick, firm-bladed scalpel should then be used to make a vertical stab incision over the symphysis. Keeping to the midline, the knife should be pressed down through the cartilage joining the two pubic bones until the pressure of the scalpel blade can be felt on the finger in the vagina. If the cartilage is not fully divided, the blade can be rotated and the cutting movement can be made back toward the top of the symphysis to finish the process. Following the delivery, there is no need to close the incision unless there is bleeding. It is, however, wise to give prophylactic antibiotics (e.g. ampicillin, gentamicin, and metronidazole). Elastic strapping from one iliac crest to the other will reduce postoperative pain, but analgesia will be necessary. The urinary catheter should be left in situ for a minimum of 5 days.

Techniques for Delivering the Head (Fig. 63–3)

It should be remembered that entrapment of the aftercoming head can also occur with cesarean section,

FIGURE 63–2

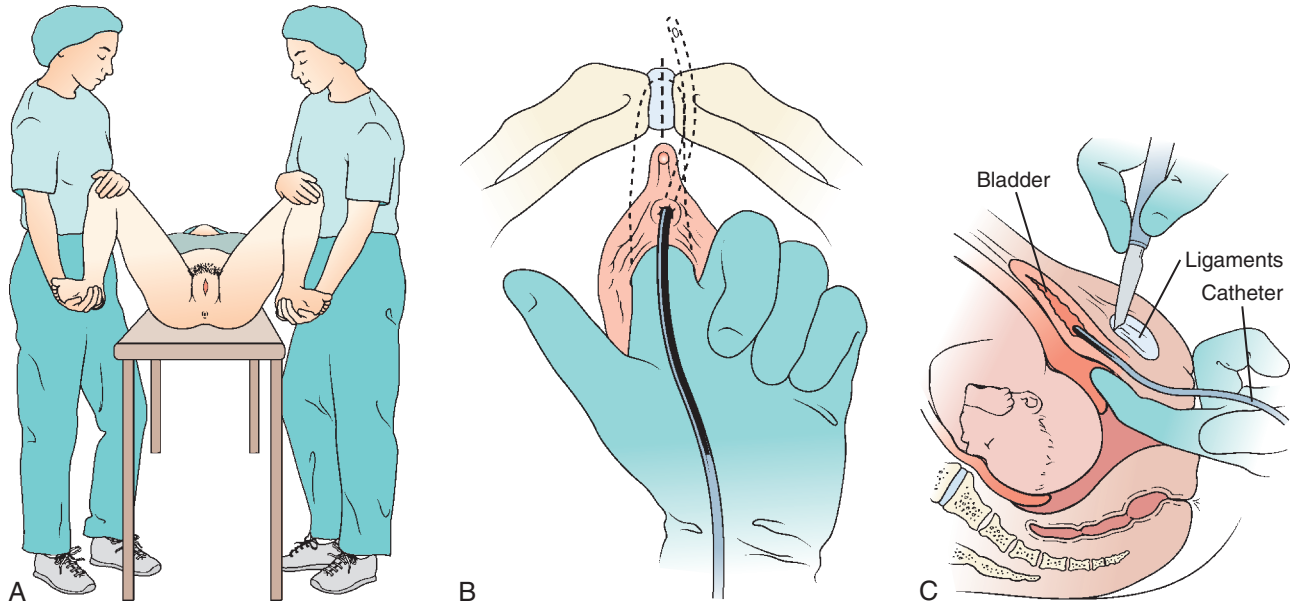
(From World Health Organization [WHO]: Managing complications in pregnancy and childbirth: A guide for midwives and doctors. Accessed at www.who.int/reproductive-health/impac/ procedures/symphysiotomy_P53_P56.html)


especially if an inadequate-size abdominal incision has been made. Robertson and colleagues[30] found no significant difference in the incidence of head entrapment by mode of delivery from 28 to 36 weeks' gestation, nor any association with adverse outcome following head entrapment. The techniques for delivery of the aftercoming head are various (see Fig. 63–3). Some authorities advise that the body should be supported on the right forearm of the operator and not be raised above the horizontal in order to minimize the chance of hyperextension of the fetal head. Others advise that the operator's assistant should grasp the ankles of the fetus and raise the body vertically above the mother's abdomen prior to any attempt to deliver the fetal head, because this will promote rotation of the fetal head and place it in the anteroposterior diameter of the pelvis. This is called the Burns-Marshall technique and may rotate the head and deliver it over the perineum without further intervention. It is, therefore, advisable to cover the perineum with the hand to prevent precipitate delivery of the head as the body is swung upward. The operator's hand can then be opened slowly in order to allow the rest of the head to deliver. Often, however, further assistance is required to deliver the head. The head may be delivered from this position using forceps applied below the fetal body. The operator should remember that the smallest part of the head is lowest in the vagina and that the tip of the forceps blade must accommodate the occiput; therefore, premature straightening of the forceps blade during application will cause undue pressure on the side of the fetal head. Forceps should be

of a type with a long enough shank to permit the operator to visualize the maneuver, because often the fetal arms obstruct the view, and if the fetal body is in the horizontal position, access is further reduced. The head should be delivered slowly (over ~1 min) to reduce the compression-decompression forces on the fetal skull that may cause tentorial tears and intracranial bleeding.

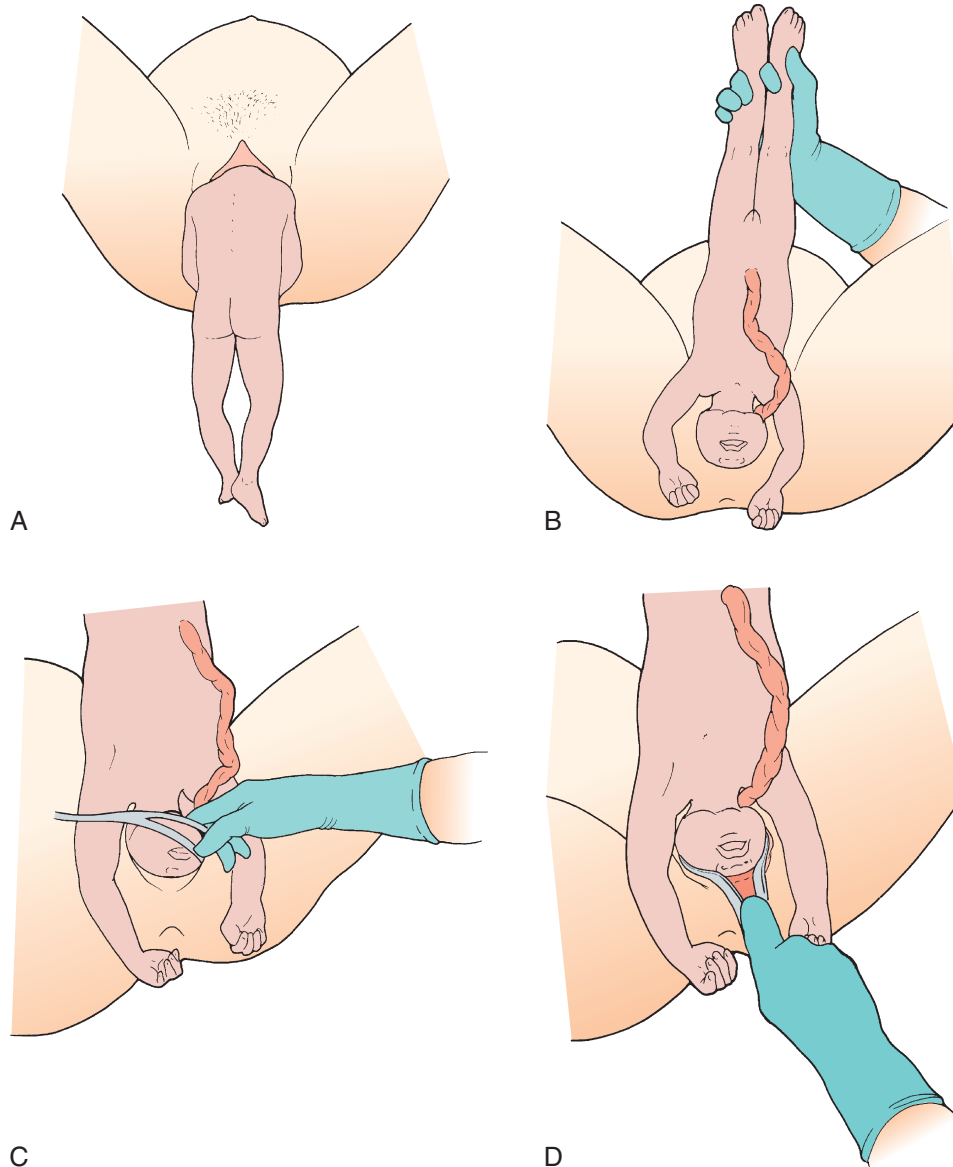
The other frequently described technique of delivering the fetal head is the so-called Mauriceau-Smellie-Veit maneuver. This is actually a variety of techniques. The principle is that of traction down the axis of the birth canal while encouraging flexion of the fetal head to present the most favorable diameters to the pelvis. With the fetus supported on the right forearm, the middle finger of the right hand is passed into the fetal throat and the forefinger and the ring finger are placed on either the fetal shoulders or the malar eminences. Pressure is applied on the tongue to flex and deliver the head. The middle finger should not be just inside the fetal mouth, because traction can produce dislocation or fracture of the mandible. If the finger is inserted too far down the throat, creation of a pseudodiverticulum of the pharynx has been described. The left hand is used to exert pressure upward and posteriorly on the fetal occiput to encourage flexion. Alternatively, suprapubic pressure can be applied to encourage head flexion and descent. All these maneuvers can be performed with the operator's assistant elevating the fetal body above the horizontal. Downward traction on the fetal shoulders tends to stretch the cervical spine and, in combination with flexion of the fetal head, will draw

FIGURE 63–3
Forceps delivery of the aftercoming head. *A*, Allowing the trunk to hang flexes the head and encourages descent. *B*, Once the head is in the pelvis, rotating the trunk over the mother's abdomen delivers the face. *C*, Applying forceps to the aftercoming head. *D*, Forceps used to control the rate of delivery of the head.

A

B

C

D


the base of the skull away from the vault, thus causing a tentorial tear. Therefore, traction on the trunk should not be used. All these permutations have been described by various authors as the Mauriceau-Smellie-Veit maneuver.

A pediatrician should always be present at the delivery, and ideally, the mouth and pharynx should be sucked out on the perineum prior to complete delivery of the head, although often the head delivers too quickly for this to be done.

The Zavanelli maneuver has also been described for the delivery of the breech with an entrapped aftercoming head. Tocolysis is used to facilitate replacement of the fetal body into the uterus, and cesarean section completes the delivery.[123] Because experience with this

maneuver is very limited, its use in this desperate situation remains controversial.

Considerations in the Performance of Breech Extraction (Fig. 63–4)

Currently, breech extraction is rarely performed because of the risks of fetal and maternal trauma and because of the effects of excessive traction on the fetal body. Its main current indication is for the delivery of a second twin after internal podalic version or if cord prolapse complicates the late second stage. It may also be appropriate if the fetus is dead. Groin traction is performed to draw the breech over the perineum, Lovset's maneuver is employed routinely, and downward traction is exerted to bring the head into the pelvis. In effect,

FIGURE 63–4
Active breech delivery (breech extraction).

all the stages of assisted breech delivery are achieved actively by the obstetrician.

Choice of Mode of Delivery

CESAREAN SECTION

Practical Considerations in the Performance of Cesarean Section for the Delivery of the Term Breech

The orthodox obstetric practice of considering any woman with a breech presentation and any other medical or obstetric complication for delivery by elective cesarean section has much to recommend it. Elective and even emergency cesarean section for the term breech should present few technical problems. It should be remembered that the performance of a cesarean section does not prevent the possibility of birth injury, and many of the foregoing considerations about the careful delivery of the aftercoming head and the dangers of traction on the fetal spine still apply. The lower segment will be the site of choice for the incision with a term breech presentation. Schutterman and Grimes[124] reviewed 416 breeches of all gestations allocated randomly to transverse or low vertical incisions in the uterus and found no advantages for low vertical incisions. An elective cesarean section when adequate liquor is still present and the uterus is less likely to contract rapidly before completion of delivery of the breech will present few problems to the experienced operator. Forceps may be employed for delivery of the aftercoming head. Cesarean delivery at full dilation in the absence of liquor may be difficult because an arm may prolapse through the uterine incision; it should immediately be pushed back. Instead, a leg (or preferably both legs) should be grasped and brought through the incision: Traction will then effect the rest of the delivery. The head can be trapped by a well-contracted lower segment, and the incision will then need to be enlarged in a J-shaped fashion to increase access. In general, the mode of effecting delivery through the uterine incision is the same as for vaginal breech delivery, and many of the same complications may arise.

The fetal head may become entrapped in the uterine incision at the point of delivery, because the lower uterine segment contracts rapidly down. For this reason, even at an elective cesarean section, it is prudent to have a pediatrician present for delivery. Tocolytics cannot be recommended for routine deliveries but might be useful when delivery is expected to be difficult or traumatic.[125]

Deficiencies in the conduct of vaginal breech deliveries, resulting in perinatal death, have been systematically evaluated in a blinded case-controlled audit. The authors concluded that infant death at term was to a large extent potentially avoidable, but that in control breech infants who survived, suboptimal care was not uncommon.[107,126]

ACTIVE BREECH DELIVERY

With increasing consumer pressure in the United Kingdom during the 1990s toward less interventionist obstetrics, a demand for an active method of delivering the breech appeared. This was satisfied by a group of mainly midwife practitioners who performed a so-called active breech delivery. This encouraged women to be active during labor and, although allowing the woman to adopt the most comfortable position during labor, favored a standing position for the delivery itself. Nonpharmacologic analgesia and maternal participation in the birth were encouraged. The breech was allowed to deliver spontaneously without any interference from the birth attendants. The author's experience of 21 of such deliveries conducted in her own maternity unit is that 1 baby died during the final stages of birth, 1 had persisting neurologic damage resulting in a large medicolegal settlement, and another may have such damage. In the light of these poor outcomes, the technique cannot be recommended.

SUMMARY OF MANAGEMENT OPTIONS
Breech Presentation

Management Options	Evidence Quality and Recommendation	References
Term Breech Presentation		
Fetal Assessment		
Confirm diagnosis and determine placental site.	—/GPP	—
Confirm normality as association of breech presentation with congenital anomalies.	III/B	42
Version in Prenatal Period		
There is insufficient evidence to advocate postural methods to promote spontaneous version.	Ia/A	50
Recommend ECV at 36+ weeks' gestation.	Ia/A	53
Tocolysis increases the success of ECV.	Ia/A	62–70
There is insufficient evidence that epidural anesthesia increases the effectiveness of ECV.	Ia/A	62
Need for fetal heart rate monitoring before and after ECV.	III/B	49
If the Woman Chooses to Attempt a Vaginal Delivery		
Assess the health of the mother and baby.	IV/C	93–96
Perform ultrasound to confirm the diagnosis, check for fetal abnormalities, and assess placental site, fetal attitude, and estimated fetal weight.	IV/C	89,93–96
A written protocol is advisable, and a skilled birth attendant for labor and delivery is mandatory.	IIb/B	81
Pelvimetry need not be used routinely.	III/B	113,115
Labor and Delivery		
Evidence is that planned cesarean section for breech at term is the preferred method of delivery because it significantly reduces perinatal mortality and morbidity rates.	Ia/A	1
	Ib	90,91
Preterm Breech Presentation		
Prenatal		
There is insufficient evidence that ECV before term offers any benefit.	Ia/A	53
Labor and Delivery		
There is insufficient evidence to recommend cesarean section for the preterm breech.	Ib/B	46,127
For the preterm breech in labor, perform an ultrasound scan to confirm the presentation and normality; determine the mode of delivery in close consultation with the woman and her family.	IV/C	46

Unstable Lie, Malpresentations, and Malpositions

IAN Z. MACKENZIE

INTRODUCTION

The concepts of unstable lie, malpresentation, and malposition have not changed for centuries probably, and there is no reason to anticipate a significant change will present in the foreseeable future. Various techniques for improving diagnostic accuracy and clinical care are periodically proposed and either become established clinical practice or disappear, sometimes to be resurrected at a later date.

Near term and during labor, the fetus usually assumes a longitudinal lie and presents to the maternal pelvis with the head, the neck flexed, and the vertex in the lowermost part of the uterus. In approximately 5% of labors, the lie is not longitudinal; this can be dangerous for both mother and fetus and demands intervention. As with much of medicine, the prior identification of the pregnancy at particular risk for unstable lie, malpresentation, or malposition can prompt intervention in advance of a complication developing and improve the outcome. Although relevant to unstable lie and malpresentation, this chapter does not consider issues relating to fetal breech presentation in detail because these are dealt with elsewhere (see Chapter 63).

DEFINITIONS

Unstable Lie

Unstable lie is a description generally used beyond 37 weeks' gestation when the fetal lie and presentation repeatedly change, the lie varying between longitudinal, transverse, and oblique, and the presentation between cephalic, limbs, breech, or a combination. Conventional wisdom teaches that the fetal presentation will not be cephalic at the start of the third trimester in around 25% pregnancies and this proportion drops to around 3% to 5% by term. This teaching is supported by longitudinal ultrasound examination studies.[1–3]

By 37 weeks' gestation, the fetus usually adopts a "stable" lie and presentation that will be unchanging until labor; fetal position, describing the relationship of the fetal back to the maternal side, may and often does change. A longitudinal fetal lie is, however, unlikely to change once labor has established, unless the presenting part is "high" in relation to the pelvis, and particularly if there is polyhydramnios or the maternal abdominal wall muscles are weakened by high parity.

Malpresentation Including Compound Presentation

The *presenting part* is defined as that part of the fetus that is lowermost in the uterus. The vertex is the "normal" and most common presenting part. The alternatives include face, brow, breech, and shoulder; compound presentations involve more than one fetal part presenting to the pelvis. This may include a combination of the head with a limb or limbs and any presentation that includes the umbilical cord.

Malposition

Fetal malposition occurs when the vertex presents to the maternal pelvis in a position other than flexed occipitoanterior. Malpositions thus include occipitotransverse and occipitoposterior positions and may involve asynclitism (sideways tilt of the head).

Figure 64–1 shows the various positions that the vertex, brow, or face may adopt during labor.

ETIOLOGY

Unstable Lie

Unstable lie is much more common in parous than in nulliparous women and may be caused by or associated with a number of factors. Any situation that discourages or prevents the fetal head or breech from entering the maternal pelvis may predispose to an abnormal and/or unstable fetal lie. Figure 64–2 illustrates many of these factors.

Maternal Factors
HIGH PARITY

Reduced maternal abdominal wall muscle tone leading to a failure to brace and maintain a longitudinal fetal lie is probably the most frequent factor. There is a commonly held view that the highly parous uterus also has reduced muscle

Etiologic factors and conditions associated with unstable fetal lie.

tone, thereby contributing to instability of the fetal lie, but this has not been proved and is, therefore, of questionable relevance.

PLACENTA PREVIA

A persistently changing fetal lie may be the only clinical feature leading to the diagnosis of placenta previa. In addition, the placenta situated in the fundus may also predispose to an unstable lie.[4]

PELVIC CONTRACTURE

Reduced pelvic dimensions or a distorted pelvic cavity due to congenital malformation, disease processes compromising bone development, or trauma to the pelvis, can prevent the presenting pole engaging in the pelvis in late pregnancy.

PELVIC TUMORS

Ovarian cysts of only moderate dimensions situated in the pouch of Douglas and fibroids in the lower pole of the uterus, as well as those that are pedunculated and occupying the sacral curve, can prevent the fetal head or breech entering the pelvis and predispose to a transverse or oblique lie.

UTERINE MALFORMATION

Uterus cordiformis, subseptus, or septus can be causative, but more severe forms of anomaly including uterus unicornis, bicornis, and didelphys are less likely to lead to an unstable lie because of the restricted capacity of the uterine cavity; a predisposition to fetal breech presentation, however, often results.

DISTENDED MATERNAL URINARY BLADDER

Maternal urinary retention with bladder distention can cause a changing fetal lie, usually only temporarily, with resolution occurring with urinary voiding or bladder catheterization.

Fetal Factors

POLYHYDRAMNIOS

Polyhydramnios (excessive volumes of amniotic fluid) may produce marked uterine distention, enabling the fetus to move around more freely. This probably represents the most common "pathologic" cause for an unstable lie and is also potentially the most hazardous for mother and fetus (see Chapter 12).

OLIGOHYDRAMNIOS

By restricting fetal movement, oligohydramnios can prevent the fetus presenting by the breech from undergoing complete spontaneous version to cephalic.

MULTIPLE PREGNANCY

The discovery of an abnormal lie during the last 3 weeks of pregnancy may arouse suspicion of a multiple pregnancy and lead to investigations that result in the diagnosis being reached. Nowadays, such a diagnosis is unlikely to have been missed until this stage of pregnancy with the widespread use of routine ultrasonography during the first 20 weeks of gestation. When the lie of one or both fetuses repeatedly changes, there is usually polyhydramnios.

FETAL MACROSOMIA

Fetal macrosomia produces the same effect as pelvic contracture and must also be considered in such cases.

FETAL ABNORMALITIES

Significant hydrocephaly, tumors of the fetal neck or sacrum, fetal abdominal distention as with hydrops fetalis, and fetal neuromuscular dysfunction (including extended legs) may impede or discourage engagement of a fetal pole in the maternal pelvis. In cases of intrauterine death, the fetus is more likely to present abnormally due to loss of tone, sometimes requiring delivery by cesarean section because vaginal birth is impossible.

Compound Presentation

Compound presentations are most usually associated with polyhydramnios and high parity and are more common during the early weeks of the third trimester. Multiple pregnancies, especially monoamniotic, represent a particular risk. Pelvic tumors, including uterine fibroids situated low in the uterine body or an ovarian cyst situated in the pouch of Douglas, also predispose to compound presentations.

Malpresentations that involve the umbilical cord are similarly associated with the factors previously mentioned. Fetal breech presentation, especially with one or both knees flexed, is the most common malpresentation associated with cord presentation and prolapse.[5–8] Abnormalities of the cord, including reduced content of Wharton's jelly, true knots, and chronic fetal acidosis reducing tissue turgidity, have been cited as predisposing factors.[9]

Brow and Face Presentations

The majority of cases of brow and face presentation are thought to arise when there is a minor degree of deflexion of the presenting vertex, which then undergoes further extension. With increasing extension, a brow becomes a face presentation. This may occur during the antepartum period, resulting in a primary face presentation, or during labor, resulting in a secondary face presentation. Primary presentations are generally associated with fetal malformations, including anencephaly, meningocele, dolichocephaly, congenital branchiocele, goiter or other anterior neck tumors, and tense extensor neck muscles. Polyhydramnios with the increased space within the uterus and a tight nuchal cord have also been implicated as predisposing factors. Secondary presentations are thought to be associated with a contracted or abnormally shaped pelvis. This was considered responsible for 40% of face presentations in a series reported from the Johns Hopkins Hospital early in the last century.[10] It is also much more common in preterm labor, probably due to the more capacious pelvis being able to accommodate the relatively small fetus.[11]

Malpositions

Data derived from ultrasound examinations at the start of labor have suggested that the majority (68%) of occipitoposterior positions confirmed toward the end of labor were in an occipitoanterior position at the beginning of labor; the other 32% were initially in an occipitoposterior position, and these labors are more likely to result in an assisted delivery.[12]

Pelvic shape is probably the major determinant of fetal position prior to labor. When the anteroposterior dimension of the pelvic brim equals or exceeds that of the transverse dimension (the android pelvis), occipitoposterior positions are favored. Thus, women with an android pelvis are more likely to have an occipitoposterior position in late pregnancy and at the start of labor because the larger dimensions toward the back of the pelvis encourage the broader occiput to be accommodated there rather than in the anterior compartment. In addition, when there is a high-assimilation pelvis with an extra vertebra included in the formation of the sacrum, the inclination of the brim increases and favors an occipitoposterior position. The much less common anthropoid-shaped pelvis, with lessening of the posterosagittal diameter (the distance between the midpoint of the widest transverse diameter and the sacrum), affects not only the brim but also commonly extends to the lower levels of the pelvis and to the outlet. In particular, the concavity of the sacrum from promontory to tip is often reduced or abolished (flat sacrum), leaving a reduced space in which the sinciput can turn, should internal rotation commence. This leads to the head becoming impacted in the pelvis, resulting in a "deep transverse arrest." It has been suggested that increased muscle tone in the extensor muscles of the fetus might also predispose to an occipitoposterior position, but there is little evidence to support this theory.

Most important is the observation that a high proportion of women with a malposition who make poor progress through labor often respond to augmentation of uterine contractions with oxytocin and achieve a successful spontaneous vaginal delivery.[13] This suggests that the quality of uterine contractions plays a significant part in determining the position and attitude of the fetal head. As well as uterine contraction strength being important, there is now good evidence that the tone of the pelvic floor is relevant. Use of

regional anesthesia for the management of pain relief during labor has been implicated as a mechanism for the increased rates of malposition in late labor,[14,15] although this is disputed. Regional anesthesia provides an extremely effective method of reducing the distress of labor, distress that is more common with a preexisting occipitoposterior position. The issue of cause and effect thus comes into play. The experience reported from Dublin provides some evidence to suggest that regional blockade is not causal in the evolution of fetal malposition. It was noted that despite a 30-fold increase in intrapartum epidural usage between 1975 and 1998, occipitoposterior position at the end of a first labor decreased from 3.8% to 2.4%.[15,16]

INCIDENCE

Unstable Lie

Figures are not generally available for the incidence with which unstable lie is encountered antenatally; it is influenced by the proportion of multiparas and particularly the numbers of grand-multiparas in the population. Also, in societies where malnutrition is prominent and maternal or fetal skeletal deformities are relatively more common, the incidence will be higher. In a well-nourished and developed population where high parity (>4) is uncommon, the incidence will be in the range of 0.1% to 1.0%, and the occurrence rate of transverse lie in labor is in the region of 0.4%.[17]

Compound Presentations

There is a relatively sparse literature on the incidence of compound presentations that involve one or more limbs and the fetal head or breech. Overall, the incidence has been quoted to be between 1 in 377 and 1 in 1213 deliveries[18–20]; personal experience suggests that the lower incidence is more usual in the developed world. Combinations involving the upper limbs and head are the most common. Diagnosis in late labor is the usual situation, with as many as 50% of compound presentations being diagnosed during the second stage of labor.

The incidence of cord presentation, when a segment of umbilical cord is situated between the fetal presenting part and the cervix with intact membranes, has not been widely reported. although cord prolapse, by definition following membrane rupture, occurs in around 1 in 300 to 1 in 700 total births,[5,7,21,22] 1 in 900 cephalic presentation labors, 1 in 56 breech labors, 1 in 23 twin labors,[7] and 1 in 5 to 1 in 10 compound presentations that involve a limb.[18,19,23] Thus, cord prolapse in a singleton pregnancy with a cephalic presentation at term has an incidence of around 1 in 1400 labors. These rates are almost certainly lower than the incidence of cord presentation, because recognized cord presentation is likely to be managed by cesarean section before prolapse occurs.

Brow and Face Presentation

Face presentation in labor has an incidence of between 1 in 200 and 1 in 500 labors[24–26] and brow presentations around 1 in 600 to 1 in 1500 deliveries.[27–29] The incidences during pregnancy are less well documented, especially for brow presentation, because it is probable that this presentation is only transient, with reversion to vertex presentation with flexion of the neck or face presentation with further deflexion.

Malpositions

During the antepartum period, prior to the onset of labor, the occipitoposterior position exists in around 11% of singleton pregnancies.[30,31] Once labor starts, the incidence is in the region of 20% to 25%; if the fetal back is on the maternal left, the occipitoposterior position is much less common than when the back is on the maternal right.[20] It is said to be more common in cases of membrane rupture before the onset of labor, with an incidence of 27%.[32] When there is an occipitoposterior position at the start of labor, this position will remain to the end of labor in 20% to 35%, indicating that 65% to 80% undergo spontaneous rotation during labor. Only approximately 1% to 5% are delivered in an occipitoposterior position.[33,34]

DIAGNOSIS

Unstable Lie

This diagnosis is made when a varying fetal lie during the last month of gestation is found at repeated clinical examinations. Occasionally in those women in whom clinical examination is not easy (including those with a raised body mass index), the diagnosis may fortuitously be made by an ultrasound examination performed for other reasons. An unstable lie would appear to be more common than is presently thought, from the evidence of the frequency with which fetal breech presentation is missed prior to the onset of labor despite frequent and recent antenatal clinical examinations. Further, the observation of spontaneous and unexpected version of the fetus from a cephalic to breech presentation during the last weeks before birth adds weight to this observation.[35,36]

Compound Presentations

A compound presentation involving a fetal arm with the head or an arm with a leg is likely to be diagnosed only during the antepartum period as a coincidental finding at an ultrasound examination or rarely on radiographic or magnetic resonance imaging. The high nonengaged head that cannot be encouraged into the maternal pelvis might prompt an ultrasound examination that leads to the diagnosis.

Diagnosis during labor may be suspected because of delay in the presenting part entering the pelvis, which is confirmed on vaginal examination by identifying the errant limb or limbs. Occasionally, the diagnosis is made unexpectedly at a vaginal examination during preterm labor when the maternal pelvis is large and the interloping limb with the head or breech does not delay engagement of the presenting part.

Compound presentations involving the umbilical cord are usually classified according to Naegele, who distinguished "presentation" before membrane rupture and "prolapse" after membrane rupture. A diagnosis of cord presentation will not usually be made prior to the onset of labor except in those cases of an unstable lie when a vaginal examination

RIGHT MENTO-POSTERIOR
POSITION

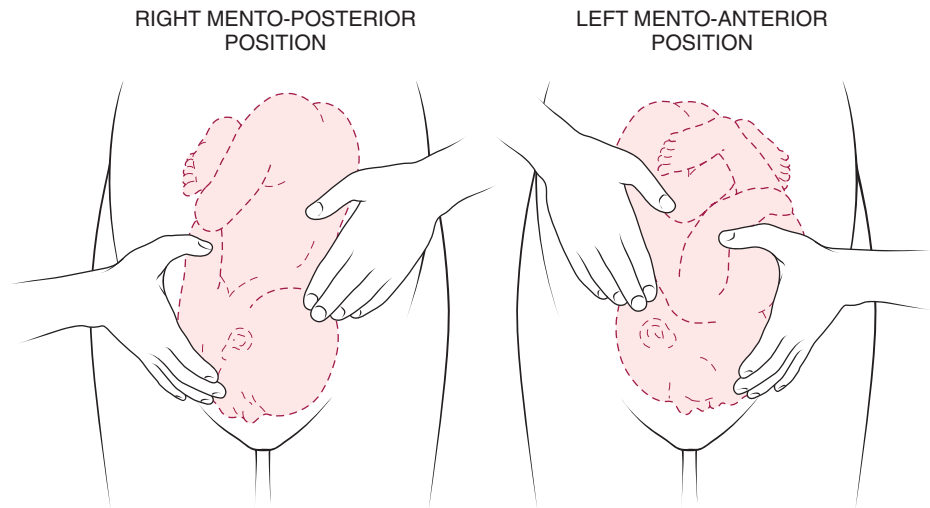
LEFT MENTO-ANTERIOR
POSITION


FIGURE 64–3
Palpation of the fetus and the landmarks
associated with a face presentation.

is performed as part of the assessment for the strategy for continued management. Although some have documented reaching the diagnosis with ultrasound, this is not a widely reported observation,[37] and cord prolapse occurring during subsequent labor appears to be an infrequent consequence.[38]

Face Presentation

Older texts report that abdominal palpation allows the diagnosis of face presentation by the recognition of a much broader than usual lower pole presenting to the pelvis and the marked depression between the fetal back and the occiput (Fig. 64–3). This is more easily demonstrated if the fetus is lying in a dorsoanterior or mentoposterior presentation, which is less common than a mentoanterior presentation.[24] It is also said that the fetal heart sounds are very easily heard when listened to over the fetal chest, especially with a mentoanterior position; this potentially valuable clinical sign is lost if hand-held Doppler machines are routinely used to detect fetal heart pulsations in preference to a Pinard stethoscope. Despite this, the author's experience is that these clinical signs are difficult to elicit, even in those cases of face presentation already confirmed by radiology or ultrasonography.

Confirmation of the presentation should be made by vaginal examination during the intrapartum period. The obstetrician, however, should be wary of confusing a face and a breech presentation; facial edema readily forms during labor and, with the added difficulty associated with a high presenting part and a poorly dilated cervix, differentiation can be difficult. Identification of the supraorbital ridges, the ridge of the nose, and the alveolar processes within the mouth should establish the diagnosis. If the technology is available, an ultrasound examination can be used to confirm the clinical suspicion.[39]

Brow Presentation

Although occasionally a brow presentation may be recognized during the antenatal period, usually coincidentally at an ultrasound examination, this is not permanent in most instances. The suspicion of a broader than expected head resting above the pelvic brim compared with the size of the body may (rarely) lead the astute clinician to suspect this possibility. Diagnosis during the intrapartum period is likely to be made only in advanced labor when the cervix is moderately well dilated and the brow is palpable to the examining fingers. Identification of the anterior fontanelle and the supraorbital ridges confirms the diagnosis, but any significant caput succedaneum can mask these landmarks. As with face presentations, ultrasound examination is the most practical way to confirm or refute the diagnosis.

Malpositions

It is often written that the outline of the distended uterus occasionally suggests an occipitoposterior position by the "flatness" and a dip between the head and the trunk. Certainly, fetal movements may be readily observed over much of the anterior surface of the abdomen if the baby is active at the time of the examination. However, the fetal back may be difficult to identify on palpation, although the shoulder is felt toward the flank with the limbs often obvious to palpation over the abdomen. With Pawlik's grip, the sinciput is said to be prominent, but personal experience would not suggest this to be a reliable feature. Importantly, the fetal heart is heard maximally in the flank to which the back is directed; the Pinard stethoscope allows this clinical sign to be elicited whereas the small Doppler fetal heart detectors generally do not. An ultrasound examination would confirm or refute the clinical findings.

During labor, the anterior fontanelle is easier to reach when the position is occipitoposterior rather than occipitoanterior, although caput succedaneum can make this difficult, especially late in labor. Palpation of the more anterior ear can be helpful, but this may be misleading if the pinna has been turned forward. At this examination, not only the degree of flexion but also any asynclitism should be noted. Diagnosis of a deep transverse arrest should not present difficulties unless there is marked caput succedaneum or prominent asynclitism. Once again, palpation of the fetal ear could

be helpful, or if available, ultrasound to confirm the position.[40,41]

RISKS

Unstable Lie and Compound Presentation

There are no hazards to mother or fetus during the antenatal period from unstable lie per se. It is possible that cord entanglement is a greater risk, although this has not been positively shown. During the latter weeks of pregnancy, spontaneous resolution to a longitudinal lie before the onset of labor occurs in approximately 85%.[42–44]

There are, however, very serious risks to mother and fetus with the onset of labor if the lie is not longitudinal. Once the membranes rupture, with or without accompanying uterine contractions, there is approximately a 9% risk of cord prolapse if the fetal lie is oblique or transverse or the presenting part is high above the pelvic inlet.[45] This may result in damaging hypoxia or even stillbirth; perinatal death has generally been reported in 5% to 10% of cases[7,46,47] or, according to one series, as high as 43%.[48] The risk of hypoxic damage is less well documented and it may be as infrequent as 1% in survivors,[7] although this must depend on the speed and availability of first aid to rescue the situation. Keeping the interval between cord prolapse and delivery as brief as possible is likely to be important.[46,49]

If labor starts when the lie is not longitudinal, a compound presentation may result or the pelvis may remain empty. If left unattended, fetal distress will eventually supervene, ultimately resulting in fetal death. A Bandl or retraction ring (Fig. 64–4) may form, making delivery even by cesarean section potentially hazardous.[50] In addition, uterine rupture is a real possibility especially in multiparas, with an incidence of 3%,[45] with potentially serious consequences for mother and fetus (see Chapter 67).

Malpresentation

Face

Cord prolapse may be marginally increased with a face over vertex presentation, but once established in labor with the head engaged in the pelvis, this is no more likely. Progress should be as for a vertex presentation without any additional risk to the fetus because the presenting head diameters are similar (Fig. 64–5). However, with the largest presenting diameter (biparietal) displaced toward the back of the pelvis, a generous episiotomy should be performed to reduce the risk of a third-degree tear. Providing the face is mentoanterior, vaginal delivery is likely. If there is any delay in delivery, assistance with forceps is appropriate but the ventouse is contraindicated because it cannot be applied safely with a face presentation. The parents should be advised in advance of delivery that their baby will initially appear very unattractive owing to the inevitable bruising and marked edema, both of which disappear within a few hours of birth.

Brow

There are no added risks to the mother with a fetal brow presentation during the antenatal period. As with a face presentation, the risk of cord presentation and prolapse is increased.

Except with very preterm labor, the fetus cannot be delivered as a persistent brow unless there is a very capacious pelvis, because of the large mentovertical diameter that presents to the pelvis (see Fig. 64–5). If continued extension of the neck to a face presentation does not occur and the brow presentation persists, the chances of fetal distress and even uterine rupture in a parous woman are high if labor is not progressing and left to continue for too long.

Malpositions

Few risks are associated with a fetal malposition prior to labor. As already stated, there is a belief that prelabor rupture of the membranes is more common with an occipitoposterior position. Because the head is usually not engaged and may not be well settled into the pelvis, the risk of cord prolapse is marginally increased.

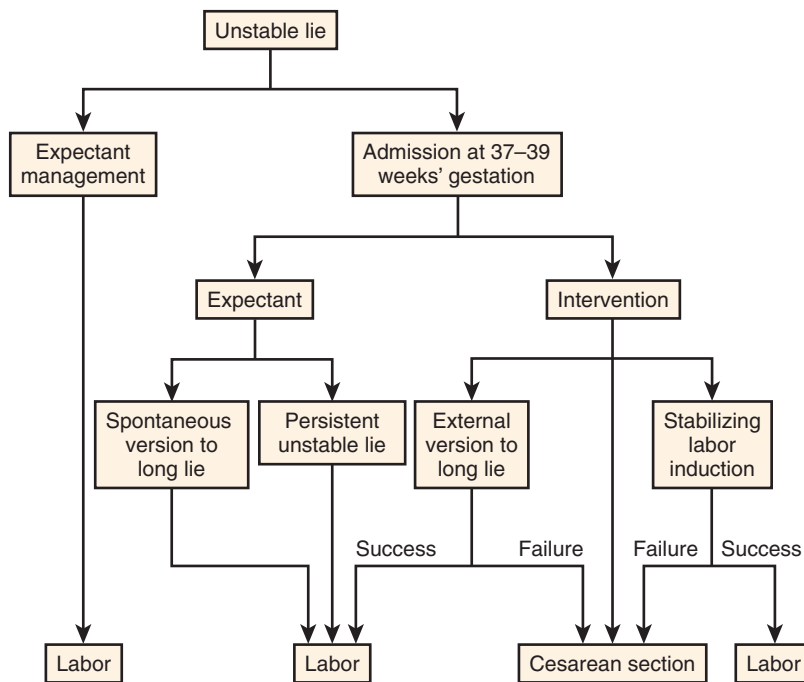
Once in labor, progress may be slower than with an occipitoanterior position and maternal discomfort is often increased, particularly in the back. In addition to a protracted first stage of labor, there is often a delay during the second stage with the need for augmentation of contractions with oxytocin, and maybe manual rotation or instrumental delivery using ventouse or forceps with or without initial rotation. With the present reluctance to engage in rotational forceps deliveries, especially if fetal distress is suspected, together with the higher failure rates with the ventouse, delivery by cesarean section is increased.
FIGURE 64–5
The largest sagittal dimensions of the fetal head according to presentation.


FIGURE 64–6
Algorithm for the antepartum management of unstable lie in late pregnancy.

It has been shown by one group that the occipitoposterior position that persists to the time of vaginal delivery presents a significant risk of anal sphincter damage for all parities.[16]

MANAGEMENT OPTIONS

Unstable Lie and Compound Presentation

Prenatal

During the antenatal period, management can be expectant or active, whereas delivery can either await spontaneous onset of labor or be arranged as a planned event. An algorithm of the various options is illustrated in Figure 64–6.

EXPECTANT MANAGEMENT

Once an unstable lie is identified, no specific action is taken in anticipation that the lie will become longitudinal before the membranes rupture or labor starts: this is likely to occur in more than 80% of cases.[42–44] Manipulation to a longitudinal lie at an antenatal examination can sometimes be performed. Every attempt should be made to identify any obvious mechanical cause for the unstable lie, especially if it is likely to result in obstructed labor requiring elective cesarean section. The patient should be advised of the risks associated with an unstable lie and the need for urgent attention should labor start or the membranes rupture. If she lives a long distance from the delivery unit, it may be wise to

admit her at 37 to 39 weeks' gestation to await the onset of labor to ensure prompt attention if required. A number of physical exercises, including adopting the knee-elbow position for short periods each day, have been advocated to encourage spontaneous version, generally from a breech to a cephalic presentation.[51–54] Such maneuvers possibly improve the chances of longitudinal lie by 5% to 10%, but there is no established evidence base for this proposition.

ACTIVE MANAGEMENT

Admission is often advised from 37 to 39 weeks' gestation, which provides the opportunity for (1) daily observations of fetal lie and presentation to be made, (2) active treatment to correct the lie if necessary, (3) calling for immediate assistance upon membrane rupture or the onset of labor, and (4) urgent delivery if the lie is not longitudinal, fetal distress occurs, or the cord is presenting or has prolapsed. Evidence to support this approach is provided by one small study of expectant management for unstable lie after 37 weeks' gestation that reported that 17% presented in labor with a transverse lie and 6% had a prolapsed cord resulting in neonatal death in 1%.[44] If spontaneous resolution to a longitudinal lie occurs and a cephalic or breech presentation is maintained for 48 hours, the women may be discharged home to await labor. Some currently discourage labor with a breech presentation and reference should be made to the relevant chapter on this topic (see Chapter 63). If spontaneous resolution of an abnormal lie does not occur, an active approach to management may be adopted. External cephalic version can be attempted if facilities permit immediate delivery in the event of placental abruption, membrane rupture, cord prolapse, or acute fetal distress for any reason.[49,55] Rhesus immunoprophylaxis should be given to at-risk women either before or soon after the version attempt, and an estimate of the volume of any fetomaternal hemorrhage made about 20 minutes after the attempt at version, using the Kleihauer-Betke method or flow cytometry to determine whether additional prophylaxis is necessary.[56,57] If a longitudinal lie is not maintained, the version can be repeated as often as necessary, and if unsuccessful, the women should be kept in the hospital after the birth. The success of version for unstable lie is unclear, but it is probably greater than for breech presentation, which is usually quoted around 40% to 65%.[46,48,58] Tocolysis can be used, including infusions of ritodrine 50 μg/min for 15 minutes[46] or terbutaline sulfate 250 μg intravenously over 1 to 2 minutes,[31] but is often unnecessary with a transverse or oblique lie (see Chapter 63).

In the event the lie remains unstable, a stabilizing induction may be performed usually at 38 to 39 weeks' gestation. Following transfer to the labor suite, an external cephalic version is performed if necessary to convert the fetal lie to longitudinal. Once the fetus is in position, regular abdominal palpations are performed to confirm the lie is maintained and a titrated intravenous infusion of oxytocin commenced to stimulate uterine contractility.[47] Although contractions can also be stimulated with local (vaginal) or oral prostaglandins, this is probably less advisable because the response to prostaglandins can be unpredictable and occasionally hyperstimulation occurs, which would be especially concerning if the lie reverts to oblique or transverse, when tocolysis and/or emergency cesarean section is required. As soon as contractions are occurring at 10-minute intervals or more

frequently, a low amniotomy is performed, having ensured at vaginal examination that the lie is still longitudinal, the presentation is not compound, and in particular, the cord is not presenting. If the cord presents, an emergency cesarean section is necessary. Once low amniotomy is performed, a reasonable volume of amniotic fluid should be released, followed by confirmation that the cord has not prolapsed and the presenting part is fixed in the pelvic brim. Thereafter, once labor is established, management continues as for uncomplicated cases, being ever mindful that cord prolapse might still occur.

Hindwater amniotomy using a Drew-Smythe catheter[59] can be performed providing a low posterior placenta has been excluded by an ultrasound examination. The catheter is guided through the cervix between the uterine wall and the fetal membranes behind the presenting part, taking all possible care to avoid trauma to the fetus and the uterine wall. When in position, with the catheter tip above the presenting part, the stylet in the catheter is advanced to puncture the membranes and allow a controlled release of amniotic fluid. This procedure aims to reduce the chances of cord prolapse occurring, but it is rarely used in modern practice.

Finally, a decision to deliver by elective antepartum cesarean section at 38 to 40 weeks' gestation is a legitimate management option.[44] Ideally, an attempt should be made to convert the lie to longitudinal immediately before the laparotomy or after opening the peritoneum but before incising the uterus. If successful, a lower segment incision in the uterus can be used for the delivery, but if the lie remains transverse, the classic (vertical midline) incision may be preferable to reduce the chances of fetal and uterine trauma being caused by a difficult fetal extraction from the uterus. Planned cesarean section is particularly appropriate if antenatal external cephalic version is contraindicated, previous attempts at version fail, or there is a mechanical obstruction to vaginal delivery.

Intrapartum

When the fetal lie is transverse or oblique and the membranes rupture or labor starts, the options for management are illustrated in the algorithm in Figure 64–7, which depend on (1) whether there is a cord presentation or prolapse, (2) the stage of labor whether before full cervical dilation or during the second stage, and (3) whether the membranes are intact or ruptured.

FIRST STAGE OF LABOR

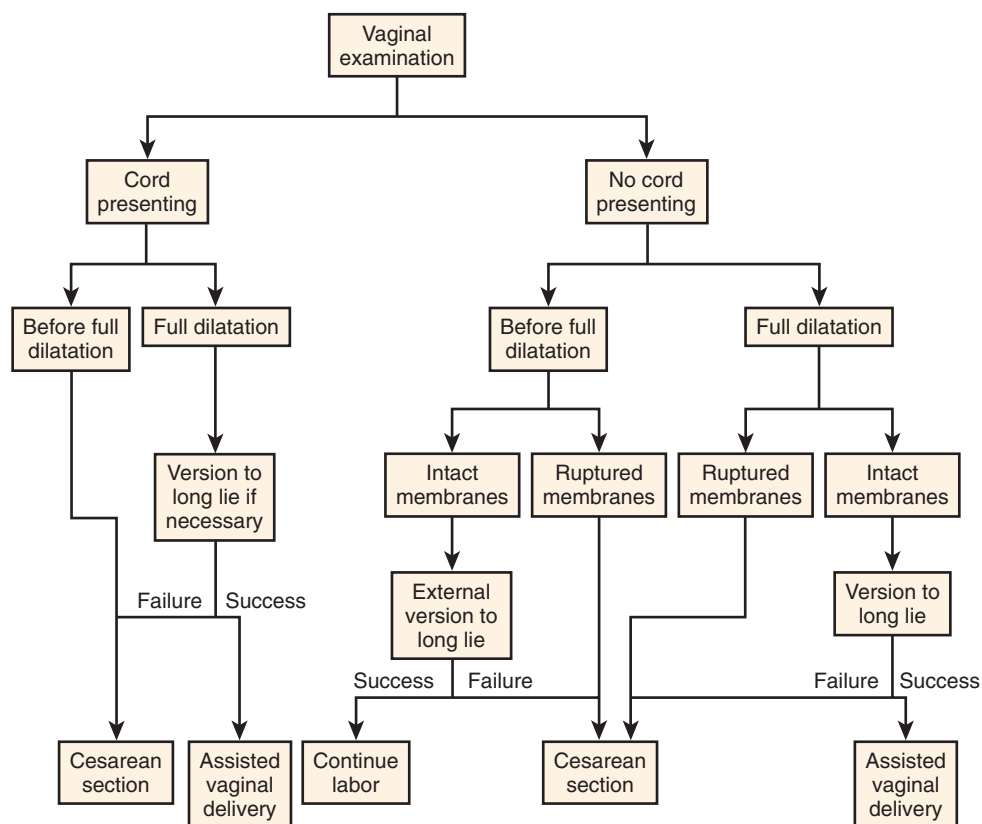
Management depends on whether the fetal membranes are intact or ruptured. With intact membranes, an external version can be attempted. This is performed between contractions with or without tocolysis to relax the uterus before the attempt. Tocolytic agents that can be used in this situation include β-agonists such as terbutaline infused at 5 to 20 μg/min, salbutamol (albuterol) 2.5 to 4.5 μg/min, ritodrine 100 to 350 μg/min,[60] or the oxytocin antagonist atosiban, given as a single intravenous bolus dose of 6.75 mg.[50] If the version is successful, a repeat vaginal examination should be performed to exclude cord presentation or prolapse. Once this has been confirmed, labor can be allowed to establish, ensuring the lie remains longitudinal until the presenting part engages in the pelvis,


FIGURE 64–7
Algorithm for the intrapartum management of unstable lie.

with progress augmented with oxytocin if necessary. If the version has been unsuccessful, delivery by cesarean section should be performed (see later discussion). With ruptured membranes, delivery by cesarean section is generally the only option unless the woman is in very early labor and an attempt at external cephalic version is successful. If there is a compound presentation involving a hand or arm, attempts should be made at vaginal examination to push the arm up or nip one of the fetal fingers to try to encourage its withdrawal from in front of the head. It is also reasonable to allow labor to continue with close supervision in anticipation that spontaneous withdrawal will occur with continuing uterine contractions causing discomfort to the arm and hand; cord prolapse is a remote but real possibility.

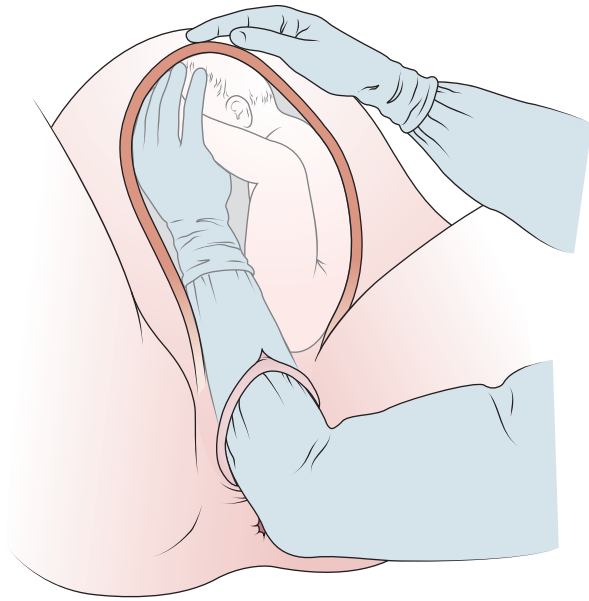
A shoulder presentation, which may include an arm prolapsed into the vagina, is a serious situation (see Fig. 64–4). Clamping of the uterine wall around the fetus by a retraction or Bandl's ring may have contributed. Delivery must be by cesarean section. Administration of a uterine relaxant such as halothane administered by the anesthetist can facilitate the delivery, which is most safely achieved through a classic uterine incision. This incision allows the fetus to be withdrawn through the fundus of the uterus, whereas a lower segment incision makes it nearly impossible to manipulate the fetus into a position that will allow delivery without damage to the fetus and uterus. This approach to delivery is still indicated even if the fetus has already died, to avoid uterine rupture and other serious uterine trauma at the time of the delivery.

SECOND STAGE OF LABOR WITH INTACT MEMBRANES

If fetopelvic disproportion has been excluded, correction to a longitudinal lie by external cephalic or internal podalic version followed by an assisted vaginal cephalic or breech delivery should be anticipated. If internal podalic version is attempted, this requires adequate anesthesia (either general or fully effective regional block). Using appropriate aseptic techniques, the obstetrician introduces a hand into the uterus, confirms the foot of the anteriorly positioned leg by identifying the heel, and applies traction on the foot, withdrawing the foot and leg and subsequently the breech through the vagina (Fig. 64–8). It is ideal if both feet can be grasped and pulled down, as this avoids the "splits," with one leg down and one leg up, which can splint the baby and lead to a difficult delivery. The management is then as described for breech extraction (see Chapter 63). Great care must be taken to avoid both fetal bony injury and laceration of the uterus. Tocolysis may be helpful for this procedure. If version is not successful, delivery should be achieved by cesarean section; attempts at version should be performed only when immediate resort to section is available. The obstetrician should be aware of the possibility of atonic primary postpartum hemorrhage when uterine relaxants have been administered to assist the delivery (see Chapter 75).

SECOND STAGE OF LABOR WITH RUPTURED MEMBRANES

If there is a compound presentation involving a hand and the fetal head is engaged in the pelvis, it may be possible with vaginal manipulation to encourage the hand to withdraw from the pelvis so that an assisted vaginal delivery can

Principle of securing the foot of the anterior leg at internal podalic version.


continue. Otherwise, cesarean section is required. If the fetus is in a transverse or oblique lie or there is a significant compound presentation, delivery should be performed as urgently as possible using a classic cesarean section incision unless an attempt at external version can be successfully made on opening the abdominal wall immediately before the uterus is incised. A transverse incision in the lower uterine segment may be inadequate for fetal extraction because the loss of amniotic fluid reduces the surgeon's ability to manipulate the fetus within the uterus. Struggling to deliver the fetus through a lower segment incision can cause serious trauma to the fetus, uterus, or both, and the uterine incision will probably need to be extended to an inverted T- or U-shaped incision. Such incision extensions may result in compromised healing and a vulnerable area of scar integrity, which may predispose to uterine rupture in future pregnancies or labors.

CORD PRESENTATION AND PROLAPSE—FIRST STAGE OF LABOR

With cord presentation, delivery by cesarean section should be organized with some urgency if fetal distress is suspected. Cord prolapse before full dilation of the cervix requires a "crash" or "category 1" cesarean section. While preparations are in hand for the surgery, an attempt should be made to reduce any pressure on the umbilical cord that could restrict or obstruct the cord circulation with consequent fetal hypoxia. A number of strategies have been used or proposed. Probably the most widely adopted involve applying digital counterpressure with the gloved fingers within the vagina or moving the patient into the Trendelenberg or knee-chest positions.[7,9] Alternatives recommended include bladder catheterization and distention,[11,61,62] administering tocolysis,[63,64] wrapping the exteriorized cord in warm saline-soaked swabs, or manually replacing the cord into the vagina.[21] Although the attempt at replacement of the cord may be successful[21] (see Chapter 69), there are concerns that its manipulation might provoke vascular spasm of the vessels and further compromise fetal oxygenation.[65]

CORD PRESENTATION AND PROLAPSE—SECOND STAGE OF LABOR (See Also Chapter 69)

Cord presentation at full dilation may be managed by external cephalic or internal podalic version if the lie is not longitudinal, and following amniotomy, proceeding to assisted vaginal delivery. Delivery by cesarean section should be arranged urgently if the expertise for version is not immediately available or the attempt is unsuccessful. If cord prolapse has occurred and the lie is not longitudinal, a crash/category 1 cesarean section is required. If the lie is longitudinal, immediate vaginal delivery using forceps for a cephalic presentation or breech extraction should be advanced if the necessary skills are available and the presenting part is low enough in the pelvis.[9] Because the ventouse is associated with a higher failure rate than forceps, forceps should perhaps be preferred if the necessary skill is available.[66–68]

If membranes are not ruptured	—/GPP	—
• For ECV or internal version* and vaginal delivery if successful.		
• If version is unsuccessful, cesarean section is necessary.		

* The use of internal podalic version should be limited to the obstetrician with experience with the technique and when fetopelvic disproportion is not suspected.
ECV, external cephalic version; GPP, good practice point.

Malpresentation

Prenatal

Once an identifiable specific cause for the malpresentation has been diagnosed if present, such as polyhydramnios, a distended urinary bladder or a pelvic ovarian cyst, treatment of the cause may be indicated. For those cases without identifiable cause, there are no recognized and universally accepted procedures to use for correcting a fetal brow or face presentation. In view of the increased risk of cord presentation and thus cord prolapse with brow presentation, the woman should be advised of early admission when labor starts or membrane rupture occurs.

As with unstable lie, admission from 39 weeks' gestation should be considered for this reason, although there is little objective evidence to support this recommendation. If delivery at this gestation is indicated for other reasons, planned cesarean section without recourse to labor may be safer than inducing labor if there is a high presenting fetal part. The alternative is labor induction with either local prostaglandins or intravenous oxytocin, with low amniotomy once contractions are established and the fetal head is engaged or fixed in the pelvic brim. Preparation should have been made to allow for rapid cesarean section should cord presentation or prolapse be diagnosed, with the woman forewarned of this possibility.

Intrapartum

Labor management is the same as for a vertex presentation, assuming routine maternal and fetal observations are satisfactory and progress in labor is maintained. Many brow presentations convert to a face or vertex, and the majority of face presentations present as mentoanterior. Oxytocin augmentation is acceptable if uterine contractions are inadequate, but caution should always be shown because labor may become obstructed with dire consequences if left unattended. If progress in labor is slow, resort to cesarean section may be a wiser option. Figure 64–9 illustrates the management options.

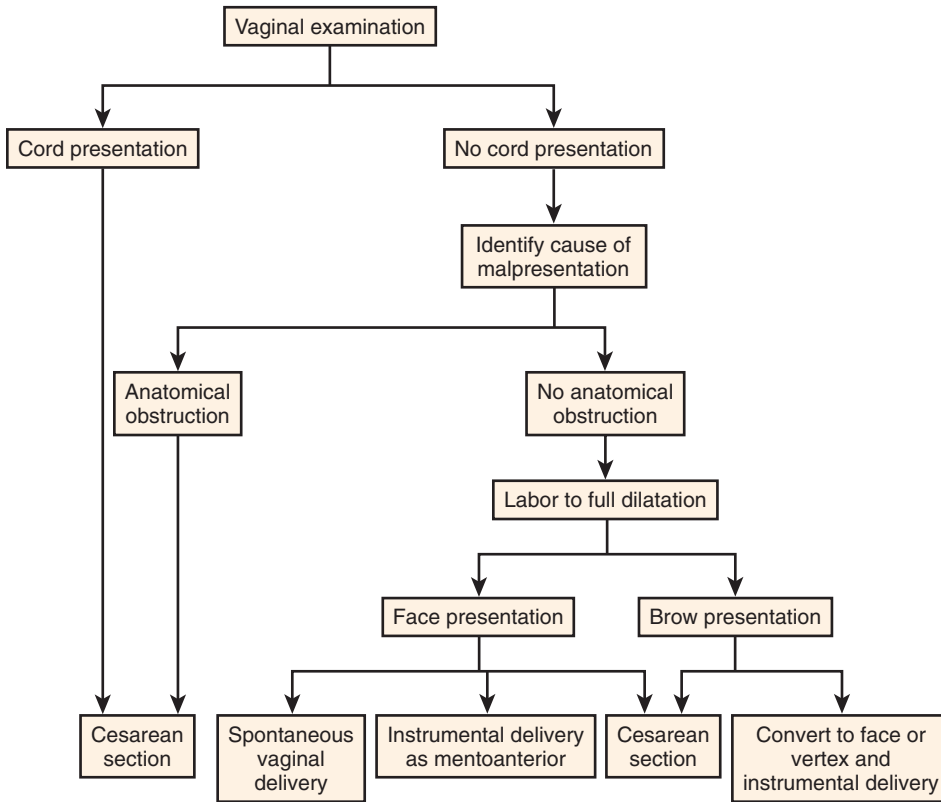
Once full dilation is reached with a brow presentation, spontaneous delivery will not follow unless the fetus is very small or the pelvis is unusually capacious. Providing the assessment of the pelvis indicates that there is no evidence of absolute disproportion, the presentation can be converted with rotational forceps to face or vertex, whichever proves to be the easier, and then delivered. Some have advised the use of the ventouse in this situation, but this requires the cup


FIGURE 64–9
Algorithm for the intrapartum management of face and brow malpresentation.

to be applied behind the bregma and this is unlikely to be possible in the majority of cases (see Chapter 72). The majority view is that unless the head is engaged in the pelvis at the start of vaginal manipulations, delivery by cesarean section is recommended.

With a face presentation, vaginal delivery should be anticipated if the head is engaged, with the delivery occurring spontaneously or assisted with forceps. The head should be in a mentoanterior position at the delivery, corrected by forceps rotation if necessary (see Chapter 72). The ventouse has no place in the management of a face presentation. Thus, cesarean section may be necessary if the obstetrician does not have the necessary skills to conduct a rotational forceps delivery.

GPP, good practice point.

Malposition

Prenatal

There is probably little benefit from trying to alter an occipitoposterior position diagnosed during the antenatal period because the majority of cases correct themselves before or after labor starts. There may be some virtue in advising the woman that (1) her membranes may rupture prior to the onset of contractions, (2) labor may be more uncomfortable and possibly more prolonged, and (3) there is a greater chance of requiring an instrumental delivery or cesarean section, compared with an occipitoanterior position. Some women say that they find difficult labor easier to cope with if forewarned and they may be more inclined to choose a regional anesthetic early in labor. Conversely, many occipitoposterior positions will spontaneously correct to occipitoanterior during labor, in which case anxiety will have been generated to no purpose, but it may increase the likelihood of a maternal request for delivery by antepartum cesarean section. Some have suggested the patient adopts a variety of positions to encourage rotation of the fetus. An analysis of the literature, concentrating on the use of the maternal hands-knees position during the antenatal and intrapartum periods, concluded that this position compared with others resulted in a short-term reversion to an anterior position.

There is no indication that this strategy improves labor outcome, however.[69]

Intrapartum

When the diagnosis of malposition is made early in labor, as much information as possible should be gathered about the fetal position, including (1) the amount of head palpable *per abdomen*, (2) the degree of deflexion and asynclitism, (3) the amount of molding and caput formation, (4) the level of the presenting part in relation to the ischial spines, and (5) maternal pelvis size and shape. Issues relating to fetal well-being including fetal heart rate pattern and the state of the liquor should also be taken into account, as with all labors.

Options at this point are as illustrated in the algorithm (Fig. 64–10) and include

- No specific action if acceptable progress is being made.
- Providing oxytocin augmentation if uterine contractions are incoordinate, infrequent, or of poor quality.
- Encouraging the patient to lie on the same side as the fetal back.[70]
- Abandoning labor in favor of cesarean section.

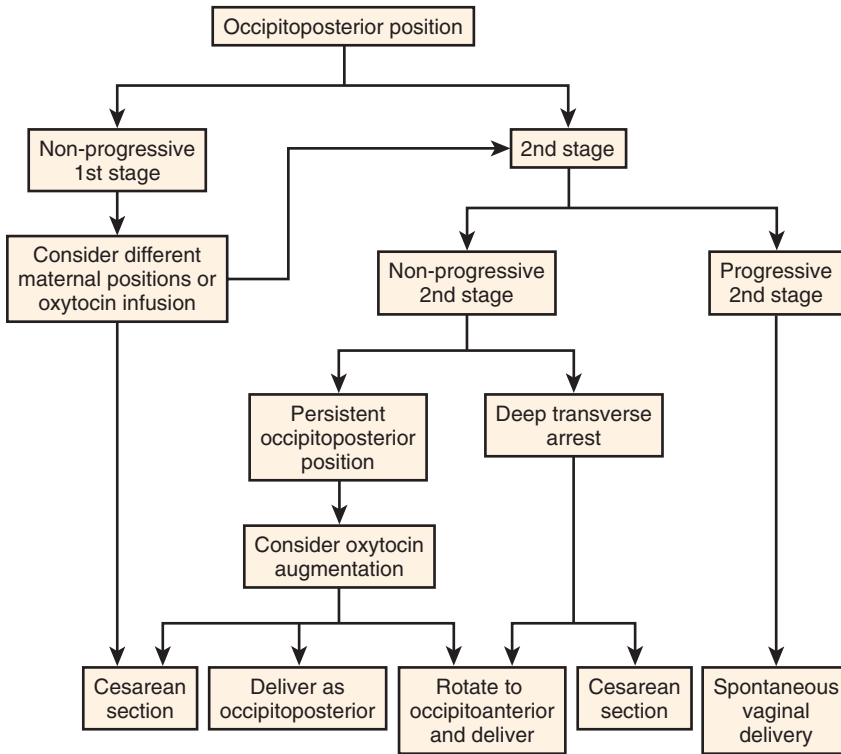
Once the second stage of labor has been reached, spontaneous delivery in the occipitoposterior position may result, or spontaneous rotation may still occur with delivery


FIGURE 64–10
Algorithm for the intrapartum management of malposition of the fetal head.

occipitoanterior. Alternatively, delivery may be delayed by a persistence of the occipitoposterior position or incomplete rotation to a deep transverse arrest. It has been suggested that mechanical rotation to the occipitoanterior position followed by delivery should be avoided if fetal distress is suspected when delivery by cesarean section is favored. The decision on management at this stage should logically be determined by assessing which method of delivery is most likely to result in an earlier and less traumatic birth.

Prolonged Pregnancy

IMELDA BALCHIN and PHILIP J. STEER

INTRODUCTION

Prolonged pregnancies are associated with an increased risk of perinatal mortality and morbidity compared with pregnancies ending at term.[1–4] Consequently, induction of labor in order to prevent the complications of prolonged pregnancy is one of the commonest interventions in pregnancy, with up to 29% of pregnant women undergoing this procedure.[5] It is, therefore, important to clarify the upper limit of a normal human gestation, so as to determine when an intervention is justified. We immediately encounter the problem of defining "normal." For example, a pregnancy may be considered statistically prolonged if the gestation falls in the top 5% of the distribution of gestational lengths for a given population. Conversely, a pregnancy is considered prolonged from a clinical management point of view when the risk of continuing the pregnancy to the fetus is higher than its risk after birth. On a population basis, we therefore need to discover when in the statistical distribution of gestational age the increasing risks of postmaturity justify induction, which is not in itself risk-free. Moreover, because individual fetuses mature at different rates, we need to look for factors in each individual pregnancy that can be used to modulate the average risk. One hypothesis for the increased risk of perinatal mortality in a clinically prolonged pregnancy is "placental insufficiency," in which the aging placenta is no longer able to keep pace with the demands of the growing fetus, resulting in either fetal malnutrition or asphyxia, or both.[6,7] Assessment of fetal growth and well-being can, therefore, be used to modify in each individual pregnancy the precise gestation at which postmaturity is judged to be a risk justifying induction.

DEFINITION

The current World Health Organization (WHO) definitions for preterm, term, and post-term took effect in 1977, sanctioned by the International Federation of Gynecology and Obstetrics (FIGO).[8] A baby is born at "term" if the delivery occurred at or between 37 completed weeks and 41 weeks + 6 days from the first day of the last menstrual period (LMP). From 42 completed weeks, or 294 days, from the LMP onward, a pregnancy is designated prolonged, or "post-term." It is important to make sure that the expression "post-term" is used correctly in this way, and not used to mean "after the due date" (which is better described using the American terminology of "postdates"). The WHO definition was based on the statistical distribution of the timing of delivery from the LMP (i.e., it was a statistical definition, and not based on any clinical considerations). According to this definition, preterm birth occurs in approximately 4% to 15% of all births in the developed world, with an average rate of 10%.[9,10] Similarly, the incidence of post-term birth ranges from 4% to 15% with an average rate of 10%.[11,12] Therefore, "term" is simply the length of time from the LMP during which approximately 80% of births occur. The definition "preterm" is not synonymous with "prematurity," and likewise, "post-term" is not synonymous with "postmaturity." Prematurity and postmaturity describe how the baby functions, and not its gestational age. Some babies are mature at 36 weeks (and, therefore, function normally after birth at this gestation), whereas some babies still suffer from the problems of prematurity (in particular, respiratory distress syndrome) at 38 or even 39 weeks' gestation. It is important to remember that a baby born at 38 weeks may have been physiologically programed to deliver at 42 weeks and, therefore, be 4 weeks "premature," and vice versa. A few babies will show the manifestations of postmaturity even when born at 40 weeks.

THE NORMAL LENGTH OF GESTATION

A gestation period begins at the time of conception and ends at birth. In humans, the gestational length is calculated from the LMP, instead of the day of conception, because it is not usually possible to ascertain the exact timing of natural conceptions. For almost 2 centuries, it has been the convention to use Franz Carl Naegele's method for estimating the date of birth, based on the assumptions that the gestation period is 266 days, and that ovulation occurs on day 14 of a 28-day menstrual cycle.[13,14] Hence, the estimated date of delivery (EDD) is calculated as 280 days from the first day of the LMP. However, dating a pregnancy using the LMP alone is unreliable.[15,16] Even in women who are certain of their menstrual dates, estimating the date of delivery using the LMP alone gives a prediction error (1 standard deviation) of 9 to 11 days.[17] This is probably due to errors in recall, the tendency to digit preference when recalling dates, and falsely

identifying nonmenstrual bleeding as a menstrual period[18,19] (in addition to the natural variation in gestational length from one pregnancy to another because of the different rates at which individual babies mature). In addition, the timing of ovulation is erratic and varies from one cycle to another, even in women with regular menses.

ETIOLOGY OF PROLONGED PREGNANCY

Studies of pregnancies ending in spontaneous labor show that the average gestational length varies in different populations, and within populations, it varies according to maternal racial origin.[20–23] This is perhaps because gestational length is determined by maternal genetic factors, in combination with a small contribution from paternal genes in the fetus,[24] and these factors, being genetic, are inherited. The recurrence rate of prolonged pregnancy in one Danish birth cohort was 20%, and this risk increased with increasing gestation of the index pregnancy, but reduced to 15% with a change of partner.[25] It should be noted that this increased rate is only moderately above the background level, and therefore, even after a previous prolonged pregnancy, the majority of births will not be post-term.

In addition, the observed variation in gestational length may indicate a variation in the rate of fetal maturity. The trigger for the onset of labor in humans is still unknown. Because approximately 90% of labors occur after 36 completed weeks of gestation, fetal maturity is probably involved in initiating the timing of labor. In support of this, it has been shown that in a human fetus with anencephaly, where there is little or no brain development, and without excessive amniotic fluid volume, there is a tendency for the pregnancy to be prolonged.[26] It is thought that at fetal maturity, the fetal hypothalamus and the placenta increase their secretion of corticotropin-releasing hormone, stimulating the production of adrenocorticotrophic hormone by the fetal pituitary gland and cortisol production by the fetal adrenal glands, and leading to the increased production of dehydroepiandrosterone (DHEA). Cortisol and DHEA in turn activate the increase in estrogen and prostaglandins that stimulate labor.[27]

In North West London, allowing for potential confounding factors, the average gestational length for singleton pregnancies was 39 weeks for South Asians (women who self-reported as originating from India, Pakistan, Bangladesh) and blacks (black British, black Africans, and black Caribbeans), and 40 weeks for whites (all white European groups, previously commonly called "Caucasian," although a minority of white Europeans actually come from the Caucasus).[20] In Norway, the average pregnancy length is 282 days.[28] It has been shown that South Asian or black populations have higher rates of preterm birth. However, the risk of neonatal respiratory distress syndrome in these racial groups is significantly lower than in white babies of similar gestational age.[29] From 37 weeks' gestation onward, the faster rate of fetal gut maturity results in higher rates of meconium passage in utero in black and South Asian fetuses than those in whites. Consequently, the late gestation incidence of respiratory morbidity and perinatal mortality in these racial groups is also higher than that in whites. Finally, in full-term South Asian fetuses, the late gestation rise in antepartum stillbirth, possibly due to placental insufficiency

associated with postmaturity, begins to rise 1 week earlier than in white babies.[30] These patterns remained significant even after adjusting for socioeconomic factors and suggest that the shorter gestational length in South Asian and black populations is associated with an accelerated fetal maturity compared with that white populations.[31]

In addition to genetic predisposition, maternal obesity is also an independent predictor of post-term pregnancy. It is well established that women with a low prepregnancy body mass index (BMI), less than 20 kg/m², have a higher risk of preterm birth. In contrast, the risk of post-term pregnancy increases with increasing prepregnancy BMI. In women with a prepregnancy BMI of 25 to 29 kg/m², the adjusted risk of post-term pregnancy is approximately 24% higher than women of normal BMI. This risk is increased to 37% in women with BMI of 30 to 34, and 52% if BMI was 35 kg/m² or more.[32,33] Other risk factors for post-term pregnancy include nulliparity and placental sulfatase deficiency.

RISKS

Fetal and Neonatal Risks

Antepartum Stillbirth

Continued pregnancy after 40 weeks' gestation is associated with a significant increase in the risk of perinatal mortality, and about 60% of these deaths occur before the onset of labor (antepartum stillbirths).[30] Evidence using survival analysis (i.e., using a denominator of continuing live pregnancies instead of babies delivering at a particular gestation) and maternity data collected in 1958 in the United Kingdom showed that the rate of stillbirth increased from 0.4 per 1000 continuing pregnancies at 37 weeks' gestation to 1 in 1000 at 42 weeks, to 2.1 per 1000 at 43 weeks.[34] Similar figures have been reported from many countries, for example, Australia (Fig. 65–1).

A more recent U.K. study carried out a survival analysis of North West London maternity data from 1988 to 2000 and showed that the risk of antepartum stillbirth in white babies was 0.28 per 1000 continuing pregnancies at 37 weeks (95% confidence interval [CI] 0.22–0.34), 0.67 (95% CI 0.54–0.81) at 40 weeks, 1.12 (95% CI 0.83–1.39) at 41 weeks, and 1.54 (95% CI 0.79–2.30) at 42 weeks' gestation.[30] This demonstrated that in contemporary U.K. obstetric practice, the rate of antepartum stillbirth is significantly higher at 41 weeks than at 40 weeks; gestation (although the difference in mortality at 41 and 42 weeks' gestation was not statistically significant). The rate of antepartum stillbirth in South Asian babies in North West London was statistically significantly higher than in white babies, with a rate of 1.95 (95% CI 1.30–2.60) at 40 weeks and 3.21 (95% CI 1.81–4.62) at 41 weeks' gestation (Fig. 65–2). The most significant factor associated with antepartum stillbirth at term and post-term in South Asian babies was a birth weight less than 2000 g (clearly representing serious intrauterine growth restriction).

A higher antepartum stillbirth rate was also seen in black babies when compared with white babies with a rate of 1.39 (95% CI 0.63–2.14) at 40 weeks and 1.96 (95% CI 0.51–3.40) at 41 weeks' gestation, although the difference between the two groups was not statistically significant, perhaps due to lack of statistical power. More data are required to confirm

this suggestion of a higher antepartum stillbirth rate in black babies.

Placental dysfunction, or placental insufficiency, is thought to be the etiology of perinatal mortality and morbidity in prolonged pregnancies. Histologic studies of the post-term placenta show an increased incidence of infarcts, calcification, intervillous thrombosis, perivillous fibrin deposits, arterial thrombosis, and arterial endarteritis.[6,7] Placental insufficiency is associated with intrauterine growth restriction and a reduction in the amniotic fluid volume (oligohydramnios).[35] Oligohydramnios in turn may lead to umbilical cord compression and "fetal distress."[36,37] At 40 or more weeks' gestation, oligohydramnios defined by an amniotic fluid index (AFI) of less than 5 cm is found in about 8% of pregnancies. This is significantly associated with meconium aspiration, birth asphyxia, cesarean section for fetal distress in labor, cord pH less than 7 at delivery, and low Apgar scores.[38]

Long-term Developmental Outcome

In a follow-up of 129 post-term children up to the age of 2 years, there were no difference in developmental outcome compared with that in children born at term.[39] However, another study based on a cohort of babies identified through the Swedish national birth registry followed 354 post-term babies and 379 controls up to school age and showed that post-term children had more definite or strongly suspected neurologic developmental disorders than the controls, with an adjusted odds ratio (OR) of 2.20 (95% CI 1.29–3.85), and boys had more deviations than girls (OR 1.92; 95% CI 1.11–3.45).[40] One suspects on clinical grounds that the long-term outcome will depend very much on the appropriateness of the intrapartum management of post-term babies.

Maternal Risks and Attitudes toward Prolonged Pregnancy

The main risk to the pregnant woman is not from prolonged pregnancy itself, but from the anxiety associated with prolonged pregnancy and the consequences of interventions to prevent prolonged pregnancy.

A Cochrane systematic review concluded that intervention with routine induction of labor at 41 or more weeks' gestation reduces perinatal mortality without increasing the overall risk of cesarean section or operative delivery to the mother.[41] However, it should be taken into account that the risk of cesarean section depends upon organizational factors governing the management of labor in maternity hospitals. These factors include policies concerning active management of labor, one-to-one midwifery care, the presence of a member of the family or other companion during labor, the timing of routine vaginal examinations, the training of obstetricians and midwives in electronic fetal monitoring, and the number and seniority of the midwives and obstetricians attending the labor ward. Thus, in a well-staffed maternity unit with a midwife well trained in the interpretation of fetal heart rate traces and dedicated to the care of a single woman in labor, induction of labor may increase the chance of a vaginal delivery. On the contrary, induction of labor in an understaffed maternity unit is an unwelcome burden and is likely to carry additional risks.

It has been shown that undelivered women at 41 weeks' gestation have a significantly higher anxiety score than women who have already given birth.[42] Most women prefer to be induced at 41 weeks and report positive experiences of labor induction when compared with expectant management.[43] This is despite reports of experiencing more intense and more frequent contractions than those in women who had spontaneous onset of labor. A Norwegian study has shown that 74% of women who underwent induction of labor preferred this management in a subsequent pregnancy compared with only 38% of women who had expectant management with serial monitoring.[44] Furthermore, the percentage of women with a positive attitude toward expectant management decreases with advancing gestation.[44,45]

The average rate of cesarean section in women induced for prolonged pregnancy is about 20%. However, the cesarean section rate in nulliparous women induced for prolonged pregnancy is significantly higher than in multiparous women (28% vs. 9%).[46] In addition, pre-induction cervical length can be used to predict the use of cesarean section. The use of ultrasonography to measure cervical length is a better predictor of cesarean section than using the Bishop score or measuring cervical length by vaginal examination. The risk of cesarean section is higher in nulliparous women with the same cervical length as multiparous women. For example, in a nulliparous women with a sonographic cervical length of more than 30 mm, the risk of cesarean section following induction of labor for prolonged pregnancy is greater than 70%.[47]

For antenatal fetal monitoring, counting of fetal movements by the pregnant woman in prolonged pregnancy does not decrease the risk of stillbirth.[48] Ultrasonographic screening for oligohydramnios using the AFI is superior than measuring a single deepest pool.[49] However, the sensitivity of oligohydramnios in predicting adverse outcomes is low (i.e., only ~12% for predicting a cord pH < 7.00 at delivery). Thus, routine screening for oligohydramnios increased the likelihood of intervention without improving perinatal outcomes.[49]

Observational studies suggest that cardiotocography and Doppler assessment of fetal and uteroplacental arteries are unlikely to predict fetal outcome reliably. A randomized trial of cardiotocography and measurement of the AFI compared with induction of labor suggested that the rates of cesarean section and meconium below the vocal cords were increased in pregnancies beyond 42 weeks' gestation.[50] Another randomized trial compared a modified biophysical profile score with cardiotocography combined with maximum depth of the amniotic fluid and found that there were more abnormal results in the women randomized to measurement of the biophysical profile score, but with no apparent benefit to the infant.[51]

MANAGEMENT OPTIONS

Prenatal—Early Pregnancy

Dating methods using ultrasonography of the fetal size before 20 weeks' gestation has reduced the percentage of pregnancies classified as "post-term" by up to 74% compared with dating based on LMP only.[16,17,52–54] The effect of routine early pregnancy ultrasound scan includes the reduced incidence of induction of labor for apparent "post-term" pregnancy and the increased incidence of termination of pregnancy owing to the increased detection of fetal abnormalities.[55–57] However, there is no evidence of a reduction in perinatal deaths. Some authors have used routine fetal ultrasonography alone to date pregnancies.[58] However, this would be valid only if there was no variation in fetal growth in early pregnancy and if all pregnant women were booked for antenatal care before 24 weeks' gestation. In reality, variation in fetal growth has been shown to occur from early pregnancy in women with known dates of conception.[59] In pregnant women who book late for antenatal care, ultrasound dating becomes less unreliable beyond 24 weeks, owing to the increased variation in the fetal growth rate.[60] In the United Kingdom, the National Institute of Health and Clinical Excellence (NICE) has recommended that all pregnant women should be offered an early ultrasound scan between 10 weeks + 0 days and 13 weeks + 6 days to assist in the determination of gestational age and to detect multiple pregnancies.[61] The key measurement is crown-rump length, but if this is above 84 mm, head circumference measurement should be used instead.

Prenatal—At Term

Owing to medicolegal and ethical concerns, the current practice in the United Kingdom is to offer induction of labor in all uncomplicated pregnancies at 41 or more weeks' gestation, as recommended by NICE.[62] The guideline recognizes that there are important racial differences and that, therefore, the recommended policy of induction to prevent prolonged pregnancy at 41 to 42 weeks' gestation may not be appropriate for all women (see p. 24). Moreover, the absolute increase in perinatal mortality rate after 41 weeks is very small, and therefore, expectant management with serial antenatal fetal monitoring is an appropriate management policy. The NICE antenatal care guideline recommends that before pharmacologic or surgical methods of induction are used, a "membrane sweep" should be offered. This policy remains controversial. An early study by Allott and Palmer[63] reported that inserting a finger through the cervix and "sweeping the membranes" reduced the need for induction of labor from 18.8% in the control group to 8.1% in the swept group. However, a subsequent paper by Foong and coworkers[64] reported that the beneficial effects on labor and delivery (shorter labors and fewer cesarean sections) were limited to nulliparas with unfavorable cervices who needed priming with prostaglandin E_2. A Cochrane review in 2005 found that routine use of sweeping of membranes from 38 weeks of pregnancy onward does not seem to produce clinically important benefits.[65] The authors commented that when used as a means for induction of labor, the reduction in the use of more formal methods of induction needs to be balanced against women's discomfort and other adverse effects. Moreover, a study published in 2008 reported a randomized trial of 300 women who were randomly assigned into sweep or no-sweep groups and found no effect on the average gestational age at delivery or the need for induction.[66] They found that the incidence of prelabor rupture of membranes was significantly higher if the cervix was more than 1 cm dilated at the time of membrane sweep. This might increase the risk of intrapartum infection, particularly in carriers of

group B streptococcus. In the experience of the authors, many women find the procedure extremely unpleasant, often indeed painful, and we therefore suggest that the procedure be used only in women who are particularly keen to avoid artificial rupture of membranes or the use of prostaglandins/ intravenous oxytocin.

Studies have not shown a significant difference in maternal or neonatal morbidity between alternatively serial antenatal fetal monitoring or induction of labor after 41 weeks' gestation.[50] However, the evidence for the efficacy of antenatal fetal monitoring is poor, and there are no randomized trials of sufficient size to assess the possibility of a type 2 error (that we are missing a real difference). If women decline induction, there is no evidence that complex monitoring (e.g., using biophysical profiles) is of any benefit to compare it with more simple surveillance using ultrasound estimation of the maximum amniotic pool depth and cardiotocography (preferably daily and least twice weekly).[51] The decision to choose either induction of labor or expectant management is, therefore, dependent on the resources available in each maternity unit and the individual woman's wishes.

Intrapartum Care

It is generally recognized that there is an increased risk of meconium aspiration and umbilical cord compression in post-term labors. The details of fetal monitoring for these conditions are covered in Chapter 69. However, NICE recommends that both induction of labor and post-term labor are indications for continuous electronic monitoring.[67]

SUMMARY OF MANAGEMENT OPTIONS
Prolonged Pregnancy

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Establish gestational age as soon as possible, preferably 10–14 wk gestation.	Ia/A	15–18
Sweeping membranes at term increases the incidence of spontaneous labor but has risks, may not be clinically important, and women often dislike it.	Ia/A	62–66
41 Weeks		
Induction of labor at 41 wk reduces perinatal mortality without increasing adverse outcomes.	Ia/A	41
Expectant management:	GPP	51
• Monitoring with measurement of amniotic fluid volume, estimated fetal weight, and CTG recommended at least twice weekly.		
Labor and delivery: vigilance for fetal hypoxia and meconium staining of the amniotic fluid.	GPP	

CTG, cardiotocography; GPP, good practice point.

Induction of Labor and Termination of the Previable Pregnancy

LUIS SANCHEZ-RAMOS and ISAAC DELKE

INDUCTION OF LABOR

Definition

Labor induction is the stimulation of regular uterine contractions before the spontaneous onset of labor, using mechanical or pharmacologic methods in order to generate progressive cervical dilation and subsequent delivery. Although the term generally refers to patients who are at term, it is also employed for women who are at least 20 weeks' gestation. It is important to distinguish labor induction from *augmentation*, which refers to stimulation of uterine contractions when spontaneous contractions during labor have been considered inadequate.

Introduction

Induction of labor is an important and common clinical procedure in obstetrics. The rate of labor induction in the United States continues to rise significantly for all gestational ages. Data for the year 2006 from the National Center for Health Statistics indicated that the rate was 22.5% for that year, a slight increase over 2005, and double the rate for 1990.[1] The reason for this increase is unclear, although it may partly reflect a growing use of labor induction for postdate pregnancies and an increasing trend toward elective induction of labor for other indications (including maternal request).

Indications and Contraindications

Generally, labor induction is indicated when the benefits of delivery to the mother or fetus outweigh the potential risks of continuing the pregnancy. The most appropriate timing for labor induction is the point at which the maternal or perinatal benefits are greater if the pregnancy is interrupted than if the pregnancy is continued. Ideally, most pregnancies should be allowed to reach term, with the onset of spontaneous labor being the sign of physiologic termination of pregnancy. However, occasionally a woman is best delivered before the spontaneous onset of labor. Commonly accepted indications for labor induction are listed in Table 66–1. Of the standard indications for labor induction, pregnancy-induced hypertension and postdate pregnancies are among the most common, accounting for more than 80% of reported inductions (see Chapters 35 and 65). Given that there is an indication for induction, the risks to mother and fetus must then be considered, to make sure that the benefit outweighs these risks. The risks to the mother are mainly related to an increased chance that she will need operative delivery, rather than labor following the spontaneous onset of labor. The risks to the fetus are those of prematurity. Whenever there is evidence of fetal lung maturity (although it is important to remember that a mature lecithin-to-sphigomyelin ratio is not a guarantee of normal respiratory function after birth) or the pregnancy has reached at least 39 weeks (confirmed by an early ultrasound), the decision to induce labor is not so difficult. Maternal consent to any increased risk of operative delivery (e.g., with an unfavorable cervix) should be obtained, and although the fetus is not likely to be at risk for complications that cannot be dealt with in a modern neonatal unit, the very small risk of permanent sequelae such as pulmonary hypertension following persistence of fetal circulation should be mentioned because it has long-term significance, and moreover, an admission to a neonatal unit is worrying for the parents. Induction of labor from 39 weeks at maternal request (usually owing to intolerance of the discomforts of pregnancy, but sometimes for social reasons, e.g., the limited availability of the father to attend the birth or logistic factors such as distance from the hospital or a history of rapid labor and delivery) remains controversial. It should not be encouraged, but the risk/benefit ratio can be assessed on a case-by-case basis, and many obstetricians feel that it is sometimes justified. Whether induction of labor to suit the obstetrician's schedule is ethical makes for an interesting discussion.

However, the decision to induce labor prior to fetal maturity having been achieved is far more difficult. In such cases, premature delivery should offer the fetus clear benefits that outweigh the potential problems associated with preterm birth. Generally recognized relative and absolute contraindications to labor induction are listed in Table 66–2. There are few absolute contraindications to labor induction, and there can be certain clinical situations in which induction is usually contraindicated but exceptional circumstances make

Prelabor rupture of membranes
Chorioamnionitis
Severe intrauterine growth restriction
Isoimmunization
Maternal medical problems (diabetes mellitus, renal disease, lupus)
Fetal demise
Postdates pregnancy
Oligohydramnios
Logistic factors (risk of rapid labor, distance from hospital)

TABLE 66–2
Contraindications to Labor Induction

Placenta or vasa previa
Transverse fetal lie
Prolapsed umbilical cord
Prior classic uterine incision
Active genital herpes infection
Pelvic structural deformities

TABLE 66–3
Criteria for Fetal Maturity

Fetal heart tones have been documented for 20 wk by nonelectronic fetoscope or for 30 wk by Doppler.
It has been 36 wk since a positive serum or urine human chorionic gonadotropin pregnancy test was performed by a reliable method.
An ultrasound measurement of the crown-rump length, obtained at 6–11 wk, supports a gestational age of 39 wk or more.
An ultrasound scan, obtained at 12–20 wk, confirms the gestational age of 39 wk or more determined by clinical history and physical examination.

---

induction appropriate (e.g., prolapsed umbilical cord in the presence of fetal demise). A number of clinical situations that are not generally considered contraindications to labor induction but require caution include breech presentation, borderline clinical pelvimetry, grand multiparity, non-reassuring fetal testing not requiring emergency delivery, polyhydramnios, and multifetal gestation.

Requirements for Labor Induction

Prior to inducing labor, the obstetrician should carefully review the indication(s) for ending the pregnancy and obtain informed consent. In addition, the mother and fetus should be carefully examined and, if indicated, fetal pulmonary maturity should be documented. In order to avoid iatrogenic prematurity, an amniocentesis may be required to assess fetal lung maturity. Table 66–3 lists criteria, which, if met, allow fetal maturity to be assumed, so that amniocentesis need not be performed.[2] It is worthy of note that, although testing for pulmonary maturity is widely practiced in the United States, in many other countries, including the United Kingdom, the decision whether to induce labor is based on other criteria (such as evidence of actual or incipient fetal or maternal compromise) and pulmonary maturity is not considered to be an important factor (management of respiratory distress syndrome being very efficient in modern neonatal units); accordingly, amniocentesis is rarely performed.

Preinduction Status of the Cervix

Successful labor induction is clearly related to the state of the cervix. Women with an unfavorable cervix, who have not experienced a cervical-ripening phase prior to labor, present the greatest challenge with regard to labor induction. In addition, the duration of labor induction is affected by parity and to a minor degree by baseline uterine activity

and sensitivity to oxytocic drugs. Many investigators have identified the importance of assessing cervical status prior to induction of labor. Calkins and colleagues[3] were the first to carry out systematic studies of the factors influencing the duration of the first stage of labor. The authors concluded that the length, thickness, and particularly, the consistency of the cervix are important parameters. In 1955, Bishop[4] devised a cervical scoring system for multiparous patients with planned elective induction of labor in which 0 to 3 points are given for each of five factors. He determined that when the total score was at least 9, the likelihood of vaginal delivery following labor induction was similar to that observed in patients with spontaneous onset of labor. Although several modifications have been suggested, the Bishop score has become a classic parameter in obstetrics and has since been applied to a much wider group of patients. Nulliparous women with a Bishop score no greater than 3 have a 23-fold increased risk of induction failure and a 2- to 4-fold increased risk of cesarean delivery compared with nulliparous women with a Bishop score of at least 4.[5] Similarly, multiparous women with a Bishop score of no greater than 3 have a 6-fold increased risk of failed induction and a 2-fold increased risk of cesarean birth compared with women with higher Bishop scores.[5,6]

The Bishop score has become the most commonly employed preinduction scoring system. Several studies have assessed the predictive accuracy of ultrasound cervical measurement for successful labor induction.[7–9] However, there is a lack of convincing evidence that this technique provides significant additional information when compared with digital examination. A recently published systematic review with meta-analysis of 20 diagnostic studies and 3101 aggregate particpants concluded that sonographic cervical length was not an effective predictor of successful labor induction.[10] However, the assessment of cervical wedging appears to be a useful diagnostic test, but needs further evaluation.[10]

Preinduction Cervical Ripening

Cervical ripening is the process that culminates in the softening and distensibility of the cervix, thus facilitating labor and delivery. There is an inverse relationship between the Bishop score and the failure of labor induction, with low scores being associated with a high rate of failed induction. Moreover, not only is inducing uterine contractions in the presence of an unripe cervix more likely to lead to delivery by cesarean section, but even if vaginal delivery is eventually achieved, the labor will often have been prolonged. This is

TABLE 66–4

a particular problem if the induction is for fetal indications, because then prolonged fetal monitoring is also required. In addition, an extended exposure to uterine contractions and the resulting reduction in intervillous blood flow can result in fetal hypoxia and acidosis. Thus, it is useful to employ cervical-ripening agents to prepare the unripe cervix for labor induction. Ideally, a ripening agent would act upon the cervix to make it more favorable without inducing uterine activity; the length of the active phase of labor would thereby be minimized, limiting the stress on the fetus to the minimum. Unfortunately, it has proved difficult to separate methods of cervical ripening and labor induction. Patients with an unripe cervix may undergo cervical ripening without initiating labor contractions when a pharmacologic agent such as dinoprostone (prostaglandin E_2 [PGE_2]) is employed, but sometimes, contractions ensue before the cervix has ripened. A considerable amount of research has been directed toward various methods to prepare or ripen the cervix prior to the induction of labor. Although many of these methods also initiate uterine activity, it should be appreciated that the principal role of these agents is to soften the unripe cervix independently of uterine activity. The various methods for cervical ripening can be divided into two categories (Table 66–4):

- Mechanical.
- Pharmacologic.

Mechanical Methods

FOLEY CATHETER

Mechanical methods have been employed for many years to ripen the cervix prior to labor induction.[11] Barnes, in the mid-19th century, was one of the first to describe the use of a balloon catheter to ripen the uterine cervix.[12] Since that time, several variations of this method have been popularized. The balloon catheter currently most frequently used is a Foley catheter with a 25- to 50-mL balloon, which can be passed through an undilated cervix before inflation of the balloon above the internal os. It is thought that the mechanical separation of the fetal membranes from the cervix and lower segment stimulates local cytokine and prostaglandin (PG) release, and these act upon the ground substance of the cervix to break down the cross-links between the glycosaminoglycans. More recently, extra-amniotic saline

infusion has been a successful modification to the use of balloon catheters for cervical ripening, presumably by enhancing this effect.[13–15] A review of 13 trials in which balloon catheters were used for cervical ripening concluded that with or without extra-amniotic saline infusion, the method resulted in improved Bishop scores and decreased induction-to-delivery intervals.[16] Simultaneous use of balloon-tipped catheters and pharmacologic agents has been shown to be even more effective for cervical ripening than for labor induction; however, the cost of such combination therapy is substantial.

Several reports observed an increased risk of intrapartum chorioamnionitis, but none of the reports individually had adequate sample size to demonstrate a statistically significant difference. A recently published systematic review with meta-analysis of 30 randomized, controlled trials comparing cervical ripening with mechanical methods with alternative pharmacologic agents or placebo demonstrated that maternal and neonatal infections were increased in women who underwent cervical ripening with mechanical methods.[17] This finding raises the question of whether prophylactic antibiotics are indicated in such patients.

LAMINARIA TENTS

Laminaria tents, natural and synthetic, have been used as a mechanical method for cervical ripening for many years. Although their safety and efficacy in the second trimester have been established, use of laminaria during the third trimester of pregnancy is associated with a high incidence of infection.[18] Synthetic hygroscopic cervical dilators have also been used for many years as agents to prepare the cervix for pregnancy termination. Several studies have shown that these osmotic dilators can also be successfully employed for cervical ripening in viable pregnancies with an unripe cervix.[19–21] Advantages to the use of osmotic dilators are their low cost and ease of placement and removal.

MEMBRANE STRIPPING

Membrane stripping (sometimes known as "membrane sweep") is a simple technique not infrequently used to ripen the cervix, in which a finger is inserted through the cervix and "swept" around the lower segment above the internal os in a circular motion. As with the Foley catheter, it appears to work by release of PG (especially $PGF_{2\alpha}$) from the decidua and the adjacent membranes. However, presumably because it is more vigorous, it often stimulates uterine contractions as well as causing ripening. A systematic review of 22 trials with 2797 aggregate participants comparing membrane sweeping with PGs and with oxytocin revealed that stripping of the membranes was associated with a reduced frequency of post-term pregnancies.[22] As with other mechanical methods, there has been a concern that membrane sweeping may increase the rates of maternal and perinatal infections. However, a more recent systematic review showed no evidence of an increase in the risk of maternal or perinatal infection when "sweeping" is used.[23] However, there are adverse effects such as discomfort during the necessarily vigorous vaginal examination and occasionally bleeding from the cervix or placental margins if the placenta is low-lying. Moreover, if the induction is for fetal compromise, the ensuing contractions mandate fetal monitoring even if labor does not become established.

ACUPUNCTURE

Although much more common in Asia, acupuncture for cervical ripening and labor induction is also becoming more available in the western world. One study concluded that acupuncture at points LI4 (large intestine 4) and SP 6 (spleen 6) induces cervical ripening at term, and in postdated pregnancies, it shortens the time interval between the estimated date of confinement and the actual time of delivery.[24] However, a randomized, controlled trial comparing acupuncture with sham acupuncture for women scheduled for a post-term induction did not reduce the need for induction methods or the duration of labor.[25] There is still a need for more well-designed randomized, controlled trials to evaluate the role of acupuncture to induce labor and for trials to assess clinically meaningful outcomes.

Pharmacologic Methods
PROSTAGLANDINS

The use of PGs for cervical ripening has been reported extensively, involving a variety of PG classes, doses, and routes of administration.[26–28] The distinction between cervical ripening and labor induction is blurred in patients receiving PGs because many women will go into labor even when PGs are being used primarily for ripening. Dinoprostone (PGE_2) is the PG most commonly employed. The local application of PGE_2 results in direct softening of the cervix by at least three mechanisms: (1) It softens the cervix by altering the extracellular ground substance of the cervix, (2) it increases the activity of the smooth muscle of the cervix and uterus, and (3) it leads to gap junction formation that is necessary for the coordinated uterine contractions of labor.[29,30]

Meta-analyses have shown that PGs are superior to placebo and oxytocin alone in ripening the cervix.[31,32] A systematic review including at least 5000 pregnancies from more than 70 prospective trials suggests that PGE_2 is superior to placebo or no therapy in enhancing cervical effacement and dilation.[31]

Two forms of PGE_2 (dinoprostone) are available commercially in the United States, although even more forms are available in other western countries. In randomized trials, the two forms are similar in efficacy.[33–35] The first is formulated as a gel and is placed endocervically, but not above the internal os. The application, 0.5 mg, can be repeated in 6 hours, not to exceed three doses in 24 hours. The second form is a 10-mg vaginal insert that is placed in the posterior fornix of the vagina. This formulation allows for controlled release of dinoprostone over 12 hours, after which it is removed.

Misoprostol (synthetic analogue of PGE_1) has been the subject of numerous articles describing its use as a cervical-ripening agent.[36–54] Doses of 25 to 50 μg administered vaginally or orally have been shown in several studies to be effective in inducing cervical ripening and labor. However, because the majority of patients experience regular uterine contractions soon after the initial dose, misoprostol should be considered primarily a labor-induction agent, which occasionally ripens the cervix without uterine activity.

The role of cytokines in cervical ripening has been the subject of several studies.[55] Interleukin-8 (Il-8) can lead to neutrophil chemotaxis, which is associated with collagenase activity and cervical ripening.[56] These inflammatory agents may be particularly important as mediators of cervical ripening associated with preterm labor. Nitric oxide synthase (NOS) and nitric oxide (NO) have been postulated to have a regulatory role in the myometrium and cervix during pregnancy and parturition.[57–59] In the human cervix, ripening is associated with an increase in inducible NOS (iNOS) and neural NOS expression in the cervix.

Resident and migrating inflammatory cells can cause an increase in iNOS activity. In the primate, cervical ripening has many aspects of an inflammatory process: tissue remodeling and breakage of chemical bridges between collagen fibers. Inflammatory agents such as Il-1, tumor necrosis factor-α, and Il-8 all seem to be involved in cervical ripening.[60–62] Currently, however, there is no commercial product available that exploits these properties directly.

Relaxin is a polypeptide hormone, similar to insulin, produced by the ovaries, decidua, and chorion. Because of its effect on connective tissue remodeling, it has been studied as a cervical-ripening agent.[63,64] Based on data from animal studies, relaxin was predicted to have a cervical-ripening effect in humans. The findings that porcine relaxin induces cervical ripening in humans supported this prediction. However, because studies showed that in fact administered human relaxin has no effect on the human cervix, the usual role played by relaxin in human pregnancy and parturition is unclear. At the present time, relaxin, either purified porcine or recombinant human, is not produced commercially as a cervical-ripening agent, and its future potential in this context remains unclear.

Pharmacologic Methods for Labor Induction
Oxytocin

Oxytocin, a neurohormone originating in the hypothalamus and secreted by the posterior lobe of the pituitary gland, is the most commonly used drug for the purpose of labor induction in viable pregnancies. This octapeptide is secreted in a pulsatile manner, a fact that is reflected in the marked variability observed in minute-to-minute measurements of maternal plasma oxytocin concentration.[65] The half-life of oxytocin is 10 to 12 minutes.[66] The metabolic clearance rate is similar for men, pregnant women, and nonpregnant women: 20 to 27 mL/kg/min.[67] The similarity of the metabolic clearance rate between men and pregnant women is striking in view of the large increase that occurs during pregnancy in the plasma concentration of leucine-aminopeptidase, an enzyme capable of hydrolyzing oxytocin. This suggests that factors other than this enzyme are responsible for the degradation of oxytocin.

There is considerable confusion regarding the pharmacokinetics of oxytocin; much of the original pharmacokinetic work was done prior to the availability of a reliable radioimmunoassay for oxytocin.[68] Indeed, the potency of oxytocin is still based on a bioassay of avian vasopressive activity with 1 United States Pharmacopeia (USP) unit being equivalent to 2 μg of oxytocin. Traditionally, it has been held that oxytocin levels reached a steady-state level within 15 to 20 minutes of beginning an infusion or increasing the dosage. Work using a sensitive oxytocin radioimmunoassay has shown that approximately 40 minutes is required for any

particular dose of oxytocin to reach a steady-state plasma concentration.[69]

It is well established that there is a marked variability in the response of the uterus to oxytocin, but in general, the sensitivity of the uterus to oxytocin increases dramatically as pregnancy progresses.[70] This increase in responsiveness is likely due to the increasing concentrations of oxytocin receptors in the myometrium and decidua with increasing gestational age.[71] It appears that oxytocin has direct stimulatory effects on the myometrium in addition to stimulating decidual PG production.[72] An increased level of $PGF_{2\alpha}$ metabolite was demonstrated in women undergoing successful oxytocin induction of labor, whereas this increase was not present in failed inductions.[73] The direct effect of oxytocin on the myometrium is believed to be mediated by polyphosphoinositide hydrolysis with production of inositol phosphates that act as a second messenger and lead to the mobilization of intracellular calcium ion.[74]

Other organs that show a response to oxytocin include breast, vascular smooth muscle, and kidney. Oxytocin stimulates contraction of the myoepithelium surrounding the alveoli of the mammary gland, leading to the milk ejection reflex. At dosages typically used for the induction of labor, there is no demonstrable effect on vascular smooth muscle tone. However, intravenous boluses of as little as 0.5 IU transiently decrease peripheral vascular tone, leading to hypotension.[75] Similarly, at low dosages, oxytocin exerts negligible effect on renal function; however, at high infusion rates, it exhibits a marked antidiuretic effect (which is not surprising, given its similarity in structure to antidiuretic hormone, also produced in the posterior pituitary). Excessively high infusion rates, coupled with infusion of crystalloid, have led to deaths from water intoxication.

Oxytocin can be administered by any parenteral route. It is also absorbed by the buccal and nasal mucosa. When administered orally and swallowed, oxytocin is rapidly inactivated by trypsin. The intravenous route is now used almost exclusively to stimulate the pregnant uterus because it allows precise measurement of the amount of medication being administered and a relatively rapid discontinuation of the effects of the drug when infusion is discontinued.

TECHNIQUES FOR THE ADMINISTRATION OF OXYTOCIN

Oxytocin is administered as a dilute solution with the flow rate into the intravenous line precisely regulated by an infusion pump. The health care professionals who attend the patient during an induced labor must be familiar with the use and potential complications of oxytocin. Likewise, a qualified physician who is able to manage any complications that may arise with the use of oxytocin should be readily available. Fetal monitoring is indicated prior to beginning the infusion to assess the baseline level of uterine activity and fetal status, and should then be continued during the infusion. Either external or internal monitoring is acceptable as long as uterine activity and fetal heart rate (FHR) are adequately documented. Consideration should be given to the use of internal monitoring when high doses of oxytocin are required or when satisfactory progress in labor is not being made (see also Chapter 67). The tracing should be inspected frequently and carefully for any evidence of hyperstimulation as manifested by increased baseline tonus, tachysystole, or the onset of late decelerations;

the infusion of oxytocin must be stopped immediately should they occur.

Significant difference of opinion exists regarding the initial dose of oxytocin and the interval and frequency of dosage increase. A controlled intravenous oxytocin infusion remains the preferred method of induction of labor. Several trials have compared various regimens of oxytocin dosage increase and time intervals between dose increases.[76–80] Starting doses have ranged from 0.5 to 2.0 mU/min, with some as high as 6 mU/min. Increments of dose increase have ranged from a low of 1 to 2 mU/min up to 6 mU/min, with adjustments for increased uterine activity. Time intervals between increases have ranged from 15 to 40 minutes. Although low-dose regimens (initial dose 0.5–2.0 mU/min, with incremental increases of 1–2 mU/min every 15–40 min) are commonly utilized in the United States, high-dose regimens (initial dose 6–8 mU/min, with incremental increases of 6 mU/min every 15–40 min) have been reported to be safe and effective for labor induction in patients with viable pregnancies, provided there was close fetal monitoring and early recourse to cesarean delivery in the event of fetal distress.[81] A meta-analysis of 11 trials comparing low-dose with high-dose oxytocin for labor induction found that larger dose increases and shorter intervals between increases were associated with shorter labors and lower rates of intra-amniotic infections and cesarean delivery for dystocia, but more hyperstimulation was noted.[82] Based on pharmacokinetic data,[83,84] many obstetricians have moved to a regimen whereby the dose of oxytocin is increased by 1 to 2 mU/min every 40 minutes. Advantages of this regimen derive from not increasing the oxytocin dose before steady-state levels of oxytocin have been reached. This leads to a lower total dosage of oxytocin being used, in addition to a lower incidence of the hyperstimulation that can result from increasing the oxytocin dose before a steady state is reached. A disadvantage is that women who are relatively insensitive to oxytocin may have a very prolonged course before adequate labor is established. Nearly 90% of patients will respond to 16 mU/min or less, and it is most unusual for a patient to require more than 20 to 40 mU/min.[85]

The recognition that endogenous oxytocin is secreted in spurts during pregnancy and spontaneous labor has prompted exploration of a more physiologic manner of inducing labor with this agent. In 1978, Pavlou and associates were the first to describe a protocol of pulsatile infusion.[86] Several randomized trials have compared the safety and efficacy of pulsatile oxytocin administration with continuous infusion.[87–89] Most authors conclude that, although there does not appear to be a shortening of the induction-to-delivery interval, pulsatile administration of oxytocin reduces the amount of oxytocin required for successful labor induction.

SIDE EFFECTS AND COMPLICATIONS OF OXYTOCIN INFUSION

Although oxytocin is a safe medication with appropriate administration and monitoring, there is always the potential for adverse occurrences. The most common complication related to oxytocin induction of labor is uterine hyperstimulation. Uterine hyperstimulation may present as tachysystole with more than five contractions in 10 minutes, contractions of greater than 90 seconds' duration, or an increase in the

baseline uterine tonus. The decreased intervillous blood flow associated with hyperstimulation ultimately leads to decreased oxygen transfer to the fetus, as indicated by the appearance of late decelerations. Oxytocin infusion should be discontinued immediately in the presence of hyperstimulation. If there is evidence of fetal distress, standard intra-uterine resuscitation measures should be instituted, including oxygen administration and positioning the patient in the left lateral decubitus position.

Uterine rupture is a very uncommon complication when oxytocin is used appropriately. There are no prospective data in the literature describing the incidence of uterine rupture in oxytocin-induced labor. Retrospective series of uterine rupture have implicated oxytocin in 4.3%[90] to 12.5%[91] of occurrences. Factors that may reduce the risk of uterine rupture include avoidance of oxytocin in the grand multipara, use of internal uterine pressure monitoring for patients with previous cesarean delivery and when high doses of oxytocin are required, and avoidance of oxytocin in obstructed labors.

Water intoxication, an infrequent complication of oxytocin administration, may be avoided with appropriate management. The minimum effective dose of oxytocin should be used to avoid the antidiuretic effects of high-dose oxytocin. The risk of water intoxication increases in women who have received large volumes of free water; therefore, 5% dextrose solutions without electrolytes should generally not be used during labor induction. Symptoms occur as the plasma sodium concentration falls below 120 to 125 mEq/L and may include nausea and vomiting, mental status changes, and ultimately, seizures and coma. Mild instances of water intoxication can be treated by discontinuing the hypotonic fluid and restricting fluid intake. With severe symptoms, correction of hyponatremia by saline infusion may be necessary.

Concern has been raised regarding a possible association between oxytocin-induced labor and an increased incidence of neonatal jaundice. Many of the older studies claiming that oxytocin leads to neonatal jaundice failed to control for confounding variables such as gestational age and the infusion of large volumes of free water. The more recent literature has not identified any correlation between oxytocin induction and neonatal hyperbilirubinemia.[92,93]

Prostaglandins

Exogenous PGs, particularly dinoprostone (PGE_2), are frequently used as cervical-ripening agents.[94–101] Because the PG-induced cervical-ripening process often includes initiation of labor, approximately half of women treated with dinoprostone enter labor and deliver within 24 hours. PGs have the dual capability to ripen the cervix and initiate uterine contractility. As a consequence, induced labor with PGs appears to be similar to that of spontaneous labor. The use of PGs as labor-induction agents has been reported extensively in a variety of PG classes, doses, and routes of administration.[31] Prior to 1992, most trials assessing the impact of PGs as cervical-ripening and labor-induction agents included various dosages of intracervical (0.3–0.5 mg) or intravaginal (3–5 mg) dinoprostone (PGE_2). In 1992, the U.S. Food and Drug Administration (FDA) approved PGE_2 (0.5 mg intracervically) for cervical ripening and labor induction. In 1995, a slow-release 10-mg dinoprostone

vaginal insert also was approved for the same indications. Because most trials have compared these PG preparations with placebo, the relative efficacy of these two PG preparations has been difficult to assess. In addition, once cervical ripening was completed and uterine activity initiated, most patients studied required further augmentation with oxytocin.

The optimal route for PGE_2 administration has not yet been determined. The intracervical route has been used in the majority of trials, especially those comparing the effectiveness of the FDA-approved formulations (Prepidil and Cervidil). Although intracervical administration of gel is more difficult than intravaginal administration, the former route appears to cause more significant cervical ripening. The intracervical method also appears to be associated with a lower risk of hyperstimulation. However, the easiest and most practical way to apply PGE_2 in routine clinical practice is via the vaginal route, be it by gel, tablet, or vaginal pessary. It has been suggested that the dose of PGE_2 should be varied according to the patient's cervical score, permitting a lower dose of PGE_2 to be used in many cases. Just as there is no consensus about the optimal dose and route of administration of PGE_2, the optimal frequency of administration is still a matter of debate. The approach used for cervical ripening and labor induction with PGE_2 depends on the dose and route of administration. In the United States, 0.5 mg of dinoprostone gel is inserted into the cervical canal just below the internal os. If there is no change in the cervical score to the initial dose, repeat dosing may be given. The recommended repeat dose is 0.5 mg of dinoprostone with a dosing interval of 6 hours. The maximum recommended cumulative dose for a 24-hour period is 1.5 mg of dinoprostone. The recommended interval before considering augmentation with oxytocin should be 6 to 12 hours. In the United Kingdom and other European countries, dinoprostone vaginal gel is the preferred agent for cervical ripening and labor induction.[102] The usual dose is 1 mg inserted into the posterior fornix. For nulliparous patients, 2 mg can be given. The interval for a second dose is generally 6 hours and the cumulative dose should not exceed 4 mg. The dosage of dinoprostone in the vaginal insert is 10 mg designed to be released at approximately 0.3 mg/hr. The vaginal insert should be removed upon the onset of active labor or 12 hours after insertion. Delaying oxytocin augmentation or induction for 30 to 60 minutes after removal of the vaginal insert is sufficient. Irrespective of the route and dose of PGE_2 employed, for the majority of patients, dinoprostone preparations should be regarded mainly as cervical-ripening agents, and are not reliable as labor-induction agents.

MISOPROSTOL FOR LABOR INDUCTION

Misoprostol is a synthetic PGE_1 analogue that has been marketed in the United States since 1988 as a gastric protective agent for the prevention and treatment of peptic ulcers. It was licensed in a tablet form designed for oral absorption. Early studies performed in the late 1980s and early 1990s demonstrated that oral administration of misoprostol caused uterine contractions in early pregnancy.[103–105] Subsequent studies, performed abroad and in the United States, showed that intravaginal administration of misoprostol tablets can terminate first-trimester and second-trimester

pregnancies.[106–110] A large number of published controlled trials have shown that misoprostol, administered either vaginally or via the oral route, is an effective agent for cervical ripening and labor induction in patients with viable pregnancies.[35–54,111–119] An initial meta-analysis suggested a significantly reduced cesarean delivery rate for patients induced with misoprostol.[120] Follow-up meta-analysis showed that 84% of patients receiving misoprostol go into active labor, with only 29.4% requiring oxytocin augmentation. A significantly higher proportion of patients receiving misoprostol achieved a vaginal delivery within 12 hours (37.6% vs. 23.9%). Similarly, 68.1% of patients receiving misoprostol achieved a vaginal delivery within 24 hours. Use of misoprostol for cervical ripening and labor induction is associated with an approximately 5-hour reduction of the interval from the first dose to delivery when compared with dinoprostone. The reduced induction-to-delivery interval seen with misoprostol compared with dinoprostone implies that either it produces higher levels of uterine activity or it is a more efficient cervical-ripening agent. Consistent with the former hypothesis, compared with women receiving dinoprostone, Foley catheter, or placebo, women receiving misoprostol are twice as likely to experience tachysystole and uterine hyperstimulation, with the incidence of these conditions closely related to the dose of misoprostol administered.[120]

In relation to cervical ripening, most of the individual studies in meta-analyses assessing the efficacy and safety of misoprostol and dinoprostone have not shown a significant reduction in the overall cesarean delivery rate. However, the lack of a positive finding was probably because the sample sizes of the trials were small. The 44 trials included in a systematic review with meta-analysis provide data for 5735 subjects participating in trials assessing the impact of misoprostol treatment on the cesarean delivery rate.[120] When all the trials were pooled, subjects receiving misoprostol had a significantly lower cesarean rate than subjects in the comparison groups (17.3% vs. 22.9%). The most common indications for cesarean delivery were arrest of dilation or descent, failed induction, and abnormal FHR tracings. The rate of cesarean deliveries performed because of FHR abnormalities was similar for misoprostol-induced patients and those in the comparison group. Similarly, no difference was noted for the rate of cesarean deliveries because of dystocia. Patients receiving misoprostol had a significantly lower rate of cesarean deliveries because of failed induction. This suggests that misoprostol may be better than dinoprostone at ripening the cervix.

No evidence of adverse perinatal or maternal effects has been noted.[121] The statistical power resulting from the aggregation of 44 studies included in the meta-analysis increases confidence in our ability to assess safety. The number of subjects studied affords a power of at least 90% to detect a difference in neonatal intensive care unit admission rates of at least 4 percentage points (from 14% to 18%). Sufficient power was also noted for the detection of at least a doubling in the rate of abnormal 5-minute Apgar scores (from 1.4% to 2.8%).

Accordingly, these data provided support for the conclusion that misoprostol decreases the cesarean delivery rate among women undergoing labor induction compared with women receiving alternate induction agents. However, more recent meta-analyses, assessing the impact of misoprostol on

the cesarean delivery rate, have not shown a significant reduction in cesarean section rate in the various subgroups analyzed.[122] This may be due to the lower doses now being used, aimed at improving safety by reducing hyperstimulation rates.

ORAL VERSUS VAGINAL ADMINISTRATION

Initial pharmacokinetic studies compared the pharmacokinetics of vaginal and oral administration of misoprostol.[123–126] These studies showed that the peak plasma concentration of misoprostolic acid was higher and achieved earlier after oral administration, but the detectable plasma concentration lasted longer after vaginal administration. Systemic bioavailability of vaginally administered misoprostol was noted to be three times higher than that of orally administered misoprostol.[123] In all patients studied, independent of the dose or route of administration, the first effect of misoprostol treatment was an increase in uterine tonus. After oral administration, the effect was more rapid and the initial increase was more pronounced than after vaginal treatment. However, after vaginal treatment, tonus remained at a higher level for a longer time.

A significant proportion of the published randomized studies have evaluated the safety and efficacy of vaginally administered misoprostol for cervical ripening and labor induction. Seven randomized trials have compared oral versus vaginal administration of misoprostol for labor induction.[114–119,127] In aggregate, 1191 patients were randomized to receive misoprostol orally ($n = 602$) or by the vaginal route ($n = 589$). The oral doses employed ranged from 50 μg to 200 μg every 4 to 6 hours. Vaginal misoprostol was administered in doses ranging from 25 μg to 100 μg every 3 to 4 hours. No difference was noted in the proportion of patients who delivered vaginally within 12 and 24 hours in each group. Similarly, the intervals from start of induction to vaginal delivery were not different. The proportion of patients experiencing increased uterine activity (tachysystole or hyperstimulation) was similar for both groups. In addition, no difference was noted for the incidence of abnormal 5-minute Apgar scores and rates of NICU (neonatal intensive care unit) admissions. Interestingly, the rate of cesarean delivery was significantly lower among those induced with oral misoprostol. Although both routes of misoprostol administration seem to be efficacious, the evidence documenting the safety of vaginally administered misoprostol is much more extensive.

DOSES OF MISOPROSTOL FOR LABOR INDUCTION

Owing to the small number of studies employing oral misoprostol and the lack of uniformity in dosage, the most appropriate dose of misoprostol for labor induction has not been determined. At the present time, oral doses of 100 μg administered every 3 to 4 hours appear to be safe and effective. Further studies are needed to determine whether higher doses can improve efficacy without increasing the rate of adverse maternal and perinatal outcomes.

Because the majority of studies have assessed the safety and efficacy of vaginal administration, more data are available to determine the most appropriate dose. Although dosing regimens as high as 200 μg have been reported in the literature, most authors have used vaginal misoprostol doses of 25 μg or 50 μg. Because of the increased incidence

of uteronic effects, some authors have advised against the use of doses greater than 25 μg. However, the data that form the basis for this recommendation are limited. Six randomized clinical trials have been specifically designed to compare the safety and effectiveness of 25 μg or 50 μg of misoprostol administered intravaginally.[128–133] These trials, although generally well designed, are hampered by small sample size and thus prone to type II errors. A systematic review with meta-analysis of five randomized trials concluded that intravaginal misoprostol at doses of 50 μg for cervical ripening and labor induction is more efficacious, but it is unclear whether it is as safe as the 25-μg dose.[134]

In addition to the six randomized trials and the systematic review, two separate studies have compared the two doses (25 μg vs. 50 μg). These two studies compared intravaginal misoprostol with intracervical dinoprostone gel (Prepidil).[41,42] The misoprostol dosage for the first study was 50 μg every 3 hours for a maximum of six doses, whereas the second study used 25 μg every 3 hours for a maximum of eight doses. Taken together, these two studies indirectly compared two doses of misoprostol: 25 μg and 50 μg. Subjects allocated to receive 50 μg experienced shorter intervals to vaginal delivery and no differences in overall cesarean or operative delivery rates, cesarean deliveries for FHR abnormalities, or NICU admission rates. Although subjects receiving 50 μg of misoprostol experienced a greater incidence of tachysystole, no significant increases in adverse maternal or perinatal outcomes were noted. Meconium-stained fluid was noted more frequently for those receiving 50 μg of misoprostol. Given the reassuring perinatal findings noted previously, this latter finding, however, is of questionable importance. Because these two separate studies by Wing and associates[41,42] indirectly compare two doses of misoprostol, 25 μg and 50 μg, they were incorporated into the present analysis. Altogether, 906 patients were compared: 479 received doses of 25 μg and 427 received doses of 50 μg. Patients who received the 25-μg dose had a lower incidence of tachysystole and hyperstimulation; however, they also had a longer interval to vaginal delivery, and a lower proportion of these patients delivered vaginally within 12 and 24 hours. No differences were noted in the cesarean delivery rate, cesareans performed for FHR abnormalities, operative delivery rates, or NICU admissions.

An American College of Obstetricians and Gynecologists (ACOG) Committee Opinion in 1999[135] stated that if misoprostol is used for cervical ripening and labor induction, 25 μg should be considered for the initial dose. This recommendation has been reinforced in a recent ACOG Practice Bulletin.[136] This opinion is based on the greater incidence of tachysystole noted with larger doses of misoprostol. Despite increased uterine activity with greater doses, however, greater rates of adverse maternal or perinatal outcomes have not been reported. Although existing evidence suggests that both the 25- and the 50-μg doses of misoprostol are currently appropriate for intravaginal administration, we consider that further large prospective trials are required to define an optimal dosing regimen.

There has been recent interest in the use of low-dose oral misoprostol for induction of labor. A recent meta-analysis of nine randomized, controlled trials comparing low-dose (20–25 μg) oral misoprostol with dinoprostone, vaginal misoprostol, and oxytocin for labor induction concluded that 20 μg of misoprostol administered orally every 2 hours seems as effective as both vaginal dinoprostone and vaginal misoprostol.[137] There was also a reduction in cesarean delivery rates and hyperstimulation with low-dose oral misoprostol.

Cervical Ripening and Labor Induction in Special Circumstances

Previous Cesarean Delivery

Among patients with a previous cesarean section, the incidence of uterine disruption is greater with induced labor than with spontaneous labor (0.65% vs. 0.40%).[138] Patients in this group undergoing cervical ripening and labor induction with PGE$_2$ (dinoprostone) experience a rupture rate of 0.9%.[139]

In women with unscarred uteri, vaginal or oral administration of misoprostol has been found safe and effective for patients with unfavorable cervices who require labor induction. There are indirect data, however, from which to assess the risks and benefits of using misoprostol to ripen the cervix and induce labor in women with a previous lower uterine segment scar. A substantial number of publications have suggested that the use of misoprostol in patients with previous cesarean delivery is associated with a high frequency of uterine disruption (dehiscence or frank rupture).[140–146] Most of these publications consist of a few case reports or are based on retrospective uncontrolled studies. A randomized trial designed to compare the safety and efficacy of vaginally administered misoprostol in women with previous cesarean deliveries was terminated prematurely when 2 of 17 women being induced with misoprostol had major uterine ruptures.[141] At the time this study was halted, however, the study had not met the specified criteria for early termination of the trial.[147]

We used several sources to identify all publications that have reported the use of misoprostol for cervical ripening and labor induction in women with previous cesarean delivery. Eleven studies have been published indicating the use of misoprostol for cervical ripening and labor induction in women with scarred uteri.[140–146,148–151] Uterine disruptions, dehiscence, or rupture were reported in 6 of the studies.[140–145] Of 355 patients included in these 11 studies, 16 (4.5%) experienced uterine disruption. Because several confounding factors were present, however, it is important to analyze these data in detail. Data are available for 10 of 16 patients reported to have experienced uterine disruptions. The mean age of the patients was 29.6 ± 4.7 years with a mean gestational age of 39.5 ± 2.1 weeks. Three patients had two previous cesarean deliveries and, in 2 other patients, the type of scar was unknown. Although the information is not precise, it appears that in at least in 3 cases, the patients had a dehiscence of the previous incision. Most patients were induced with single or multiple vaginal doses of 25 μg of misoprostol. Two patients received four doses, and 2 others received at least three doses of misoprostol. The median interval from the last dose of misoprostol until the diagnosis of uterine disruption was 10 hours (interquartile range 8.5–17.2 hr). Seven patients received oxytocin infusion after misoprostol was administered and before the diagnosis of uterine disruption. Only 2 experienced tachysystole, and all patients were delivered by cesarean. The mean birth weight was 3438 ± 572 g. Four cases of neonatal acidemia and 1 neonatal death were reported.

Because of the paucity of data, there is a lack of sufficient evidence from which to assess the risks and benefits of using misoprostol or other PGs to induce labor in women with a scar from a previous lower segment cesarean delivery. Randomized, controlled trials are needed to assess outcomes including vaginal delivery rates, interval to delivery, and number of failed inductions. Because uterine disruption is such an uncommon event, however, only a large multicenter randomized, controlled trial will yield adequate statistical power to assess safety in this population of patients. To detect a difference in uterine rupture from 1% to 3.7%, such a trial would have to include 565 patients in each group ($\alpha = 0.05$, $\beta = 0.80$). Until such a trial is performed, an alternative approach would be to perform a case-control study. In the meantime, the use of misoprostol for cervical ripening and labor induction in women with a previously scarred uterus should occur only in the setting of a research protocol.

Twin Pregnancies

Twin pregnancies frequently involve maternal and fetal complications, which require early delivery. In addition, the optimal timing of birth for women with an otherwise uncomplicated twin pregnancy at term is uncertain, with clinical support for both elective delivery at 37 weeks as well as expectant management. Elective delivery at term may be performed via an elective cesarean or vaginally with the use of mechanical or pharmacologic agents for cervical ripening and labor induction. At present, there are insufficient data to support a practice of elective cesarean delivery for women with an otherwise uncomplicated twin pregnancy at term.

The safety and efficacy of uterotonic agents, particularly oxytocin, for labor induction in women with twins are not as clear as in those with singleton pregnancies. Some clinicians believe that the overdistended uterus encountered with twins is resistant to oxytocin and may require high doses to obtain adequate uterine contractions. In addition, some clinicians suspect that a gravida with twins is prone to hyperstimulation or even uterine rupture with relatively low doses of oxytocin. Although there are no large randomized trials attesting to the safety and efficacy of cervical ripening and labor induction in patients with twin pregnancies, several retrospective studies have suggested that labor induction, with a variety of induction agents, is acceptably safe. A case-matched control study compared the safety and efficacy of labor induction with oxytocin versus spontaneous labor in 62 women with twin pregnancies.[152] Twin pregnancy had no adverse impact on the effectiveness or efficiency of oxytocin labor stimulation; indeed, it appeared to be associated with fewer side effects. Additional case series of labor induction in twin pregnancies have included the use of intrauterine balloon catheters,[153] oral dinoprostone or PGE2,[154] and oxytocin.[155]

Although misoprostol has been shown to be a safe and effective agent for labor induction in singleton pregnancies, there are no published studies in women with twin pregnancies. If misoprostol is chosen for labor induction in twins, continuous monitoring of the FHR and uterine contractions should be performed. Repeated doses should be used only if there is definitely no evidence of regular uterine activity.

According to ACOG, twin pregnancies do not necessarily constitute a contraindication to labor induction.[156] However, as with misoprostol, patients with twin pregnancies who undergo labor induction with oxytocin, or with any other agent, need to be monitored very closely.

Fetal Death

The ideal method for termination of pregnancy in cases of intrauterine fetal demise should be effective and safe and should have minimal side effects. In the past, oxytocin infusion and PGE2 vaginal suppositories (referred to as "pessaries" in the United Kingdom) were the most commonly used methods for labor induction in patients with fetal death.

INTRAVENOUS OXYTOCIN

Intravenous oxytocin is a time-honored, effective, and safe method for inducing labor in cases of intrauterine fetal demise. However, oxytocin infusion is less effective when used in patients with a very unripe cervix and in those remote from term. Large doses and prolonged administration may be required, circumstances that increase the risk of water intoxication and attendant central nervous system complications. For patients who are remote from term, some authors have reported the use of high-dose oxytocin.[157] One regimen describes the use of approximately 300 mU/min (200 units of oxytocin in 500 mL of 5% dextrose lactated Ringer solution or 5% dextrose and half-normal saline at 50 mL/hr). In this setting, 5% dextrose and water has been associated with hyponatremia. Electrolytes should be checked before beginning oxytocin and should be repeated every 24 hours or if signs and symptoms of water intoxication occur. Attention should be paid to fluid intake and urinary output. For patients at or near term, lower doses of oxytocin are usually required. Laminaria, or other mechanical means of cervical ripening, may be beneficial before the use of oxytocin for induction.

PROSTAGLANDINS

Many cases of fetal death can be managed simply and effective by PGE2 vaginal suppositories. The customary dose is one 20-mg suppository inserted vaginally every 4 hours until contractions are sufficient to promote progressive cervical change. Generally, this dose is used only for patients who are at no more than 28 weeks' gestation. However, some authors have reported safe use in the third trimester.[158] Reported side effects with higher doses (20 mg) of PGE2 vaginal suppositories include fever, nausea, vomiting, and diarrhea. These annoying side effects may be ameliorated with appropriate and specific pretreatment medications. Although PGE2 vaginal suppositories have been used safely in the third trimester, the risk of uterine rupture is increased.

More recently, misoprostol (synthetic analogue of PGE1) has been used safely and effectively for cervical ripening and labor induction in patients with fetal death. Mariani-Neto and coworers[159] first reported the use of oral misoprostol (400 μg q4h) for induction of labor following fetal death. The authors reported their experience with 20 patients with fetal demise at 19 to 41 weeks' gestation. All patients delivered successfully with a mean interval to delivery of 552 minutes. The mean dose of misoprostol required was 1000 μg (400–2800 μg). Additional studies have assessed the safety and efficacy of misoprostol in the management of fetal death.[160,161] The doses and routes of administration have

varied significantly among the studies. Oral doses of 200 μg and vaginal doses ranging from 50 to 200 μg every 4 to 6 hours have been employed. Some authors have combined misoprostol with mifepristone; patients receive a single dose of 200 mg mifepristone orally, following which a 24- to 48-hour interval is recommended prior to administering 100 to 200 μg of misoprostol in the vagina every 3 hours.[160,161]

Wagaarachchi and associates[162] first reported a combination of vaginal and oral misoprostol after priming with mifepristone. Women received a single dose of 200 mg mifepristone followed by a 24- to 48-hour interval before administration of misoprostol. For gestations of 24 to 34 weeks, 200 μg of intravaginal misoprostol was administered, followed by four oral doses of 200 μg at three 1-hour intervals. Gestations over 34 weeks were given a similar regimen but a reduced dose of 100 μg misoprostol. The average induction-to-delivery interval was 8.5 hours, which was the shortest among the previous regimens. Improved patient

acceptability and reduced risk of introducing intrauterine infection are potential advantages of oral over vaginal route.

High doses of misoprostol (vaginal or oral administration) may be associated with fever, chills, and diarrhea. Pretreatment with antidiarrheal and antiemetic agents may reduce adverse effects.

EXTRA-AMNIOTIC SALINE INFUSION

Extra-amniotic saline infusion has been shown to be successful in inducing labor in antepartum deaths after 20 weeks' gestation.[163] An 18-Fr Foley catheter is inserted through the cervix under direct vision. The balloon is inflated with 30 mL of sterile water, and the catheter is usually strapped to the thigh under slight traction. Normal saline (0.9%) infusion is started to run at 30 drops/min, and a maximum volume of 2 L should be infused into the extra-amniotic space.

SUMMARY OF MANAGEMENT OPTIONS
Induction of Labor

Management Options	Evidence Quality and Recommendation	References
Prenatal—General		
Bishop score is still the most reliable indicator of success of induction.	III/B	4
Prenatal—Indications		
Women should have a valid indication for IOL and no contraindications (see Tables 66–1 and 66–2).	III/B	85
Indications should be such that mother or fetus will benefit from a higher probability of a healthy outcome than if birth is delayed.	III/B	85
For a consideration of the validity of specific indication for induction of labor, see other chapters including 35 and 65.	—/—	22

Mechanical Methods		
• Foley catheter.	Ia/A	16
• Laminaria tents.	Ib/A	19,20
• Membrane sweep.	Ia/A	8
• Acupuncture.	IIb/B	24
Pharmacologic Methods		
• PGs.	Ia/A	31,32
Labor Induction		
Oxytocin is effective.	Ib/A	77,78,80
PGs are effective.	Ia/A	102
In women with intact membranes, vaginal PGE_2 is superior to oxytocin.	Ia/A	31,32
Although both routes are equally effective, intravaginal PGE_2 is preferable to intracervical because it is less invasive.	Ia/A	276
PG tablets (3 mg) are equally effective as PG gel (1–2 mg) q6h, but tablets offer financial savings.	Ia/A	276
Oxytocin use in women with intact membranes should be combined with amniotomy.	III/B	85

Management Options	Evidence Quality and Recommendation	References
Oxytocin should not be started for 6 hr following PG administration.	III/B	85
Oxytocin starting dose is 1–2 mU/min, increased at intervals of 30–40 min.	III/B	85
Misoprostol appears to be a cheap, effective induction agent. Safety issues are probably related to dose or route and are being assessed.	Ia/A	120
Other methods such as mechanical methods, estrogens, relaxin, hyaluronidase, castor oil, bath, enema, and breast stimulation have varying efficacy.	III/B	85
Labor Monitoring		
Fetal well-being should be established prior to induction of labor.	III/B	85
Following insertion of PG, fetal well-being should be established once contractions begin.	III/B	85
When oxytocin is being used for induction, continuous electronic monitoring should be used.	III/B	85
If there is uterine hypercontractility, tocolysis should be considered.	Ia/A	41,42,134

IOL, induction of labor; PG, prostaglandin.

TERMINATION OF PREGNANCY FOR FETAL ANOMALY

Introduction

In 2005, 12% of all legal terminations of pregnancy (TOP) reported to the U.S. Centers for Disease Control and Prevention (CDC) occurred after 13 weeks' gestation.[164] Only 5.0% were performed after 15 weeks' gestation: 3.7% at 16 to 20 weeks and 1.3% at 21 weeks or more. Dilation and evacuation (D&E) accounted for 96% of these procedures. From 1974 through 2005, the percentage of second-trimester TOP performed by D&E increased from 31% to 96%; and the percentage of second-trimester TOP performed by intrauterine instillation (intra-amniotic, extra-amniotic) using hypertonic saline, urea, or $PGF_{2\alpha}$ decreased from 57% to 0.4%. The percentage of medical abortions increased from 1.0% in 2000 to 9.9% in 2005.[164]

D&E, preceded by cervical preparation, is safe and effective when undertaken with appropriate instruments by practitioners who have a sufficient workload to maintain their skills.[165,166] Compared with intra-amniotic instillation methods, D&E has lower complication rates.[166–169] However, almost all the comparative data relate to obsolete abortifacients (such as saline and urea solutions) that are rarely used today.

The introduction of PG analogues in the late 1970s changed the management of TOP in the second trimester; they were initially instilled into the amniotic cavity, and later used for cervical ripening. The subsequent introduction of the antiprogestin mifepristone shortened the induction-to-TOP interval still further, and the dosage of PG analogues required was reduced. Today, medical TOP is the method of choice in many centers that perform second-trimester TOP.[170,171]

Both D&E and medical induction are relatively safe, with low complication rates.[167,172] Second-trimester TOP by D&E in well-selected patients in a dedicated outpatient facility can be safer and less expensive than hospital-based D&E or induction of labor.[173] The method chosen is largely dependent on physician preference and level of technical expertise, coupled with the patient's informed decision.

Definition

Termination of pregnancy is the medical or surgical removal of a pregnancy before the time of fetal viability while preserving the life and health of the mother. Patients in need of TOP can be identified at any gestational age; however, the great majority are performed at 24 weeks' gestation or less.

Indications

The most commonly accepted indications for TOP are
- A pregnancy that would result in the birth of a child with anomalies incompatible with life or associated with significant physical or mental morbidity.
- Fetal death.
- To save the life of the mother or preserve the health of the mother.

Fetal Conditions

Significant structural and chromosomal conditions affect at least 3% to 5% of all births, and an increasing number of women will be faced with the decision to end a pregnancy based on fetal health concerns.[174,175] Unfortunately, because fetal assessment (e.g., using biochemical screening, ultrasound, chorionic villus sampling, or amniocentesis) is not available until the second trimester, TOP for this indication is usually later in gestation than TOP for social indications. The number of fetal conditions that can be identified during pregnancy continues to expand because of the steady improvement of the technology available for prenatal diagnosis. Conditions that can be identified include

- Chromosomal disorders (e.g., trisomy 21, 18, 13).
- X-linked disorders (e.g., hemophilia).
- Metabolic disorders (e.g., Tay-Sachs).
- Neural tube defects (e.g., anencephaly, spina bifida).
- Structural anomalies associated with exposure to teratogens.
- Infections (e.g., rubella, cytomegalovirus, toxoplasmosis).
- Structural anomalies of multifactorial or unknown etiology.
- Other fetal indications, including preterm prelabor rupture of membranes prior to 24 weeks and fetal death at 24 weeks or less.

Maternal Conditions

TOPs to save the life or preserve the health of the mother are rare events. Some women with chronic medical conditions choose pregnancy termination only after discovering for the first time during pregnancy that continuing the pregnancy poses significant health risks for themselves. This failure of preconception counseling is unfortunately more common than it should be. For most chronic medical conditions, sufficient data exist to permit accurate decisions as to the likelihood and magnitude of risks associated with a continuing pregnancy, although it is often impossible to say precisely who will be affected. For example, although one can quote a 30% to 50% mortality rate for pregnancy in association with Eisenmenger's syndrome or pulmonary hypertension, half the women counseled will survive, and it is usually impossible to say which half. In the case of other medical indications for TOP, such as severe hypertensive vascular disease and certain malignancies, the prognosis can be given with more certainty.[176–178] Decision for TOP in this context should be based on the collaborative agreement of a multidisciplinary team. At minimum, the team should consist of the patient, the obstetrician, a medical specialist, and an expert in genetic counseling. Additional members may include family members, spiritual counselors, nurses, intensive care specialists, and ethicists. The decision must be individualized for each patient.

Legal Termination of Pregnancy Services

In the United States, only a few states provide public funding for TOP, and one third of private insurance plans provide limited or no coverage.[179] Women with federally funded medical care are covered for TOP services only if the woman's life is threatened, or in cases of rape or incest (32 states), when medically necessary (16 states), and in cases of life endangerment (2 states). Hence, cost contiderations pose formidable barriers to women seeking TOP, even when there is gross fetal malformation.

Clinicians performing D&E procedures need training from an experienced mentor and the opportunity to maintain proficiency through ongoing experience. In the United States, only 44% of all facilities providing TOP offer services at 14 weeks' gestation; the proportion declines dramatically as gestation advances, to 22% at 20 weeks and 7% at 24 weeks.[180] Moreover, only 7% of obstetrics and gynecology residency programs provide routine training in second-trimester TOP.[181] Labor induction is an integral part of obstetrics and gynecology training; training in D&E for second-trimester TOP is not. Among graduating obstetrics and gynecology residents in U.S. programs, 43% had never performed a D&E, and 81% had performed 10 or fewer procedures.[181] Therefore, despite the safety advantages of D&E, women requesting second-trimester TOP may be limited to labor-induction methods simply because practitioners trained and willing to perform D&E are unavailable. Thus, the future availability of D&E, especially beyond 15 weeks' gestation, is uncertain. As the availability of D&E procedures decreases, the need for safe, efficacious methods of medical TOP will increase.

Patient Assessment and Counseling (See also Chapters 7 and 8)

Patient assessment should include history, physical examination, appropriate laboratory studies, and counseling.

History

The complete medical history should focus on the timing and reliability of the last normal menstrual period. If there is the slightest doubt about gestational age (e.g., a discrepancy between the history and the examination findings), assessment of fetal size with ultrasound is crucial. Knowledge of past reproductive history, sexual history, current medications, allergies, prior pelvic surgery, and any known uterine anomalies is important. Women with medical conditions severe enough to warrant TOP may require additional evaluation and stabilization prior to the procedure.

Physical Examination

Physical examination must include vital signs, weight, uterine size, and cardiopulmonary assessment. A sterile speculum examination should be done, seeking cervical pathologic problems, such as active cervicitis, deformities, and past trauma. A small, stenotic, or scarred cervical os may impair the cervical dilation necessary for safe surgical TOP.

Laboratory Studies

Few laboratory studies are required in young healthy women, but hematocrit, Rh status, indirect Coombs, and urinalysis results should be obtained.

- A complete blood count (CBC) and blood typing are the minimum laboratory studies required for surgical TOP.
  - A CBC is required to identify patients with significant anemia, who are at risk if excessive blood loss occurs. Transfusion may be needed, particularly in second-trimester TOPs. Patients with severe anemia are best treated in a setting in which transfusion is available.
  - Blood typing is required so that Rh-negative women can be identified and given anti-D immunoglobulin (RhoGAM) to prevent Rh sensitization in subsequent pregnancies.
  - Screening for common sexually transmitted infections (STIs) should be addressed in geographic areas of high prevalence, in age groups at high risk (i.e., <25 yr), and in at-risk groups (e.g., those with histories of STIs, multiple sex partners, substance abuse).
- Additional laboratory testing is dictated by the medical history and physical examination findings.

Coagulation studies are indicated for patients with conditions such as a history of coagulopathy, hematologic malignancies, hemorrhage with previous surgical procedures, petechiae, bruising, and hepatosplenomegaly.

Liver function tests are indicated for patients with conditions such as hepatitis, alcohol abuse, cancer, hepatomegaly, and jaundice. Renal function tests are indicated for patients with conditions such as renal disease, recurrent urinary tract infections, oliguria, hematuria, and proteinuria.

Electrolyte assays are necessary in patients who develop significant vomiting associated with the use of medical TOP techniques.

Ultrasound, in addition to its value for prenatal diagnosis, is used for determination of gestational age, placental location, and detection of uterine fibroids or the presence of uterine anomalies (e.g., uterus didelphys, unicornuate uterus, septate uterus).

Counseling

When a congenital fetal anomaly is diagnosed, the clinician should meet with the patient for the following reasons:

- To explain to the patient the nature and severity of the anomaly.
- To discuss the treatment options available for the management of the anomaly.
- To explain the implication(s) of the anomaly for the child and on the family.
- To refer the patient for expert opinion if the clinician is uncertain about the congenital anomaly or its implication(s), treatment, and so on.

The purpose of counseling is to help the patient understand her options regarding the pregnancy. In cases with severe anomaly, TOP may be offered as an option when there is a substantial risk that if the child were born, it would suffer from such physical or mental abnormality as to be seriously handicapped. If the clinician, based on his or her professional opinion, disagrees with the patient on her decision regarding TOP, the patient should be reminded that she can seek a second opinion.

At the minimum, the patient should know the diagnosis, purpose of the procedure, risks and possible complications, alternative treatments, and the likelihood of successful treatment.

Therefore, the woman should be given appropriate information related to the choice between TOP and continuing her pregnancy to viability, regardless of the physician's personal views about rearing a child with such an anomaly or about TOP. However, although physicians have a duty to give full and accurate information, they have no obligation to be involved in the procedure itself if they have ethical objections. For this reason, training in carrying out TOP should not be mandatory, although it is mandatory for physicians to be knowledgeable about the procedure and its complications so that they can give accurate advice and make an appropriate referral to someone who is willing to perform it.[182]

Choice of Methods

Termination of pregnancy can be achieved by surgical means or with pharmacologic agents alone, in combination, or as an adjunct to a surgical method. The methods described refer to pregnancy termination at 13 to 24 weeks' gestation. The decision over which method to use is primarily determined by

- The gestational age.
- The expertise of the available medical staff.
- Patient preference.
- The clinical importance of obtaining an intact fetus.
- Presence of other complicating clinical conditions.

Generally, dilation and suction evacuation can be used up to 14 weeks' gestation, but thereafter, specific techniques of cervical preparation and special instruments for D&E need to be used. Modern methods of aggressive cervical preparation coupled with extensive clinical experience of the procedure have resulted in improved safety for D&E.[173,183]

From a provider perspective, D&E allows predictable scheduling and avoids the prolonged period of medical observation typical of labor induction. Patients having a TOP for fetal anomaly may find that the prospect of a prolonged induction and delivery compounds the anguish of their decision and loss. A surgical TOP, possibly under general anesthesia, may be less traumatic emotionally. Shulman and colleagues[184] observed that patients in their institution recovered more quickly after D&E and required fewer referrals for postoperative counseling than patients had a medical TOP. However, D&E places a greater emotional burden on the surgeon and support staff.[185]

Although some women elect to have a medical TOP out of a desire to avoid surgery, the rate for the use of surgical aspiration or curettage to treat incomplete TOP is 15% to 30% or higher.[172–175]

Conversely, grieving is important for many parents of a fetus with congenital abnormality, and seeing and holding the fetus are important components of healing.[186] In addition, medical TOP results in the delivery of an intact fetus and, therefore, allows optimal evaluation and confirmation of suspected genetic or structural abnormalities. This information is vital in counseling couples about the likelihood of recurrence.

Currently, medical TOP with misoprostol is a safe alternative to surgical TOP in patients with acute medical conditions and chronic debilitating illnesses. In our experience, misoprostol combined with mechanical cervical dilators such as a Foley catheter or laminaria tents can be used safely in patients with severe hypertensive disorders, cardiac disease, or asthma.[187]

In difficult or challenging cases, especially at or beyond 16 weeks, the physician, in consultation with the patient, must choose the most appropriate method based upon the patient's individual circumstances.[188,189]

Clincal Setting

Surgical D&E can be performed safely in a variety of outpatient settings, including a physician's office, provided there is an efficient system for emergency transfer.[190–192] In contrast, medical TOP services are usually provided in hospital settings.

Surgical Methods

Surgical methods include D&E, dilation and intact extraction (D&X), hysterotomy, and hysterectomy. The use of

real-time ultrasound scanning during D&E can reduce perforation rates.[193] Hysterotomy or hysterectomy is seldom used owing to higher rates of morbidity and mortality.[194] Prerequisites for surgical TOP include cervical preparation, adequate cervical dilation to use a 16-mm suction cannula, special grasping forceps, adequate anesthesia, oxytocic agents, antibiotic prophylaxis, and appropriate postoperative care.

DILATION AND EVACUATION

Anesthesia

The choice of anesthesia must be based on the medical, psychiatric, and emotional condition of the patient. Consultation with anesthetists, medical specialists, and psychiatric specialists may be necessary to determine the best choice for the individual patient. In general, paracervical block with light sedation provides sufficient anesthesia for many patients; however, the full range of anesthesia options must be available. Use of short-acting barbiturates by intravenous bolus infusion is a simple, effective form of general anesthesia that obviates the need for muscle relaxants, intubation, and halogenated gases.[195]

Cervical Preparation

A variety of mechanical and pharmacologic methods have been utilized (see Table 66–4).

Use of Osmotic Dilators

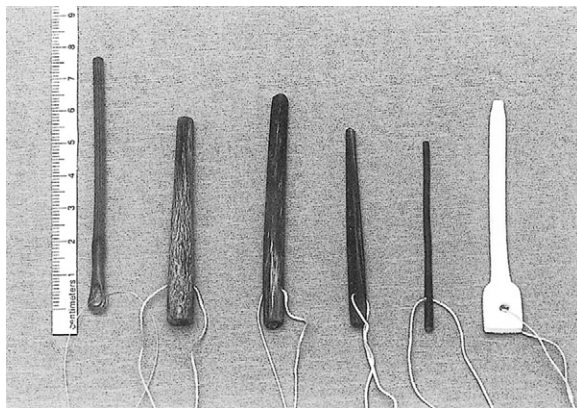
There are four types of osmotic dilators—laminaria japonica, two synthetic dilators (Lamicel, Dilapan) (Fig. 66–1),[196] and isaptent. Laminaria, derived from the seaweed genus *Laminaria* (*L. japonica*, *L. digitata*), are one of the oldest devices used for cervical ripening. Tents prepared from *L. japonica* are commercially available and are packaged in a variety of sizes.


FIGURE 66–1

Osmotic dilators. *Left to right*: Dilapan, a single-sized synthetic polyacrylonitrile rod (hypan) currently available outside the United States; *Laminaria japonicum*, dried and compressed stalks of seaweed, four sizes (available in sizes ranging from 2 to 10 mm); Lamicel, a magnesium sulfate-impregnated polyvinyl alcohol sponge (available as 3 and 5 mm).

(From Williamson DW: Resources for abortion providers. In Paul M, Lichtenberg ES, Borgatta L, et al [eds]: A Clinician's Guide to Medical and Surgical Abortion. New York, Churchill Livingstone, 1999, p 292, Fig. 20–13.)

Although tents prepared from *L. digitata* are available, they are less useful clinically; they become gelatinous with expansion and are prone to fragment or become trapped in the cervix. The tents absorb water, swell, and ultimately dilate and soften the cervix. The tents expand most rapidly in the first 4 to 6 hours but continue to swell for up to 24 hours. In general, laminaria will expand up to four times their original diameter, resulting in concomitant dilation of the cervix. Placement of several smaller tents rather than one large tent may result in improved dilation and facilitate their later removal.

Compared with laminaria, Dilapan swells more rapidly and to a greater diameter, therefore, fewer Dilapan on average are needed for similar efficacy.[197] However, Dilapan is more likely to disintegrate, or retract, and it is no longer available in the United States.[198] Lamicel was found to be inferior to laminaria for mid-trimester cervical ripening prior to D&E.[199] Lamicel is seldom used alone, because the sponges are difficult to insert in aggregate and become too soft on expansion to achieve the dilation needed.

Isaptent, although not used widely in the United States, is an alternative osmotic dilator that is effective for mid-trimester cervical ripening. These commercially available tents (Dilex C.; Central Drug Research Institute, Lucknow, India) are prepared from granulated seed husk powder, derived from the isopgol plant (*Plantago ovata*), which is compressed and sealed into a cylindrical polythene sheath. The tents expand to a maximum diameter of 9 to 11 mm within 8 to 12 hours.[200] Comparison of isaptent with laminaria for cervical ripening demonstrates similar efficacy.[201]

Strategies may range from use of a single osmotic dilator with same-day surgery during the early second trimester to serial insertion of a variety of types and size of dilators for more advanced gestations. For procedures at up to 16 weeks' gestation, placing the dilators 4 to 8 hours prior to surgery may suffice. Beyond 16 weeks, it is common practice to allow overnight dilation, and some mid to late second-trimester procedures call for a second insertion in 12 to 24 hours. Repeated laminaria applications significantly increase cervical dilation as compared with a single application, and therefore, treatment must be individualized.[198,202]

Adequate dilation is required in order to pass the 16-mm suction cannula and grasping forceps and to remove all the fetal parts. The minimum dilation required to insert grasping forceps depends on the type and size of the instrument used (13 mm for small Sopher, 14–15 mm for large Sopher, 16 mm for small Bierer, and 17 mm for large Bierer).[166] Prior to starting the procedure, sufficient cervical dilation must be confirmed. If cervical dilation is inadequate, additional osmotic dilators can be placed and the procedure delayed for at least 4 to 6 hours (or rescheduled to the next day).

Adequate pretreatment with laminaria may effect enough dilation prior to D&E to avoid the need for additional forced dilation in the operating room. Laminaria is the current mainstay in the United States for achieving cervical dilation for second-trimester TOP. Dilapan is still used widely in countries where it is available.

Methods of Insertion

After placing the speculum in the vagina and exposing the cervix, the cervix should be cleaned with antiseptic solution. Some women require no anesthesia or analgesia, but local

anesthesia is helpful in women who are anxious or when the procedure is technically difficult. Use of a 50:50 mixture of lidocaine (1% or 0.5%) and bupivacaine (0.25%) provides rapid onset and a longer duration of action than lidocaine alone.

The anterior lip of the cervix is grasped with a long Allis clamp. The cervical canal is carefully sounded, without rupturing the membranes, to identify its length. If desired, the cervix can be dilated mechanically using finely tapered dilators (such as Pratt and Denniston), and this allows insertion of more or larger osmotic dilators.

The large end of each osmotic dilator is grasped with a ring, packing, or ovum forceps and inserted into the cervical canal, laying successive dilators on top or next to the previous ones. Coating the dilators with lubricating jelly may ease insertion. Laminaria should be inserted leaving a 2- to 4-mm length protruding from the external os to facilitate its removal. The surgeon should ensure that the tips of the osmotic dilators pass through the internal os (Fig. 66–2).[166] If not, the result is a funnel-shaped canal and an inadequately dilated internal os (Fig. 66–3).[188] After inserting the dilators, they can be kept in place while the speculum is removed by placing a gauze sponge in a sponge holder over the cervix. The number and type of osmotic dilators inserted should be recorded.

In the event of inadvertent or spontaneous membrane rupture, the osmotic dilators should still be placed, but left in place for only 12 hours rather than 24 hours. The patient may resume normal activities, depending on how she feels.

Cervical Priming with Prostaglandins Prior to D&E

Lauersen and coworkers[203] found a superior dilating effect with four to six laminaria tents placed 12 hours prior to D&E than with either PGE$_2$ vaginal suppositories (30 or 60 mg) or 15(S)-methyl PGF$_{2\alpha}$ (0.5 or 1.0 mg). Vaginal and oral misoprostol have also been found useful in this setting.[204,205] More recently, buccal administration of misoprostol (600 μg given 2–4 hr prior to the procedure) was found to be as effective as laminaria tent for cervical preparation.[206]

PROCEDURE

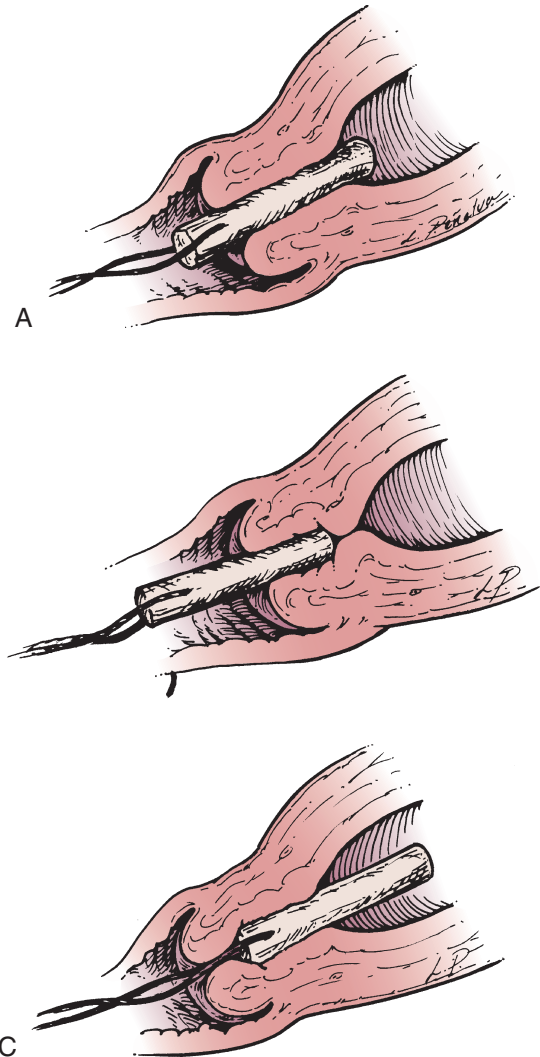
DILATION AND EVACUATION

This procedure consists of removal of the osmotic dilators, assessment of cervical dilation, and insertion of a 16-mm suction cannula to rupture the membranes and evacuate the amniotic fluid and fetal elements, followed by mechanical destruction and evacuation of fetal parts using special grasping forceps (preferably under ultrasound guidance).

The osmotic dilators are removed digitally or with packing forceps. The number of dilators should be counted to ensure they are all removed. Following this, a gentle digital examination will establish the extent of cervical dilation (particularly at the internal os). If sufficient dilation cannot be accomplished, the procedure should be delayed to repeat the osmotic dilation, or consideration should be given to admitting the patient for a medical TOP.

FIGURE 66–2

Osmotic dilator insertion. *A*, Laminaria placed appropriately through the internal os. *B*, Laminaria does not pass through the internal os. Swelling results in funneling of the endocervical canal and inadequate dilation of the internal os. *C*, Laminaria inserted too far into the endocervical canal. This placement may result in rupture of the membranes and difficult removal.

(*A–C*, From Haskell WM, Easterling TR, Lichtenberg ES: Surgical abortion after the first trimester. In Paul M, Lichtenberg ES, Borgatta L, et al [eds]: A Clinician's Guide to Medical and Surgical Abortion. New York, Churchill Livingstone, 1999, p 130, Fig. 10–2.)


Once dilation is deemed adequate, the bladder should be emptied with a rubber catheter before D&E is started. The cervix is grasped with a long Allis clamp and a cannula is passed into the uterine cavity to rupture the membranes and evacuate as much amniotic fluid as possible with vacuum suction. The suction cannula should always be advanced fully into the uterine cavity before suction is applied. Up to 15 weeks' gestation, a 14-mm cannula should suffice, but gestations of 16 weeks and more require a 16-mm cannula. During removal of the amniotic fluid, it is common for some membranes and placental tissue to be evacuated. However, complete placental extraction is generally delayed until the fetal parts have been removed.

A

B

C

With a 14-mm cannula, suction alone is usually adequate to remove 13- to 16-week pregnancies. Beyond 16 weeks, some fetal parts remain in the uterus after suctioning and require extraction by forceps; most commonly, these remnants include the spinal cord and calvarium. To extract the remaining fetal parts, a grasping forceps appropriate for the amount of cervical dilation should be used. In cases past 16 weeks, the fetus is extracted, usually in parts, using Sopher or similar forceps and other destructive instruments.
The choice of forceps (Fig. 66–4)[207] depends on operator preference and the extent of cervical dilation. We prefer Sopher forceps with its long shafts and bulkier grasping surfaces with sheltered serrations.

Once inserted, the forceps should be opened widely and one blade inserted along the anterior uterine wall in order to grasp the fetal parts. When fetal parts are felt between the blades on closing the handles, they are removed with a gentle twisting motion. The calvarium is the part most likely to be left behind. If fetal parts remain in the uterus, gentle probing with a small sharp curette may locate and retrieve them, although use of a sharp curette always carries the risk of perforating the uterine wall. Alternatively, sonography can be used to locate any remaining fetal parts and aid in their evacuation. In one study, use of intraoperative ultrasonography reduced the incidence of uterine perforation at D&E from 1.4% to 0.2%.[193]

Complete removal of the placenta generally requires one or more passes with the 14- to 16-mm suction curette. Before concluding the procedure, the fetal parts should be assembled to determine whether TOP was complete. Similarly, the quantity of placental tissue should be visually assessed to ensure that it is commensurate with the gestation.

Use of Oxytocic Agents

The use of uterotonic agents during surgical TOP is a matter of preference. We use an intravenous infusion of oxytocin 20 to 40 units in 500 mL crystalloids given intraoperatively after rupture of membranes and continued postoperatively for 30 minutes. If the full 40 units is given, care should be taken to avoid excessive further infusion of crystalloid, because of the risk of water intoxication due to the antidiuretic effect of oxytocin.

Antibiotic Prophylaxis

Routine oral antibiotic prophylaxis reduces the risk of infection after surgical TOP.[208–210] It is commonly started on the first day of osmotic dilator placement. Antibiotics such as tetracycline, clindamycin, and metronidazole have all been used to good effect.

Postoperative Care

Minimum observation periods for recovering D&E patients are 1 hour for early and mid second-trimester cases and 2 hours for late D&E, usually defined as more than 19 to 20 weeks' gestation.

INTACT DILATION AND EXTRACTION

ACOG in its general policy statement related to TOP[211] described "intact dilatation and extraction" (intact D&X) as containing all the following four elements:

- Deliberate dilation of the cervix, generally accomplished with multiple, serial osmotic dilators over 2 days or more.
- Instrumental conversion of the fetus to a footling breech.
- Breech extraction of the body excepting the head.
- Partial evacuation of the intracranial contents of a living fetus to effect vaginal delivery of a dead but otherwise intact fetus.

According to the CDC, only 5.0% of TOPs performed in the United States in 2005 (the most recent data available) were performed after the 16th week of pregnancy.[164] It is unknown how many of these were performed using intact D&X.

Intact D&X is a very controversial procedure in the United States. A select panel convened by ACOG could identify no circumstances under which this procedure, as defined here, would be the only option to save the life or preserve the health of the woman.[211] In the authors' institution, medical TOP, with concurrent use of a 30-mL balloon Foley catheter or laminaria tents and misoprostol, is the method of choice after 18 weeks' gestation. The physician, in consultation with the patient, must choose the most appropriate method based upon the patient's individual circumstances.

HYSTEROTOMY AND HYSTERECTOMY

In rare circumstances, hysterotomy or hysterectomy for TOP is preferable to either D&E or medical TOP. The possible indications include failed medical TOP if D&E cannot be safely performed; myomas in the lower uterine segment obstructing extraction; prior placement of an abdominal cerclage, which it is desired to leave in place; uterine anomalies (e.g., uterus didelphys, unicornuate or septate uterus); and some cases of cervical cancer.[188]

Another clinical challenge is the patient with complete placenta previa presenting for second-trimester TOP.[212] In ultrasound studies, the reported prevalence of second-

trimester placenta previa ranges from 2% to 6%. Thomas and colleagues[213] reported on 131 patients with and without placenta previa who underwent second-trimester D&E. The 23 patients (17.6%) with ultrasound-documented placenta previa averaged only 21 mL more blood loss and had no other complications.

Conversely, placenta accreta occurs in 1 to 2 per 10,000 second-trimester TOPs and usually results in heavy bleeding during the procedure. Placenta accreta is frequently associated with previous uterine surgery, suggesting a pre-existing defect in the basal layer of the endometrium (decidua basalis).[214] Occasionally, patients with placenta accreta or placenta percreta require laparotomy with hysterotomy or hysterectomy despite the increased morbidity and mortality risks associated with these procedures.[215] These patients may benefit from preoperative placement of embolization balloon catheters using interventional radiology techniques.[216,217] Second-trimester TOPs by D&E in well-selected patients in a dedicated outpatient facility can be safer and less expensive than hospital-based D&E or induction of labor.

Medical Termination of Pregnancy

The introduction of PG analogues and mifepristone has revolutionized the management of second-trimester TOP and fetal death since the early 1990s. Gemeprost and misoprostol are the two most extensively studied PG analogues that are used in this period. Gemeprost is the only licensed synthetic PG analogue for second-trimester TOP in the United Kingdom. However, it is expensive and needs to be stored in a refrigerator. Misoprostol is inexpensive and can be stored at room temperature. It has been widely used for induction of labor in cases of fetal death and second-trimester TOP for fetal anomaly. The combination of either gemeprost or misoprostol with mifepristone is most effective. With these regimens, over 90% of women abort within 24 hours and the mean induction-to-delivery interval is about 6 hours. Mifepristone is expensive and is not available in many countries. Therefore, PG analogue-only regimens can be the only option. These regimens are still effective, with a TOP rate above 90% in 48 hours; however, the induction-to-TOP interval (15 hr) is much longer. Intracervical tents can be used to shorten the induction-to-delivery interval.[171,172]

Instillation into the uterine cavity through the intra-amniotic or extra-amniotic routes of substances designed to kill the fetus and promote delivery (such as hypertonic saline, hyperosmolar urea, $PGF_{2\alpha}$, ethacride lactate) is obsolete.[170–172] A review by Ramsey and Owen[218] detailed the limited role of vaginal PGE_2 and intramuscular $PGF_{2\alpha}$ as well as high-dose oxytocin infusion for second-trimester TOP.

FETOCIDAL PROCEDURES

Use of medical TOP has been associated with live birth rates from 4% to 10%.[219] In borderline viable gestations, patients, physicians, and nurses express concern about the dilemma of resuscitation in the event of a live birth after a PG-induced TOP. Moreover, such live birth is beset with ethical, medical, and legal implications. Because of concern among patients, practitioners, and hospitals, many TOP services perform a fetocidal procedure prior to or concomitantly with PG-induced TOP at 20 weeks' gestation or more.

The most common fetocidal agents used in developed countries are potassium chloride (KCl) and digoxin.[220,221]

The procedure involves transabdominal insertion of a 20-gauge spinal needle into the fetal cardiac chambers by ultrasound guidance and instillation of 2 to 3 mL of KCl in a concentration of 2 mEq/mL. Cardiac standstill is usually observed within 1 to 3 minutes. An alternative is the instillation of digoxin in doses varying from 0.25 to 2 mg, by the intracardiac, intrathoracic, intrafetal, and intra-amniotic routes. There were no failures using a 1.0-mg intrafetal dose, but failures occurred with 0.5 mg for intra-amniotic (8.3%) and intrafetal administration (3.6%).[221]

CERVICAL PREPARATION
Physical Methods

Osmotic dilators can be useful before induction of labor (see earlier discussion). There has been a resurgence of interest in catheter-based techniques, specifically in relation to the concurrent use of extra-amniotic saline infusion and misoprostol. A variety of balloon catheter devices have been shown to be effective for cervical ripening.[218] Foley catheters with a 30-mL balloon are more commonly used in the United States. Extra-amniotic saline infusion (EASI) is an effective adjuvant to both mid-trimester and term labor inductions.[222] Using aseptic technique and countertraction, a lubricated 26-Fr Foley catheter with a 30- to 50-mL balloon is grasped with ring forceps and inserted through the internal os, after which the catheter balloon is inflated in the lower uterine segment. For the tightly closed, nulliparous cervix, a smaller-diameter catheter (e.g., 18 Fr) can also be used. Normal saline is infused through the catheter lumen at a nominal rate of 30 to 60 mL/hr, and traction is not used. Overall, EASI appears to be a safe and effective alternative to laminaria for mid-trimester cervical priming. Advantages of EASI include low cost, reversibility, and lack of systemic side effects. Although EASI and laminaria appear to be equally efficacious, EASI offers the potential advantageof easier placement and less patient discomfort.

Pharmacologic Cervical Ripening

Mifepristone (RU-486; Mifeprex) received FDA approval in the United States in September 2000. Mifepristone shortens the induction-to-delivery time and decreases pain with cervical ripening when compared with laminaria for second-trimester induction.[223,224] The value of intracervical tents in regimens using misoprostol is less clear.[225]

The World Health Organization (WHO) recommended that cervical preparation should precede all TOPs induced after 14 weeks.[226] Whenever possible, mifepristone should be used as the cervical-priming agent before second-trimester TOP. If mifepristone is not available, an intracervical tent should be used.

Prostaglandins and Their Analogues   PG receptors are present throughout all stages of pregnancy, and thus, PGs and their analogues are effective in terminating both first- and second-trimester pregnancy. The natural PGs, $PGF_{2\alpha}$ and PGE_2, were the first to be tested clinically for medical TOP, but they were soon replaced by synthetic PG analogues because of the high incidence of gastrointestinal side effects when given parenterally or vaginally.[170–173]

The PGE and PGF analogues have been used clinically for second-trimester TOP. The PGE analogue is preferable because it has a more selective action on the myometrium and causes less gastrointestinal side effects. The most extensively studied PGE and PGF analogues for second-trimester TOP are carboprost, meteneprost, sulprostone, gemeprost, and misoprostol.

Prostaglandin E_2 Analogues   Two PGE_2 analogues, dinoprostone (Prostin) and meteneprost (9-methylene PGE_2), are commercially available and have been investigated for midtrimester TOP. Of these, only Prostin is FDA-approved in the United States as an abortifacient in the mid-trimester and for fetal death up to 28 weeks' gestation. The recommended dosage regimen of Prostin for second-trimester termination is 20 mg administered as a vaginal suppository every 3 to 4 hours (maximal exposure 24 hr). In a series of midtrimester TOPs with vaginal PGE_2, 20 mg every 4 hours with osmotic dilators, the mean induction-to-delivery interval was 17 hours.[171,172] PGE_2 is not thermally stable and must be kept refrigerated. It has been widely investigated and has been proved effective for second-trimester TOP. However, intravaginal misoprostol was at least as effective as PGE_2 and without the cost and side effects associated with PGE_2 use.[105]

Prostaglandin $PGF_{2\alpha}$ Analogues   A synthetic $PGF_{2\alpha}$ analogue, carboprost tromethamine (15S)-15-methyl-$PGF_{2\alpha}$ tromethamine (Hemabate), is the only other commercially available PG that is FDA-approved and marketed in the United States as a mid-trimester abortifacient at 13 to 20 weeks' gestation. The recommended dosage regimen of carboprost for second-trimester TOP is 250 µg, administered by intramuscular injection every 1.5 to 3.5 hours (maximal exposure 12 mg or 48 hr). A test dose of 100 µg may be administered to confirm patient tolerance before administration of the full 250-µg dose. The successful TOP rate with intramuscular carboprost reached 80% to 90% in 36 hours, but it was associated with a high rate of gastrointestinal side effects.[171,172]

Prostaglandin E_1 Analogues   The three most extensively studied PGE analogues are sulprostone, gemeprost, and misoprostol. Sulprostone (16-phenoxy-(ω)-17–18,19,20-tetranor PGE_2, methyl sulphonylamide) was studied in the early 1980s for medical termination of second-trimester pregnancies. However, intramuscular sulprostone is no longer used clinically for medical TOP because of its association with myocardial infarction.[227] Therefore, gemeprost and misoprostol are the principal drugs used for second-trimester medical TOP today.

Gemeprost   Gemeprost (16,16-dimethyl trans-Δ^2 PGE_1 methyl ester) is a PGE_1 analogue. It is the only PG licensed in the United Kingdom for medical TOP. It is administered as a vaginal pessary. Studies using a vaginal gemeprost-only regimen gave a complete TOP rate of 80% to 96.5% in 48 hours.[228–231] The most common regimen is 1 mg every 3 to 6 hours for five doses in 24 hours. It is repeated if delivery does not occur in this time. The mean induction-to-delivery interval ranged from 14 to 18 hours. The most common side effects were vomiting, diarrhea, and fever. Cost and the need for refrigeration are the drawbacks with gemeprost; these factors make its use practical only in developed countries.

Misoprostol Misoprostol (15-deoxy-16-hydroxy-16-methyl PGE_1) is a synthetic PGE_1 analogue. It was discovered that it could be used "off-label" as an abortifacient. It is cheap, stable at room temperature, and readily available in many developing countries. Vaginal misoprostol is as effective as gemeprost.[229–231]

Studies mainly focus on the optimization of misoprostol dosing regimens by comparing various dosages, dosing intervals, and routes of administration.[232–237] The dosage of misoprostol used ranged from 100 to 800 μg with dosing intervals of 3 to 12 hours. The efficacy of misoprostol is improved when a higher dose (400–800 μg) is given at shorter intervals (3–4 hr) (Table 66–5). The vaginal route is more effective than the oral route.[236,238] The greater bioavailability of vaginal misoprostol probably explains the clinical results. Zieman and coworkers[126] compared the absorption kinetics of misoprostol with oral versus vaginal (400 μg) administration in pregnant women. It was shown that the systemic bioavailability of vaginally administered misoprostol is three times higher than that of the oral route. The plasma level was sustained up to 4 hours after vaginal administration. However, women preferred the oral route because it was less painful, gave more privacy, and was more convenient.[238]

A randomized study demonstrated that misoprostol 600 μg given vaginally, then 200 μg orally every 3 hours was probably the optimal regimen for second-trimester TOP.[239] A regimen that involves the administration of the first dose of misoprostol vaginally and subsequent doses orally might have a number of beneficial effects. It will minimize the number of vaginal examinations required to insert subsequent doses while preserving the possible direct cervical-priming effect of the first dose.

			87.3 (nullipara)	13.0	

PGE₂, prostaglandin E₂; TOP, termination of pregnancy,

Sublingual administration of misoprostol has also been developed. The sublingual route was chosen because it was considered as the most vascular area of the buccal cavity. It also avoids the first-pass effect through the liver in oral administration and the uncomfortable vaginal administration. Reports have shown that both sublingual and vaginal administrations of misoprostol were equally effective in inducing medical abortion during second trimester but the sublingual route was preferred by the patients.[240,241]

Mifepristone and Synthetic Prostaglandin Analogues

Mifepristone is the antiprogestin that is approved for use clinically for TOP. It increases the sensitivity of the uterus to PGs. The use of oral mifepristone 36 to 48 hours before PG administration can increase the successful TOP rate, shorten the induction-to-delivery interval, and reduce the total dose of PGs required (Table 66–6).[242–251] The first recommended dose of mifepristone was 600 mg, but it has been shown in a randomized trial that the successful TOP rate and induction-to-delivery interval were the same even if the dose was reduced to 200 mg.[248]

If mifepristone pretreatment is used before gemeprost (1 mg q6h), the induction-to-delivery interval can be decreased from 15.7 hours to 6.6 hours and the successful TOP rate in 24 hours is increased from 72% to 95% (see Table 66–6).[246]

To improve patient acceptability and to maintain the efficacy, a combination regimen including both the oral and the vaginal routes has been developed. El-Refaey and Templeton[247] compared two misoprostol regimens in women pretreated with 600 mg mifepristone for 36 to 48 hours. The first group received 800 μg vaginal misoprostol as the first dose and 400 μg vaginal misoprostol every 3 hours. The second group received 800 μg vaginal misoprostol as the first dose and 400 μg oral misoprostol every 3 hours. The mean induction-to-TOP interval was 6.0 and 6.7 hours, respectively. The 24-hour TOP rate was 97% in both groups (see Table 66–6). Ashok and Templeton[250] used mifepristone 200 mg followed by 800 μg vaginal misoprostol as the first dose and 400 μg oral misoprostol every 3 hours. They achieved 97% abortion rate; the median induction-to-abortion interval was 6.5 hours. Pretreatment with mifepristone significantly reduced the induction-to-TOP interval when compared with a misoprostol-only regimen. It was thought that vaginal misoprostol as the first dose could have a cervical priming effect.

Current evidence shows that the combination of oral mifepristone and vaginal misoprostol is an effective method for termination of second-trimester pregnancy. If mifepristone is not available, vaginal misoprostol alone can be used but the induction-to-TOP interval will be slightly longer.

USE OF PROSTAGLANDIN WITH A SCARRED UTERUS

With the rising cesarean delivery rate, an increasing number of women undergoing second-trimester TOP will have a previous uterine scar. No matter what method is used, the risk of uterine rupture is higher than for those without a scar. The reported risk of scar rupture at the time of medical termination in the presence of a previous uterine scar varies from 3.8%[252] to 4.3%.[253] This rate compares with a uterine rupture rate of 0.2% in patients with an intact uterus.[254,255] Uterine scar rupture has been reported with both gemeprost

TABLE 66-7

Induction Agents and Reported Adverse Effect (% Occurrence)

AGENT	INDUCTION-ABORTION INTERVAL (HR)	ADVERSE EFFECTS (%)	COMMENTS
Hypertonic saline	20–46	Fever, vomiting (5%–12%) Hemorrhage	Intra-amniotic injection; used with oxytocin augmentation
Oxytocin	8–13	Water intoxication (rare) Nausea and vomiting (less than with PGs)	Significantly fewer gastrointestinal side effects than prostaglandins (PGs) Requires intravenous infusion
$PGF_{2\alpha}$	14–37 (dose-dependent)	Incomplete abortion Hemorrhage Live-born fetus (rates higher than with saline) Nausea, vomiting, diarrhea (30%)	Intraamniotic instillation; most patients require oxytocin augmentation No longer available in United States in form used for induction Potent bronchoconstrictor
15-Methyl $PGF_{2\alpha}$	8–16	Vomiting, diarrhea, fever (2–3 episodes per patient)	Intramuscular (has also been used via intra-amniotic, extra-amniotic, vaginal routes)
Dinoprostone (PGE_2)	11–14 (6-7 hr with cervical ripening)	Fever, nausea, vomiting, diarrhea (most patients experience at least one side effect)	Vaginal suppositories Must be refrigerated
Sulprostone (PGE_2)	11	Vomiting (12%–46%) Diarrhea (6%–17%)	Given intramuscular or intravenously Not available in United States
Gemeprost (PGE_1)	15	Vomiting (1%–14%)	Vaginal pessary
+ mifepristone	6–8	Diarrhea (2%–20%)	Not available in United States
Misoprostol (PGE_1)	9–14	Vomiting (4%–10%)	Oral or vaginal routes
+ mifepristone	6–10	Diarrhea (4%–15%)	Inexpensive; no refrigeration required
+ laminaria	10–22		

PG, prostaglandin.

and misoprostol regimens with or without priming by mifepristone.[256–263] No well-controlled study has shown any method as being better than the others. All oxytocic agents should be used with caution in patients with previous cesarean deliveries. Women should be appropriately counseled about the risks and consequences, and practitioners should be prepared to deal with a rupture if and when it occurs. The optimum chance for successful outcome is provided by an informed and alert clinician who appreciates the potential risks of the procedure and who is prepared to deal with those risks.

SIDE EFFECTS AND COMPLICATIONS

Second-trimester TOP is a relatively safe procedure in countries where it is legal, accessible, and performed under modern medical conditions. However, both the patient and the practitioner must be aware of procedure- and medication-related side effects and complications, including acute medical events and potential long-term reproductive risks.

Side Effects of Prostaglandin-Induced Termination of Pregnancy

The use of PGs gemeprost and misoprostol, with or without mifepristone, is a safe and effective method for second-trimester TOP. Side effects including nausea, vomiting, and diarrhea are characteristics of PG administration and due to PG's stimulatory effect on the gastrointestinal tract. Diarrhea is more common in women using gemeprost, whereas fever is more common with misoprostol.[170,174] The advantages of using misoprostol for second-trimester TOP compared with

other PG agents are the relatively low incidence of reported side effects (Table 66–7). Side effects reported from the use of high-dose oxytocin regimens include nausea and vomiting. Prolonged usage may cause water intoxication. The suggested high-dose oxytocin regimen includes an alternating period of oxytocin infusion and a drug-free interval to allow for clearance of the oxytocin to avoid water intoxication.

Complications Associated with Medical Termination of Pregnancy

Complications common to most medical TOP include retained placenta and associated hemorrhage or infection, failed TOP, live birth, and serious complications such as uterine rupture.

Retained Placenta (Incomplete Abortion) Patients who underwent medical TOP compared with those who had D&E were more likely to have retained products of conception that required operative intervention (21% vs. 0.7%). Although patients who underwent medical TOP with misoprostol were less likely to have complications than patients who underwent medical TOP by other methods (22% vs. 55%), these patients still had more complications than surgical patients (22% vs. 4%). Patients who elect to undergo second-trimester medical abortion should be advised that they have a significant risk (21%) of requiring surgery for retained products of conception, because this knowledge may assist them in making an informed decision.[174]

Sixty percent of subjects passed the placenta spontaneously within 2 hours, with approximately two thirds of the expulsions occurring within the first 30 minutes. The rate of complications (hemorrhage and febrile morbidity) increased over time, reaching 4% at 30 minutes and 9% at 2 hours.[264] Retained tissues can lead to hemorrhage, infection, or both, and usually manifests itself within several days of the TOP. Cramping and bleeding can be accompanied by fever. If complete placental expulsion did not occur within 4 hours of fetal delivery, the placenta was removed manually or by forceps or curettage.[264,265]

Infection   During the second trimester, infection rates for both medical and surgical TOP methods have remained within the narrow range of 0.4% to 2.0% in North America and Great Britain.[172,174] Infection is usually associated with retained products of conception, but there are no data to analyze the incidence of infection separately in cases with or without retained tissue. Typically, signs and symptoms of post-TOP infection arise within the first 48 to 96 hours. The patient may present with pain, fever, and pelvic tenderness. The cervix should be cultured for sexually transmitted pathogens—*Neisseria* (gonorrhea) and *Chlamydia*. Established risk factors for post-TOP infection include age younger than 20 years, nulliparity, previous pelvic inflammatory disease, and presence of pathogens in the cervix at the time of TOP. The latter association has been reported with documented *Chlamydia* infection, gonorrhea, and bacterial vaginosis.[209] Most post-TOP infections, however, occur in women without these risk factors. Routine antibiotic prophylaxis may prevent up to half of all post-TOP infections in the United States and is highly cost-effective. Tetracyclines or nitroimidazoles (metronidazole or tinidazole) were equally efficacious for preventing infection.[208] Ascending genital tract infections are typically polymicrobial. Patients who present with post-TOP metritis should receive a full course of broad-spectrum antibiotic therapy. When retained tissue is evident or suspected, prompt evacuation is indicated.

Failure of Medical Termination of Pregnancy   *Failed induction* has been defined as a failure to achieve TOP within 24 to 48 hours and is a significant clinical problem. Management options include deferring TOP when membranes are intact for a predetermined time, aggressive cervical dilation with sequential laminaria application and another trial of induction, changing the induction agent used, or recommending D&E.

Uterine Rupture   Serious complications including uterine rupture, major hemorrhage, and cervical tear are rare.[172,174] Cases of uterine rupture were reported to occur with both gemeprost and misoprostol, and the use of mifepristone did not exclude the possibility.[261,262] The incidence of uterine rupture was estimated to be 0.2% in the second trimester. Risk factors for uterine rupture include previous cesarean delivery, grand multipara, advanced gestation, prolonged PG therapy, and use of oxytocin in addition to PGs.[261]

Live Birth   Second-trimester medical TOP with PG analogues has been associated with live birth rates of 4% to 10%.[175,219] Physicians should have a protocol to induce fetal

TABLE 66–8

Comparison of Complication Rates among Medical and Surgical TOP Study Subjects

COMPLICATION	MEDICAL (*n* = 158)	SURGICAL (*n* = 139)	*P* VALUE
Patients with any complication	45 ± 28.5	5 ± 3.6	<.001
Failed initial method	11 ± 7.0	0 ± 0	<.01
Hemorrhage with transfusion	1 ± 0.6	1 ± 0.7	NS
Infection with intravenous antibiotics	2 ± 1.3	0 ± 0	NS
Retained products of conception	33 ± 20.9	1 ± 0.7	<.001
Cervical laceration with repair	2 ± 1.3	3 ± 2.2	NS
Organ damage	2 ± 1.3	0 ± 0	NS
Hospital readmission	1 ± 0.6	1 ± 0.7	NS

NS, not significant; TOP, termination of pregnancy.

death (e.g., fetal intracardiac KCl or digoxin) before induction, and patients should be apprised of the risk for live birth and should understand the plan in advance.

Complications Associated with Dilation and Evacuation (Table 66–8)

Based on the data from the 1970s and 1980s, D&E is clearly safer than intra-amniotic instillation methods and hysterotomy or hysterectomy for second-trimester TOP through 16 weeks' gestation.[167,172,190–192] In these investigations, most of the specific complications associated with D&E occurred at rates well below 1%. A report by Autry and associates[174] confirmed both the low complication rate that is associated with D&E and its superiority over medical TOP. When skilled operators are available, D&E after cervical preparation with laminaria should be considered the preferred method for second-trimester TOP. Hence, the choice of TOP method at this later stage usually hinges on nonmedical considerations: cost, convenience, comfort, and compassion.

In challenging or difficult cases, careful assessment and choice of TOP method should be made to minimize complications. Intraoperative ultrasonography may be helpful in difficult cases.[188] Previous cesarean delivery scar does not seem to increase the perioperative risk of late termination (14–22 wk) by the laminaria and evacuation technique.[215]

Hemorrhage   Reported rates of hemorrhage vary widely, reflecting both diverse definitions and imprecise estimation of blood loss. Hemorrhage associated with TOP is not common and the Royal College of Obstetricians and Gynaecologists (RCOG) guideline group[169] reported this complication as 1.5 per 1000 TOPs overall. Factors associated with increased risk of uterine hemorrhage were operator

inexperience, advanced gestational age, advanced maternal age and parity, prior cesarean delivery, uterine fibroids, and past history of post-TOP or postpartum bleeding.[167,170] Hemorrhage associated with D&E may indicate cervical laceration, perforation, retained tissue, uterine atony, placental abnormalities, or coagulopathy. Advances in operative technique and use of uterotonic agents have resulted in reduction of both mean and median blood loss in North America.

Intraoperative use of oxytocin, ergots, and PGs reduces blood loss from uterine atony during D&E. Treatment of uterine atony includes manual uterine compression, oxytocin infusion, ergot derivatives, and PGs (15-methyl $PGF_{2\alpha}$, PGE_1).

Second-trimester TOP by D&E in the presence of placenta previa appears to be safe and apparently does not increase maternal morbidity compared with the outcome in patients without placenta previa undergoing the same procedure.[212] All placenta accreta patients had at least one cesarean delivery (mean 1.7), and prior to operation a sonogram demonstrating some form of placenta previa. The prevalence of clinical placenta accreta encountered during D&Es in the second trimester was 0.04%, the same as that reported for placenta accreta diagnosed clinically in the third trimester. Placenta accreta can be a potential complicating factor in the patient undergoing D&E in the second trimester.

Cervical Injury   The most common type of cervical injury is a superficial laceration caused by the tenaculum or Allis forceps tearing off during dilation. At the other extreme are the cervicovaginal fistula and the longitudinal laceration ascending to the level of the uterine vessels. Rates of cervical injury range from 0.01 to 1.6 per 100 suction curettage TOPs.[165,166]

Several risk factors for cervical injury during suction curettage have emerged. Among factors within the control of the physician, use of laminaria and performance of the TOP by an attending physician (rather than a resident) lower the risk significantly. Among factors beyond the control of the physician, a history of prior abortion lowers the risk, and age of 17 years or younger increases the risk. Use of laminaria and performance of the TOP under local anesthesia by an attending physician together yield a 27-fold protective effect.[167] Cervical preparation with misoprostol may confer similar benefits as laminaria, although more extensive experience will be needed to confirm this.

Perforation   Perforation is a potentially serious, but infrequent, complication of D&E. According to most reports, the incidence of perforation is about 0.2 per 100 suction curettage TOPs.[165,166]

Several risk factors for perforation exist. Performance of a curettage TOP by a resident rather than an attending physician increases the risk more than fivefold; conversely, cervical dilation by laminaria decreases the risk about fivefold. The risk of perforation increases significantly with advancing gestational age. Previous gynecologic surgery including TOP, cesarean delivery, and large loop excision of the transformation zone of the cervix (LLETZ) procedure is a risk factor for tearing of the internal os leading to perforation of the uterus during subsequent D&E procedures.[266]

Dilation of the cervix particularly for these "at-risk" procedures should be predominantly passive by the use of oral PGs such as misoprostol and osmotic dilators. The overall perforation rate was 0.029%.[267]

The use of real-time ultrasound scanning during D&E can reduce perforation rates. The routine intraoperative use of ultrasonographic imaging to guide intrauterine forceps during uterine evacuation for second-trimester TOP resulted in a significant reduction in uterine perforation, the rate declining from 1.4% to 0.2%.[193] These findings support the routine use of intraoperative ultrasonography for second-trimester TOP to reduce the incidence of uterine perforation and make the procedure a safer one.

The two principal dangers of perforation are hemorrhage and damage to the abdominal contents. Lateral perforations in the cervicoisthmic region are particularly hazardous because of the proximity of the uterine vessels. Perforations of the fundus are more likely to be innocuous. Many suspected or documented perforations require only observation. Perforation with a dilator or sound is unlikely to damage abdominal contents. Conversely, a suction cannula or forceps in the abdominal cavity can be devastating.

If the physician suspects a perforation, the procedure should stop immediately. If unmanageable hemorrhage, expanding hematoma, or injury to abdominal content occurs, prompt laparotomy is necessary. Laparoscopy can be useful in documenting perforation and assessing damage; if necessary, the physician can complete the abortion under laparoscopic visualization. Any woman with severe pain within hours after D&E should be evaluated for possible perforation with bowel injury.

ACUTE MEDICAL EVENTS

Acute medical events, such as vasovagal reaction, asthmatic reactions, amniotic fluid embolism, anaphylaxis, and seizures to anesthetic agents or laminaria, can occur at the time of TOP.[268–270] The safety of PG agents used for TOP has been established. Side effects are usually of a minor nature, although life-threatening complications can occur and include cardiac arrest.[271] This severity emphasizes the importance of medical supervision when the procedure is carried out.[247]

LONG-TERM REPRODUCTIVE RISKS

The bulk of evidence would suggest that D&E is a very safe procedure with few long-term problems. There is no proven association between D&E and subsequent fertility difficulty.[272] Second-trimester D&E is not a risk factor for mid-trimester pregnancy loss or spontaneous preterm birth. Preterm delivery in future gestations appears less likely when greater preoperative cervical dilation is achieved with laminaria, possibly because of a decrease in cervical trauma.[273–275] Published studies have not been prospective and have not been able to control for competing risk factors, such as smoking or exposure to STIs, that might overestimate the impact of induced TOP on poor reproductive outcome. Long-term complications associated with medical TOP in the second trimester using gemeprost and misoprostol with or without mifepristone are rarely reported.

Dysfunctional Labor

HARRY GEE

INTRODUCTION

It has long been recognized that dysfunctional labor leading to poor progress is associated with increased morbidity and mortality for both mother and fetus.[1] Parturition, though physiologic, places demands on the mother and fetus that may outstrip their ability to cope even under apparently normal circumstances. Not only does prolongation of labor expose underlying vulnerabilities, but harm can also arise directly from the underlying cause of delay. It is simplistic to think that accelerating progress, per se, will prevent such harm. A common theme running through currently popular interventions is that they speed up progress but fail to reduce the need for operative intervention. Poor progress is a sign of pathology rather than being, itself, pathologic. Ideally, its identification would result in a cause-specific treatment, but with our current knowledge and diagnostic ability, this is often not possible. Under these circumstances, it has been a pragmatic necessity to employ interventions on a trial-and-error basis—but such interventions should be validated by properly controlled clinical trials before being taken up into widespread use. Unfortunately, such prospective scrutiny has rarely been the case and only relatively recently have widely adopted interventions been examined—often with disappointing results. Failure to accept and acknowledge our lack of understanding has limited our ability to think laterally for solutions. As a result, our options for clinical management remain limited and often frustrating. Cesarean section rates continue to rise, and poor progress remains a major cause.[2]

This chapter provides a critical analysis of

- The physiology of labor.
- The methods for monitoring labor and their validity.
- The possible pathologies underlying poor progress.
- The effectiveness of interventions.
- The clinical options available.

THE ONSET AND DIAGNOSIS OF LABOR

Onset of Labor

In the human, no single trigger for the onset of labor has been identified. Figure 67–1 represents a possible mechanism. In the placental corticotropin model,[3,4] the appropriate endocrine environment for the onset of labor is set via the fetal pituitary-adrenal axis and the placenta. Rising fetal adrenal cortisol up-regulates the placental genes that produce more corticotropin stimulation, thereby setting in motion a positive feedback loop. Dehydroepiandrostenedione (DHEA) is a precursor for estriol production in the placenta, which creates the appropriate hormonal environment for labor in the mother. Further changes in placental function result in the generation of a number of pro-inflammatory agents (cytokines and interleukins), whereas the synthesis of prostaglandins and oxytocin integrates myometrial and cervical response.

Positive feedback systems promote change, not homeostasis. Once established, the feedback loop takes the uterus from a steady-state, pregnancy mode into active labor, which terminates only after delivery. Stimulating such a system carries a risk of hyperstimulation and uterine rupture if delivery is obstructed. This is particularly so in women who have labored before; although peculiarly, the uterus in a first labor tends to become inert in the face of obstruction. The reasons for this are not fully understood.

Efficient labor requires the coordination of myometrial activity and cervical ripening. Uterine contraction is the most easily observed and has, therefore, attracted the most attention—perhaps too much. Cervical function is much more subtle but no less important. The function of the cervix in pregnancy is to prevent delivery, and its collagenous composition with fibers wound tightly around the cervical canal are ideally suited to keeping the cervix tubular and closed. It is reasonable to propose that some instances of poor progress in the first stage of labor may be due to a lack of coordination between cervix and myometrium.[5] A cervix remaining in pregnancy mode will continue to resist dilation and delivery despite the myometrium going into labor mode with coordinated contractions.

The move from pregnancy to labor mode in the cervix is characterized by "ripening." The resultant increase in tissue compliance permits deformation. Effacement and formation of the lower segment are the initial manifestations of this, followed by dilation. In nulliparous women, these processes tend to be sequential, but in parous women, dilation may take place before effacement is complete. Either way, effacement redistributes tissue from the cervix to the lower segment and decreases cervical resistance.

MOTHER

FETUS

Myometrial activity

ACTH
FIGURE 67–1
A model for the initiation of labor.

Throughout pregnancy, the myometrium is spontaneously active, but before the onset of labor, contractions originating in any particular muscle cell or group of muscle cells are not propagated throughout the myometrium. Under the influence of estrogens and prostaglandins, spontaneous activity rises throughout gestation; in addition, gap junctions (nexuses) form between muscle cells.[6] These junctions provide preferential pathways for electrical activity to pass from cell to cell, producing a coordinated response from the myometrium. As coordination increases, contractility becomes sufficient to raise the intrauterine pressure (IUP) and Braxton Hicks contractions can be perceived. However, until they are strong enough to exert considerable tension on the uterine wall and cervix, and the cervix is ripe enough to stretch at least a little in response, they are usually relatively painless.

By the time of the onset of labor, oxytocin is already in high concentrations in the maternal circulation, and oxytocin receptors have developed on the membranes of smooth muscle cells. Thus, oxytocin is thought to facilitate labor rather than initiate it.[7]

Prostaglandins *potentiate* the action of oxytocin. Potentiation results in greater tone than would result from the simple additive effect of prostaglandin and oxytocin. Estrogens promote the production of prostaglandins in the decidua, which lies between the fetal membranes and the myometrium.[8] In addition, other agents, such as interleukins and cytokines, are involved in the inflammatory cascade[9] that characterizes labor. This is a one-way process that once started, goes to completion, stimulating the maternal positive feedback loop. This results in an exponential rise in uterine activity at the beginning of labor and a more gradual rise thereafter,[10] culminating in the second stage.

Many of the agents involved in the initiation of labor affect both cervix and myometrium with the net effect of creating the right local environment for labor to occur and progress efficiently, but they do so in different ways and over different timescales. Those affecting the cervix rely on biochemical remodeling of its constituents. This requires hours or days to take effect. Oxytocin is unusual in that its effect is almost specific to myometrial contractility and it acts rapidly (there are oxytocin receptors and a small amount of active smooth muscle in the cervix in labor,[11] but the effect of oxytocin on the cervix is minimal). Because cervix and myometrium may respond at different rates, it is reasonable to postulate that one may be in advance of the other. Thus, premature, pathologic cervical ripening may be a factor in preterm delivery, and conversely, establishment of uterine activity prior to cervical ripening will produce delay and slow cervical dilation.

Diagnosis of Labor

The diagnosis of labor is crucial because it brings with it intervention.

Two essential characteristics must be considered:
- The presence of regular uterine contractions, leading to:
- Progressive change in the cervix.

A subsidiary characteristic may be spontaneous rupture of the amniotic membranes.

Friedman,[12–14] whose graphic analysis of labor laid the foundations for current practice, based the diagnosis of labor on recognition of the onset of regular uterine contractions. Unfortunately, this is problematic because the onset of uterine activity is a smooth escalation that can take place over several days or, occasionally, longer. Precise delineation of a transition point between Braxton Hicks contractions and those leading to progressive dilation of the cervix has not been possible. Electromyography and other sophisticated methods of observation and analysis[15–17] can identify patterns of uterine activity that are characteristic of labor, but their superiority over simpler clinical methods to delineate contractions associated with cervical dilation remains to be proved.

FIGURE 67–2
Friedman's representation of cervical dilation in labor.
Thus, fundamentally, the diagnosis of progressive labor relies upon identifying changes in the cervix. Friedman used assessment of cervical dilation to divide the first stage of labor into latent and active phases (Fig. 67–2).

During the latent phase, the cervix is changing (primarily by effacement secondary to softening/ripening) but showing little dilation. The active phase is characterized by progressive cervical dilation. This is the process that is assessed regularly and used to monitor progress. The division between latent and active phases is not precise, and the latent phase often blends gradually into the active phase. Friedman's curves place the transition at 2 to 3 cm' dilation, but some would consider it to be as late as 4 cm[18] to ensure that the active phase has been entered.

Clinically, it makes good sense to restrict the diagnosis of labor to evidence of cervical dilation[19] because of the following points:

- Dilation is relatively easy to recognize and record (on a cervicogram).
- Currently accepted limits and interventions for labor apply predominantly to the active phase.

Other definitions of the onset of labor have been used for research purposes and will be found in the literature, for example, the time of admission to delivery suite.[20] This is an easily recorded and precise measure but is of little physiologic importance.

Management Options for the Diagnosis of Labor

Women are readily aware of their uterine activity. In particular, women in their first labors (though it can happen thereafter), not having experienced labor before, are prone to present as soon as regular contractions are perceived. When examined, however, it is common to find their cervices still uneffaced and/or undilated. They are often disappointed (and sometimes demoralized) to be told they are not in the active phase of labor.

The Management Options in such circumstances are

1. To diagnose labor (i.e., labor has started) and commence intrapartum care. However, premature commencement of intrapartum care with all that it entails runs the risk of misinterpreting the normal changes of early labor, resulting in unnecessary intervention.
2. To diagnose labor only when entry to the active phase has been established and progressive cervical dilation is demonstrable (usually beyond 3 cm dilation).

A clear explanation of what is happening and why patience is required should be given to the woman (and her partner/family). This requires a sympathetic approach and an understanding of the frustration that the woman often experiences. It is important to offer pain relief if this is needed, although simple measures such as warm baths and reassurance should be tried first.

It should be noted that, although regular uterine contractions with intact membranes and without evidence of progressive cervical dilation should probably not be classified as "labor," they are still associated with interruptions of the maternal intervillous blood supply and, therefore, represent a hypoxic challenge to the fetus. Thus, fetuses with poor reserve, such as those likely to be affected by uteroplacental insufficiency, should always be monitored carefully when there are contractions, even if there is no progressive cervical dilation.

LABOR MECHANISMS AND PROCESSES

Progress in labor results from the interaction of three factors:
- Powers.
- Passages.
- Passengers.

Powers

Efficient uterine activity is crucial to promote the formation of the birth canal and impart flexion and rotation to the passenger so that it can pass through the complex geometry of the canal.

In the first stage of labor, there is little change in uterine volume. Myometrial contractions are, to all intent and purpose, isometric (i.e., there is minimal shortening of the muscle fibers as they develop tension). Wall tension is required to dilate the cervix, but it is important that the muscle fibers do not shorten significantly at this stage because this would carry the risk of gradually but progressively compressing the blood vessels traversing the myometrium. This, in turn, would reduce placental perfusion continuously rather than the intermittent reduction and recovery associated with truly isometric contractions.[21]

Progress is determined by the equilibrium between force (myometrial contractions in the corpus) and resistance (lower segment and cervix). This is almost self-evident, but there is a more subtle effect. The "give" from a compliant cervix attenuates the tension generated by the myometrium.[22,23] Thus, a compliant cervix not only dilates quickly but does so with less uterine activity (as measured using changes in intra-amniotic pressure). An everyday paradox resulting from this is that multiparous women have faster rates of cervical dilation than nulliparous women but with lower levels of uterine activity.[24] Conversely, a noncompliant cervix will delay progress and may be associated with

high levels of uterine activity. Does the solution to dysfunctional labor lie with understanding the causes of these paradoxes rather than the conventional approach of simplistically applying more force?

Assessment of Uterine Activity

Four variables must be taken into account to assess uterine activity comprehensively. The first three are generated by the contractions themselves: amplitude, duration, and repetition frequency. Uterine activity can be quantified objectively by measurement of IUP. IUP is directly proportional to wall tension and indirectly proportional to uterine size. IUP monitoring is invasive, requiring insertion of either a fluid-filled catheter connected to an external transducer or a transducer-tipped catheter into the amniotic sac. This carries a small risk, from incorrect placement, abruption, uterine perforation, entanglement, and infection, although these risks are minimal with the modern designs of soft-tipped catheters. The fourth variable, basal pressure or *tone* is the product of resting muscular tone and elastic recoil of the uterus itself. External transducers can be "zeroed" against atmospheric pressure before commencing recording to give absolute values, but transducer-tipped catheters can record only relative pressure above baseline. In practice, the level of baseline tone does not contribute significantly to the rate of cervical dilation. It can, therefore, reasonably be ignored when assessing whether any particular level of uterine activity is likely to be associated with progressive cervical dilation. There are two pathologies which raise basal tone—abruption and hyperstimulation. Diagnosis of abruption depends on other clinical features, and hyperstimulation is better avoided by awareness of repetition frequency. There is an important circumstance when IUP monitoring can give false information. This occurs when attempting vaginal delivery after previous cesarean section.[25] If the scar is weak and stretches or gives way under tension, it will attenuate wall tension, thereby reducing IUP. If there is delay, this may be falsely attributed to suboptimal uterine activity.

IUP monitoring has never been shown in prospective, randomized trials to improve the management of labor. This is because the amplitude of contractions correlates with the palpable duration (most contractions become palpable only when the IUP exceeds baseline tone by more than 15 mm Hg) and overall activity is dependent in large part on repetition frequency. Thus, palpation of contractions with timing of duration and, particularly, frequency can give an adequate, albeit semiquantitative, assessment of uterine activity for most clinical purposes, including oxytocin augmentation.[26] In particular, avoiding excessive contraction frequency (universally considered to be greater than one contraction every 2 min on average, or five contractions in 10 min) is the best way to safeguard fetal oxygenation. However, contraction frequency is not always a reliable guide to amplitude (strength) of contractions, and manual palpation can also be misleading if the woman is obese (leads to underestimation) or has a low pain threshold (can lead to overestimation).

Management Options for Monitoring Uterine Activity

1. Palpation—remains the standard method of monitoring uterine activity for clinical purposes.

2. IUP monitoring—under specific circumstances:
   - Contractions are difficult to palpate, for example, in obese patients.
   - There is uncertainty as to whether augmentation of labor (e.g., with an oxytocin infusion) is producing appropriate increases in uterine activity.
   - Producing data for research purposes.

Medicolegally, it may be desirable to demonstrate close and accurate monitoring of uterine activity, for example, with induction or augmentation of labor in the presence of a uterine scar, in grand multiparas, or when the fetus is particularly at risk from uterine hyperstimulation (e.g., when there is evidence of uteroplacental insufficiency). However, no studies clearly demonstrate any advantages to IUP monitoring in these circumstances, and some would counsel against such use in case they provide a false sense of security. An equally valid management option is not to use an oxytocic at all in such cases, resorting instead to cesarean section if there is poor progress. This latter option is increasingly being chosen in modern practice and is probably the cause of at least part of the rising cesarean section rate.

Normal Range of Uterine Activity

If progressive cervical dilation is taking place, there is no need for a lower limit to be placed on acceptable uterine activity. Only when there is perceived delay in labor should the adequacy of uterine activity be questioned.

Uterine activity increases as labor progresses due to prostaglandin release from the decidua and secretion of oxytocin from the maternal posterior pituitary. Spontaneous uterine activity at the end of the first stage can be in excess of levels considered safe for induced or augmented labor[10,27] and repetition frequencies in excess of four contractions per 10 minutes can occur. At these rates, there is a risk that placental blood flow and fetal oxygenation can be compromised. This may not be deleterious to a healthy fetus, with good uteroplacental function when labor is progressing with the prospect of imminent delivery. The ability of the fetus to cope is a function of duration and degree of "stress" (or "duress"). Therefore, caution should be exercised when uterine activity is augmented for delay, because uteroplacental function can never be guaranteed and delivery may not be imminent. In these circumstances, augmentation of uterine activity to a repetition frequency of five contractions in 10 minutess, as recommended in some guidelines[18] may be cutting safety margins too fine.

Management Options

- If progress is within normal limits, uterine activity is not critical.
- A contraction frequency of three to four contractions every 10 minutes is optimal and provides a margin of safety; five in 10 minutes should be a maximum.
- Palpable contractions should last for minimum of 40 seconds.

Contractions occurring more frequently than five every 10 minutes with little or no relaxation constitute tachysystole.

Passages

The passages have often been equated solely with the bony pelvis, but the soft tissues are also important, including the cervix and lower segment in the first stage and the pelvic floor in the second stage.

Assessment of the Pelvis

Pathologically small pelvises are rare today in well-nourished populations. Childhood rickets used to be a relatively common cause of brim dystocia. If the fetal head could pass through the brim in such cases, it and the body would almost certainly traverse the rest of the pelvis. Hence, the importance obstetricians have traditionally given to "engagement." Thus, clinical and x-ray pelvimetry have poor predictive values.[28,29] More sophisticated imaging techniques, such as magnetic resonance imaging and computed tomography, coupled with ultrasound fetal biometry, have been used to improve diagnosis. This approach is logical, but further clinical research is required to establish their value.[30–33]

The shortcomings of pelvimetry, and the complex mechanism of labor with many interacting variables including flexion, rotation, molding, and even pelvic compliance, mean that clinicians have to fall back on "try it and see."

It should be noted that two out of three women who require a cesarean section for failure to progress in one labor go on to deliver normally the next time despite birth weight rising with parity. This suggests that absolute cephalopelvic disproportion is not a common cause for failure to progress.

Assessment of the Soft Tissues

The function of the cervix in pregnancy is to prevent delivery. Failure of the cervix to undergo its correct biophysical preparation may carry its pregnancy function through to labor. Abnormal connective tissue biochemistry has been demonstrated in association with poor progress.[34]

In the second stage of labor, the soft tissues of the pelvic floor help to induce the necessary rotational forces while, paradoxically at the same time, offering resistance to progress.

Measurement of the forces between the cervix and the fetal head has shown differences between progressive and delayed labor.[35–37] These data do not fit simple mechanical models, indicating that cervical dilation is a more complex process than mere stretching. Clinical application of these experimental techniques and the data they generate are awaited.

Clinical monitoring relies on the aggregate response of the cervix during labor. Digital estimation of cervical dilation is plotted against time (cervicography). This is a simple screening tool for deviation from a normal pattern, but because of the many variables that may be at play, it does not offer a diagnosis when progress is slow. It merely provides a sign associated with increased clinical risk.

Passengers

Birth weight within the normal range has poor predictive value for delivery complications. Figure 67–3 shows that

Duration of labor by birth weight. Data taken from 425,855 births with birth weight and duration of labor recorded in the North West region of London from 1988 to 2000.
there is some correlation of the duration of labor with birth weight, but the maximum variation over the extremes of birth weight is only 1.5 hours. The effects of flexion and rotation on the efficiency of the labor mechanisms are likely to be at least as important. The ability of the fetal head to mold is another important variable. Moreover, in terms of cephalopelvic disproportion, head size is not closely correlated with birth weight. For macrosomic fetuses, the main risk is shoulder dystocia. Unlike cephalopelvic disproportion, shoulder dystocia is not reliably predicted by cervical dilation rates in the first stage, and even the descent of the presenting part in the second stage can be normal.[38]

Only the extremes of birth weight have much significance in relation to mode of delivery. In recent U.K. practice, cesarean section was the mode of delivery in nearly 60% of pregnancies when the birth weight was less than 2.5 kg, and in 40% to 50% when the birth weight exceeded 5 kg (Fig. 67–4). However, there was relatively little variation in the use of cesarean section when the birth weight lay between 2.5 kg and 4 kg. In 513,381 births in the North West region of London between 1988 and 2000, this birth weight range accounted for 83.2% of all births. Thus, for the majority of babies, birth weight contributes little to the mode of delivery.

Some evidence suggests that birth weight is rising.[39] Even more important than the increasing mean birth weight is the increase in the proportion of babies weighing more than 4 kg, which in some European countries has now reached 30%. However, this increase in birth weight has to be viewed in the context of improved maternal nutrition and the general increase in maternal stature. Maternal obesity is increasing in many societies. This may influence birth weight and adversely affect the efficiency of labor itself.[40]

Assessment of Fetal Size

Even if birth weight was of crucial importance in determining progress in labor, birth weight can be predicted only to an accuracy of ±10% to 15% by ultrasound fetal biometry. The poor predictive value of these estimates means that they

FIGURE 67–4

Percentage of babies delivered by cesarean section, according to birth weight. Data taken from 513,381 births with birth weight and mode of delivery recorded in the North West region of London from 1988 to 2000.
have to be factored in very cautiously when planning delivery. They should be taken into consideration, however, when delay is apparent. Other clinical features of cephalopelvic disproportion that should be sought include excessive molding and failure of the presenting part to engage and descend. Generally speaking, it is reasonable to assume that pelvic capacity is adequate if a woman has delivered vaginally before, but birth weight increases with parity, and the increase may be substantial if the woman has developed gestational diabetes due to advancing maternal age. Therefore, it is wise to check previous birth weights and any features of the current pregnancy (such as glucose intolerance) that may indicate borderline disproportion. This baby may be just that bit too big.

Cephalic Presentation: Flexion/Deflexion

Flexion and deflexion of the head determines the part that will present. *Flexion* results in a vertex presentation, that part of the head bounded by the occiput, the posterior part of the anterior fontanel, and the biparietal eminences. This results in the smallest dimensions of the head presenting themselves to the birth canal (9.5 cm × 9.5 cm). Flexion is promoted by efficient powers—uterine contractions in the first stage and the addition of maternal pushing in the second.

Deflexion of the head produces first a brow presentation and, then, in complete deflexion, a face presentation. The dimensions of a brow presentation in a term fetus are such (13.5 cm anteroposterior) that they cannot be accommodated by a normal pelvis. Thus, the head remains high, progress of labor may become obstructed with a secondary arrest pattern, or if full dilation is reached, there may be failure of descent. Brow presentation should be considered when a multiparous patient, who has delivered normal-sized babies without a problem before, develops abnormalities of progress. Resorting to oxytocin augmentation without consideration of this possibility risks uterine rupture.

MANAGEMENT OPTIONS FOR DEFLEXION

- Judicious prevarication can be adopted to see whether there will be spontaneous flexion.
- If uterine activity is suboptimal, augmentation with oxytocin can be tried to encourage flexion. Time limits should be set for this to happen and for poor progress to resolve, for example, 2 hours. Careful fetal monitoring should be used throughout.
- Cesarean section is usually the only option if spontaneous resolution does not occur in association with poor progress.

Babies with a face presentation can deliver vaginally, but only under favorable circumstances. The mentum must rotate anteriorly. This allows the head to flex as it negotiates the curve in the birth canal. To do so with a mentum posterior requires even further deflexion, which is anatomically impossible. A good-sized pelvis and efficient powers are necessary to deliver a face presentation spontaneously. Forceps can be used to add traction in the second stage.

Position: Rotation

The vertex normally engages with the occiput in a lateral position. This allows congruence between the long axis of the head and the widest diameter of the brim of the pelvis from side to side. With descent, the lowest part (occiput) is forced forward by the levator ani muscles that form an inclined plane running from back to front. This occurs in the mid-pelvis, which when cut in cross-section presents a circular shape that is conducive to rotation. With the occiput anterior and the head flexed, it is now able to fit through the diamond-shaped pelvic outlet with matching of the long axes of the head and the outlet. The head negotiates the curve of the birth canal by gradually extending.

If the head rotates and maintains a posterior position (OP), there is a tendency to deflex and present a larger dimension to the birth canal. To follow the curve of the birth canal the head must flex further. This is anatomically difficult and unlikely to occur. In the first stage, an OP position may present with any pattern of delay.

MANAGEMENT OPTIONS FOR MALROTATION

- Wait in expectation of spontaneous resolution.
- Augment the powers with a view to encouraging flexion and rotation.
- Perform cesarean section if neither of these produces progress.

If augmentation is undertaken, its potential dangers have to be acknowledged and safeguards employed, meaning continuous electronic fetal monitoring and timely reviews, particularly in a multiparous woman if progress is arrested.

Delay in the second stage while having similar factors can be addressed by instrumentation. This is discussed in Chapter 72.

CLINICAL ASPECTS OF MANAGEMENT OF LABOR

If a woman delivers vaginally the first time, she is much more likely to do so in the future. Thus, good management of the

first labor is crucial and has a bearing on the rest of her reproductive potential.

MANAGEMENT OF THE FIRST STAGE OF LABOR

Active Management

Active management of labor carries a number of connotations and has been the subject of controversy since the early 1970s. In its broadest sense, it marked a change in philosophy from reacting to prolonged labor, diagnosed retrospectively after time had elapsed, to prospective monitoring of labor to detect delay early and instigate management.[41] As noted earlier, management should be based on a precise diagnosis, but this is often lacking. Thus, a more pragmatic approach emerged whereby prospective detection of departure from normal progress was automatically managed by augmenting the powers to accelerate progress because this was the only variable open to manipulation by the clinician.[19,42]

The Partogram

Figure 67–5 is a chart that represents the essential variables for monitoring both mother and fetus during labor. Graphic representation of data is useful because trends are important. The three sets of data relate to maternal signs, fetal signs, and progress of labor. Studies on the effectiveness of partograms have concentrated on the cervicogram component.[43,44] This is addressed later.

Maternal Signs

Maternal data comprise vital signs (pulse, blood pressure, temperature), urinalysis, and medical treatment (analgesia, uterotonics).

Fetal Signs

Fetal data comprise fetal heart rate, state of the membranes, color of the liquor, and descent and position of the presenting part.

Progress of Labor

THE CERVICOGRAM

The cervicogram is a component part of the partogram and, by definition, relates to the first stage. It represents, graphically, cervical dilation over time from the diagnosis of established labor. In practice, this applies only to the active phase. Because the usual concern is detection of delay, setting the lower limit of progress has been the focus of attention. Spontaneous, precipitate labor has been associated with risk, but this comes mainly from unexpected delivery rather than from the brevity of the process per se (although there is a reported increase in the incidence of Erb's palsy with precipitate labor—see Chapter 68).

DIAGNOSIS OF DELAY OR ABERRANCE

Friedman selected 200 nulliparous women, retrospectively, from a larger heterogeneous group of patients[13] and a similar cohort of parous women[14] to identify "ideal" labor, namely,

no iatrogenic interventions (apart from "prophylactic low forceps"), vaginal deliveries, and average-sized, healthy neonates. These patients' labor curves were analyzed to identify statistical limits as means and standard deviations.

From these data, a lower limit of maximum slope of dilation was produced. The value of 1 cm/hr has now become almost universally accepted for clinical practice. However, this rate may be an overestimate for the following reasons:

- The statistical analysis is questionable. The data were not normally distributed, having a distribution skewed toward higher rates of dilation.
- Most clinicians use an average of 1 cm/hr for the whole of the active phase and not just the phase of maximum slope.

Better statistical analysis of progress in normal labor (Fig. 67–6)[45] shows lower rates of dilation in the early part of the active phase and no inflection points at the end of the phase of maximum slope. This pattern of progress is likely to be a better reflection of physiology, but is harder to apply to practice and needs more clinical evaluation.

Several cervicograms have been produced for clinical use. Hendricks and coworkers[46] produced similar patterns of dilation but chose the slowest 20% as the statistical divide. Philpott and Castle,[47] in a southern African population, produced data from an unspecified number of cases that represented the slowest 10% of primigravidas. They demonstrated a marked difference in the rate of maximum slope compared with Friedman's data (median 1.25 cm/hr vs. 2.75 cm/hr, respectively), suggesting that there may be significant population differences. They introduced the concept of an alert line followed 4 hours later by an action line.[48] This interval has been changed by other researchers, often without clear reason or benefit. It arbitrarily alters the sensitivity and specificity. Beazley and Kurjak[49] used a "low risk" population to produce a cervicogram whose limits differentiate progress above the line, resulting in an 80% chance of a favorable outcome, compared with only a 20% chance below it. This cervicogram acknowledges differing limits for nulliparous and parous women. Studd[50] devised a cervicogram from a multiracial population in the United Kingdom having "normal" labor. An S-shaped dilation curve was produced, with the steepest gradient between 4 cm and full dilation. The statistical methodology used to produce these curves was not specified, nor were the biologic limits.

All these cervicograms, in their various ways, attempt to define a boundary that can be used to define slow progress. However, they have been devised using data from specific populations with individual characteristics, and therefore, they may not be generalizable. As they all differ, it is unlikely that they can be used reliably without prospectively testing their clinical predictive value for any particular group. For example, it seems unlikely that the same cervicogram would be applicable to a black African population with their high assimilation pelvises and high obstructed labor rates, compared with white Scandinavians with their wide pelvises and low cesarean section rates.

Using data from later papers, the positive predictive value for operative delivery from an alert line set at 1 cm/hr gradient and an action line 2 hours later (values that are widely used today in the developed world) is only 43%. Use of standard cervicogram limits for the multiethnic populations of many of today's major cities seems unlikely

to be adequate. Meta-analysis of randomized trials of the cervimetric component of partograms shows that they do not, in themselves, reduce cesarean section rates and action lines set 4 hours behind the 1 cm/hr alert line, as recommended by the World Health Organization (WHO),[51] are advised to avoid unnecessary intervention.[43,44]

Thus, cervicograms should be used only as an aid to the management of labor and not as a substitute for appropriate diagnosis. Transgression of a lower limit of progress does not indicate any particular course of action but should simply raise awareness of increasing risk, indicating the need to look for a cause.

Reanalysis of progress in nulliparous labor. (Data from Friedman FA: Cervimetry—An objective method for the study of cervical dilation in labor. SUMMARY OF MANAGEMENT OPTIONS
Conduct of Normal Labor

Management Options	Evidence Quality and Recommendation	References
Use of a partogram facilitates the management of labor.	III/B	51
The cervicogram component of the partogram does not, in itself, improve the outcome of labor. It should be used only to identify delay.	Ia/A	44
The package of • Precise diagnosis of labor (active phase). • Early amniotomy. • Regular monitoring of cervical dilation rate. • Correction of poor dilation with the empirical augmentation of uterine activity limits prolonged labor.	III/B	19
Compared with active management, a policy of no routine amniotomy and selective use of oxytocin does not adversely affect cesarean section rates or neonatal outcome.	Ia, Ib/A	67–72
Support in labor reduces operative delivery rate.	Ia/A	73

Poor Progress

Friedman and Sachtleben[52] described three patterns of aberrance from normal labor (Fig. 67–7):
• Prolonged latent phase (PLP).
• Primary dysfunctional labor (PDL).
• Secondary arrest (SA).

None of these patterns is pathognomonic of a particular pathology. They are signs of pathology, not diagnoses.

Prolonged Latent Phase

Friedman and Sachtleben[52] described the latent phase, from the onset of contractions to entry to the active phase of dilation, as lasting up to 20 hours in nulliparas (mean 8.6 hr, standard deviation [SD] 6 hr) and 14 hours in parous women (mean 5.3 hours, SD 4.1 hr). The difficulties with defining the start and end of this phase have already been discussed. Thus, the true incidence of PLP is difficult to determine, but it is less common in parous women.

The causes of this pattern of delay are uncertain, but it is probably due to delayed cervical ripening. Myometrial activity and cervical ripening are out of synchrony (see Fig 67–1).

MANAGEMENT OPTIONS

1. Conservative management: from a practical point of view, and all else being equal, reassurance for the mother, analgesia, and time are often all that is necessary to allow cervical synchrony with that of the myometrium.

FIGURE 67–7
Patterns of delay.
2. Augmentation of the powers to accelerate progress: this is not beneficial[20,53,54] and illogical. Such augmented labors exhibit a 10-fold increase in cesarean section rates compared with normal labors, with a threefold increase in low Apgar scores in the neonates.

Primary Dysfunctional Labor

Primary dysfunctional labor is defined as progress slower than 1 cm/hr during the active phase slope with an incidence of 26% in nulliparas and 8% in parous women.[53] About 80% of nulliparas and 90% of parous women will respond to oxytocin, suggesting that poor uterine activity is a significant factor. The only randomized clinical trial to test early versus delayed augmentation[55] shows that early use of oxytocin for this condition shortens labor and may reduce the need for instrumental delivery in the second stage but does not affect the cesarean section rate. Five percent of augmented labors do not respond in terms of increasing their uterine activity or rates of progress, and these nonresponsive labors are associated with cesarean section rates of 77%. Conversely, 23% still achieve a vaginal delivery,[20] so even apparent failure of response cannot be seen as an automatic indication for cesarean section. This paradox should raise questions about the cause and the validity of our definition of abnormality. Mechanical factors can be postulated (particularly malposition, malrotation and deflexion, and slow molding of the fetal head), which correct themselves in time, but sound evidence for a single causal effect is hard to find. Other possibilities have not been extensively studied. Abnormalities of cervical mechanics and biochemical preparation have been documented[34] and merit further study.

MANAGEMENT OPTIONS

1. If uterine activity is suboptimal, correct with oxytocin.
2. If uterine activity is optimal, check for
   - Malposition.
   - Malpresentation.
   - Cephalopelvic disproportion.
   - Combination of these.
   - None of these may be apparent. A decision then has to be made as to whether to do nothing in anticipation of spontaneous resolution or to use oxytocin judiciously, recognizing its accompanying

risks and employing close monitoring and frequent review.

Secondary Arrest

Secondary arrest can be identified by cessation of progress after normal active phase dilation. Incidences of 6% in nulliparas and 2% in parous women have been reported.[56] A subtle variant of secondary arrest is delay between 7 and 10 cm. Even though full dilation may be achieved, there is an increased risk of difficult instrumental delivery.[57]

Of the three patterns of arrest, SA has the most convincing link with etiology, namely disproportion and malposition. This is understandable because normal early progress suggests the powers are adequate and the cervix compliant. Although in one series, 60% of nulliparas and 70% of parous women showed improved progress with augmentation of contractions, cesarean section rates were over 10-fold greater than in normal labor.[20] The effect of uterine stimulation may be to encourage flexion and rotation of the head, promoting descent and progress. However, well-conducted randomized clinical trials are awaited.

MANAGEMENT OPTIONS

1. Uterine activity should be checked. Correct if suboptimal.
2. Uterine activity may already be optimal. Therefore, check for:
   - Malposition.
   - Malpresentation.
   - Cephalopelvic disproportion.
   - Combination of these.
   - None of these.
   2a. Do nothing in anticipation of spontaneous resolution.
   2b. Judicious use of oxytocin, recognizing the risks.
   2c. Delivery by cesarean section.

Most would opt for 2b and then 2c if no response/progress occurs.

Practice Point

Whatever the pattern of delay, identification of a clear, single etiologic factor is unlikely. This may be due to complex interactions between multiple factors, an inability to detect the contributory factor because the diagnostic tools are imprecise, lack of knowledge of other factors, or finally a combination of all three. Treatment is more likely to be successful when a diagnosis of a single pathologic process is possible. Augmentation of the powers may be the only intervention available, and the "do nothing" arm of clinical trials has been woefully absent, leaving this option surrounded with uncertainty.

Thus, the obstetrician faced with evidence of delay should be conversant with the options available and be prepared to balance the risks and benefits of any intervention to be employed.

Interventions

Amniotomy

It is commonly stated that amniotomy increases uterine activity, although the evidence for this is weak, and there are good reasons to keep the membranes intact. For example,

more fetal heart rate decelerations have been noted following amniotomy. Randomized clinical trials of routine amniotomy show that surgical intervention is not reduced, and there are no major benefits for the neonate,[58–61] though labor may be shortened. If there is poor progress with intact membranes and uterine activity is thought to be suboptimal, a case for amniotomy can be made, but even this has been called into question by a meta-analysis of trials to date.[62] Amniotomy has also been advocated to allow early detection of meconium as an aid to the assessment of fetal well-being and, therefore, may sometimes be useful if the fetal heart rate pattern is non-reassuring. In summary, all other features of labor being normal, there is no clinical benefit from routine amniotomy.

Oxytocin Augmentation

When oxytocin became readily available for clinical use in the 1960s, obstetricians were given some degree of control over one of the three variables that determine progress, namely the powers. As already stated, the powers also indirectly influence flexion and rotation of the passenger.

Oxytocin is a polypeptide hormone secreted from the posterior pituitary of both mother and fetus. The half-life of oxytocin is only 5 to 7 minutes. Therefore, its effect can be removed rapidly merely by stopping the infusion.

Binding of oxytocin to its receptor[63] opens calcium-activated channels (Fig. 67–8) and results in membrane depolarization.[7] This, in turn, opens voltage-dependent channels, producing a rise in intracellular calcium that generates tension in the contractile filaments. The primary effect is to increase the frequency of contractions, with a second effect of slowing conduction and recruiting more cells per contraction. This is beneficial when the myometrium shows "incoordinate" activity. The combined result is increased duration and amplitude. From the standpoint of clinical management, palpation of frequency and duration is a logical and simple means of monitoring oxytocin's effect.[26]

Both of these effects are beneficial when the myometrium is hypotonic, but addition of oxytocin to an already optimally acting myometrium frequently induces hypertonus, with resulting fetal hypoxia (Fig. 67–9). Careful monitoring of uterine activity is essential and infusion rates may have to be reduced as labor proceeds. Titration of dosage against

uterine activity should be performed using regimens that allow time for activity to become stabilized between increments. An interval of 30 minutes between increments is recommended.[18] Published protocols generally recommend a starting dose of 1 to 6 mU/min; in current practice, 1 to 2 mU/min is usually used. Geometrically increasing regimens (e.g., 1, 2, 4, 8, 16, 32 mU/min) reach effective doses more quickly but are more prone to cause hyperstimulation and have, therefore, generally been replaced by arithmetic increases (e.g., 1, 2, 4, 6, 8, 10, 12 mU/min). The majority of women will respond to dose rates of 8 mU/min, and few will need more than 16 mU/min.

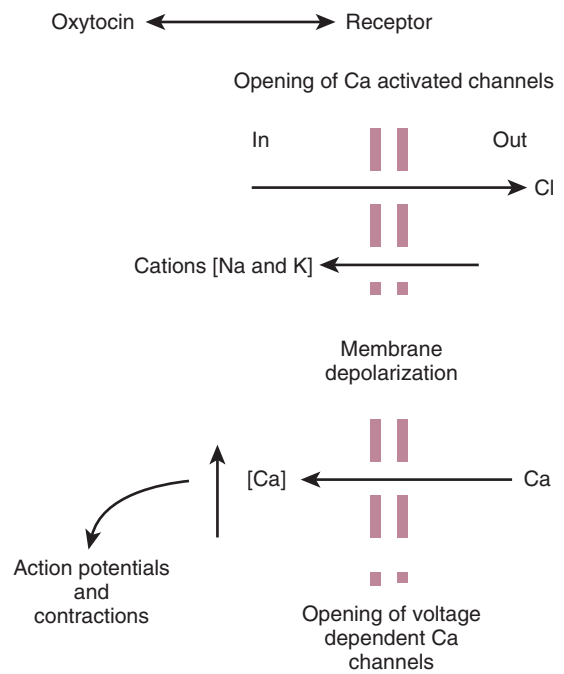
When oxytocin is used in labor, it must be maintained for the third stage and for an hour thereafter to reduce the risk of uterine atony and postpartum hemorrhage.


FIGURE 67–8
Action of oxytocin.
FIGURE 67–9
Hyperstimulation due to oxytocin showing the effect on fetal heart rate. Note the frequent small-amplitude contractions and rise in basal tone.

Postpartum hemorrhage is also associated with prolonged labor.

Meta-analysis of clinical trials of oxytocin augmentation show an increase in the parturient's subjective experience of pain and some increase in the rate of cervical dilation but little or no reduction in cesarean section and instrumental delivery rates.[64]

Epidural Analgesia

Epidural analgesia does not affect progress in the first stage of labor nor increase cesarean section rates. Second stages are longer and instrumental delivery more likely.[65]

Packaged Labor Management

In 1969, a report was published from the National Maternity Hospital, Dublin,[19] describing low cesarean section rates in a cohort of 1000 nulliparous women using a package of care that included

1. Correct diagnosis of labor.
2. Routine amniotomy.
3. Regular, frequent cervical assessment.
4. Augmentation of the powers with intravenous oxytocin if slow active phase progress was detected.

The regimen permitted one-to-one midwifery care because patients either progressed normally, responded to augmentation, or underwent cesarean section if they did not progress—all within a matter of 8 to 12 hours from admission. The simplicity of this approach and the reported low cesarean rate appealed to many clinicians, and still does.

However, the same results could not be replicated elsewhere, and concerns grew over rising cesarean section rates[66] for failure to progress despite the apparent adoption of this philosophy. Moreover, meta-analysis of the individual components of this approach has revealed that the proposed medical interventions are not effective, individually, in reducing operative intervention.[64] Thus, randomized clinical trials were eventually undertaken. They demonstrate interesting points for evidence-based practice. One showed a decrease in cesarean section associated with the adoption of "active management" from the rate prior to the study, but there was also a decreased rate in the control arm.[67] This was almost certainly a Hawthorne effect (simply by doing the trial and focusing participants' minds on the management issues produced an effect). The end result was not statistically significant. This may explain why earlier uncontrolled studies gave overoptimistic results. The largest study did not show any improvement in surgical delivery rates, though there was a reduction in maternal postnatal pyrexia.[68] These two studies started with relatively high cesarean section rates, in the region of 20%. Early studies reported the use of oxytocin in up to 50% of nulliparas.[19,69] Thus, a third study aimed to test whether relaxation of the indications to augment uterine activity would result in an increased cesarean section rate.[70] This study reported cesarean section rates of 3.9% in the active management arm compared with 2.6% in the "selective use" arm and spontaneous vaginal delivery rates of 78% and 79%, respectively. A study of the promptness with which oxytocin is used (crossing an action line set at 2 or 4 hr after the alert line) did indicate that there was a reduction in cesarean section

rate (relative risk [RR] 0.68) using the more aggressive approach.[69] This trial, though showing benefit, had to be curtailed, and there were protocol violations in the aggressive arm of the study.

Meta-analyses have been performed on clinical studies of active management. One analysis combined controlled and uncontrolled trials and concluded that there is reduced operative intervention.[71] Care must be exercised when combining such heterogeneous data. Meta-analysis of only the randomized trials fails to show any benefit. A more recent systematic review and meta-analysis of only randomized trials concluded that there are a few benefits from such packages,[72] but this conclusion could be reached only after exclusion of the largest randomized trial[68] on grounds of suspected bias from postrandomization drop-out. Other trials in the analysis also show weaknesses in study design but were retained. Furthermore, the studies varied in the component parts of the packages they used. This raises questions about the appropriateness of meta-analyses when combining the results of complex and differing packages of care. Unfortunately, even if the results are accepted from these reviews, the clinician cannot determine which elements of the package are of value and which may be useless or even dangerous. Clinicians must be aware of the limitations of meta-analyses and should not automatically accept them as the highest level of evidence. They may be better advised to evaluate the original studies themselves to judge relevance to their own practice.

The bottom line of these packages of care is that, at best, their clinical impact is marginal and, at their worst, they contain components that have been discredited.

Maternal Preparation and Support

Clinical benefit from supportive care has been demonstrated,[64,73] but this element is often undervalued and overshadowed by medical interventions. Patient confidence and a feeling of control are improved in association with a reduction in the need for pain relief and a lower incidence of cesarean section and operative vaginal delivery. The identity and qualifications of the person providing the support appears to be less important. Some studies have employed nonclinical but trained lay supporters (doulas).

Summary

Interventions demonstrated to be effective are antenatal education and preparation of the mother, personal support during labor, and correct diagnosis of labor (active phase).

MANAGEMENT OF THE SECOND STAGE OF LABOR

The second stage of labor starts at full dilation of the cervix and ends with delivery of the fetus. Descent and rotation of the passenger are the main features. Without epidural analgesia, full dilation of the cervix usually becomes apparent because of an urge to push due to the descent of the presenting part onto the pelvic floor. Epidural analgesia may abolish this sensation completely. Thus, there may be no outward signs of entry to the second stage, and diagnosis

will only follow vaginal examination. The diagnosis and, therefore, the duration of second stage have become controversial.

Physiology of the Second Stage

Maternal Changes

Cervical resistance in the first stage of labor is necessary for the generation of wall tension that is, to all intent and purpose, isometric, that is to say, tension generated without shortening of the muscle fibers. At full dilation of the cervix, the uterus ceases to be a "closed vessel," cervical resistance is lost, and descent through the birth canal begins. Myometrial activity progressively changes toward isotonic activity as the uterus empties. Reduction in uterine volume permits permanent shortening (retraction) of the myometrial fibers. This effect is maximal during the third stage, and by the end of the third stage, it is crucial for effective hemostasis. It is potentially dangerous in the second stage because it progressively impairs placental perfusion.

The myometrium is "inserted" into the pelvis via the connective tissues that surround the cervix, with the round ligaments helping to tether and direct the uterine fundus. These connective tissue supports are elastic. If the force required to stretch them is greater than the resistance offered by the birth canal, there will be progress. The rate of progress will be determined by the equilibrium established between the elasticity of the supports and the resistance offered by the birth canal. Frank obstruction to progress from the bony pelvis will merely direct all force to stretching the cervical supports against this resistance. Descent can occur without maternal bearing down ("pushing"), but there is little evidence (other than anecdotal, e.g., spontaneous delivery in paraplegic women) to show that delivery can be achieved entirely without the voluntary use of the abdominal muscles to raise intra-abdominal pressure, thus increasing the expulsive forces. Pushing increases maternal effort and interferes with breathing, inducing both respiratory and metabolic acidosis.

Fetal Changes

Studies on the acid-base balance in the fetus in the second stage show a decline in pH and a rise in lactate as pushing and descent progress.[74–76] To a degree, this is physiologic, and the metabolic changes will stimulate the neonate to breathe spontaneously. Too much acidosis, however, results in respiratory depression.

Divisions of the Second Stage

It is useful to split the second stage into passive and active sections, depending on whether pushing has commenced.[74]

Passive Section

In the passive section, prior to pushing, there is likely to be little descent to alter the character of myometrial activity, and the mother is not affecting her metabolic state by pushing. Thus, there is minimal effect on the fetus.[74] There does not appear to be a significant risk from waiting at this point prior to pushing, all else being equal. However, there does not appear to be any benefit, either.[77] Thus, when to commence pushing continues to be debated but is probably irrelevant to outcome, providing the fetus is in good condition.[78]

Active Section

The active section commences with pushing. From this point onward, the metabolic changes in the fetus described earlier begin and progress. Descent and rotation of the presenting part should be progressive, irrespective of the presence or not of an epidural anesthetic.

Monitoring Progress

Descent

Descent is monitored and represented on the partogram in two ways: abdominally by the amount of head palpable (usually in fifths) and vaginally, as the station, estimated in terms of the level of the lowest point of the presenting part in relation to the ischial spines. A second stage nomogram has also been produced.[79]

Friedman and Sachtleben[80] described progress in terms of the number of expulsive efforts the mother makes; more commonly, time alone is used as the criterion. The former is more physiologic, the latter is easier. If contractions are occurring with the usual frequency of three to four every 10 minutes, the two are the same. No robust clinical trials have been conducted concerning the optimal duration for pushing. Traditional limits of 30 minutes for parous and 45 minutes for nulliparous women have been used and maximum of 1 hour without progress has been recommended.[18] These times may seem a little short, but it should be remembered that if the woman has not delivered by this time, it can take a further 20 to 30 minutes to prepare for, and carry out, instrumental delivery. Recently, national guidelines in the United Kingdom from the National Institute for Health and Clinical Excellence (NICE) have suggested limits of 1 and 2 hours, respectively.[18] These limits are probably reasonable so long as fetal monitoring is reassuring about fetal condition, and so long as they include the time taken to perform instrumental delivery.

Rotation

Rotation is determined by vaginal examination and palpation of the sutures and fontanels on the fetal head in relation to the maternal pelvis. Scalp edema (caput), which often develops with delay, may make this difficult.

Interventions

Augmentation of the Powers

As with the first stage, efficient powers are paramount. Uterine inertia is not uncommon at full dilation when epidural analgesia is used, owing to the abolition of the reflex release of maternal oxytocin produced by the sensation of stretching of the introitus and perineum (Ferguson's reflex). Intravenous oxytocin may be required to restore uterine activity. If it is used, care should be taken to avoid overstimulation, and continuous fetal heart rate monitoring is mandatory. If the fetal head is well down, operative delivery may be a safer option.

Use of the mother's abdominal muscles to raise intra-abdominal pressure is important. Efficient pushing requires education and encouragement, particularly when epidural analgesia has removed sensation.

Maternal Posture

An upright posture of the mother reduces both the duration of the second stage and the incidence of operative delivery.[81] There are also reductions in the use of episiotomy, perception of pain, and fetal heart rate abnormalities. Maternal posture does not appear to affect malposition. Avoidance of the supine position is beneficial for the acid-base status of the fetus in the second stage.[82]

Instrumental Delivery

Instrumentation is used to shorten the second stage, either when prolonged or to avoid fetal or maternal complications. This is discussed in Chapter 72.

Episiotomy

Episiotomy is surgical reduction of resistance offered by the pelvic floor. There is no benefit from routine episiotomy.[83] Mediolateral episiotomies direct any tearing away from the rectum and anus, resulting in fewer third-degree tears, but cause more bleeding than those in the midline. They also cause more discomfort in the puerperium.

SUMMARY OF MANAGEMENT OPTIONS
Poor Progress in Labor

Management Options	Evidence Quality and Recommendation	References
Poor Progress in Latent Phase of First Stage		
Expectant management with careful watch of the fetal heart rate.	III/B	20,53,54
Augmentation may increase cesarean section rates.	III/B	20,53,54
Poor Progress in Active Phase of First Stage		
Allowing 4 hr of grace after crossing the "alert" line reduces need for augmentation and cesarean section.	Ia/A	43,44
Judicious augmentation with Syntocinon will reduce labor duration.	Ib/A	55
Studies favor 30-min incremental intervals when increasing oxytocin infusion rates.	Ib/A	64
Obstetric outcome for most cases is no better with the use of intrauterine pressure catheters, compared with the use of external methods of detecting contraction frequency.	Ib/A	26
Epidural analgesia is not associated with prolongation of the first stage of labor nor with an increase in cesarean section rates.	Ia/A	65
Poor Progress in the Second Stage of Labor		
Flexibility in the duration of the second stage is permissible if fetal condition is reassuring.	—/GPP	—
Upright posture of the mother reduces the duration of the second stage and need for operative delivery. It also reduces the need for episiotomy, perception of pain, and fetal heart rate abnormalities.	Ia/A	81
Epidural analgesia is associated with longer duration of the second stage and an increase in instrumental delivery rates.	Ia/A	65
Use of episiotomy should be limited and selective.	Ia/A	83

Shoulder Dystocia

ROBERT B. GHERMAN

INTRODUCTION

Despite its infrequent occurrence (0.2%–3% of all deliveries[1,2]), all health care providers attending vaginal deliveries must be prepared to handle this unpredictable obstetric emergency. Shoulder dystocia represents the failure of delivery of the fetal shoulder(s), whether it be the anterior, posterior, or both fetal shoulders.[3] Shoulder dystocia results from a size discrepancy between the fetal shoulders and the pelvic inlet, which may be absolute or relative (due to malposition). A persistent anterior-posterior location of the fetal shoulders at the pelvic brim occurs when there is increased resistance between the fetal skin and the vaginal walls (e.g., with macrosomia), with a large fetal chest relative to the biparietal diameter, and when truncal rotation does not occur (e.g., precipitous labor).[1] Shoulder dystocia can also occur from impaction of the posterior fetal shoulder on the maternal sacral promontory.

DEFINITION

Most authors have defined this obstetric emergency to include those deliveries requiring maneuvers in addition to gentle downward traction on the fetal head to effect delivery. Several studies have proposed defining shoulder dystocia as a prolonged head-to-body delivery interval (the mean plus 2 standard deviations, 60 sec) or the use of ancillary obstetric maneuvers.[4,5]

RISKS TO THE MOTHER, OBSTETRICIAN, AND FETUS

Postpartum hemorrhage, and the unintentional extension of the episiotomy or laceration into the rectum (fourth-degree laceration), are the most common maternal complications associated with shoulder dystocia (Table 68–1). In Gherman and coworkers' study,[6] these occurred in 11% and 3.8%, respectively, of the described shoulder dystocias. Other reported complications have included vaginal lacerations, cervical tears, bladder atony, and uterine rupture. Maternal symphyseal separation and lateral femoral cutaneous neuropathy have also been associated with overly aggressive hyperflexion of the maternal legs.[7] Risks to the physician mainly involve litigation, because brachial plexus palsy (BPP), central neurologic dysfunction, and perinatal death account for most of the shoulder dystocia–related lawsuits. A clearly documented medical record may be helpful if claims are to be rebutted.[8]

A large retrospective study that evaluated 285 cases of shoulder dystocia found that the fetal injury rate was 24.9%, including 48 (16.8%) BPPs, 27 (9.5%) clavicular fractures, and 12 (4.2%) humeral fractures.[9] Unilateral brachial plexus injuries are probably the most common neurologic injury sustained by the neonate. The right arm is more commonly affected (64.6%) owing to the fact that the left occiput anterior presentation leaves the right shoulder impinged against the symphysis pubis.[9] Brachial plexus injury has been found to complicate up to 21% of all shoulder dystocia cases.[10] Most (80%) of these nerve injuries have been located within the C5–6 nerve roots (Erb-Duchenne palsy). Other types of brachial plexus injuries that have been described include Klumpke's palsy (C8–T1), an intermediate palsy, and complete palsy of the entire brachial plexus. Diaphragmatic paralysis, Horner's syndrome, and facial nerve injuries have occasionally been reported to accompany BPP.[11] Approximately one third of BPPs will be associated with a concomitant bone fracture, most commonly the clavicle (94%).[9] Neonatal radial fracture can also be associated with the shoulder dystocia or the maneuvers employed to alleviate it.[12]

TABLE 68–1		
Common Complications Associated with Shoulder Dystocia		
MATERNAL	**ACCOUCHEUR**	**NEONATAL**
Third- or fourth-degree lacerations	Terror	Erb-Duchenne palsy
Postpartum hemorrhage	Medical liability	Klumpke's palsy
		Clavicular fracture
		Humeral fracture
		Hypoxia
		Permanent brain injury
		Death

Gherman and colleagues' study[9] compared shoulder dystocia cases according to whether or not direct fetal manipulative maneuvers (Woods', posterior arm extraction, or Zavanelli's maneuvers) had been used and found that the overall incidence of fetal bone fracture (16.5% vs. 11.4%, P = .21) and BPP (21.3% vs. 13.3%, P =.1) was not significantly different between the two groups. Similar findings had previously been reported by Nocon and associates,[13] who grouped the techniques used to disimpact the shoulder into major treatment categories. None of the major categories revealed a statistically significant difference when compared with respect to fetal injury. In Nocon and associates' study,[13] the authors found incidences of injury of 14.9%, 14.3%, 37.9%, and 20%, respectively, associated with the McRoberts maneuver, rotations, posterior arm delivery, and suprapubic pressure.

MANAGEMENT OPTIONS

Prenatal: Identifying the Pregnancy at Risk

It has been clearly shown that the risk of shoulder dystocia increases significantly as birth weight increases. The percentage of births complicated by shoulder dystocia for unassisted births not complicated by diabetes was 5.2% for infants weighing 4000 to 4250 g, 9.1% for those 4250 to 4500 g, 14.3% for those 4500 to 4750 g, and 21.1% for those 4750 to 5000 g.[14] It must be remembered, however, that approximately 50% to 60% of shoulder dystocias occur in infants weighing less than 4000 g. Moreover, even if the birth weight of the infant is over 4000 g, shoulder dystocia will complicate only 3.3% of the deliveries.[15,16]

From a prospective point of view, prepregnancy and antepartum risk factors such as previous delivery of a macrosomic infant, preexisting or pregnancy-induced diabetes mellitus, multiparity, excessive maternal weight gain, and postdates gestation have very poor predictive value for the prediction of shoulder dystocia. For example, one study found that only 32% of patients were obese (>90 kg), 25% had excessive weight gain (>20 kg), 8% had short stature (<60 inches), 6% were more than 42 weeks' gestation, 3% were of advanced maternal age, and 2% had a personal history of diabetes mellitus.[17] In Ouzounian and Gherman's large cohort of patients from a Southern California perinatal program,[18] rates for operative vaginal delivery, diabetes, epidural use, multiparity, and postdatism were similar among cases with and without shoulder dystocia. In a case-control study from the Northern and Central Alberta Perinatal Outreach Program, maternal obesity (defined as > 91 kg) was not associated with shoulder dystocia when multivariable logistic regression analysis was used to control for confounding effects.[19] Other studies have not shown any independent association between maternal obesity and an increased risk for shoulder dystocia.[20]

Ultrasonographic estimation of fetal weight, performed during either the late third trimester or the intrapartum period, has commonly been employed to estimate the risk of shoulder dystocia via prediction of birth weight. To date, however, no studies have specifically evaluated this relationship in a patient population in which routine ultrasounds are performed. Late pregnancy ultrasound displays a low sensitivity (22%–44%) and a poor positive predictive value

(30%–44%) in the detection of macrosomia, with an overall tendency to overestimate the birth weight. Moreover, there is decreasing accuracy of birth weight prediction with increasing birth weight. Using a scoring system that incorporated ultrasonographic biometric parameters and amniotic fluid index, Chauhan and coworkers[21] failed in their attempt to provide a simple scoring system that could predict shoulder dystocia among large–for–gestational age fetuses. For this reason, the American College of Obstetricians and Gynecologists has suggested that attempted vaginal delivery is not contraindicated for women with estimated fetal weights up to 5000 g in the absence of maternal diabetes.[22,23]

Patients with insulin-requiring diabetes mellitus appear to warrant special evaluation for shoulder dystocia. The risk of shoulder dystocia for unassisted births to diabetic mothers has been found to be 8.4%, 12.3%, 19.9%, and 23.5% when the birth weight is 4000 to 4250 g, 4250 to 4500 g, 4500 to 4750 g, or more than 4750 g, respectively.[13] These values are somewhat higher than for nondiabetics of similar build. Changes in fetal body configuration brought about by increased fat deposition in the fetuses of diabetic mothers, such as larger trunk and chest circumferences, increased bisacromial diameters, and chest-to-head disproportion, impede the rotation of the fetal shoulders into the oblique diameter.

In a similar fashion, patients with a history of shoulder dystocia complicating a prior vaginal delivery have a risk of recurrence ranging between 11.9% and 16.7%. Maternal and fetal factors that have been shown to be significantly associated with recurrent shoulder dystocia include birth weight greater than the index pregnancy, prolonged duration of the second stage of labor, and birth weight more than 4000 g.[1] However, a policy of universal elective cesarean delivery has not been recommended for this cohort of patients because the risks outweigh the benefits.[23] Nonetheless, antepartum counseling and discussion of recurrence risks should be undertaken, with consideration of the present estimate of fetal weight, the presence of maternal glucose intolerance, and whether or not the prior shoulder dystocia resulted in a transient or permanent neurologic injury.

Labor and Delivery: Practical Management of Shoulder Dystocia

The patient should be instructed to stop pushing after the shoulder dystocia is initially recognized. However, maternal expulsive efforts will need to be restarted after the fetal shoulders have been converted to the oblique diameter, in order to complete the delivery. If the accoucheur is alone, additional assistance may be obtained by summoning other obstetricians, an anesthetist or anesthesiologist, additional nursing support, and a pediatrician.

Umbilical cord compression, most commonly between the fetal body and the maternal pelvis, leads to a decrease in the fetal pH at an average rate of 0.04 units/min. If a nuchal cord is present and cannot be reduced easily over the fetal head, clamping and cutting of the cord should be avoided until the shoulder dystocia has been alleviated.[24] Most, if not all, of the commonly encountered shoulder dystocia episodes can be relieved within several minutes.

Although research studies have been unable to predict an exact time limit at which irreversible brain injury occurs, it is reasonable to assume that the risk of permanent central neurologic dysfunction is associated with prolongation of the head/shoulder interval thresholds. The length of delay that results in permanent brain injury will depend on the condition of the baby at the point at which the delivery is arrested. It may be as short as 4 to 5 minutes or as long as 15 minutes.

At the time of delivery, if shoulder dystocia is a concern, some clinicians have empirically advocated proceeding immediately to delivery of the fetal shoulders, in order to maintain the forward momentum of the fetus. Others support a short delay in delivery of the shoulders, arguing that the endogenous rotational mechanics of the second stage may spontaneously alleviate the obstruction. Obstetricians may also employ the McRoberts maneuver "prophylactically" in order to decrease the risk of shoulder dystocia or shorten the second stage of labor. One clinical trial randomized patients with estimated fetal weights over 3800 g either to undergo prophylactic maneuvers (McRoberts' maneuver and suprapubic pressure) or to undergo maneuvers only after delivery of the fetal head, if shoulder dystocia was identified.[25] This study found that head-to-body delivery times, an indirect proxy for shoulder dystocia, did not differ between the prophylactic and the control patients.

Although many maneuvers have been described for the successful alleviation of shoulder dystocia, no randomized, controlled trials or laboratory experiments have been conducted that directly compared these techniques (Table 68–2). Most obstetricians currently employ the McRoberts maneuver as their initial step for the disimpaction of the shoulder. In a retrospective review of 236 shoulder dystocia cases occurring between 1991 and 1994 at Los Angeles County/University of Southern California Medical Center, this maneuver alone alleviated 42% of cases. Moreover, trends toward lower rates of maternal and neonatal morbidity were associated with the McRoberts maneuver.[6]

The McRoberts maneuver, performed by sharply flexing the maternal thighs onto the abdomen, results in a straightening of the maternal sacrum relative to the lumbar spine with consequent cephalic rotation of the symphysis pubis.[26] Care should be taken to avoid prolonged or overly aggressive application of the McRoberts maneuver because the fibrocartilaginous articular surfaces of the symphysis pubis and surrounding ligaments may be unduly stretched.

The overwhelming majority of patients can assume the proper position for the McRoberts maneuver with little difficulty. Women may be instructed to grasp the posterior aspect of their thighs and pull themselves into position, with family members or health care professionals providing any assistance necessary. The obstetrician may also choose to flex both of the patient's legs. Problems may occur when moving an obese patient or a woman who has undergone a dense epidural motor blockade.

Because shoulder dystocia is considered to be a "bony dystocia," episiotomy alone will not release the impacted shoulder. The need for cutting a generous episiotomy or proctoepisiotomy must be based on clinical circumstances, such as a narrow vaginal fourchette in a nulliparous patient. This may allow the fetal rotational maneuvers to be performed with ease, as well as create more room for attempted delivery of the posterior arm. Attendants should refrain from applying fundal pressure as a maneuver for the alleviation of the shoulder dystocia. Pushing on the fundus simply duplicates a maternal directional expulsive force that has already failed to deliver the fetal shoulder(s) and serves only to further impact the anterior shoulder behind the symphysis pubis. In addition, the use of fundal pressure has been associated with an increased risk of Erb-Duchenne palsy and thoracic spinal cord injury in the neonate.[27]

Suprapubic pressure, commonly administered by nursing personnel, is typically used immediately prior to or in direct conjunction with the McRoberts maneuver. This pressure is usually directed posteriorly, in an attempt to force the anterior shoulder under the symphysis pubis. Other described techniques for suprapubic pressure have included lateral application from either side of the maternal abdomen or alternating between sides using a rocking pressure.[28]

Many cases of shoulder dystocia require the performance of several maneuvers to alleviate the impaction. Stallings and colleagues[29] found that slightly more than a third of patients required more than two maneuvers. When more complex maneuvers are required, either fetal rotational maneuvers or posterior arm extraction may be employed. In the Woods corkscrew maneuver, the practitioner attempts to abduct the posterior shoulder by exerting pressure onto its anterior surface. In the Rubin (reverse Woods) maneuver, pressure is applied to the posterior surface of the most accessible part of the fetal shoulder (either the anterior or the posterior shoulder) to effect shoulder adduction. These rotational maneuvers, however, may be difficult to perform when the anterior shoulder is tightly wedged underneath the symphysis pubis. It may, therefore, be necessary to push the fetus slightly upward in order to facilitate the rotation.

By replacing the bisacromial diameter with the axilloacromial diameter, posterior arm delivery creates a 20% reduction in the diameter that has to pass through the birth canal.[30] To perform delivery of the posterior fetal arm, pressure should be applied by the accoucheur at the antecubital fossa in order to flex the fetal forearm. The arm is subsequently swept out over the infant's chest and delivered over the perineum. Rotation of the fetal trunk to bring the posterior arm anteriorly is sometimes required. If the posterior arm is extended or lies under the fetus's body, delivery may be very difficult. Grasping and pulling directly on the

Posterior axilla traction

fetal arm, as well as application of pressure onto the mid-humeral shaft, should be avoided because bone fracture might occur.

The previously mentioned maneuvers are typically attempted 4 to 5 minutes after identification of the shoulder dystocia. If the shoulder dystocia remains uncorrected, a bilateral shoulder dystocia or posterior arm shoulder dystocia might be present. The latter is suggested by the presence of the posterior arm being maintained at the level of the pelvic inlet and an inability to perform posterior arm extraction. Intractable shoulder dystocias warrant the use of heroic techniques, such as the Zavanelli maneuver, symphysiotomy, or hysterotomy. Other options to consider include posterior axillary traction,[31] potentially to include sling traction,[32] to deliver the posterior arm.

Performance of these will be complicated by the provider's lack of clinical experience with these maneuvers, performance under emergent conditions, and the significant maternal and neonatal complications inherent in the procedures. In the Zavanelli maneuver, the head is rotated back to a pre-restitution position and then gently flexed. Constant firm pressure is used to push the head back into the vagina, and cesarean delivery is subsequently performed. Halothane or other general anesthetics, in conjunction with tocolytic agents, may be administered in preparation for, and during, the Zavanelli maneuver. Oral or intravenous nitroglycerin may be used as well. A modification of the original Zavanelli maneuver may be employed in order potentially to reduce maternal morbidity. As described by Zelig and Gherman,[33] maternal expulsive efforts were reinitiated after the obstetrician had observed that the biparietal diameter had passed back through the introitus and the shoulders were felt to disimpact. This modification relies on the possibility that the disimpacted shoulders will now rotate into the correct orientation for delivery. Because it might not work, it should be attempted only when there is no evidence of fetal compromise.

To perform a symphysiotomy, place the patient in an exaggerated lithotomy position. Although its placement may be very difficult secondary to obstruction, a Foley catheter can help to identify the urethra. With the physician's index and middle finger displacing the urethra laterally, the cephalad portion of the symphysis is incised with a scalpel blade or Kelly clamp. Hysterotomy may also be performed to either resolve the shoulder dystocia primarily or assist with vaginal techniques. The abdominal surgeon can apply pressure on the anterior fetal shoulder to allow rotation to the oblique diameter. The posterior fetal arm may be manipulated through the transverse uterine incision with passage of the hand to a vaginal assistant.

Prior to performing these techniques, one may consider using the "all-fours" technique, in which the patient is rolled from her existing position onto her hands and knees.[34] The downward force of gravity or a favorable change in pelvic diameters produced by this maneuver may allow disimpaction of the fetal shoulder. Older textbooks have described deliberate clavicular fracture as a maneuver of last resort, performed by exerting direct upward pressure on the mid-portion of the fetal clavicle. However, this has not been reported in the recent literature because it is technically difficult to perform and risks serious injury to the underlying vascular and pulmonary structures in the fetus.

Training: Shoulder Dystocia and Simulation

Owing to its infrequent occurrence and the requirement for a rapid response, shoulder dystocia is an obstetric emergency that is well suited to simulation. In addition, the 15th Report on Confidential Enquiries into Maternal Deaths in the United Kingdom identified that in 66% of neonatal deaths following shoulder dystocia, "different management could have reasonably been expected to have altered the outcome."[35] Using a standardized simulated shoulder dystocia scenario, Deering and associates have reported that trained residents had significantly higher scores, including reduced timelines of their interventions, better performance of maneuvers, and overall improved efficiency.[36] Crofts and Draycott[37–40] have developed a training mannequin with a force-monitoring system consisting of a strain gauge mounted on both clavicles. They found a reduction in the head-to-body delivery duration and the maximum applied delivery force following training, although these did not reach statistical significance. However, significant improvements in overall management were observed after training and persisted for up to 1 year.

SHOULDER DYSTOCIA AND BRACHIAL PLEXUS INJURY

BPP is a major cause of litigation, constituting 11% of the 370 obstetric claims closed by the Norwegian patient insurance system from 1988 to 1997.[41] In the past, textbooks have stated without evidence that BPP is caused by the accoucheur's application of excessive lateral traction on the fetal head and neck during attempts at alleviating the shoulder dystocia. However, since the mid 1990s, multiple lines of evidence have supported the concept that most BPPs are not caused by the accoucheur.[1,42–45] This opinion is based on several findings:

- More than 50% of cases of brachial plexus injuries are associated with uncomplicated vaginal deliveries.[42–44]
- BPP can occur in the posterior arm of infants whose anterior arm was impacted behind the symphysis pubis and can also occur with atraumatic cesarean delivery.[44]
- There is no statistical correlation with the experience of the obstetric provider nor the number or type of maneuvers used.[1]
- Rapid second-stage and disproportionate descent of the head and body of the fetus relative to the shoulder have been implicated in the pathogenesis of the injury.[42]
- Mathematical and computer-simulated models have shown that maternal endogenous forces are far greater than clinician-applied exogenous delivery loads during a shoulder dystocia episode.[46,47]

McFarland and coworkers[48] have reported that the number of maneuvers employed during the shoulder dystocia may serve as a measure of the severity of the shoulder dystocia, with this severity being the cause of injury, rather than the maneuvers themselves. When one or two maneuvers were required, the incidence of Erb's palsy was 7.7% but increased to 25% when three or more maneuvers were required ($P = 0.009$). The incidence of clavicular or humeral fracture also increased with the use of more than three maneuvers (21.4% vs. 7.7%, $P = 0.03$).

It is currently impossible to predict which infants will be affected with BPP when shoulder dystocia complicates vaginal delivery. To date, there have been only a few studies whose objective was to predict which infants would experience BPP following shoulder dystocia. In Mehta and colleagues' study,[49] after logistic regression analysis, only a second stage of delivery greater than 20 minutes remained significantly associated with neonatal injury at discharge. Poggi and associates[50] matched 80 medicolegal cases of shoulder dystocia–associated BPP with control cases taken from a database of consecutive shoulder dystocia deliveries from one hospital. There were no significant differences in maternal weight, body mass index, height, race, estimated gestational age, average number of maneuvers, head-to-body delivery interval, operative delivery rate, prolonged second stage, or precipitous second stage rate between the groups. In a retrospective case-control analysis from national birth injury and shoulder dystocia databases, Gherman and coworkers[10] matched cases of permanent BPP ($n = 49$) with cases of transient palsy. Transient BPP cases were found to have a higher incidence of diabetes mellitus than those with permanent BPP (34.7% vs. 10.2%, odds ratio [OR] 4.68, 95% confidence interval [CI] 1.42–16.32). Permanent BPPs had a higher mean birth weight (4519 + 94.3 g vs. 4143.6 + 56.5 g, $P < .001$) and a greater frequency of birth weight greater than 4500 g (38.8% vs. 16.3%, OR 0.31, 95% CI 0.11–0.87). There were, however, no statistically significant differences between the two groups with respect to multiple other antepartum, intrapartum, and delivery outcome measures.

Despite the introduction of ancillary obstetric maneuvers such as McRoberts' maneuver and a generalized trend toward the avoidance of fundal pressure, it has been shown that the rate of shoulder dystocia–associated BPP has not decreased. Comparison of shoulder dystocia deliveries between 1980 to 1986 and 1991 to 1999 indicates no significant difference with respect to BPP: 0.7/1000 deliveries versus 0.8/1000 deliveries (OR 1.10; 95% CII 0.65–1.86).[51]

Despite these observations, it is good and prudent practice for obstetricians to make a detailed and accurate account of the procedure when they have managed a case of shoulder dystocia. This should be undertaken as close to the event as possible. Table 68–3 gives a suggested list of items that may be covered in such a report.

TABLE 68–3

Suggested Medicolegal Documentation for Shoulder Dystocia

When and how shoulder dystocia was diagnosed
Position and rotation of infant's head
Which shoulder was anterior?
Presence of episiotomy, if performed
Estimate of head-to-body time interval
Estimation of force of traction applied
Order, duration, and results of maneuvers employed
Additional medical personnel present for assistance
Birth weight
One- and 5-min Apgar scores
Venous and/or arterial umbilical cord blood gas/pH/base deficit evaluation
Inform delivered woman that shoulder dystocia had occurred

SUMMARY OF MANAGEMENT OPTIONS

Shoulder Dystocia

Management Options	Evidence Quality and Recommendation	References
Prenatal Identification of At-Risk Pregnancy		
Estimation of fetal weight and risk of SD is of limited value.	III/B	15,16
May be of more use in diabetic pregnancies or those with previous SD.	IIb/B	17
Limited accuracy of ultrasound in estimating fetal weight	III/B	52
ACOG Guidelines:	IV/C	22,23
• Vaginal delivery is reasonable with estimated fetal weights up to 5 kg in the absence of diabetes because of the risks of elective cesarean section		
Despite this guideline, women with previous delivery complicated by SD may prefer to have an elective cesarean section, especially if the estimated fetal weight is similar to or greater than previously.	—/GPP	—
The following are poor predictors of SD:	IIa/B	16–21
• Previous macrosomia/large-for-dates.		
• Diabetes (preexisting or gestational).		
• Multiparity.		
• Excessive weight gain in pregnancy.		
• Postdates pregnancy.		

SUMMARY OF MANAGEMENT OPTIONS
Shoulder Dystocia—cont'd

Management Options	Evidence Quality and Recommendation	References
If vaginal delivery is to be attempted following a discussion with an at-risk patient, make a clear record in the patient's notes.	—/GPP	—
Practical Management of Shoulder Dystocia (See Table 68–2)		
No RCT data covering any aspect of SD management.	—/—	—
No evidence that "prophylactic" McRoberts' and suprapubic pressure prevents SD in at-risk cases (i.e., before SD has developed/been recognized).	Ib/A	25
Stop maternal efforts temporarily until SD is overcome.	—/GPP	—
Summon help (obstetric, anesthetic, nursing/midwifery, pediatric).	—/GPP	—
Avoid clamping and cutting a nuchal cord until SD is overcome.	IV/C	24
McRoberts' maneuver.	III/B	6
Suprapubic pressure.	IV/C	28
No evidence that episiotomy makes a difference, though often advised.	—/GPP	—
Avoid fundal pressure as it increases risk of Erb's palsy and thoracic spine injury.	IV/C	28
Rotational maneuver (Woods' or Rubin's).	III/B	1
Delivery of posterior arm (Barnum's).	III/B	1
Put woman into "all fours" position.	III/B	34
Zavanelli's maneuver.	III/B	1
Symphysiotomy.	IV/C	53
Hysterotomy and abdominal correction.	IV/C	54
Make a detailed record as soon as possible after the event (see Table 68–3).	—/GPP	—

GPP, good practice point.

Fetal Distress in Labor

PETER DANIELIAN and PHILIP J. STEER

WHAT IS FETAL DISTRESS?

Fetal distress is a term that is commonly used, but difficult to define. It is probably best taken to mean "an absence of fetal well-being," in a similar way that the expression "a flat baby" means a "neonate in need of resuscitation" and "an ill person" means "someone who is unwell." Thus, its use encompasses many different pathologies affecting the fetus, such as chronic hypoxia leading to a metabolic acidosis, mechanical trauma (e.g., excessive head compression), hyperthermia, meconium aspiration, and sepsis. Hypoxia with acidosis (often referred to as "asphyxia," although originally the term simply meant "born without an evident pulse," from the Greek *a-sphyxos*) is widely perceived to be the most important cause, but does not have a simple relationship with the condition of the baby at birth. Beard and coworkers[1] pointed out as early as 1967 that the Apgar score (a clinical measure of condition at birth) "does not differentiate between asphyxial and non-asphyxial depression of the newborn." In 1982, Sykes and colleagues[2] reported that only 27% of babies with a severe acidosis (umbilical artery pH < 7.1 and a base deficit > 12 mmol/L) had a 1-minute Apgar score less than 7. Similarly, only 21% with a 1-minute Apgar score less than 7 had a severe acidosis. Lissauer and Steer[3] subsequently noted that more than half of babies born at 32 weeks' gestation or later, and needing resuscitation by intubation and positive pressure ventilation, had either entirely normal fetal heart rate (FHR) patterns throughout labor or normal values for umbilical cord blood pH measurement. In their study, the nonasphyxial associations with depression at birth included operative delivery, anesthetic agents given to the mother, meconium-stained liquor, and tight nuchal cord. Steer and associates[4] subsequently reported that acidosis in the fetus (as measured by cord umbilical artery pH) accounted for only 7.5% of the variation in the 1-minute Apgar score, and 1.8% of the variation in the 5-minute Apgar score. Thorp and coworkers[5] reported that umbilical artery cord pH was normal in 80% of clinically depressed newborns.

Chorioamnionitis has, in recent years, been recognized as an important antecedent of cerebral palsy,[6] but it is not directly associated with asphyxia. Maberry and colleagues[7] reported that chorioamnionitis does not increase the likelihood of metabolic acidosis at birth; there were no babies with a significant metabolic acidosis or pH less than 7.0 in 123 cases of confirmed intra-amniotic infection during labor. Instead, the brain damage that later manifests as cerebral palsy may be caused by cytokine release. Nonetheless, chorioamnionitis, or even noninfective fever during labor (see Chapter 72), may potentiate the damaging effects of hypoxia-ischemia on the brain by increasing its metabolic requirements for oxygen.[8]

What Constitutes "Birth Asphyxia"?

Saling's initial publication[9] reviewed 306 babies born in vigorous condition and reported their mean capillary fetal blood sample (FBS) pH to be 7.33 with a range (±2 standard deviations [SD]) of 7.2 to 7.5. An FBS pH of 7.2 subsequently became a widely accepted lower limit of normal, below which values were taken to indicate the need for urgent delivery. However, it has become appreciated that acidosis has to be very severe (values well below 2 SD from the mean) before it is associated with long-term sequelae. For example, Winkler and associates[10] reported that none of 335 infants born with an umbilical artery pH less than 7.2 but greater than 7.0 had any neonatal complications, and only 2 of 23 born with a pH less than 7.0 had any complications attributable to asphyxia. Goodwin and coworkers[11] reviewed 129 full-term, normally formed, singleton infants born with an umbilical artery pH less than 7.0 and found that 78% were entirely normal at follow-up, with only 8% having a major neurologic defect. Nagel and colleagues[12] reported 30 newborns with an umbilical artery pH less than 7.0. All but 3 had an Apgar score of 6 or more at 5 minutes. In the neonatal period, 2 babies died, 5 had mild and 2 severe encephalopathy. Using the Denver Developmental Screening Test at ages ranging from 14 to 33 months, 23 surviving babies were normal, 2 questionable, and none had major abnormalities (31 were lost to follow-up). However, these reports should not be taken as meaning that acidosis is always benign. Severe acidosis (pH < 7.0) is still likely to be associated with a much higher incidence of depression at birth than a pH greater than 7.2. Van den Berg and associates[13] reviewed the neonatal complications of 84 nonanomalous babies with an umbilical artery pH less than 7.0 and compared them with a nonacidotic (pH > 7.24) matched control group. They found highly significant differences in

the proportions of babies requiring intubation (29% vs. 2.4%), and having pulmonary (31% vs. 11%), cardiovascular (15% vs. 8%), and neurologic (23% vs. 7%) complications. Low and coworkers[14] studied the effect of metabolic acidosis on newborn complications at 10 days of life. Fifty-nine babies had a severe metabolic acidosis (umbilical artery buffer base < 30 mmol/L) and were six times more likely to have complications than a control group without acidosis (85% vs. 14%). Neonatal encephalopathy was observed in 61% of the acidotic group versus 17% of the control group. Socol and colleagues[15] studied 28 newborns with an Apgar score of 3 or less at 5 minutes. They found that 11 of 17 neonates with an umbilical cord arterial pH greater than 7.0 had an uncomplicated neonatal course compared with only 1 of 11 with a pH less than 7.0. Low and associates[16] have subsequently studied the threshold of fetal metabolic acidosis at delivery above which moderate or severe newborn complications may be expected; they found this to be an umbilical artery base deficit of 12 mmol/L. Thereafter, increasing metabolic acidosis is associated with a progression of severity of newborn complications.

On the basis of these findings, it seems reasonable to categorize asphyxia as a cord artery pH less than 7.0 and a base deficit greater than 12 mmol/L. However, because the large majority of babies with asphyxia by this definition have a normal long-term outcome, it has been suggested that the term *birth asphyxia* should be used to indicate an even more severe situation in which, in addition to acidosis, generalized neonatal dysfunction is evident. Thus, Thorp[17] suggested the inclusion of neonatal depression as measured by the Apgar score, as well as evidence of hypoxic end-organ damage such as early neonatal seizures and renal or cardiac dysfunction. Subsequently, the American College of Obstetricians and Gynecologists (ACOG)[18] recommended that birth asphyxia be regarded as resulting from "intrapartum hypoxia sufficient to cause neurological damage," defined by an umbilical artery pH less than 7.0, a 5-minute Apgar score of 3 or less, moderate or severe neonatal encephalopathy, and evidence of multiorgan dysfunction (affecting the cardiovascular, renal, and/or pulmonary systems) (Table 69–1). Few depressed neonates fulfill these stringent conditions.[19]

Do Intrapartum Events Lead to Cerebral Palsy?

It is clear that the majority of mental handicap is not caused by intrapartum events. In 1985, the U.S. National Institutes of Health[20] reported that "the causes of severe mental retardation are primarily genetic, biochemical, viral and developmental, and not related to birth events. Associated factors include maternal lifestyle, such as poor nutrition, cigarette smoking, and alcohol and drug abuse." For example, the single most prevalent cause of mental retardation is Down syndrome. However, some forms of mental handicap are likely to be the consequence of birth asphyxia and other adverse intrapartum events. The International Cerebral Palsy Task Force suggested that birth asphyxia was a significant cause of cerebral palsy characterized by nonprogressive abnormal control of movement or posture.[21] The percentage of such cases caused by birth asphyxia remains controversial. It is widely accepted that at least some acute intrapartum events (e.g., placental abruption, cord prolapse) can cause brain injury in previously normal fetuses. In a review of 351 babies investigated by magnetic resonance imaging (MRI) or at postmortem, Cowan and coworkers[22] showed that more than 90% of full-term infants with neonatal encephalopathy, seizures, or both, but without specific syndromes or major congenital defects, had evidence of perinatally acquired insults, and in only a few babies was there any evidence of established brain injury acquired before birth. Their data do not exclude the possibility that antenatal factors could initiate a causal pathway for perinatal brain injury and that they might, possibly together with genetic predispositions to hypoxic-ischemic injury, make some infants more susceptible than others to the stresses of labor and delivery. However, although their study was not population-based, it strongly suggests that the potential for avoiding intrapartum brain damage by improved management is substantial. The Western Australia case-control study of neonatal encephalopathy[23] (which was population-based) clearly showed a protective effect of elective cesarean section (adjusted odds ratio [OR] 0.17, 95% confidence interval [CI] 0.05–0.56). This demonstrates that intrapartum events do play a role in the etiology of neonatal encephalopathy. The question of the proportion of babies with brain injury but no evidence of chromosomal anomaly or congenital anomaly that are due to intrapartum events has been addressed by Johnston,[24] who concluded that it was between 30% and 60%, depending on the setting and the efficiency of intrapartum surveillance and the risk status of the population. When addressing the likelihood of perinatal events as a cause of cerebral palsy, the criteria of Nelson can be recommended (Table 69–2).

MANAGEMENT ISSUES

Diagnosis of Fetal Distress

Diagnosis is difficult because of the problems of accessing the fetus in utero. Before the introduction of the Pinard stethoscope, the condition of the fetus remained unknown until the moment of birth. However, once the FHR could be detected with some reliability, it was discovered that both persistent fetal tachycardia and bradycardia were associated with an increased likelihood of poor condition at birth, and that meconium staining of the amniotic fluid could also be an adverse sign. Once continuous electronic fetal monitoring (EFM) was introduced in the 1960s, it was possible to detect reduced FHR variability, which is also associated with

TABLE 69–2

Criteria to Be Fulfilled before Long-Term Outcome Can Be Linked with Intrapartum Events

1. Was there evidence of severe, prolonged intrapartum dysfunction?
2. Was the child severely ill as a newborn? Were there disturbances of feeding, tone, and consciousness, and evidence of involvement of other organ systems, of which renal involvement may be especially significant?
3. Is cerebral palsy present?
4. Have other potential explanations been excluded, such as
   Congenital malformation
   Infection
   Metabolic abnormality
   Familial disease
   Microcephaly in the neonatal period
   Abnormal CT or MRI scan suggesting discrete lesions
   Maternal substance abuse (especially cocaine)
   Thyroid disease

CT, computed tomography; MRI, magnetic resonance imaging.

Fetal heart rate pattern and the associated risk of acidosis.

an increased risk of depression at birth. The introduction of FBS and pH estimation by Saling[9] allowed further assessment of fetal condition. Unfortunately, FBS is a complicated and time-consuming technique, which is uncomfortable for the mother. As a result, the approach that developed was to use EFM as a screening tool for asphyxia, and then use FBS to confirm or reject the diagnosis. Beard and colleagues, in their landmark paper of 1971,[25] showed that a normal FHR pattern is associated with a very low risk of acidosis (<2% of fetuses with a normal FHR pattern will have a pH < 7.2). However, although increasing abnormality of the FHR is associated with an increasing chance that the fetus is acidotic, even with the most abnormal pattern (a complicated baseline tachycardia), the risk of acidosis is only about 60% (Fig. 69–1). This explains the increased intervention rates for the diagnosis of fetal distress if FHR monitoring is used

without the backup of FBS and pH estimation.[26,27] Reviews indicate that the use of FBS and pH measurement not only limits the increase in operative delivery rate seen with EFM but also improves its ability to reduce the neonatal seizure rate.[28]

Most studies of EFM have examined the relationship between the heart rate pattern and asphyxia. Cardiotocogram (CTG) interpretation can, however, also indicate other pathologies, such as pyrexia (and therefore indirectly, sepsis), which is associated with a fetal tachycardia.[29] Recurrent variable decelerations with a maintained normal FBS pH suggest intermittent cord compression. Repeated umbilical cord compression may cause brain damage without asphyxia because of the major swings in blood pressure induced by repeated occlusion and release.[30] The damage may be exacerbated by nuchal entanglement (cord around the neck) because occlusion of the venous return from the brain increases intracranial pressure. Damage to the hippocampus from intermittent occlusion of the cord has been seen in fetal sheep.[31]

Does Electronic Fetal Monitoring Improve Outcome?

The widespread introduction of EFM in the 1970s was associated with substantial falls in perinatal mortality as reported by a number of retrospective observational studies.[32,33] However, during the same period, major advances were being made in neonatal intensive care, and the cesarean section rate also rose substantially. It has proved impossible to establish which of these changes, if any, was responsible for the improvement in outcome. This uncertainty led to calls for prospective, randomized, controlled trials. None of these trials was, on their own, large enough to have sufficient power to address the long-term outcome of most interest, namely cerebral palsy. Accordingly, there have been a series of meta-analyses, although these are dominated by the effect of the single largest trial, carried out in Dublin in the early 1980s.[34] Vintzileos and associates[26] reviewed nine, including in total 18,561 patients (of which 12,964 were in the Dublin trial). This confirmed a substantial increase in the cesarean section rate associated with EFM (OR 1.53, 95% CI 1.17–2.01), but disappointingly for the advocates of EFM, the reduction in the overall perinatal mortality rate was not significant (4.2/1000 in the EFM group vs. 4.9/1000 in the intermittent auscultation [IA] group). However, in a post hoc analysis, Vintzileos and associates[26] commented that there was a significant reduction in the deaths attributed to hypoxia in the EFM groups, being 0.7/1000 compared with 1.8/1000 in the auscultation group (OR 0.41, 95% CI 0.17–0.98). A similar meta-analysis was performed by Thacker and coworkers[27] with the inclusion of three further studies but with similar conclusions, except that they reported a significant reduction in the incidence of neonatal seizures in the group where EFM had been used (relative risk [RR] 0.5, 95% CI 0.30–0.82). Thus, the studies suggest some improvement in short-term outcome at the expense of an increased operative delivery rate, but were unable to address the issue of long-term outcome (a follow-up study of the Dublin trial showed that three babies in each group developed cerebral palsy[35]; however, even if the number had been doubled in the auscultation group, this would still not have been

statistically significant). It should be noted that many authorities, including the National Institute for Clinical Excellence (NICE) in the United Kingdom, state in relation to the meta-analyses that "there was no apparent difference in perinatal death rates between the two groups."[36] This is not actually correct, because most studies show a difference in favor of EFM, which is not, however, statistically significant. As already pointed out, even the meta-analyses are underpowered to address the question of perinatal mortality, let alone long-term outcome. It should always be remembered that absence of evidence is not evidence of absence, and one needs to be aware of the possibility of a type II error (i.e., there is a difference that by chance has not been found to be significant).

Fetal Heart Rate Monitoring and Fetal Blood Sampling

It will be appreciated from the previous discussion that monitoring the heart rate of the fetus should not be expected to detect all pathologies affecting the fetus during labor. For example, maternal intrapartum cardiac arrest, fetal skull fracture with brain infarct, intrapartum fetal stroke, and uterine rupture have been reported as causes of subsequent childhood handicap,[37] but none of these can be predicted reliably beforehand by FHR monitoring. (In a study of 36 cases of intrapartum rupture of a previous cesarean section scar,[38] no significant differences were noted in rates of mild or severe variable decelerations, late decelerations, prolonged decelerations, fetal tachycardia, or loss of uterine tone. Fetal bradycardia in the first and second stage was the only finding consistently associated with uterine rupture.) Equally, although intrapartum infection and meconium aspiration may be associated with fetal tachycardia, neither is consistently associated with acidosis[4,39]; therefore, a normal FBS pH may be actively misleading in their management if a normal value is taken as reassurance about fetal condition. Nevertheless, hypoxia and acidosis pose a significant threat to the fetus during labor (accounting for perhaps 20%–40% of poor condition at birth), and FHR monitoring remains the best available screening tool for its detection. The best way to detect developing acidosis in the fetus is to measure its blood pH using a FBS. Clues about other pathologies (e.g., variable decelerations with nuchal cord, FHR tachycardia with infection, sinusoidal variability with fetal anemia) can be obtained from EFM, but its use in these conditions should not be regarded as sensitive or specific.

Human Factors in the Use of Cardiotocography

A human element may factor into our inability to demonstrate that the use of EFM produces an improved outcome to the degree anticipated by the pioneers of the technique. For example, in the Dublin trial,[34] the fetal monitors used were of a relatively primitive design, staff were previously unfamiliar with their use, and during the trial, a marked Hawthorne effect was evident, which would have reduced its apparent efficacy. In a later case-control study, the intrapartum treatment of 38 babies severely asphyxiated at birth was compared with 120 controls.[40] In the control group, 29% of babies had an abnormal intrapartum FHR tracing,

but in only 9% was the abnormality severe. In contrast, in the babies asphyxiated at birth, 87% had an abnormal FHR tracing, and in 61% of cases, the abnormality was severe. The most striking finding, however, was the length of time required for the staff to recognize the FHR abnormality. With moderate abnormalities, the mean time to recognition was 71 minutes, and paradoxically, with severe abnormalities, it was 118 minutes. The authors could give no plausible reason why the standard of FHR tracing interpretation was so poor. However, it was clear from this study that if the quality of interpretation of the intrapartum FHR pattern had been higher, the benefits from EFM would almost certainly have been significantly and substantially enhanced.

In 1990, Ennis and Vincent[41] published the results of their study of 64 cases of poor perinatal outcome from the archives of the Medical Protection Society. In 11 cases, although indicated, continuous EFM was not performed. In 6 cases, the technical quality of the tracing was inadequate. In 14 cases, a significant abnormality in the FHR pattern was present, but this was either not noticed or no action was taken upon it. In only 14 cases was appropriate monitoring and action performed (the CTG was missing in 19 cases). In only 16 cases was a consultant involved in the interpretation of the tracing. In a further study from Oxford published in 1994,[19] intrapartum care was assessed in 141 cases of cerebral palsy and 62 perinatal deaths with a potential intrapartum cause. They found that abnormal FHR patterns were 2.3 times as common in babies who went on to develop cerebral palsy than in controls, and 6.7 times as common in perinatal deaths. They found that failure to respond to these clear signs of abnormality occurred in 26% of cerebral palsy cases and 50% of perinatal deaths, compared with 7% of controls. On the basis of these figures, it can be calculated that there will be approximately 1 case of potentially preventable cerebral palsy and 1 potentially preventable perinatal death in every 4000 deliveries. If one assumes 700,000 births per annum in the United Kingdom, 174 cases of cerebral palsy and 158 cases of perinatal death would be preventable.

More recently, Stewart and colleagues[42] reported that perinatal mortality in Wales is twice as high at night as during the day, and twice as high in July/August as in the rest of the year. They suggested that the excess of deaths may represent overreliance on inexperienced staff at night and a shortage of staff during the peak summer holiday months and also that it might be related to physical and mental fatigue of the caregivers. The Confidential Enquiry into Stillbirths and Deaths in Infancy (CESDI) was a U.K. national survey of perinatal deaths, now subsumed into the Confidential Enquiry into Maternal and Child Health (CEMACH, www.cemach.org.uk). The fourth annual report showed that failures in the use and interpretation of CTG were present in more than half of intrapartum-related deaths.[43] The fifth report studied the proportion of 567 cases in which there was evidence of suboptimal care in labor, and then classified this by whether improved care could possibly or probably have prevented the adverse outcome.[44] Suboptimal care was identified in 71% of cases, and a better outcome could possibly or probably have been anticipated in 28% and 22% of cases, respectively, if care had been adequate. The report commented that "fetal surveillance problems were the commonest cause [of problems in labor], with CTG interpretation … the most frequent criticism."

Maternity care currently accounts for over 50% of the U.K. National Health Service (NHS) medical litigation bill, with individual settlements reaching £6 million and even successful defense costing up to £0.5 million. At the 31st of March 2008, the total value of claims against the NHS Litigation Authority in the United Kingdom with respect to obstetrics and gynecology from April 1995 onward totaled £3.3 billion (http://www.nhsla.com). In 2006 to 2007, £579.3 million was paid out in total medicolegal settlements; 51% of this was for obstetrics.

Possible Interventions to Improve the Quality of Care

Young and associates[45] have studied the efficacy of intrapartum intervention and found that in cases of low Apgar scores, there was evidence of substandard care in labor in 74%. Following the introduction of regular audit of low Apgar scores, with feedback to clinical staff, this proportion fell to 23%, but crept back up to 32% over the following year. However, following the introduction of compulsory training in FHR pattern interpretation for all staff, the proportion of low Apgar score cases associated with substandard care fell back once again to only 9%.

Indications for Electronic Fetal Monitoring

Intrapartum EFM was intended to be a screening tool for fetal hypoxia, with FBS used as the confirmatory test. Accordingly, many authorities have advocated universal continuous EFM. However, with the growth of the "natural childbirth" movement, and the difficulty in establishing the efficacy of EFM in randomized trials, most guidelines now suggest that IA is an adequate form of FHR monitoring for "low risk" labors and that continuous EFM should be reserved for "high risk" labors. Unfortunately, it is difficult to define "low risk" labor. The 2001 guidelines of NICE in the United Kingdom[36] approached this problem by listing high risk factors that they considered indicated the need for continuous EFM (Table 69–3). We analyzed 29,443 births at the Chelsea and Westminster Hospital (London, UK) from 1988 thru 1998 inclusive and coded them as low risk if: the mother's age was younger than 40; there was no diabetes, cardiac disease, renal disease, or antepartum hemorrhage; the highest blood pressure at any time during pregnancy was less than 90 mm Hg diastolic; presentation was cephalic; gestation was 37 to 42 weeks; labor onset was spontaneous; the labor duration was less than 12 hours; epidural anesthesia was not used; and there was no oxytocin augmentation, meconium staining of the amniotic fluid, or pyrexia. Using these criteria, labors were low risk throughout labor in only 26%. Therefore, according to the NICE guidelines, IA throughout labor was applicable in only about a quarter of labors. In fact, only 11% had no EFM during labor, and the incidence of abnormal FHR pattern was 7.8%. In contrast, in the "high risk" 74%, 4.3% had no EFM during labor, and the incidence of abnormal FHR pattern was 22.8%. A similar analysis of the data from 15 other maternity units in the North West Thames region of London showed a median value for "low risk" labors of 25%, with the highest proportion of low risk labor being 34%, and the lowest 16%. In only one of these units did the proportion of low risk labor

TABLE 69–3

Possible Indications for Continuous Electronic Fetal Monitoring

Labor Abnormalities
Induced labor
Augmented labor
Prolonged labor
Prolonged membrane rupture
Regional analgesia
Previous cesarean delivery
Abnormal uterine activity

Suspected Fetal Distress in Labor
Meconium staining of the amniotic fluid
Suspicious fetal heart rate on auscultation
Abnormal fetal heart rate on admission cardiotocography
Vaginal bleeding during labor
Intrauterine infection

Fetal Problems
Multiple pregnancies (all fetuses)
Small fetus
Preterm fetus
Breech presentation
Oligohydramnios
Post-term pregnancy
Rhesus isoimmunization

Maternal Medical Disease
Hypertension
Diabetes
Cardiac disease (especially cyanotic)
Hemoglobinopathy
Severe anemia
Hyperthyroidism
Collagen disease
Renal disease

in which EFM was not used exceed 50%. Mires and coworkers[46] have reported on a randomized, controlled trial of CTG versus Doppler auscultation of the fetal heart at admission in labor in low risk obstetric population. They commented that "as the trial progressed, it became clear that … more women had complications that required continuous monitoring than had been predicted"; the overall proportion was 63% and was similar in both groups. In a study of low risk labors in Dublin, Impey and colleagues[47] reported that if an admission CTG was performed, 58% of women had continuous EFM during labor, but that even if IA was used from the outset, 42% of women had continuous EFM. The updated NICE guideline on care in normal labor[48] has reduced the number of indications for continuous EFM (Table 69–4), but it is unlikely that this will significantly change the proportion of women requiring this intervention.

Fetal Monitoring by Intermittent Auscultation

Evidence regarding the value of EFM is limited, but the evidence regarding the use of IA is even worse. Recommendations, therefore, have to depend entirely on custom and practice and "expert" opinion. These were summarized in the United Kingdom in the 2001 NICE guidelines,[36] which followed ACOG and the Society of Obstetricians and Gynaecologists of Canada in recommending that (1) during the

active phase of the first stage of labor, the FHR should be auscultated and recorded every 15 minutes and (2) during the second stage of labor, the FHR should be auscultated and recorded every 5 minutes. Ideally, the heart rate should be counted over 30 to 60 seconds, in the minute after a contraction (to detect late decelerations). The 2007 U.K. National Collaborating Centre for Women's and Children's Health (NCC-WCH)/NICE guideline modified these recommendations slightly and stated that in the first stage IA of the fetal heart should occur after a contraction for at least 1 minute, at least every 15 minutes, and the rate should be recorded as an average,[48] and in the second stage, after a contraction for at least 1 minute, at least every 5 minutes.[49]

The "Admission" Cardiotocogram

The incidence of emergency cesarean section for fetal distress is higher in the first hour of labor than in any subsequent single hour. This is because the onset of contractions reveals the fetus that is unable to cope with the relative hypoxia of labor. For this reason, performing EFM for the first hour of labor even in low risk pregnancies ("admission test") has become popular in some maternity units. Unfortunately, no studies of sufficient size have been conducted to enable an evaluation of the usefulness of this approach.[36]

Technical Aspects of Electronic Fetal Monitoring

A cardiotocograph machine is used to produce a continuous recording of FHR and uterine contractions, known as a CTG. It reveals information about aspects of FHR such as baseline variability, which cannot be measured using IA. It also produces recordings of FHR decelerations in relation to contractions, which are easier to detect and analyze, and an automatic paper recording is produced for archival purposes (optical disks are increasingly being used for convenient storage). This record is available for subsequent independent review, which is valuable for audit and teaching, although it may be a mixed blessing in medicolegal terms if it reveals abnormalities previously overlooked.

EFMs can measure the FHR and uterine contractions via external transducers using Doppler ultrasound and a tocodynamometer (strain gauge attached to a belt) or via internal sensors such as a fetal electrode and an intrauterine catheter. Despite the fact that the latter methods are more reliable and accurate, and probably more comfortable for the average woman in labor than the belts necessary to attach the external transducers, they are more invasive, and thus, most EFM is performed using external devices. This mode of EFM has a number of problems. First, modern machines generally use a form of autocorrelation or cross-correlation analysis to produce the FHR from ultrasound signals, but the systems are now so sensitive that if the fetus is dead, they sometimes produce a recording of the maternal rate, which can be mistaken for that of the fetus. This is particularly likely if the mother is anxious and has a tachycardia so that her heart rate is similar to that expected of her fetus and can even lead to the erroneous emergency delivery of a dead baby.[50] To avoid this problem, it is good practice always to ensure that rate calculation is derived from the characteristic signals of the fetal heart (sharp and distinct, sometimes sounding like the hooves of a galloping horse), rather than to rely on the "whooshing" sound produced by reflections from fetal blood vessels.

Second, good recording of the FHR depends greatly on correct placement of the transducers on the abdomen. This is not always achieved, and constant readjustment is often necessary if the mother is very active. Unfortunately, it is often the mothers who wish to have an active birth and who are very mobile who decline the use of internal monitoring. This commonly results in loss of adequate signal and FHR information at a most critical time in the labor, the second stage.

Third, the information obtained about uterine contractions using an external transducer is essentially limited to timing them. The external contraction transducer (tocodynamometer) gives only a relative indication of contraction strength, and the recording is attenuated if, for example, the mother is obese or the transducer is poorly placed. This may mislead the birth attendant into underestimating the strength of contractions, particularly in a stoic woman, and thus lead to overdosage with uterine stimulants such as oxytocin. By comparison, the recordings obtained from a directly applied fetal electrode and an intrauterine catheter are much more accurate and less susceptible to recording failure.

One factor that militates against the use of scalp electrodes is the increasing prevalence of the HIV virus. The Royal College of Obstetricians and Gynaecologists (RCOG; UK) advises that women who carry the HIV virus should not have their fetuses monitored using an electrode that breaches its skin, for fear of increasing the risk of transmission of the virus to the fetus. Although women with a detectable viral load are now advised to have their babies delivered by cesarean section, and HIV-infected women normally choose vaginal delivery only if their viral load is undetectable, anonymous testing reveals that in about 25% of cases, women positive for HIV choose not to have antenatal testing and, therefore, go through labor unaware they are at risk.

Interpretation of Fetal Heart Rate Recordings

The key to reliable and consistent interpretation of FHR tracings from CTG machines is a systematic approach. Four

main aspects of the FHR should be assessed: the baseline rate, baseline variability, the presence or absence of accelerations, and the presence and classification of decelerations (slowings of the FHR, or "dips"). Many errors of interpretation occur because of an excessive concern with decelerations and a consequent failure to appreciate the significance of the other three aspects of the FHR. A detailed account of how the FHR can be assessed using a CTG is given in Table 69–5.

A normal CTG pattern is highly reassuring that the fetus is not acidotic; the significance of an abnormal pattern is much more difficult to judge. In general, the more of the four basic aspects of the FHR (baseline rate, baseline variability, accelerations, decelerations) that are abnormal, the more likely the fetus is to be acidotic. However, other factors should modulate the response to such a pattern.

The Time Factor

The fetus does not become acidotic as soon as the FHR becomes abnormal; Fleischer and associates[51] showed that a well-grown fetus can cope with hypoxic stress for as long as 90 minutes before the pH of fetal blood starts to fall. Thus, a normal fetal scalp blood pH 60 minutes after the CTG has become abnormal does not indicate that the abnormality is a "false-positive." The pH of the fetus may begin to fall at any subsequent time; accordingly the only safe plan is to repeat the FBS at hourly intervals (more often if the pattern is severely abnormal) or to deliver the baby.

In contrast, a low pH may be an acute response to temporary interference with maternal placental blood flow and gas exchange. This can occur, for example, after an epidural top-up (with or without maternal hypotension) or because of uterine hyperstimulation with oxytocics. Action should be taken to correct the problem. This can include turning the mother to the left lateral position to correct supine hypotension, stopping any infusions of oxytocic drugs, and giving the mother oxygen by face mask; persisting hypotension from epidural anesthesia can usually be corrected by intravenous injection of a vasoconstrictor such as ephedrine, and excessive uterine activity may be corrected by an infusion of a tocolytic drug such as ritodrine or salbutamol. If the FHR pattern returns to normal, a low pH is often corrected, and immediate delivery of the fetus would be inappropriate. Therefore, it is probably unnecessary to take an FBS in response to an acute FHR abnormality unless the resuscitative measures described earlier do not correct the abnormality of the FHR within 15 to 20 minutes.

Intrauterine Growth Restriction

Any baby thought to be seriously small for gestational age on antenatal assessment or with intrauterine growth restriction seen on serial ultrasound scanning should be treated as particularly at risk during labor.[52] There is an increased likelihood of abnormal FHR patterns and acidosis, so FBSs should be taken more readily and more often than with well-grown babies, and the threshold for operative delivery should be reduced.

Early Gestational Age

Preterm babies are more susceptible to the effects of intrauterine hypoxia than full-term babies; in particular, hypoxia has a damaging effect on the type 2 pneumocytes that produce surfactant in the lungs, increasing the incidence and severity of the neonatal respiratory distress syndrome (hyaline membrane disease).[53] However, the incidence of hypoxia and acidosis in fetuses in preterm labor is not increased compared with fetuses in full-term labor.[54] Preterm babies are more likely to have low Apgar scores than full-term babies, but this is due to functional immaturity and not to the effects of hypoxia.[55] A baby born at 28 weeks' gestation is likely to have poor respiratory effort, to have reduced tone, and to have less reflex irritability, and thus, a lower Apgar score than its full-term counterpart; however, given a normal FHR pattern, it is no more likely to be hypoxic or acidotic.[54] The interpretation of the FHR pattern of the preterm fetus in labor is similar to that of its full-term counterpart.[56] However, some subtle differences may be seen in the FHR pattern.[57] Short-term baseline variability is often rather less, and FHR accelerations less frequent (the differentiation between quiet and active sleep patterns sometimes does not develop until 28 to 32 weeks' gestation). Small, brief (<20 sec) decelerations are often seen and are insignificant (cause unknown).

Presentation of the Fetus

Although current recommendations favor elective cesarean delivery for babies in breech position,[58] there is still a place for vaginal delivery if this is what the mother requests (see Chapter 63). The second stage of labor is prolonged when the fetus is in breech presentation, and therefore, it is probably wise not to embark on a vaginal breech delivery if there is any suggestion of fetal compromise at the onset of the second stage. Thus, if the FHR pattern is entirely normal, vaginal delivery can proceed, but if the FHR is abnormal, fetal condition should be checked by an FBS pH measurement. This can readily be taken from the buttock, and pH values are the same as for babies in cephalic presentation.[59] If the FBS pH is normal, the delivery can be allowed to proceed, but if the FHR abnormality persists, the FBS should probably be repeated if delivery has not occurred within 30 minutes. The passage of meconium is common with a breech presentation and, unless it occurs very early in labor, is not a useful monitoring variable.

Twins or Higher-Order Pregnancy

Because of the increased risk of perinatal mortality associated with being a second twin, there is an increasing trend for elective cesarean delivery. However, vaginal delivery is a reasonable option if that is the parents' preference.[60] The use of ultrasound allows the heart rate of the second twin to be recorded accurately, and in view of the higher mortality rates for the second twins, such monitoring is recommended. The second twin may have heart rate changes suggestive of hypoxia while that of the first twin remains normal.[61] In this case, because FBS is impossible until the first twin has been delivered, cesarean section is probably appropriate.

Instrumental Delivery

Fetal distress is commonly cited as an indication for urgent instrumental vaginal delivery. However, great caution should be applied if the fetal head needs to be rotated. Hypoxia and acidosis can cause cerebral edema, and an edematous brain is stiffer and less flexible than normal. Twisting forces applied in this situation may cause tentorial tears, which

Interpretation of Fetal Heart Rate Pattern (Cardiotocogram)

Admission Test

Normal, reassuring, or reactive
Two or more accelerations (>15 beats/min for 15 sec) in 20 min
Baseline FHR 110–150 beats/min
Baseline variability 5–25 beats/min
Absence of decelerations
Moderate tachycardia/bradycardia and accelerations
Interpretation/action: Risk of fetal hypoxia in next 2–3 hr in spontaneous labor, is low other than following acute events

Suspicious, equivocal, or nonreactive
Absence of accelerations, reduced baseline variability (5–10 beats/min), or silent pattern (5 beats/min), for >40 min, although baseline rate normal (110–150 beats/min)
Baseline FHR < 100 beats/min or >150 beats/min
Variable decelerations (depth < 60 beats/min, duration < 60 sec)
Interpretation/action: Continue CTG, consider vibroacoustic stimulation/fetal scalp pH estimation if CTG not normal in 1 hr

Pathologic/ominous
Silent pattern and baseline FHR > 150 beats/min or < 110 beats/min with no acceleration
Repetitive late decelerations and/or complicated variable decelerations
Baseline FHR < 100 beats/min or prolonged bradycardia (>10 min)
Interpretation/action: Exclude cord prolapse, placental abruption, and scar dehiscence. If small fetus, or thick meconium, or previously abnormal trace, consider immediate delivery. In other situations, consider fetal scalp pH estimation (and, e.g., tocolysis if uterine hyperstimulation, IV fluids if related to epidural "top-up")

First-Stage Intrapartum CTG

Normal, reassuring, or reactive
Two or more accelerations (>15 beats/min for >15 sec) in 20 min
Baseline FHR 110–150 beats/min
Baseline variability 5–25 beats/min
Early decelerations (in late first stage)

Suspicious, equivocal, or nonreactive
Absence of accelerations for > 40 min
Baseline FHR 150–170 beats/min or 100–110 beats/min (normal baseline variability, no decelerations)
Silent pattern > 40 min (normal baseline rate, no decelerations)
Baseline variability > 25 beats/min in the absence of accelerations
Variable decelerations (depth < 60 beats/min, duration < 60 sec)
Occasional transient prolonged bradycardia (FHR drops to < 80 beats/min for > 2 min or < 100 beats/min for > 3 min)
Interpretation/action: Continue CTG, vibroacoustic stimulation or fetal scalp pH estimation if CTG not normal in 1 hr

Pathologic/ominous
Baseline FHR > 150 beats/min and silent pattern and/or repetitive late or variable decelerations
Silent pattern for > 90 min
Complicated variable decelerations (depth ≥ 60 beats/min, duration ≥ 60 sec) and changes in shape (overshoot, decreased or increased baseline heart rate following the deceleration, absence of baseline variability, slow recovery)
Combined/biphasic decelerations (variable followed by late)
Prolonged bradycardia (FHR drops to < 80 beats/min for > 2 min or < 100 beats/min for > 3 min) in a suspicious trace
Prolonged bradycardia (FHR drops to < 80 beats/min for > 2 min or < 100 beats/min for > 3 min) > 10 min
Repetitive late decelerations
Pronounced loss of baseline variability
Sinusoidal pattern with no accelerations
Interpretation/action: Consider fetal scalp pH estimation

Second-Stage Intrapartum CTG

Normal, reassuring, or reactive
Normal baseline heart rate, normal baseline variability and no decelerations, frequent accelerations, both periodic and scattered
Baseline heart rate 110–150 beats/min and baseline variability 5–25 beats/min with or without early and/or variable decelerations

Suspicious, equivocal, or nonreactive
Baseline heart rate > 150 beats/min, persisting or compensatory following each deceleration
Reduced baseline variability or silent pattern decelerations of > 60 sec duration
Mild bradycardia, heart rate catches up between contractions and may reach above 100 beats/min, especially when baseline variability is normal
Interpretation/action: Observe trace for increasing baseline heart rate or bradycardia

Pathologic/ominous
Baseline heart rate < 100 beats/min of different patterns
Progressive bradycardia: baseline heart rate gradually decreases between contractions; absence of baseline variability can be seen especially when heart rate < 80 beats/min
Persisting bradycardia, baseline < 80 beats/min. The additional absence of baseline variability represents a more ominous feature
Baseline tachycardia (>150 beats/min) with reduced variability and severe variable and late decelerations
Interpretation/action: Expedite delivery if not imminent

CTG, cardiotocography; FHR, fetal heart rate.
Courtesy of Hewlett Packard Asia-Pacific Medical Products Group.

would otherwise not occur. Thus, rotational deliveries when the FHR pattern is abnormal should probably be undertaken only after an FBS pH has been measured and found to be normal.[62]

Maternal Preference

A scientific basis for deciding when labor should be terminated operatively for fetal indications remains elusive. Such decisions cannot, therefore, be taken in isolation from the social context, and the wishes and anxieties of the parents should always be taken into account. Some parents have particular anxieties about labor; for example, they may have a sibling with residual damage attributed to birth asphyxia or trauma. In such cases, they may request delivery by cesarean section if there is any sign of fetal dysfunction or delay in labor. In view of the very low mortality and morbidity rates associated with cesarean section in modern practice, especially in the absence of any acute emergency, it is probably wise to accede to such requests unless delivery is imminent and the obstetrician very confident of a successful outcome.

PROCEDURE

FETAL BLOOD SAMPLING

Position

The use of the lithotomy position should be avoided because of the risk of supine hypotension. This can produce iatrogenic hypoxia and acidosis in the fetus, leading to unnecessary operative delivery. The sampling is most comfortably performed with the woman in the left (or right) lateral position.

Procedure

Under aseptic conditions, an amnioscope is passed up the vagina to rest on the presenting part of the fetus. Sufficient pressure must be used to exclude amniotic fluid, which will otherwise contaminate the sample. The fetal skin is then dried with a dental swab in a holder and sprayed with ethyl chloride. The evaporation of the ethyl chloride cools the skin, and as it warms up again, a reactive hyperemia is produced, which aids bleeding. The skin is smeared with a water-repellent gel (often

silicone) so that when the skin is stabbed with a guarded 2-mm blade, a droplet of blood forms. This droplet is allowed to flow into a preheparinized thin glass tube by capillary action (it helps to tilt the tube slightly downward at the operator's end). Mouth-operated suction should not be used because of the risk of the operator ingesting potentially infected blood.

Analysis

The sample is then transferred to a blood gas analyzer for measurement. It is preferable to measure oxygen pressure (PO_2), carbon dioxide pressure (PCO_2), pH, and calculate the base deficit. If the values are normal, but the FHR pattern remains abnormal, it will usually be necessary to repeat the sampling within 15 to 30 minutes.

Use of Intravenous Fluids during Labor and Its Effect on Fetal Acid-Base Balance

Women in labor are commonly advised not to eat, because of the risk of Mendelson's syndrome (aspiration of stomach contents) should they unexpectedly need general anesthesia. As a result, they often develop ketonemia. For this reason, it is common practice to give parenteral fluid containing glucose and electrolytes, particularly if labor lasts more than a few hours. However, Ames and coworkers reported in 1975[63] that infusion of glucose-containing solutions could give rise to maternal lactic acidosis. This is because the rise in maternal blood glucose concentration increases the production rate of lactate, according to Michaelis-Menton kinetics. Subsequently, it was confirmed that maternal infusion of glucose at 100 g/hr (I L of 10% glucose over 1 hr) produced a significant fall in average pH and rise in lactate in fetal as well as maternal blood.[64] However, lactic acidosis does not occur if the glucose infusion rate is restricted to 30 g/hr,[65,66] and there is some evidence to suggest that physiologic amounts of glucose in infused fluids (i.e., 5%) may be associated with less fetal acidosis than glucose-free solutions.[67] These studies indicate that in labor, as at other times, care must be taken to monitor the volume and content of intravenous infusions to ensure they are compatible with the maintenance of normal physiology.

SUMMARY OF MANAGEMENT OPTIONS
Screening for Fetal Distress in Labor

Management Options	Evidence Quality and Recommendation	References
Prevention of Fetal Hypoxia		
Avoid unnecessary induction of labor and excessive use of oxytocic agents.	III/B	36
Preload with IV fluids in women who are having epidural analgesia in labor to reduce the risk of maternal hypotension.	Ib/A	67
Remember the effect of maternal drugs on fetal heart rate patterns.	—/GPP	—

Management Options	Evidence Quality and Recommendation	References
Indications for Continuous EFM		
See Tables 69–3 and 69–4 for conditions associated with an increased risk of intrapartum fetal hypoxia. These indications may classify up to 80% of women as at-risk.	III/B	36
Fetal Monitoring in "Low Risk" Labor		
The advice from the American, Canadian, and British Colleges is that intermittent auscultation can be used in such labors; however, there are no studies of sufficient size to evaluate this approach.	III/B	36
Use of EFM in "High Risk" Labor		
Meta-analysis of randomized, controlled trials shows significant reductions in the short-term neonatal morbidity rate and a significant reduction in perinatal deaths due to hypoxia, but a significant increase in cesarean delivery rates. However, studies are underpowered to show an effect on overall perinatal mortality or cerebral palsy rates.	Ia/A	26,27
Concomitant use of FBS to estimate pH significantly reduces rates of cesarean delivery.	Ia/A	26–28
Admission EFM Recording ("Admission Test")		
This is common practice, but studies of sufficient size to evaluate this approach are lacking.	Ib/A	36,46,47
Interpretation of EFM Findings		
Human factors that adversely affect the outcome of EFM are delays in response times and failure to interpret the findings accurately. Education improves human responses, but this benefit is lost with time.	III/B	19,40–43, 45
Because of the rate of decline in fetal pH after fetal hypoxia, FBS should be performed at least hourly if EFM abnormality is detected. Shorter intervals are advisable with intrauterine growth restriction.	III/B	49,50
If EFM abnormality is detected: • Correct/avoid caval compression. • Give maternal facial oxygen. • Correct hyperstimulation (stop oxytocics, use tocolytics). • Give IV fluids if the patient has epidural-induced hypotension.	III/B	36
EFM in a preterm fetus requires the use of slightly different criteria.	IV/C	56
The maternal pulse may be mistakenly recorded as fetal. The maternal pulse should be regularly recorded clinically by palpation to reduce this risk.	IV/C	48
FBS can be used in breech presentations.	IV/C	59
EFM in twins requires careful confirmation of separate fetal recordings.	IV/C	61
The use of rotational forceps with abnormal EFM is controversial and they should not be used if the fetal scalp pH < 7.15.	IV/C	62
Technical Aspects		
EFM recordings should be retained.	—/GPP	—
External tocometry can lead to difficulty in interpreting the timing of EFM abnormalities (e.g., due to movement, maternal obesity).	—/GPP	—
The conventional advice is that fetal scalp electrodes should not be used in women with HIV.	III/B	36

Management Options	Evidence Quality and Recommendation	References
Other Methods of Fetal Monitoring		
Evidence suggests that pulse oximetry is no better than EFM.	III/B	91
No data are available on the value of near-infrared spectroscopy.	Ia/A	92
Fetal scalp lactate measurement offers practical advantages over pH measurement (less volume of blood and less affected by air bubbles), but no evidence of clinical advantage over pH.	Ib/A	94,95
Electrocardiogram shows no evidence of improved outcome in practice.	Ib/A	48
Expert systems should give better interpretative accuracy. Randomized, controlled trials are awaited.	III/B	88

EFM, electronic fetal monitoring; FBS, fetal blood sampling; GPP, good practice point.

IATROGENIC CAUSES OF FETAL DISTRESS

Excessive Oxytocin Augmentation of Labor

Every uterine contraction above 4 to 6 kPa causes a cessation of maternal intervillous placental blood flow.[68] This produces a period of relative hypoxia for the fetus, such that the fetal PO_2 falls by about 0.5 to 0.75 kPa during each contraction, reaching its lowest level at the end of the contraction, after which the flow is restored and the PO_2 recovers. Because it takes some time for the oxygen-depleted maternal pool of blood to be replaced, recovery takes about 60 to 90 seconds. The total period of reduced oxygenation is therefore 120 to 150 seconds, emphasizing the importance of an adequate intercontraction interval to ensure fetal oxygenation. Poorly controlled oxytocin infusions, which produce excessively frequent contractions, can cause iatrogenic fetal hypoxia and acidosis (see Chapter 67). In practical terms, this means that if the FHR becomes abnormal, oxytocin infusions should be stopped immediately.

Epidural Anesthesia

Before preloading of the circulation with colloid came into practice, abnormalities of the FHR occurred in approximately one third of cases following insertion of an epidural anesthetic. With preloading, this can be reduced by two thirds.[69]

Epidural anesthetics may also cause a fetal tachycardia by inducing hyperthermia in the mother (see Chapter 70). Such tachycardia is not likely to be associated with significant fetal hypoxia, and fetal pH is not affected, but it can give rise to an erroneous diagnosis of fetal distress. It may also lead to a false diagnosis of intrauterine infection, greatly increasing the proportion of newborns investigated with cultures and treated with antibiotics.[70] Probably, the correct response is to cool the mother with tepid sponging.

Drugs

Drugs given to the mother may cross the placenta and affect the fetus. β-Blockers such as propranolol and α- and β-blockers such as labetalol may interfere with the reflex responsiveness of the fetal circulation and impair its response to hypoxia. Other hypotensives such as hydralazine can cause hypoxia by producing maternal hypotension. Sedatives such as pethidine (meperidine) and diazepam (Valium) may depress the fetal central nervous system, reducing the variability of the FHR and producing neonatal depression. Care must be taken to give the minimum of any necessary drug in labor, and the effects on the fetus must always be considered.

OTHER METHODS OF MONITORING FOR FETAL DISTRESS

Fetal Electrocardiogram Analysis

Since the fetal electrocardiogram (ECG) was first demonstrated by Cremer in 1904, attempts have been made to assess fetal well-being by assessing changes in ECG waveform.[71] One approach has been to analyze changes in the PR/R-R interval ratio, but this has not been found to be of value in a prospective, randomized, controlled trial.[72] Another approach used the T/QRS ratio as a measure of acidosis (based on the hypothesis that it is altered by the production of lactate in the fetal heart secondary to hypoxia) and can reduce the need for FBS.[73,74] Two prospective, randomized, controlled trials suggested that it could reduce the need for operative delivery for fetal distress, as well as the incidence of both of metabolic acidosis at delivery and neonatal encephalopathy.[75,76] There have now been a large number of trials of automated fetal ECG (ST segment) analysis. The device used in all these trials (STAN, Neoventa Medical, MoeIndal, Sweden) uses a modified fetal scalp electrode to obtain the fetal ECG. These trials have shown conflicting results. A reduction in the number of instrumental deliveries for fetal distress, admissions to neonatal intensive care, and low Apgar scores has been found (but with no reduction in cesarean section rate) with no adverse effect on neonatal outcome,[77] while others have found no reduction in operative delivery but a reduced need for FBS in labor.[78,79] An improvement of neonatal outcome (fewer cases of metabolic acidosis) has been found in observational studies,[80] whereas others have found only that there was no benefit compared with conventional CTG and FBS.[81]

There have been reports of adverse outcomes, poor signal quality, and difficulty in interpretation of the CTG, with the consequent recommendation for intensive training in the use of the STAN monitor and strict adherence to detailed guidelines in its use.[82,83] Adverse outcomes have occurred when the ECG monitoring was started when the CTG was already pathologic. Because the monitor registers only ECG changes in response to *change* in fetal hypoxia, a fetus that was already hypoxic may not be detected until there is further deterioration. Although it was recommended that in this circumstance, an FBS must be taken before the ECG monitoring was started, sometimes this did not happen, owing to poor understanding of the new technology. In response, detailed guidelines for the use and implementation of this fetal ECG analysis technology have been agreed upon by European experts.[84]

It has also been reported that the system has poor sensitivity (43%) for metabolic acidemia at birth, with a specificity of 74%. Poor ECG quality occurred 11% of the time.[85] In addition, fetal ECG changes have been found to occur frequently—in over 50% of recordings in the first stage of labor and in nearly 25% in the second stage—and occur even when the CTG is normal.[86]

A large prospective, multicenter, randomized, controlled trial comparing CTG plus ECG analysis with conventional CTG plus FBS has now been completed.[87] This has shown no reduction in metabolic acidosis in the CTG + ECG arm of the trial. The protocol for FBS in this trial was detailed; it seems likely that if FBS is used effectively in this manner, together with good CTG interpretation, there would be fewer cases of metabolic acidosis at birth.

Use of the ECG waveform analysis requires the application of a fetal scalp electrode, and so can be used only after rupture of the membranes. This might be considered to be unnecessarily invasive for the majority of low risk women in whom the CTG will be normal. However, many studies have shown that its use can reduce the need for FBS, which is an invasive and often unpleasant procedure for the laboring woman, especially if repeated at regular intervals throughout labor.

Expert Systems

Studies of the efficacy of EFM have consistently found the human component to be the weakest link. Computerized analysis is now commonplace in the evaluation of the adult ECG waveform. Keith and colleagues[88] reported a study in which the ability of an "expert" computer system (Fig. 69–2)
FIGURE 69–2
Principles of expert system cardiotocogram interpretation.
(From Keith RDF, Beckley S, Garibaldi JM, et al: A multicentre comparative study of 17 experts and an intelligent computer system for managing labor using the cardiotocogram. Br J Obstet Gynaecol 1995;102:688–700.)

designed for the interpretation of FHR and FBS data was compared with the opinions of 17 clinicians experienced in fetal monitoring from 16 centers in the United Kingdom. Fifty cases with complete intrapartum CTGs and clinical data were reviewed by the system and each expert independently on two occasions, at least 1 month apart. The system agreed with the experts well and significantly better than chance (67.3%, $K = 0.31$, $P < 0.001$). It was highly consistent (99.16%, $K = 0.98$, $P < 0.001$) when used by two operators independently. It recommended no unnecessary intervention in cases that ended with a normal delivery of a baby in good condition (cord artery pH > 7.15, vein pH > 7.20, 5-min Apgar ≥ 9, and no resuscitation). This was better than all but 2 of the experts. It recommended delivery by cesarean section in 11 cases; at least 15 of the 17 experts in each review also recommended cesarean section delivery in these cases. Most did so within 15 minutes of the system, and two thirds did so within 30 minutes. It identified as many of the birth-asphyxiated cases (cord arterial pH < 7.05 and base deficit ≥ 12, and Apgar score at 5 min ≤ 7 with neonatal morbidity) as the majority of the experts, and 1 more than was acted upon clinically. The experts were found to be consistent and to agree; with the exception of expert "Q." This expert was the only one who declined all information from FBS and attempted to make all decisions on the basis of the FHR alone. In fact, this was the second most inconsistent expert in scoring and obtained the lowest agreement with the other experts (58%, $K = 0.12$). "Q" was also the most inconsistent in recommending cesarean section; in 9 cases, cesarean section was recommended in the first review and not the second or vice versa. "Q" also recommended 2 cesarean sections and 1 second-stage intervention unnecessarily in cases with a normal delivery and a good outcome. Keith and colleagues[88] commented, "in the hands of the experts, this additional information [FBS] clearly adds to the accuracy of decision-making. This information supports the current RCOG [1993] recommendations for using FBS appropriately." A trial to assess the value of this system prospectively in 46,000 labors has been funded by the U.K. Health Technology Assessment Programme and randomization commenced on January 4, 2010 (http://www.hta.ac.uk/1734).

A recent multicenter observational study to determine the sensitivity and specificity of another system of computerized CTG analysis to predict fetal acidemia during labor reported that the sensitivity of the system to predict acidemia is relatively good (95%) when the computer classifies the CTG as suspicious or pathologic, but the specificity is low (22%).[89] This is perhaps not surprising given the known high proportion of false-positive CTGs encountered during labor. Individual features of the CTG (e.g., variability, decelerations) had much lower individual sensitivities.

Transcutaneous Gas Measurements

In the late 1970s, transcutaneous P_{O_2} measurements using a modified Clark electrode became possible. However, the technique was difficult; the scalp had to be shaved, dried, and readily accessible to a fairly large probe, which then had to be glued to the skin or held on by suction. The probe had to be heated to arterialize the circulation and allow oxygen to diffuse out of the fetal arterioles. There were

problems with trauma and heat injury. In addition, the measurement of PO_2 is a measure of hypoxic stress but does not quantify response (acid-base buffer reserve) in the way that measuring pH does; it is very susceptible to local and acute changes.

Further attempts to improve acceptability have been made by using pulse oximetry, which does not require the probe to be heated; instead, it uses infrared light to detect changes in oxygenated hemoglobin concentration in the tissues during the arterial pulsation cycle. However, this system also has problems: it cannot work through hair (which leads to practical difficulties with placement) or meconium, it is susceptible to maternal and fetal movement, and it sometimes produces inconsistent results. Results suggest that 30% to 60% saturations are the normal range in the human fetus, indicating that prolonged desaturation is physiologic in the human fetus.[90] This makes the significance of the readings difficult to assess clinically. If a cutoff of 30% saturation is used, values below this have a sensitivity of 94% in detecting pH less than 7.13, but the specificity is only 38%.[90] This means that the technique is similar to, but not better than, continuous FHR monitoring as a screening test for acidosis. Some studies have shown a reduction in cesarean section rate, or in the need for FBS, but there have been conflicting results and meta-analysis has shown no benefit from the use of fetal pulse oximetry in labor.[91]

Near-infrared spectroscopy is a related technique that uses infrared light at two frequencies to assess the difference in concentrations between oxygenated and deoxygenated hemoglobin concentrations and, hence, the oxygen saturation of the blood. However, the method is expensive and presents many technical difficulties, including frequent probe detachment. No published trials have examined the ability of near-infrared spectroscopy in assessing fetal condition during labor.[92]

Fetal Scalp Lactate Measurement

In theory, lactate measurement assesses hypoxic and anerobic metabolism leading to a metabolic acidosis, which is very similar to that obtained by measuring base deficit. In practice, two randomized, controlled trials using lactate compared with pH to assess metabolic acidosis have shown no significant differences in clinical performance.[93,94] The practical advantages in measuring lactate are that very small sample volumes are needed (5 μL vs. 25 μL for pH estimation), and the values are not significantly altered by contamination of the sample with air bubbles.[95]

CORD PROLAPSE

Prolapse of the umbilical cord in labor is an uncommon event; reported incidences vary from 1 in 265 to 426 labors. The occurrence of cord prolapse is most commonly associated with breech and other malpresentations, a high head at the onset of labor, multiple gestation, grand multiparity, abnormal placentation, preterm labor, polyhydramnios, and obstetric manipulations such as forceps delivery.[96] The diagnosis is commonly made during a vaginal examination; the examiner feeling a soft, usually pulsatile structure. In one series, in 4% the cord was presenting, in 11% it was alongside the presenting part, in 45% it was in the vagina, and in 39% the cord appeared at the introitus.[97] The last mentioned is more likely to occur after artificial, or sudden spontaneous, rupture of the forewaters than in association with a hindwater leak. Occasionally, the diagnosis may be suggested by the sudden appearance of large variable decelerations on the CTG. The mode of delivery remains controversial. As neonatal care has improved, so has the perinatal mortality associated with cord prolapse steadily declined, irrespective of the mode of delivery. For example, in one series reported in 1977, the perinatal mortality rate was 430 per 1000 births,[97] in 1985, 162 per 1000 births, and in 1988, 55 per 1000 births[98]; although a recent report from Israel found a perinatal mortality of 83 per 1000.[96] Some studies emphasized the danger of prolonged prolapse-to-delivery interval and urged prompt cesarean section unless the cervix is fully dilated and the presenting part is at or below the ischial spines so that the fetus is immediately deliverable by forceps (which is the case in about 20%–30%). While the woman is being prepared for the operation, it is usually recommended that she be nursed in the traditional knee-chest position facing downward or, alternatively (and often more practically), in steep Trendelenburg position. It may be necessary for a birth attendant to keep a gloved hand in the vagina to elevate the presenting part and relieve pressure on the cord. One technique first suggested by Vago in 1970 and since commended by others[99] is to fill the urinary bladder with 500 to 700 mL of saline, elevating the presenting part and relieving pressure on the cord. However, more recently, one paper championed manual replacement of the cord[98] (termed *funic reduction*), describing a successful vaginal delivery in seven of eight cases so treated (one was too far advanced in labor for this to be feasible and a cesarean section was performed). The interval between replacement of the cord and final delivery ranged from 14 to 512 minutes (8.5 hr!).

SUMMARY OF MANAGEMENT OPTIONS
Cord Prolapse

Management Options	Evidence Quality and Recommendation	References
Cesarean section while pressure on the cord is relieved until delivery:	III/B	99
• Manual elevation of the head away from the cord.		
• Knee-chest position.		
• Steep Trendelenburg position.		
• Filling of the bladder with up to 700 mL normal saline.		

Cord Prolapse—cont'd

Management Options	Evidence Quality and Recommendation	References
Instrumental delivery if the patient is in the second stage of labor, the presenting part is below the level of the ischial spines, and easy, prompt vaginal delivery is anticipated.	III/B	99
The value of funic reduction (manual replacement) is uncertain because few patients have been studied.	III/B	98

INTRAPARTUM FETAL RESUSCITATION

In general, if acute fetal hypoxia is evident and acidosis is rapidly developing, the best management is emergency cesarean section, preferably within 15 minutes. If the presentation is occipitoanterior, the presenting part is at or below the spine, and there is no obvious evidence of disproportion, a nonrotational forceps delivery is an appropriate alternative. Various studies have reported attempts at intrauterine resuscitation of the fetus, and maneuvers recommended include turning the mother to the left side, giving her oxygen by face mask, stopping any oxytocic infusion, uterine tocolysis, and correction of any hypotension. Although there is anecdotal evidence that these maneuvers may be effective in appropriate circumstances, no randomized studies attest to their efficacy.

MECONIUM STAINING OF THE AMNIOTIC FLUID

Aspiration of meconium by the fetus remains a relatively common cause of perinatal mortality and morbidity because it is difficult to prevent. The fetus passes meconium into the amniotic fluid in approximately 10% of all pregnancies; in up to 5% of these (i.e., in 1:200 of all pregnancies), the meconium is aspirated and can lead to meconium aspiration syndrome (MAS). MAS can cause, or contribute to, neonatal death in up to 0.05% (i.e., 1:2000 of all pregnancies).[100,101] In addition, up to one third of all cases in which aspiration occurs develop long-term respiratory compromise.[102,103] The incidence of MAS may be falling in developed countries: fewer pregnancies are proceeding beyond 42 weeks because of increased use of ultrasound dating of pregnancy and induction between 41 and 42 weeks.[104]

It seems likely that the causes of meconium passage by the fetus are not necessarily the same as those that cause aspiration, and so in the account that follows, the two aspects are addressed separately.

Passage of Meconium

Mechanism

Meconium is passed into the amniotic fluid by peristalsis of the fetal gut accompanied by relaxation of the internal and external anal sphincters. In the adult, this process is a complex interaction of hormonal, myogenic, and neurogenic factors. Peristalsis is principally controlled by local reflexes acting via the neural complexes in the gut wall, but is usually modified by extrinsic innervation. Sympathetic activity inhibits rectal activity and causes constriction of the internal anal sphincter, whereas parasympathetic activity has the opposite effects. In the resting state, the internal and external sphincters are constricted. In the adult, involuntary defecation can occur in response to stress ("flight-or-fight reaction"). This is mediated centrally by the hypothalamus (and possibly the amygdala), which in turn, causes stimulation of the visceral parasympathetics.[105,106] In contrast, pathophysiologic stresses such as pain, heat, cold, injury, exercise, and nonintestinal infections all produce gut stasis and constipation.[105] It is attractive to suggest that the fetus may exhibit a similar response to the "emotional" stress of labor, but this concept is likely to remain an untested theory. The fetus is stressed pathophysiologically in labor by hypoxia, pyrexia, or compression, which by extrapolation from adult physiology would be more likely to produce gut stasis than increased motility. However, fetal physiology differs in many ways from that of the adult, and our knowledge of the mechanisms of gut motility and meconium passage in the fetus is poor.

The Effect of Maturity and Gestation on Passage of Meconium

Meconium is found in the fetal gut from 10 weeks' gestation,[107] but passage of meconium is rare before 34 weeks.[4] The incidence of meconium passage increases with gestational age and reaches approximately 30% at 40 weeks' gestation and 50% at 42 weeks.[4,108] The presence of meconium in the amniotic fluid may reflect fetal gastrointestinal maturity.[109] Fetal gut transit time does decrease with gestational age, and gut motility increases. The low gut motility in the preterm fetus has been attributed to a lack of gut wall musculature, but this is unlikely because peristalsis has been reported before 12 weeks' gestation and muscle development must have occurred before this.[110]

Immature innervation of the fetal gut is more likely, with preterm fetuses having fewer myelinated axons and ganglion cells in the colon than full-term infants. Meconium passage in the preterm fetus can occur if it becomes infected with organisms that can cause a fetal enteritis (e.g., *Listeria monocytogenes*, *Ureaplasma urealyticum*, rotaviruses).[111] The fetal gut

must be sufficiently developed for peristalsis to occur and meconium to be passed even in the preterm fetus.

Hormonal Control of the Passage of Meconium

The intestinal hormone motilin has been implicated in the passage of meconium in utero; it causes contraction of smooth muscle in the gut wall. Motilin levels in umbilical venous blood increase with gestation, and if they reflect levels in the fetal gut, this could be a factor in explaining the tendency for the mature fetus to pass meconium.[112] Cord levels are also higher in infants that have passed meconium prenatally,[113,114] and one study found that they were also higher if an FHR abnormality had occurred in labor.[99] This latter finding was not confirmed in a later study in the same year,[114] but different definitions of FHR abnormality were used. It is possible that stress on the fetus could cause release of motilin and thus passage of meconium, but this remains conjectural. The hormonal and other factors that control gut motility are largely unknown, even in the adult.

Infection and the Passage of Meconium

Meconium-stained amniotic fluid is associated with increased peripartum infection rates, independent of other risk factors for infection. Thick meconium, in particular, is associated with a marked increase in peripartum infectious morbidity.[115–117] It is not yet clear whether the presence of meconium encourages infection or whether infection promotes the passage of meconium by the fetus. In favor of the former, prophylactic intravenous ampicillin-sulbactam significantly reduces intra-amniotic infection in patients with meconium-stained amniotic fluid,[118] although the possibility remains that the presence of the infection antedated the appearance of the meconium and was unrecognized. In addition, meconium is a chemoattractant and activator of polymorphonuclear leukocytes in vitro and for cytokines such as tumor necrosis factor-α (TNF-α), interleukin-1 (Il-1), and Il-8.[119] It may be that meconium increases the damaging effects of infection by increasing the presence of these inflammatory mediators.

Obstetric Cholestasis

The risk of meconium passage increases in association with cholestasis of pregnancy.[120] This may be secondary to elevated levels of bile acids in the maternal circulation, which cross the placenta and affect the fetus. Cholestasis of pregnancy also increases the bile acid content of meconium.[121] The same study also found that, although maternal ursodeoxycholic acid (UDCA) therapy caused a reduction in serum bile acid levels in the mother, there was no associated reduction in the levels of meconium passage in the fetus. The implications of this are unclear, but it is possible that if UDCA does not affect fetal bile acid levels significantly, perinatal loss rates associated with cholestasis of pregnancy will not improve.

Risks

Fetal Hypoxia

An association between meconium passage in utero and poor condition of the neonate has been suggested since ancient times. Aristotle reported opium-like effects in neonates born

through meconium-stained fluid, and there have been references to meconium in association with perinatal death from as early as 1676 (quoted in Schulze[122]). Subsequently, many authors have suggested that fetal hypoxia causes intestinal peristalsis, relaxation of the anal sphincter, and thus, passage of meconium. This view has largely been assumption, with little or no direct evidence to support such a hypothesis. Stander[123] claimed that meconium was a sign of impending fetal "asphyxia" due to "relaxation of the sphincter ani muscle induced by faulty aeration of the blood" and proposed prompt delivery whenever meconium was seen. Desmond and associates[124] claimed that meconium staining of the amniotic fluid was a marker of fetal hypoxia, but no blood gas analysis of either fetal or neonatal blood was performed; the diagnosis of hypoxia being made on clinical grounds alone. These observations were made despite the report of Schulze,[122] who had concluded from a study of a series of more than 5500 births in California, that passage of meconium during labor "is in the large majority of cases independent of fetal asphyxia" and that the presence of old meconium in the amniotic fluid was of no prognostic significance for the later development of asphyxia (asphyxia here was not defined but appears to mean "lack of respiratory effort at birth"). She also observed that in cases associated with asphyxia, there were always changes of the FHR during labor and that these changes should be the sole guide to the necessity for delivery. However, in a later study, meconium passage was associated with low umbilical vein oxygen saturation, and thick meconium with lower levels of PO_2 than thin meconium.[125] This remained the principal experimental evidence linking fetal hypoxia with meconium passage and was widely quoted, often as the sole evidence, for at least the subsequent 20 years.

Fenton and Steer[126] made one of the first attempts to separate meconium passage from other markers of fetal compromise such as abnormality of heart rate, but again, had only presumptive evidence of hypoxia in the fetus. They stated that there were other, benign causes of meconium passage and suggested that the passage of meconium was not significant if the FHR was greater than 110 beats/min. The introduction of FBS began to clarify the situation. Miller and coworkers[127] found no difference in scalp blood pH, umbilical cord artery and vein pH, and neonatal arterial pH up to 64 minutes of life, between meconium and nonmeconium groups, if the FHR during labor had been normal. They concluded that meconium in the absence of other signs was not a sign of fetal distress (defined as "late decelerations on the CTG and umbilical artery acidosis"). Further studies confirming the same finding (that there is no obvious link between the presence of meconium and hypoxia) continue to be published regularly and include the use of fetal pulse oximetry and fetal hemoglobin analysis.[128–130]

If the FHR pattern is abnormal, however, the presence of meconium is associated with an increased chance of a baby being acidotic, born in poor condition, and needing resuscitation at birth.[4,127] In the data presented by Steer and associates,[4] 140 babies had an abnormal CTG pattern in the first stage of labor. The mean cord artery pH was 7.22 (SD = 0.10) in the 108 cases with clear amniotic fluid compared with 7.17 (SD = 0.12) in the 32 cases with meconium-stained amniotic fluid ($t = 2.37$, $P = .0096$, one-tailed). The incidence of 1-minute Apgar scores less than 7 was 19% (3%

at 5 min) if the amniotic fluid was clear compared with 56% (9% at 5 min) if the amniotic fluid was meconium-stained. The difference was significant at 1 minute ($P = 0.0001$; Fisher's exact test). However, they commented that the reduction in the 1-minute Apgar score may have been due at least in part to the use of pharyngeal suction or endotracheal intubation by the attending pediatrician suppressing spontaneous respiration and, thus, iatrogenically reducing the Apgar score.

Despite the lack of a clear relationship between meconium staining of the amniotic fluid and fetal acidosis in the absence of FHR changes, we cannot conclude that the presence of meconium is not a threat to the fetus or neonate even if the FHR is normal. Yeomans and colleagues[39] studied 323 pregnancies with meconium-stained amniotic fluid at 36 to 42 weeks' gestation. Although there was a significantly higher incidence of meconium below the vocal cords if an umbilical artery pH was less than 7.20 compared with when the umbilical artery pH was 7.20 or greater (34% vs. 23%), the difference in the incidence of clinical MAS according to pH was not significant. Moreover, 69% of babies with meconium below the cords had cord arterial pH of 7.2 or greater. Thus, a normal pH does not exclude the possibility of meconium aspiration, and most babies with meconium aspiration do not have acidosis. These data do not support the hypothesis that fetal hypoxia is a major cause of meconium passage in labor, and indeed, Naeye and associates[131] reported that meconium staining of the amniotic fluid was not more common, even when the neonate was hypoxic.

Evidence that hypoxia per se does not lead to passage of meconium has been available for many years. Becker and coworkers[109] showed reduced peristalsis in the fetal guinea pig after induction of maternal hypoxemia, and a similar result was seen in the monkey fetus. In the adult with spinal shock, although the external sphincter relaxes, constipation occurs owing to the loss of the other defecation reflexes. If meconium passage does occur in response to reduced intestinal blood flow, it must be an early event for the neurogenic reflexes still to be present. Meconium passage may occur as a result of vagal stimulation, and this could account for coexisting reduction in the FHR.[126] Parasympathetic stimulation is known to occur with cord compression, and this is supported by meconium passage being more common with increasing gestational age. Emmanouilides and colleagues[132] found that in the sheep fetus, if one umbilical artery was ligated, passage of meconium occurred only as a very late phenomenon, after chronic fetal wasting had developed. Although it is widely stated that fetal hypoxia leads to meconium passage in laboratory animals, the studies usually cited were concerned with the investigation of fetal breathing movements and do not state that meconium was passed in response to hypoxia.[133,134] However, recent work in the sheep and rat suggests that a possible mechanism for hypoxia-related meconium passage may be mediated by corticotropin-releasing factor (CRF).[135] It is postulated that stress (including hypoxia) leads to increased release of CRF, which in turn, increases gut motility. Inhibitory CRF receptors in the fetal gut decrease toward term, and stimulatory receptors increase.[136] It has been demonstrated that hypoxia is a potent inducer of meconium passage in the fetal rat, and this appears to be mediated by a CRF-dependent pathway.[137]

Whether this pathway is similar in the human fetus is yet to be determined.

Meconium Aspiration

The passage of meconium is not a risk to the fetus, but aspiration of the meconium into the fetal or neonatal lung is associated with clinical disease ranging from mild transitory respiratory distress to severe respiratory compromise and occurs in up to one third of cases. *Meconium aspiration* is commonly defined as the presence of meconium below the vocal cords and occurs in up to 35% of live births with meconium-stained liquor.

Aspiration of meconium was thought by many authors to occur at delivery as the newborn infant took its first breath. Oropharyngeal suction, and endotracheal intubation of the infant before the first breath were widely promoted, to prevent meconium aspiration. However, it now seems likely that meconium aspiration is largely an intrauterine event. This change of view has occurred because of compelling evidence that severe MAS still occurs despite adequate suction at delivery.[39,138,139]

The current view is that meconium aspiration occurs owing to fetal breathing movements, causing inhalation of amniotic fluid with meconium, if present. Two types of breathing movements cause inhalation of amniotic fluid: gasping and deep breathing. Gasping is a normal response to hypoxemia and can be induced experimentally by occluding the umbilical cord or by occluding the maternal aorta.[134,140]

The fetus may also inhale meconium by deep irregular breathing in utero, not initiated by hypoxia. These breaths become more frequent as gestation advances and account for 10% of all fetal breathing movements.[134] The passage of amniotic fluid deep into the lung has been demonstrated by radiolabeling experiments that also showed that the human fetus inhales 200 mL/kg/24 hr of amniotic fluid.[141] Fetal hypercapnia and acidemia also increase these breathing movements, but they still occur in most, if not all, normal fetuses.[134,142] Although some infants with meconium aspiration are severely compromised at birth, there is little or no difference in umbilical cord acid-base status between infants with meconium below the cords and those without.[39] Meconium aspiration is more common if the meconium is thick rather than thin. This may be a reflection of the fact that oligohydramnios (and therefore thick undiluted meconium) is more likely to lead to fetal hypoxia due to cord compression and, consequently, increased fetal breathing.

Meconium Aspiration Syndrome
GENERAL

MAS represents a wide spectrum of disease ranging from transient respiratory distress with little therapy required to severe respiratory compromise requiring prolonged mechanical ventilation and high levels of oxygen administration. Neonatal death occurs in up to 40% of cases.[143]

Severe MAS is associated with profound hypoxia, which is secondary to right-to-left shunting, a persistent fetal circulation, resistant pulmonary hypertension, pulmonary hemorrhage, necrosis of pulmonary vessels, and muscularization of distal pulmonary arterioles.[101,144,145] These changes may be due to intrauterine hypoxia, rather than to the meconium

itself, although the inhalation of meconium exacerbates the problem in several ways in the neonatal period.

Meconium inhaled by an infant who has not been subjected to hypoxia usually causes mild disease only and is asymptomatic in 90% of cases. Exposure to intrauterine hypoxia causes pulmonary vasoreactivity that persists after birth. Large increases in pulmonary artery pressure in response to very small falls in oxygen tension then result. The severity of this pulmonary vasospasm seems to depend on the severity of the fetal hypoxia and may be fixed (completely unresponsive) in the most severe cases. These changes have been demonstrated experimentally and observed clinically. A vicious circle of hypoxia, pulmonary vasospasm, shunting, and therefore, worsening hypoxia can develop. Jovanovic and Nguyen[146] showed in the guinea pig that meconium or amniotic fluid aspiration in the absence of hypoxia caused minimal damage, whereas lung damage (necrosis of alveoli and diffuse hemorrhage) in the hypoxic cases was severe whether the amniotic fluid contained meconium or not. The degree of lung destruction seems to depend primarily on the length and degree of hypoxia, not simply the aspiration of meconium. Hypoxic damage also reduces the clearance of aspirated meconium or amniotic fluid.[147] Meconium does, however, exacerbate the problems faced by the neonate. It displaces surfactant, causing atelectasis and hyaline membrane formation[148–150] and causes a chemical pneumonitis possibly due to cytotoxicity to the type II pneumocytes caused by bile salt–induced accumulation of calcium.[151] In addition, it enhances bacterial growth and is associated with intrauterine infections. Aspiration may lead to infectious pneumonitis.

Some bacterial toxins cause pulmonary vascular spasm, exacerbating the effects of hypoxia.[111,152,153] Meconium has been demonstrated to cause vascular necrosis and vasoconstriction in the umbilical cord and may cause similar damage in the lung.[154] The umbilical vasoconstriction may cause hypoxia in utero, leading to aspiration. Inhaled thick meconium may cause a physical obstruction to the airways, leading to distal lung collapse, with hyperinflation in other areas of the lung. In total, 95% of severe cases of MAS occur when the meconium is thick, which is more common in post-term pregnancies when a relative oligohydramnios develops. Oligohydramnios may also be due to hypoxia, causing reduced fetal urine output,[155] or may be a sign of uteroplacental insufficiency.

METHODS OF PREVENTING MECONIUM ASPIRATION SYNDROME

During the 1950s and 1960s, it was thought that meconium-stained amniotic fluid was a marker of fetal compromise, and efforts were made to detect meconium in the amniotic fluid in late pregnancy and to deliver the fetus either before, or as soon as, meconium appeared. Amnioscopy was introduced for pregnancies more than 10 days past the expected date of confinement. It was stated that the finding of meconium indicated "impending danger" and that immediate amniotomy and FBS should be performed; the ensuing uterine contractions were thought to be therapeutic for the fetus. A threefold reduction in perinatal mortality was claimed,[156,157] but other investigators have been unable to reproduce these results. Saldana and associates[158] showed no benefit from amnioscopy and delivery. Amnioscopy has not been shown to be beneficial, is uncomfortable for the mother, may result in accidental rupture of the membranes or induce labor, can cause infection, and has to be repeated at regular arbitrary intervals until delivery.

Benacerraf and coworkers[159] reported the detection of thick meconium by ultrasonography, but further studies showed that vernix can produce an ultrasonically indistinguishable image in the absence of meconium.[160,161]

Because meconium passage is more common with advanced gestational age, many studies have investigated the effect of inducing labor at an earlier gestation. In a controlled trial, Cole and colleagues[162] significantly reduced the incidence of meconium-stained liquor by inducing at 39 to 40 weeks' gestation, but no effect on perinatal mortality or respiratory disease was seen. Other studies of induction of labor have not shown a decrease in meconium aspiration, even if the incidence of meconium staining of the liquor was reduced.[163–165] There is, thus, no evident benefit from induction of labor before meconium appears or from the routine use of amnioscopy, and disadvantages to both procedures exist.

In the 1970s, it was widely believed that meconium aspiration developed by inhalation of the meconium at delivery when the infant took its first breath. To prevent this, aggressive policies of oropharyngeal suction, endotracheal intubation, and splinting of the thorax to prevent aspiration were proposed. Despite these interventions, cases of meconium aspiration still occurred, and further studies showed little or no reduction in MAS. A decline in the mortality from meconium aspiration is probably due to concurrent advances in perinatal medicine, rather than to the introduction of suction protocols. Suction and intubation are not free of risk. Cordero and Hon[166] reported apnea and bradycardia in infants having nasopharyngeal suction, and Linder and associates[167] found no benefit from the intubation at birth of meconium-stained but otherwise normal infants. All cases of meconium aspiration in this study occurred in the intubated group, and two cases of laryngeal stridor also required repeated hospitalization with residual hoarseness at 6 months of age. Cunningham and coworkers[168] recommended routine oropharyngeal suction but not intubation. There is now widespread acceptance that routine suctioning and intubation of neonates that have passed meconium have little, if any, effect on aspiration and may have deleterious side effects. A recent review of the year 2000 Neonatal Resuscitation Program (NRP) guidelines[169] has confirmed that the recommended fall in intubation rates has had no effect on outcome for babies born through meconium-stained amniotic fluid, and ACOG[170] endorses this approach, only recommending intubation and suction if the neonate is depressed at birth.

Amnioinfusion, the instillation of normal saline into the uterus during labor, has been proposed as a method to reduce meconium concentration and, therefore, the effects of aspiration. It may reduce cord compression in cases of oligohydramnios and, therefore, fetal gasping. Large randomized, controlled trials in Africa have shown significant improvements in outcome,[171,172] but a large multicenter trial in Europe, North America, South America, and South Africa failed to show the same benefits.[173] Meta-analysis of the randomized studies investigating amnioinfusion has concluded that there is no benefit in clinical settings with

standard peripartum surveillance, but that the risk of MAS is reduced in settings with limited peripartum surveillance where the risk of MAS is more common.

The beneficial effect of amnioinfusion may be due to a reduction in cord compression during uterine contractions and, therefore, possible fetal hypoxia or directly to a reduction in the concentration of meconium. However, because thick meconium is often associated with oligohydramnios, the benefits of amnioinfusion may be due solely to correction of amniotic fluid volume.

Attempts have been made to classify meconium in labor according to its concentration, because thick meconium has been associated with increased incidence and severity of MAS. However, any grading system is subjective because amniotic fluid draining during labor may not be representative of the fluid in utero, and no fluid may drain at all in cases of oligohydramnios, masking the presence of meconium. Quantifying the meconium concentration by centrifuging samples of amniotic fluid and measuring the amount of solid matter in the sample has been attempted,[174,175] but the same problems of obtaining amniotic fluid representative of the intrauterine milieu exist. In addition, neither author addressed the problem of vernix and solid matter other than meconium in the liquor producing false-positive results.

Two reports suggested that social support during labor reduces the incidence of meconium staining,[176,177] but in both cases, more oxytocin was used in the group with no support, which could have lead to unphysiologic contractions and fetal hypoxia.

Evidence linking fetal distress and meconium should be viewed with caution because the events during labor and delivery do not represent the intrauterine environment at the time of meconium passage. In addition, it is unlikely that prevention of meconium passage or aspiration will be successful until there is some elucidation of the underlying causes. Intrauterine probes to measure meconium concentration in the amniotic fluid continuously during labor, using a light-reflectance method, have been developed.[178] Although this enabled observation of the events at the time of meconium passage (e.g., FHR changes, epidural top-ups) and was able to detect meconium not otherwise visible to the birth attendants, it is unlikely to be clinically useful in the foreseeable future.

Management Options with Meconium Staining of the Amniotic Fluid

When amniotic fluid is seen to drain, it should always be inspected carefully for the presence of meconium. If meconium is detected, continuous electronic FHR monitoring is recommended. If the FHR pattern remains normal, no specific action is necessary, except to avoid actions that might precipitate acute fetal hypoxia (supine hypotension, epidural hypotension, uterine hyperstimulation with oxytocics). In particular, there is no indication for routine FBS and pH estimation as long as the FHR pattern is normal. At delivery, a pediatrician should be present. If the baby is vigorous and cries promptly, there is no need for further action. Although there is no proof of efficacy, some pediatricians prefer to suction the pharynx as soon as possible after delivery of the head, and this is acceptable as long as care is taken not to traumatize the pharynx or larynx, because this may precipitate meconium aspiration.

If the FHR pattern is abnormal during labor, the likelihood of acidosis is substantially increased. Consideration should be given to immediate delivery, if necessary by cesarean section. If rapid progress in cervical dilation is occurring, it may be appropriate to take an FBS and allow the labor to continue if the pH is above 7.20, but this decision must take into account other factors such as the wishes of the mother, and whether there are other risk factors, such as intrauterine growth restriction. Amnioinfusion should be considered if it is decided to allow the labor to continue. Amnioinfusion can also be considered even if the FHR pattern is normal, as a preventive measure.

Umbilical Cord Blood Gas Sampling

Cord blood gas analysis provides an objective measure of the condition of the baby at birth. An umbilical arterial metabolic acidemia will be present if the fetus has experienced significant hypoxia prior to delivery. RCOG[179] and NICE[36] have recommended measurement of umbilical artery and vein blood pH and base deficit in all cases, whereas ACOG[180] recommends sampling for cases of cesarean delivery for fetal compromise, low 5-minute Apgar score, severe growth restriction, abnormal fetal heart rate tracing, maternal thyroid disease, intrapartum fever, and multifetal gestation. Cord blood gas analysis has important medicolegal implications: normal values will make the attribution of any handicap to intrapartum events very difficult (see earlier). Audit of practice can utilize cord blood gas results as a measure of the standard of intrapartum care, and in addition, knowledge of the result may assist analysis of clinical events and management in labor.

PROCEDURE

UMBILICAL CORD BLOOD GAS SAMPLING

Procedure

- A segment of cord must be isolated between two sets of clamps after delivery.
- (Changes in the pH, Pco_2 and Po_2 of cord blood occur slowly. Cord blood can be left at room temperature for up to 1 hour without significantly affecting the results and for several hours if left on ice.)
- Use commercially preheparinized blood gas syringes to take cord blood samples.
- (Heparin is acidic and if too much is used (>10% of sample volume) can cause significant errors.)
- Blood must be taken from both artery and vein and the results checked to ensure both vessels have been sampled. If both results are very similar, it is likely that the umbilical vein has been sampled twice (the vein is much easier to obtain a sample from).
- Sample the cord vessels with the needle at an acute angle to the vessel especially when sampling the umbilical artery—this makes it less likely to insert the needle through the distal arterial wall into the vein.

Analysis

- The normal values are given in Table 69–6.
- Cord arterial values reflect fetal acid-base status, whereas those of the vein reflect maternal and placental status.
- The umbilical vein pH may be normal but the arterial pH low if there has been a interruption to umbilical blood flow (e.g., cord compression or if the fetal hypoxia has been of short duration).
- If both artery and vein have a low pH, this indicates that the hypoxia is of longer duration and is usually due to metabolic acidemia.

TABLE 69–6

Umbilical Cord Blood Gas Values

	NORMAL VALUES (MEAN, 5th, 95th CENTILE)	
	UMBILICAL ARTERY	UMBILICAL VEIN
pH	7.23 (7.1, 7.34)	7.32 (7.19, 7.43)
P_{O_2} (kPa)	2.9 (1.5, 4.9)	3.7 (2.1, 5.4)
P_{CO_2} (kPa)	6.1 (4.2, 8.4)	4.9 (3.5, 6.9)
BDecf (mmol/L)	−7.7 (−14.5, −1.8)	−6.4 (−11.7, −1.6)

Note: Gestational length has no significant effect on cord blood gas values.
BDecf, base deficit of extra cellular fluid; P_{CO_2}, carbon dioxide pressure; P_{O_2}, oxygen pressure.
From Eskes TK, Jongsma HW, Houx PC: Percentiles for gas values in human umbilical cord blood. Eur J Obstet Gynecol Reprod Biol 1983;14: 341–346.

SUMMARY OF MANAGEMENT OPTIONS

Meconium Staining of the Amniotic Fluid

Management Options	Evidence Quality and Recommendation	References
Incidence		
Meconium aspiration syndrome contributes to neonatal death in approximately 1 in 2000 births.	III/B	100–102
The main influence on the passage of meconium is gestational age.	III/B	108,109
Meconium aspiration is associated with infection, particularly in the lungs.	III/B	115–119
Fetal passage of meconium is more common in cholestasis of pregnancy.	III/B	120,121
Hypoxia and acidosis do not, per se, lead to the passage of meconium.	III/B	39,128
The combination of severe hypoxia and meconium aspiration causes lung damage.	III/B	147–149
Prevention		
A pediatrician should be present for delivery, but should not perform routine oropharyngeal suction in the absence of evidence of fetal hypoxia because suction does not reduce the incidence of meconium aspiration syndrome.	IIa/B	166,167
Meconium aspiration and acidosis are reduced by amnioinfusion of normal saline.	Ia/A	171

Neuraxial Analgesia and Anesthesia in Obstetrics

LAWRENCE C. TSEN

INTRODUCTION

In 1847, the obstetrician James Young Simpson ushered in the use of anesthetic agents for obstetrics with the application of diethyl ether to assist a vaginal delivery. Over the next half century, an evolution in the agents and techniques used for the provision of obstetric analgesia (pain relief) and anesthesia occurred. Regional anesthetic techniques, which deliver pain relief to a discrete region of the body, metamorphosed to include the use of medications near the spinal cord via the central neuraxial (i.e., spinal [subarachnoid], or epidural) spaces. Since Oskar Kreis first described the use of spinal anesthesia in obstetrics in 1900, neuraxial techniques have evolved from single, limited-duration injections into the spinal sac to titratable, controlled infusions through flexible catheters most commonly placed into the epidural space. The combined spinal-epidural (CSE) technique, first introduced to obstetrics in the 1980s, consists of the delivery of medications through a needle into the spinal sac and, later, through a catheter into the epidural space; the spinal and epidural spaces are approached within a single procedure (Fig. 70–1).[1] The CSE technique provides rapid and profound initial pain relief with the ability to extend the analgesia or anesthesia. The use of epidural, spinal, and CSE techniques has increased dramatically owing to the quality and safety of the analgesia and anesthesia produced, the ability to titrate the degree and duration of pain relief as required by the circumstances, and the limited maternal and fetal effects. Currently, in most developed countries, neuraxial techniques provide labor analgesia for 30% to 50% of all parturients and the anesthesia for the majority of instrumental and operative deliveries (Fig. 70–2).[2–4]

In this chapter, the indications and implications of neuraxial techniques to provide obstetric analgesia and anesthesia are discussed. Emphasis is placed on the novel indications for these techniques as well as the association of these techniques with two outcomes of common obstetric and anesthetic concern: progress and outcome of labor and maternal temperature alterations.

INDICATIONS

The use of epidural, spinal, and CSE techniques for vaginal, instrumental, and operative deliveries has been well described in numerous texts and articles.[5,6] The use of these techniques, as well as nonpharmacologic modalities, systemic medications, and peripheral nerve blocks, are discussed in the obstetric setting. The philosophical shift favoring the use of regional versus general anesthesia is further elucidated, and two novel obstetric applications of these techniques—external cephalic version (ECV) and postoperative pain management—are discussed in greater detail.

Although the quality, titratability, and patient satisfaction associated with the use neuraxial analgesia and anesthesia are responsible for their increasingly frequent use, the main benefit may be a reduction in maternal mortality. Airway management difficulties during the provision and recovery from sedative or general anesthetic agents remain the leading cause of anesthetic-related mortality and an important cause of overall maternal morbidity and mortality.[7,8] Although the number of deaths involving general anesthesia has remained stable in the United States, the estimated rate of maternal deaths from complications of general anesthesia increased from 20.0 to 32.3 deaths per million in the time periods of 1979–1984 to 1985–1990, respectively (Fig. 70–3).[9] The case fatality ratio for general versus neuraxial anesthesia over the same periods increased from 2.3:1 to 16.7:1[9]; subsequently, the same investigators found that the relative risk decreased significantly to 1.7:1 in the years 1997 to 2002.[10] The risk of general anesthesia will most likely always be overstated, because this form of anesthesia is used principally when neuraxial techniques are contraindicated for medical reasons or time constraints. However, the reduction in the case fatality ratio may reflect the growing acceptance and use of neuraxial techniques in the presence of significant comorbid conditions (e.g., severe preeclampsia).

Despite this, neuraxial techniques still represent an underutilized option in patients who would benefit from the avoidance of systemic sedation or general anesthesia. This group includes parturients with a high likelihood of having a difficult airway (e.g., high body mass index [BMI]), worsening pathology (e.g., preeclampsia), or an operative delivery (e.g., placenta previa, trial of labor after cesarean [TOLAC], high-order multiple gestation). In such parturients, consultation optimally should occur early in the third trimester and shortly following their arrival on the labor and delivery ward. Evaluation should be made regarding the suitability of an early ("prophylactic") placement of a

catheter-based neuraxial technique (Table 70–1), even if the birth attendants or the woman herself is not sure that a neuraxial block is desired or will be required.[11] To allay such concerns, the catheter need not be dosed until a later time when an analgesic or anesthetic is requested or required.

This approach significantly decreases the incidence of emergently managing a difficult airway or confronting airway issues owing to a "perceived lack of time."[4]

The antenatal consultation should focus on the physiologic changes of pregnancy that can make airway management more difficult. As early as the fourth week of gestation, and particularly with preeclampsia/eclampsia, capillary engorgement of the oropharyngeal and respiratory mucosa makes these structures more friable, vascular, and edematous. With labor, the airway structures become further engorged, making the oropharyngeal area even smaller.[12] In addition, the anteroposterior and transverse diameters of the thorax increase during pregnancy, resulting in a substernal angle that, in combination with increases in breast tissue, serve to make laryngoscopy more challenging. Finally, arterial oxygen desaturation occurs more quickly in apneic parturients owing to smaller functional residual capacity and increased oxygen consumption. These alterations make the provision of general anesthesia more challenging; difficult intubations with the need for special airway management devices and techniques were observed in up to 16% of the cases in a 6-year report of general anesthesia performed for cesarean delivery in a tertiary care hospital.[4] These airway concerns persist in the postoperative period following

extubation and with the administration of sufficient systemic analgesic agents, most often opioids, to allay pain; postoperative respiratory compromise is a growing concern, particularly in women of high BMI.[7,8]

The physiologic and anatomic alterations of pregnancy are further accentuated in high-BMI patients, a group that has dramatically increased since the 1990s.[13] In addition to an increased association with hypertension and preeclampsia, aortocaval compression, obstructive sleep apnea, gestational diabetes, and fetal macrosomia, high BMI can result in dysfunctional labor, increased emergency cesarean delivery, and postpartum hemorrhage.[13] Catheter-based neuraxial techniques (e.g., epidural or spinal catheter) placed early in the course of labor can minimize the need for systemic analgesics, reduce the discomfort and physiologic responses to labor induction or augmentation, provide a readily available anesthetic method for emergent operative delivery that avoids airway manipulation, and eliminate the relaxing effects of volatile general anesthetic gases on uterine tone, which can contribute to further blood loss. Moreover, neuraxial techniques, particularly if continued for postpartum analgesia, can contribute to improved postoperative pain control, faster recovery of pulmonary function, and a lower incidence of venous thromboembolism.[13,14] Whereas neuraxial techniques may, therefore, represent a viable and perhaps optimal mode of analgesia or anesthesia for high-BMI patients, the greater difficulties involved with their use in such patients, including the amount of time required for placement and the incidence of technique failure,[15] indicate that other modalities and methods should be readily available.

MANAGEMENT OPTIONS FOR PAIN DURING PARTURITION

Nonpharmacologic Techniques

Psychological support and sensory stimulation are two basic classifications of nonpharmacologic modalities for the reduction of pain during labor. The most popular forms of psychological support are "natural childbirth" and "psychoprophylaxis," which were popularized by Dick Read and Fernand Lamaze, respectively. These methods, which utilize a series of preparative classes to explain the process of labor and teach methods for relaxation and allaying pain, have been observed to reduce the amount of analgesia used,[16] but the degree of pain relief experienced appears limited.[17] Potential problems with these techniques include hyperventilation[18] and postpartum depression if analgesic techniques are eventually utilized.[19] Hypnosis, a temporary alteration in consciousness characterized by increased suggestibility, focuses on producing physical and mental relaxation and changing the interpretation of physical stimuli. Although few randomized, controlled trials have evaluated the modality, a meta-analysis[20] reports that hypnosis can be successful in the management of labor pain. Trained individuals called *doulas* can also be a source of emotional and physical support during labor. When doulas provide continuous, rather than intermittent, support during labor and delivery, a decrease in the amount of analgesic agents requested, labor duration, and instrumented deliveries has been observed.[21]

Massage, superficial application of heat and cold, hydrotherapy, acupuncture and acupressure, transcutaneous electrical nerve stimulation (TENS), intradermal sterile water injections, and music and audio analgesia are all methods of sensory stimulation and have been used with some success during labor. These methods are hypothesized to use innocuous stimuli, such as touch, vibration, and pressure, to compete with painful stimuli at the site of their convergence in the substantia gelatinosa of the dorsal horn of the spinal cord. This competitive inhibition, accompanied by descending messages from the brain cortex and brainstem, is believed to modulate the transmission of pain information. To date, few randomized, controlled trials have been performed with these modalities, and thus, only limited conclusions can be drawn. Systematic reviews of acupuncture and TENS for labor analgesia demonstrate a high degree of patient acceptability and satisfaction, despite a weak analgesic-sparing effect.[20,22] The novel use of TENS as an adjuvant to other modalities has been investigated. Tsen and associates[23,24] found that TENS was ineffective in augmenting the duration or quality of analgesia produced by small amounts of spinal or epidural local anesthetics and opiates during labor. Overall, despite the limited scientific evidence supporting the analgesic value of these psychological and sensory stimulation modalities, many patients consider them to be an integral and helpful part of their labor experience.

Systemic Medications

Medications given by injection were among the first agents routinely utilized for childbirth pain relief. In the 1950s and 1960s, the combination of morphine and the anticholinergic scopolamine was used to induce analgesia, sedation, and amnesia termed "twilight sleep."[25] Scopolamine, now more commonly utilized in smaller doses as an antiemetic, had a number of side effects including delirium, agitation, and excitement, that prompted the use of other, more effective forms of analgesia.

Oral, subcutaneous, intramuscular (IM), and intravenous (IV) injection techniques have all been utilized for administration of systemic labor analgesia. The more rapid onset and ease of IM and IV drug administration have allowed the frequent use of these routes despite IM routes having variable onset time, duration, and degree of analgesia. Injection into the deltoid muscle, for instance, will result in better absorption than injection into the less-perfused gluteus muscle. Intravenous patient-controlled analgesia (IV-PCA), which utilizes a pump programmed to give a dose of an analgesic agent on demand at predetermined intervals, yields some control to the patient, thereby improving maternal satisfaction, reducing overall drug dosing, and decreasing provider workload.[26]

Opioids, despite their side effects of nausea, emesis, drowsiness, dysphoria, hypoventilation, and neonatal respiratory depression, are the most widely used medications for labor analgesia because of their availability and the degree of analgesia produced. Morphine is given in doses of 5 to 10 mg intramuscularly or 2 to 3 mg intravenously for a peak effect in 2 hours and 20 minutes, respectively, but may result in greater neonatal depression than meperidine at equianalgesic doses.[27] Meperidine (Demerol; known as pethidine in Europe), the most commonly used opioid for labor analgesia,

is given in dosages of 50 to 100 mg intramuscularly or 10 to 50 mg intravenously to produce 2 to 4 hours of pain relief. To minimize neonatal respiratory depression, IM administration of meperidine should be avoided within a window of 1 to 3 hours before delivery.[28] (Clinically, avoiding this window may be difficult, because many women thought to be hours away from giving birth deliver suddenly and unexpectedly. In practice, provided that bag and mask ventilation of the neonate and IM naloxone are given, the risk to the baby from IM meperidine is minimal.) Fentanyl, alfentanil, and sufentanil are potent synthetic morphine analogues that are generally not used intramuscularly owing to their short duration of action and narrow therapeutic index; with the advent of IV-PCA, however, these agents are being used more frequently.[26] Opioids with agonist/antagonist properties have the advantage of a "ceiling effect" for maternal respiratory depression, and include pentazocine, nalbuphine, and butorphanol. Pentazocine is utilized less commonly because of its potential for the psychomimetic effects of dysphoria and a perception of impending death.[29] Nalbuphine and butorphanol are given in IM or IV doses of 3 to 5 mg or 1 to 2 mg, respectively and are equianalgesic to meperidine with less nausea and emesis.[30]

Tranquilizers such as benzodiazepines and phenothiazines are occasionally used to reduce anxiety during labor and delivery. Diazepam can be used in doses up to 10 mg IM/IV,[31] but lorazepam and midazolam should be avoided owing to their pronounced neonatal depressant and maternal amnesic effects, respectively. Phenothiazines can be used synergistically to reduce the dose of opioids, thereby increasing sedation and reducing side effects. Hydroxyzine given in doses of 50 to 100 mg intramuscularly and promethazine given in doses of 24 to 50 mg intramuscularly or 15 to 25 mg intravenously have been observed to improve maternal analgesia without significant neonatal effects.[32] Promazine, chloropromazine, and prochlorperazine are avoided because of their strong α-adrenergic blocking activity, which can produce hypotension.[33]

Barbiturates, such as secobarbital and pentobarbital, can allay anxiety. However, as a class, the efficacy of these agents during labor is limited owing to their lack of analgesic properties, their potential to increase the sensation of pain, and the presence of protracted effects on the newborn.[34] In low doses of 0.2 to 0.5 mg/kg intravenously, ketamine can produce intense analgesia with limited neonatal effects; however, maternal dysphoric reactions may result.[35] The concomitant use of midazolam 2 to 4 mg intravenously can decrease these effects. In higher doses of 1 to 2 mg/kg, ketamine can be used as induction agent for general anesthesia; however, when the dose exceeds 2 mg/kg, increases in uterine tone may occur and be associated with lower Apgar scores or abnormally increased neonatal muscle tone.[35]

Inhalational Analgesia

The first form of analgesia used for labor in modern medicine, inhalational analgesia remains popular in many maternity centers, particularly within the United Kingdom. Inhalation of subanesthetic doses of nitrous oxide, trichloroethylene, methoxyflurane, enflurane, isoflurane, and recently, sevoflurane has been used to provide safe and effective analgesia during labor and delivery. Most effective during the early stages of labor, inhaled analgesics are administered either intermittently (i.e., during contractions only) or continuously with the dose regulated according to the patient's response. A mixture of 50% nitrous oxide and 50% oxygen (Entonox) is the most common formulation in current use[36] and has been demonstrated to bring relief to approximately 50% of parturients. Entonox may also be used as an adjuvant, but not a complete analgesic, to a pudendal nerve block for forceps delivery, perineal suturing, or manual removal of the placenta.[37] The inhalational technique can safely provide amnesia and analgesia; however, the possible loss of consciousness, diminished airway reflexes with the associated risk for aspiration and hypoxia, and unscavenged gas pollution of the labor suite are issues that may occur. The risk for loss of consciousness and airway reflexes are more commonly witnessed with halogenated agents.

In rare instances, general anesthesia is induced with inhalational halogenated agents (e.g., isoflurane, sevoflurane) for vaginal delivery. Two of the more common scenarios include a need for greater anesthesia without time to administer a neuraxial anesthetic (i.e., fetal distress requiring forceps delivery) or a need for maximum uterine relaxation (i.e., need for intrauterine manipulation). In contrast to anesthetic agents given neuraxially, inhaled halogenated agents cause uterine relaxation in a dose-dependent manner,[38] with the administration of greater than 0.5% minimum alveolar concentration (MAC) potentially decreasing uterine smooth muscle responses to oxytocin.[39]

Regional Analgesia and Anesthesia

A variety of regional techniques can provide pain relief for labor and delivery. As both expected and unexpected physiologic sequelae may occur following these techniques, IV access should be established and resuscitation equipment should be readily available. All of these techniques are performed through the injection of short- to long-acting local anesthetics (i.e., chloroprocaine, meperidine, lidocaine, and bupivacaine), based in part on the location and desired duration of the blockade.

Paracervical Block

A technique that relies on blocking the nerve ganglion located immediately lateral and posterior to the cervicouterine junction, the paracervical block is primarily effective for the first stage of labor. Owing to the frequent occurrence of fetal bradycardia, which may result from local anesthetic-induced uteroplacental vasoconstriction or direct fetal myocardial depression, this technique is now used infrequently.[40]

Lumbar Sympathetic Block

By interrupting pain signaling through the visceral afferent sensory fibers in the lumbar vertebrae region, the lumbar sympathetic block provides analgesia limited primarily to the first stage of labor. Although seldom used owing to the requirement for injections at multiple sites along the lumbar sympathetic chain, this technique has been advocated for early labor analgesia owing to the near absence of motor blockade.[26,41]

Pudendal Block

Effective for the second stage of labor, the use of outlet forceps, and episiotomy repairs, this block interrupts the terminal nerve transmissions of the pudendal nerve. Owing to the distal nature of the nerve blockade, this form of anesthesia is not effective for mid-forceps delivery, postpartum examination or repair of the upper vagina or cervix, or exploration of the uterine cavity.[42] Maternal and neonatal blood levels of local anesthetic following a pudendal block are comparable with those seen following an epidural technique.[43]

Perineal Infiltration

One of the most commonly performed techniques for labor and delivery, perineal infiltration interrupts pain transmissions from the terminal nerves in the posterior fourchette. Because direct injection into the fetal scalp can occur, the quickly metabolized agent 2-chloroprocaine may be preferable to lidocaine or longer-acting local anesthetics.[44]

Caudal Block

A technique that uses the lowermost segment of the epidural space, the caudal block has lost favor to the higher, more approachable lumbar block. The change to the lumbar approach was also motivated by an association of the caudal block with inadvertent injections of anesthetic into the fetal head, the theoretical increased risks of infection owing to a closer proximity to the rectum, and difficulty in extending the cephalad level of the blockade for cesarean delivery.

Antenatal Use of Regional Techniques: External Cephalic Version

Epidural, spinal, and CSE techniques have been reported to improve success rates of ECV. Schorr and coworkers[45] randomized 69 patients (all of whom received tocolytics to relax the uterus) to undergo an ECV attempt either with or without epidural anesthesia. In demographically and obstetrically similar groups, the first attempt and overall success rates of ECV were higher in the epidural group (69% vs. 32%). No cases of fetal distress or abruptio placentae were observed in either group, and ultimately, vaginal delivery occurred in 66% of the epidural group versus 21% in the control group. In comparison with tocolytics, a preliminary report by Samuels and colleagues[46] of 76 patients undergoing ECV noted greater success with an epidural anesthetic versus ritodrine (76.3% vs, 60.1%).

Spinal techniques have also been used for ECV attempts, with varying analgesic doses resulting in contrasting results. Dugoff and associates[47] noted no improvement with the spinal administration of bupivacaine 2.5 mg with sufentanil 10 μg (44% vs. 42%), whereas Birnbach and coworkers[48] noted a significant improvement (80% vs. 33%) with the use of sufentanil 10 μg alone. The variation in outcome may reflect differences in obstetric or patient factors, including the amount of force applied or the degree of maternal discomfort tolerated for a given level of analgesia. When spinal anesthesia (lidocaine 45 mg with fentanyl 10 μg) was used, even in the more difficult setting of previously failed ECV attempts, a high success rate (83%) has been reported.[49]

Whether utilized for primary or failed ECV attempts, a CSE technique with a short-duration spinal anesthetic may represent the optimal technique.[49] The short anesthetic duration allows for a timely discharge from hospital in the event of a successful version, and if success or failure results in either a trial of labor or an operative delivery on the same day, the epidural catheter can be left in place to allow additional analgesia or anesthesia to be administered.

Neuraxial analgesic and anesthetic techniques most likely improve ECV success by relaxing the abdominal wall muscles, improving patient comfort during the ECV attempt, and allowing the obstetrician to make a more concerted attempt.[48,50] The use of neuraxial anesthetic techniques for ECV attempts has been associated with an improved maternal and fetal outcome, a reduced need for operative deliveries with general anesthesia, and a favorable cost-benefit analysis.[50,51]

Anesthesia for Vaginal Delivery

Spinal Anesthesia

The finite duration of action of a single injection, and an increased risk of a post–dural puncture headache (PDPH) with multiple injections, limit the utility of "single-shot" spinal anesthesia for the management of labor. Spinal techniques, however, can be used successfully during delivery, especially in the event of an assisted vaginal breech delivery, the need to use outlet forceps or vacuum extraction, or the repair of extensive tears or lacerations. For these procedures, a low-level spinal anesthetic block can be used; in the event of a "trial of forceps," a dose of local anesthetic appropriate for a cesarean delivery or a spinal or epidural catheter-based approach should be considered to provide coverage for a potential operative delivery. Clear communication between the obstetrician and the anesthetist on their expectations regarding delivery is essential if the optimal technique is to be chosen. Variations of the spinal technique that offer more flexibility include its use as part of a CSE technique (discussed later) or the placement of a catheter into the spinal space, called a "spinal catheter" or "continuous spinal anesthesia" technique. The benefits of these techniques have been observed particularly in patients with conditions such as morbid obesity and cardiac disorders or following an unintentional dural puncture during an attempted epidural catheter placement. The spinal catheter is a method for providing a reliable, precisely titratable blockade,[52] although this option is less attractive than the same 20-gauge catheter placed in the epidural space owing to a significantly greater risk of a PDPH. A recent trial of a 28-gauge spinal catheter observed a less than 1% incidence of neurologic complications and better initial labor analgesia with improved maternal satisfaction but more technical difficulties and analgesic failures when compared with a 20-gauge epidural catheter.[53] Further investigations will be needed to validate the benefits and safety of spinal microcatheters; earlier reports that the use of 27- to 32-gauge spinal microcatheters resulted in complications (e.g., technique failure, cauda equina syndrome)[54] led the U.S. Food and Drug Administration (FDA) to remove these catheters from the U.S. market in 1992.

COMPLICATIONS

A number of complications may occur following a spinal technique. Hypotension, defined as a 20% to 30% decrease in systolic blood pressure from baseline, can be observed in

up to 100% of pregnant women following spinal anesthesia owing to the production of a sympathetic vasomotor block-ade.[55] Persistent hypotension may result in decreased utero-placental perfusion as well as fetal hypoxia and acidosis.[56] Preventive measures include maternal intravascular volume expansion (preloading with IV fluid, usually 500–1000 mL of crystalloid such as Hartmann's solution) and the avoid-ance of aortocaval compression by uterine displacement. Treatment includes titrated IV doses of vasopressors such as ephedrine (5–10 mg) and phenylephrine (40–100 µg). Vasopressor use can significantly reduce the nausea and vomiting following a spinal technique and may be associ-ated with reductions in sympathetic tone, blood pressure, and cerebral blood flow.[57] PDPH occurs in approximately 1% to 3% of the obstetric population following a spinal technique and is most likely related to the needle size and tip design, with larger, cutting needles associated with a greater incidence.[58] Typically, a PDPH presents as a posi-tional headache that worsens in the upright position and improves in the recumbent position. The differential diag-nosis should include other types of headache, hypertensive disorders, infectious diseases, dural venous sinus thrombo-ses, and other intracranial pathologies. Pain relief may be provided by bedrest,[59] hydration, and the oral intake of caf-feinated and analgesic products (including Fioricet or Fiori-nal) for 24 to 48 hours. The administration of an epidural blood patch, whereby 10 to 20 mL of autologous blood is placed in the epidural space, has been associated with a greater than 80% incidence of success.[56,60] Neurologic com-plications (e.g., peripheral neuropathy, subarachnoid bleed) as a result of spinal anesthesia in the obstetric population are extremely rare[60]; however, should these events occur, a con-sultation with a neurologist may assist in the diagnosis and management. Finally, spinal anesthesia can result in an unexpected high level of blockade, which can result in hypotension, dyspnea, the inability to speak, and a loss of consciousness; these usually transient occurrences empha-size that immediate ventilatory and circulatory support should always be readily available when this technique is provided.

Epidural Analgesia and Anesthesia

One of the most effective methods of pain relief for labor and delivery,[5] the epidural technique with an indwelling catheter provides a reliable form of analgesia that can be titrated as the situation evolves. Labor analgesia can be con-verted to surgical anesthesia for an instrumental or operative delivery, laceration repair, or postpartum tubal ligation by changing the dose or type of local anesthetic administered through the catheter.

The optimal selection of agents for use in the epidural space depends on the degree and duration of pain relief desired. The goal during labor and delivery is to provide lumbar and sacral sensory analgesia with minimal motor blockade[12]; this should allow the pregnant woman to appre-ciate a sense of pressure, without pain, during each contrac-tion and retain the ability to move her lower extremities. Almost every local anesthetic developed has been tested for its value in obstetric analgesia. Of the shorter-duration agents, mepivacaine has a prolonged half-life and may cause neonatal depression. Chloroprocaine 3% and lidocaine 2%

TABLE 70–2

Local Anesthetics for Epidural Analgesia and Anesthesia

ANESTHETIC	USUAL CONCENTRATION (%)	ONSET	DURATION
Analgesia			
Lidocaine	1–1.5	Moderate	Intermediate
Bupivacaine	0.0625–0.25	Slow	Long
L-Bupivacaine	0.0625–0.25	Slow	Long
Ropivacaine	0.1–0.2	Slow	Long
Anesthesia			
2-Chloroprocaine	2–3	Fast	Short
Lidocaine	2–5	Moderate	Intermediate
Mepivacaine	2	Moderate	Intermediate
Bupivacaine	0.5	Slow	Long
L-Bupivacaine	0.5	Slow	Long
Ropivacaine	0.5–1	Slow	Long
Tetracaine	1	Slow	Long

produce a dense sensory and motor block appropriate for surgical anesthesia. The longer-duration agents are best suited for labor analgesia when used in low concentrations. Bupivacaine has a high sensory-to-motor block ratio and is commonly used in concentrations between 0.0625% and 0.125% to initiate and maintain labor epidural analgesia.[12] Ropivacaine and L-bupivacaine are also longer-duration agents that may result in slightly less motor blockade and cardiotoxic effects when given in equipotent concentrations to bupivacaine.[61,62] The dose, onset, and duration of various local anesthetics for epidural labor analgesia are well char-acterized (Table 70–2). Although epidural opioids alone are often sufficient for analgesia in the first stage of labor, a combination of agents is often necessary to provide ade-quate analgesia during the second and third stages of labor.[63,64] The addition of local anesthetics to opioids improves the quality of analgesia and allows a reduction in drug dosages, thereby minimizing motor blockade and pru-ritus, respectively. Epidural administration of small doses of sufentanil (0.2–0.3 µg/mL) or fentanyl (0.2 µg/mL) com-bined with low doses of bupivacaine 0.0625% or 0.125% results in excellent analgesia for vaginal delivery. An epidural bolus of fentanyl 100 µg, with or without local anesthetic, can be of assistance during the second stage of labor when patchy analgesia or perineal sparing cannot be remedied with local anesthetics alone.[65]

Once the initial sensory blockade has been established, epidural analgesia can be maintained by intermittent bolus injections, a continuous infusion, or both techniques simul-taneously. The development of programmable infusion pumps has enabled the delivery of a dilute solution of an opioid and a local anesthetic agent by continuous infusion, coupled with patient-controlled intermittent bolus top-up injections. This combined method reduces the total amount of medication used, decreases the amount of motor block-ade, and increases patient satisfaction when compared with a continuous infusion or intermittent bolus methodologies alone.[66,67]

TABLE 70–3

Advantages of the Combined Spinal-Epidural Technique for Labor Analgesia

Advantages over an Epidural Technique

More rapid onset

Lower maternal, fetal, and neonatal blood concentrations of local anesthetic than with epidural techniques alone

Better sacral analgesia

Assists in identification of the epidural space in technically difficult placements

Advantages over a Spinal Technique

Allows ability to titrate the level, density, and duration of the blockade

Catheter can be used for postoperative pain management

Combined Spinal-Epidural Analgesia

Introduced in the early 1980s for surgical procedures, the CSE technique, with a few modifications, has become one of the most popular techniques for labor analgesia. The technique consists of an epidural needle placement, a spinal needle placed most often through the shaft of the epidural needle into the subarachnoid space (e.g., the "needle-through-needle" approach), the delivery of spinal medications, and then placement of an epidural catheter. In comparison with the epidural or spinal techniques alone, the CSE technique has a number of advantages (Table 70–3). A mixture of local anesthetics with opioids appears to be the optimal combination for initial labor analgesia with this technique, and its application, even early in labor, may have beneficial effects on the progress of labor.[68,69] Used later in labor, the CSE technique can provide quick onset of analgesia and the ability to extend the duration or level of the blockade should delivery methods mandate such augmentation.

COMPLICATIONS

Relatively few complications are inherent to the CSE technique. The CSE technique may actually reduce the risk of a dural puncture with the larger epidural needle, because the spinal needle protrudes 10 to 15 mm beyond the tip of the epidural needle when placed through its shaft. Cerebrospinal fluid flowing through the spinal needle indicates that the dura has been traversed, thereby providing the position of the dural sac relative to the epidural needle and cautioning against significant further advancement. The likelihood of an 19- to 20-gauge epidural catheter passing through a 25- to 27-gauge spinal needle dural puncture is low, based on both laboratory and clinical studies.[70] However, drugs placed in the epidural space can pass through the 25- to 26-gauge spinal dural hole and result in improved onset, sacral spread, and bilateral sensory blockade[71]; by contrast, the risk of a high spinal blockade appears negligible.[71]

Because the spinal portion of a CSE technique gives an initial period of analgesia, the epidural catheter remains "untested" and may not prove reliable as a route for further anesthetic agents should additional analgesic and anesthetic needs arise. Although epidemiologic evidence suggests that the epidural catheter following a CSE versus an epidural

technique has a lower failure rate,[72] in those parturients with a difficult airway or a high probability of an instrumental or operative delivery, a standard epidural technique, which tests the function of the catheter at the time of placement, may be safer.

MANAGEMENT OPTIONS FOR ANESTHESIA FOR CESAREAN DELIVERY

Despite repeated calls to reduce the rate of cesarean deliveries from both lay and professional organizations in the United States and Europe, the incidence of surgical delivery continues to increase. Although a number of difficult airway management devices and algorithms have improved the safety of general anesthesia for cesarean delivery, the majority of maternal deaths due to anesthesia still occur during or following the provision of general anesthesia. However, in deciding between neuraxial and general anesthetic techniques, the urgency of the procedure, the health and comorbidities of the mother and fetus, and the desires of the mother and health care providers all need to be considered.

Spinal Anesthesia

A simple and reliable technique with rapid onset, spinal anesthesia provides an awake and comfortable patient with minimal risks for aspiration. Despite the lower abdominal incision, a thoracic (T4) dermatome level is required to prevent referred pain from traction on the peritoneum and uterus. The type and dose of local anesthetic agent used to provide spinal anesthesia must include consideration of the duration of the surgery, the postoperative management of pain, and the preferences of the anesthesiologist. Hyperbaric bupivacaine is the agent most commonly used because it provides a blockade of long duration while avoiding the extensive motor block produced by tetracaine. The potential toxicity advantages of ropivacaine and L-bupivacaine are limited given the extremely small doses of agent used. The use of adjuvant spinal medications, such as opioids and epinephrine, may augment the quality and duration of the anesthesia and analgesia and reduce the local anesthetic dose even further.[73,74]

With the onset of spinal anesthesia, the patient may complain of dyspnea. Dyspnea can be due to several factors, including the blunting of thoracic proprioception, the partial blockade of abdominal and intercostal muscles, and the recumbent position allowing the abdominal contents to apply pressure against the diaphragm. Despite these changes, significant respiratory compromise is unlikely because the blockade rarely affects the cervical (phrenic) nerves that control the diaphragm. Should the patient lose the ability to vocalize, give a strong hand grip, or demonstrate normal oxygen saturation by pulse oximetry, a rapid-sequence induction with cricoid pressure and placement of an endotracheal tube can be performed to maintain ventilation and prevent pulmonary soiling with gastrointestinal contents (the so-called gastric aspiration syndrome).

The most common complications of spinal anesthesia have been described earlier and include hypotension, nausea and vomiting, and the risk of a PDPH. Hypotension presents the greatest risk to maternal and fetal comfort and health[55];

prevention and prompt treatment with the administration of IV fluids and vasopressors has been observed to be beneficial but, on occasion, not completely successful.[75,76] In terms of volume expansion, spinal anesthesia in the urgent setting should not be delayed until a fixed, arbitrary volume has been infused. In addition, aggressive hydration with large fluid volumes (>20 mL/kg crystalloid) may increase the risk of edema with only limited reductions in hypotension.[75] Colloid solutions appear to be more effective than crystalloids in preventing the hemodynamic consequences of spinal anesthesia,[77] but have allergic, cost, and coagulation implications. Investigations with vasopressors for prevention and treatment of hypotension in this setting have suggested that either intravenous phenylephrine or ephedrine may be used.[78]

Epidural Anesthesia

Since the 1980s, an increase in the use of epidural anesthesia for cesarean delivery has been observed, primarily owing to the widespread use of an epidural catheter-based technique to provide labor analgesia. Dosing the in situ catheter with local anesthetic agents allows for a relatively rapid onset of anesthesia should an operative delivery be necessary. Although drugs used in the spinal and epidural space are identical, the doses and volumes in the epidural space are 5 to 10 times greater to encourage adequate blockade and spread. These dose alterations can be explained primarily by anatomic differences in nerve exposure and the capacity of the spaces.

Advantages of the epidural technique include a slower onset of maternal hypotension owing to a more slowly developing sympathetic blockade, the response of physiologic compensatory mechanisms, and the ability of the anesthesiologist to titrate fluids and vasopressors. The level, density, and duration of epidural anesthesia can be titrated. The anatomic and hormonal changes of pregnancy appear to promote greater sensitivity of nerves to local anesthetic agents, which can be observed clinically through a decrease in anesthetic requirements for epidural blockade.[79,80] For cesarean delivery, the most common agents used are 2% lidocaine with epinephrine 1:200,000 and 3% 2-chloroprocaine. Chloroprocaine is the agent of choice for emergency cesarean deliveries because of its rapid onset and rapid maternal and fetal metabolism; fetal accumulation, especially when acidosis is present, is therefore minimized.[81] However, chloroprocaine is avoided for routine, nonurgent deliveries because the short duration requires multiple doses and its use can adversely affect the efficacy of subsequent epidural opioid analgesia.[82] In addition, when used in higher total volumes (>40 mL), chloroprocaine can increase the incidence of back pain.[83] Alkalinization with sodium bicarbonate hastens the onset time of local anesthetics significantly and is recommended for use in urgent cesarean deliveries[84]; caution must be applied in its use, however, because certain local anesthetics (particularly longer-acting agents such as bupivacaine) have a low threshold for precipitation.[85]

The complications of epidural anesthesia have been described previously and include hypotension, risk of PDPH, systemic toxic reactions, and rarely, neurologic complications. Epidural techniques can provide patchy or inadequate blockade owing to anatomic or technical reasons[86] and may require supplementation with IV or inhalational agents or conversion to general anesthesia.

Combined Spinal-Epidural Anesthesia

The principal advantage of the CSE technique is the ability to provide dense, initial anesthesia with the ability to augment the duration by dosing the epidural catheter. This is particularly useful in obstetrics, in which a delay in the timing prior to or during surgery can potentially occur (e.g., possible placenta accreta, history of multiple abdominal surgeries, high index of suspicion for gravid hysterectomy).

Contraindications to Neuraxial Anesthesia

Although neuraxial anesthesia is used whenever possible to avoid the potential airway complications associated with general anesthesia, certain conditions or time constraints may contraindicate its use.[4] Such comorbidities include localized infection or generalized sepsis, coagulation disorders, severe hypovolemia, or cardiac disorders in which hypotension may be detrimental. Severe obstetric hemorrhage in the antepartum period, including uterine rupture and acute, severe fetal distress, may also contraindicate neuraxial anesthesia procedures because of the time necessary to establish a surgical anesthetic.

Patients with severe preeclampsia or hypertension may undergo rapid hemodynamic changes with regional techniques; however, both epidural and spinal techniques can and have been used successfully in this setting, and of interest, preeclamptic patients may have less hemodynamic changes than normal parturients undergoing spinal anesthesia.[87,88] In addition, gravid hysterectomies have been performed safely with neuraxial techniques.[89] Overall, however, if questions exist regarding the ability of maternal compensatory mechanisms to react to the neuraxial anesthesia, general anesthesia should be considered.

General Anesthesia

There are few, if any, absolute contraindications to general anesthesia; however, neuraxial anesthesia remains a preferred method to avoid the risks of airway management and allow the patient the ability to witness the delivery. General anesthesia may offer advantages when uterine relaxation would be beneficial; such cases include difficult breech extractions, retained placenta, uterine inversion, or in utero fetal surgery.

The importance of proper airway evaluation, during the antenatal period or in early labor if possible, cannot be overemphasized, because failed intubation, failed ventilation and oxygenation, difficult extubation, and pulmonary aspiration of gastric contents are the leading anesthetic causes of maternal death.[90,91] If the airway evaluation suggests the possibility of a difficult intubation, strong consideration should be given to the establishment of a continuous neuraxial technique early in labor.[92] If a difficult airway is discovered upon an intubation attempt, options include allowing the patient to awaken, using alternate techniques to place an endotracheal tube, or using alternative airway devices.

The laryngeal mask airway (LMA), although not able to prevent pulmonary soiling with gastric contents, can be a life-saving measure in failed intubation situations[93] and has been used safely in elective cesarean deliveries.[94]

Attempts should be made to minimize the risk of maternal aspiration, even when the need for intubation is not anticipated. With an elective cesarean delivery, adherence to a nil per os (NPO; nothing by mouth) policy for 8 hours prior to surgery is advised.[12] A nonparticulate antacid is believed to decrease the damage to the respiratory epithelium if aspiration occurs,[95] and H_2 antagonists (cimetidine, ranitidine) and promotility agents (metoclopramide) can reduce gastric acid secretion and facilitate emptying, respectively.[96,97]

Preoxygenation and denitrogenation with 100% oxygen reduces the rapidity of hypoxemia onset due to the parturient's decreased functional residual capacity and increased oxygen consumption. In urgent situations, eight vital capacity breaths within 1 minute or four vital capacity breaths within 30 seconds of 100% oxygen will provide adequate preoxygenation.[98] An induction agent (e.g., thiopental or propofol) is followed in quick succession with the muscle relaxant succinylcholine; as the induction of anesthesia occurs, increasing pressure (30 N) is applied to the cricoid cartilage until endotracheal intubation is confirmed. The use of preoxygenation, cricoid pressure with induction, and avoidance of active ventilation until endotracheal intubation is achieved is referred to as a "rapid-sequence induction." Its purpose is to rapidly secure the maternal airway to minimize the risk of gastric aspiration. On occasion, particularly if a preoperative examination reveals that a parturient might be a difficult intubation, modifications to this sequence, including the use of an awake fiberoptic intubation, are performed. A halogenated volatile anesthetic agent (e.g., isoflurane, sevoflurane) is used in 100% oxygen to maintain anesthesia; after neonatal delivery, lower concentrations of volatile anesthetic agent can be used through the addition of a 50%/50% oxygen–nitrous oxide mixture. The 25% to 40% increase in sensitivity to halogenated agents during pregnancy allows lower doses to be used[99]; this may be of benefit in attenuating the side effects of volatile agents, which reduce uterine tone and interfere with the action of oxytocin.[100] However, very low concentrations (<0.5 MAC) of volatile anesthetics combined with a reliance on neuromuscular blockade to limit movement should be avoided to limit the possibility of maternal awareness under anesthesia.[101] At the conclusion of surgery, the patient should be allowed to awaken sufficiently to follow verbal commands prior to extubation to maximize the ability to protect the maternal airway and maintain spontaneous ventilation.

Neonatal outcomes following general versus epidural anesthesia for cesarean delivery suggest small, transient differences.[102] However, with either technique, when the uterine incision to delivery is greater than 180 seconds, lower Apgar scores and greater fetal acidosis have been observed (although this may reflect relative difficulty in delivery of the baby rather than the direct effects of the anesthetic agents).[103] Redistribution of general anesthetic agents from the fetal fat to the circulation can result in secondary depression of neonatal ventilatory effort. The presence of a pediatrician in such cases is advisable until a normal ventilatory pattern is observed.
MANAGEMENT OPTIONS FOR POSTOPERATIVE PAIN

Since Wang and colleagues[104] published the first report of spinal opioid administration in humans in 1979, the analgesic efficacy and benefit of epidural and spinal opioids have been demonstrated by numerous investigations.[105] Epidural and spinal opioids blunt nociceptive input by directly activating spinal and supraspinal opioid receptors and produce analgesia of greater intensity than doses administered parenterally or intramuscularly (Fig. 70–4).[106,107] A number of opioids, including meperidine, fentanyl, sufentanil, hydromorphone, diamorphine, methadone, buprenorphine, and butorphanol, have been utilized in the epidural and spinal spaces (Table 70–4). Morphine has emerged as the most common agent used internationally for postcesarean delivery pain management owing to its long duration of action and low cost.

The low lipid solubility of morphine slows the penetration of the drug from the epidural space into the spinal tissues; this results in analgesia that has a delayed onset of peak effects (60–90 min)[108] but persists for up to 24 hours.[108,109] Epidural morphine in doses of up to 5 mg has been used for postcesarean analgesia.[109–111] In a prospective, randomized manner, Palmer and associates[111] performed a dose-ranging study of epidural morphine (1.25–5 mg) for postcesarean analgesia and observed that the quality of analgesia increased to a dose of 3.75 mg; further increases in dose did not improve analgesia. Pruritus and nausea, which are common side effects of opioids, were not found to be dose-related. A separate study found that an infusion of naloxone, a narcotic antagonist, can reduce the severity but not the incidence of pruritus following epidural morphine.[112]

The choice of local anesthetic for epidural anesthesia may influence the efficacy of epidural morphine. Kotelko and coworkers[113] observed that postcesarean analgesia was significantly reduced, usually to less than 3 hours, in patients who received 2-chloroprocaine (a short-acting, rapid-onset

TABLE 70–4

Neuraxial Opioids

OPIOID	EPIDURAL DOSE	SPINAL DOSE	DURATION (HR)	COMMENTS
Morphine	2.5–5 mg	0.1–0.2 mg	18–24	Gold standard
Fentanyl	50–100 μg	10–20 μg	3–4	Useful as an intraoperative adjuvant
Sufentanil	10–20 μg	5–10 μg	3–4	Useful as an intraoperative adjuvant
Meperidine	25 mg		2–3	
Hydromorphone	1 mg		12	
Methadone	4–5 mg		5–6	
Diamorphine	2.5–5 mg		5–15	Not available in United States

local anesthetic used primarily for emergent cesarean deliveries) versus other local anesthetics.

Patients in whom a prolonged duration or level of analgesia is desired (e.g., an extended laparotomy for operative issues or complications) may benefit from a continuous infusion of low-concentration epidural local anesthetics with opioids (e.g., bupivacaine with fentanyl or morphine).[114,115] Such epidural infusions may be operated by patient-controlled pumps, often with a small on-demand bolus dose combined with a continuous basal infusion.[115]

The delivery of a single spinal dose of opioid has also become an attractive option for postcesarean analgesia. Morphine is the leading spinal opioid used for this purpose, with a duration of action (18–24 hr) and side effect profile similar to its use in the epidural space.[116,117] Spinal opioid doses are approximately one tenth of their corresponding epidural dose, owing to the direct access to the spinal cord opioid receptors. Despite this anatomic relationship, spinal morphine still requires 45 to 60 minutes for peak effect. Palmer and colleagues[73] observed little advantage in using spinal doses greater than morphine 0.1 mg for postcesarean analgesia; increasing doses to 0.5 mg resulted in a greater incidence of pruritus, but not nausea and vomiting.

Postoperative analgesia has been greatly improved through the use of neuraxial techniques, particularly with the administration of a single dose of morphine. Spinal and epidural opioids enhance both the quality and the duration of postoperative analgesia with an improved and acceptable side effect profile when compared with oral or intravenous analgesic agents.

MANAGEMENT OPTIONS FOR ANALGESIA AND ANESTHESIA IN HIGH RISK PARTURIENTS

Invasive Monitoring (See also Chapter 78)

Although the noninvasive measurement of blood pressure, heart rate, oxygen saturation, urinary output, and fetal cardiotocography is standard practice in most modern labor and delivery facilities, the use of invasive monitors is variable and controversial. This controversy stems from the complexity of the information, which can be difficult to properly interpret despite practice guidelines written by a number of professional organizations, including the Joint Task Force of the American College of Physicians, the American College of Cardiology, and the American Heart Association.[118] A number of studies suggest that incorrect collection and interpretation of hemodynamic data from invasive monitors remain the key problem with their use.[119,120]

Knowing when invasive monitoring is warranted is a vital clinical skill. The indications for invasive arterial blood pressure monitoring during pregnancy are relatively straightforward and include a desire to more carefully manage blood pressure, the need for more reliable blood pressure measurements, the need for vascular access for blood studies, and the planned use of certain hemodynamic agents. The indications for invasive central monitoring are not as clear. A central venous pressure (CVP) catheter is often inserted to approximate volume status (or to follow a trend in blood loss or replacement therapy) and give a greater appreciation of the mechanical phases of the cardiac cycle. Management of oliguria unresponsive to a fluid challenge, pulmonary edema, and refractory hypertension are clinical situations in which some clinicians desire CVP monitoring.

A pulmonary artery (PA) catheter can assist in determining the etiology of pulmonary edema, oliguria with a normal CVP, or cardiovascular failure; however, its use is the most controversial. Advocates of PA catheter use suggest that it can provide information on left and right ventricular function, systemic vascular resistance, and cardiac output. Detractors question the validity of the data, noting that in the setting of preeclampsia, for example, the correlation between CVP and the pulmonary capillary wedge pressure (PCWP) is unreliable when the CVP reading exceeds 6 cm H_2O.[121] In deciding between a PA and a CVP catheter, the clinician should recognize that, although the insertion-related complications are similar,[122] the PA catheter is associated with more use-related complications including balloon rupture, pulmonary infarction, valvular damage, and erosion of the PA. Thus, the benefits of PA catheter use should clearly outweigh its inherent risks before it can be recommended; the updated practice guidelines of the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia state that "the decision to perform invasive hemodynamic monitoring should be individualized and based on clinical indications that include the patient's medical history and cardiovascular risk factors."[12] To date, although PA catheter use has been reported in parturients (primarily with cardiac disease), no controlled trials are available that confirm the benefit of PA catheter monitoring

on maternal or fetal outcome.[12] This being noted, the PA pressures observed with different etiologies of pulmonary edema are shown in Table 70–5.[123] Similarly, the PA pressures observed with different etiologies of oliguria are shown in Table 70–6.[124]

Minimally invasive (limited to derivations of arterial line data) and noninvasive modalities for hemodynamic monitoring are currently being developed and validated in the pregnant population. These monitors, some of which are derived from Doppler ultrasound and echocardiography technologies, may offer advantages over the more invasive modalities (e.g., transesophageal echocardiography, PA catheter) that are currently available.[125] These new monitors may provide dynamic information on cardiac function, even in the presence of comorbid conditions such as preeclampsia.[126]

Hypertensive Disorders of Pregnancy

Whether preexisting, gestational, or a function of preeclampsia or eclampsia, hypertension is a common medical problem in parturients and is associated with higher maternal, fetal, and neonatal mortality and morbidity. Preeclampsia, with its systemic vasoconstriction, intravascular volume and protein depletion, and simultaneous retention of extravascular sodium and water, is of particular concern to anesthesiologists. In addition to individual organ dysfunction, abnormalities in coagulation and edema of the brain, larynx, and lungs may occur. Medical management of blood pressure should be optimized prior to obstetric or anesthetic interventions if possible, and control with labetalol, hydralazine, or infusions of nitroglycerin or nitroprusside should be commenced with arterial and central venous monitoring in

severe cases. Prehydration to maintain CVP has been demonstrated to improve urine output, maintain mean arterial pressure, and decrease diastolic pressure.[127] If oliguria persists after normalization of the CVP (usually between 2 and 3 cm H_2O) or the physiologic state is complicated with pulmonary edema or cardiovascular decompensation, a PA catheter may be helpful. A cardiology consultation and an assessment of cardiopulmonary function with a transthoracic echocardiogram may also assist with the diagnosis and management. The course of preeclampsia can be complicated by mild to severe coagulopathy even in the presence of a normal platelet count.[128,129] For the benefit of both obstetric and anesthetic management, if the initial platelet count is less than an arbitrary 75×10^9/L, the clinical history and the results of additional studies such as a PT/PTT (prothrombin time/partial thromboplastin time) or a thromboelastograph should be reviewed. A risk-benefit analysis will ultimately determine the anesthetic technique of choice and whether the administration of blood products such as fresh frozen plasma or pooled platelets should commence prior to any intervention.

During labor, epidural analgesia offers the advantage of limiting pain or stress, thus reducing catecholamine release, decreasing maternal blood pressure, and indirectly increasing placental perfusion.[127] Epidural anesthesia can also be a preferred technique for cesarean delivery owing to the ability to slowly titrate the dose of medications as an aid to the management of blood pressure. The possibility of spinal technique–induced hypotension should not necessarily eliminate this anesthetic option. Although data are limited, one small prospective, randomized study of preeclamptic women did not reveal significant blood pressure differences between spinal and epidural anesthesia.[130] A retrospective study of women with severe preeclampsia also observed that the incidence of hypotension was not different between spinal and epidural anesthesia use.[131] Moreover, spinal anesthesia may be associated with less hypotension in women with severe preeclampsia versus healthy women undergoing cesarean delivery at similar gestational ages.[87]

The relative hypovolemia associated with preeclampsia, the use of antihypertensive medications, and the administration of magnesium as seizure prophylaxis may augment the hypotension that can develop following spinal or epidural techniques. However, restraint is advocated when responding to hypotension with vasopressors or large amounts of crystalloids. Patients with hypertensive disorders may exhibit an accentuated response to vasopressors and may quickly extravasate IV fluids that are infused.[132] A hypertensive response may also result during endotracheal intubation

TABLE 70–5

Pulmonary Artery (PA) Pressures Observed with Different Etiologies of Pulmonary Edema

ETIOLOGY	PA WEDGE PRESSURE	STROKE WORK INDEX

and emergence from general anesthesia and result in intracerebral bleeding or pulmonary edema. This hypertension can be blunted with a number of agents, including β-blockers, calcium channel blockers, hydralazine, nitroprusside, nitroglycerine, trimethaphan, and opioids.

Finally, significant edema may be encountered in preeclamptic patients, and sufficient attention and preparation should be given for managing difficult intravenous or intraarterial catheter placements, airway techniques, and neuraxial placements.

Cardiac Disease

Cardiac disease is becoming increasingly prevalent during pregnancy. Although stable in overall adult prevalence, coronary heart diseases (including those associated with hypertension) and valvular pathologies have become more relevant as the parturient population ages. More significant, however, is the dramatic increase in adult patients who have benefited from improvements in the diagnosis, treatment, and surgical correction of congenital heart disorders (CHDs). In the United States alone, adults with CHDs have grown from an estimated 300,000 in the 1980s to an anticipated 1.4 million in the year 2020.[133] Many of these individuals are women of childbearing age, and with pregnancy, CHD can have profound effects on maternal and fetal outcome.

At one time, general anesthesia was regarded as the method of choice for all cesarean deliveries in patients with either acquired heart disorders or CHDs. However, with advances in the understanding of cardiac disorders and the effects of anesthesia, especially in the relation to the anomalous or diseased myocardium, neuraxial techniques have been reconsidered. Neuraxial anesthesia has many beneficial effects, including the ability to provide pain relief, minimize the release and effects of catecholamines, and avoid airway manipulation. General anesthesia can result in moderate, sometimes detrimental, inotropic and chronotropic alterations in heart physiology, especially during the induction, intubation, and extubation periods.

The independent and related complexities of cardiac disorders and pregnancy make the sharing of patient data with all interested parties of vital importance. Because the cardiac alterations of pregnancy usually plateau from the 20th to the 24th gestational weeks until the onset of labor, this represents an ideal time to assess whether adequate compensation is occurring. This is not to say that decompensation cannot occur prior to this period or at any time during the peripartum experience. Although benign arrhythmias occur commonly without symptoms or sequelae during pregnancy,[134] in the setting of congenital cardiac lesions, even if "corrected," hemodynamic compromise may result. Communication with the patient's cardiologist is vital, and a full analysis of prior diagnostic studies should be made. Despite the presence of CHD, other causes of arrhythmias or decompensation (e.g., electrolyte and thyroid abnormalities, magnesium use) should be considered. Should complete cardiopulmonary arrest occur late (after the 24th week) in pregnancy, an event that occurs in approximately 1 in 30,000 pregnancies,[135] resuscitation must consider both maternal and fetal health. Rapid CPR (cardiopulmonary resuscitation), intubation, prevention of aortocaval compression with uterine displacement, and immediate delivery within 4 to 5 minutes of

maternal cardiac arrest may maximize the chances of maternal and fetal survival.[136] In terms of medications, intubation, and defibrillation protocols, there are no alterations to the basic ACLS (advanced cardiorespiratory life support) algorithms.[136]

Acquired Cardiac Disorders

Despite the widespread use of antibiotics, in many parts of the developing world, rheumatic heart disease remains the leading cause of cardiac abnormalities in women of childbearing age.[137] Valvular lesions include mitral stenosis (75%–90%), mitral regurgitation (6%–12%), aortic regurgitation (2%–5%), and aortic stenosis (1%).

In general, the primary goal with stenotic lesions is to maintain a normal to slow sinus heart rate with preservation of systemic vascular resistance (SVR). These goals are particularly important when controlling the physiologic responses to neuraxial blockade, which can often dramatically reduce the SVR (i.e., cause hypotension) and result in compensatory tachycardia. Incremental titration of catheter-based epidural or spinal techniques, or initial use of spinal analgesia with opioids alone, can limit the sympathetic blockade produced by local anesthetics. Treatment of hypotension with phenylephrine (an α-adrenergic vasopressor) may avoid the tachycardia observed with the use of ephedrine (a combined α- and α-adrenergic vasopressor). In contrast to stenotic lesions, regurgitant valvular disorders, such as mitral and aortic insufficiency, are best managed with normal to slight increases in sinus heart rate and reductions in SVR. Thus, the sympathetic reduction observed with neuraxial blockade can be beneficial in providing afterload reduction and minimizing the influences of stress catecholamines on SVR. Preserving venous return and intravascular volume are important. However, on occasion, the normally helpful increased intravascular volume of pregnancy or the rapid return of SVR following delivery can result in left ventricular failure and pulmonary edema.[138]

Congenital Cardiac Disorders

Congenital heart disease in the adult is not simply a continuation of the childhood experience. The growth of the cardiac chambers allows arrhythmias to change in character and frequency and ventricular dysfunction and failure to occur. Bioprosthetic replacement valves and conduits can also fail over time, often as a result of adult comorbidities or conditions, including pregnancy. With some congenital disorders, a complete repair is made and cardiovascular function, pressures, and blood flow patterns develop relatively normally. For the most part, these individuals require no special treatment. However, three important differences should be recognized: First, because some cardiac disorders are inherited, fetal echocardiography at 20 to 24 weeks' gestation is desirable. Second, antibiotic prophylaxis may be warranted. Third, arrhythmias are more common owing to the scar tissue in the heart acting as an arrhythmogenic focus. Other disorders, however, may present as uncorrected or partially corrected lesions in decompensated or poorly compensated states, thereby making the anesthetic management more challenging. The most commonly observed CHDs during pregnancy include left-to-right shunts, tetralogy of Fallot, Eisenmenger's syndrome, and aortic coarctation (see Chapter 36).

The physiologic impact of a small septal defect or a patent ductus arteriosus is usually a trivial to modest left-to-right intracardiac shunt. In general, modest left-to-right shunts are well tolerated during pregnancy, although several alterations in management have been suggested.[139] Because air embolization may occur through IV lines, or with the loss-of-resistance-to-air technique of epidural placement, the use of air filters and loss-of-resistance-to-saline epidural placement techniques is recommended.[140] In addition, because increases in pulmonary vascular resistance with hypoxia, hypercarbia, and acidosis may allow for reversal of shunt flow, the application of supplemental oxygen appears prudent. Finally, the overall management goal for these defects should focus on limiting maternal catecholamine and SVR increases. In this regard, the use of neuraxial analgesia provides exceptional control; however, the block should be administered slowly, because rapid decreases in SVR may result in a pronounced right-to-left shunt with maternal hypoxemia.[139]

Parturients with uncorrected or partially corrected cyanotic congenital heart disease (i.e., right-to-left shunts) may tolerate pregnancy poorly. Management focuses on maintaining adequate SVR, intravascular volume, and venous return and preventing increases in SVR (often due to pain, hypoxemia, hypercarbia, and acidosis). The use of supplemental oxygen and the use of arterial and central venous catheters may facilitate care and hemodynamic management. The use of PA catheters remains controversial owing to difficulties in placement, the risk of PA rupture and cardiac arrhythmias, and the limited information obtained in the setting of a severe fixed pulmonary hypertension and a large intracardiac shunt.[141] Neuraxial analgesia produced with intrathecal opioid administration may minimize decreases in SVR, and if provided with a CSE technique, the judicious addition of epidural local anesthetics can be titrated as needed. In the event of a cesarean delivery, neuraxial anesthesia remains preferable to general anesthesia owing to the diminished cardiac output that can occur from halogenated agents and positive-pressure ventilation. If neuraxial anesthesia is contraindicated, a controlled versus rapid-sequence induction of general anesthesia minimizes critical decreases in SVR and myocardial function. Regardless of the technique employed, hemodynamic alterations must be promptly resolved, and ephedrine and dopamine, rather than phenylephrine, are vasopressors of choice because of their maintenance of both SVR and heart rate.

Diabetes

Analgesic and anesthetic management of diabetic parturients should focus on glucose management and the responses of the physiologic systems most affected: coronary, cerebral and peripheral vascular, gastrointestinal, renal, and autonomic systems. The analgesia and anesthesia produced by neuraxial techniques can increase placental perfusion through reductions in maternal catecholamines and decrease the incidence of fetal acidosis occurring with maternal labor hyperventilation. The cardiovascular, autonomic, and uteroplacental blood flow changes caused by diabetes make the prevention and early treatment of hypotension a significant concern. The frequent and severe maternal hypotension witnessed in diabetics can be associated with spinal and epidural anesthesia for cesarean delivery.[142] However, it is possible

that dextrose-containing IV fluids may have played a role. With strict observation and reaction to maternal blood pressure, volume expansion with a non–dextrose-containing solution, and maternal glucose control, spinal anesthesia can be performed without an associated fetal acidosis.[143]

In addition to the improved hemodynamic control seen with the slow initiation of epidural analgesia and anesthesia, this technique may offer other beneficial effects during labor and delivery. Insulin resistance has been demonstrated to occur in a dose-response relationship with the amount of stress following surgery, burns, trauma, and sepsis. More recently, pain per se has been demonstrated to impair insulin sensitivity by affecting nonoxidative glucose metabolism.[144] Although studies have not been performed in laboring diabetic parturients or even in females, this suggests that glucose regulation can be improved by the administration of pain relief in stressful states. Indeed, when epidural anesthesia was compared with general anesthesia as a control group, an attenuation of the hyperglycemic response to abdominal surgery was observed through a modification of glucose production, without affecting glucose utilization.[145] Protein metabolism, by contrast, was not influenced by epidural blockade. These investigations suggest a possible benefit from the use of neuraxial analgesia and anesthesia in parturients with diabetes.

If general anesthesia is required, the possibilities of gastroparesis, limited atlanto-occipital joint extension, and impaired counterregulatory hormone responses to hypoglycemia should be considered and integrated into the management.[146]

EFFECTS OF NEURAXIAL ANALGESIA ON PROGRESS AND OUTCOME OF LABOR

Whether neuraxial analgesia affects the progress and outcome of labor remains a controversial topic. The myriad of maternal and fetal variables adds complexity to the issue, as well as differing institutional and individual anesthetic and obstetric practices. Moreover, the contemporary pattern and progress of labor appears slower than previously described a half a century earlier by Friedman.[147] Zhang and associates,[148] noting a significant delay in the progress of labor in nulliparous women, pointed to several factors possibly responsible including higher maternal age and weight, increasing fetal size, and higher induction and epidural use rates. Together, these changes make practice patterns and outcomes difficult to compare.

Study Design Issues

The greatest challenge in uncovering an association between neuraxial analgesia and progress of labor is that the ideal prospective, randomized, double-blinded, placebo-controlled study is exceptionally difficult, if not impossible, to perform. Retrospective or nonrandomized studies may underestimate the importance of confounders. For instance, women requesting epidural labor analgesia may be inherently different from those choosing natural childbirth; such differences have included having smaller pelvises, more occiput posterior fetal presentations,[149] greater use of oxytocin for induction or augmentation, and more painful labors

(which may be associated with slower labor and instrumental delivery).[150] Moreover, in nulliparous parturients with larger fetuses and eventual dystocia, a requirement for larger amounts of epidural local anesthetic for pain relief has been reported.[151–153]

The complexity of assessing prospective studies begins with enrollment procedures, because women open to randomization of the timing and technique of analgesia may not be representative of the majority of parturients. In addition, parturients who deliver either very slowly or very quickly may not remain in their randomized group. Blinding the obstetrician, anesthesiologist, nurse, and patient to neuraxial versus other analgesic forms is also difficult. Such blinding is necessary to remove any subtle or overt influences on decision-making; for example, instrumental deliveries may be more common in those patients with epidural analgesia because they can more comfortably accept forceps delivery.[154] Finally, women utilizing parenteral opioids, commonly used as a control group, may not progress in a manner representative of the natural progress of labor,[155] thus, not giving a true comparison of epidural techniques with the natural birth experience. No study has so far succeeded in meeting all these objectives; however, certain insights can be gained from the literature to date.

Study Results

The American College of Obstetricians and Gynecologists (ACOG) issued guidelines[156] on the use of obstetric anesthesia services. Among the recommendations to reduce the incidence of cesarean delivery was delaying epidural analgesia initiation until cervical dilation of 5 cm or greater was achieved. The data cited, primarily observational and nonrandomized, found an association between earlier epidural placement and dystocia. Using a case-control methodology, investigators at the National Maternity Hospital in Dublin (the pioneers of the active management of labor) observed that epidural initiation at less than 2 cm dilation was a significant risk factor for prolonging labor in nulliparous women.[157] Thorp and coworkers,[158] in nulliparous women with cervical dilation less than 5 cm and dilation rate less than 1 cm/hr, observed a sixfold increase in cesarean delivery for dystocia in association with the use of regional analgesia. Similarly, Lieberman and colleagues,[159] using a multivariate regression technique on observational data, noted cervical dilation less than 5 cm and station less than 0 at time of epidural initiation as strong risk factors for cesarean delivery. Such cohort studies, however, have not uniformly supported differences in progress and outcome with epidural analgesia. Ohel and Harats[160] failed to show any difference in labor outcome when epidural analgesia was initiated prior to or after 3 cm cervical dilation. Holt and associates,[161] in a prospective cohort study, found an association between cesarean delivery and higher station, but not cervical dilation, at the time of epidural placement.

An interesting form of retrospective analysis evaluates those institutions in which epidural analgesia becomes suddenly available. These studies, though nonrandomized, offer an analysis of an entire patient cohort in which a "sentinel event" has occurred but other variables, such as obstetric practice styles, are unlikely to change dramatically. A meta-analysis of such studies found no association between a sudden increase in the utilization of epidural analgesia and higher rates of cesarean delivery.[162]

The majority of randomized, controlled trials indicate little overall effect of epidural analgesia on the progress and outcome of labor. Luxman and coworkers[163] found no difference in length of labor or mode of delivery in 60 nulliparous parturients randomized to receive epidural analgesia prior to or after 4 cm cervical dilation (mean 2.3 cm vs. 4.5 cm). Chestnut and colleagues, in evaluating women closer to 5 cm cervical dilation (mean 4 cm vs. 5 cm), demonstrated no differences in labor outcome in either spontaneous[164] or induced[165] labors. A meta-analysis of 10 trials comparing parturients of mixed parity randomized to epidural analgesia or parenteral opioids noted a prolongation of the first and second stages of labor by 42 minutes and 14 minutes, respectively, in association with the use of epidurals.[166]

Specific studies, however, do appear to indicate that anesthetic practice differences may influence the progress and outcome of labor. Although the Comparative Obstetric Mobile Epidural Trial (COMET)[167] found no differences in the incidence of cesarean delivery, a higher proportion of instrumental deliveries was observed in patients with "traditional" epidurals versus CSE or parenteral opioids. In the "traditional" epidural group, intermittent boluses of 0.25% bupivacaine were administered, a method not commonly used in contemporary practice in which lower concentrations and continuous infusion pumps are usual. Regardless, the findings suggest that differences in neuraxial technique may alter outcomes; this conclusion has been supported by other studies comparing CSE and epidural techniques. In nulliparous parturients at less than 3 cm cervical dilation, Tsen and coworkers,[68] using 1 mL versus 12 to 15 mL of 0.25% bupivacaine in the spinal and epidural spaces, respectively, observed faster cervical dilation and progress of labor in the spinal (CSE) group. Further, Wong and associates[69] found that the median time from initiation of analgesia to complete dilation was significantly shorter after spinal (CSE) versus systemic analgesia (295 min vs. 385 min, $P < .001$), as was the time to vaginal delivery (398 min vs. 479 min, $P < .001$).

Obstetric practice style may also influence the outcome and progress of labor. Meta-analyses of randomized trials have found that, although instrumental delivery rates increased in patients receiving epidural analgesia, the resulting incidences were widely divergent, perhaps reflecting substantial practice style differences.[166] In terms of cesarean delivery, one study noted that apart from nulliparity, the identity of the individual obstetrician was the variable with the greatest influence on cesarean delivery rates.[168] Moreover, the use of peer review and education have been demonstrated to result in a 50% decrease in cesarean rates despite a simultaneous doubling of epidural analgesia use.[169,170]

In summary, although problems with methodology make an association difficult to evaluate, the use of epidural analgesia appears to affect the progress and outcome of labor remarkably little. Although the risk of cesarean delivery does not appear to be influenced, instrumental vaginal delivery appears to be increased with the use of epidural analgesia. It is possible that these associations may reflect variances in patient demographics or differences in anesthetic and obstetric practice styles.

TEMPERATURE CHANGES IN LABOR

Humans have the ability to maintain body temperature within a narrow range despite changes in environmental temperature. Although the extremities and skin can vary over several degrees, the average core body temperature of healthy adults is 37°C with diurnal variations of ± 0.5°C.[171] Thermoregulation is centered in the hypothalamus and responds to receptors found predominantly in the skin and spinal cord. Established through a balance of heat uptake, production, and loss, temperature equilibrium can be distorted by processes that change the thermoregulatory threshold (set value) or the response to temperatures above or below this value.

Clinically, a temperature greater than 38°C represents a fever. Most commonly, fever is the result of exogenous or endogenous pyrogens that disturb the "thermostat" set value to allow thermoregulatory mechanisms to maintain an elevated temperature. Less commonly, thermoregulatory responses to hyperthermia are prevented (such as a blockade of sympathetically mediated vasodilation or sweating) or overwhelmed (such as immersion in hot water). Of interest, endogenous pyrogens, which act on the thermoregulatory center and are triggered by the release of interleukin-1 (Il-1) and -6 from macrophages, are partially mediated by prostaglandin metabolism.[172] The relationship of this finding to the many pregnancy-induced alterations in the production and distribution of prostaglandins has yet to be elucidated.[173]

Thermoregulation during Pregnancy

During pregnancy, the mother attempts to maintain a normal temperature. The fetus relies on the uteroplacental circulation and the amniotic fluid interface for heat exchange; these limited routes for heat egress result in a normal fetal temperature approximately 0.5°C to 0.75°C higher than maternal body temperature.[174] With extreme hyperthermia, experimental evidence suggests that fetal deterioration may occur. Morishima and colleagues,[175] utilizing radiant heat to produce maternal hyperthermia of 107°F in anesthetized baboons, observed increased uterine activity and deterioration in fetal condition. Similarly, Cefalo and Hellegers[176] demonstrated fetal deterioration in anesthetized gravid ewes with levels of hyperthermia that produced maternal cardiovascular collapse. Although these extreme degrees of hyperthermia are unlikely to be clinically applicable, lesser increases of temperature may have various effects, including changes in umbilical blood flow.[176]

In terms of neonatal effects, epidemiologic evidence suggests that mild maternal fever may not be as benign as previously assumed based on the animal data. Lieberman and associates,[177] in a retrospective review of 1218 nulliparous women with singleton, term pregnancies in spontaneous labor who were afebrile on admission, noted that 1-minute Apgar scores less than 7, hypotonia, and the need for bag and mask ventilation were more common in parturients with a body temperature greater than 101°F. Although it remains unclear whether temperature per se, independent from underlying infectious or inflammatory processes, can cause neurologic injury, an association between maternal intrapartum fever and neonatal encephalopathy,[178] cerebral palsy,[179] and persistent developmental cognitive deficits[180] has been

observed. Moreover, maternal outcome may be directly or indirectly influenced by the presence of even low-grade fever. Lieberman and coworkers[181] retrospectively observed a twofold higher incidence in operative vaginal and cesarean deliveries in nulliparous women who were afebrile at admission and subsequently developed a fever greater than 99.5°F compared with those who remained afebrile, even when controlled for birth weight, length of labor, and analgesic choice. More recently, Shipp and colleagues[182] noted an association between postpartum fever after cesarean delivery and an increased risk of uterine rupture in a subsequent trial of labor.

Epidural Analgesia and Maternal Pyrexia

Study Design Issues

To date, nearly all the clinical studies of maternal fever associated with epidural analgesia have been nonrandomized. Similar to the progress and outcome of labor studies, it is possible that women who request epidural labor analgesia have risk factors that predispose them to fever, including greater rates of nulliparity,[183] prolonged rupture of membranes,[183,184] prolonged labor,[183,185,186] higher temperature on admission,[183] early chorioamnionitis,[183] and frequent cervical examinations.[187] Using a case-control methodology, Vallejo and associates[186] compared women with histologically confirmed chorioamnionitis with two groups of women who received epidural analgesia (with and without chorioamnionitis). Fever was more common in infected women in all groups; however, the incidence of fever in uninfected women with epidurals was only 1%. In a similar study of 149 women who delivered greater than 6 hours following membrane rupture, Dashe and coworkers[188] noted an increased incidence of fever in 54% of parturients who received epidurals. However, when parturients with evidence of placental inflammation were excluded, the incidence of fever was similar in women with and without epidural analgesia (11% vs. 9%).

Study Results

Although an infection is the most common reason for fever during pregnancy, the influence of neuraxial techniques on maternal temperature is of interest. Neuraxial anesthesia administered for surgery, including cesarean delivery, typically results in peripheral vasodilation, redistribution of body heat, and hypothermia.[189] By contrast, in laboring women receiving neuraxial analgesia, a rise in temperature has been noted. Fusi and colleagues[190] reported an increase in vaginal temperatures of approximately 1°C over 7 hours in 18 parturients receiving epidural analgesia with no evidence of infection; this contrasted with stable temperatures in 15 parturients who received intramuscular meperidine. Using a method perhaps more reflective of core temperature, Camann and associates[185] measured tympanic membrane temperature in 53 laboring parturients divided into three groups. One group received IV nalbuphine; the other two groups, composed of women who chose epidural analgesia, were randomized to receive epidural bupivacaine with or without fentanyl. With ambient room temperature maintained at 20°C to 22°C, epidural analgesia did not affect maternal temperature for the first 4 hours. Thereafter, the
mean tympanic membrane temperature increased by 0.07°C/hr in both epidural groups, with no differences observed in those receiving epidural fentanyl (Fig. 70–5).

Macaulay and coworkers[191] evaluated maternal oral and intrauterine and fetal skin temperatures in 33 and 27 parturients undergoing labor with and without epidurals, respectively. With an ambient temperature ranging from 23.3°C to 29°C, 10 fetuses within mothers with epidurals reached a maximum fetal skin temperature of greater than 38°C versus none in the group without epidurals. Of interest, only 2 women, both in the epidural group, reached an oral temperature greater than 37.5°C. Ultimately, no differences in Apgar scoring or umbilical cord blood gases were found. Most recently, Mantha and colleagues[192] observed in 92 healthy, term, nulliparous women in spontaneous labor that temperature elevation to 38°C occurred more commonly in the initial 4 hours in women receiving continuous versus intermittent labor epidural analgesia, although mean maternal temperatures did not differ between the groups at any time, nor were neonatal temperature or sepsis evaluation rates different. Overall, a number of investigators have observed an incidence of clinical fever (>38°C) in 1% to 36% of laboring women receiving epidural analgesia, with a temperature elevation rate of approximately 0.1°C/hr of epidural analgesia, usually after a 4- to 5-hour delay.[183,184,193,194]

The mechanisms by which epidural analgesia may produce changes in maternal temperature during labor remain unclear. Although high ambient temperatures (24°C–26°C) have been suggested as a possible etiology,[190] an association between ambient temperature and maternal or fetal temperatures has not been uniformly demonstrated.[184,191] A second possibility could be epidural-induced reductions in heat loss mechanisms, including an increase in sweating thresholds (by 0.55°C in volunteers)[195] and a reduction in hyperventilation during labor.[196,197] A third possibility could be

alterations that result in, or are related to, shivering. In those parturients who shivered following the initiation of epidural analgesia versus those who do not, pyrexia developed as early as 1 hour later, in comparison with longer than 4 hours later.[198] In addition, shivering parturients ultimately attained higher maximum temperatures and had a threefold increase in clinical fever. A final possibility could be alterations in the parturients not receiving an epidural technique. The opioids frequently utilized in these groups may suppress temperature elevations.[199] A retrospective study of systemic use[200] and a prospective, randomized study of epidural use[185] of opioids, however, failed to demonstrate temperature curve changes with the addition of opioids.

Impact and Interventions

In addition to the fetal concerns discussed earlier, temperature elevations may alter neonatal exposure to antibiotics and subsequent care. Mayer and associates[201] retrospectively evaluated 300 low risk nulliparous women who received systemic opioids, epidural analgesia, or both (*n* = 100 in each group). The incidence of maternal fever (2%, 16%, and 24% in the preceding groups, respectively) and intrapartum maternal antibiotics (6%, 19%, 22%) was highest in the combined opioid and epidural group. Of note, in the 10 patients who ultimately demonstrated laboratory evidence of chorioamnionitis, maternal fever was not the only presenting symptom; fetal tachycardia and meconium-stained or abnormal amniotic fluid were also found. This suggests that the administration of antibiotics should not be guided by maternal fever alone. In a secondary analysis of 1657 low risk nulliparous women enrolled in a trial of active management of labor, the incidence of maternal fever (15% vs. 1%), neonatal sepsis evaluation (34% vs. 10%), and antibiotic treatment (15% vs. 4%) was increased when epidural analgesia was used.[193] However, the incidence of actual neonatal sepsis was exceedingly low in epidural and nonepidural groups (0.3% vs. 0.2%), and of interest, although the indications for sepsis evaluations was not provided, was the finding that two thirds of the evaluations occurred in infants of mothers who did not have intrapartum fevers. Moreover, the mothers who received epidural analgesia had larger infants, longer labors, and a twofold increase in the labor induction rate. Although it is possible that the active management protocol of frequent cervical examinations and early amniotomy may have influenced the risk of fever, a subsequent study evaluated nonrandomized parturients whose temperature remained below 100.4°C throughout labor.[202] Neonatal sepsis evaluations were more common in parturients who had epidural analgesia (20.4% vs. 8.9%) even after controlling for gestational age, birth weight, maternal smoking history, active labor management, premature rupture of membranes, and admission cervical dilation. Epidural analgesia was associated with both major (rupture of membranes > 24 hr, fetal heart rate > 160 beats/min) and minor criteria (maternal temperature > 99.5°F, rupture of membranes 12–24 hr) for sepsis evaluation. These data suggest that multiple factors should be present prior to initiating a sepsis evaluation. Moreover, of those babies investigated for sepsis because of risk factors, few will ultimately prove to have been infected.

The rate of neonatal sepsis evaluation and treatment can be modified by neonatology admission criteria and practice

style. Yancey and coworkers,[203] reviewing the effects of an on-demand epidural analgesia service in which epidural use increased overnight (because of a change in policy in the unit) from 1% to 83%, observed that maternal temperatures greater than 99.5°F and 100.4°F increased 3-fold and 18-fold, respectively. Despite this increase in maternal temperatures, neonatal blood counts and cultures increased modestly (relative risk 1.5–1.7), and no changes in the proportion of infants who received antibiotic treatment for presumed sepsis were observed. Similarly, Kaul and colleagues[204] noted in a retrospective review of the delivery records of 1177 nulliparous women that the incidence of neonatal sepsis evaluations was no different (7.5% vs. 9.4%) despite women with epidural analgesia having more fever. Both investigators cited more stringent neonatal sepsis treatment guidelines, which did not include the treatment for maternal fever in the absence of chorioamnionitis, as being responsible for their results.

Attempts to diminish maternal temperature increases during labor have thus far been limited. Goetzl and associates[205] randomized 42 nulliparous women to receive acetaminophen 650 mg every 4 hours versus placebo in women receiving epidural analgesia. The incidence of fever did not differ between groups (23.8%). Of note, despite all neonatal blood cultures being negative, maternal serum and cord blood markers of inflammation (Il-6) were higher in mothers who had fever. This suggests that inflammatory markers can be elevated in the absence of neonatal infection. In a separate study, Goetzl and coworkers[206] randomized 200 term nulliparous patients undergoing labor with epidural analgesia to receive low- or high-dose corticosteroids (methyl-prednisolone 25 mg q8h or 100 mg q4h, respectively) or placebo to assess the rate of intrapartum fever (>100.4°F). The incidence of maternal fever and neonatal sepsis evaluations were significantly reduced in the high-dose corticosteroid group; however, an increased incidence of asymptomatic neonatal bacteremia was also observed. A significant reduction in the presence of Il-6 was observed in the high-dose corticosteroid group only when compared with the placebo group. The investigators concluded that high-dose corticosteriods, such as those used as an intrapartum maternal stress dose, could reduce maternal fever and inflammatory cytokines, but could not be currently recommended as a prevention strategy owing to the risk of neonatal bacteremia.

In conclusion, epidural analgesia does appear associated with increases in temperature, although most of these increases are mild. This being said, maternal fever has been linked with adverse neonatal outcomes. Further studies of the mechanism of these temperature elevations with epidural use and a reanalysis of maternal and neonatal evaluation and treatment policies are warranted.

Perineal Repair and Pelvic Floor Injury

ROHNA KEARNEY and COLM O'HERLIHY

INTRODUCTION

Pelvic floor injury at the time of vaginal delivery can result in the later development of urinary incontinence, pelvic organ prolapse, and fecal incontinence. In the United States, the direct annual cost of pelvic organ prolapse surgery alone was estimated to be over $1 billion at the turn of the millennium, with 22 women per 10,000 having surgical correction for this indication.[1,2] The annual direct cost of urinary incontinence was even higher, at $12.4 billion.[3] The cost 10 years later is likely to be substantially higher. The lifetime risk of a woman in the United States undergoing surgery for incontinence or prolapse by the age of 80 has been estimated as 11%.[4] With growing awareness of the impact of pelvic floor injury, attention is now increasingly focused on the prevention of these problems. Vaginal delivery is the factor most subject to modification in the etiology of pelvic floor injury.[5–7] In order to prevent injury and minimize the impact of delivery on the pelvic floor, it is necessary to have an understanding of the anatomy and the pathophysiology of injury.

ANATOMY

The primary function of the pelvic floor is to prevent the pelvic organs from downward displacement in the upright position, while at the same time allowing parturition and elimination. The levator ani muscles, which are composites of the pubococcygeus, puborectalis, and iliococcygeus on each side, are the most important constituents of the pelvic floor and resemble a horizontal shelf that acts to close like a valve when the female assumes the upright position.[8] The pubococcygeus, more recently referred to as the "pubovisceral muscle," comprises the puboanalis, pubovaginalis, and puboperineus subdivisions.[9,10] The pubococcygeus and puborectalis arise from the inner surface of the pubic bone, whereas the iliococcygeus arises from the arcus tendineus levator ani. The pubococcygeus inserts into the vaginal wall (pubovaginalis), perineal body (puboperineus), and intersphincteric groove (puboanalis). The puborectalis forms a sling around the rectum and inserts into the deep external sphincter, and the iliococcygeus inserts into the iliococcygeal raphe.

The perineal membrane is a triangular sheet of fibromuscular tissue with the striated urogenital sphincter lying above. It provides support by attaching the vagina, urethra, and perineal body to the ischiopubic rami. Above it, the striated urogenital sphincter consists of the compressor urethra, urethrovaginal sphincter, and sphincter urethra.

The endopelvic fascia refers to the condensation of the adventitial layers of the pelvic organs. This connective tissue layer attaches the pelvic organs to the lateral pelvic walls and, together with the levator ani, shares the load on the pelvic floor. Support for the vagina has been identified at three levels[11,12] (Fig. 71–1). Level I consists of the uterosacral and cardinal ligaments, which represent a medial and lateral thickening of the endopelvic fascia connecting the cervix and upper vagina to the pelvic sidewalls. These structures are vertical in the standing position and serve to keep the uterus, cervix, and upper vagina tethered in a posterior position over the levator ani muscles.

At level II, the middle third of the vagina is attached by the paracolpium to the arcus tendineus and levator ani muscle fascia. The arcus tendineus fascia pelvis runs from the pubic bone anteriorly to the ischial spines posteriorly. At level III, the lower third of the vagina is attached directly to the perineal membrane, perineal body, and levator ani.

The proximal urethra is supported by the endopelvic fascia and anterior vaginal wall, which act like a hammock and attach it to the arcus tendineus fascia and levator ani, thus resulting in compression and closure of the urethral lumen in response to increases in intra-abdominal pressure.[13]

The perineal body is covered by skin and lies between the lower vagina and the anus. It is attached by the perineal membrane to the inferior pubic rami and ischial tuberosities. The perineal body receives the insertion of the bulbocavernosus muscles and posteriorly is attached to the coccyx by the external anal sphincter.

The anal sphincters are located in the posterior compartment of the pelvic floor. The external anal sphincter is a voluntary muscle consisting of three components: a subcutaneous part, a superficial part connecting the perineal body to the coccyx, and a deep part, which surrounds the rectum. The internal anal sphincter is a downward extension and thickening of the circular smooth muscle of the rectum. The

intersphincteric groove runs between the internal and the external anal sphincters. The ischiorectal fossas lie between the levator ani and the obturator internus muscles. The external anal sphincter and bulbocavernosus muscles are supplied by the pudendal nerve, which arises from the anterior primary rami of S2, S3, and S4. The nerve leaves the pelvis through the greater sciatic foramen and runs in the pelvic side wall close to the ischial spine and sacrospinous ligament to enter the pudendal (Alcock's) canal through the lesser sciatic foramen. It divides into three terminal branches—the clitoral, perineal, and inferior rectal. Autonomic nerves from the pelvic plexus supply the internal anal sphincter.

PATHOPHYSIOLOGY

Pelvic floor injury can result from damage to the nerve supply, muscles, or connective tissue, which together maintain pelvic floor function. There is good evidence that damage to the innervation of the pelvic floor is a causative factor in the development of urinary and fecal incontinence following vaginal delivery.[14,15] Partial denervation of the pelvic floor has been shown in 80% of women following a single vaginal delivery.[16] Fetal macrosomia and a prolonged second stage (either active or passive) are associated with an increased risk of neuropathic damage.[17]

The levator ani and endopelvic fascia act together to maintain urinary continence and pelvic organ support. If the muscle is damaged, the connective tissue has to play a greater compensatory role, and this frequently fails over time, most commonly after the menopause. The arcus tendineus fascia is found to be detached (most commonly from the ischial spines) in women with anterior vaginal wall prolapse,[11] and histologic studies have documented levator ani muscle fibrosis following vaginal delivery.[18] Such changes are also seen in women with stress urinary incontinence and pelvic organ prolapse.[19,20] Magnetic resonance imaging is providing increasing information about pelvic floor injury following childbirth.[21] Abnormalities of the levator ani

muscle are seen in 20% of women after their first vaginal delivery.[22] Forceps delivery, prolonged second stage, and older maternal age at first delivery have been identified as associated risk factors for the development of levator ani injury.[23] Computer simulation of levator ani muscle stretch during fetal head descent demonstrates that the medial portion of the pubococcygeus muscle undergoes the greatest degree of strain during fetal head descent and that the tissue stretch ratio is proportional to fetal head size.[24] Further studies have shown that levator ani abnormalities are found more commonly in women with prolapse than in women with normal support, suggesting that injury to this muscle during vaginal delivery is a predisposing factor to the future development of prolapse.[25,26]

Similarly, the anal sphincters are vulnerable to injury during vaginal delivery, which have been generically called OASIS (obstetric anal sphincter injuries). Factors associated with OASIS and the future development of anal incontinence are discussed under "Third-Degree Anal Sphincter Injury."

UTEROVAGINAL PROLAPSE

Effects of Pregnancy, Childbirth, and Parity

Nulliparous pregnant women have been shown to exhibit altered pelvic floor support when compared with nulliparous nonpregnant women. In the nonpregnant group, 43% had stage 0 prolapse and 57% had stage 1, but in the pregnant group, 10% had stage 0, 43% had stage 1, and 48% had stage 2.[27] Interestingly, the greatest changes observed were in the length of the anterior wall and the perineal body, which may explain the common occurrence of urinary incontinence during pregnancy. The increase in perineal body length may represent an adaptation that reduces the occurrence of anal sphincter damage. Another study of nulliparous women delivered at term showed that at 36 weeks' gestation, 46% had prolapse, with 26% having a stage 2 prolapse[28]; at 6 weeks postpartum, there was a similar

incidence of new prolapse in women delivered vaginally and by cesarean section. Thus, regardless of the mode of delivery, being pregnant of itself impairs pelvic floor support.

That the risk of prolapse increases with the number of vaginal deliveries is well documented. Mant and associates[5] have shown that a woman after two vaginal deliveries has an 8-fold increased risk of developing pelvic organ prolapse compared with the nulliparous woman and that this risk rises to 12-fold after four vaginal deliveries.

Risks

Uterine prolapse occurring for the first time during pregnancy is rare, occurring in 1 in 10,000 to 15,000 deliveries.[29] It can occur acutely following a fall or trauma in nulliparous women[30] but is more commonly seen in parous women with prolapse prior to pregnancy. Much of the literature relating to uterine prolapse in pregnancy consists of case reports prior to 1970[29–33] when the condition was seen more frequently owing to higher average parity.[34] Thus, current data on maternal and fetal risks are lacking. A large review up to 1940 reported a substantial fetal and maternal complication rate,[29] which included a 10% risk of miscarriage[30] and an increased risk of preterm birth.[31] Fetal and maternal death have also been reported.[31] Cervical elongation, hypertrophy, and edema are present in all cases in which the pregnancy progresses to term.[29] Urinary obstruction can occur and may require catheterization.[35] Abnormalities of labor are common. On the one hand, weakness of the pelvic floor can lead to precipitate delivery with resultant cervical lacerations. On the other hand, cervical infection and bleeding during pregnancy are common and can lead to scarring and fibrosis with resultant cervical dystocia. This typically manifests as secondary arrest in cervical dilation, usually between 5 and 7 cm.[32] At one time, it would have been managed by Duhrssen's cervical incisions with or without the use of forceps, but at present, cesarean section is preferred. Accordingly, although spontaneous vaginal delivery rates of 40% to 80% have been reported,[31,32] cesarean or instrumental deliveries are more common. Primary postpartum hemorrhage, due to uterine atony, may be difficult to control, because manual uterine compression is hindered by the prolapse.

Management Options

Prenatal

Uterine prolapse occurring prenatally requires admission to hospital if it is not possible to reduce the prolapse in the clinic. Treatment consists of bedrest in the Trendelenburg position combined with an indwelling urinary catheter and saline soaks to reduce cervical edema. Once edema has been reduced, the prolapse can usually be manually replaced and a pessary then inserted to prevent recurrence; a Hodge pessary is the one most commonly used. Antibiotic creams are often prescribed to reduce associated cervicitis. There is no evidence that systemic antibiotics are beneficial. In the past, vaginal packing and even surgical closure of the introitus have been described as effective.[34] The introitus is reopened at term to allow vaginal delivery. Pessary treatment is often required only until the fifth month of pregnancy, when the uterus lifts out of the pelvis, thereby alleviating prolapse symptoms.[36] Incarceration of a retroflexed gravid uterus in association with severe prolapse has been reported, requiring epidural anesthesia to dislodge the uterus from the pelvis.[35] Incarceration is more likely to occur in the presence of severe prolapse, which allows the uterus to enlarge without concomitant lifting out of the pelvis.

Labor and Delivery

Careful intrapartum monitoring of the rate of cervical dilation is essential for early detection of both precipitate delivery and cervical dystocia. In the event of the latter, (Duhrssen's) intracervical incisions can be considered, but today, cesarean section is usually more appropriate.

Postnatal

If the prolapse is untreated, it will almost certainly recur in future pregnancies. Surgery is the definitive cure, but a vaginal pessary is an appropriate immediate treatment during postnatal genital involution. Longer-term use of a pessary should be considered if more pregnancies are desired, because a surgical repair is likely to be undone by another vaginal delivery, and an elective cesarean to avoid recurrent prolapse carries its own risks.

PREVIOUS PELVIC FLOOR REPAIR/ VAGINAL SURGERY

Maternal Risks

Despite a general decline in family size, the combined effects of increasing rates of surgical intervention for pelvic organ prolapse and urinary incontinence and delayed child-bearing mean that many women are becoming pregnant having previously undergone reconstructive surgery. The current use of suburethral tapes for the treatment of stress urinary incontinence and laparoscopic or vaginal mesh procedures with uterine preservation for the management of prolapse provide less invasive surgical treatments that are more likely to be offered at an earlier stage, because women are now less prepared to accept the burden of pelvic floor symptoms. As a consequence, the number of women becoming pregnant following pelvic floor surgery may well increase in the future. This poses a dilemma for the obstetrician. Both pregnancy and especially delivery can pose a threat to the continued efficacy of successful surgical repair. It is important to provide the woman with information on the likelihood of symptoms recurring during pregnancy, persisting following delivery, and necessitating further treatment. However, published evidence on which to base management is scanty. The urethra lengthens during pregnancy,[37] and the bladder becomes an abdominal organ. Stress incontinence occurs commonly in pregnancy[38] and is a risk factor for persistent urinary incontinence. Thus, pregnancy of itself poses a risk of prolapse recurring. However, the main obstetric concern following previous successful pelvic floor surgery is mode of delivery. Reported outcomes among women delivered abdominally or vaginally following previous surgery for pelvic organ prolapse and stress urinary incontinence provide conflicting results. In the largest series of 89 women who conceived following colporrhaphy (66 of whom had undergone cervical amputation), 34 miscarried or delivered prior to 32 weeks. Twenty-four had a cesarean section to preserve pelvic floor function. At 6 to 8 weeks postpartum, there was recurrence of symptoms in 7% of women, but at 1 year postpartum, 22% had symptoms severe enough to require further surgery.[39] Cesarean section failed to prevent recurrence, with 9 of the 25 (36%) delivered abdominally suffering recurrence at 5 years compared with 7 of the 49 (14%) delivered vaginally. Conversely, in another series of 78 women who had surgery for prolapse, 31 were

followed up after subsequent pregnancy. Twenty-five had vaginal deliveries and 4 of them had recurrent prolapse,[40] 6 had cesarean section, and none had any recurrence of prolapse (although this difference is not statistically significant). Of 6 reported vaginal deliveries following uterosacral sacrospinous suspension for prolapse, 1 patient suffered a recurrence of symptoms requiring further surgery.[41]

The literature relating to women delivering after previous continence surgery is also conflicting. A study of five women who delivered vaginally following a previous Burch colposuspension reported that three suffered recurrent incontinence,[42] whereas all the women delivered by cesarean section had maintained continence at 1 year postcesarean (despite a majority having had incontinence in the third trimester). A review of pregnancy and delivery after midurethral sling procedures cited 24 cases in the literature of women becoming pregnant after sling procedures with 12 delivering vaginally and 11 by cesarean, with 1 ongoing pregnancy at publication.[43] This showed that of the 12 women delivered vaginally, 10 were continent at 2 to 36 months, with 9 of the 11 women after cesarean remaining continent. Information available to date on pregnancies following tension-free vaginal (TVT) and transobturator suburethral tape (TVT-O) insertions indicates that recurrence of stress incontinence is unusual and that vaginal delivery does not increase this risk.[44–46] The optimal mode of delivery following previous pelvic floor surgery is still unclear, and many other factors need to be considered in individual cases.

Fetal Risks

The Manchester repair (Fothergill) operation performed prior to pregnancy has been associated with greater miscarriage and preterm delivery rates, but this operation is now rarely performed.

Management Options

Prepregnancy

All women planning a pregnancy after previous pelvic floor surgery for urinary incontinence or prolapse should be advised of a possible functional deterioration during pregnancy that may persist, even if an elective cesarean section is performed.

Prenatal

Timely assessment of symptom recurrence and reassurance of probable resolution of symptoms following delivery are important. Intensive pelvic floor physiotherapy may be indicated, but there are inadequate data on its effectiveness in this situation for it to be recommended with confidence.

Labor and Delivery

If symptoms have been largely cured by a prolapse or incontinence repair procedure, current consensus would favor performing an elective cesarean section in order to minimize the risk of recurrent symptoms. There have, however, been many reports of women delivering vaginally with no recurrence of symptoms. If a vaginal delivery is planned, an episiotomy may be beneficial to reduce stretching of rigid or scarred tissues.[37]

Postnatal

Pelvic floor exercises should be continued. A decision regarding further surgical management should ideally be deferred until 6 months following delivery, because recovery of function continues to occur until then.[41] Any plans for further childbearing should be discussed; the woman should be made aware that any subsequent pregnancy risks producing a recurrence of symptoms requiring further surgery once childbearing is complete.

PERINEAL INJURY

Trauma to the perineum, of varying degree, constitutes the most common form of obstetric injury.[47,48] Its severity is generally classified according to the degree of perineal disruption:

- First-degree tear involves only perineal or vaginal skin.
- Second-degree tear occurs when perineal skin and muscles are torn.
- Third-degree tear occurs when, in addition to perineal skin and muscle, the anal sphincter muscle is torn.
- Fourth-degree tear occurs when sphincter muscle disruption is complete with additional extension into the anal mucosa; this implies that both external and internal anal sphincter muscles have been severed.

Further subdivision of third-degree tears are discussed under "Third-Degree Anal Sphincter Injury."

First- and Second-Degree Tears

General

First- and second-degree perineal tears are very common. The incidence of a completely intact perineum, without even minor tears, following delivery after a first vaginal birth is very low, approximately 6%.[48] The maternal position at delivery may be important; one study reported an overall 66% intact perineum rate associated with the lateral position at delivery, compared with 42% in the squatting position.[49] Because of the frequent need for suturing of tears and the limited availability of experienced surgeons, repair is often performed by relatively inexperienced personnel. All staff supervising even the most normal births should, therefore, receive early and thorough training in perineal repair.[47] The principles of management include immediate assessment to exclude deeper injury involving the anal sphincter, appropriate surgical repair, and effective postpartum analgesia and advice.

Maternal Risks

Second-degree tears can result in significant morbidity. Women who sustain them resume sexual intercourse later and report greater frequency of dyspareunia than women who have intact perineums or first-degree tears.[50] Use of teaching models for instruction of midwifery and medical staff in repair technique is effective in reducing such complications.[51]

Management Options

PRENATAL

Prenatal and intrapartum perineal massage have been advocated as interventions to reduce the incidence of second- and greater-degree tears, but the evidence in its favor is conflicting.[52] In one study of 1340 women, massage and stretching during the second stage of labor did not increase the rate of perineums intact after delivery.[53] However, a second study of 861 nulliparas randomized to antenatal perineal massage demonstrated a reduction in episiotomy, and second- and third-degree lacerations, with the greatest benefit among women older than 30 years.[54] Two recent prospective reports indicate that massage is neither protective nor detrimental to the risk of perineal and anal sphincter trauma.[55,56] Pelvic floor muscle exercises performed prenatally and postnatally have been shown to reduce self-reported incontinence in late pregnancy and up to 6 months postpartum.[57]

LABOR AND DELIVERY

The Peri-Rule is a very simple plastic measuring device that was developed by the Birmingham Perineal Research Evaluation Group as an aid in measuring second-degree tears. Three measurements can be made by the birth attendant: the depth of the tear from the fourchette to the perineal body, the length from the fourchette to the vaginal apex, and the length of the tear along the perineum. Use of this device encourages a standardized assessment of perineal tears, and good interobserver reliability for use of the Peri-Rule has been reported.[58]

Despite an absence of evidence on outcome, the practice of nonsuturing of perineal tears has been proposed.[59] Several studies have examined the method of perineal repair. Use of polyglactin suture material is associated with less perineal pain and lower resuture rates compared with chromic catgut.[60,61] It would appear that more rapidly absorbed polyglactin requires less frequent suture removal compared with standard polyglactin.[62] A two-stage continuous repair leaving the skin unsutured also seems to be associated with less pain. More recently, the Cochrane systematic review of continuous versus interrupted suturing of the perineum showed that the continuous suturing method was associated with less pain up to 10 days postpartum. There was also less need for suture removal in the continuous suturing group, but there was no difference in the need for resuturing or the incidence of long-term pain between both groups.[63] It is thought that during the immediate healing period, tension in the tissues is likely to be distributed more evenly in the continuously sutured wound, resulting in less pain.

The Role of Cesarean Section

There is no consensus about the role of elective cesarean section in the prevention of obstetric pelvic floor injury. However, some are so convinced of its benefit that they even advocate obtaining "informed consent" regarding the risks of perineal injury before women elect to have a vaginal birth.[64] Although traumatic mechanical injury to the anal sphincter occurs only with vaginal delivery, evidence exists to show that if performed late in labor, cesarean section may fail entirely to protect the anal sphincter mechanism, with one study showing neurologic injury in women delivered by cesarean section after 8 cm dilation.[65] Parous women delivered only by cesarean section still have a 3.5-fold increased relative risk of urinary incontinence compared with women who have never been pregnant, although the risk is higher still after vaginal delivery.[66,67] Long-term and severe stress urinary incontinence symptoms are less influenced by mode of delivery,[68,69] and indeed, urgency symptoms may be increased after cesarean birth.[70] These data, and comparison between twin sisters,[71] suggest that the pregnant state of itself (regardless of mode of delivery) can influence function and indicate that more research is required into the pathogenesis of obstetric pelvic floor injury before definitive advice on mode of delivery can be offered.

POSTNATAL

Analgesia is the main priority.

SUMMARY OF MANAGEMENT OPTIONS
First- and Second-Degree Tear

Management Options	Evidence Quality and Recommendation	References
Prenatal		
There is conflicting evidence on the value of perineal massage before and during labor.	Ib/A	52–56
Pelvic floor exercises before and after labor are associated with a lower incidence of self-reported incontinence up to 6 mo.	III/B	57
Labor and Delivery		
Polyglactin suture material is associated with a lower incidence of pain and lower resuture rates than chromic catgut.	Ib/A	60,61
Three-stage continuous suture is associated with less pain and less need for suture removal than with repair using interrupted sutures.	Ib/A	62,63
Postnatal		
Analgesia and pelvic floor exercises are recommended.	III/B	57

TABLE 71–1

Standardized Bowel Function Questionnaire: Fecal Continence Scoring System

FEATURE	NEVER	RARELY	SOMETIMES	USUALLY	ALWAYS
Incontinence for solid stool	0	1	2	3	4
Incontinence for liquid stool	0	1	2	3	4
Incontinence for flatus	0	1	2	3	4
Wears pad	0	1	2	3	4
Fecal urgency	0	1	2	3	4

Add one score from each row. A score of 0 implies complete continence. A score of 20 implies complete incontinence.

Third-Degree Anal Sphincter Injury

General

Altered fecal continence is common following primary repair of third- and fourth-degree perineal injury, that is, when anal sphincter muscle disruption is clinically recognized after vaginal delivery. Up to 50% of women experience some incontinence symptoms within the weeks and months after a third-degree tear.[72,73] These symptoms do not correlate with the mode of sphincter repair. Consequently, all women known to have sustained anal sphincter trauma should have their continence routinely assessed at the conclusion of the puerperium.

Postnatal continence assessment should include direct questioning using a standardized bowel function questionnaire (Table 71–1)[74] so that a reliable continence score can be allotted to facilitate monitoring of the progress of symptoms over time. Continence of flatus, liquid, and solid feces should be documented, together with inquiry concerning fecal urgency, a socially debilitating symptom defined as an inability to defer defecation for longer than 5 minutes; the complaint of urgency incontinence may reflect external anal sphincter dysfunction.

Digital examination of the anal canal may provide an approximation of the integrity of the sphincter and perineal body but is not otherwise diagnostically reliable. Conversely, palpable defects in the levator ani musculature have been shown to correlate with magnetic resonance images of the pelvic floor.[21] Nevertheless, anorectal physiologic testing is necessary to determine objectively the nature and prognosis of any residual anal sphincter damage and routinely consists of the following investigations:

- Anal manometry is performed to evaluate sphincter tone and contractile function.
- Endoanal ultrasound is used to examine the anatomic integrity of the sphincter.
- Neurophysiologic testing of the pelvic floor is done to identify pudendal neuropathy.

These tests should be applied not only to women who have sustained third- and fourth-degree tears but also to other puerperal patients complaining of fecal incontinence. Disturbance of resting tone on anal manometry is indicative of predominant internal anal sphincter dysfunction, whereas a reduction in squeeze incremental pressure on voluntary contraction is consistent with reduced external sphincter muscle power. Manometry is performed using a multichannel, water-perfused catheter in the left lateral position, and reductions in the pressure profile, although diagnostically reliable, do not differentiate traumatic muscular from

TABLE 71–2

Obstetric Risk Factors for Anal Sphincter Injury

First vaginal delivery

Instrumental delivery (forceps > vacuum)

Prolonged second stage of labor (>1 hr)

Epidural anesthesia

Persistent occipitoposterior position

Macrosomia (birth weight > 4 kg)

Shoulder dystocia

Previous third-degree perineal tear

Midline episiotomy

neurologic injury. High-quality endoanal endosonography provides clear and reproducible images of both internal and external sphincters[75,76] but may overestimate the significance of muscular defects. Many women are found to have small defects that do not correlate with antecedent obstetric events or fecal incontinence symptoms,[77] whereas internal anal sphincter disruption more commonly predisposes to persistent disturbances of continence.[78]

Pudendal nerve assessment should include testing both conduction along the entire length of the nerve, for example, using clitoral-anal reflex assessment, and anal sphincter electromyography (EMG), which assesses motor unit recruitment and action potential morphology. Neuropathy is responsible for at least one third of fecal continence disturbances, and its assessment provides essential information on prognosis and appropriate management.[79]

Risk Factors for Anal Sphincter Injury
(Table 71–2)

VAGINAL DELIVERY

Normal vaginal delivery inevitably increases the risk of damage to the sphincter mechanism, compared with prelabor cesarean section. Nonetheless, intrapartum cesarean section can be followed by continence disturbance, consistent with first-stage influences on anal sphincter function.[65] Prelabor cesarean section should, therefore, be chosen when any risk to the pelvic floor is to be avoided.

PRIMIPARITY

Because first labors are most often associated with inefficient uterine contractility, dystocia, prolonged labor, use of epidural anesthesia, and episiotomy, puerperal fecal

incontinence most often follows first vaginal delivery. Risk is increased between two- and fivefold,[80] which reflects the reduced elasticity of the pelvic floor among nulliparas.

INSTRUMENTAL DELIVERY

Both forceps and vacuum extraction significantly increase the risk to the fecal continence mechanism two- to sevenfold.[16,80] Although vacuum extraction is somewhat less commonly traumatic, completion of the delivery with forceps when a vacuum attempt fails, generally due to poor adhesion of the vacuum cup, compounds the incontinence risk.[81]

PROLONGED SECOND STAGE OF LABOR AND EPIDURAL ANALGESIA

Effective epidural analgesia, now a very widely applied form of intrapartum pain relief, abolishes the maternal bearing down reflex in late labor. As a consequence, the passive phase of the second stage of labor is prolonged, sometimes for several hours, before maternal pushing is encouraged. Such a prolonged passive second stage doubles the risk of subsequent incontinence, apparently secondary to pudendal neuropathy. Randomized evidence does not support an expectant policy in the second stage under epidural blockade, because the instrumental delivery rate is not reduced and the duration of labor is needlessly prolonged.[82]

INTRAPARTUM MECHANICAL FACTORS

Third-degree tears occur three times more frequently when the fetus is macrosomic (birth weight > 4 kg) compared with lower birth weights. Shoulder dystocia also predisposes to anal sphincter injury, as does persistent occipitoposterior position of the fetal head in the second stage of labor.[23]

MIDLINE EPISIOTOMY

Episiotomy is performed with the objective of preventing deep perineal lacerations and anal sphincter trauma and is one of the most frequent surgical interventions. The perineal incision can be made either mediolaterally or in the midline posteriorly. Although there is a widespread assumption that it can do more harm than good,[83–87] population data suggest that selective mediolateral episiotomy may be protective of the sphincter mechanism.[88] The angle of mediolateral incision has been shown to have an important bearing on the risk of sphincter injury, with episiotomies made close to 45 degrees least often associated with third-degree tears,[89] so that instruction in optimal mediolateral technique should be emphasized.[90] Conversely, there is little doubt that midline episiotomy, which is particularly favored in North America, greatly increases the risk of third-degree tear[91] to the extent that its use should probably be abandoned. This risk is compounded when midline episiotomy is combined with other interventions, such as epidural analgesia and instrumental delivery.

PREVIOUS ANAL SPHINCTER DISRUPTION

The incidence of third-degree tears of varying severity is about 2.5% of primiparous and 0.5% of multiparous vaginal deliveries, with an overall average rate of about 1.5%.[76] Following satisfactory postnatal repair, at subsequent vaginal delivery, the risk of a further tear increases fourfold to about 4%[92] if mediolateral episiotomy is practiced and to over 10% with midline episiotomy.[93]

Management Options

Bearing in mind the inherent anatomic vulnerability of the anal sphincter during childbirth, some risk of trauma exists even when obstetric management is optimal. Avoidance of postpartum fecal incontinence rests partly with measures to avoid occurrence of third-degree tears but, even more significantly, in the appropriate management of anal sphincter injury when it occurs at delivery.

PRIMARY PREVENTION

Primary preventive measures include augmentation of myometrial contractions during first labors, using intravenous oxytocin to correct dystocia; in this way, the incidences of instrumental delivery, occipitoposterior position, and prolonged first and second stages of labor can be minimized (for a somewhat different view, see Chapter 69). Vacuum extraction should be the first choice for low-cavity instrumental delivery, although the potentially traumatic sequence of failed vacuum followed by forceps delivery should not be ignored. Abbreviation of the passive, nonpushing second stage of labor is advisable, even in the presence of effective epidural anesthesia (again, for a somewhat different view, see Chapter 72). When episiotomy is performed, midline procedures should be eschewed in favor of mediolateral incisions approximating as closely as possible to 45 degrees.

OPTIMIZING PERINEAL REPAIR

A standard classification of the severity of anal sphincter injury has been recommended in a recent Royal College of Obstetricians and Gynaecologists (RCOG) publication[94] (Table 71–3), principally on the grounds that the degree of perineal injury correlates approximately with long-term symptomatic outcome. It is inevitable that the functional outcome following repair of extensive tears involving the internal anal sphincter and anal mucosa (fourth-degree tears) will be intrinsically more predisposed to continence sequelae than when only partial-thickness external sphincter trauma has occurred. Nevertheless, well-trained obstetric surgeons using appropriate operative techniques will produce the best functional outcomes, regardless of the extent of injury.

T A B L E 7 1 – 3

Classification of Perineal Injury

First degree	Injury to perineal skin only
Second degree	Injury to perineum involving perineal muscles but not involving the anal sphincter

Third degree	Injury to perineum involving the anal sphincter complex:
	  3a: <50% of EAS thickness torn
	  3b: >50% of EAS thickness torn
	  3c: Both EAS and IAS torn

Fourth degree	Injury to perineum involving the anal sphincter complex (EAS and IAS) and anal epithelium

EAS, external anal sphincter; IAS, internal anal sphincter.

Available at http://www.rcog.org.uk/womens-health/clinical-guidance/management-third-and-fourth-degree-perineal-tears-green-top-29 (accessed August 21, 2009).

MANAGEMENT OF OBSTETRIC SPHINCTER DISRUPTION

Timing of Repair Procedure

It is standard obstetric practice to repair anal sphincter tears immediately or within a few hours of vaginal delivery—the so-called primary repair. Early repair abbreviates the patient's inconvenience and discomfort but should not preclude performance of the repair procedure by an appropriately trained obstetric surgeon. If a skilled operator is not immediately available, then delayed primary repair within 24 hours has much to recommend it, provided that hemostasis and analgesia have been achieved. Delayed repair will, however, almost inevitably enhance the patient's anxiety and sense of grievance concerning her injury, with a potential incremental effect on resort to complaint and litigation.

Surgical Technique

Anal sphincter repair should be conducted with full surgical precautions, instrumentation, and lighting in an operating room setting. Slowly absorbed synthetic monofilament suture materials such as polyglyconate (Maxon) or polydioxone (PDS) should be used. When the external sphincter is completely torn (3b) it can be repaired end-to-end or with an overlapping technique. Several randomized, controlled trials (RCTs) have compared end-to-end and overlap repairs. Fitzpatrick and coworkers[72] found no difference between the two groups, although there was a trend toward more symptoms in the end-to end group. Garcia and colleagues[95] looked only at 3b, 3c, and fourth-degree tears in a small study and showed no difference. More recently, Fernando and associates[96] studied 64 women with 3b or greater tears in an RCT and found a higher incidence of fecal incontinence (24% vs. 0%) and urgency (32% vs. 3.7%) in the end-to end group at 12 months. From these studies, end-to-end repair should be carried out on 3a tears and overlapping repair may be considered for 3b, 3c, and fourth-degree tears, if access to the disrupted anal sphincter stumps permits. Distortion of the normal anal anatomic relationships following deep perineal lacerations means that endoanal ultrasound does not appear to offer useful intraoperative assistance in improving surgical muscle realignment. Ultrasound may have a potential role, however, in the early postnatal screening of women with ostensibly intact anal sphincters so as to facilitate selective monitoring of fecal continence among those who sustain occult forms of anal sphincter injury.

Postnatal Management

Although firm evidence is scanty, it appears likely that prophylactic broad-spectrum antibiotic therapy (e.g., co-amoxyclavulanic acid) enhances the integrity of primary anal sphincter repair during the first 3 to 5 postnatal days. Conversely, firm randomized, controlled data exist to support the use of a laxative rather than a constipating postoperative regimen during the early puerperium.[97] Use of lactulose or ispaghula to soften the stool is associated with a shorter and less painful recovery period when compared with codeine phosphate treatment as employed by coloproctologists following elective anal surgery.

Routine Postnatal Review of Fecal Continence

Because up to 50% of women who sustain a third- or fourth-degree tear experience some puerperal symptoms of fecal incontinence, routine follow-up assessment of anal sphincter function is advisable once postnatal healing is complete. Such a review is probably best performed at 8 to 12 weeks following delivery and should consist, as delineated previously, of an assessment of fecal continence symptoms, anal manometry, and endoanal ultrasound combined with pudendal nerve evaluation, if indicated. The examination should optimally take place in an obstetric setting because it provides the patient with an opportunity to discuss not only her current continence status but also the antecedent circumstances surrounding her anal injury. The results of the anal physiology investigations facilitate the planning of further treatment and provide invaluable insights into prognosis.

Symptomatic Therapy

Minor postnatal fecal incontinence symptoms such as intermittent fecal urgency or constipation are frequently transient in nature and can often be effectively managed using loperamide or ispaghula, respectively. Perineal pain, secondary to discomfort in the sutured tissues, is amenable to targeted local injection of a combination of 2% bupivicaine, hyaluronidase, and methylprednisolone acetate. More significant tenderness and dyspareunia associated with perineal anatomic distortion can be corrected by minor surgical intervention under local or general anesthesia. Associated psychosexual dysfunction responds to early psychotherapeutic counseling initiated before secondary deterioration in sexual interaction has developed.

Postnatal Physiotherapy

Even without active treatment, fecal incontinence symptoms of minor degree are frequently transient and disappear or attenuate within a few months of delivery. Kegel pelvic floor exercises are not effective in alleviating incontinence, but the addition of operant conditioning through biofeedback physiotherapy using an endoanal stimulating probe[98] significantly improves anal sphincter function. Biofeedback therapy is particularly effective in maintaining muscle bulk while healing occurs and neuropathy recovers.

Secondary Anal Sphincter Repair

Persistent symptoms of fecal incontinence lasting for more than 6 months following delivery usually necessitate surgical repair of the damaged anal sphincter muscle. Before considering surgery, it is mandatory to exclude a coexistent neuropathic cause for the symptoms and to confirm pudendal nerve integrity. If severe neuropathy is identified, colostomy diversion or an artificial sphincter procedure may be necessary.

Counseling during Subsequent Pregnancies

The recurrence rate of third-degree tears was 4.4% in a study of 20,111 consecutive deliveries when mediolateral episiotomy was used.[92] Therefore, 95% of women with a previous third-degree tear did not have another third-degree tear. Women who already suffer persistent and debilitating fecal incontinence after childbirth are likely to experience deterioration in their symptoms after further vaginal deliveries.[99] Transient symptoms that do not persist but are associated with abnormally low resting and squeeze manometric

pressures and a large residual anal sphincter defect may recur following further vaginal deliveries. Conversely, the continence of asymptomatic women with relatively normal manometric profiles is not likely to deteriorate, even in the presence of documented anal sphincter scarring on endoanal ultrasound examination. Ultrasound tends to overdiagnose functional deficits in continence[77] but should, nonetheless, be performed, together with anal manometry, when planning the mode of next delivery in women with a history of third- or fourth-degree anal sphincter injury. The risk of anal and fecal incontinence occurring after another delivery seems higher in women who have sustained a fourth-egree tear.[100]

Summary

As a generalization, in the absence of clear evidence of the optimal approach in such women, it is probably best to individualize the management. An empirical approach is suggested in Table 71–4.

In women who have achieved normal continence following primary obstetric anal sphincter injury and repair, further vaginal delivery is a reasonable option. However, elective prelabor cesarean section is advisable to protect the continence mechanism following successful secondary repair of the anal sphincter. The use of prophylactic cesarean delivery in women with asymptomatic ultrasonically identified sphincter defects is not justified by the published evidence.

TABLE 71–4

Proposed Management of Multiparas in Pregnancies after Anal Sphincter Injury

TYPE OF INJURY	INVESTIGATION PROFILE	MANAGEMENT
1. Previous third-degree tear—asymptomatic	Normal manometry and ultrasound	Allow vaginal delivery
2. Previous third-degree tear—symptomatic incontinence	Abnormal manometry and/or ultrasound	Prelabor cesarean section
3. Successful secondary sphincter repair	Normal manometry and ultrasound	Prelabor cesarean section
4. Previous third-degree tear or "occult" injury—asymptomatic	Abnormal manometry and ultrasound	Discuss vaginal or cesarean delivery

FEMALE CIRCUMCISION (FEMALE GENITAL MUTILATION)

The World Health Organization (WHO) defines female genital mutilation (FGM) as including all procedures involving partial or total removal of the external female genitalia or other injury to the female genital organs for cultural, religious, or nontherapeutic reasons.[101] This practice occurs predominantly in Africa, although affected women and girls may present anywhere in the world as immigrants from these countries. Consequently, FGM is now a global concern with human rights organizations devoted to the elimination of this practice and many countries prohibiting it by law. Medical professionals caring for affected women require knowledge and understanding of FGM.[102] Countries in which there is a high prevalence of FGM include Egypt, Sudan, Eritrea, Ethiopia, Djibouti, Somalia, Mali, Senegal, Guinea, and Sierra Leone, and WHO estimates that currently 100 million to 140 million women live with the consequences of this procedure, with a further 2 million girls at risk each year. In 2008, an interagency statement on eliminating female genital mutilation was published.[103] This statement signed by a wider group of United Nations agencies was issued to address concerns about the continuing prevalence of FGM and with the aim of eliminating the practice in one generation. It clearly states that FGM is a violation of human rights and advocates the education and empowerment of women to ensure the elimination of this practice.

There are several forms of FGM that carry differing health implications:

- Type I: partial or total removal of the clitoris and/or prepuce (clitoridectomy).
- Type II: partial or total removal of the clitoris and the labia minora with or without excision of the labia majora (excision).
- Type III: narrowing the vaginal orifice with creation of a covering seal by cutting and appositioning the labia minora and/or the labia majora with or without excision of the clitoris (infibulation).
- Type IV: all other harmful procedures to the female genitalia without any medical purpose, for example, pricking, piercing, incising or scraping, and cauterization.
- The greatest health risks are in women who have undergone infibulation, which accounts for about 15% of cases. FGM is usually performed on women between 5 and 8 years of age and has physical, psychological, and sexual consequences.

General Risks

Immediate risks of the FGM procedure itself when performed by a traditional practitioner using crude instruments and no anesthesia include shock, hemorrhage, sepsis, and death. There are few reliable figures of FGM-related mortality rate. Ulceration of the genitalia and acute urinary retention can also follow, as can transmission of HIV and hepatitis.

Delayed complications include urinary and vaginal infections, large epidermal cysts, abscesses, keloid scarring, obstructed menstruation, urinary incontinence, and coital and psychosexual problems, which may lead to infertility.[104]

Maternal Risks

The incidence of pregnancy complications or maternal deaths related to FGM is unknown. The risks depend on the type of FGM performed; infibulation, in particular, can cause tender introital scarring that precludes adequate prenatal examination, investigation, and treatment. Vaginitis is common, as are urinary tract infections. Miscarriage may be complicated by retention of products in the vagina, leading to sepsis. When labor occurs, assessment of cervical dilation may be difficult or impossible. Urinary retention in labor is common. Dystocia, usually due to soft tissue obstruction in the second stage, can have serious consequences for the mother and fetus if undetected or improperly managed. Vaginal delivery is associated with increased risks of perineal damage and hemorrhage.[105] The increased incidence of postpartum hemorrhage is mainly due to the need for anterior episiotomy or lacerations extending to the urethra, bladder, or rectum. Postpartum pain is also more severe owing to a greater degree of perineal injury. Postnatal wound infections, dehiscence, and fistulas can occur.

Fetal Risks

Stillbirth and neonatal death have been reported with higher frequency in circumcised women, secondary to fetal asphyxia due to prolonged obstructed labor.[106] This sequence is generally confined to women with severe types of FGM.

Management

Prenatal

Sensitive prenatal care is essential. Women may not volunteer that they are affected by FGM, necessitating an increased awareness when treating women originating from countries in which FGM is practiced. Early recognition provides sufficient time for assessment, discussion, and the development of a management plan. The extent of damage, scar tissue, and physical obstruction to vaginal delivery should be clearly documented so that unnecessary repeated examinations can be avoided. Women with a tight introitus, 1 cm or less, have the greatest risk of perineal damage. However, if the urinary meatus can be observed or two fingers can be inserted on digital examination, significant delivery problems are unlikely to ensue. Parous women who have been sutured at a previous delivery are at risk of developing significant scar tissue with subsequent infection and wound problems. Antenatal assessment also provides an opportunity to establish whether the woman would wish introital dilation to allow comfortable intercourse or to undergo a complete reversal of the procedure. Ideally, complete reversal should be avoided during pregnancy or immediately postpartum owing to the greater likelihood of hemorrhage at that time. Optimally, an anterior episiotomy sufficient only to expose the urethra should be performed during the late second stage, but occasionally, this procedure must be performed earlier to allow adequate investigation or treatment during pregnancy, for example, in the case of pain and bleeding in early pregnancy. Antenatally, the health care provider can also educate affected women so as to eliminate the practice of FGM in her offspring.

Labor and Delivery

The diagnosis of labor may be difficult in the presence of a small introitus. In this case, defibulation may need to be performed to allow adequate assessment. In skilled hands, intrapartum defibulation is a safe and effective procedure.[104] This procedure can be done under local anesthesia. If the opening is large enough to permit digital examination, the decision on defibulation can be deferred to the second stage. Extra care is essential in the second stage because the delivery of the fetal head may be obstructed by scar tissue. This can result in fetal asphyxia or severe tearing in the mother, leading to hemorrhage and fistula development. If introital obstruction develops, a timely anterior episiotomy should be performed to the urethra but not beyond because of the risk of hemorrhage.

Following delivery of the placenta, a careful examination of the genital tract is necessary. In particular, the presence of high vaginal lacerations and damage to the anal sphincter, rectum, or bladder should be noted. The sides of the midline anterior incision should be oversewn to secure hemostasis, leaving the urethra exposed. Reinfibulation should not be performed, irrespective of the wishes of the woman, because this will result in further scarring and problems; ideally, this issue will have been discussed prenatally.

Postnatal

Good postnatal analgesia is important because anterior divisions are associated with more pain. Affected women may need education in relation to differences in urination, menstruation, and coital function. A specific postnatal visit should be arranged to assess healing and to discuss sexual activity.

PROCEDURE

DEFIBULATION

1. Locate opening and paint with antiseptic solution.
2. Administer local anesthetic to the introitus if epidural anesthesia is not present.
3. Raise scar tissue from underlying area and incise in midline to expose urethral meatus. Do not incise beyond this.
4. Suture raw edges for hemostasis.

SUMMARY OF MANAGEMENT OPTIONS
Female Genital Mutilation or Circumcision

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Identify women at risk.	—/GPP	—

Assisted Vaginal Delivery*

STEPHEN W. LINDOW and ROBERT HAYASHI

Videos corresponding to this chapter are available online at www.expertconsult.com.

INTRODUCTION

Assisted vaginal delivery (AVD) offers the option of an operative procedure to safely and quickly remove the infant, mother, and obstetrician from a difficult or even hazardous situation. When spontaneous vaginal delivery does not occur within a reasonable time, a successful AVD or operative vaginal delivery trial avoids cesarean section with its attendant uterine scar and implications for a future pregnancy and avoids potential birth asphyxia from prolonged fetal and cord compression. Reviews of delivery statistics show considerable variation in the incidence of AVD, but the range is usually between 10% and 20% of all deliveries.[1] Whether the method employed is the ventouse (vacuum extractor) or obstetric forceps, the operator can expect optimal results only when careful attention is given to the indications, prerequisites, and performance of the procedure.

INDICATIONS

Maternal indications are most commonly those of maternal distress, maternal exhaustion, or undue prolongation of the second stage of labor. Prolongation of the second stage of labor is a relative indication. Many have argued that specific time limits are not needed if monitoring of the fetus shows no evidence of distress and progress is not obviously arrested. However, in cases without regional anesthesia and with reassuring fetal monitoring parameters (e.g., a normal fetal heart rate pattern), it is probably appropriate to consider intervention if the second stage in a nullipara lasts longer than 2 hours (1 hr in a multipara). A further hour is often allowed in the presence of regional anesthesia, provided the mother wishes it and the fetal condition is satisfactory. The increased need for intervention following epidural anesthesia has been well documented.[2,3] This approach conforms to the ACOG (American College of Obstetricians and Gynecologists) guidelines.[4] Less common but more medically significant indications for AVD include cardiopulmonary or vascular conditions in which the stresses of the second stage should be minimized. With vaginal birth after previous cesarean section, decreasing the stress on the uterine scar may be a relative indication, although dehiscence or rupture is rare if the ACOG guidelines are followed. It has been suggested that if use of the ventouse has failed to deliver the infant but the fetal head has been brought down sufficiently, a cautious low or outlet forceps procedure is safe.[5] However, a review of a large series of AVDs in California suggest that there is an increased risk for intracranial injury when two different sequential instrumental deliveries are attempted.[6] Significant bleeding per vaginam is also an indication for a cautious approach to an AVD; whether the source of the bleeding may be maternal or fetal (e.g., placental abruption or vasa previa).

Fetal indications commonly encountered are malpositions of the fetal head, with relative dystocia. The occiput posterior (OP) and occiput transverse (OT) positions occur more frequently with regional anesthesia.[3,7] This may result from disturbance of the tone of the musculature of the pelvic floor impeding spontaneous rotation to the optimal occiput anterior (OA) position. Similarly, the maternal expulsive (bearing down) force may be compromised. Intervention with forceps for protection of the premature infant remains controversial. In the infant weighing below 1500 g, forceps delivery offers no advantage[8] and may in fact be deleterious,[9] owing to an increased incidence of intracranial bleeding. Use of the ventouse carries the same risk; vacuum extraction is probably best avoided at less than 34 weeks. Spontaneous delivery (with a generous episiotomy if delivery is delayed at the perineum or the outlet appears tight) and manual control of the head appear preferable, with abdominal delivery if operative intervention is needed.[9] In the low–birth weight infant (1500–2500 g), AVD is more widely accepted but should be managed with caution and minimal force.[10,11]

Fetal distress is a commonly cited indication. This expression is subject to varied interpretation, which may range from a brief bradycardia to prolonged late decelerations with acidosis. "Presumed fetal jeopardy" may be a preferable term, in conjunction with recording of as precise a description of the situation as possible in order to validate the indication.[4]

Vaginal delivery of the breech is considered by some to be an indication for forceps to the aftercoming head.[12,13] When the management decision is made to deliver vaginally

(see Chapter 63), forceps to the aftercoming head may be considered routinely. The procedure becomes mandatory if the body has delivered and the Mauriceau-Smellie-Veit maneuver has failed. A putative advantage is the avoidance of traction force on the trunk and cervical spine, together with automatic control of the flexion of the fetal head. This may decrease the risk of hyperextension[14] and cervical plexus injuries.[15]

CONTRAINDICATIONS

Lack of engagement (leading bony point at or above the level of the ischial spines) suggests pelvic inlet dystocia and is usually considered an absolute contraindication to AVD. Conditions in which vaginal delivery per se is contraindicated include known pelvic abnormality with fetopelvic disproportion and fetal anomalies if obstructive or subject to damage from vaginal delivery. Certain fetal malpositions, such as a brow presentation or a face presentation in other than chin anterior position, are not suitable cases, nor is the dead fetus with postmortem changes. Inability to diagnose the position of the fetal head accurately or to apply the instrument properly are major contraindications.[1,16,17]

Several factors are relative contraindications. Fetal macrosomia may be such a factor. In general, the higher the head, the greater the difficulty and the need for performance skill. An increased risk of shoulder dystocia with midcavity procedures with macrosomia and an arrest has been reported.[18] The proficiency and experience of the operator are also factors to be considered. Finally, caution should be used with a ventouse procedure on a fetus who has had fetal scalp blood samplings performed because of the possibility of enhanced fetal scalp bleeding.[12]

DEFINITIONS

Significant comparative statistics have always been difficult to collect owing to differences in the classification, initially of forceps, but now of all AVDs. ACOG has proposed a more specific classification,[4,19] which has proved to be of clinical value[20,21] and deserves universal adoption. This classification is given in Table 72–1. It applies equally to vacuum extractor and forceps procedures.[4] To the classification of low forceps, a significant clinical addition would be the observation that on examination, the head must fill the hollow of the sacrum.[22] Station of the head is measured in plus or minus centimeters of distance between the leading bony point of the skull and the ischial spines.

Neonatal results comparable with those of spontaneous delivery can be expected, with procedures categorized as outlet or low with rotation less than 45 degrees.[1,23–27] Mid-pelvic and rotational procedures are generally associated with a higher rate of morbidity than spontaneous delivery.[28] However, when compared more properly with appropriate alternatives of management, namely, manual rotation followed by forceps or ventouse extraction or delivery by cesarean section, results are equivalent.[24,28–32] It is clear that abdominal delivery is associated with a much higher rate of maternal febrile morbidity. The controversy continues; appropriate selection and proficiency in execution of the maneuver remain the unmeasurable variables that often determine the results of trials.

TABLE 72–1

Classification of Forceps Deliveries According to Station and Rotation

TYPE OF PROCEDURE	CLASSIFICATION
Outlet forceps	Scalp is visible at the introitus without separating labia.
	Fetal skull has reached pelvic floor.
	Sagittal suture is in anteroposterior diameter or right or left occiput anterior or posterior position.
	Fetal head is at or on perineum.
	Rotation does not exceed 45 degrees.
Low forceps	Leading point of fetal skull is at station ≥ +2 cm, and not on pelvic floor.
	Rotation ≤ 45 degrees (left or right occiput anterior to occiput anterior, or left or right occiput posterior to occiput posterior).
Midforceps	Rotation > 45 degrees.
	Station above +2 cm but head engaged.
High forceps	Not included in classification.

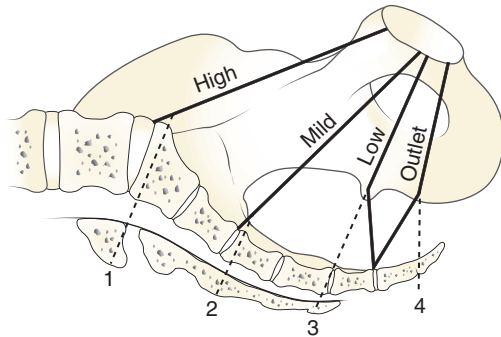
From American College of Obstetricians and Gynecologists (ACOG): Operative vaginal delivery (Technical Bulletin No. 196). Washington, DC, ACOG, 1994.

"Failed forceps" and "failed ventouse" are terms that have a pejorative implication. They can carry the stigma of poor judgment, poor obstetrics, and perhaps negligence in that disproportion was unrecognized. Alternatively, a "trial" (psychologically a better term) of forceps or ventouse connotes a cautious attempt at vaginal delivery with the option of altering management if unusual difficulty is met.[14] A trial of forceps or ventouse is appropriately carried out in an operating theater with immediate recourse to cesarean section if vaginal delivery is not achieved. The procedure deserves greater utilization.[33] A gentle negative trial should not alter outcome.[34,35]

PREREQUISITES

In management of an AVD, certain prerequisites must be met.[4] The head must be engaged (as defined by the biparietal diameter having passed through the plane of the inlet of the pelvis [Fig. 72–1]). Generally, this will have occurred when the leading bony point has reached the ischial spines. It must be remembered that certain conditions may lead to a higher than anticipated level of the biparietal diameter.[22] This is true with molding, particularly with macrosomia. Asynclitism and OP positions are associated with a higher level of the biparietal diameter, as is any extension of the fetal vertex away from a well-flexed position. These factors must always be considered when estimating engagement of the head if the assessment is to be accurate.

The position and attitude of the head must also be known if an accurate and effective application of the chosen instrument is to be made. Should the operator be unable to diagnose the position of the fetal head from the fontanels and suture lines, feeling for the location of an ear can be helpful. This can, however, produce a loss of station and backward rotation of the head due to the necessary displacement of the vertex, which may then mitigate against delivery. The

The obstetric planes of the pelvis and forceps classification: 1, Plane of inlet. 2, Plane of greatest pelvic dimension. 3, Plane of least pelvic dimension. 4, Plane of outlet.
(From Dennen PC [ed]: Forceps Deliveries, 3rd ed. Philadelphia, FA Davis, 1988.)


use of ultrasound (with the transducer placed just above the symphysis pubis) may also help determine fetal head position.

The maternal pelvis should be evaluated for the adequacy of the fetopelvic relationship. Factors such as maternal overweight or diabetes with related fetal macrosomia should be considered. An obvious disproportion contraindicating vaginal delivery must not be present. Clinical evaluation rather than radiographic pelvimetry should be adequate for estimation of the midpelvis and the pelvic outlet.

The bladder should be empty for procedures at other than outlet level. Membranes must be ruptured and the cervix must be fully dilated and retracted, or marked obstruction to rotation and descent of the head will result. There is no place in modern obstetrics for manual or mechanical dilation of the cervix or for cervical incisions to facilitate an operative procedure.[14] The rare exception may be the trapped head in a breech delivery.[36] Appropriate anesthesia is needed for any AVD, although applying the ventouse usually causes less maternal discomfort and the requirement for anesthesia may, therefore, be less. Although outlet and possibly some low-forceps procedures may be performed with local perineal infiltration, a pudendal block is usually more appropriate. For any rotational procedure, a regional block (epidural or spinal) is necessary.[36] In rare circumstances, a general anesthetic may be necessary.[36] In the United Kingdom, it has been suggested to be medicolegally advisable to have an anesthesiologist attend and confirm that adequate analgesia has been produced before proceeding with any but the most urgent operative vaginal delivery. This does not happen in the majority of units.

Although the simplest operations may be undertaken in an informal birthing room setting, most procedures deserve a delivery room/operating theater. Facilities, equipment, and personnel should be adequate for support of patient, infant, and operator in case of any adverse development. A negative trial of AVD should result swiftly in abdominal delivery instead.[4]

Because complications tend to increase in inverse ratio to the technical skill and experience of the operator, physician knowledge of the instruments and the physical forces involved in their use is essential. The operator must know

his or her limitations and be prepared to abandon the procedure in case of difficulty. The use of greater force is the worst of the available options.

COMPLICATIONS AND RISKS

Most of the complications of AVD have also been reported following spontaneous vaginal and even abdominal delivery, but their incidence is greater with AVD. Assessment of causation is frequently problematic because this type of delivery is so often accompanied by other fetal and labor factors that are also associated with birth injury. However, it is obviously difficult for the operator to disclaim responsibility for an injury subsequent to an instrumental delivery. Maternal complications are usually those of soft tissue trauma and tend to be reported more frequently with the use of forceps than with ventouse. They can include uterine, cervical, or vaginal injury, laceration, or hematoma. Bladder or urethral injury may occur, including postpartum urinary retention and late fistula formation. Rectal laceration (with or without episiotomy) and subsequent fistula may occur, as well as later problems in defecation.[1] Increased blood loss is common with more difficult procedures. Maternal injury with use of the ventouse includes inadvertent entrapment of the cervix or vaginal wall between the cup edge and the fetal head with consequent laceration of the maternal periurethral and vaginal tissues. Placement of the cup should never be done carelessly or forcefully.

Fetal complications of forceps delivery include transient facial marks, facial palsies, and fracture of facial bones or skull. Severe cervical cord damage following midforceps rotation has been reported,[37] but such serious trauma is extremely rare. Injury from the ventouse includes minor, and occasionally severe, scalp injury, including scalp bruising, abrasion, laceration, cephalhematoma, subgaleal hematoma, and intracranial hemorrhage. Subgaleal hematomas are thought to be due to disruption of the diploic vessels in the loose subaponeurotic scalp tissue that allows a large volume of bleeding to occur over time.[20] The entire scalp can be elevated. Tentorial tears have been associated with mechanical injury to the fetal cranium and are thought to be related to the shearing forces on the tentorium, resulting in rupture of the deep venous system or laceration of the inferior surface of the cerebellum.[21] Although the pathophysiology is not clearly understood, the vacuum extractor may produce stress on the fetal cranium in the occipital frontal diameter, with tension on the tentorium. The tentorium may then rupture, causing intracranial hemorrhage. Because of these uncommon, but serious, sequelae in infants following a ventouse delivery, all such infants should be carefully observed following birth for any neurologic signs of irritability, drowsiness, tachypnea, seizure activity, or an enlarging head size.[38] Any such signs should be carefully investigated.

Cephalhematoma may be associated with an underlying skull fracture.[39] Fortunately, most documented series of vacuum extractions report no such serious complications. However, neonatal jaundice and retinal hemorrhage are found more frequently with the ventouse.[36] Brachial plexus palsy related to shoulder dystocia and facial nerve palsies are slightly more common after AVD than after spontaneous deliveries.[38,40] Opinions vary on the risk of long-term neurologic damage related to AVD. The subject is under

continuing investigation.[11] Some studies show a relationship between abnormal outcomes and difficult forceps procedures,[28] whereas others fail to confirm such a relationship.[29] It is generally believed that most neurologic deficit is unrelated to incidents occurring at delivery or to substandard intrapartum obstetric care.[41]

RISK MANAGEMENT

In the vast majority of AVDs, the normal outcome gives no reason for complaint. However, in our litigious society, a bad outcome increases the risk of litigation against the operator or hospital, regardless of the cause.

In lawsuits against physicians who chose the option of AVD, the common allegations[42] are inadequate indication, failure to rule out cephalopelvic disproportion, and faulty performance causing fetal injury (this may include incorrect diagnosis of station or position, improper use of instruments, or the use of excessive force). The lack of informed consent is frequently cited. Although strongly urged by attorneys, obtaining fully informed consent is often not feasible in an emergency situation. In such circumstances, the best defense is to be able to demonstrate the need for and appropriateness of the procedure and its performance (in other words, the indications for intervention should be absolute and not relative, and execution of the intervention must be competent). As an absolute minimum, if prior informed signed consent is not obtained, the chart should note a discussion of the procedure with the woman, her partner, and even (if appropriate and there is time) with her family. Physicians in training may be particularly vulnerable to lawsuits unless adequate supervision is present. The "learning curve" excuse is invalid because all patients are entitled to the same standard of care.

In any suit following a bad outcome, regardless of the delivery mode, the operator is forced into a defensive position, attempting to prove that the outcome was due to factors other than the alleged misdeeds. After the fact verbal explanations of usually poorly remembered events may appear to be merely an effort to escape responsibility. Careful documentation is the keystone in the operator's defense. Notes that outline the clinical circumstances, the cognitive steps in choice of options of delivery, and a detailed operative note of maneuvers used are mandatory. Consideration of a cesarean section option, possibly with simultaneous preparations, should be noted, particularly with a midpelvic procedure. Many institutions routinely measure cord gases in all AVDs in order to document the infant's condition at birth. The fear of litigation should not dictate medical practice; AVD remains good medical practice in appropriate circumstances and with appropriate safeguards. Despite this exhortation, however, a survey showed that by 1996, over half of ACOG fellows had already abandoned midcavity AVDs in favor of cesarean section.[43]

Cesarean section at full cervical dilation, however, is not an easy operation. A prospective study of 393 women who underwent operative delivery at full dilation in theater found that a body mass index (BMI) greater than 30, birth weight greater than 4 kg and an OP position all doubled the odds of cesarean section. Women were delivered by immediate cesarean in one quarter (approximately) of cases and by cesarean for failed instrumental delivery in another quarter. Major hemorrhage and extended hospital stay were more common after delivery by cesarean than by the vaginal route.[44] Neonates from cesareans were more likely to need intensive care unit admission but less likely to suffer trauma than those delivered by forceps. One-year follow-up demonstrated that the women delivered by instrumental delivery had more chance of pain stopping intercourse (29% vs. 8%) and urinary incontinence (17% vs. 5%) than those delivered by cesarean.[45]

The complexity of the data make firm conclusions on the relative safety of vaginal versus abdominal delivery difficult, other than to say that the decision to perform an operative vaginal delivery or second-stage cesarean should be undertaken by those with the appropriate level of experience.

CHOICE OF INSTRUMENT AND PROCEDURE

Ventouse/Vacuum

The principal idea of the vacuum extractor is to use a cup device attached by tubing to a pump to create enough negative pressure between the cup and the fetal scalp to allow traction on the scalp, thereby pulling the fetus through the birth canal. Traction is applied during a uterine contraction, resulting in descent of the fetal head by a push-pull effect. Positioning of the cup on the fetal head and the development of a caput succedaneum are important considerations.

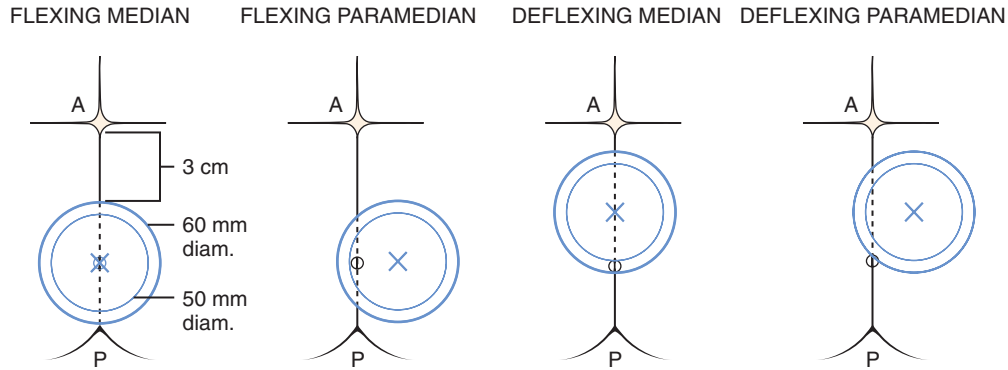
Malström devised a metal cup with rounded edges and an outside diameter of 60 mm, with the vacuum tubing and traction chain coming off the center of the back of the cup dome. By gradual increments of negative pressure, the fetal scalp is sucked into the hollow of the shallow cup to create a caput succedaneum called a "chignon." Placement of the chignon is very important and a major determinant of outcome. If properly placed at the "flexing point" of the fetal head, a point located on the sagittal suture 3 cm in front of the posterior fontanel, traction will result in maximal flexion of a synclitic head (the head is equidistant between the two fetal shoulders).[46,47] Incorrect placement may result in deflexed and asynclitic (tilted to one side) fetal head attitudes and consequent failure of the vacuum extractor technique (Fig. 72–2). Assuming that the length of the sagittal suture is approximately 9 cm at term, when the cup is properly placed on the flexion point, the leading edge of the cup will be about 3 cm away from the anterior fontanel.[47] Proper cup positioning is crucial to move the fetal head from a midpelvic level to the plane of the outlet of the birth canal, and thus, positioning should always be a primary concern when performing a ventouse delivery.

An important modification to the Malström vacuum extractor was designed by Bird.[46] He moved the vacuum hose attachment from the dome to the lateral wall or rim of the cup. This modified cup was to be used specifically for posterior and lateral positions of the occiput. This alteration allowed easier placement of the cup over the flexing point, and its utility has been supported by an observational study in Portsmouth.[48]

Traction force studies have suggested that 22.7 kg (50 lb; 222.5 N) of traction force may be the upper limit of fetal safety for AVDs.[49–51] Duchon and coworkers[52] noted that with a vacuum cup having a diameter of 60 mm, a vacuum of 550 to 600 mm Hg ($0.8 kg/cm^2$) will allow 22 kg of

FIGURE 72–2

Applications of a 50-mm vacuum cup: the "flexing median" application should be used in order to avoid deflexion and asynclitism.

(From Chalmers I, Enkin M, Keirse MJNC [eds]: Effective Care in Pregnancy and Childbirth. Oxford, Oxford University Press, 1989.)


traction force before detachment or "pop-off" occurs. This should be considered the end-point of safety, and inappropriate increases in vacuum should be avoided to minimize fetal morbidity. Repeated detachments of the cup are often associated with scalp injury.

In 1973, Kobayashi introduced a single-unit pliable Silastic cup with a stainless steel valve on the stem that allows for relief of a significant amount of the suction force to the scalp between contractions without loss of application of the cup to the fetal head.[53] The Silastic cup diameter is 65 mm and fits over the fetal occiput like a skull cap. The advantage of this design over the metal cup is that there is less scalp trauma because the cup has no rigid edge and can shape to the fetal head. Also, there is no need to take time to develop a chignon so that traction can be applied shortly after proper application. The disadvantage is that placement of the cup center over the flexing point of the fetal head is not easily done on a nonflexed head in the midpelvic area. Two randomized comparisons of the soft cups with rigid cups have been reported.[54,55] Both found a higher failure rate with the Silastic cup, especially with OP positions. On this basis, use of the Silastic cup should be restricted to easy or outlet procedures. Nevertheless, because of the perceived increased safety and convenience of the soft cup, this device has almost completely replaced the metal cup for use in vacuum extractor deliveries in the United States.

In 1973, a three-component plastic system vacuum extractor composed of a disposable plastic replica of the Malström cup with a flexible handle stem that can be attached to disposable plastic tubing and reusable hand pump was described by Paul and associates[56] from the University of Southern California. They reported favorably on their experience with the device. The cup was 50 mm in diameter and required the development of a chignon as with the rigid cup. The advantage over the rigid cup was the simplicity of assembly because there were fewer parts to fit together. Also, defective tubing and rough edges on the cup were avoided. In later years, the cup was modified to remove the necessity of forming a chignon before traction. The cup diameter was increased to 60 mm and the cup shaped like a teacup (i.e., the dome was deepened). This device is called a Mityvac.

Subsequently, another ventouse device, the Kiwi Complete Delivery System, has been introduced that has incorporated several important aspects of past experience and innovative new ideas. The innovative aspect of this completely disposable system is the use of a hand-pump/traction system directly attached to the vacuum cup that allows the obstetrician to develop the negative pressure by pumping the traction handle while measuring the negative pressure generated via an accurate vacuum indication gauge in the handle. The two vacuum cups available utilize past experience for design. The Kiwi Pro Cup is a soft, flexible, 65-mm diameter cup, similar to the Kobayashi cup that expands to mold to the fetal head in the low OA position. The Kiwi Omni Cup is a rigid, flat plastic cup, 50 mm in diameter, similar to the Malström metal cup. The traction/suction line is anchored in the center of the back of the cup and can flex into a radial recession on the back side of the cup to allow lateral traction as with the Bird modification of the Malström cup. This design facilitates the rotational function of the device for malpositions such as OT or OP. Because of its unique design and convenience for the operator, the Kiwi Complete Delivery System has become popular (Fig. 72–3). Initially, it was claimed to be as successful at achieving delivery as the Bird cup,[57] but two subsequent studies suggested that failure to complete delivery was more common with the Kiwi cup.[58,59] However, a subsequent trial showed no difference in success rates,[60] whereas a study published in 2009 reported that the Kiwi cup was more successful than the Mitysoft device.[61] It appears likely that a major element in the success of any instrument is the training the operators receive and the skill they develop in its use.

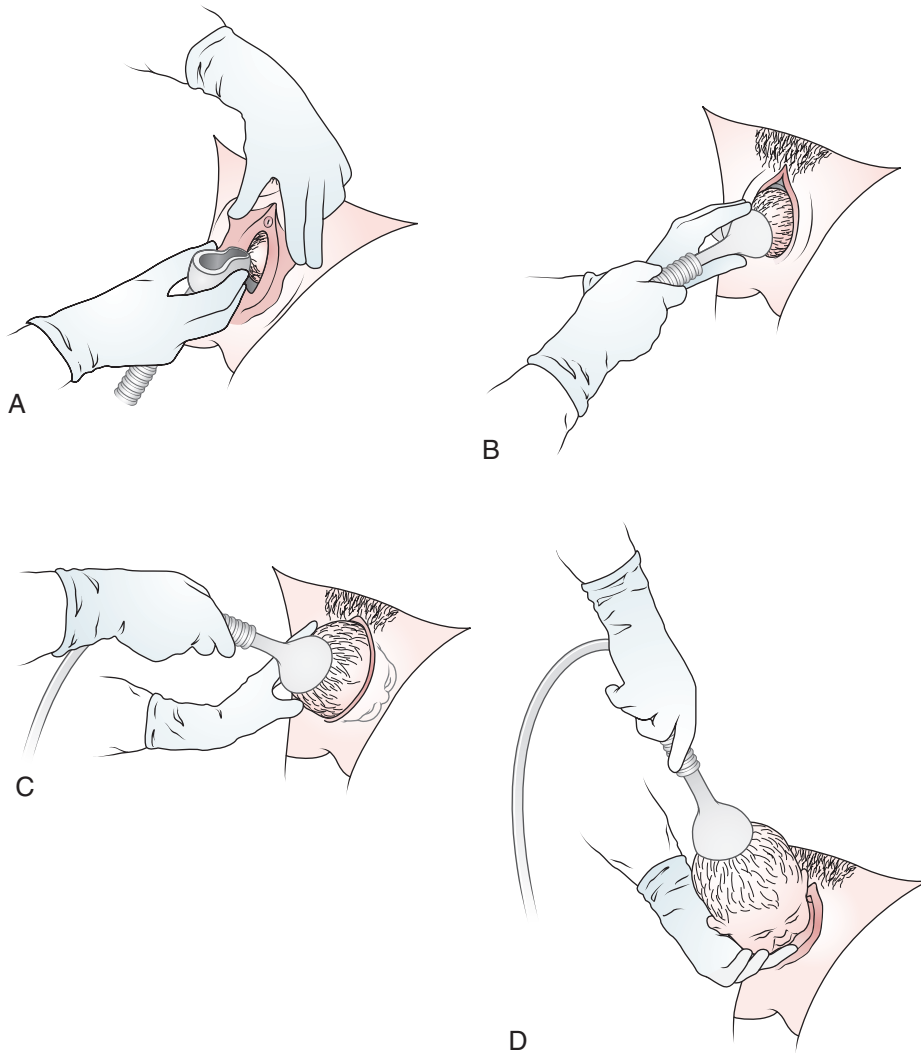
Because maintained vacuum or negative pressure is crucial for effective use of the ventouse extractor and pop-off can result in fetal scalp trauma, properly maintained equipment to provide an airtight seal within the pump and tubing is essential. The equipment should be regularly serviced and defective parts (including smooth-rimmed cups) replaced. The operator should test run the system for air leakage immediately before applying the cup to the fetal head. The elimination of the need for maintenance is a major advantage of the disposable types.


FIGURE 72–3
Delivery with ventouse/vacuum.

PROCEDURE

VENTOUSE DELIVERY

General

After determining that there is a clear indication for a ventouse delivery, the operator should discuss the following issues with the patient or her partner:
- The alternative methods of delivery available.
- The advantages and disadvantages of the vacuum extractor.
- The expected outcome.
- Any possible complications (both minor and serious).

These issues should be recorded in the notes at some time close to the procedure. Ideally, the operator should have a choice of vacuum extractor type, so that they can choose an appropriate instrument for the situation.

Silastic or Plastic Cup

This can be used for a flexed, relatively synclitic fetal head at the pelvic outlet, whereas for a deflexed, asynclitic fetal head, use of the Kiwi cup carries a higher chance of successful delivery. If fetal head malposition, such as OP or OT, causes dystocia, then use of the Bird cup (or Kiwi Omni Cup) would be a good choice. An incorrectly chosen instrument lessens the chance of a successful outcome. Before application of the cup to the fetal head, the operator must check the pump, hose, and cup, fully assembled, for proper and maintained negative pressure when the cup is applied to the palm of a gloved hand.

After the patient has been washed with antiseptic solution and draped in the dorsal lithotomy position for delivery, the operator should empty the urinary bladder and then check the fetal head position and station. Analgesia should preferably be by regional block, placed previously. However, an alternative for deliveries expected to be straightforward is a pudendal block with perineal infiltration of local anesthetic.

The application technique of the cup will differ, depending on whether the cup is metal or soft.

Malström Metal Cup

For the Malström metal cup, povidone-iodine (Betadine) or an antiseptic soap solution is applied to the rim of

the cup and the cup slipped carefully into the vagina. The cup is then positioned over the flexing point of the fetal head with the rim nearest to the anterior fontanel positioned 3 cm from it (see Fig. 72–2). The negative pressure of the system is increased to 0.2 kg/cm^2, and the perimeter of the cup is checked for entrapped cervical or vaginal tissue. Negative pressure is increased by 0.2 kg/cm^2 every 2 minutes to a maximum pressure of 0.8 kg/cm^2 in order to build the chignon. At this point, traction in the axis of the birth canal can be applied during uterine contractions.

By placing a hand in the vagina with the thumb on the cup and the index finger on the fetal scalp, traction force can be monitored in the following manner:

- Gradually increase the traction force until the cup begins to slip away from the fetal scalp, diminish the traction somewhat, and then hold for the remainder of the uterine contraction.
- Release traction between uterine contractions.

The expectation is that the presenting part should descend with each push-pull event and that the head will be delivered within a maximum of five pulls. The fetal heart rate is monitored throughout the procedure with an external fetal heart rate monitor. Once the head is delivered, the suction is disconnected and the cup is removed.

Soft Cup (see Fig. 72–3)

For application of the soft cup, presume a flexed synclitic fetal head position. After applying povidone-iodine or antiseptic soap solution to the cup rim, carefully fold in the edges of the cup to diminish its diameter and then insert into the vagina. Because of the larger overall size of the Silastic cup, periurethral and labial lacerations can occur easily unless extra care is taken. Once on the fetal head, palpate around the edges of the cup to clear any trapped tissues, move the stem of the cup as close to the flexing point near the occiput as possible, and pump the negative pressure to 0.2 kg/cm^2. Make a further check for any tissue under the cup rim, then await a uterine contraction. With the onset of a uterine contraction, increase the negative pressure to 0.8 kg/cm^2 and exert traction, placing the intravaginal hand and fingers as noted previously to monitor the traction force (see Fig. 72–3). After the contraction, trigger the partial release valve mechanism to drop the negative pressure to 0.2 kg/cm^2 between contractions. Expectations for progress are the same as noted previously. The operator using a vacuum extractor must be willing to abandon the technique if obvious progress of descent is not evident with five push-pull events or after several pop-offs. An attempt at forceps delivery at this point is ill-advised.

Forceps

Obstetric forceps in current use may be loosely grouped in two major categories—classic and special. Classic instruments are related to those devised by Sir James Y. Simpson (1848) and by George T. Elliot (1858). Simpson-type forceps are characterized by a spread shank and somewhat longer cephalic curve. Examples of the type are the long and short Simpson, Simpson-Braun, Luikart-Simpson, DeLee, Hawks-Dennen, Neville Barnes, and Wrigley, as well as the DeWees and many obsolescent axis traction instruments. They are preferred by many for their superior traction ability. The Elliot-type forceps are characterized by overlapping shanks and a shorter cephalic curve. Examples of the type include the Elliot, Tucker-MacLane and its Luikart modification, and Bailey-Williamson.

Special instruments include the Piper forceps designed for the aftercoming head in breech delivery, the Kielland forceps for rotational delivery at any station, the Barton forceps for transverse arrest in the flat pelvis, the divergent forceps of Laufe and Zeppelin, the Moolgaoker, the Shute, and other cleverly designed instruments. A key feature of instruments such as Kielland or Moolgaoker forceps is their lack of pelvic curve, which facilitates atraumatic rotation but reduces their effectiveness for axis traction.

The choice of instrument is often influenced by regional as well as personal preferences. For example, the Wrigley and Neville Barnes instruments commonly used in the United Kingdom and Canada are almost unknown in the United States. Some operators prefer to approach most clinical situations with the same instrument, thereby losing the unique clinical advantages of the various available forceps. The larger, more molded head is more accurately contacted by the blades with the longer tapering cephalic curve of a Simpson type, whereas the unmolded head is better accommodated by the shorter, full cephalic curve of an Elliot type.[22,36,62]

With the occiput in an anterior quadrant, any classic instrument with the appropriate cephalic curve may be chosen. Most commonly used for outlet or low forceps are the Wrigley, the Simpson (short or long), or an Elliot type of instrument. For low forceps with rotation greater than 45 degrees, several alternatives are available. Most operators prefer a special instrument for rotation, such as the Kielland, the Moolgaoker, or Shute; however, either an Elliot or a Simpson type of classic forceps may also be used. At midforceps level, the same choices apply, but the need for axis traction becomes more important. In the United Kingdom, it is traditional not to use forceps with a cephalic curve for rotation because of the supposed increased risk of spiral tears of the vagina. For forceps to the aftercoming head, Piper forceps are generally preferred, although the Kielland forceps and even classic forceps have been used effectively.

PROCEDURE

FORCEPS DELIVERY

Position

Numerous texts outline many of the specifics of procedure for forceps delivery. Certain principles given here have universal pertinence to the use of forceps, regardless of the type of instrument chosen. In some areas, the least complicated procedures may be performed with the patient in Sims' lateral recumbent position. For clarity, the use of the lithotomy position (with

wedging under the right buttock to produce some lateral tilt and avoid caval compression and maternal hypotension) is assumed in the following discussion. Once the prerequisites for forceps use have been observed (indication explained to the mother and permission obtained, adequate analgesia ensured, maternal bladder emptied, membranes ruptured, position and station of the head determined), the aspects of application and traction must be considered.

Application (Fig. 72–4)

Application is extremely important to the safe and accurate control of the head as force is transmitted from

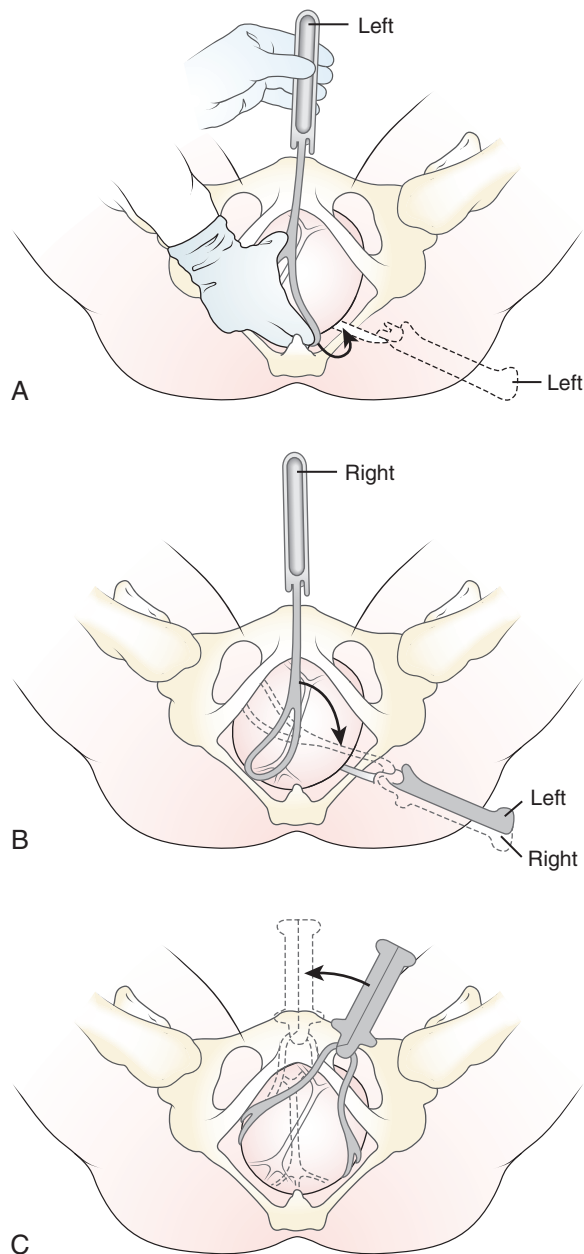
FIGURE 72–4
Forceps application left occiput anterior position.

the operator to the fetal skull via the instrument. To minimize the amount of force required and the potential for trauma, descent of the long axis of the head must be accomplished in the axis of the pelvis. If the landmarks on the head are obscured and the fetal position is unknown, the operator should not use forceps.[16]

In an oblique anterior position of the occiput, first insert the blade of a classic instrument going to the posterior segment of the pelvis.[4] The posterior blade then splints the head, preventing rotation to a less favorable occiput transverse as the anterior blade is wandered into place. With classic instrument applications, hold the left blade in the left hand and apply to the left side of the mother's pelvis and to the left side of the fetal head. These four points of laterality are reversed for the right blade. Exceptions, when a left blade would go to the right side of the head, would include application to an OP position, to an aftercoming head, or with certain special instruments and maneuvers such as the Scanzoni rotation.

To commence insertion, hold the posterior blade vertically, perpendicular to the long axis of the patient. Approximate the cephalic curve of the instrument to the curve of the fetal skull, guided by the fingers of the opposite hand. Gently move the handle in an arc away from the midline toward the thigh, then downward, then back toward the midline. The toe of the blade slides higher on the head to seat over the malar eminence. Repeat this with the anterior blade. The amount of downward component in the arc traversed by the handles is the same for each blade in the case of an OA position. Increasing rotation of the occiput away from OA decreases the downward component of the arc of the posterior blade insertion while increasing the downward arc of the anterior blade insertion. The anterior blade is often more subject to temporary obstruction as it is wandered into the anterior segment of the pelvis. Lock the blades and check the application. Checks for accurate application are as follows[21]:

- The sagittal suture should be perpendicular to the plane of the shanks of the forceps. Any other situation is an asymmetrical application.
- The posterior fontanel should be midway between the blades and one fingerbreadth above the plane of the shanks. Greater distance above the plane of the shanks indicates an extended head, whereas a lesser distance indicates an overflexed attitude. In either case, a less favorable diameter is presented to the pelvic axis and relative resistance to descent results. This applies to all vertex presentations.
- With fenestrated blades, a small but equal amount of fenestration should be felt on each blade. The presence of a large amount of palpable fenestration suggests a short application of the blades on the head, increasing the risk of facial nerve injury and slipping of the blades.

When the checks indicate improper application, readjustment is necessary. Should the sagittal suture be oblique to the plane of the shanks rather than perpendicular, a dangerous brow-mastoid application is present. Unlock the blades, then separately wander them to the correct position. Relock and recheck the


blades. Correction of the flexion attitude is readily accomplished by unlocking and separately shifting the blades to bring the plane of the shanks to one finger-breadth below the posterior fontanel. The presence of more than a fingertip of fenestration is an indication to unlock the blades and separately adjust them higher in the pelvis. These readjustments are all done without removal of the forceps. If proper application cannot be accomplished, remove the forceps, reevaluate the situation, then reapply.

Traction

The ultimate and dominant function of the obstetric forceps is traction to accomplish descent of the head in the birth canal. The pelvic curve, so carefully designed into the instrument, is mechanically effective with the occiput in the anterior position. Increasing rotation of the occiput away from OA decreases the pelvic curve until it is nonexistent in OT. Thus, a correctional rotation of the head to OA should be accomplished either before or with the onset of traction. Rotate the head along its long axis by rotating the handles in a wide arc ending with the occiput at OA. The toes of the blades should describe as small an arc as possible in the upper pelvis.

Compression of the fetal head is an undesirable forceps effect and should be minimized by the use of the finger-guards rather than squeezing the handles during traction. Force applied at the fingerguards is so close to the fulcrum at the adjacent lock that negligible compressive force is applied to the head. The natural compression supplied by the pelvic walls and intervening soft tissues serves to maintain the position of the instrument on the head. Assuming that the clinical situation permits, traction should be timed to coincide with uterine contractions and voluntary expulsive effort by the mother. The operator may be seated or standing, well balanced, using principally shoulder and arm muscles. Traction force should be increased gradually rather than rapidly. Jerking the instrument increases the risk of injury to fetus and mother. Maintain a steady pull and then gradually release as the contraction wanes. The number of pulls and the force required will vary with the case. Delivery should usually be effected by traction with no more than three contractions, employing no more than moderate force. There are two components of traction, both of which must be considered: direction and amount.

The direction of traction must be in the axis of the pelvic curvature, the curve of Carus. This direction alters with the different obstetric planes of the pelvis (see Fig. 72–1). The critical head diameter that must be moved is the biparietal diameter. Effective force must be directed perpendicular to the plane of the pelvis at the level of the biparietal diameter (Fig. 72–5) using an axis traction principle. This is done manually with the Pajot-Saxtorph maneuver with traction outward on the fingerguards and downward on the shanks of the instrument (Fig. 72–6). The resultant vector of force ideally is in the proper direction. This vector must be estimated by the operator and is more difficult with the biparietal diameter at a higher station. The axis traction

Line of axis traction (perpendicular to the plane of the pelvis at which the head is stationed) at different planes of the pelvis: 1, High. 2, Mid. 3, Low. 4, Outlet.

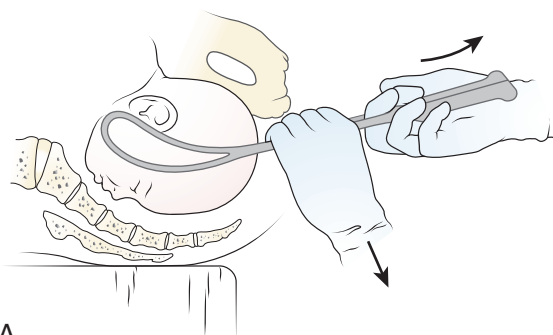

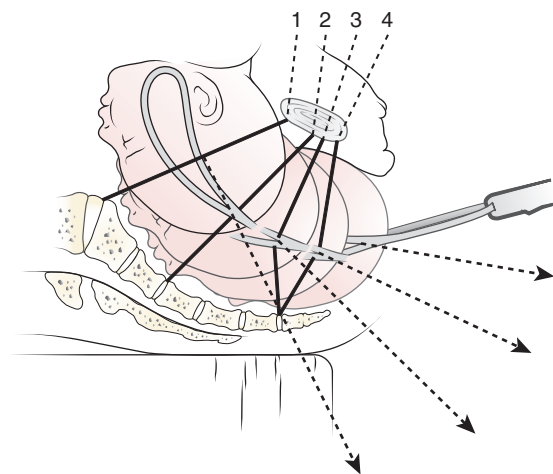

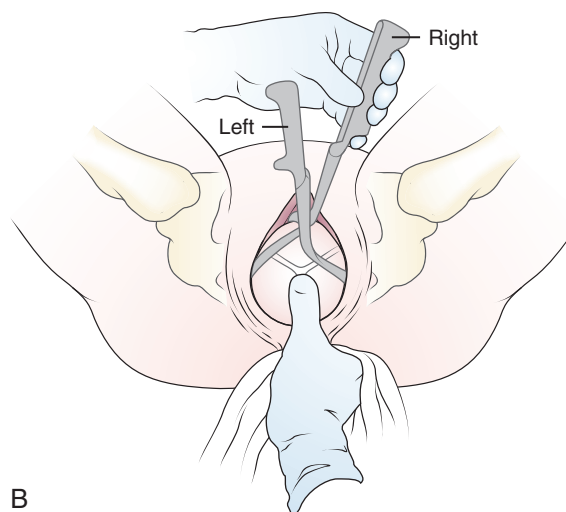

FIGURE 72–6
A, Traction. *B*, Removal of forceps; Ritgen head control.

principle is more easily accomplished instrumentally with an attachment such as the Bill handle, which will fit any classic forceps, or with an axis traction instrument.

As the biparietal diameter descends, the direction of traction and the level of the handles rise. The long axis of the head tends to be held in the axis of the pelvis by maternal structure pressure. With traction and elevation of the handles, observation of the edge of the instrument in relation to the adjacent scalp can show the operator the proper direction of pull. If the instrument is elevated too soon, the scalp appears to sink in relation to the upper edge of the blade. Conversely, late elevation of the instrument results in the scalp rising as the head is forced to extend. As the occiput passes under the symphysis pubis, the handle elevation may reach 45 degrees above the horizontal. Higher elevation of the handles increases the risk of vaginal sulcus tears.

The amount of traction force should always be the least possible to accomplish reasonable descent. Maximum permissible force is 45 lb (20 kg; 196 N) in the nullipara or 30 lb (13 kg; 127.4 N) in the parous woman.[13] Most deliveries are accomplished with considerably less force. The amount of vectored force may be difficult to estimate when using manual axis traction. With a traction attachment, the vectored force is equal to the total traction force exerted.

The routine performance of an episiotomy with an AVD has been advocated for many years but has recently been studied prospectively. U.K. and Irish obstetricians were generally of the view that an episiotomy was a part of the routine care with a forceps delivery but was not always needed with a vacuum delivery. De Leeuw and colleagues[63] performed a retrospective review of the use of episiotomy in Holland and found that there was a reduction in anal sphincter tears when an episiotomy was performed for both forceps and vacuum deliveries. Contrasting data derive from a prospective cohort of 1360 women who were delivered in the United Kingdom by forceps or vacuum, where the performance of an episiotomy did not protect against anal sphincter tears (9.9% with episiotomy and 7.1% without).[64] A randomized trial of routine versus restrictive use of episiotomy at operative vaginal delivery found that the 200 women randomized had different episiotomy rates (88% for vacuum and 95% for forceps in the routine episiotomy group, compared with 17% and 64%, respectively, in the restricted group); however, there was no difference in the rates of anal sphincter damage or any other outcome.[65] It is possible that the technique of episiotomy is the most important protective aspect, and not the decision to perform an episiotomy per se. Midline episiotomy appears to have an increased tendency to extend into a third- or fourth-degree tear compared with a mediolateral episiotomy when retrospective data are reviewed.[1] A randomized, controlled trial of routine midline episiotomy versus restricted use also reported an association between the routine performance of a midline episiotomy and extension into a third-/fourth-degree tear in nulliparous women.[66]

If a mediolateral episiotomy is performed, the angle of the incision relative to the midline is related to the incidence of extension to a third-/fourth-degree tear. Case-control studies involving third-degree tears and women who did not sustain a sphincter injury demonstrated that as the angle of a mediolateral episiotomy increases, the risk of third-degree tears reduces.[67] A third-degree tear was associated with an average angle of 30 degrees and intact sphincters associated with an average angle of 38 degrees. Another study demonstrated that the angle of the episiotomy and not the depth, length, or distance from the anal canal was the critical parameter of the episiotomy incision.[68]

During extension of the head over the perineum, the forceps may be removed and a Ritgen maneuver (delivery of a child's head by pressure on the perineum while controlling the speed of delivery by pressure with the other hand on the head) performed for completion of delivery of the head. The fetal heart rate should be monitored between contractions throughout the procedure.

Should reasonable effort not produce descent of the head, the initial management should be to direct traction force to a lower plane, rather than using more force. If this is not helpful, the blades should be removed and the situation completely reevaluated. The same, or another, instrument may be carefully applied. Abdominal delivery is the appropriate alternative for a second negative trial. A trial of ventouse is not advised following a failed forceps delivery.

MANAGEMENT OF SPECIAL SITUATIONS

Occiput Transverse Position

Although possible with a flat pelvis, spontaneous delivery as an OT rarely occurs; most will rotate to OA or OP. Should timely delivery become necessary with an OT position, or in cases of the relatively common persistent OT and deep transverse arrest, several options are available, with equivalent results for all methods.[69]

PROCEDURE

OCCIPUT TRANSVERSE POSITION

Manual Rotation

Manual rotation (Fig. 72–7) is a method used successfully by some operators. Used alone and followed by spontaneous delivery, there is a significant decrease in the danger of sulcus and vaginal tears.[62] Assuming planned subsequent forceps use, the hand used for rotation depends upon the location of the occiput. Because the left hand would be used to guide the toe of the right forceps blade after manual rotation from a right OT to OA, the left hand is used for rotation from right OT. Conversely, the right hand rotates from left OT. Introduce the fingers into the vagina behind the

FIGURE 72–7
Manual rotation of the head.
posterior parietal bone with the palm upward and the thumb over the anterior parietal bone. Then flex the head, if possible, and rotate toward OA. Fundal pressure fixes the head, and apply the posterior blade of the forceps as the fingers splint the head in its new position. Rotation is usually easiest with the biparietal diameter at the plane of greatest pelvic dimension. Higher displacement of the head, even disengagement, is considered potentially hazardous. Some operators feel that resorting to this alternative is an acceptable risk, with fundal pressure reengaging the rotated head in OA, provided that immediate recourse to abdominal delivery is available.

Classic Forceps

Classic forceps rotation is commonly used in the United States, although accurate application to the head in OT is more difficult to accomplish than in anterior positions. More points of obstruction may be met in wandering the anterior blade. Midforceps rotations are particularly difficult because the pelvic curve of the instrument is not available in the transverse position, and in application, the perineum may obstruct adequate depression of the handle of the anterior blade. The Simpson-type instrument may be used, but the Elliot-type overlapping shanks offer less resistance to rotation and application may be slightly easier.[70]

Initial application of the anterior blade has been advocated.[16] Most prefer application of the posterior blade first. Introduce the blade (left blade in a left OT) directly posterior to the head following the plane of least resistance until the handle is below the horizontal. The handle is lower with increasing height of the head. To compensate for the pelvic curve of the instrument, the handle must deviate laterally away from the midline during insertion so that the toe stays in the midline. Introduce the anterior blade (the right blade in the case of a left OT) as high as possible under the pubic ramus with the handle initially almost vertical. The handle descends through an arc of nearly 180 degrees. Wander the heel of the blade simultaneously upward with pressure from the fingers of the vaginal hand. Lock the blades with the shanks as close as possible to one fingerbreadth medial to the posterior fontanel. Standard checks of application apply. Then

accomplish rotation with rotation of the handles upward through a wide arc consistent with the pelvic curve of the instrument. If obstruction is met, the head may require slight upward displacement so that rotation may be facilitated close to the plane of greatest pelvic dimension. Recheck and readjust the application, if necessary, prior to traction for delivery.

Kielland Forceps

Kielland forceps (Fig. 72–8) are the most popular instrument worldwide for transverse positions of the occiput, although this may be changing with a trend toward using the ventouse, especially in Europe.[71] The construction of the instrument offers a single accurate application for correction of asynclitism, rotation, and extraction, with a semiaxis traction pull. Use of the instrument should yield fetal results equivalent to those of cesarean section for the same clinical situation.[29,31,67] Early studies, which suggested a poor outcome, have since been criticized as indicating that inappropriate selection criteria had been used.[72,73]

The instrument should not be used in a flat pelvis or when short anteroposterior diameters are present. In such cases, rotation is associated with an increased risk of maternal injury.[5] The lack of pelvic curve may also increase the risk of vaginal injury during extension of the head at delivery. Owing to the special characteristics of this instrument, the operator must not use the same approach as with conventional forceps.

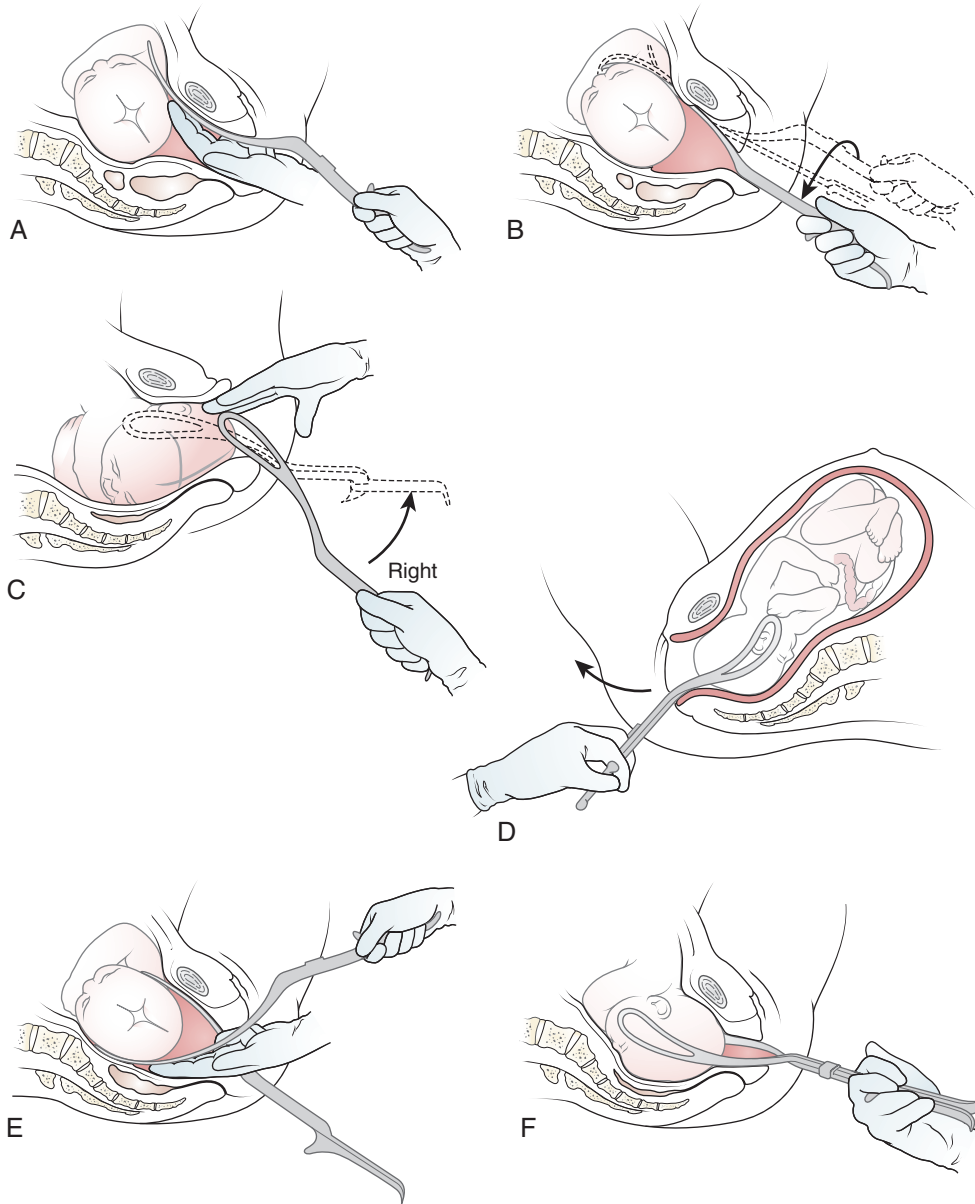
Before application, the bladder should always be emptied and the patient positioned with the buttocks slightly overhanging the edge of the delivery table. Orient the instrument in a position of use with the knobs, or buttons, on the shanks toward the occiput. Always insert the anterior blade first. Four application methods are possible. With a very low station, the blade may be applied directly from below upward. In Kielland's original inversion application (sometimes called the "classic application"), insert the blade in an inverted manner, concavity of the cephalic curve upward, beneath the symphysis and anterior to the head. Carry the toe is carried until the "elbow" of the leading edge of the shank is close to the pubis. At this point, rotate the blade 180 degrees on its own axis in the direction of the button. The blade will then drop onto the head with the cephalic curve applied to the anterior parietal bone. If difficulty is encountered, remove the anterior blade in favor of a wandering application. The third and fourth methods involve wandering over the occiput in case of a flexed head or over the face in case of an extended head. Some operators mistakenly fear the inversion method will tear the lower segment, and routinely use the wandering method. With the anterior blade in place, introduce the posterior blade posterior to the head, with the cephalic curve upward, following the plane of least resistance. Obstruction is frequently met at the sacral promontory. This is overcome with a lateral shift to avoid the obstruction. When in place, engage the instrument's sliding lock with the handles at approximately 45 degrees below the horizontal in a midforceps procedure. The level of the handles depends on the level of the biparietal


FIGURE 72–8
The use of Kielland's forceps with a left occiput transverse position. *A* and *B*, Classic (inversion) method of application of anterior blade. *C*, Direct application of anterior blade to low head. *D*, Wandering application of anterior blade. *E*, Direct application of posterior blade (anterior blade in place). *F*, Traction after rotation to occiput anterior position.

diameter, being higher with a lower head. Any asynclitism is corrected by equalizing the level of the finger-guards. Correction of inadequate flexion is facilitated if the blades are unlocked and separately wandered to one fingerbreadth medial to the posterior fontanel. Then relock and move back toward the midline.

Rotation toward OA position is accomplished, usually with remarkably little effort, by rotating the instrument along its own axis. If resistance is met, try lowering the plane of the handles. Continued resistance may be due to a relative obstruction at that level. First, draw the head downward in transverse position by 1 cm and attempt rotation. If unsuccessful, displace the head to 1 cm above the original station and rotate. Following rotation to OA, recheck the application. Extraction may be performed with the Kielland forceps. The operator must remember that the nearly straight instrument must be pulled in a lower plane below the horizontal

and should not be raised above the horizontal at delivery. Some operators change to another instrument for better traction.

Other Forceps

Barton forceps, with its hinged anterior blade, is another alternative for managing transverse arrest. Its main indication is a flat maternal pelvis, which is a contraindication for the Kielland forceps.[22,62,74] With Barton forceps, bring the head down in the transverse position, then rotate to OA as it traverses the plane of the outlet. The need for this instrument is so infrequent that the reader is referred to a standard text for its use.[14,16]

In the United States and Canada, special instruments (e.g., Mann, Laufe, Shute) have been devised for rotation from OT or from OP. These instruments have regional advocates. Similarly, the Moolgaoker[75] has attracted followers in the United Kingdom and on

the European continent. The ventouse and, of course, cesarean section are also alternate management options.

Occiput Posterior Position

Heads in OP position may eventually spontaneously rotate to OA and deliver. Similar options to those for the OT are available when delivery is required from an OP. Before any procedure is carried out, the operator must know in which direction to rotate the head, if it is not in an oblique posterior position. The recorded position earlier in labor, palpation of the fetal back, or even ultrasonographic location of the back should resolve the question. Obviously, the occiput must be rotated only in the direction of the fetal back.

OCCIPUT POSTERIOR POSITION

Manual Rotation

Manual rotation either with or without subsequent forceps extraction is an option. The technique is similar to that for an OT with rotation being carried up to 180 degrees rather than 90 degrees.

Classic Forceps

Classic forceps rotation from OP is usually performed with the modified Scanzoni maneuver, a double-forceps application method. A single upside-down application from below followed by a 180-degree rotation has been described but is not popular.[62] In the Scanzoni technique, an Elliot-type instrument is preferred.[70] It is applied to the OP head as if it were an OA. In a right OP position, the blades would be applied as if the position were LOA. When the application is checked, the plane of the shanks should be just above the posterior fontanel. The rotation to OA is accomplished with rotation of the handles through a wide arc, ending with the handles pointing downward. The blades are now upside-down with toes pointing posteriorly. Leave one blade as a splint against backward rotation while removing the other downward, then invert and reinsert between the splinting blade and the head. Then remove the splinting blade downward prior to reapplication in standard manner to the vertex, which is now in OA position. An ordinary forceps technique is then used for delivery. Some operators prefer to substitute a better tractor at the reapplication. The use of a solid blade or indented fenestration instrument for rotation prevents insertion of the blade through the fenestration of the vaginal splinting blade.

Kielland Forceps

Kielland forceps rotation is probably the most popular method of rotation of an OP. The previous comments on the instrument (see "OT Management," discussed earlier) apply. Application to an OP differs in that the blades, with buttons toward the occiput, are applied

directly from below the thighs to the appropriate position on the head. Other aspects of technique are not different from those discussed in rotation from OT.

Occiput Posterior Delivery

Delivery from the OP position is an option that is advocated by those who fear that rotational procedures may be traumatic. An indication for delivery without rotation can exist in an anthropoid pelvis with narrow transverse dimensions. Also, with a funnel pelvis, usually android, with the head molded into the outlet under a narrow arch, delivery in OP may be indicated. An OP delivery is relatively traumatic because unfavorable diameters must be brought through the pelvis. The biparietal diameter is usually at a higher station than anticipated. More force is required and the direction of the force is critical. More perineal space is required. An axis traction instrument or at least a Simpson-type instrument should be employed. Applied as in the first step of a Scanzoni, the shanks are depressed against the perineum to get close to the posterior fontanel. The blades are then locked and the application is checked. With traction, after the anterior fontanel clears the symphysis, the head is delivered by flexion rather than by extension.

"AFTERCOMING" HEAD OF A BREECH

Following delivery of the arms and body of the infant, wrap the body in a towel, care of which is placed in the hands of the necessary assistant This serves to keep fetal extremities out of the field, and when excessive elevation of the body is avoided, there is less chance of cervical hyperextension injury.[15] In the controlled breech delivery, the back is upward and the head enters the pelvis within a few degrees of mentum posterior. The position is determined by palpation. Apply the Piper forceps upward from a kneeling position. Apply the left blade first, guided by two fingers of the right hand. Start the handle beneath the patient's right thigh, then sweep downward and medially as the toe passes upward to the right parietal area of the infant. The handle then rests 45 to 50 degrees below the horizontal. Similarly apply the right blade upward from beneath the left thigh. Check the application by palpation of the chin between the shanks of the instrument. Then allow the infant to straddle the instrument, and apply traction in a direction and manner similar to routine forceps use. Vectoring is not needed because the pelvic curve of the instrument gives the instrument axis traction. Routine deliver the head with the forceps in place.

AT CESAREAN SECTION (See Also Chapter 74)

Although cesarean section is not within the purview of AVD, it should be noted that the use of instruments to deliver the head from the uterine incision at cesarean

section[54] can decrease traumatic extension of that incision. Wrigley or short Simpson forceps are often employed. A single vectis blade, to turn and elevate the occiput through the uterine incision, can have the same effect, as can the curved, unhinged blade of the Barton forceps. The Murless instrument, with a single, hinged, locking blade, is more popular in the United Kingdom. It is introduced laterally and slipped beneath the head. When locked in position, it acts as a vectis and elevator to deliver the head.[62] The ventouse has also been advocated for this purpose and is an excellent option.

vacuum technique offers lower rates of maternal trauma such as genital tract lacerations, but higher rates of newborn scalp trauma and cephalhematoma than forceps. Efficacy of the two techniques is fairly equivalent.[76–91]

In a mid-1990s survey of residency training programs in the United States, 210 of 291 identified programs answered a questionnaire about their practice.[74] Forceps are the primary instrument in most programs (68%), but nearly one third of responding centers prefer vacuum extraction. Nearly all the responding programs (199 of 209 [95%]) taught AVD using vacuum, mainly the soft cup vacuum extractor (metallic cups were used in only 14% of centers). Instruction in midpelvic operative vaginal delivery was offered in only 64% of the programs. Deep transverse arrest is handled initially by forceps in half the responding centers, whereas 28% and 22% would proceed with cesarean section or attempt a vacuum extraction, respectively.

Comparison of Ventouse and Forceps

Operative vaginal delivery trials comparing the obstetric forceps with the vacuum extractor have documented that the

SUMMARY OF MANAGEMENT OPTIONS		
Assisted Vaginal Delivery		
Management Options	**Evidence Quality and Recommendation**	**References**
Indications		
Maternal indications include distress, exhaustion, and certain maternal medical disorders (see text).	IV/C	4,86,87
Fetal indications include presumed fetal jeopardy and breech delivery (forceps to aftercoming head).	IV/C	4,86,87
Process indications include malposition (OP, OT, asynclitism) and unsuccessful ventouse procedure (forceps trial with caution and facilities for cesarean section standing by).	IV/C	4,86,87
Comment: Practitioners should be aware that no indication is absolute and must be able to distinguish "standard" from "special" indications.	IV/C	86
Contraindications		
Unengaged head (two fifths or more palpable abdominally or at or above ischial spines vaginally).	IV/C	86
Cervix not fully dilated.		
Inability to define position.		
Malposition (face, brow).		
Suspected or actual cephalopelvic disproportion (pelvic anatomy– or macrosomia-related).		
Certain fetal anomalies.		
Prematurity (? <34 wk for ventouse).		
Repeated scalp pH estimations (ventouse).	III/GPP	89,90
Operator inexperience or lack of training with instrument.	IV/C	86
Prerequisites		
Engaged head (but one fifth palpable abdominally or above +2 station is potentially hazardous).	IV/C	86,87
Fully dilated, membranes ruptured.		
Empty bladder (? not for outlet delivery).		
Known presentation, position, and station.		
Adequate analgesia/anesthesia.		

Management Options	Evidence Quality and Recommendation	References
Experienced operator and adequate support facilities.		
Willingness to abandon procedure if difficult.		
Informed and consenting patient.		
Working, serviced equipment for ventouse and matching blades for forceps.		
OT or OP Options		
Manual rotation/ventouse/rotational forceps.	—/GPP	—
Possible delivery as OP position.	—/GPP	—
Selection by circumstances, individual experience, and preferences rather than scientific guidelines.	IV/C	86
Requires experience and skill.	IV/C	86
Choice of Instrument		
Practitioners should use the most acceptable instrument for individual circumstances.	IV/C	86
Deficient knowledge and incorrect technique contribute to increased complications. Practitioners should be aware of the potential risks and necessary safety measures.	IV/C	86
Vacuum versus Forceps	Ia/A	88
• Vacuum has higher rates of delivery failure, cephalhematomas, retinal hemorrhages, and jaundice.		
• Forceps has higher rates of regional/general anesthesia and maternal trauma.		
• No differences in rates of cesarean section, Apgar scores, long-term (5 yr) maternal and baby follow-up.		
Soft versus Metal Vacuum Cups	Ia/A	91
• Soft cup has higher rates of delivery failure (especially with OP, OT, and difficult OA positions).		
• Metal cup has higher rates of neonatal scalp trauma.		

GPP, good practice point; OA, occiput anterior; OP, occiput posterior; OT, occiput transverse.

Delivery after Previous Cesarean Section

GORDON C. S. SMITH

INTRODUCTION

Rates of primary cesarean section have increased dramatically since the 1980s. Consequently, an increasing proportion of pregnant women attending for care have had a previous cesarean and face the question of mode of delivery. The dictum of "once a cesarean, always a cesarean" largely applied in the United States until the 1980s (although not in the United Kingdom or Europe). However, a series of studies in the 1980s reported the relative safety of attempting vaginal birth following cesarean delivery (VBAC). Rates of VBAC increased in the United States until 1996[1] and then declined following reports of the risks of uterine rupture.[2] Further studies from 2000 onwards have described risks of VBAC that may well increase the trend toward planned repeat cesarean delivery (PRCD). However, the choice between PRCD and VBAC, like almost every other medical choice, involves a balance of risks and benefits, and the balance differs according to the mother's characteristics. Estimating the risks and benefits requires the interpretation of large numbers of studies that are exclusively observational in nature.

The risks of mode of delivery among women with a previous cesarean delivery can be classified at several different levels. First, risks can be divided into maternal risks and risks to the infant. Each can be further divided into short-term and long-term. Some of these outcomes favor VBAC and some favor PRCD. Moreover, the balance depends on factors that are inherently uncertain, such as whether the VBAC attempt will ultimately be successful and the number of future pregnancies the woman will ultimately have. Furthermore, the research question of how to assess the risks and benefits of VBAC is complex owing to the reliance on observational data. Virtually all studies will be open to some form of criticism. However, even studies with obvious weaknesses can still yield useful information if assessed in an unbiased manner. Many parties involved in the debate about VBAC start with strongly held prior beliefs about whether it is a "good" or a "bad" thing. Consequently, there is a tendency in much of the literature for reviews of VBAC to fall into camps of believers and nonbelievers. The reliance on analyses of flawed but partially informative research studies means that biased parties can interpret the literature in a way that confirms their prior belief. The aim of this chapter is to attempt an unbiased summary of the risks and benefits associated with delivery of pregnant women who have previously been delivered by cesarean section.

ASSESSING THE EVIDENCE

It is relatively simple to dismiss all discussion of the evidence behind decisions around VBAC with the term "there is no evidence to demonstrate. …" Theoretically, the ideal method for comparing the relative risk of VBAC and PRCD would be a randomized, controlled trial. In practice, this is unlikely to occur because most women would not accept the choice being made in a randomized fashion. Moreover, many of the events of interest are relatively uncommon, such as uterine rupture, hysterectomy, or perinatal or maternal death. Consequently, it is likely that even if a trial were organized, it would not be sufficiently powered to address the questions of central clinical interest. Assessing the evidence around VBAC highlights some weaknesses in the normal approach to the hierarchy of evidence. All cohort studies are graded at the same level (level III). However, not all cohort studies are equally well designed or conducted. Given the rarity of many of the key outcomes associated with VBAC, many analyses are retrospective and utilize routinely collected data. In practice, in many of these data sources, quite complex diagnoses are coded by nonclinical staff. A key distinction is, for example, between uterine dehiscence and uterine rupture. Many cohort studies have described nonzero rates of uterine rupture for planned cesarean delivery. In reality, it is extremely unlikely that a true uterine rupture would be discovered during a nonemergency, prelabor cesarean section. The nonzero values referred to previously most likely reflect miscoding of uterine dehiscence. A large-scale multicenter study by the National Institute of Child Health and Human Development (NICHHD) Maternal-Fetal Medicine Units Network overcame the shortcomings of retrospective cohort studies by having a prospective cohort design combined with a large sample size and standardized definitions for assessing outcomes and coding performed by clinical staff.[3] This study is significantly more informative than many others that fall into the same "level of evidence." Many other technical issues influence the

validity of different studies employing the same design, and collectively, these mean that the evidence around VBAC cannot be addressed as simply as, for example, the data supporting a new drug treatment. Moreover, attempting to address this complex question using a simplistic approach has the potential to result in drawing misleading conclusions.

ASSESSING ELIGIBILITY FOR VBAC

Perhaps the first approach to a woman with a previous cesarean section who is considering mode of delivery is to determine whether there are any contraindications to VBAC. These can be classified into two groups:

• Contraindications arising from the past history.
• Contraindications arising during the current pregnancy.

The latter includes contraindications to attempting vaginal birth that could affect any woman, such as major placenta previa. A major component of the specific issues around VBAC relates to the previous surgery. Ideally, assessment should involve a review of the operation notes of the previous cesarean delivery, although this is not always possible. Planned VBAC is contraindicated in women with a previous uterine rupture (the risk of recurrent rupture is unknown, but it can be assumed to be high), with previous upper segment vertical classic cesarean section (risk of uterine rupture 2%–9%), and with more than two previous cesarean deliveries (reliable estimate of risks of uterine rupture risk are unknown).[4] However, it is recognized that in certain extreme circumstances (e.g., second-trimester loss, intrauterine fetal death), for some women in the previously discussed groups, the vaginal route (although risky) may be preferred. A number of other variants are associated with an increased risk of uterine rupture, including a prior inverted T or J incision (risk of rupture 1.9%) and prior low vertical incision (risk of rupture 2%).[3] Analysis of the NICHHD study showed that the rate of uterine rupture in VBAC among women with two or more previous cesarean sections was slightly higher (9/975 [0.92%]) than among women with a single previous cesarean section (115/16,915 [0.68%]). However, the 95% confidence intervals (CIs) of the difference in risk extended from –0.36% to +0.85%. Nonetheless, the data do not rule out a small but clinically significant increase in the absolute risk of rupture among women with two previous cesarean births.[5] The rates of hysterectomy (0.6% vs. 0.20%) and blood transfusion (3.2% vs.1.6%) were increased in women with two previous cesarean births. So, although the risks of VBAC following two previous cesarean sections are higher, they are not dramatically so, and therefore, planned VBAC may be considered provided the women have been carefully assessed and counseled. Additional maternal characteristics suggesting caution include obesity, advanced age, no previous vaginal births, and previous cesarean for dystocia.

COUNSELING WOMEN ELIGIBLE FOR VBAC

For some women, the decision to attempt VBAC may already be very definitely planned at their first antenatal visit (based on a combination of maternal preference and lack of obvious contraindications). In such cases, it may be acceptable, following thorough counseling, for such women to have their next formal policy review postdates, to discuss issues around

induction of labor in the event that they do not go into labor spontaneously. In the meantime, they can have routine antenatal care. For all other women, a further policy review at 36 weeks' gestation can be helpful because it permits reconsideration while there is still time for a PRCD to be scheduled. These women should be provided with an information leaflet detailing VBAC and PRCD options in appropriate language. Moreover, there should be a discussion of the possibility that she may attend in preterm labor prior to the scheduled date for review, and the plan for such an event should be documented in her clinical notes.

VBAC and the Risk of Emergency Cesarean Section

One of the key factors that determines the risk of complications when attempting VBAC is the level of likelihood that the attempt will be successful, because the risk of maternal and perinatal morbidity is highest among women who attempt VBAC and end up having an emergency cesarean delivery (see later). Individual studies report successful vaginal birth rates of 72% to 76% for planned VBAC after a single previous cesarean, which concurs with pooled rates derived by systematic and summative reviews. Previous vaginal delivery, particularly previous VBAC, is the single best predictor for successful VBAC. The adjusted likelihood ratio for cesarean associated with a previous vaginal birth is 0.3,[6] and overall, these women have an approximately 85% to 90% planned VBAC success rate.[7] The probability of successful VBAC is not further increased with more than one previous successful VBAC.[8] Women with previous cesarean delivery for multiple pregnancy or fetal malpresentation also have higher than average VBAC success rates.[7,9] Induced labor, no previous vaginal delivery, body mass index greater than 30, and previous cesarean for dystocia are associated with an increased rate of unsuccessful VBAC.[7] If all these factors are present, only 40% of women will deliver vaginally after a trial of VBAC. Other factors associated with failed VBAC include delivery at or after 41 weeks' gestation; birth weight greater than 4000 g (difficult to assess before birth); no epidural anesthesia; previous preterm cesarean delivery; cervical dilation at admission of less than 4 cm; less than 2 years from previous cesarean delivery; advanced maternal age (>35 yr); nonwhite race; short stature; and a male infant.[4] There is limited and conflicting evidence on whether the cervical dilation achieved at the primary cesarean for dystocia impacts on the subsequent VBAC success rate.[4] Several preadmission- and admission-based multivariate models have been developed to predict the likelihood of VBAC success or uterine rupture.[6,10,11] Among women attempting VBAC, the risk of composite morbidity is lowest among those with the highest predicted chance of success.[12]

Short-Term Maternal Risks of VBAC and PRCD

The most obvious risk associated with an attempt at VBAC is scar rupture. This is distinct from uterine dehiscence in that the full thickness of the uterine wall, including the serosa, is breached. However, this accounts for only approximately 10% of short-term morbidity associated with VBAC and has an overall frequency of about 7 per 1000 VBAC

attempts.[3] The risk of this event among women delivered by PRCD is zero.[3] Composite short-term morbidity is higher among women attempting VBAC (5%–6%) compared with women having PRCD (3%–4%), and this is not wholly explained by variation in the risk of uterine rupture. Women undergoing planned VBAC are at greater risk (compared with PRCD) of requiring blood transfusion (1.7% vs. 1%) and experiencing endometritis (2.9% vs. 1.8%).[3] The increased risk of morbidity overall among women attempting VBAC is due to higher rates among women who attempt VBAC and are unsuccessful (the morbidity associated with an emergency CS is substantially higher than after a PRCD). The NICHHD study showed that unsuccessful planned VBAC compared with successful VBAC is associated with an increased risk of uterine rupture (2.31% vs. 1.1%), uterine dehiscence (2.1% vs. 0.145%), hysterectomy (0.46% vs. 0.145%), transfusion (3.19% vs. 1.16%), and endometritis (7.67% vs. 1.16%).[3] Similar trends were identified in a retrospective study from a Canadian dataset.[13] However, there was no statistically significant difference between planned VBAC and PRCD groups in relation to hysterectomy (0.23% vs. 0.3%), thromboembolic disease (0.04% vs. 0.06%), or maternal death (17/100,000 vs. 44/100,000), although the rarity of these events makes meaningful comparison of the groups very difficult. Anesthetic procedure-related complications are extremely rare.[14] Of the women undergoing cesarean section (emergency and elective) in the NICHHD study ($N = 37,142$), 93% received a regional anesthetic and only 3% of regional procedures failed. There was 1 maternal death (2.7/100,000) attributed to an anesthetic problem (failed intubation).[15] The vast majority of cases of maternal death in women with prior cesarean section arise owing to complications other than uterine rupture, including thromboembolism, amniotic fluid embolism, preeclampsia, and surgical complications. Maternal death due to uterine rupture in planned VBAC occurs in less than 1 in 100,000 cases in the developed world, and this estimate is based on analysis of single cases.[13,16]

Multivariate analysis of the Maternal-Fetal Medicine Unit (MFMU) network study demonstrated two independent associations between maternal characteristics and the risk of uterine rupture.[8] Any previous vaginal birth was associated with a reduced risk of rupture (odds ratio [OR] 0.44, 95% CI 0.27–0.71), whereas induction of labor (all methods) was associated with an increased risk of rupture (OR 1.73, 95% CI 1.11–2.69). The protective effect of a previous successful VBAC appears to be the same irrespective of the number of previous successful VBACs.[8] Interestingly, when a large population of women attempting VBAC were divided into quintiles of the predicted probability of having an emergency cesarean delivery, women in the highest quintile of risk had a fourfold risk of uterine rupture compared with women in the lowest quintile of predicted risk.[6] Hence, the maternal characteristics associated with an increased chance of success are also associated with a lower risk of uterine rupture. In summary, the risk facing a woman choosing a VBAC is polarized into a lower risk than that of PRCD if she is successful in achieving vaginal birth, and a significantly higher risk if she is unsuccessful and needs a repeat cesarean section as an emergency. Because mode of delivery cannot be predicted with certainty, the consequences of choosing to attempt VBAC are inherently more unpredictable than choosing PRCD.

Long-Term Maternal Risks of VBAC and PRCD

As the number of repeat cesarean sections increases, the following morbidity becomes more common: placenta accreta; injury to bladder, bowel or ureter; ileus; the need for postoperative ventilation; intensive care unit admission; hysterectomy; blood transfusion requiring 4 or more units; and the duration of operative time and hospital stay.[17–21] In the NICHHD study of 30,132 prelabor cesarean sections, among women undergoing their first, second, third, fourth, fifth, sixth or more repeat cesarean deliveries, the incidence of placenta accreta was 0.24%, 0.31%, 0.57%, 2.13%, 2.33%, and 6.74%, respectively; and the incidence of hysterectomy was 0.65%, 0.42%, 0.90%, 2.41%, 3.49%, and 8.99%.[21] In the same analysis, among 723 women with placenta previa, the risk for placenta accreta was 3%, 11%, 40%, 61%, and 67% for first, second, third, fourth, and fifth or more repeat cesarean deliveries, respectively. A retrospective study of approximately 3000 women from Saudi Arabia showed a linear increase in the risk of bladder injury (0.3%, 0.8%, 2.4%), hysterectomy (0.1%, 0.7%, 1.2%), and transfusion requirement (7.2%, 7.9%, 14.1%) with a history of two, three, and five cesarean sections, respectively.[19] Consequently, the major long-term risk of PRCD to the mother is to increase the risk of complications in future pregnancies. Hence, knowledge of the woman's intended number of future pregnancies may be an important factor to consider during the decision-making process for either planned VBAC or PRCD.

Perinatal Risks of VBAC and PRCD

Hypoxic Ischemic Encephalopathy

The incidence of intrapartum hypoxic ischemic encephalopathy (HIE) at term is significantly greater in planned VBAC (7.8/10,000) compared with PRCD (zero rate).[3] Approximately half of the increased risk in planned VBAC arises owing to the additional risk of HIE caused by uterine rupture. Severe neonatal metabolic acidosis (pH < 7.00) occurred in 33% of term uterine ruptures.[3] There is no information comparing long-term outcome, such as cerebral palsy, associated with VBAC and PRCD. However, given that cerebral palsy following birth at term is rare (~10/10,000) and only 10% of cases of cerebral palsy are thought to be related to intrapartum events,[22] appropriate analysis of this question would require a study involving hundreds of thousands of women. No adequately powered study has been reported to date.

Perinatal Death

In the NICHHD study,[3] perinatal mortality at term was significantly greater among women having a planned VBAC than PRCD: 3.2 per 1000 for planned VBAC vs. 1.3 per 1000 for PRCD (relative risk [RR] VBAC 2.40, 95% CI 1.43–4.01) and the RR was similar after removing deaths due to fetal anomaly: 2.4 per 1000 vs. 0.93 per 1000, respectively (RR 2.52, 95% CI 1.37–4.62). The increased risk of perinatal mortality is largely attributable to a statistically significantly increased risk of antepartum stillbirth beyond 37 weeks in planned VBAC compared with PRCD (1.96/1000 vs.

0.8/1000; RR 2.45, 95% CI 1.27–4.72) in infants without fetal malformation. Approximately 43% of such stillbirths among women who planned VBAC were at or after 39 weeks' gestation (~0.9/1000 women delivering at or after 39 weeks), and may have been prevented by PRCD at 39 weeks. The absolute risk of antepartum stillbirth at or after 39 weeks among women with one prior cesarean section was similar in an analysis of nationally collected data from Scotland (1.06/1000).[23]

In the NICHHD study,[3] rates of delivery-related perinatal death were 0.4 per 1000 for planned VBAC and 0.14 per 1000 for PRCD. A report of data for the whole of Scotland demonstrated higher overall rates of delivery-related perinatal death associated with attempted VBAC of 1.29 per 1000, whereas the risk of death associated with PRCD was comparable with the U.S. study at 0.11 per 1000.[24] The reason for the higher rate of delivery-related deaths among women attempting VBAC in Scotland may reflect the fact that these were population-based data whereas the U.S. data were exclusively from tertiary centers. Consistent with this interpretation, a further study of data from Scotland demonstrated a lower risk of perinatal death due to uterine rupture in larger centers.[25]

Accepting the limitations of using these observational data, a reasonable summary is that planned VBAC is associated with a 1 per 1000 risk of antepartum stillbirth beyond 39 weeks and a 0.4 per 1000 risk of delivery related perinatal death (if conducted in a large center). It is likely that these risks can be reduced by PRCD at the start of the 39th week, but direct evidence to support this is lacking. It may be helpful to emphasize to women that the absolute risks of delivery-related perinatal death associated with VBAC are comparable with the risks for nulliparous women.[24]

Respiratory Morbidity

Three observational studies, pooling data from around 90,000 deliveries, have shown an increased risk of neonatal respiratory morbidity (transient tachypnea [TTN] or respiratory distress syndrome [RDS]) among term infants delivered by elective cesarean (3.5%–3.7%) compared with vaginal delivery (0.5%–1.4%).[26–28] The NICHHD study[3] reported that the incidence of TTN following PRCD was 3.6% and following planned VBAC was 2.6% (RR 1.40, 95% CI 1.23–1.59; number need to harm with PRCD = 98).[3] Evidence from a series of observational studies[26–29] and a trial[30] has shown a beneficial effect on reducing respiratory morbidity by delaying elective cesarean section to at least 39 weeks. The trial reported respiratory morbidity was 11.4%, 6.2%, and 1.5% at 37, 38, and 39 weeks' gestation, respectively.[30] Thus, delaying delivery by 1 week from 38 to 39 weeks enables around a 5 per 100 (1/20) reduction in the incidence of respiratory morbidity, but this delay may be associated with a 5 per 10,000 (1/2000) increase in the risk of antepartum stillbirth.[23] Furthermore, the trial evaluated the effect of prophylactic antenatal maternal administration of betamethasone on the risk respiratory morbidity (TTN or RDS) among infants delivered by planned cesarean delivery. The rate was 2.4% among infants exposed to antenatal glucocorticoid and 5.1% among the controls (RR 0.46, 95% CI 0.23–0.93). The protective effect of steroids was still apparent when confined to births at 39 weeks (0.6% vs. 1.5%,

respectively).[30] However, there is no information on the long-term effects on the offspring of giving high doses of synthetic glucocorticoids at such late gestations, and so this is not currently routine practice.

Injury at the Time of Cesarean Section

Fetal injury affects approximately 1% of infants born by cesarean section, and over two thirds of these are skin lacerations.[31] The overall risk of injury was somewhat lower among women having a PRCD (0.5%) and was highest in women who had a cesarean delivery following an unsuccessful attempt at operative vaginal delivery (~7%). Other risk factors for fetal injury were any nonstandard uterine incision and a short interval from skin incision to delivery.[31]

VBAC in Special Circumstances

Preterm

A retrospective cohort study found that women attempting VBAC who went into labor prior to term (<37 wk) had higher success rates (82%) than women attempting VBAC at term (74%). There was also a nonsignificant trend toward reduced rates of uterine rupture.[32] However, the NICHHD study[3] found that VBAC success rates were similar for preterm and term pregnancies (72.8% vs. 73.3%, respectively). This study did, however, confirm lower rates of uterine rupture (0.34% vs. 0.74%, respectively) and dehiscence (0.26% vs. 0.67%, respectively) among women attempting VBAC preterm compared with term.[33] Thromboembolic disease, coagulopathy, and transfusion were more common in women undergoing preterm than term VBAC, although the overall risk of composite morbidity was less than 3% in the preterm VBAC group. Perinatal outcomes were similar with preterm VBAC and preterm PRCD.[33] Interestingly, the risk of uterine rupture seems to be increased among women attempting VBAC in whom the previous cesarean section was performed preterm.[34]

Twins

The NICHHD study[9] (N = 186 twins), a U.S. retrospective cohort study[35] (N = 535 twins), and a review[36] (7 studies, N = 233 twins) have reported successful rates of VBAC in twin pregnancies similar to those in singleton pregnancies (65%–84%). However, a population-based study reported a lower VBAC success rate (45%) but a comparable risk of uterine rupture (0.9%).[37]

Suspected Fetal Macrosomia

A number of studies have reported significantly decreased likelihood of successful trial of VBAC for pregnancies with infants weighing 4000 g or more (55%–67%) compared with smaller infants (75%–83%).[7,36] The risk of uterine rupture was reported in one of the retrospective studies to be increased only in those who did not have previous vaginal delivery (RR 2.3; P < .001).[38] A subgroup analysis of the NICHHD study[39] showed that among women with previous cesarean delivery for dystocia, those whose second infant was larger than the first had an increased risk of failed VBAC. However, in reality, birth weight is only ever established retrospectively, and antenatal prediction of birth weight using ultrasound is associated with substantial errors in a

large proportion of cases.[40] There are no reliable data on the extent to which antenatal estimation of fetal weight predicts the outcome of a VBAC attempt.

Short Interpregnancy Interval

Three observational studies of limited size[41–43] have shown a two- to threefold increased risk of uterine scar rupture for women with short interpregnancy or interdelivery intervals (<12–24 mo, respectively) from their previous cesarean

section. In the NICHHD study,[7] women undergoing planned VBAC whose previous cesarean delivery was within 2 years of their labor had an increased risk of cesarean delivery compared with women whose labor was more than 2 years from their previous cesarean (32% vs. 25%, respectively). Although this information is useful antenatally, it should also be shared with women postnatally to enable them to plan their preferred spacing intervals for subsequent pregnancies.

SUMMARY OF MANAGEMENT OPTIONS
Delivery after Cesarean Section
Decisions Regarding Mode of Delivery

Management Options	Evidence Quality and Recommendation	References
The evidence that forms the basis of informed discussion of VBAC vs. PRCD is based on observational studies only, with the potential for bias.		
Overall, women attempting VBAC have 50% greater morbidity, although this depends on the background risk of failure.	III/B	3
Absolute risk of maternal morbidity: • Highest with failed VBAC—14.1%. • Intermediate with PRCD—3.6%. • Lowest with successful VBAC—2.4%.	III/B	3
Women with higher predicted chance of successful VBAC have less morbidity.	III/B	12,23,25
The major risks of VBAC are • Overall risk of uterine rupture risk is ~0.7% with VBAC compared with 0% risk with PRCD. • Risk of hypoxic ischemic encephalopathy is 7.8/1000 (~50% associated with uterine rupture) compared with 0 risk with PRCD. • General risks associated with vaginal birth, such as intrapartum asphyxia and perineal trauma. • Risk of antepartum stillbirth while awaiting onset of labor is ~1.0/1000. • Risk of intrapartum stillbirth or neonatal death of is ~0.4/1000 (risk of may be higher in low-throughput obstetric units).	III/B	12,23,25
The major risks of PRCD are • Increased risk of neonatal respiratory morbidity: 3.6% in PRCD vs. 2.6% in attempted VBAC, usually mild (transient tachypnea of the newborn), although can be severe (respiratory distress syndrome or primary pulmonary hypertension).	III/B	3
• Injury to the infant (~0.5%), principally skin laceration.	III/B	31
• Rare but serious complications in future pregnancies, particularly among women having 5 or more repeat cesareans (absolute risks: hysterectomy 3%–7%, placenta accreta 2%–7%, bladder injury 2.4%, and blood transfusion 14%).	III/B	3,19

SUMMARY OF MANAGEMENT OPTIONS
Delivery after Cesarean Section
Decisions Regarding Mode of Delivery—cont'd

Management Options	Evidence Quality and Recommendation	References
Successful VBAC is more likely with	III/B	3,6–11
• Breech or fetal distress as indication for original CS (rather than poor progress).		
• Previous vaginal delivery (85%–90% success rate).		
• Spontaneous onset of labor.		
• Normal or low body mass index.		
• Delivery before 41 wk gestational age.		
• Normal or tall stature.		
• Female infant.		
• No diabetes.		
• Lower birth weight.		
• Normal progress in labor.		
Uterine rupture more likely with	III/B	3,25,38,41–43
• Non–low transverse previous incision.		
• No previous vaginal birth.		
• Shorter interpregnancy interval.		
• Higher birth weight.		
• Induction of labor with prostaglandin.		
The decision to attempt VBAC is complex, requires careful counseling. Factors that may favor an attempt at VBAC include	—/GPP	
• Strong maternal motivation to achieve a vaginal birth.		
• Less concern about rare but serious adverse outcomes (see above).		
• Presence of factors that are associated with a higher likelihood of successful VBAC (particularly previous vaginal birth).		
• Plans for multiple future pregnancies, or capacity for many future pregnancies (e.g., younger mother).		

CS, cesarean section; GPP, good practice point; PRCD, planned repeat cesarean delivery; VBAC, vaginal birth after cesarean.

CONDUCT OF VBAC

Location

A retrospective study of data from Canada demonstrated that the RR of uterine rupture when comparing planned VBAC with PRCD increased twofold in low-volume obstetric units (<500 births/yr) compared with high-volume (>500 births/yr) units, even though lower-volume units had a lower-risk obstetric population.[13] A retrospective study of data from Scotland demonstrated that planned VBAC in low-volume hospitals (<3000 births/year) was not associated with an increased risk of uterine rupture overall but was associated with an increased risk of uterine rupture that led

to perinatal death.[25] It is likely that the availability of resources for immediate delivery and neonatal resuscitation may reduce the risk of infant morbidity and mortality due to uterine rupture. Hence, these observations provide a rationale for the continuous availability of obstetric, midwifery, anesthetic, operating theater, neonatal, and hematologic support during a VBAC attempt.

Analgesia and Anesthesia

Concerns that epidural analgesia might mask the signs and symptoms associated with uterine rupture were based on a

single case report[44] and VBAC is not, now, regarded as even a relative contraindication for epidural analgesia.[14] In the NICHHD study,[7] planned VBAC success rates were higher among women receiving epidural analgesia than among those not receiving epidural analgesia (73.4% vs. 50.4%). The authors suggested that this difference may relate to the disproportionate use of spinal anesthesia in planned short VBAC labors or opting for nonepidural analgesia in cases with non-reassuring fetal well-being.

Fetal Heart Rate and Contraction Monitoring

An abnormal fetal heart rate pattern is the most consistent finding in uterine rupture and is present in 55% to 87% of cases.[45] Moreover, continuous electronic fetal monitoring is generally used among women during planned VBAC, and therefore, the estimates of risk of both lethal and nonlethal perinatal asphyxia associated with VBAC are in this context. The RRs and absolute risks of severe adverse events in the absence of continuous electronic fetal monitoring are unknown. Statements to the effect that "there is no direct evidence to support the use of electronic fetal monitoring" are potentially misleading. The statement relates to an absence of randomized, controlled trial data rather than the presence of high-quality information from which to draw a negative conclusion.

Observational studies, with varying methodology and case mix, have shown intrauterine pressure catheters may not always be reliable and are unlikely to add significant additional ability to predict uterine rupture over clinical and continuous fetal heart rate surveillance.[46–48] Furthermore, intrauterine catheter insertion may be associated with risk.[49] However, some clinicians may prefer to use intrauterine pressure catheters in special circumstances (e.g., in obese women, when augmenting labor with oxytocin).

Diagnosing Uterine Rupture

Early diagnosis of uterine scar rupture followed by expeditious laparotomy and resuscitation is essential to reduce associated morbidity and mortality in mother and infant. There is no single pathognomic clinical feature that is indicative of uterine rupture, but there are a number of symptoms and signs that should raise the concern that this event may have occurred, including abnormal fetal heart rate patterns; severe abdominal pain, especially if persisting between contractions; acute onset scar tenderness; abnormal vaginal bleeding or hematuria; cessation of previously efficient uterine activity; maternal tachycardia, hypotension, or shock; and loss of station of the presenting part.[50] The diagnosis is ultimately confirmed at emergency cesarean section or postpartum laparotomy or can be diagnosed by examination of the uterine cavity per vaginam (PV) following delivery.

Induction and Augmentation

In the NICHHD study,[3] the risks of uterine rupture were 1.02%, 0.87%, and 0.36% for induced, augmented, and spontaneous labor VBAC, respectively. This compares with an overall risk of uterine rupture of 2 per 10,000 in women with no previous history of uterine surgery.[51] Both augmentation and induction are associated with an increased risk of emergency cesarean section: in the NICHHD study,[7] the rates of cesarean section in women undergoing planned VBAC were 33%, 26%, and 19% for induced, augmented, and spontaneous labor groups, respectively. In the NICHHD study,[3] prostaglandin (PG) induction compared with non-PG induction was associated with a nonsignificantly higher risk of uterine rupture (1.4% vs. 0.89%; $P = .22$).[3] In an analysis of nationally collected data from Scotland, PG induction compared with non-PG induction was associated with a statistically significantly higher uterine rupture risk (0.87% vs. 0.29%) and a higher risk of perinatal death due to uterine rupture (1.12/1000 vs. 0.45/1000).[25] This latter figure compares with an estimated 0.6 per 1000 risk of perinatal death in women induced by PG and with no previous history of uterine surgery.[52] Given these risks, it is important not to exceed the safe recommended limit for PG priming in women with prior cesarean delivery.[4] Moreover, a decision to induce labor using PGs in a women with a previous cesarean should be made only by a senior obstetrician and a maximum dose of PGs should be specified. The woman should be specifically counseled about these increased risks and should ideally sign a consent form to this effect before she is induced.

There is no direct evidence to recommend what is acceptable or unacceptable cervicometric progress in women being augmented with a previous cesarean section.[53–57] Among women with no previous history of uterine surgery, it is suggested that there is unlikely to be a higher vaginal delivery rate if augmentation continues beyond 6 to 8 hours.[58] Awareness of the increased risk of uterine rupture in women with a previous cesarean justifies adopting a more conservative threshold to the upper limit of augmentation in women with prior cesarean delivery. A small-sized, retrospective, case-control study suggested that early recognition and intervention for labor dystocia (specifically, not exceeding 2 hr of static cervicometric progress) may have prevented a proportion of uterine ruptures among women attempting VBAC.[57] Hence, although augmentation is not absolutely contraindicated, it should be implemented only following careful obstetric assessment and maternal counseling, and the decision should be made by a senior obstetrician. Moreover, oxytocin augmentation should be titrated such that contractions should not exceed a maximum rate of four in 10 minutes, and careful, serial and regular cervical assessments, preferably by the same person, should be carried out. Augmentation should only continue in the presence of adequate rates of cervical dilation (>0.5 cm/hr).

When counseling women for induction (PG or non-PG methods) and/or augmentation, clear information should be provided on all potential risks and benefits of such a decision and how this may affect her long-term health. For example, women who are contemplating many future pregnancies may be prepared to accept the short-term additional risks associated with induction and/or augmentation of labor in view of the reduced risk of serious complications in future pregnancies if they have a successful VBAC.

SUMMARY OF MANAGEMENT OPTIONS
Conduct of Trial of Labor

Management Options	Evidence Quality and Recommendation	References
Attempt at VBAC should be conducted only in a setting with resident obstetric/anesthetic/neonatal staff and access to full laboratory support.	III/B	25
The issue of intravenous access and cross-matching of blood are controversial.	—/GPP	
Conduct critical review of progress of labor.	—/GPP	
Judicious use of oxytocin is acceptable but should be discontinued if response to uterine stimulation does not occur promptly, and vigilance for uterine hyperstimulation should be maintained.	III/B	53–58
Continuously monitor fetal heart rate.	—/GPP	
Routine insertion of intrauterine pressure catheter is of no proven benefit.	III/B	46–48
Regional anesthesia is not contraindicated.	IV/C	14
Digital palpation/examination of scar is not routinely indicated.	III/B	4

INTRODUCTION

Of the profound alterations in the practice of obstetrics over the past century, one of the most apparent has been the progressive increase in the frequency of cesarean delivery. Sporadically reported throughout medical history, cesarean birth has, only during the last century, been technically refined and rendered safe for both mother and fetus. The safety of the lower uterine segment technique, the evolution of anesthetic proficiency, the availability of blood products and antibiotics, the broadening of indications for the operation, the recognition of the fetus as a patient, the feasibility of vaginal delivery following cesarean section, and the acceptance of this procedure by women have characterized the evolution of cesarean birth in the 20th and 21st centuries. These factors have all contributed to the rise in the incidence of cesarean birth over the past 50 years. The early 21st century has seen further evolution of cesarean birth as an issue of choice for women as a preferred mode of delivery, producing intense polarization of both medical and lay opinion.[1–7] In addition, the secondary rise in repeat cesarean delivery has been associated with an increase in severe complications of cesarean birth, particularly complications of placentation.[8,9] Placenta accreta and its subtypes have been reported with increasing frequency in association with repeat cesarean birth.[10,11] Such abnormalities of placentation clearly have great potential to increase maternal morbidity for repeat cesarean birth.

INCIDENCE

During the 1970s and early 1980s, the cesarean delivery rate progressively increased throughout the world, more dramatically in some countries than in others. Since the 1990s and beyond, most countries have seen a progressive increase in cesarean birth and there is no evidence to suggest this trend is declining. In this, the first decade of the 21st century, women are four times more likely to have a cesarean birth than 30 years ago.[12] The reasons for this increase in cesarean birth are multifactorial, and include the increasing number of women with a prior cesarean delivery, the increase in multifetal gestations, the use of intrapartum electronic fetal monitoring, changes in obstetric training, medicolegal concerns, alterations in parental and societal expectations of pregnancy outcome, and maternal autonomy in decision-making regarding delivery mode.

In 1984, cesarean delivery became the number one in-hospital operative procedure in the United States, accounting for 21% of all live births,[13] and this situation has not subsequently altered. By 2006, the U.S. cesarean birth rate climbed to 31.1%, a 50% increase over the previous decade.[14] Advocacy for vaginal birth after cesarean (VBAC) in the late 1980s and 1990s was probably associated with a temporary lessening of the incidence in the United States, and in 1996, the cesarean delivery rate was 20.5%.[15] However, increasing concerns about the potential complications of VBAC[16,17] have reduced some of the early enthusiasm for this technique and the observed decline has been short lived, with the resumption of a progressive increase in the cesarean birth rate. In 2004, the U.S. cesarean delivery rate was 29.1%, and the rate of VBAC fell to 9.2%.[18] For the majority of women who have a cesarean birth, a subsequent vaginal delivery is currently unlikely.

In Europe and the United Kingdom, an increase in cesarean birth has also been evident, but with wide national variation. In a review of cesarean birth in Norway, the cesarean delivery rate had increased sharply from 2.5% in 1972 to 12.8% in 1987 with a slight rise to 13.6% in 1999,[19] and in 2004, it was 15%.[20] This relatively low rate of cesarean delivery in Nordic countries has not been manifest in other areas of Europe, apart from the Netherlands with a 14% incidence.[20] In 1980, the cesarean delivery rate in England was 9%, increasing to 13% in 1992,[21] 21.3% in 2000,[22] and 23% in 2004.[20] Italy has one of the highest cesarean birth rates in the world at 40% in 2005,[20] having risen from 22.5% in 1995.[23] In Australia, there has been a continual increase in the incidence of cesarean birth, with a cesarean delivery rate of 30.8% in 2006.[24] In the author's state of Western Australia, cesarean birth has steadily increased from 15.7% in 1986, to 20.3% in 1995, and to 32.7% in 2007,[24] with no suggestion of a decline or plateau in the incidence. In 2007, the VBAC rate was 12.7% in Western Australia, and the persistent downward trend of VBAC rates appears universal.

The contrary situation exists in sub-Saharan Africa, where very low cesarean birth rates, generally less than 5%, have been reported for many years.[25] This phenomenon most likely represents inadequate access to medical services in economically depressed countries. High maternal and perinatal mortality rates typify many areas of sub-Saharan Africa. In Ethiopia, the cesarean delivery rate was 0.6% in 2000, in Zambia 2% in 2001, in Ghana 4.2% in 2003, in Tanzania

2.2% in 1998, and in Kenya 4.2% in 2003.[26] A publication from Ronsmans and coworkers[26] highlights this socioeconomic inequity for women in developing countries. The very poorest women had the lowest cesarean section rates with large population sections of Africa having rates less than 1%. There was a strong association with cesarean birth rate and socioeconomic status, with cesarean delivery increasing as wealth increased. Paradoxically, while discussions continue about increasing cesarean delivery rates in most First World countries, it is clear that millions of women and their babies in Third World countries are being denied access to life-saving surgery.

INDICATIONS

There are four principal indications for cesarean delivery:
- Dystocia (inadequate labor progress).
- Suspected fetal compromise.
- Malpresentation.
- Prior cesarean birth.

These indications account for more than 70% of cesarean deliveries and are, therefore, the major determining factors of the cesarean birth rate[27] (Table 74–1). Programs designed to alter cesarean delivery rates have tended to focus on modifying these four primary operative indications (e.g., active management of labor protocols, increasing VBAC rates). Several other issues have been correlated with cesarean birth rates, including hospital type and facilities, individual medical practices, health insurance status, women's childbirth attitudes, and medicolegal influences.

Recently, there has been much attention given to maternal request for cesarean birth in the absence of a traditional obstetric indication. Although there are bipartisan views on this contentious issue, several points need to be addressed. First, it is recognized that women must be involved in the management decisions regarding their pregnancy and birth. Women vary greatly in their birth experience desires, and individualization is central to any delivery mode policy. Second, it is now appreciated that much of the increased mortality previously ascribed to cesarean birth did not discriminate between elective procedures and nonelective procedures. In a low risk woman, an elective cesarean section

with appropriate perioperative care has an extremely low mortality risk. Third, there is an increasing amount of knowledge and discussion of the long-term effects of vaginal birth on the female pelvic floor and sexual function. Fourth, although the first cesarean delivery may be uncomplicated, subsequent pregnancies are clearly associated with an increased risk of placenta previa and accreta. Finally, within the specialty of obstetrics are several practitioners who believe cesarean birth to be the most appropriate delivery mode and have published their views widely, whereas others believe it is a major surgical procedure with attendant risks.[1,2,28] In March 2006, the National Institutes of Health (NIH) published an expert opinion consensus paper specifically addressing cesarean delivery on maternal request.[29] The panel of independent experts concluded that the proportion of women who actually request a cesarean delivery in the absence of any recognized indication is difficult to quantify accurately. They noted that there is a dearth of well-conducted studies on the short- and long-term risks and benefits of delivery modes. Indeed, their conclusion was not particularly helpful or illuminating for those in clinical practice seeking guidance: "any decision to perform a cesarean delivery on maternal request should be carefully individualized and consistent with ethical principles." The debate will continue; however, it is clear that obstetric paternalism is giving way to patient autonomy. Education and discussion remain the keystones in obstetric care with continuing research and audit of outcomes essential.

ISSUES IN THE OPERATIVE TECHNIQUE

Cesarean delivery is the most frequent major surgical procedure performed in obstetrics and gynecology. There is, however, wide variation in the surgical techniques used in cesarean birth and the quality of evidence to support the techniques used.[30,31] Randomized, controlled clinical trials (RCTs) are not widely used in the evaluation of surgical procedures, with such therapies usually characterized by observational evidence. This lack of RCTs of surgical interventions has not gone unnoticed.[32] History, personal prestige, commercial competition, surgical equipoise, inadequate funding and infrastructure, inadequate surgeon education in epidemiology, and the presence of emergency or rare conditions are cited as obstacles to the conduct of RCTs in surgery.[32] The particular issue of the "learning curve" is problematic in the conduct of the surgical RCT, because there will inevitably be a bias in favor of the familiar technique and errors are more likely to occur during the acquisition of skills with a new procedure.

A survey of British obstetricians observed a wide range in the techniques for procedures in cesarean delivery.[30] Relative concordance of technique was observed in only a few aspects of cesarean delivery (e.g., double-layer closure of the uterine incision, prophylactic antibiotic use, and Pfannenstiel abdominal entry).[30] There were large variations in the technique of uterine entry, abdominal packing, uterine closure techniques, peritoneal closure, used of subrectus sheath wound drainage, and superficial fat closure. Despite evidence from RCTs, many obstetricians continued to use practices that have been demonstrated to increase morbidity (e.g., 27.6% performed manual removal of the placenta).

TABLE 74–1	
Indications for Cesarean Section	
INDICATIONS	**RATE (%)**
Previous cesarean section	44.2
Dystocia	14.9
Malpresentation	11.6
Suspected fetal compromise	18.2
Others	11.1

Placental disorders
    Multifetal gestations
    Fetal disease
    Maternal medical/physiologic conditions	

Data from Nguyen N, Gee V, Le M: Perinatal Statistics in Western Australia, 2007. Twenty-fifth Annual Report of the Western Australian Midwives' Notification System. Perth, Western Australia Department of Health, December 2008.

Dandolu and colleagues[33] surveyed 400 obstetric and gynecology residents in the United States on some technical aspects of cesarean delivery. The Pfannenstiel incision was used by 77% of respondents in both emergency and elective procedures. Closure of the uterus was conducted with a single-layer technique by 55% and a double-layer closure by 37%. This survey is clinically important because it reviews the practices of junior medical staff who frequently perform cesarean deliveries as an after-hours emergency without the supervision of a more senior practitioner. As with the earlier British survey, this study again demonstrates the disparity between clinical practice profiles and available evidence.

SURGICAL TECHNIQUES

Preoperative Assessment and Preparation

Women should have a medical and anesthetic review prior to the conduct of cesarean section. It is expected as a minimum that a hemoglobin level be available, blood group and antibody screen be performed (with blood readily available in high risk settings), and an infection screen performed for HIV, hepatitis C, and other relevant diseases.[34,35]

There is no apparent benefit from bathing or washing with chlorhexidine, to reduce surgical site infection, prior to moving the patient into the operating room.[36] Three placebo-controlled trials involving 7691 subjects have been performed to assess the efficacy of preoperative bathing with chlorhexidine gluconate in reducing surgical site infections.[37–39] Preoperative bathing/washing with skin antiseptic did not result in a significant reduction in surgical skin infections compared with placebo (relative risk [RR] = 0.91, 95% confidence interval [CI] 0.80–1.04). A further three trials with 1443 subjects compared bathing/washing with chlorhexidine with bar soap, again with no alteration in the risk of surgical site infection (RR 1.02, 95% CI 0.57–1.84).[40–42]

The Abdominal Incision

Preparation of the Patient in the Operating Room

Preoperative positioning with left lateral tilt will minimize maternal inferior vena caval compression, reducing the risk of hypotension and reductions in placental perfusion. A urinary catheter usually remains in situ perioperatively, draining continuously to a closed system. It is often recommended that suprapubic and abdominal hair should be removed as soon before the procedure as possible, on the basis that skin infections may occur if shaving is performed remote from the surgery, owing to the occurrence of grazes during shaving, and theoretically this may increase the incidence of wound infections. However, a Cochrane review of preoperative hair removal practices from a total of 11 randomized trials found no difference in surgical site infections among patients who had hair removed 1 day prior to surgery compared with those that had the hair removed on the day of surgery.[43] In contrast, patients with preoperative hair removal by clipping or depilatory creams had significantly fewer surgical site infections than if they had been shaved with a razor.

Prior to the incision, an antiseptic solution (usually povidone-iodine) is applied to the skin. Iodophor-impregnated adhesive films have been assessed in a small clinical trial,[44] and although not appearing to alter postoperative wound infection rates, this did reduce the skin preparation time, a consideration in emergency situations. Two randomized trials have evaluated the role of vaginal preparation with povidone-iodine in decreasing infectious morbidity postcesarean delivery, both showing no reduction in overall postcesarean febrile morbidity.[45,46] In the study by Reid and associates,[45] the preoperative preparation of the vagina with iodine had no significant impact on infectious morbidity (endometritis, wound infection, or postpartum fever). The second trial also demonstrated no alteration in wound infection or febrile morbidity with the use of vaginal iodine preparation, but a significant decrease in endometritis was observed (14.5% vs. 7.0%, control vs. vaginal iodine preparation, $P = .045$).[46] Neither of these trials was powered to address endometritis as a separate entity, which may explain the disparate results, and further studies are warranted to clarify this issue. Standard plastic adhesive drapes are no more effective than linen drapes in preventing wound infections, and if they become detached at the edge of the wound incision, they may allow the accumulation of fluid, which then contaminates the wound during closure, adversely affecting healing (in one study, it caused a sixfold increase in infection[47]). Thus, if adhesive drapes are used, care should be taken to make sure they remain firmly adherent to the skin during the procedure. Adhesive drapes have become popular when coupled with integral gutters to collect the blood and amniotic fluid shed during the operation, reducing contamination, a consideration of particular importance in areas of high hepatitis B and HIV prevalence.

The Choice of Skin Incision

The choice of the abdominal incision and its closure should be individualized to the characteristics of the woman and the circumstances demanding operative intervention. The massively obese multigravida will require a different operative technique than that used on the unscarred abdomen of a thin primigravida. The ideal incision provides prompt surgical access, adequate exposure, and a secure wound closure.

The transverse suprapubic skin incision is the most common technique used for cesarean delivery in the developed world. The Joel-Cohen incision has been proposed as the quickest method of delivering the fetus compared with the Pfannenstiel or midline vertical abdominal incision.[48–50] The Pfannenstiel incision is a straight horizontal incision about 2 cm above the pubic symphysis with its midportion within the shaved area of the pubis. A Joel-Cohen incision is also a straight horizontal incision, but higher, being about 3 cm below the line joining the anterior superior iliac spines. It can, therefore, be rather longer than the Pfannenstiel incision, and it is easier to pull aside the rectus muscles at this level.

Three RCTs have examined techniques for cesarean section with the procedure for abdominal entry as their primary focus.[51–53] Two of the RCTs have compared the Pfannenstiel and Joel-Cohen incisions for surgical acess.[51,52] Franchi and coworkers[51] evaluated the Pfannenstiel and Joel-Cohen incisions in 310 women with pregnancies beyond 32 weeks gestation. The total operative time was similar

(Pfannenstiel 33 min [range 18–70 min] vs. Joel-Cohen 32 min [range 12–60 min]), although the time taken to deliver the fetus was more rapid with the Joel-Cohen incision (Pfannenstiel 240 sec [range 50–600 sec] vs. Joel-Cohen 90 sec [range 60–600 sec], $P = .05$). There was no significant difference in the incidence of perioperative complications or infant neurodevelopmental outcome at 6 months. The reduction in fetal extraction time did not appear to have a clear maternal-fetal benefit. In addition, the authors of this study commented that the cosmesis of the Joel-Cohen incision (a component of the technique known in toto as the Misgav Ladach method) was inferior to that of the Pfannenstiel incision.

Mathai and colleagues[52] evaluated the Pfannenstiel and Joel-Cohen abdominal entry incisions in 101 women with the primary aim of evaluating analgesic requirements in the first 4 hours postdelivery. There was a significant reduction in the requirement for early postoperative pain relief in those in whom the Joel-Cohen incision was used compared with the Pfannenstiel (45.1% vs. 82%, $P = .0001$; RR 0.55, 95% CI 0.4–0.76). Again, the time to deliver the fetus was less in the Joel-Cohen incision group (mean 3.7 min vs. 5.6 min, Joel-Cohen vs. Pfannenstiel, respectively, $P < .0001$). In this study, the overall operative time from skin incision to closure was 33.1 minutes for the Joel-Cohen approach compared with 44.5 minutes for the Pfannenstiel ($P < .0001$). In addition, there was a significant decrease in postoperative febrile morbidity in those women randomized to the Joel-Cohen incision (6% vs. 24%, Joel-Cohen vs. Pfannenstiel, $P = .01$) and a reduction in the duration of hospitalization postdelivery (mean 4.4 days vs. 5.9 days, $P < .001$). The authors concluded that the Joel-Cohen incision was a more favorable approach to abdominal entry than the Pfannenstiel incision.

A recent Cochrane review of approaches to abdominal incisions for caesarean delivery calculated that use of the Joel-Cohen incision was associated with a 65% reduction in reported postoperative morbidity (RR 0.35, 95% CI 0.14–0.87) compared with the Pfannenstiel incision.[54] This review concluded that the Joel-Cohen incision had several short-term advantages compared with the Pfannenstiel incision, including a lower incidence of pain, requirement for analgesia, and fever; a reduction in blood loss; and a shorter operative time and hospital stay.

A randomized trial published by Giacalone and associates in 2002[53] compared the Pfannenstiel incision with the Maylard muscle-cutting incision in 97 women. There were no significant differences in perioperative morbidity or pain among the two groups.

An earlier trial published in 1987 used a quasi-randomization study design to compare the Maylard transverse muscle-splitting incision with the Pfannenstiel incision in 97 women.[55] In this study, the time to achieve delivery was longer in the Maylard group (10.4 ± 3.1 min vs. 7.6 ± 4.1 min, Maylard vs. Pfannenstiel, respectively, $P < 0.05$). There was no significant difference in febrile morbidity (odds ratio [OR] 0.72, 95% CI 0.22–2.39) or blood loss as estimated by hemoglobin alteration (3.1 ± 0.6 g/L vs. 3.0 ± 0.8 g/L). The Maylard incision was significantly larger than the Pfannenstiel (18.3 ± 4.5 vs. 14 ± 2.1 cm), which, although providing an increased surgical field, may have some cosmetic disadvantages in contemporary elective cesarean birth.

The size of the abdominal incision was a critical factor in the degree of difficulty of delivery, with a significant negative correlation between perceived delivery difficulty and incision size reported. An abdominal incision size of 15 cm or greater was associated with significantly less difficulty in cesarean delivery.

A vertical skin incision was the original approach to enter the peritoneal cavity, although it now has been usurped by the more cosmetic low transverse incision. The skin is usually incised in the midline between the umbilicus and the pubic symphysis, although a paramedian approach may also be used.[56] The incision may be extended cephalad if more surgical access is required. The rectus sheath is opened in the relatively avascular midline, providing access to the peritoneum, which is similarly opened vertically. The main indications for its use are a previous midline vertical incision, obesity, or uncertain operative diagnosis, for example, in trauma to the pregnant abdomen or an intra-abdominal tumor mass. In an observational study in 1976, Haeri,[57] reported no significant difference between the two incisions in terms of operating time (53 min vs. 45 min, transverse vs. vertical incision, respectively), postoperative febrile morbidity (30% vs. 48%), and postcesarean hemoglobin less than 10 g/dL (28% vs. 36%). There was, however, an increase in the incidence of complete wound breakdown in the vertical skin incision group (0% vs. 7%) and total maternal morbidity (OR 0.46, 95% CI 0.25–0.86). In modern practice, mass closure using looped nylon is associated with a very low risk of wound breakdown. This improved method of closure has also reduced the advantage of a paramedian versus a midline incision.

In the massively obese patient, a vertical skin incision with avoidance of the subpanniculus fold may be indicated. The higher wound infection rate in this subpopulation requires modifications of perioperative procedures. Gallup[58] reduced the wound infection rate from 42% to 3% by careful perioperative techniques. If a transverse incision is chosen for the obese patient, it should be away from the subpanniculus fold, and a subcutaneous closure used to reduce dead space and subsequent seroma formation.

The Uterine Incision

The clinical situation prompting the need for abdominal delivery determines the uterine incision to deliver the fetus. The low transverse uterine incision is used in over 90% of cesarean deliveries. This high prevalence is due to its ease of repair, reduced adhesion formation, lower blood loss, and low incidence of dehiscence or rupture in subsequent pregnancies.[59] A previous low transverse uterine incision may render the woman eligible for a trial of labor in a subsequent pregnancy. The disadvantages of the low transverse incision are primarily restricted to situations in which the lower uterine segment is undeveloped. In this circumstance, there is a greater chance of lateral extension into the major uterine vessels, resulting in maternal morbidity from hemorrhage. If the initial incision is inadequate to deliver the fetus, extension of the uterine incision to a J, U, or inverted T incision will be required, creating a more vulnerable scar.

The low vertical incision, also a lower segment incision, may be used in situations in which the transverse incision is inappropriate, predominantly in patients with an underdeveloped lower uterine segment. When used in these

circumstances, there is a lower risk of lateral extension into the uterine vessels. The incision may be extended upward into the body of the uterus if more room is needed. An upper uterine segment extension renders closure more difficult and precludes a subsequent trial of labor. More extensive dissection of the bladder is necessary to keep the vertical incision within the lower uterine segment. If the incision extends downward, it may tear through the cervix into the vagina and possibly the bladder. The low vertical incision may be used if a contraction ring needs to be cut in order to deliver the infant. If the vertical incision is confined to the lower uterine segment, there is a lower probability of dehiscence and/or rupture in a subsequent pregnancy.[59]

Infrequently performed in modern obstetrics, the classic uterine incision is a vertical incision into the upper uterine segment. It is required in circumstances in which exposure of the lower uterine segment is inadequate, in elective cesarean hysterectomy, or in cases of a noncorrectable backdown transverse lie. The incision permits rapid delivery and reduces the risk of bladder injury, because the bladder is not dissected. When an anterior placenta previa is present, an upper segment incision may be used to avoid incising the placenta. However, dissection around the placenta following a lower segment incision can eliminate the need for a classic uterine incision. The many disadvantages of the classic uterine incision result in its limited use in obstetrics today. The incision is more complicated and time-consuming to repair, the incidence of infection is higher, and adhesion formation is common. There is a greater risk of incision rupture during subsequent pregnancies,[59,60] and if rupture occurs, the resultant bleeding is much greater than with the relatively avascular lower segment. The fetus is also more likely to be expelled from the uterus into the peritoneal cavity. For these reasons, most obstetricians consider a vertical upper uterine incision to be a contraindication to a trial of vaginal delivery, committing women to elective repeat cesarean deliveries.

In a review of 19,726 consecutive cesarean deliveries between 1980 and 1998, Patterson and colleagues[61] observed a distribution of uterine incisions of 98.5% low transverse, 1.1% classic, and 0.4% inverted T. Over the period of the study, there was an increase in the incidence of inverted T incisions, from 0.2% to 0.9%. Maternal morbidity—expressed as puerperal infection, blood transfusion, hysterectomy, intensive care unit admission, and maternal death—was significantly higher in classic cesarean delivery than in the low transverse incision. Perinatal morbidity was also increased in classic and inverted T incisions compared with low transverse cesarean, reflecting the preterm birth preponderance with the former incisions.

Considerable variation exists among obstetricians in the surgical technique used in the conduct of a low transverse uterine incision for cesarean birth. In the survey by Tully and coworkers,[30] 54.7% of surgeons used predominantly blunt dissection and 45.7% predominantly sharp dissection to enter the uterine cavity (the latter inevitably carrying a small risk of cutting the baby). Manual removal of the placenta was utilized by 24.7%, and 33.7% routinely closed the parietal peritoneum.

Formal investigation of the creation of the uterine incision consists of four RCTs involving 526 women[62–65] assessing the use of absorbable staples compared with extending the incision manually or with scissors in low transverse uterine cesarean delivery. Stapling techniques had been introduced to decrease blood loss from the incision margins. In a meta-analysis of these trials by the Cochrane collaboration,[66] the stapling technique did not offer any reduction in total operation time (weighted mean difference = − 1.17 min, 95% CI −3.57 to 1.22), although there was a significant increase in the incision to fetal delivery time (0.85 min, 95% CI 0.48–1.23). There was a reduction in intraoperative blood loss with stapling techniques (weighted mean difference = −41.22 mL, 95% CI −50.63 to −31.8). The evidence currently available does not warrant the routine use of stapling techniques in the creation of the lower uterine segment incision, and the incision-to-delivery interval delay could have adverse consequences in some situations. In addition, the cost of the guns and staples is considerable; this will probably limit their wider use.

The comparison of blunt and sharp extension of the uterine incision has been compared in two randomized trials involving 1231 women.[67,68] In the study by Rodriguez and associates,[67] there was no difference in the incidence of unintended uterine incision extension (13.2% vs. 11%, sharp vs. blunt extension, $P = .686$), intraoperative duration, or estimated blood loss between the two techniques. The primary correlate of incision extension was the stage of labor, being significantly greater when cesarean section was performed in the second stage of labor regardless of the uterine incision technique employed. The small sample size of this trial (286 women) does render the conclusion of the study that the techniques are equivalent open to some debate. The larger study of 945 women by Magann and coworkers[68] demonstrated a significantly higher incidence of intraoperative hemorrhage when sharp dissection was used (median blood loss 886 mL vs. 843 mL, $P = .001$), although the difference was small. However, the alteration in hematocrit was greater (6.1% vs. 5.5%, $P = .003$), the incidence of postpartum hemorrhage was greater (13% vs. 9%; RR 1.23, 95% CI 1.03–1.46), and the need for transfusion was higher (2% vs. 0.4%, RR 1.65, 95% CI 1.25–2.21) in the sharp compared with the blunt extension technique. The occurrence of uterine incision extension was significantly greater in the sharp extension group (30.2% vs. 10.7%, $P < .001$). The systematic review of uterine entry techniques demonstrated a significantly lower risk of uterine extension with the blunt uterine entry approach (RR 0.41, 95% CI 0.31–0.54).[69] There was no significant difference in endometritis in either study (RR 0.88, 95% CI 0.72–1.09).

Techniques for delivery of the placenta at cesarean birth have been the subject of several RCTs recently reviewed by the Cochrane collaboration.[70] Manual removal of the placenta is consistently associated with a significant increase in maternal blood loss and postoperative infectious morbidity. Although there was significant trial heterogeneity, the Cochrane systematic review reported manual removal of the placenta to be associated with an RR of 1.64 (95% CI 1.42–1.9) for endometritis compared with the use of cord traction. In addition, blood loss was greater (weighted mean difference 94.42 mL 95% CI 17.19–171.64 mL), duration of hospitalization longer (weighted mean difference 0.39 days, 95% CI 0.17–0.61 days) with manual placental removal. Lasley and colleagues[71] randomized 333 women to manual

or spontaneous placental delivery and observed an increase in wound infection rates (OR 2.33, 95% CI 0.72–8.73) and a strong trend to an increase in endometritis with manual removal (OR 1.85, 95% CI 0.97–3.53). Manual placental removal at cesarean section should, therefore, be performed only when clinically indicated and not as a routine practice. Disappointingly, in the survey by Tully and coworkers,[30] 25.1% of obstetricians routinely employed manual removal of the placenta at cesarean delivery.

Maternal antibiotics to decrease the incidence of postoperative endomyometritis are administered prophylactically in many centers, although there remain a surprising number who do not use the technique[72] despite compelling evidence of its efficacy in trials involving over 10,000 women.[73] Commonly, a single dose of a first- or second-generation cephalosporin is given, although either the addition of metronidazole or the use of ampicillin plus clavulanic acid or sulbactam to cover gram-negative anaerobes is increasing and has been shown to be more effective than ampicillin alone.[74] The Cochrane collaboration meta-analysis of 47 published RCTs of antibiotic prophylaxis regimens[75] demonstrated ampicillin and first-generation cephalosporins to have a similar efficacy in reducing endometritis (OR 1.27, 95% CI 0.84–1.93) with no benefit in using more broad-spectrum agents (ampicillin vs. second- or third-generation cephalosporin OR 0.83, 95% CI 0.54–1.26; first-generation cephalosporin vs. second- or third-generation cephalosporin OR 1.21, 95% CI 0.97–1.51). A multiple-dose regimen for prophylaxis was no more effective than a single-dose regimen (OR 0.92, CI 0.70–1.23). Antibiotic administration is sometimes given on a selective rather than a comprehensive basis (e.g., not given in cases of elective cesarean section without prior rupture of the membranes), although the evidence suggests it is of value in all cases.[76]

Attention has focused recently on the timing of antibiotic administration at cesarean delivery.[77] The prophylactic administration of antibiotics at cesarean delivery has classically been after delivery of the fetus and cord clamping, based on the concept of minimization of fetal exposure to antibiotics. However, evidence from studies in the nonpregnant surgical population demonstrate improved effectiveness if prophylactic antibiotics are administered 30 to 60 minutes prior to surgery to maximize the tissue concentration.[78,79] Although pre-incision administration of antibiotics for cesarean section had been suggested in earlier nonrandomized studies to increase neonatal sepsis investigations without modifying postcesarean infection rates,[80,81] more recent studies of cesarean delivery antibiotic prophylaxis have demonstrated both a statistically and a clinically significant reduction of 50% in postcesarean infection when administered prior to surgery.[82] In addition, there are suggestions that an extended-spectrum antibiotic regimen may be advantageous, especially with agents such as azithromycin.[83] At present, more data are required before a universal alteration in practice is implemented, but the data are swinging toward the use of antibiotic prophylaxis prior to surgical incision to decrease maternal infection after cesarean delivery.[77] Before there is a widespread change in practice, however, it is important that there are studies of the long-term outcome for the baby to ensure that changes in the acquisition of gut flora that may be induced by being born with significant circulating levels of antibiotics do not result

in increases in allergy and infection with more pathogenic organisms.

The uterus may be exteriorized for repair. This procedure is not a necessary routine but does assist visualization and technically facilitates repair of the uterine incision, especially if there have been lateral extensions. The relaxing uterus can be promptly recognized and massage applied, potentially decreasing intraoperative blood loss. Hershey and Quilligan[84] reported lower blood loss in women undergoing exteriorization repair (mean reduction in hematocrit 6.2 ± 0.35 vs. 7.0 ± 0.43, exteriorization vs. intraperitoneal, respectively, $P < .01$), although Magann and associates[85] did not confirm this significant reduction in their trial. No increase in febrile morbidity has been reported with uterine exteriorization.[84,85] The main adverse effect is pain and vagal-induced vomiting with traction on the broad ligament when the woman is awake and the cesarean is being performed under regional analgesia. The incidence of venous air embolism is increased when uterine exteriorization and manual removal of the placenta are performed at cesarean section.[86]

The Cochrane collaboration has provided a review of the six RCTs of uterine exteriorization versus intraperitoneal repair at cesarean delivery.[87] These trials recruited 1221 women.[84,85,88–91] There were no significant differences between the groups except for febrile morbidity and duration of hospital stay. Uterine exteriorization was associated with a reduction in the duration of postcesarean fever (OR 0.40, 95% CI 0.17–0.94), and a nonsignificant trend to fewer infections and gastrointestinal disturbance. No difference in blood loss was found. This review concluded there was insufficient information to make a recommendation on the routine use of uterine exteriorization. A further trial has been recently published with 637 women randomized to exteriorized or in situ uterine repair.[92] There was no significant difference between extra-abdominal and intra-abdominal repair of the uterine incision at cesarean delivery, but the number of sutures used was lower and the surgical time shorter with extra-abdominal repair, although moderate and severe pain at 6 hours was less frequent with in situ uterine repair. Although these results do not support routine exteriorization of the uterus, the fact that it does not significantly increase most measures of morbidity does mean that it is a very reasonable management option if it is necessary to improve visualization of the lower segment to repair an extended incision or to insert uterine compression sutures.

Surgical Closure Techniques

The uterine incision can be closed with one or two layers. Use of a single-layer closure technique reduces operating time without any obvious short-term detrimental effects.[93–96] A small follow-up study from Tucker and coworkers[97] involving 292 women did not demonstrate an increase in uterine scar dehiscence in the single-layer closure compared with the conventional two-layer closure group. However, an observational cohort study from Canada has raised concerns about single-layer closure safety, reporting a fourfold increase in uterine rupture following a single-layer closure compared with a double-layer closure.[98] Gyamfi and colleagues[99] in an small observational series have also reported an apparent increase in uterine rupture during a subsequent labor in women with a single- compared with a double-layer

closure (8.6% vs. 1.3%, $P = .015$). These are not controlled studies, they are skewed in that there are many more women with a double-layer closure than a single, and the reason for the closure type is frequently unknown and subject to potential publication bias—however, they do raise issues for consideration when considering uterine closure. Jelsema and associates,[95] in an observational study of 200 women, compared continuous, nonlocking, single-layer closure with the standard two-layer uterine closure. No differences in the febrile morbidity rates were observed, although there was an increased need for additional hemostatic sutures. The Cochrane review of single- versus two-layer uterine closure from 11 single-center studies noted a reduction in mean blood loss of 70 mL, a reduction in operating time of 7.4 minutes, and a decrease in postoperative pain.[69] In the United Kingdom, however, the vast majority of surgeons (96.3%) use a two-layer uterine closure technique.[30] Given the concerns raised about long-term outcomes following single-layer uterine closure, more data are required before any firm recommendation can be given.

It has been traditional surgical procedure to close the peritoneum. The reasons for peritoneal closure have never been scientifically validated; however, they include restoration of surgical anatomy and a potential reduction in infection, wound dehiscence, and adhesion formation. However, on the contrary, animal experimentation has suggested that adhesion formation may be greater with peritoneal closure owing to foreign body reaction to the suture material.[100,101] No significant short-term differences in postoperative complications have been observed in trials of peritoneal nonclosure in general surgery[102,103] or gynecology.[104,105] The Cochrane review of peritoneal closure included 14 trials involving 2908 women.[106] There was considerable heterogeneity in the quality of the trials reviewed, although the results were consistent across methodologic qualities. Operating time was reduced by a mean of 6.05 minutes if the peritoneum was not closed. There were reductions in postpartum fever, analgesic requirements, and hospital stay in those women randomized to nonclosure of the peritoneum. The reviewers concluded that there was an improvement in short-term morbidity in women in whom peritoneal nonclosure was used, although no long-term data were available. Therefore, the available clinical and nonclinical data appears to support the concept of peritoneal nonclosure at cesarean birth. These data have been reflected in clinical practice with the majority of obstetricians favoring nonclosure of both the pelvic (71.1%) and the parietal (66.2%) peritoneum in Tully and coworkers' survey.[30]

Closure of the subcutaneous tissue has been the subject of several trials and a Cochrane review.[107] Del Valle and coworkers[108] investigated the efficacy of subcutaneous closure in 438 women and concluded that a running closure with absorbable suture such as plain catgut was associated with a lower incidence of superficial wound disruption. A similar RCT conducted in women with more than 2 cm of subcutaneous fat also demonstrated a lower incidence of wound disruption (14.5% vs. 26.6%, $P = .02$), a lower seroma formation rate (6% vs. 19%, $P = .003$), and a trend to lower overt wound infection rate (6.0% vs. 7.8%, not significant) in the women allocated to subcutaneous closure group.[109] The Cochrane review of seven trials involving 2056 women reported a significant reduction in the risk of hematoma and

seroma formation with closure of the subcutaneous fat (RR 0.52, 95% CI 0.33–0.82).[107] In addition, the incidence of overall wound complications, including wound infection, wound separation, and seroma and hematoma formation, was reduced (RR 0.68, 95% CI 0.52–0.88). No long-term outcomes were reported, and there is a need for more data on this aspect of cesarean delivery.

Wound drainage, with drains sited under the rectus sheath or in the subcutaneous tissue, is used to facilitate the removal of blood or serous fluid from the abdominal cavity, with the primary aim of reducing postoperative collections and pelvic infection. Most obstetricians do not use wound drainage routinely; however the survey of Tully and coworkers[30] reported that more than half of practitioners use them when they considered them to be surgically indicated. Typically, closed-suction drainage systems are used in the peritoneal cavity and the loss can be measured in collection bottles. Corrugated drains may be used in the subcutaneous tissues with drainage to a superficial dressing.

There have been several randomized trials comparing wound drainage with no drainage following caesarean delivery, although the study end-points have varied considerably between trials.[110–116] A Cochrane review of these trials concluded that there is no evidence to support the practice of routine wound drainage at cesarean delivery.[117] This meta-analysis could demonstrate no difference in the risk of wound infection (RR 0.91, 95% CI 0.58–1.43), other wound complications (RR 0.87, 95% CI 0.41–1.84), postoperative fever (RR 0.89, 95% CI 0.66–1.20), or endometritis (RR 1.14, 95% CI 0.71–1.82) whether a drain was used or not.

A recent systematic review of published data of prophylactic subcutaneous drainage in women having a cesarean delivery has shown no reduction in wound disruption rates (OR 0.74, 95% CI 0.39–1.42) , infectious morbidity (OR 1.15, 95% CI 0.70–1.90), hematoma formation (OR 1.05, 95% CI 0.33–3.3), or seroma (OR 0.44, 95% CI 0.14–1.43) when compared with women receiving no subcutaneous drainage.[118]

Closure of the skin following a cesarean birth may be achieved with interrupted sutures, staples, or a subcuticular suture, the technique and suture material usually being related predominantly to personal preference. Skin closure with staples is more rapid than other techniques[119] but has been associated with increased wound pain and reduced cosmesis. Skin closure techniques have been the subject of several clinical studies.[120–123] Frishman and colleagues[120] conducted a randomized trial comparing skin closure with subcuticular suture or staples for Pfannenstiel incisions in 66 women. The operating time was less in those women randomized to skin closure with staples. Analgesic use was less in women randomized to the suture group and also a suggestion of improved cosmesis; however, this was a small trial with methodologic problems, limiting the validity of the results. The use of blunt- or sharp-tipped needles demonstrated no difference in the rate of wound infections.[121] The overall incidence of wound infection in this study of 204 women was low and the study underpowered to exclude a small but clinically significant difference. In another small trial of the cosmesis of intracuticular and subcuticular sutures, satisfaction scores were higher for the intracuticular suturing technique at 4 or more months postprocedure.[122]

Conversely, in a randomized study of skin closure techniques, Gaertner and associates[124] reported no significant difference in scar cosmesis and patient satisfaction in 100 women at 4 months postcesarean delivery. Recently, Rousseau and colleagues[123] reported a randomized trial of 101 women with follow-up to 6 weeks postcesarean delivery to evaluate postoperative pain and satisfaction for skin closure with subcuticular sutures of staples. There was a significant reduction in operative time with staples compared with the subcuticular suture group (24.6 min vs. 32.9 min, $P < .001$. At the 6-week review, pain was significantly less in the staple closure group. Despite this lack of consistent data in terms of skin closure techniques, the majority of U.K. obstetricians reported subcuticular skin closure as their routine (73.9%).[30] Given the lack of evidence of major differences between the two techniques, it is probably reasonable to ask women if they have preferences of their own; many of them do (often preferring the subcuticular suture because they have heard that the staples are painful to remove, and they dislike their cosmetic appearance in the immediate postoperative period). In relation to subcuticular sutures, there is a growing trend to use absorbable (poliglecaprone, Monocryl) rather than nonabsorbable (polypropylene, Prolene) sutures, thus obviating any need to have the suture removed.[125] At present, there is insufficient evidence to judge whether the absorbable suture increases the risk of subsequent keloid formation.

Alternative Techniques

Alternative surgical techniques to the traditional surgical approach to cesarean birth have been reported. The Misgav Ladach, Pelosi, and Stark techniques of cesarean section have been the subject of several reports.[49,50,126–128] The Misgav Ladach technique was developed in Israel and involves the Joel-Cohen abdominal incision, single uterine closure, and nonclosure of the visceral and parietal peritoneum. Björklund and coworkers[126] evaluated this technique in Africa in an RCT of 339 women and reported a 20% reduction in blood loss, a 50% reduction in the use of suture material, and a reduction in operating time of 7.3 minutes.

There was no difference in overall postoperative infection rates. Similarly, Darj and Nordstrom[50] observed a reduction in operating time (mean of 13.4 min) and blood loss (mean 160 mL) with the Misgav Ladach compared with the Pfannenstiel technique. The Stark technique, which also involves omission of peritoneal closure and single uterine closure, was associated with a lower febrile morbidity rate (7.7% vs. 19.8%), reduced antibiotic use (33.3% vs. 81.3%), and a lower adhesion incidence in subsequent surgery (6.3% vs. 28.8%) compared with Pfannenstiel incision, double uterine closure, and peritoneal closure in an observational study of 125 women.[129] The Pelosi technique, in which the formation of the bladder flap is eliminated, has been associated with a decrease in operating time, postoperative febrile morbidity, and hospital costs when compared with traditional techniques.[127,128]

It is clear that eliminating operative steps in cesarean delivery reduces the total operating time. It is not clear whether this reduction is translated into other benefits or if the infectious morbidity, pain, and blood loss alterations are real or the effect of small trials with inadequate methodology. It is also clear that large, rigorously designed and conducted clinical trials with assessment of both short- and long-term outcomes are required to adequately address the surgical technique issues in cesarean delivery. In the United Kingdom, this issue is being addressed with the CAESAR Study (caesarean section surgical techniques), an RCT of 3031 women recruited from 47 hospitals throughout the United Kingdom and Italy designed to evaluate three aspects of cesarean section: single- versus double-layer uterine closure, closure versus nonclosure of the pelvic peritoneum, and restricted versus liberal use of rectus sheath drainage. The results of this study are expected soon. In addition, the CORONIS Trial (international study of cesarean section surgical techniques),[130] an international study of cesarean delivery surgical techniques is in progress. This trial, with a planned sample size of 15,000 women, is designed to evaluate surgical interventions such as blunt versus sharp abdominal entry, exteriorization of the uterus for repair, single- versus double-layer uterine closure, and peritoneal closure.

SUMMARY OF MANAGEMENT OPTIONS
Cesarean Section

Management Options	Evidence Quality and Recommendation	References
Preparation		
Hair removal with depilatory creams or with clipping results in fewer surgical infections than shaving.	I/A	43
Vaginal preparation with povidone-iodine does not reduce postcesarean infectious morbidity.	Ib/A	45,46
There is no evidence that adhesive drapes confer benefits over conventional linen drapes.	Ib/A	44
	III/B	47
Cross-match blood with anticipated above-average blood loss (e.g., placenta previa, multiple cesarean sections).	III/B	34,35
Experienced surgeon for anticipated complicated cases (e.g., fibroid uterus, extreme prematurity, placenta previa, multiple cesarean sections).	—/GPP	—

Management Options	Evidence Quality and Recommendation	References
Skin Incision		
Transverse incisions are associated with lower maternal morbidity, including dehiscence, than vertical incisions.	Ib/A	57
Pfannenstiel incisions result in faster operations than Maylard incisions.	IIa/B	54
Joel-Cohen incision is faster than Pfannenstiel incision but cosmetically less acceptable. There are no other differences.	Ib/A	51
Uterine Incision		
Transverse lower uterine incision is associated with less maternal morbidity.	III/B	59,60
Absorbable staples for uterine wound cannot be recommended at present for routine practice.	Ia/A	66
There is no evidence of benefit of blunt versus sharp dissection/extension of uterine incision.	Ib/A	67
Delivery of the Placenta		
Manual removal is associated with increased maternal blood loss and infection.	Ia/A	70
Exteriorization of Uterus		
There is no evidence of increased morbidity associated with exteriorization of the uterus for repair.	Ia/A	88
Closure		
Uterus: A single-layer uterine incision closure is not associated with increased maternal morbidity; but trials are small and no justification for changing practice exists.	Ia/A	31,69
Peritoneum: Closure is not necessary in routine practice.	Ia/A	31,69
Subcutaneous layer: Closure is associated with less superficial wound dehiscence, especially in obese women.	Ib/A	108,109
Subrectus suction drainage: This reduces the rate of wound infection in high risk cases.	Ib/A	117
Skin closure: Skin staples may be superior to subcuticular sutures.	Ia/A	123
Perioperative Measures		
Prophylactic antibiotics are associated with reduced maternal morbidity in emergency cesarean section and with reduced incidence of endometritis in elective cesarean section.	Ia/A	31,69
Antibiotic regimens: Ampicillin and first-generation cephalosporins are equally effective in reducing postoperative endometritis. Single-dose regimens are as effective as repeat doses, with the exception of urinary tract infections.	Ia/A	75
Thromboprophylaxis is recommended for all women undergoing cesarean section.	IV/C	136
Oral intake: There is no justification for withholding early oral intake.	Ia/A	134

GPP, good practice point.

COMPLICATIONS

Cesarean delivery is a major abdominal surgical procedure and is thus subject to the standard complications—medical, anesthetic, and surgical—associated with a laparotomy (Table 74–2). It is beyond the scope of this chapter to deal with all the potential complications that may surround a cesarean birth. However, maternal morbidity and mortality associated with cesarean delivery are increased in women with preexisting medical disorders. The long-term complications of cesarean section are increasingly being recognized, particularly placenta accreta and cesarean scar ectopic pregnancy (see Chapters 73 and 75 for more details on this aspect).

Hemorrhage

Hemorrhage at the time of cesarean delivery may be related to the operative procedure, such as damage to the uterine vessels, or be incidental, such as due to uterine atony or

placenta previa/accreta. The origin of the excess blood loss is generally apparent at the time of surgery and dealt with as is appropriate to the etiology. The management is covered in detail in Chapter 75; only a summary is presented here.

The incidence of placenta accreta is increasing,[10,11,131] and it is second only to uterine atony as an indication for emergency hysterectomy for obstetric hemorrhage. There is an association of placenta accreta with placenta previa and previous cesarean delivery, both of which have been increased by the recent trend toward more liberal indications for cesarean delivery. Clark and associates[10] reported that 25% of women undergoing cesarean for placenta previa in the presence of one or more uterine scars subsequently underwent cesarean hysterectomy for placenta accreta. This risk appears to increase directly with the number of previous uterine incisions. If the placenta is accreta, effective management usually requires total abdominal hysterectomy, although additional options including the use of uterine compression sutures or leaving the placenta in situ have been reported. The uterus, vagina, or broad ligament may be lacerated during a cesarean delivery. Traumatic deliveries or poor delivery technique are associated with an increased frequency of operative lacerations. Lacerations involving uterine tissue are usually sutured without difficulty. Vertical lacerations into the vagina or lateral extensions into the broad ligament may be associated with substantial blood loss and the potential for ureteric damage during their repair. Prior to commencement of the repair of lacerations into the broad ligament, identification of the ureter is frequently necessary. The initial suture must be inserted just distal to the apex of the laceration.

Urinary Tract Injuries

Injuries to the urinary bladder occur with variable incidence during the course of cesarean delivery.[132,133] The Pfannenstiel incision with lower entry into the peritoneal cavity increases the risk of inadvertent cystotomy, especially after prolonged labor in which the bladder is pulled cephalad. Scarring and secondary obliteration of the vesicouterine space following previous cesarean section increase the incidence of trauma secondary to attempts at dissection. The

bladder may also be damaged secondary to a uterine laceration, particularly in association with a low vertical uterine incision.

Various techniques are employed to reduce the incidence of intraoperative bladder injury. Preoperative catheterization of the bladder and peritoneal entry as far cephalad as possible are important. Injuries to the base of the bladder are most frequent during a repeat procedure in which clear tissue planes do not always exist. Careful sharp rather than blunt dissection of the bladder will reduce the occurrence of inadvertent cystotomy as well as reduce blood loss. If there is concern as to possible bladder injury, the abdomen must not be closed until the issue is resolved by transurethral instillation of methylene blue–colored saline with leakage of fluid identifying the cystotomy site. Full-thickness bladder lacerations should be repaired with a two-layer closure with continuous or interrupted 2-0 or 3-0 chromic catgut or polyglycolic acid/polyglactin (Dexon/Vicryl) sutures. The site of the bladder laceration is important because repair of a laceration of the bladder dome and its subsequent repair is usually straightforward. The bladder base is thinner, receives less blood flow, and appears to heal more slowly, whereas occlusion of the ureteric orifice is also a possibility. Fistula formation is not usually a problem if accidental cystotomy is promptly recognized and repaired.

Ureteric injury is one of the most dreaded complications of any pelvic operation. It is, however, an uncommon occurrence at cesarean section. Eisenkop and coworkers[133] reported 7 ureteric injuries in 7527 women undergoing cesarean delivery. In 5, the ureteric injury occurred during an attempt to control hemorrhage from extension of the uterine incision. When controlling hemorrhage, it is useful to apply direct pressure while identifying the course of the ureter to permit accurate suture placement and reduce the potential for ureteral injury.

Postoperative Complications

Respiratory complications remain a primary cause of postoperative morbidity following major surgical procedures. Deep-breathing exercises, incentive spirometry, chest percussion, and postural drainage all have merit, depending on the clinical circumstance.

Gastrointestinal dysfunction is not uncommon after a cesarean delivery and is usually restricted to a transient ileus. The Cochrane review of postoperative feeding assessed six trials to evaluate the effect of early and delayed oral intake after cesarean birth.[134] Although the studies were of variable quality, on the available data, the review concluded there was no justification for withholding early oral intake after cesarean birth. Early oral intake was associated with a reduced time to return of bowel sounds, a reduced postoperative stay, and a trend to a reduction in abdominal distention. Urinary tract infections are a common complication of cesarean section and occur with a variable frequency of 2% to 16%, the rate depending on the duration of catherization and the preoperative health of the woman.[132,135]

Thromboembolic disease during pregnancy is an uncommon event but remains a major cause of maternal morbidity and mortality. Indeed, pulmonary thromboembolism is a leading cause of maternal death in the United Kingdom with a death rate of 1.94 in 100,000 confinements.[136] The highest

incidence in the puerperium is among cesarean patients, particularly if the surgery is performed as a nonelective procedure during labor. Other factors increasing the risk of venous thromboembolism include advanced maternal age, obesity, and inherited thrombophilia disorders. The risk of a deep venous thrombosis after cesarean delivery is three to five times greater than after vaginal delivery.[137] The reactive thrombocytosis after cesarean birth, the impact of which is compounded by anemia, infection, and postpartum hemorrhage, further increases the risk. In 1995, the Royal College of Obstetricians and Gynaecologists[138] published a Working Party Report on prophylaxis against thromboembolism in the United Kingdom. This document drew attention to the risks of thromboembolic disorders after cesarean birth and the need to consider prophylaxis for high risk women. Routine prophylaxis against postoperative deep vein thrombosis now includes the use of mechanical calf compression intraoperatively (e.g., Flowtron boots), the use of calf compression stockings (e.g., TED), and subcutaneous heparin, either unfractionated or low-molecular-weight heparin[138] (Table 74–3). Low-molecular-weight heparin is now commonly used peripartum because it can be administered on a once-daily dosage regimen.[139] These heparins are not secreted in breast milk and, therefore, can be used in lactating women.

Endomyometritis

In the absence of prophylactic antibiotics, postcesarean endomyometritis occurs with an incidence of 20% to 40%.[140,141] Postoperative infections may be reduced by 50% to 60% with the use of prophylactic antibiotics at the time of cesarean delivery.[142,143] In approximately 10% of cases, concurrent bacteremia will accompany postcesarean endomyometritis.[143,145] Uncommonly, postcesarean endomyometritis may be complicated by pelvic abscess, septic shock, and septic pelvic thrombophlebitis. The major risk factors for the development of postcesarean infection are young age, low socioeconomic status, prolonged labor, prolonged ruptured membranes, and multiple vaginal examinations.

Postcesarean section endomyometritis is a polymicrobial infection with bacteria normally present in the lower genital tract—aerobic streptococci (group B and D streptococci), anaerobic gram-positive cocci (peptococcus and peptostreptococcus), aerobic (*Escherichia coli*, *Klebsiella pneumoniae*, *Proteus* spp.), and anaerobic gram-negative bacilli (*Bacteroides* spp. and *Gardnerella vaginalis*).[143] The symptoms and signs of endomyometritis usually develop 24 to 48 hours postsurgery. The main clinical manifestations are fever, tachycardia, lower abdominal pain, uterine and adnexal tenderness, and peritoneal irritation. Following appropriate laboratory investigation, including complete blood count, aerobic and anaerobic blood cultures, and aerobic and anaerobic endometrial cultures, antibiotic therapy is instituted. There are several effective regimens available: clindamycin plus an aminoglycoside or aztreonam; penicillin plus aminoglycoside and metronidazole; or one of the extended-spectrum penicillins such as ticarcillin-clavulanic acid or ampicillin-sulbactam. If a cephalosporin has been administered for prophylaxis, a penicillin should be used owing to the possibility of enterococcus.

Most patients show a clear response to treatment within 72 hours. The two most common causes of apparent treatment failure are concurrent wound infection and resistant microorganisms. If a wound infection develops, incision and drainage is indicated, but a change in antibiotics usually is not necessary. The principal microorganisms likely to be resistant to initial treatment regimens are aerobic gram-negative bacilli, enterococci, and *Bacteroides* spp. If a resistant organism is thought to be present, antibiotic therapy should be modified. Parenteral therapy should be continued for a minimum of 24 hours after the patient becomes afebrile and asymptomatic. At this point, therapy may be discontinued. Patients do not need to be maintained on oral antibiotics after discharge from hospital.[142] Extended therapy of this nature is expensive and increases the risk of side effects without providing any measurable therapeutic benefit.

TABLE 74–3

Thromboprophylaxis Guidelines following Cesarean Section

HIGH RISK	MODERATE RISK	LOW RISK
	Risk Factors	
• Three or more moderate risk factors • Extended major pelvic or abdominal surgery (e.g., cesarean hysterectomy) • Personal history of deep venous thrombosis or pulmonary embolism • Thrombophilia • Family history of deep vein thrombosis, pulmonary embolism, thrombophilia • Paralysis of lower limbs • Antiphospholipid antibody syndrome	• Age > 35 yr • Weight > 80 kg at booking visit • Para 4 or more • Severe varicose veins • Current infection • Preeclampsia • Immobility prior to surgery (≥5 days) • Major current illness (e.g., heart or lung disease, cancer) • Emergency cesarean section in labor	• Includes women having an elective cesarean section and who have had an uncomplicated pregnancy with no other risk factors
	Prophylaxis includes:	
• Knee-high compression stockings • Calf stimulation by a calf stimulation device during surgery • Subcutaneous low-molecular-weight heparin (minimum 5 days) • Early mobilization • Adequate hydration	• Knee-high compression stockings • Calf stimulation by a calf stimulation device during surgery • Early mobilization • Adequate hydration • Consider subcutaneous low-molecular-weight heparin.	• Knee-high compression stockings • Calf stimulation by a calf stimulation device during surgery • Early mobilization • Adequate hydration

From Macklon NS, Greer IA: The deep venous system in the puerperium: An ultrasound study. Br J Obstet Gynaecol 1997;104:198–200.

In patients who fail to improve after a change in antibiotic therapy, another detailed examination should be performed to detect a wound infection or pelvic abscess. Other possible causes of poor treatment response include viral infections, venous thrombophlebitis, and drug fever.

Wound Infection

Adverse outcomes associated with abdominal wounds in obstetric patients occur more frequently in the presence of anemia, premature rupture of the membranes, prolapsed cord, and meconium staining. Reported wound infection rates associated with cesarean section range from 2.5% to 16.1%.[144–146] Nielson and Hokegard[147] found rates of 4.7% for elective cases and 24.2% for emergency cases. A mixture of anaerobic and aerobic bacteria (*E. coli*, *Proteus mirabilis*, *Bacteroides* spp., β-hemolytic streptococci) are isolated from postcesarean wound infections, similar to those of postpartum endomyometritis. *Staphylococcus aureus* is isolated from postcesarean wound infections in 25% of cases and appears to originate from the skin rather than the endometrium.[148] Early diagnosis is important, and frequent inspection of the cesarean wound and temperature review are paramount.

Prevention of wound infections involves careful preoperative preparation. Preoperative hexachlorophene showers,[149] clipping of abdominal hair rather than shaving,[149,150] liberal application of skin antiseptic agents in the operating room, and use of wound drapes are simple but effective measures to decrease the incidence of wound infection. Sterile technique, attention to hemostasis, obliteration of tissue dead space, and removal of devitalized tissues are important surgical factors that promote appropriate wound healing and prevent wound infection. The use of closed drainage systems is preferable to Penrose-type drains, because the former remain sterile as long as flow continues.

As with any infective process, prompt recognition and treatment are essential. An infected wound is usually characterized by local pain, tenderness, erythema, and purulent discharge, typically becoming clinically evident 4 to 7 days postsurgery. Systemic evidence may also be present with fever and leukocytosis. The early development of a wound infection, usually in association with cellulitis and high spiking fever, is characteristic of group A and group B β-hemolytic streptococcus. Initial treatment involves opening the wound along the affected area to the fascia and culturing the exudate (anaerobic and aerobic). Incision and drainage with debridement of necrotic tissue is vital. Applications of hydrogen peroxide to chemically debride the area should follow initial local surgical efforts. Because antiseptic solutions are cytotoxic, saline lavage must follow their application with the application of wet-to-dry dressings. When all necrotic tissue has been removed and granulation tissue forms, cessation of debriding agents is important and the use of wet-to-wet dressings instituted. The wound may be reapproximated once granulation tissue appears or be left to close by secondary intention. Drainage is usually sufficient, and systemic antibiotics are not indicated for simple wound infections. A serious complication of wound infection is necrotizing fasciitis, a synergistic infection that destroys subcutaneous tissues. Repeated, aggressive debridement is vital in association with broad-spectrum antibiotics and hyperbaric oxygen therapy to achieve cure.

Postpartum Hemorrhage and Other Problems of the Third Stage

MICHAEL A. BELFORT and GARY A. DILDY III

INTRODUCTION

Postpartum hemorrhage (PPH) remains one of the leading causes of maternal death, in both industrialized and nonindustrialized nations. Approximately 140,000 women die annually from PPH worldwide, and more than 50% of these mortalities occur within the first 24 hours postpartum.[1–3] The World Health Organization (WHO) reports that in sub-Saharan Africa, hemorrhage is by far the leading cause of maternal death, accounting for more than a third (35%) of cases in the region and as much as 60% in some individual countries.[4] WHO has also estimated that not only is maternal mortality high but also approximately 20 million mothers per year suffer significant morbidity from PPH.[1,4]

A recent study in the United States showed that 12% of all maternal mortality is due to obstetric hemorrhage, and that obstetric hemorrhage is the third most common cause of death related to pregnancy, after complications of preeclampsia and amniotic fluid embolism[5] (Table 75–1). Review by a group of experienced obstetricians led to the conclusion that the majority (73%) of deaths reported from obstetric hemorrhage could have potentially been prevented by more prompt attention to the clinical signs of bleeding and associated hypovolemia.[5] The recent CEMACH report[6] on maternal deaths in the United Kingdom between 2003 and 2005 showed obstetric hemorrhage to be the third most common cause of death (0.66/100,000 maternities) after thrombosis/thromboembolism and preeclampsia/eclampsia. In this report, 59% of mortality due to hemorrhage was associated with substandard care.

Stafford and colleagues[7] recently reported estimated blood loss (EBL) according to mode of delivery (Fig. 75–1) and degree of perineal laceration (Fig. 75–2) in a cohort of predominantly indigent women delivering at University Hospital in New Orleans.[7,8] There was a progressive increase in EBL with complexity of delivery, and operative vaginal delivery EBL was similar to that in cesarean delivery. As expected, there was a correlation between EBL and degree of perineal laceration, and EBL was similar between vaginal delivery complicated by third-/fourth-degree perineal lacerations and cesarean delivery. There was also noted to be a consistent underestimation in EBL by visual means compared with calculated EBL using a formula with the predelivery and postdelivery hematocrits. Underestimation of EBL is common in obstetric clinical practice and is a consistent factor in late recognition and treatment of hemorrhagic shock.[7]

There is no single accepted definition of "obstetric hemorrhage." PPH is usually defined as a blood loss greater than 500 mL, although detailed measurements of average blood loss in which to all the measured loss is added, including blood eluted from drapes and sponges (using dilute hydrochloric acid and measuring hemoglobin as acid hematin), show that approximately 50% of women will lose this amount during and after their first birth. This has led some to redefine a significant PPH as greater than 1 L. An alternative pragmatic definition is that of continuing hemorrhage despite the "usual treatment." Obstetric hemorrhage is reported to occur in approximately 1 : 200 to 1 : 250 deliveries in developed countries, with a case fatality rate of between 1 : 600 and 1 : 800.[5,6] Although death from obstetric hemorrhage is uncommon in the United Kingdom, it is interesting to note that for every death from obstetric hemorrhage, more than 60 women will have an emergency peripartum hysterectomy to stop bleeding (41/100,000 maternities). Because peripartum hysterectomy represents a reasonable "near-miss" event for maternal mortality, the extent of the problem, even in developed countries, should not be underestimated. Recent reports from Ireland[9] and The Netherlands[10] have highlighted the seriousness of the "near miss" and the importance for close monitoring of such cases in any quality assurance program. Major obstetric hemorrhage was seen in 4.5/1000 deliveries in The Netherlands,[10] and in most cases, substandard care was identified. In the Irish study, a ratio of severe maternal morbidity to maternal mortality of almost 27 : 1 was found, and 77% of the cases of severe maternal morbidity were due to massive obstetric hemorrhage.[9]

THE NORMAL THIRD STAGE OF LABOR

Recognizing the sequence of events in the third stage of labor and understanding the mechanism of placental separation may aid the detection of cases at risk for third-stage complications and the management of pathology.

The Most Common Causes of Maternal Mortality in a Series of 1.5 Million Deliveries within One U.S. Healthcare System between the Years 2000 and 2006

CAUSE OF DEATH	N	%	
Complications of preeclampsia	15	16	
Amniotic fluid embolism	13	14	
Obstetric hemorrhage	11	12	73% are judged preventable
Cardiac disease	10	11	
Pulmonary thromboembolism	9	9	
Nonobstetric infection	7	7	
Obstetric infection	7	7	
Accident/suicide	6	6	
Medication error or reaction	5	5	
Ectopic pregnancy	1	1	
Other	11	12	
Total	**95**	**100**

ESTIMATED BLOOD LOSS
MODE OF DELIVERY
FIGURE 75–1
The relationship between visualized estimated blood loss (vEBL), calculated estimated blood loss (cEBL), and mode of delivery. CD, cesarean delivery; OVD, operative vaginal delivery; SVD, spontaneous vaginal delivery.

Prostaglandin F (PGF), $PGF_{2\alpha}$, and oxytocin are the biochemical agents primarily involved in the third stage of labor. During the first and second stages of labor, only $PGF_{2\alpha}$ and oxytocin are significantly raised in maternal plasma compared with prelabor concentrations. At 5 minutes after birth, maternal PGF and $PGF_{2\alpha}$ concentrations peak at about twice the levels found at the commencement of the second stage. A rapid increase in prostaglandin concentrations is also found in umbilical cord venous blood, suggesting that this postpartum prostaglandin surge originates in the placenta.[11] After placental separation, the concentrations

The relationship between visualized estimated blood loss (vEBL), calculated estimated blood loss (cEBL), and perineal laceration.

ESTIMATED BLOOD LOSS
VAGINAL DELIVERY – PERINEAL LACERATION
decrease but at rates slower than the metabolic clearance of prostaglandin, indicating that its production continues in the decidua and myometrium. Plasma oxytocin also drops to prelabor levels within 30 minutes of delivery, unless sustained by exogenous infusion.

Continuous real-time ultrasound, performed during the third stage of labor, has revealed that the process of placental separation can be divided into four phases[12] (Table 75–2):
1. **Latent**—uterine wall at the placental site remains thin; placenta free wall contracts.
2. **Contraction**—thickening of uterine wall at the placental site.
3. **Detachment**—actual separation of the placenta from the adjacent uterine wall.
4. **Expulsion**—sliding of the placenta out of the uterine cavity.

Forceful uterine contractions in the latent phase induce shearing forces between the uterine wall and the unyielding placental tissue, initiating the separation of the placenta. A wave of separation begins at one of the placental poles, usually at a point near to the lower segment, and propagates toward the fundus during the contraction and detachment phases.[13] Separation of the fundal placenta begins at more than one of the placental poles, and the central part is last to separate. (This is the reverse of the Schultze and Mathews Duncan mechanisms described in most texts.) In almost half of the cases with a previous cesarean section. the separation pattern was reversed, commencing at the fundus, suggesting that myometrial strength in the region of the uterine scar may have been compromised.[13]

Although spontaneous delivery of the placenta usually occurs within 10 minutes of the baby's birth, the third stage is not considered prolonged unless it lasts more than 30 minutes. Combs and Laros,[14] in an 11-year study of 12,979 consecutive, singleton vaginal deliveries, demonstrated that the duration of the third stage followed a lognormal distribution, with a median of 6 minutes (interquartile range

TABLE 75–2

Summary of Clinical and Ultrasound Findings at Different Stages of Placental Separation and Recommendations for Management

| | STAGE OF PLACENTAL SEPARATION | | | |
	FULLY ADHERENT	PARTIALLY SEPARATED	FULLY SEPARATED: TRAPPED	FULLY SEPARATED: NORMAL
Clinical Signs				
Duration third stage		>30 min		<30 min
Uterine fundus	Above umbilicus			Below umbilicus
Uterus	Broad	Broad	Small, contracted	Small, contracted
Cord lengthening	No	No	Sometimes	Yes
Bleeding	No	Yes	Yes	Yes
Ultrasound Appearance				
Myometrium (placental site)	<2 cm thick across entire placental site	<2 cm thick at fundus, >2 cm at lower pole	<2 cm thick at all levels; surrounding placenta	>2 cm thick at all levels; above placenta
Placental position	Upper segment	Upper segment	Upper segment	Lower segment or vagina
Doppler flow (myometrium-placenta)	Present	Absent	Absent	
Management				
Initial: 30–60 min	Expectant	Hemabate 250 µg IM; misoprostol 1000 µg PR	Controlled cord traction; glyceryl trinitrate	Maternal effort; gentle controlled cord traction
>60 min	Umbilical vein uterotonic	Manual removal	Manual removal	
Failed	Methotrexate/hysterectomy	Hysterectomy		

4–10 min). The prevalence of a third stage in excess of 30 minutes was 3.3%. Although stating that prophylactic oxytocic agents were not used routinely, their figures for duration are remarkably similar to those from the much larger series (45,869 singleton vaginal deliveries) reported by Dombrowski and coworkers,[15] who estimated that using active management of the third stage, 90% of term placentas will deliver spontaneously by 15 minutes and only 2.2% will be undelivered at 30 minutes. The incidence of prolonged third stage associated with different uterotonic agents has been reported[16–18] as follows:

- Oxytocin (Pitocin, Syntocinon): 1.4% to 1.8%.
- Oxytocin/ergometrine (Syntometrine): 1.6% to 2.8%.
- Misoprostol (Cytotec): 1.4%.

Management Options

There are markedly polarized views between those who believe in active management and those who believe in expectant (natural) management of the third stage.

Active management of the third stage includes

- Administration of a prophylactic oxytocic agent or prostaglandin within 2 minutes of the baby's birth to induce uterine contraction.
- Immediate cutting and clamping of the cord to enhance placental separation.
- Placental delivery by controlled cord traction.

In expectant management, there is

- No prophylactic oxytocic.
- No cord clamping until pulsations cease.
- Delivery of placenta by maternal effort and gravity rather than cord traction.

Use of Prophylactic Uterotonic Agents

There no longer appears to be any valid argument in favor of the physiologic approach, because two substantive studies comparing active management with expectant management have clearly indicated the advantages of active management. The Bristol trial,[19] in which active management had been the norm, and the Hinchingbrooke trial,[20] in which expectant management had been the norm, both demonstrated significant reductions in the incidence of PPH with active management compared with expectant management (5.9% vs. 17.9% and 6.8% vs. 16.5%, respectively). Both studies were terminated after interim analysis because the difference in PPH rates was so great.

Which Uterotonic Agent?

In recent years, considerable attention has been paid to the choice of uterotonic agent, in particular comparing the cheap and orally administered prostaglandin misoprostol with the combination agent Syntometrine (oxytocin/ergonovine, which is used in much of Europe and Africa but is not available in North America). The findings seem to indicate that rectal misoprostol is a viable alternative to oxytocin in areas in which storage and parenteral administration of drugs are problems (oxytocin has to be stored at 4°C to retain its efficacy, whereas tablets of misoprostol kept dry retain their efficacy even at tropical temperatures for several years or more),[21] but its side effects (shivering, pyrexia, nausea, and diarrhea) and slightly lower efficacy make it unsuitable for routine prophylaxis against PPH. Oxytocin (Pitocin) or oxytocin combined with ergometrine (Syntometrine), therefore, remain the preferred drugs for routine use in developed countries. Some trials have suggested that

oxytocin alone is as efficacious as Syntometrine, whereas others have reported that it is not as effective. Intravenous ergometrine is associated with an increase in the incidence of retained placenta, possibly as a result of myometrial spasm distal to a fundally placed placenta leading to its forced retention, and should not be the agent of choice for routine administration.[22] Ergometrine also causes peripheral vasoconstriction and a rise in blood pressure and should be given only with caution, if at all, to women with hypertension. Contraindications to ergometrine include heart disease, autoimmune diseases associated with vasospasm and Raynaud's phenomenon, peripheral vascular disease (such as with severe diabetes), arteriovenous shunts even if they have been surgically corrected, and preeclampsia/eclampsia. Oxytocin, conversely, when given as an acute bolus, can cause a marked drop in blood pressure. Caution should, therefore, be exercised when giving oxytocin to women with cardiovascular problems, and a continuing low-dose infusion is probably preferable to bolus injection.

The active and passive management approaches represent the two extremes of the spectrum of common practice. Although the randomized, controlled trials performed to date have only compared these two approaches, the benefits of early cord clamping and controlled cord traction in the prevention of PPH have not been established separately from the use of prophylactic uterotonic agents. It is from these two aspects that most criticisms of active management arise.

Timing of Cord Clamping

The umbilical cord can be clamped immediately after birth, clamped after pulsations cease, or left unclamped. The cord may need to be clamped before birth if there is tight nuchal entanglement. Although early clamping of the cord has been reported to be associated with significant shortening of the third stage, this has been demonstrated only in trials in which no prophylactic oxytocin was given.[23,24] The difference in the effects of early versus late cord clamping on the neonate are relatively minor, and opinions differ as to their relative risks and benefits. The deferral of cord clamping until 3 minutes after birth results in a neonatal transfusion of about 80 mL of blood from the placenta.[25] This contributes about 50 mg of iron, which may reduce the frequency of iron-deficiency anemia later in childhood.[26]

The theoretical downsides of this blood transfusion are hypervolemia, polycythemia, hyperviscosity, and hyperbilirubinemia. In practice, however, these have not been found to produce a clinically relevant increase in neonatal morbidity.[27]

The WHO review of evidence on management of the third stage concludes that there is no clear evidence to favor one practice over the other. Delaying cord clamping until the pulsations stop is the physiologic way of treating the cord and is not associated with adverse effects, at least in normal deliveries. Early cord clamping conflicts with traditional beliefs and is an intervention that needs justification.[28] In preterm infants, delay in cord clamping has demonstrable benefits and has been shown to decrease the need for blood ($P < .001$) and albumin ($P < .03$) transfusions during the first 24 hours of life.[29]

Controlled Cord Traction

The use of cord traction has a long history, with the earliest records dating back to Aristotle. Simple cord traction was displaced in the 1800s by the introduction of the Credé maneuver.[30] In this maneuver, the placenta is expelled by downward pressure on the fundus of the uterus in the direction of the birth canal, with the thumb placed on the posterior surface and the flat of the hand on the anterior surface of the fundus. This was proposed as an alternative means to manual removal for expelling the retained placenta and was found to avoid the uterine inversion that was occasionally associated with cord traction. Brandt in 1933 and Andrews in 1940 independently introduced similar methods to improve the use of cord traction to deliver the retained placenta. These involved traction on the cord with countertraction applied to the uterus abdominally. It was not until the 1960s, however, that the modern technique known as *controlled cord traction* was introduced by Spencer,[31] accompanied by the routine administration of ergonovine.

The current consensus is that when traction is applied to the umbilical cord, it should be done only during a uterine contraction while controlling the uterus by Brandt-Andrews maneuver to prevent uterine inversion. However, it should be noted that the benefits of both early cord clamping and the use of routine controlled cord traction to prevent PPH have not as yet been supported by evidence from randomized, controlled trials.

SUMMARY OF MANAGEMENT OPTIONS
Normal Third Stage of Labor

Management Options	Evidence Quality and Recommendation	References
Active management of third stage is advised for all women, and includes all of the following:	Ia/A	19,20
• Administer oxytocic agent (oxytocin [Pitocin] or oxytocin and ergometrine [Syntometrine]).	Ib/A	19,20
• Clamp and cut cord.	—/GPP	—
• Use controlled cord traction (no randomized, controlled data to show it reduces PPH rates of itself).	III/B	31

Management Options	Evidence Quality and Recommendation	References
Timing of Cord Clamping		
• No evidence to indicate optimum timing in term delivery.	Ia/A	28
• In preterm infants, delay in clamping may be of benefit.	III/B	29
Ensure intravenous access for women at risk.	—/GPP	—
Save serum for rapid cross-match if needed, or actually cross-match 2 units, for women at risk.	—/GPP	—

GPP, good practice point; PPH, postpartum hemorrhage.

RETAINED PLACENTA

Diagnosis and Definition

Using a diagnostic cutoff of 30 minutes for a prolonged third stage, 42% of retained placentas deliver spontaneously within the next 30 minutes,[32] with very few delivering spontaneously after 1 hour.[33] Because the incidence of significant PPH rises after 30 minutes in the third stage,[14] active intervention to deliver the placenta between 30 and 60 minutes into the third stage is advised. Dombrowski and coworkers[15] noted that compared with term pregnancies, the frequency of retained placenta (2.0% overall) was markedly increased among very preterm (gestation < 27 wk) and preterm pregnancies (gestation < 37 wk), with odds ratios of 20.8 and 3.0, respectively.

Management Options

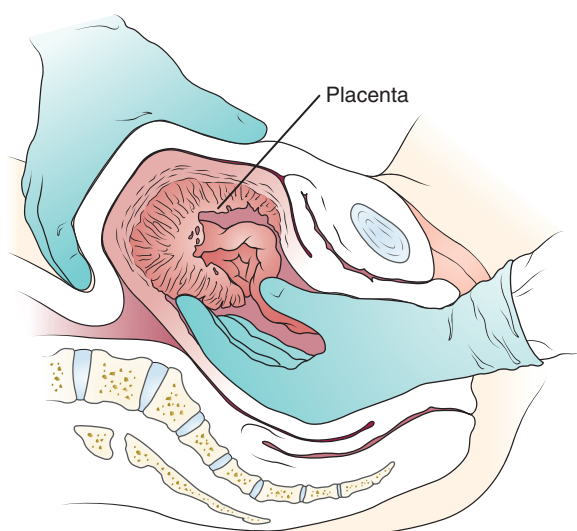
Manual removal appears to be the management of choice for retained placenta (Fig. 75–3). However, it is associated


FIGURE 75–3
Manual removal of placenta. The fingers are moved from side to side until the placenta is completely detached.
(Reproduced from Cunningham FG, MacDonald PC, Gant NF [eds]: Abnormalities of labor and delivery: Abnormalities of the 3rd stage of labor. In: Williams Obstetrics, 18th ed. Norwalk, CT, Appleton & Lange, 1989.)

with a risk of infection (endometritis) and trauma (perforation of the uterine wall). Ely and associates,[34] in a retrospective study of 1052 manual removals, found that clinical endometritis developed in 6.7% of cases compared with only 1.8% following spontaneous placental delivery.

In some studies, manual removal appears to be aggressively pursued, with rates exceeding 3% and often performed only 15 to 20 minutes into the third stage. The rate generally quoted internationally is 1% to 2%.[33]

In the absence of hemorrhage, there is no urgency to resort to manual removal when less invasive alternatives are available. In addition, consideration of the potential for placenta accreta or percreta should always precede the attempt, and if there is any real potential for a morbidly adherent placenta, preparations to deal with complications such as major hemorrhage should be in place before going ahead with manual removal.

Patients with a prolonged third stage are often treated as a homogeneous group, although they have different clinical conditions. These include the retention of an already detached placenta (trapped placenta), an adherent placenta, and placenta accreta. Each condition should be distinguished from the others, and each requires a specific clinical approach. Herman[35] noted that each of these conditions is associated with a different sonographic appearance and concluded that "proper utilization of ultrasound may be crucial for optimal management."

Trapped Placenta

Trapped placenta often follows the intravenous administration of ergometrine when the onset of uterine contraction is very rapid. This tends to close the cervix at the same time as placental detachment occurs, trapping the placenta. Intramuscular injection of ergometrine results in the onset of uterine contraction in 10 minutes, which is likely to follow rather than precede placental separation, so trapped placenta is less likely to occur. The clinical findings of a trapped placenta include a small, contracted fundus, with some vaginal bleeding and cord lengthening indicative of placental separation, and the placental margin may be palpable through the closed cervical os. On ultrasound examination, the entire myometrium is thickened and a clear demarcation may be seen between it and the placenta.[12]

Delivery of a trapped placenta can usually be achieved using controlled cord traction, which encourages cervical dilation. Intravenous glyceryl trinitrate (100–200 μg) is useful as a short-term tocolytic agent, appears efficacious

and safe, and may obviate the need for general anesthesia for uterine relaxation.[36] Releasing the cord clamp, to allow blood trapped in the placenta to drain, may also help.

Adherent Placenta

With an adherent placenta, the uterine fundus remains broad and high and myometrial contractions may be weak or absent, but there is no bleeding while the placenta remains wholly attached. Adherent placenta is caused by a deficiency in the contractile force exerted by the myometrium underlying the placental site despite normal anatomy (i.e., it is not caused by pathologic invasion of the placenta into the uterine muscle, known as *placenta accreta*). On ultrasound, the myometrium appears thick and contracted in all areas, except where the placenta remains attached, and the uterine wall remains less than 2 cm in thickness.[12] If the placenta becomes partly separated, the myometrium over the detached area appears thicker, but that underlying the adherent part remains thin (<2 cm).[12] Detachment usually starts in the lower part of the uterus and is associated with bleeding from the placental bed.[13] Treatment options depend on the amount of bleeding:

- In the absence of bleeding, a conservative approach can be adopted and manual removal of the placenta can be postponed while the problem is investigated (by ultrasound).
- When there is active bleeding, immediate active management is necessary.

Effective treatment of the adherent placenta is based on stimulating a contraction of the underlying myometrium that has sufficient strength to induce separation of the placenta. Oxytocin, ergonovine, and misoprostol are all capable of inducing sustained myometrial contractions. However, there is no evidence that systemic and repeated administration of either oxytocics or prostaglandins is able to assist in the delivery of the adherent placenta.

Recent studies have shown that uterotonic agents administered via umbilical vein injection may be effective in causing the adherent placenta to separate,[37] and this method is currently recommended as the first line of treatment by the WHO.[38]

The Pipingas technique has been shown to be effective in delivering drugs to the placental bed.[39] A size 10 nasogastric tube is passed along the umbilical vein until resistance is felt, then retracted about 5 cm, and $PGF_{2\alpha}$ (20 mg diluted in 20 mL of normal saline) or oxytocin (30 IU diluted in 20 mL of normal saline) is injected through the catheter.[40] Alternatively, a solution of misoprostol may be used.[41]

SUMMARY OF MANAGEMENT OPTIONS
Retained Placenta

Management Options	Evidence Quality and Recommendation	References
Retained placenta should be diagnosed if it is not delivered within 30–60 min.	III/B	14,32,33
Trapped Placenta		
• Perform ultrasound to confirm separation.	III/B	12
• Use controlled cord traction with a short-acting tocolytic such as glyceryl (trinitrate).	III/B	36
Adherent Placenta		
• If there is active bleeding, manual removal is necessary.	—/GPP	—
• If there is no active bleeding, consider intraumbilical uterotonic agents before resorting to manual removal.	III/B	37–39

GPP, good practice point.

ADHERENT PLACENTA (PLACENTA ACCRETA, INCRETA, PERCRETA)

Placenta accreta is a condition in which all or part of the placenta is adherent to the uterine wall because of myometrial invasion by chorionic villi. It may occur when there is either a primary deficiency of or secondary damage to the decidua basalis and Nitabuch's layer.[42] Abnormal trophoblast invasion has been associated with up-regulation of vascular endothelial growth factor (VEGF) and angiopoietin-2 and down-regulation of VEGF-receptor (VEGF-R) and Tie-2.[43]

Three grades are defined according to the depth of myometrial invasion:

- **Accreta**—chorionic villi are in contact with the myometrium, rather than being contained within the decidua (80% of cases).
- **Increta**—extensive villous invasion into the myometrium (15% of cases).
- **Percreta**—villous invasion extends to (or through) the serosal covering of the uterus (5% of cases).

Factors associated with a higher incidence of accreta include multiparity, prior uterine surgery (e.g., myomectomy), advanced maternal age, placenta previa, prior uterine curettage, and previous cesarean delivery.[42,44,45] Uterine irradiation for intra-abdominal cancer therapy has also been identified as a risk factor for percreta.[46] Placenta percreta has been reported to occur after endometrial ablation.[47] Placenta

FIGURE 75–4
The relationship between the number of prior cesareans and placenta previa (*left*), and if placenta previa, the risk of placenta accreta (*right*). (From Clark SL, Koonings PP, Phelan JP: Placenta previa/accreta and prior cesarean section. Obstet Gynecol 1985:66:89–92.)
accreta rarely complicates vaginal delivery, with an incidence of only 1 in 22,000 in the absence of placenta previa.[48] Rarely, abnormal attachment is seen in the absence of prior surgery (e.g., associated with Asherman's syndrome and submucous fibroids). Interestingly, the adherence is not necessarily over the site of the previous scar. Placenta percreta has also been reported in pregnancy with a noncommunicating rudimentary uterine horn, and patients with a known uterine anomaly of this type should be counseled about the potential for such a complication.[49]

The reported incidence of placenta accreta has increased from 1 : 2510 in the 1980s, to 1 : 533 in 2002, to 1 : 210 in 2006, and this is most likely related to increasing cesarean delivery rates.[44,45,50,51] Clark and coworkers[45] showed an almost linear increase in the incidence of placenta previa with repeat cesarean section with a rate of approximately 10% in women with four prior cesarean sections (Fig. 75–4). This group also showed that placenta previa in the face of prior cesarean section significantly increased the risk of morbid adherence of the placenta. Several studies have found a direct relationship between the number of prior uterine incisions and the subsequent occurrence of placenta accreta, with reports of a twofold increased risk of accreta with one prior cesarean delivery.[44] In a Maternal-Fetal Medicine Units Network study evaluating over 30,000 cesarean deliveries and associated comorbidities, women having their fourth or additional cesarean delivery had a 9- to 30-fold increased risk of placenta accreta.[51] The risk of accreta in women with a placenta previa and a prior cesarean section increased from 3% with one previous cesarean section, to 11%, 40%, 61%, and 67% with two, three, four, or more repeat cesarean sections, respectively.

There has been particular concern about the risk for accreta in women with a prior cesarean section scar and an anterior or low-lying anterior placenta. Twickler and colleagues[52] specifically addressed this issue using data from 653 patients with a previous cesarean section. In their cohort, there were 152 patients who had an anterior placenta and 43 with an anterior low-lying placenta. None of these patients had an accreta. Of the 20 patients with a previous cesarean section scar who were diagnosed with placenta previa, however, 9 had a placenta accreta (45%) and 15 required cesarean hysterectomy for uncontrolled bleeding (75%).

In patients with a placenta previa and a prior cesarean section, accreta is much more common when the previa is anterior or central and overlies the scar (29%) than when it is lateral or posterior and does not contact the scar (6.5%).[48]

The majority of cases of morbidly adherent placenta present as accreta. Approximately 5% present as percreta with surrounding organ involvement. In these patients, intra-abdominal bleeding, hematuria, or bladder symptoms may be present. With the presence of coexisting placenta previa, antepartum hemorrhage rates approach 30% and are more likely to result in preterm delivery secondary to hemorrhage.

All three grades of placenta accreta can result in profuse PPH owing to incomplete separation of the placenta. Being alert to this possibility is essential in patients who have a combination of placenta previa and a history of previous uterine surgery. If the diagnosis of placenta accreta is suggested on ultrasound or magnetic resonance imaging (MRI), plans for delivery by cesarean section by a surgeon experienced in dealing with such cases, and in a facility in which resuscitation and intensive care are available, should be made. Placenta percreta still represents one of the highest-risk complications of pregnancy, and despite our best efforts, there remains a 7% mortality rate even when 50% of patients treated for this condition are recognized as having it preoperatively.[53]

Diagnosis

The antepartum diagnosis of placenta accreta/percreta is usually accomplished using ultrasound[54–57] (Fig. 75–5) or MRI.[58] Sonographic criteria are summarized in Table 75–3. Although the addition of color Doppler ultrasound may enhance visualization of vascular lacunae, it has not been shown to improve the sensitivity of detection of accreta.[52,54] Loss of the hypoechoic zone, especially in the third trimester, has proved to be less useful than the other criteria and has also been shown to be less specific.[57] Twickler and colleagues[52] reported that two specific ultrasound criteria were predictive of accreta: (1) Myometrial thickness less than 1 mm and (2) large intraplacental blood lakes. If both of these findings were present, the sensitivity for placenta accreta was 100%, the specificity was 72%, the positive predictive value (PPV) was 72% and the negative predictive

Ultrasound (*left*) shows a mid-sagittal view of the lower uterine segment, with thickened placenta, large vascular lakes, and irregular areas at the placental-myometrial interface. Color Doppler ultrasound (*right*) shows vascular projections into the bladder wall and lumen, suggesting placenta percreta.

TABLE 75–3

Sonographic Assessment of Placenta Percreta

1. Loss of the normal hypoechoic retroplacental myometrial zone (clear space)[43,50]
2. Thinning or disruption of the hyperechoic uterine serosa-bladder interface[44]
3. Blood vessels crossing the regions of interface disruption[55]
4. Myometrial thickness of < 1 mm[52]
5. Presence of vessels bridging the uterine-placental margin[55]
6. Visualization of placental lacunae (defined as multiple linear, irregular vascular spaces) within the placenta, which gives the placenta a "Swiss cheese" appearance
7. Focal nodular projections into the bladder beyond the expected uterine-bladder interface[56]
8. Color Doppler ultrasound enhancement of vascular lacunae[52-54]

---

value (NPV) was 100%. The sensitivity and specificity of these findings for hysterectomy was 80%, PPV was 92%, and NPV was 57%. Others have suggested that disruption of the placental–uterine wall interface and the presence of vessels crossing these areas of disruption are the only two criteria of real predictive value. Because of concerns about the capability of the individual ultrasound criteria for distinguishing accreta from nonaccreta, Wong and associates[55] have developed a composite scoring system for ultrasound criteria that they report to be 89% sensitive and 98% specific for the diagnosis.[55]

The use of MRI for assessing placental invasion has yielded conflicting results.[54,58] The addition of gadolinium-based contrast agents seems to improve the specificity of this modality, but most radiologists are unwilling to use gadolinium in pregnancy for fear of fetal effects. MRI should be considered in cases in which sonographic evaluation is inconclusive and there is a concern about invasion of trophoblast into surrounding organs and tissue, especially if parametrial or posterior invasion is suspected.[54,59] MRI information in such cases will help with operative planning. Routine MRI scanning of all patients with sonographic evidence of accreta has not been shown to affect the management of the pregnancy unless there is concern for percreta. Other diagnostic modalities that have been used to obtain

a conclusive diagnosis in cases of suspected percreta include cystoscopy, sigmoidoscopy, and laparoscopy.[53]

Although most studies describe sonographic detection techniques in the second and third trimester, abnormal placental adherence has been identified as early as the first trimester. In these cases, the presence of a low-lying gestational sac in close proximity to the hysterotomy scar has been linked to massive bleeding with dilation and curettage or cesarean hysterectomy in the second and third trimester.[60,61] One third of these gestations ended with early fetal demise.[53]

Laboratory Tests

Abnormally elevated second-trimester serum α-fetoprotein has been associated with placenta percreta, and it has been suggested that there is a direct relationship between the extent of invasion and the elevation of this analyte.[53,62] Creatine kinase has also been reported as a marker for increta and percreta.[63]

Management Options

The management of the morbidly adherent placenta can be divided into two specific, and very different, categories: (1) The suspected placenta accrete/percreta and (2) the unsuspected placenta accrete/percreta discovered at the time of delivery or at emergency presentation for sudden onset of obstetric hemorrhage. These represent two very different situations. With a known placenta accreta/percreta, there is almost always time to make arrangements for the best possible circumstances for controlled delivery and management of potential hemorrhage. In an unsuspected placenta accreta, there is often very little time to prepare the patient for controlled surgery, and frequently, the massive hemorrhage is already under way at the time of diagnosis. Both of these situations are dealt with later. Although even under the best of circumstances, planned cesarean hysterectomy still carries a significant maternal mortality rate,[53] the great majority of the mortality associated with placenta accreta/percreta occurs in the previously unrecognized case in which potentially avoidable actions result in uncontrollable bleeding. In many cases of previously unknown accrete/percreta, a

heightened awareness of the potential for accreta/percreta, recognition of the signs of abnormal placentation at the time of surgery or vaginal delivery, total avoidance (or cessation if necessary) of any attempts to deliver the placenta if there is concern about accrete/percreta, attention to the hemodynamic status of the patient and aggressive resuscitation with early blood product administration, early recourse to definitive surgery, adjustments to the surgical techniques, and the team approach to the problem can all be life-saving and may limit the sequelae of massive hemorrhage in those who survive.

Known Placenta Accreta/Percreta

PREOPERATIVE CONSIDERATIONS

Patient and Family Counseling

Once the diagnosis is established, the treatment options and potential complications should be clearly discussed with the patient and the discussion should be documented in detail. The patient should be counseled regarding the increased risk of maternal death, the almost certain need for hysterectomy and blood transfusion, and the risk of unilateral or bilateral oophorectomy during the surgery. Unilateral oophorectomy is necessary in up to 10% of cases because of persistent bleeding. The patient should also understand the increased risks of (1) organ damage (particularly renal and cerebral) from hypotension, (2) bowel, bladder, and ureteric damage from the surgery, and the increased postoperative risks of (3) infection, (4) thromboembolism, (5) reoperation for persistent bleeding, and (6) iatrogenic complications from interventional radiology procedures that may be required to stop uncontrolled hemorrhage. The appropriate location and timing of delivery should be addressed to optimize the logistics of the support facilities and personnel.

Multidisciplinary Team Approach

Cesarean hysterectomy for placenta percreta is best managed by a dedicated and practiced team of clinicians and support personnel. These include the services mentioned in the following paragraphs:

Blood Transfusion Service Preoperative consultation with blood bank personnel is essential because of the likelihood of massive transfusion. Patients undergoing cesarean hysterectomy have an average intraoperative blood loss of 3000 to 5000 mL.[64–66] Placenta percreta cases will often require more blood products than the average hospital blood bank has in stock; when a patient has a rare blood type or antibodies, this issue becomes even more important. Elective surgery may require delay until additional units of blood can be located and transported to the blood bank. With a known placenta percreta case when massive hemorrhage is expected and highly likely, it is recommended that adequate amounts of packed red blood cells (PRBCs), fresh frozen plasma (FFP), platelets, and cryoprecipitate should be available to prevent (or treat) coagulopathy.[64] The definition of adequate is difficult to codify but, based on military surgical experience with massive trauma/hemorrhage (in which a set protocol for massive hemorrhage has been developed), one standardized protocol includes 6 U of PRBCs, 6 U FFP, 6 packs of platelets, and 10 U cryoprecipitate in separate coolers.[67] It is also advisable to have recombinant Factor VIIa

(rFVIIa) in the operating room (OR) at the time of the surgery (see later discussion). In select stable preoperative patients, erythropoietin administration with total-dose iron infusion may be used to correct anemia and maximize iron stores prior to surgery. The expected rise in hematocrit levels will be apparent within 2 weeks.[64]

Preoperative hemodilution has been described as a technique to minimize blood loss in patients who refuse blood transfusion,[68] and in such cases, as many as 3 units of blood can safely be removed immediately prior to surgery and replaced with crystalloid. This reduces the hematocrit and limits the red cell mass lost at the time of surgery. The blood removed before surgery is then transfused back during or after the procedure.

Cell Saver (Autotransfusion) The use of the Cell Saver has been somewhat limited in obstetrics because of a concern that the autotranfusion of fetal cellular debris and amniotic fluid may lead to amniotic fluid embolism. The rigorous washing and filtering techniques used in modern Cell Saver machines have made this concern largely theoretical. Fetal red blood cells may still be present in the final product (range 0.13%–4.35%), and in the case of an Rh-negative patient, there is a risk of alloimmunization (which is mainly a concern if she retains her fertility). There is now a growing body of evidence that there is little or no possibility for amniotic fluid contaminants to enter the re-infusion system when used in conjunction with a leukodepletion filter.[69] When used, we recommend double washing of the recovered blood, which should be collected only after double irrigation of abdominal cavity following delivery to remove as much fetal/placental/amniotic debris as possible. Attention should also be paid to the volume of re-infused washed PRBCs to ensure that adequate FFP, cryoprecipitate, and platelets are given with the Cell Saver blood because of the lack of these products in the reconstituted red cells. Although transfusing washed red cells will increase the hematocrit, unless FFP and platelets are transfused simultaneously, there will be a risk of dilutional coagulopathy.

Anesthesiology Preoperative anesthesia consultation is essential to allow appropriate planning and allocation of personnel. Anesthetic considerations include the need for general endotracheal anesthesia in anticipation of prolonged surgical time, consideration of a lumbothoracic epidural catheter for postpartum pain relief, and readiness for massive blood and blood product transfusion. OR temperature control is important, as is patient temperature regulation with warming blankets and forced-air heating devices. The anesthesia service will be primarily responsible during the surgery for preventing the deadly triad of hypovolemia, hypothermia, and acidosis that increases the risk for coagulopathy. If hypothermia occurs in the face of coagulopathy, reversal of the coagulation disorder is often extremely difficult.

Shock trauma fluid infusion devices capable of high flow rate transfusion of blood products, adequate central venous access (bilateral central line sheaths with quadruple catheter capability), arterial line placement, and multiple suction devices should all be part of the anesthesia preparation. In addition, thromboembolism prophylaxis should also be considered and initiated before surgery. Compression stockings

placed before induction of anesthesia, lower limb and foot compression/pulsation devices, and prophylactic unfractionated heparin are also accepted prophylactic maneuvers.[64] We have found that on-site blood testing with a portable device that allows rapid bedside assessment of hematocrit, platelets, electrolytes, blood gases, and coagulation function is extremely helpful and enables the anesthesia team to begin transfusion in a timely manner, as well as to monitor the effects of their interventions more efficiently. If practical, we suggest allocating a member of the team to documenting hematocrit, platelet count, blood gases, and coagulation function in a spreadsheet on a regular basis (every 15–30 min or as required). This strategy helps keep the team aware of trends and the need for changes in strategy before equilibrium becomes too displaced.

Urologic Preparation Bladder involvement is extremely common in anterior placenta previa with accreta/percreta, and in such cases, there is frequently hypervascularity and distortion of the ureterovesical junction. In such cases, preoperative cystoscopy and placement of ureteric stents allow palpation of the ureters during difficult and often obscured surgery and are very reassuring and, certainly, in our experience, shortens the procedure. In addition, the cystoscopy will warn of any potential need for re-implantation of the ureters, allowing preemptive changes in operative strategy and preparation. In those cases in which there is obvious penetration of the trophoblast into the bladder wall, it is helpful to create an intentional cystotomy in an uninvolved area of the bladder to visualize directly the area of invasion. This allows for a better appreciation of the extent of bladder invasion and assists in the protection of the trigone and ureterovesical junction. Another benefit is that it allows the surgeon to excise that portion of the bladder involved in the percreta under direct vision without the risk of inadvertently increasing the hemorrhage during blind dissection of percreta tissue. In our experience, sacrificing a nonessential portion of the bladder is not associated with long-term complications, speeds up the surgery, and significantly reduces intraoperative blood loss.

Prophylactic Internal Iliac Artery Balloon Catheters Preoperative pelvic artery occlusion has been proposed as an adjunct to minimize blood loss at the time of hysterectomy.[70] We and others[71] have determined that preoperative placement of balloon catheters in the internal iliac arteries has not proved useful and we no longer use this technique. We feel that inflation of the balloons after delivery may actually complicate the hysterectomy by opening up collateral vessels deeper in the pelvis that are more difficult to control than the immediate branches of the internal iliac artery. We have not noted any significant benefit to preoperative balloon catheter placement and suggest that, if necessary, intraoperative internal iliac artery ligation may be preferable. The placement of balloon catheters may also add to the complexity of the surgery and can potentially result in significant complications such as insertion site hematoma, abscess formation, and tissue infarction and necrosis.

Surgery Gynecologic oncology, urology, and general and vascular surgery consultants should be recruited as necessary for assistance in cases of placenta accreta/percreta. These specialists are invaluable when major pelvic vessel, lateral pelvic sidewall, bladder, or bowel invasion has occurred. The nursing staff in the OR should be fully informed of their expected surgical needs, and all consultants should be questioned as to their particular instrument and equipment requirements so that these things are available in the OR before they are needed. We have found that a slide presentation about placenta percreta (with mention of the specific details of the case to be performed) for the involved OR staff, blood bank personnel, and the providers from all involved services a few days before the surgery is an excellent forum in which questions and concerns can be aired. It also allows the people involved to perceive themselves as a team with a common purpose.

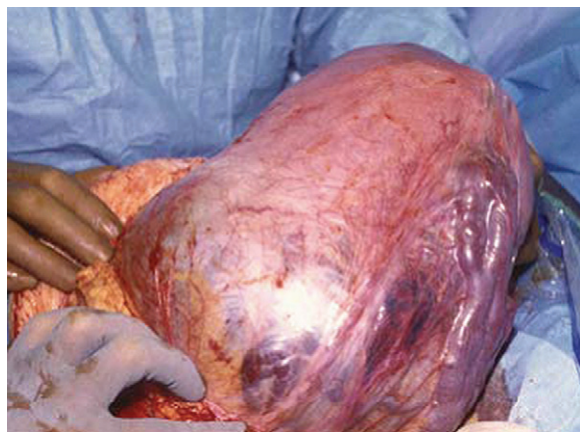
Neonatology Most planned cases of cesarean hysterectomy will be performed between 34 and 37 weeks' gestation, and for this reason, it is prudent to have adequate neonatal personnel present to deal with the specific issues of prematurity. If delivery appears likely prior to 34 weeks (e.g., antenatal vaginal bleeding), glucocorticoid prophylaxis to reduce the risk of respiratory distress syndrome should be considered. In addition, the neonatologist should be prepared for emergency resuscitation of the neonate in the event that profound maternal hemorrhage occurs before delivery of the baby. In most cases, this will not be an issue because the surgery is specifically planned to avoid uterine entry anywhere near the placenta. Occasionally, when antenatal hemorrhage precipitates an emergency delivery, fetal hemorrhage can occur, resulting in fetal anemia. In elective cases, the most frequent issues the neonatology team will need to deal with are prematurity and the effects of general anesthesia.

Intraoperative Management

We have found that the patient is best placed in a low lithotomy position for the surgery. This allows ureteric stent placement, access to the maternal vagina after delivery of the baby for placement of a vaginal pack, and space for an assistant to stand between the mother's legs. The patient should be prepared and draped from the chest to the groin, including the vulva and vagina.

Entry into the abdomen is best via a vertical skin incision (median or paramedian) dependent on the site of placental invasion. In cases in which the placenta has invaded the anterior abdominal wall, intraoperative ultrasound may be used to avoid placental disruption during entry into the abdomen.

Once within the abdomen, signs of increta/percreta include visualization of a distorted, hypervascular lower uterine segment with extremely dilated and often tortuous and abnormal vessels in the broad ligament. In unruptured cases, the lower segment of the uterus is usually bulbous and distended with areas of extremely thinned out uterine wall and, in places, placental tissue visible under a single layer of visceral peritoneum (Fig. 75–6). Frequently, small hematomas and dilated vessels are visible. If the bladder is involved, it will usually be pulled up against the lower uterine segment with large blood vessels traversing from the pelvic side walls. It is essential to avoid disturbing the placenta during delivery of the baby and a vertical upper segment uterine incision (fundal or posterior classic) is recommended. The site of the

FIGURE 75–6
Placenta percreta with bladder invasion, prehysterotomy.


incision can be planned before delivery by mapping the placental site with ultrasound. To confirm the appropriate site for incision, intraoperative ultrasound can be used, with the ultrasound transducer in a sterile sleeve so that scanning can be done directly on the uterus. If the placenta is anterior and extensive, the incision may need to be made in the posterior wall of the uterus. This requires complete exteriorization of the uterus with the fetus in situ (see Fig. 75–6) and the abdominal incision should be planned to allow this option. It is important to minimize the chances of inadvertent partial placental separation or placental disruption before the major supplying vessels are ligated and the uterus is devascularized; partial separation and bleeding will convert a controlled case into an emergency situation.

After delivery of the fetus, no attempts should be made to remove the placenta manually. The umbilical cord should be tied off and replaced within the uterus. Uterotonics can be given (an infusion of Syntocinon, or rectal misoprostol 1000 μg). If it is not certain that the placenta is accreta, then the uterus can be observed to see whether a spontaneous separation of the placenta will take place without excessive bleeding. If there is no separation, significant bleeding starts, or the diagnosis of accreta is already confirmed, the uterus should be closed in a single layer with a locked suture. We then infiltrate the uterus with 15-methyl-PGF$_{2\alpha}$ (250 μg carboprost tromethamine [Hemabate] in 20 mL saline) given through a 22-gauge spinal needle in multiple areas to facilitate contraction. It is quite possible to lose a significant amount of blood into the uterine cavity during the surgery without any outward indication, and uterine size should be monitored carefully to alert the surgeon of this occurrence. In some cases, a red rubber catheter can be used as a tourniquet above the level of the placental edge to help compress the uterus.[64]

Following delivery of the baby and closure/contraction/clamping of the uterus, the operative scene should be carefully assessed as long as the patient is hemodynamically stable. The abdominal retractor can be optimally placed, the bowel packed away, and pelvic visualization optimized. We have found a rigid ring self-maintaining retractor system such as the Kirshner or Bookwalter is best for this. The

vagina should also be packed because this helps with elevating the cervix and lower uterine segment into the pelvis and also shows the vaginal fornices more clearly, preventing unnecessary removal of vaginal tissue.

In all cases, a reassessment of the operative scene should follow the cesarean section. If the percreta was anticipated, MRI and magnetic resonance angiogram data may be available to help with surgical planning. Even so, after reduction in the size of the uterus, a reevaluation of the extent of the placental invasion may show that any attempts at surgical removal will be more risky than anticipated. A flexible approach is important. A percreta that has penetrated the lateral wall of the uterus and has deeply invaded into the broad ligament and structures of the lateral pelvic side wall may be deemed impossible to remove without damaging vital structures or causing uncontrolled bleeding. In such cases, as long as the patient is stable and not actively bleeding from the placenta (i.e., partial separation), the safest approach is probably to close the abdomen and manage the patient conservatively (see later) or to transfer the patient to another facility that is in a better position to deal with the problem.

If anatomy is as expected and the decision is made to proceed to hysterectomy, this should be performed using careful systematic stepwise devascularization. It is essential to remember that many of the abnormal blood vessels seen supplying the area of percreta do not have normal vascular structure in terms of muscular media. Neovascularization leads to immature blood vessels that are extremely friable and do not contract well. Such thin-walled vessels need to be tied/clipped because coagulation frequently results in simply opening up a vessel that cannot contract down. The surgeons need to avoid making any holes in the peritoneal covering of the placenta, which is usually all that covers the highly vascular placental tissue. The most common error in this regard is traction or compression of the lower segment by an assistant, or puncture with a retractor, during efforts to expose the lateral pelvic side walls. The inadvertent puncture of the peritoneal covering of the placenta before uterine devascularization can turn a controlled, minimally bloody procedure into a hemorrhagic emergency.

The technique of the hysterectomy in a case of placenta percreta needs to be modified from that used in a hysterectomy for a nonpregnant patient and from a cesarean-hysterectomy for a nonpercreta-related reason. Because of the extreme vascularity (often massively enlarged collateral vessels and neovascularization), the blood supply to the uterus is frequently unrecognizable from that seen in other cases. The uterine arteries may not be easily identified, and there may be multiple other arterial feeders to the abnormally implanted placenta via vascular anastamoses originating from the superior and inferior vesical and rectal cascades. This will often require careful dissection of the retroperitoneal space, and judicious devascularization well clear of the sides of the uterus to avoid tearing through the friable and highly vascular tissue close to the placenta. The procedure for removal more often resembles a modified radical hysterectomy with removal of the uterus along with a significant portion of the broad ligament and lateral structures. Clearly, this type of surgery should be attempted only by a team who are experienced and familiar with the anatomy and radical surgery.

The approach to each case needs to be individualized. The principle of unhurried stepwise devascularization of the uterus is, however, paramount. Once this is achieved, intentional cystotomy should be performed to identify the extent of the adherent bladder.[64] This region can then simply be excised and left attached to the uterus, as long as it does not involve the trigone. The bladder can then be reconstituted. This technique avoids unnecessary bleeding that will occur with attempted dissection of an adherent bladder. In some cases, because of extreme vascularity, it is better to approach the uterine arteries posteriorly from the uterosacral ligaments and to work from posterior to anterior.

Supracervical Hysterectomy The use of supracervical hysterectomy in true placenta previa percreta is to be discouraged because, in most such cases, the placental tissue invades the cervix and attempts to remove the corpus of the uterus simply result in the disruption of huge vascular channels supplying the placenta. Until the uterus and cervix have been devascularized, any incision into the cervix will not help and will usually increase the blood loss. Even when the uterus appears to have been devascularized, care should be taken until the placenta has been separated from surrounding tissue. Collateral blood supply to the uterus and cervix via the bladder, bowel, pelvic side wall, or other organs attached to the placenta may still lead to massive hemorrhage from the uterus if a supracervical hysterectomy is attempted too early in the process.

Intraoperative Blood Product and Fluid Administration (See also Chapter 78)   A full discussion of blood product replacement strategies in massive hemorrhage in pregnancy is beyond the scope of this chapter. However, there are recent data, both from the battlefield and from civilian life, that suggest that patients with massive hemorrhage from trauma benefit from early and extensive use of FFP and platelets, in a 1:1:1 ratio with PRBCs, resulting in speedier correction of coagulopathy, a decreased need for PRBCs in the intensive care unit, and reduced mortality.[67,72,73] It should be emphasized that there are no comparable data for use of this ratio in obstetrics, but the empirical use of early FFP in a 1:1 ratio with PRBCs in massive obstetric hemorrhage is potentially a strategy that could be of benefit, and one deserving of investigation.

The associated potential acute metabolic effects of massive transfusion should also be kept in mind. These are discussed in the following paragraphs.

Hypothermia Hypothermia is common, mostly owing to the loss of thermal regulation that accompanies shock and evaporation from the exposed abdominal contents. This may be compounded by intravascular infusion of cold fluids and a cold environment. Warming of crystalloid solutions should be supplemented with blood warming when blood is rapidly infused through a central line and/or when the infusion rate is faster than 50 mL/kg/hr (60 mL/min in an adult). Acidosis and coagulopathy are most likely to develop secondary to hypoperfusion and hypothermia rather than from the massive blood replacement.

Citrate Toxicity By chelating calcium, citrate prevents clotting in blood products during storage. During massive transfusion, the dose of citrate infused is influenced primarily by the type of blood component and by the rate of administration. The infused citrate is rapidly metabolized and excreted by the liver and kidneys, respectively, with bicarbonate being the end product. Citrate toxicity can be manifested by hypocalcemia or neuromuscular or cardiac abnormalities. Laboratory evaluations for acid-base status and ionized calcium are strongly recommended prior to initiation of pharmacologic therapy, because calcium overtreatment is associated with significant morbidity and mortality.

Hyperkalemia Potassium leaks out of the red cell during storage (contents of 4–8 mEq of potassium per red cell unit in a 250- to 300-mL volume). This extracellular potassium load is only a transient effect, because once infused, potassium is taken up by red cells and/or eliminated by urinary excretion secondary to the bicarbonate production of the citrate metabolism. More often than not, recipients of massive transfusion actually become hypokalemic and may require potassium supplementation. Transfusion-associated hyperkalemia may be observed in patients with renal failure.

Use of Activated Factor VIIa There are many case reports and case series of the use of rFVIIa for control of hemorrhage in massive obstetric bleeding. The data are generally encouraging, although caution is still advised. In one study of 97 patients with primary PPH reported to the Northern European Registry[74] who were given activated rFVIIa for treatment of obstetric hemorrhage, improvement was reported in 80% after a single dose. The rFVIIa failed in 14% of patients. There were some serious adverse events noted related to rFVIIa administration: four cases of thromboembolism and one case of myocardial infarction.[74] Franchini and coworkers[75] published a review of 31 studies with 118 cases of massive PPH treated with rFVIIa. These cases included primary and secondary postpartum bleeding. A median dose of 72 μg/kg rFVIIa was reported to be effective in stopping or reducing bleeding in nearly 90% of the reported cases. The authors stated, however, that caution should be exercised in interpreting these results, because the studies from which they were derived were uncontrolled. Well-designed prospective clinical trials are still needed to determine the optimal dose, the effectiveness, and the safety of rFVIIa in this setting.

Guidelines have been published for the use of rFVIIa in nonobstetric hemorrhage, but there are no published protocols in widespread use for PPH. In 2008, a multidisciplinary group of Australian and New Zealand clinicians (obstetrics, anesthesia, and hematology) was convened by the manufacturer.[76] This group produced an opinion and guideline based on their experience and the published international literature on the use of rFVIIa[76] (Fig. 75–7). Persons using their guideline are asked to report the patient to their Registry at http://www.med.monash.edu.au/epidemiology/traumaepi/haemostasis.html

Persistent Hemorrhage Massive bleeding is always challenging to control in the setting of coagulopathy. Temporary compression of the infrarenal (or infradiaphragmatic) aorta can decrease blood loss and allow time for resuscitation

Postpartum hemorrhage (PPH) algorithm for management.

INTERVENTIONS
(Notify local transfusion specialist of possible need for activation of Massive Transfusion Protocol)

Medical:
• Treat: hemodynamic instability: hypothermia: acidosis
• Uterine massage/compression
• Uterotonic agents
• Coagulation studies and treat coagulopathy

Blood Component Therapy
(a) 4 U packed red blood cells (PRBCs)
(b) Coagulopathy correction
   • 4 U PRBCs
   • 4 U FFP
   • Single adult dose of platelets
(c) Repeat PRBCs, FFP and platelets
(d) Administer calcium as appropriate
Repeat (b) and (c) as necessary

Surgical (as available and appropriate)
• EUA and repair
• Uterine tamponade
• B–Lynch suture
• Arterial ligation
* Radiological arterial embolization

Checklist for 'off-label' use of rFVIIa in obstetrics
• Remember the high risk of thromboembolism
• Consider physical measures for thromboprophylaxis
• Monitor all women for signs of improvement and adverse events
* Report all patients receiving rFVIIa to the Haemostasis Registry (Monash University http://www.med.monash.edu.au/epidemiology/traumaepi/haemostasis.html)

with blood products. In cases in which massive hemorrhage is expected, exposure of the infrarenal aorta and femoral arteries can be accomplished before removal of the uterus, and these vessels can be temporarily occluded to provide pelvic isolation if massive blood loss is encountered.[64] In cases in which bleeding is uncontrolled and hypovolemia is so severe as to cause cardiac decompensation or dysrhythmia, aortic cross-clamping may be required as a temporary measure to allow resuscitation.

Pelvic Pressure Pack   In those cases in which there is refractory bleeding after removal of the uterus, placement of a pelvic pressure pack should be considered. This temporizing step has been shown to be effective in allowing hemodynamic stabilization of the patient and correction of coagulopathy.[77]

Internal Iliac Artery Embolization   In cases in which there is persistent bleeding that does not result in hemodynamic collapse but that require continued transfusion, the patient may be transported to the interventional radiology suite for arterial embolization. It must be stressed that this procedure is not suitable for the acutely unstable patient. A number of reports have suggested that this technique is the preferred method to manage persistent but noncatastrophic bleeding.[78,79] The authors are, however, personally aware of a number of cases of severe morbidity associated with complications from attempted selective embolization under emergency conditions in unstable patients. These patients suffered hepatic, pancreatic, splenic, gluteal, and limb ischemia that required emergency surgery and resulted in permanent injury. As with any salvage procedure, individualization is essential.

Temporizing Management in Uncontrolled Hemorrhage
In cases of uncontrolled massive pelvic bleeding at the time of hysterectomy, we have found that temporary cessation of surgery, infrarenal aortic clamping, pelvic packing, closure of the skin with towel clips, aggressive resuscitation with blood products, and patient warming can be life-saving. Persistent efforts to stop continued oozing from difficult to locate bleeding points may be counterproductive and lead to hypothermia, worsening coagulopathy, and hemodynamic collapse. If the bleeding can be slowed with temporizing methods to a point at which resuscitation is effective, waiting for reversal of coagulopathy before resuming surgery is frequently the best option. This may involve keeping the patient on the OR table, or if appropriate, transporting them to an adjacent intensive care unit until return to the OR is possible. The placement of wide-bore pelvic drains is important to warn of persistent significant bleeding.

Postoperative Management

Postoperatively, patients who have had prolonged surgery for placenta percreta with massive transfusion may be at risk for a number of problems. These include intra-abdominal

bleeding, pelvic thromboembolism, renal compromise, bowel ischemia, pulmonary edema, myocardial depression, transfusion-related acute lung injury and/or acute respiratory distress syndrome, Sheehan's syndrome, and infection. The postoperative management team should anticipate and be ready for such complications.

Conservative Management In some cases, it may be deemed that removal of the placenta and uterus is simply impossible or too dangerous to attempt. A number of case reports and small case series describe successful conservative approaches that have included closure of the uterus with the placenta in situ and the use of postoperative methotrexate,[80] selective arterial embolization,[81] and expectant management.[80] Without adequate randomized, controlled trials, there is considerable risk of publication bias (failure to publish bad outcomes), and caution is advised before employing these techniques liberally. There have been some reports of serious morbidity with conservative management[82,83] with subsequent massive hemorrhage and septic shock being the most serious of these complications. Although mortality for placenta accreta is now uncommon,[5] morbidity remains high; consequently, peripartum hysterectomy remains the current treatment of choice in most cases.

Management of Unexpected Placenta Accreta/Percreta at the Time of Delivery

Sometimes, accreta or percreta is discovered only at the time of delivery. Very occasionally, this will be at the time of vaginal delivery (often with a history of prior uterine surgery) and will be heralded by a retained placenta. In a stable patient with a retained placenta, it is always advisable to rule out the potential for accreta before proceeding with manual removal. In those cases in which there is a risk of accreta, it would be wise to delay any action that could potentially result in sudden onset of massive hemorrhage until all preparations have been made to deal with such an eventuality.

More usually, the placenta accreta or percreta is discovered at the time of repeat cesarean section. As underscored earlier, if the lower segment appears unusually distorted or thinned, as long as there is no active bleeding, the uterine incision should be delayed until all preparations have been made. In addition, there should be no attempt to remove the placenta if there is any suspicion of anything more than small areas of focal accreta.

Sometimes, there is discovery of a partially accretic placenta during cesarean section. Hemostasis may be achieved, if the accretic area is not too extensive, by placing sutures deep into the myometrial bed using a multiple 3-cm square suturing pattern over the area of maximal bleeding: Cho and colleagues[84] reported successful use of this technique in 23 cases of refractory bleeding with apparently normal uterine cavities on follow-up evaluation. Other methods have been attempted such as: inversion of the cervix into the uterine cavity, suturing the inverted cervical tissue over the area of bleeding placental bed,[85] and two parallel vertical compression sutures that are used to suture the anterior and posterior walls of the lower segment together to compress the bleeding placental bed.[86]

The overarching principle in such cases should always be to limit the hemorrhage as quickly as possible and to perform definitive surgery before the patient develops coagulopathy, hypothermia, or circulatory instability. A large part of the mortality and morbidity in these situations is related to unnecessary delay compounded by fruitless attempts to preserve the uterus. Recognition of the problem and decisive surgical action, combined with aggressive resuscitation and use of blood products, is required to deal with massive hemorrhage from accreta.

SUMMARY OF MANAGEMENT OPTIONS
Morbidly Adherent Placenta (Accreta, Increta, Percreta)

Management Options	Evidence Quality and Recommendation	References
Diagnosis of problem is difficult, but real-time ultrasound, color Doppler, and MRI in advance of labor/delivery may help.	III/B	52,54–59
Ensure intravenous access and resuscitation.	—/GPP	—
Options for treatment:		
• Leave in situ and monitor, provided no PPH.	III/B	80
• Administer methotrexate.	III/B	80
• Perform curettage once β-hCG levels become undetectable.	III/B	80
• Removal manually.	III/B	80

Treat any associated uterine atony as described under Primary Postpartum Hemorrhage.	—/GPP	—

β-hCG, β-human chorionic gonadotropin; GPP, good practice point; MRI, magnetic resonance imaging; PPH, postpartum hemorrhage.

PRIMARY POSTPARTUM HEMORRHAGE

Definition

Primary (early) PPH refers to excessive blood loss (>500 mL) during the third stage of labor or in the first 24 hours after delivery; thereafter, significant bleeding is referred to as secondary (late) PPH. Secondary PPH is discussed in detail in Chapter 76.

Significance

In the absence of anemia, blood loss up to 500 mL can be considered physiologic (i.e., within normal limits) and is unlikely to lead to cardiovascular compromise. For those who already have severe anemia (<5 g/dL), this amount of blood loss may induce heart failure or cardiovascular collapse.

   Maternal deaths due to obstetric hemorrhage are often associated with substandard care.[2] Accurate estimation of blood loss, prompt recognition and treatment of clotting disorders, early involvement of experienced clinicians, availability of anesthetic support, appropriate fluid replacement, and adequate physiologic monitoring are factors that govern maternal survival.[87]

Etiology

Approximately 80% to 90% of cases of primary PPH are associated with uterine atony. However, a combination of improvements in drug therapy for uterine atony and increased cesarean section rates in developed countries have resulted in uterine atony often taking second place to placenta accreta as a cause of morbidity.[88] Less common causes of PPH are upper (uterus, cervix) and lower (vagina, perineum) genital tract trauma, uterine inversion, retained placental tissue, acquired coagulopathy, and disseminated intravascular coagulation (DIC).

Management Options

Prevention

Major reductions in the frequency and severity of PPH have followed the adoption of routine prophylactic administration of oxytocics in the management of the third stage.[89] This consists of injections of synthetic oxytocin, methylergometrine, or a combination of the two (Syntometrine) with crowning of the head, delivery of the baby's anterior shoulder, or immediately after delivery.

   In high risk situations (multiple pregnancy, obstructed labor, or manual removal of the placenta), prophylaxis may be extended by the infusion of 40 units oxytocin in 500 mL of crystalloid over 4 hours. However, the effectiveness of this has not yet been proved by randomized, controlled trial, and many of those delivered by emergency cesarean section show evidence of loss of myometrial oxytocin receptors, reflected by a decrease in binding sites and very low mRNA concentrations (Table 75–4).[90]

Uterine Atony—Emergency Procedures

Fundal massage is the simplest treatment for uterine atony, is effective, and can be performed while initial resuscitation
FIGURE 75–8
Bimanual compression of the uterus and massage with abdominal hand will usually effectively control hemorrhage from uterine atony.

and administration of uterotonic drugs are in progress. If this fails to control hemorrhage rapidly, bimanual compression may be successful. A fist or hand is placed within the vagina such that the uterus elevated—stretching of the uterine arteries reduces blood flow (Fig. 75–8). The abdominal hand continues fundal massage, while also compressing the uterus. A urinary catheter may be inserted; not only does this aid assessment of fluid status, but also a distended bladder may interfere with uterine contractility. Controlled cord traction, early cord clamping, and prophylactic oxytocic administration reduce PPH by 500 to 1000 mL.

   Aortic compression is a temporizing procedure that can be used in life-threatening hemorrhage, particularly at cesarean section. A closed fist compresses the aorta against the vertebral column just above the umbilicus.[91] Sufficient force is required to exceed systolic blood pressure—this can be assessed by absence of the femoral pulses. Intermittent release of pressure to allow peripheral perfusion then enables bleeding intra-abdominal vessels to be identified.

   Following vaginal delivery, external aortic compression may be possible, owing to lax abdominal musculature.[92] A study of the hemodynamic effects of aortic compression on healthy nonbleeding women within 4 hours of vaginal delivery found that leg blood pressure was obliterated in 55%, with a substantial reduction in a further 10%. No significant elevation in systemic blood pressure was noted, and the authors concluded that this procedure is safe and a potentially useful maneuver for patient stabilization and transport. However, there have been no studies addressing the feasibility and efficacy of external aortic compression in patients with uterine atony following vaginal delivery; a high fundus may mean that adequate compression is impossible in this situation.

Uterine Atony—Medical Treatment

The prophylactic use of uterotonic drugs is an effective means of preventing PPH from uterine atony. Either

Summary of Risk Factors, Clinical Findings, and Recommendations for Management for the Major Causes of Primary Postpartum Hemorrhage

RISK FACTORS	CLINICAL FINDINGS	DIAGNOSIS	INITIAL ACTION	SECOND-LINE
Obstructed labor Multiple pregnancy, polyhydramnios Tocolytics	Soft, relaxed uterus	Uterine atony	Massage/compression Repeat oxytocin, either systemic or intramyometrial	Hemabate 250 μg, either systemic or intramyometrial
Obstructed labor Fetal distress Difficult or rotational forceps deliver PROM	Contracted uterus	Uterine rupture	Repair rupture if possible	Hysterectomy
Delayed second stage Ventouse/forceps delivery Precipitate labor	Contracted uterus	Cervical/vaginal tear	Repair tears	Vaginal tamponade
Retained placenta	Fundus not palpable abdominally	Uterine inversion	Reduce inversion by manual or hydrostatic pressure; tocolysis if necessary	Hysterectomy
Retained placenta	Fundus palpable	Retained products	Uterine exploration/curettage	Hysterectomy
Amniotic fluid embolism	Contracted uterus	DIC	Fresh frozen plasma, fresh whole blood transfusion	Heparin
Placental abruption	Bleeding from IV site or sutures			
Fulminating preeclampsia	Vaginal bleeding from abruption, generalized petechiae or bleeding from thrombocytopenia or DIC	Platelet count, PT, PTT, fibrinogen	Blood component therapy (platelets, fresh frozen plasma, cryoprecipitate)	

DIC, disseminated intravascular coagulation; PROM, premature rupture of membranes; PT, prothrombin time; PTT, partial thromboplastin time.

oxytocin alone (5 IU or 10 IU intramuscularly) or syntometrine (5 IU of oxytocin plus 0.5 mg ergometrine: not available in the United States) may be used. The combination drug is more effective but has more side effects.[93] These drugs are also first-line treatment for PPH due to atony.

Oxytocin binds to specific uterine receptors and intravenous administration (dose 5–10 IU) has an almost immediate onset of action.[94] The mean plasma half-life is 3 minutes, and therefore, to ensure a sustained contraction, a continuous intravenous infusion is necessary. The usual dose is 20 to 40 U/L of crystalloid, with the dose rate adjusted according to response. Plateau concentration is reached after 30 minutes. Intramuscular injection has a time of onset of 3 to 7 minutes, and the clinical effect is longer lasting, at 30 to 60 minutes. Compared with other agents, oxytocin has been found to reduce the need for manual removal of the placenta, regardless of the route of administration (IM versus dilute IV solution).[95]

Oxytocin is metabolized by both the liver and the kidneys. It has approximately 5% of the antidiuretic effect of vasopressin and, if given in large volumes of electrolyte-free solution, can cause water overload (headache, vomiting, drowsiness, and convulsions)—symptoms that may be mistakenly attributed to other causes. Water intoxication (which can be fatal) becomes a significant risk when 100 IU or more of Syntocinon has been given. Rapid administration of an intravenous bolus of oxytocin results in relaxation of vascular smooth muscle. Hypotension with a reflex tachycardia may occur, followed by a small but sustained increase in blood pressure. Oxytocin is stable at temperatures up to 25°C, but refrigeration may prolong shelf life.

Methylergonovine/ergometrine and its parent compound ergometrine result in a sustained tonic contraction of uterine smooth muscle via stimulation of α-adrenergic myometrial receptors.[96] The dose of methylergonovine is 0.2 mg, and of ergometrine is 0.2 to 0.5 mg, repeated after 2 to 4 hours if necessary. Time of onset of action is 2 to 5 minutes when given intramuscularly. These agents are extensively metabolized in the liver, and the mean plasma half-life is approximately 30 minutes. However, plasma levels do not seem to correlate with uterine effect, because the clinical action of ergometrine is sustained for 3 hours or more. When oxytocin and ergometrine derivatives are used simultaneously, PPH is therefore controlled by two different mechanisms, oxytocin producing an immediate response and ergometrine a more sustained action. In a recent large meta-analysis comparing ergometrine-oxytocin with oxytocin alone, a small but statistically significant reduction in PPH was found with blood loss greater than 500 mL. However, there were no differences between the two groups with greater degrees (>1000 mL) of blood loss.[96]

Nausea and vomiting are common side effects of ergometrine and its analogues. Vasoconstriction of vascular smooth muscle also occurs as a consequence of the α-adrenergic action. This can result in elevation of central venous pressure and systemic blood pressure, and therefore, pulmonary edema, stroke, and myocardial infarction. Contraindications include heart disease, autoimmune conditions associated

with Raynaud's phenomenon, peripheral vascular disease, arteriovenous shunts even if surgically corrected, and hypertension. Women with preeclampsia/eclampsia are particularly at risk of severe and sustained hypertension.

With intravenous administration, onset of action is almost immediate but is associated with more severe side effects. This route may be indicated for patients in whom delayed intramuscular absorption may occur (e.g., shocked patients). The drug should be given over at least 60 seconds with careful monitoring of blood pressure and pulse. Initial reports suggested that methylergonovine resulted in hypertension less frequently than ergometrine, but no difference has since been reported in randomized, controlled trials. Ergometrine and its derivatives are both heat- and light-sensitive, and should be stored at temperatures below 8°C and away from light.

PROSTAGLANDINS

$PGF_{2\alpha}$ results in contraction of smooth muscle cells.[97] Hemabate (Carboprost or 15-methyl-$PGF_{2\alpha}$) is an established second-line treatment for PPH unresponsive to oxytocic agents. It is available in single-dose vials of 0.25 mg. It may be given by deep intramuscular injection or by direct injection into the myometrium—either under direct vision at cesarean section or transabdominally/transvaginally after vaginal delivery. It is not licensed for the latter route and there is concern about direct injection into a uterine sinus, although it is commonly used in this way.[98] In addition, it may be more efficacious in shocked patients, when tissue hypoperfusion may compromise absorption following intramuscular injection.[99] A second dose may be given after 90 minutes, or if atony and hemorrhage continue, repeat doses may be given every 15 minutes to a maximum of 8 doses (2 mg), with ongoing bimanual compression and fundal massage.

Small case series have reported an efficacy of 85% or more in refractory PPH.[100,101] The largest case series to date has involved a multicenter surveillance study of 237 cases of PPH refractory to oxytocics and found that it was effective in 88%.[102] The majority of women received a single dose. When further oxytocics were given to treatment failures, the overall success rate was 95%. The remaining patients required surgery and many of these had a cause for PPH other than atony, including laceration and retained products of conception.

F-class prostaglandins cause bronchoconstriction, venoconstriction, and constriction of gastrointestinal smooth muscle. Associated side effects include nausea, vomiting, diarrhea, pyrexia, and bronchospasm. There are case reports of hypotension and intrapulmonary shunting with arterial oxygen desaturation; thus, they are contraindicated in patients with cardiac or pulmonary disease. Studies have demonstrated no significant difference between injectable carboprost compared with ergot compound injections in rates of PPH.[95] Carboprost is expensive and, therefore, unaffordable in many developing countries. Dinoprost ($PGF_{2\alpha}$) is more readily available; intramyometrial injection of 0.5 to 1.0 mg is effective for uterine atony. In randomized, controlled trials comparing intramuscular $PGF_{2\alpha}$ with ergometrine and combinations of oxytocin and ergometrine, no differences between interventions in measures of blood loss or need for transfusion were found. Low-dose intrauterine infusion via a Foley catheter has also been described, consisting of 20 mg dinoprost in 500 mL saline at 3 to 4 mL/min for 10 minutes, then 1 mL/min.[101] Intravenous infusion of dinoprost has not been shown to be effective.

PGE_2 (dinoprostone) is generally a vasodilatory prostaglandin; however, it causes contraction of smooth muscle in the pregnant uterus.[95] Dinoprostone is widely available on labor wards as an intravaginal pessary for cervical ripening. Rectal administration (2 mg given q2h) has been successful as a treatment for uterine atony—vaginal administration probably being ineffective in the presence of ongoing uterine hemorrhage. Owing to its vasodilatory effect, this drug should be avoided in hypotensive and hypovolemic patients. However, it may be useful in women with heart or lung disease in whom carboprost is contraindicated.[102] Case reports also document the use of gemeprost pessaries, a PGE_1 analogue, but with actions resembling those of $PGF_{2\alpha}$ rather than its parent compound. Both rectal and intrauterine administration have been reported.[103,104]

Misoprostol is a synthetic analogue of PGE_1 and is metabolized in the liver. The tablet(s) can be given orally, vaginally, or rectally. As prophylaxis for PPH, an international multicenter randomized trial reported that oral misoprostol was less successful than parenteral oxytocin administration.[105] Misoprostol may, however, be of benefit in treating PPH. In a recent meta-analysis, oral or sublingual misoprostol at a dose of 600 μg was found to be useful in PPH but did not demonstrate a benefit over other uterotonics.[106,107]

Two small case series have reported an apparently rapid response in PPH refractory to oxytocin and syntometrine, with rectal doses of 600 to 1000 μg. Sustained uterine contraction was reported in almost all women within 3 minutes of its administration.[107,108] A single-blinded, randomized trial of misoprostol 800 μg rectally versus Syntometrine intramuscularly plus oxytocin by intravenous infusion found that misoprostol resulted in cessation of bleeding within 20 minutes in 30 of 32 cases (93%) compared with 21 of 32 (66%) of cases when oxytocin was used.[109] There was no difference in the need for blood transfusion or the incidence of coagulopathy. In a meta-analysis analyzing the evidence for rectal misoprostol, no difference was found between rectal misoprostol and placebo or combinations of ergometrine and oxytocin, although there was a small decrease in blood loss greater than 500 mL.[95,110] Adverse effects include maternal pyrexia and shivering. Of note, misoprostol is inexpensive, is heat- and light-stable, has a long shelf-life, and does not require sterile needles and syringes for administration. It may, therefore, be of particular benefit in developing countries.

If bleeding continues despite adequate uterine contraction, exploration of the genital tract is necessary to detect other causes such as trauma (uterine, cervical, or vaginal tears) or retained placental tissue, particularly in cases in which risk factors were present (i.e., obstructed labor, fetal distress, difficult operative delivery, manual removal of placenta).

In the event that these measures fail to control bleeding, hysterectomy may be resorted to as a life-saving procedure. However, as with placenta accreta, there will be occasions

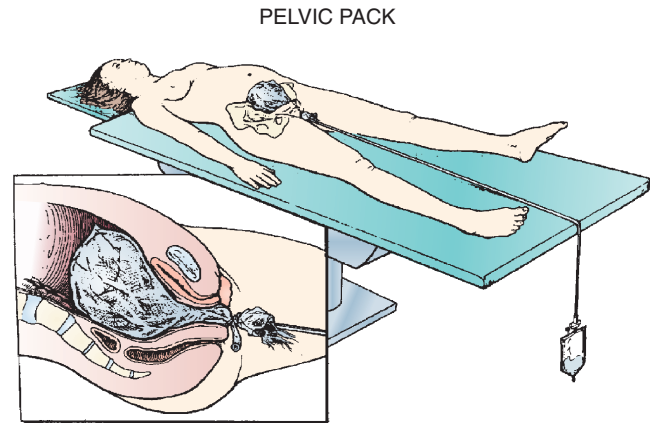
when conservation of the uterus is important to the patient, and alternative therapies may be attempted.

Uterine Tamponade

Uterine packing is a procedure long abandoned by many units, but more recently revived with case reports detailing new techniques for tamponade of the bleeding placental bed. Historically, uterine packing was performed using sterile gauze, with up to 5 m of 5- to 10-cm gauze introduced into the uterus, using either a specific packing instrument or long forceps.[111] Gauze is applied in layers from side to side, to give maximum pressure on the uterine wall, with the lower segment packed as tightly as possible. Indications for uterine packing include atony, placenta previa, and placenta accreta. Packs are generally left in situ for 24 to 36 hours, and prophylactic antibiotics are given.

Uterine packing fell out of use owing to concerns about concealed bleeding, infection, trauma, and problems in performing adequate packing. However, there is little documented evidence to support these concerns, and it has been suggested that the risks have been overstated.[111,112] Small studies have demonstrated that uterine packing is effective for controlling hemorrhage refractory to other medical treatment.[113,114] In a case series involving 20 women with PPH, failure of the uterine packing to control bleeding was demonstrated in only 3 women.[115]

The pelvic pressure pack, also known as the "mushroom," "umbrella," or "Logethotopulos" pack has been successfully used for control of posthysterectomy hemorrhage in both gynecologic and obstetric patients (Figs. 75–9 and 75–10). Although studies are limited, the success rate of the pelvic pressure pack in controlling post-hysterectomy bleeding in obstetrics has approached 86% after other therapies were attempted.[77]

Several inflatable mechanical devices have more recently been employed as alternative means of uterine tamponade (Fig. 75–11). Proponents of these devices state that their advantages are that they are rapid and easy procedures to perform and that whether they are working or not can be


PELVIC PACK

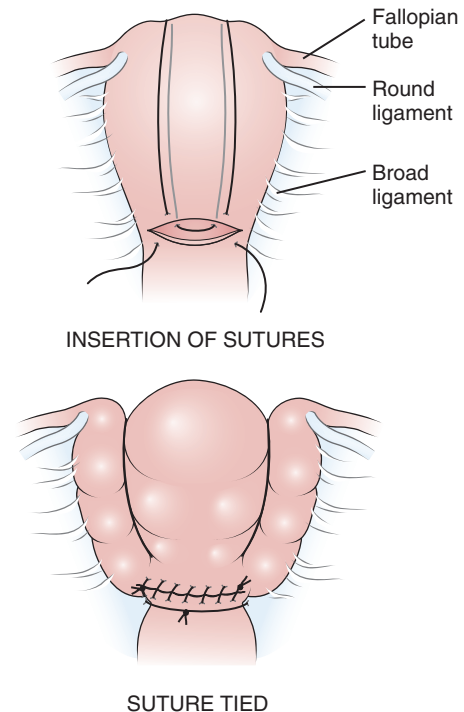
determined quickly and reliably. A Sengstaken-Blakemore tube has been utilized in this context.[112,116] The first report inflated the gastric balloon with normal saline, and the second inflated only the esophageal balloon. Balloon tamponade has also been performed with a Rusch urologic hydrostatic balloon catheter inflated with 400 to 500 mL of saline. This was effective in two women with hemorrhage due to morbidly adherent placentae.[117] In a more recent study, the Rusch hydrostatic balloon was effective in controlling PPH in seven out of eight women when inflated with 1000 mL of normal saline.[118] Balloon tamponade has also been accomplished with the use of a sterile condom inflated with up to 500 mL of solution tied to a Foley catheter.[119] Several case reports have demonstrated similar results with a Foley catheter inflated with 300 mL.[120] There is now commercially available a balloon designed specifically for obstetric use, the Bakri balloon.[121] These contain a central lumen that ends above the balloon, so that any blood still being lost above the level of the uterine tamponade can drain and be measured. These temporizing agents may allow for correction of coagulopathy in anticipation of surgical intervention. Often they lead to cessation of hemorrhage all together and should be used in cases in which future fertility is a consideration or in low-resource areas. A continuous oxytocin infusion and prophylactic antibiotic coverage are advised for these procedures. Of interest is the recent case report of PPH arrested with a Sengstaken-Blakemore catheter with cessation of bleeding after placement of the balloon. When examined with ultrasound, it was shown that the balloon was not within the uterine cavity and was inappropriately placed to have stopped the bleeding by direct compression on the endometrial surface. The authors suggest that balloon tamponade may actually work by compression of the vascular structures supplying the uterus.[122] This hypothesis deserves formal study.

UTERINE BRACE (COMPRESSION) SUTURE

The B-Lynch suture is a uterine brace suture designed to vertically compress the uterine body in cases of diffuse bleeding due to uterine atony.[123] In order to assess whether the suture will be effective, bimanual compression is applied to the uterus. If bleeding stops, compression with a brace suture should be equally successful. Single or multiple stitches may be inserted at the same time, and according to the shape, they may be called *brace suture*,[123] *simple brace*,[124] or *square sutures*.[125] The patient is placed in the Lloyd-Davies position on the operating table to enable assessment of vaginal bleeding. If delivery occurred via lower segment cesarean section, the incision is reopened. If delivery was vaginal and retained products have been excluded via manual exploration, hysterotomy is not necessary. The uterus is exteriorized, and response to bimanual compression assessed. If vaginal bleeding is controlled, the "pair of braces" suture is inserted using a 70-mm round-bodied needle with No. 2 chromic catgut suture (Fig. 75–12). The two ends are tied while an assistant performs bimanual compression and the lower segment incision is closed as normal. The authors described five cases in which the procedure was attempted with success in all cases. They included hemorrhage due to uterine atony, coagulopathy, and placenta previa. They state that the advantages of this method are its surgical simplicity

INSERTION OF SUTURES

SUTURE TIED


and that adequate hemostasis can be assessed immediately after its completion. Multiple case reports have described similar success with this procedure with and without other interventions including radiologic procedures or uterotonics.[126–128] Normal uterine anatomy has been demonstrated on follow-up.[129] Resumption of normal menses along with uncomplicated pregnancies following the B-Lynch procedure for PPH has also been described.[130] Unexpected occlusion of the uterine cavity with subsequent development of infection (pyometra) has been reported with the occlusive square stitch.[131]

A modification of the B-Lynch suture has been described[124,132] (Figs. 75–13 to 75–15). A less complex procedure is involved, consisting of two individual sutures, tied at the fundus. A lower segment incision is not necessary, and the authors suggest that more tension may be applied with individual sutures than with one continuous suture. They also describe tying the loose ends of the sutures together to prevent slippage laterally. A summary of published studies is the subject of a review article.[133]

Uterine Devascularization

Uterine devascularization is a long-practiced technique for PPH due to atony, placenta previa, and trauma.[134] These techniques can also be used prophylactically in women with pregnancies complicated with placenta accreta in the OR at

the time of delivery. Ligation of the uterine arteries and internal iliac arteries are described; ovarian artery ligation may also be performed, generally as an adjunctive procedure. Evidence for the efficacy of these techniques is based on published case series. The expertise and experience of individual obstetricians and the supporting staff of their units are important determinants of the surgical approach to PPH.

Bilateral Uterine Artery Ligation

The pregnant uterus receives 90% of its blood supply from the uterine arteries. Bilateral ligation (Fig. 75–16) of the ascending branches of the uterine artery is considered by its practitioners to be a simple, safe, and efficacious alternative to hysterectomy.[134] This procedure was originally utilized to control PPH at cesarean section. Mass ligation of the uterine artery branches and veins is performed 2 to 3 cm below the

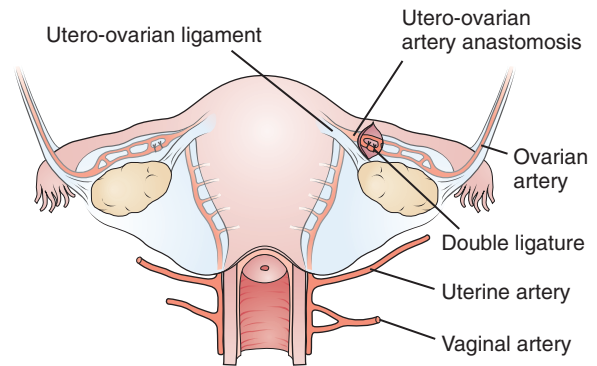
lower segment incision. The suture is placed laterally through an avascular window in the broad ligament and medially through almost the full thickness of the uterine wall to include the uterine vessels and 2 to 3 cm of myometrium. The vessels are not divided, and inclusion of myometrium avoids vascular damage and obliterates intramyometrial ascending arterial branches. An absorbable suture such as No. 1 Dexon or Vicryl on an atraumatic needle is used. Nonabsorbable and figure-of-eight sutures are avoided because they are considered to increase the risk of arterio-venous sinus formation. If vaginal delivery has occurred, the bladder may need to be adequately mobilized prior to suture insertion to avoid ureteric injury.

The largest case series of uterine artery ligation was published in 1995.[135] This was a 30-year study involving 265 patients with postcesarean PPH of greter than 1000mL, refractory to oxytocics, methylergonovine, and carboprost. Bilateral uterine artery ligation failed to control hemorrhage in only 10 women, giving a 96% success rate. An immediate effect was reported, with visible uterine blanching; myometrial contractions sometimes occurred, but even if the uterus remained atonic, hemorrhage was usually controlled. No long-term effects on menstrual patterns or fertility have been reported.[135,136] In women who have subsequently undergone repeat cesarean section, the uterine vessels appeared to have recanalized.

Failure of this procedure is most commonly associated with placenta previa, with or without accreta. More recently, low bilateral uterine artery ligation has been described for ongoing bleeding from the lower segment in these cases. A series of 103 patients involving stepwise uterine devascularization reported a 75% success rate with conventional uterine artery ligation.[136] Success was highest with uterine atony and abruption. Of 7 cases of placenta previa with/without accreta, hemorrhage continued in 4 women. A further bilateral ligation was performed 3 to 5 cm below the first sutures, following further mobilization of the bladder. Ligation therefore includes the ascending branches of the cervicovaginal artery and the uterine artery branches supplying the lower segment and upper cervix. This procedure was effective in all cases. A vaginal route for uterine artery ligation has also been described with moderate success.[137] This intervention includes incising the anterior cervix near the cervicovaginal fold with the bladder retracted. The uterus is than gently pulled to the contralateral side of the intended suture placement. A single absorbable suture is than placed around the vessels while including myometrial tissue. Although this technique may be quick and minimally invasive, more studies are required to prove its utility in PPH.

Unilateral or bilateral ligation of the ovarian artery may be performed as an adjunct to ligation of uterine arteries (Fig. 75–17). The ligature is tied medial to the ovary to preserve ovarian blood supply. This was the final phase of the stepwise uterine devascularization approach described previously.[136] Following uterine artery ligation, 13 of 96 cases that did not involve placenta previa/accreta had ongoing bleeding. Of these, 7 responded to unilateral ovarian artery and 6 to bilateral ovarian artery ligation. All patients in this case series, therefore, avoided hysterectomy.

FIGURE 75–17

Area for ovarian artery ligation. Two free ties of 2-0 silk suture are used to ligate the ovarian artery bilaterally near its anastomosis with the uterine artery. An avascular area of mesovarium near the junction of the utero-ovarian ligament with the ovary is the site chosen. (Reproduced from Pauerstein C [ed]: Clinical Obstetrics. New York, Wiley, 1987.)


Bilateral Internal Iliac Artery Ligation

Internal iliac artery ligation was first performed as a gynecologic procedure by Kelly in 1894.[138] He termed this "the boldest procedure possible for checking bleeding" and assumed that the blood supply to the pelvis would be completely arrested. From the 1950s, internal iliac ligation was increasingly performed for gynecologic indications, mostly for carcinoma of the cervix. Ligation was still considered to shut off arterial flow, despite the fact that necrosis of pelvic tissues had not been observed. In the 1960s, Burchell reported cutting a uterine artery following bilateral internal iliac ligation in order to demonstrate the absence of flow. However, to the surprise of those present, blood still flowed freely. This observation led to extensive studies of the hemodynamic effects of internal iliac ligation. These were performed on gynecological patients, but are quoted widely in the obstetric literature.[138,139] Aortograms performed between 5 minutes and 37 months postligation demonstrated an extensive collateral circulation, with blood flow throughout the internal iliac artery and its branches. Three collateral circulations were identified: the lumbar and iliolumbar arteries; the middle sacral and lateral sacral arteries; and the superior rectal and middle rectal arteries. Ligation above the posterior division resulted in collateral and, therefore, reversed flow in its iliolumbar and middle sacral branches (Fig. 75–18). Ligation below the posterior division caused collateral flow only in the middle hemorrhoidal artery, again in a retrograde direction. Flow to more distal branches of the internal iliac artery was normal.

A second study involved intra-arterial pressure recordings before and after ligation.[138] Following bilateral ligation, distal arterial pulse pressure decreased by 85%, with a 24% reduction in mean arterial pressure. In addition, a 48% reduction in blood flow resulted following ipsilateral ligation. The authors concluded that internal iliac ligation controls pelvic hemorrhage mainly by decreasing arterial pulse pressure. The smaller diameter of the anastamoses of the collateral circulation was proposed to explain this
phenomenon. The arterial system was considered transformed into a venous-like circulation, with clot formation able to arrest bleeding at the site of injury. These studies have been extensively quoted; however, similar studies have not been performed in postpartum women. A single case report found no change in uterine artery Doppler waveform velocity before and 2 days after bilateral internal artery ligation performed to control hemorrhage due to uterine atony.[140]

Internal iliac artery ligation is a more complex procedure than uterine artery ligation. The bifurcation of the common iliac artery is identified at the pelvic brim, and the peritoneum opened and reflected medially along with the ureter.[132] The internal iliac artery is identified, freed of areolar tissue, and a right-angled clamp passed under the artery. Two ligatures are tied 1 to 2 cm apart. The artery is not divided. Both the uterine and the vaginal arteries are branches of the anterior division, and ligation should if possible be distal to the

origin of the posterior division. This is more efficacious and does not compromise blood supply to the buttocks and gluteal muscles. A retroperitoneal approach may be used when hemorrhage has followed vaginal delivery. Complications of this procedure include damage to the internal iliac vein and ureter. Tissue edema, ongoing hemorrhage, and the presence of a large atonic uterus may make identification of anatomy difficult and prolong operating time. Incorrect identification of the internal iliac artery may result in accidental ligation of the external or common iliac artery, resulting in lower limb and pelvic ischemia. Femoral or pedal pulses should, therefore, be checked before and after the procedure. Recanalization of ligated vessels may occur, and successful pregnancy has been reported whether or not recanalization has taken place.

Demonstration of the extensive collateral circulation explains why the efficacy of internal iliac ligation is less than for uterine artery ligation. Success rates are generally reported to be approximately 40%.[132] A 1985 study reported a success rate of 42% in a series of 19 patients, with hysterectomy necessary in the remainder.[65] Morbidity was higher than for a group of patients in whom hysterectomy was performed as a primary procedure; mean blood loss was 5125 mL for patients with unsuccessful internal iliac artery ligation followed by hysterectomy and 3209 mL for those undergoing hysterectomy alone. Complications associated with unsuccessful arterial ligation in this series were associated with delay in instituting definitive treatment (hysterectomy) rather than as a consequence of arterial ligation. These authors consider that there is only a limited role for this procedure in the treatment of PPH: restricted to hemodynamically stable patients of low parity in whom future fertility is of paramount concern.

Arterial Embolization

Uterine devascularization by selective arterial embolization has recently gained popularity in centers with expertise in interventional radiology. Access is via the femoral artery and the site of arterial bleeding is located by injection of contrast into the aorta. The bleeding vessel is selectively catheterized, and pledgets of absorbable gelatine sponge injected.[141] These effect only a temporary blockade and are resorbed within approximately 10 days. If the site of bleeding cannot be identified, embolization of the anterior branch of the internal iliac artery or the uterine artery is performed.

In published studies, uterine atony and pelvic trauma are the major indications for embolization, and overall success rates of 85% to 100% are reported.[142] Higher failure rates are associated with placenta accreta and procedures performed following failed bilateral internal iliac artery ligation.[143] Subsequent successful pregnancies have been documented.

Compared with surgical devascularization, embolization has several advantages. It is less invasive and generally results in visualization of the bleeding vessel. Occlusion of distal arteries close to the bleeding site is possible, thereby reducing the risk of ongoing bleeding from a collateral circulation.[141] The efficacy of embolization can be assessed immediately, and repeated embolization of the same or different arteries can be performed. Disadvantages are the

necessity of rapid availability of specialist equipment and personnel and the need for transfer of a hemorrhaging patient to the radiology suite. Embolization may also be a time-consuming procedure, generally requiring between 1 and 3 hours, although with hemostasis of the major bleeding vessel frequently established within 30–60 minutes. Pelage and colleagues[143] evaluated the role of selective arterial embolization in 35 patients with unanticipated PPH. Bleeding was controlled in all except one who required hysterectomy for rebleeding 5 days later. All women in this series who had successful embolization resumed normal menstruation. Similar findings have been reported in other studies.[144,145] Patients with life-threatening hemorrhage have also been successfully treated with arterial embolization. A 1998 case series included 27 women with life-threatening bleeding, 12 of whom were intubated and ventilated, and 4 were successfully resuscitated following cardiac arrest.[143] Fever, contrast media renal toxicity, and leg ischemia are rare but reported complications of this procedure.

A variation on this theme is the prophylactic placement of inflatable balloon catheters in internal iliac arteries of patients who are expected to bleed excessively at the time of surgery, for example, elective cesarean delivery in a patient with placenta percreta. In this situation, the patient is taken to the interventional radiology suite prior to surgery and the balloon catheters are placed but not inflated. Following delivery of the baby, the catheters can be immediately inflated. Such catheters can be deflated at the completion of surgery and left in situ during the next 24 to 48 hours to be reinflated if required. The use of prophylactic occlusion balloons in the internal iliac arteries before selective embolization has shown a greater than 80% success rate for control of PPH.[142,145] Various reports have confirmed these findings with normal resumption of menses within 3 to 6 months and subsequent uncomplicated pregnancies.[146–148] However, our local experience with this technique has not been favorable (see earlier).

Hysterectomy

Peripartum hysterectomy is frequently considered the definitive procedure for obstetric hemorrhage, but is not without complications. In the long term, the loss of fertility may be devastating to the patient. In the emergency situation, the major concern is that peripartum hysterectomy can be a complex procedure, owing to ongoing blood loss and grossly distorted pelvic anatomy due to edema, hematoma formation, and trauma. Pritchard[149] showed an average blood loss of 1435 mL when hysterectomy was performed at the time of elective repeat cesarean section. At emergency hysterectomy for postpartum bleeding, mean blood loss attributed to the procedure was 2183 mL, with a mean loss of 2125 mL by the time of decision for hysterectomy.[150] Adequate hemostasis is not always achieved, and further procedures may be necessary. Uterine artery embolization has been performed for ongoing bleeding following hysterectomy, both with and without success.[143,151] Relook laparotomy may also be required; this has been reported in up to 13% of patients.[152] The incidence of febrile morbidity is high, with rates of 5% to 85% in different series.

Hysterectomy is indicated if conservative procedures such as embolization or uterine devascularization fail to control bleeding. The time lapse between delivery and successful surgery is the most important prognostic factor. If the primary procedure fails, it is recommended that hysterectomy is performed promptly, without attempts at another conservative measure.[151] In severely shocked patients with life-threatening hemorrhage, hysterectomy is in most circumstances the first-line treatment.[132] Hysterectomy may, therefore, be associated with a higher mortality than other surgical procedures.[151,152]

Uterine atony is the major indication for peripartum hysterectomy, although other factors such as placenta accreta and abruption are frequently present.[151] Many studies have described the profound hemorrhage associated with placenta previa, with one analysis[153] revealing blood loss greater than 3000 mL in 23% of patients with this condition. In this series, approximately 10% of patients required greater than 5 units of blood products and hysterectomy.[153] Surgical reexploration secondary to postoperative bleeding is needed in up to 7% of patients with placental invasion.[153,154] Other indications for peripartum hysterectomy include placenta previa, uterine rupture, and other genital tract lacerations. Trauma sustained at vaginal delivery may result in concealed bleeding and is, therefore, associated with a worse outcome. Hemorrhage at cesarean section is more readily recognized and more promptly remedied.

A subtotal hysterectomy can generally be performed if bleeding is from the uterine body. It is generally simpler than a total hysterectomy—the cervix and vaginal angles can be difficult to identify in women who have labored to full dilation. There is also less risk of injury to the ureter and bladder. One study reported the incidence of urinary tract injury to be 13% for subtotal hysterectomy compared with 25% for total hysterectomy.[152] If placenta accreta is suspected, the use of prophylactic ureteral stents may help determine the location of the ureters and assist with difficult dissection planes. In addition, perioperative intentional cystotomy may improve visualization of bladder invasion. If bleeding is from the lower segment (placenta previa, trauma), the cervical branch of the uterine artery must be ligated, and a total hysterectomy will be necessary. Anesthetic considerations include the need for general endotracheal anesthesia in anticipation of prolonged surgical time, placement of a lumbothoracic epidural catheter for postpartum pain relief, and readiness for massive blood transfusion. Prophylaxis for thromboembolism should also be considered and initiated before surgery. Compression stockings placed before induction of anesthesia and prophylactic low-molecular-weight heparin or unfractionated heparin are also acceptable.[64]

The need for close postpartum observation cannot be overemphasized, and in most cases, these patient should recover in an intensive care unit setting. Frequently, because of prolonged operative time combined with massive transfusion, there is a risk for laryngeal edema, pulmonary edema, delayed extubation, and prolonged ventilation. Continuous vital sign determination and pulse oximetry along with hourly urine output measurement are warranted after significant hemorrhage and blood or product replacement. Patients with periods of prolonged hypotension during surgery should also be followed postoperatively for evidence of the partial or full Sheehan syndrome.

SUMMARY OF MANAGEMENT OPTIONS
Primary Postpartum Hemorrhage

Management Options	Evidence Quality and Recommendation	References
Prevention		
Active management of third stage is advised for all women, comprising all the following:	Ia/A	19,20
• Administer oxytocic agent (oxytocin or Syntometrine).	Ib/A	19,20
• Clamp and cut cord.	—/GPP	—
• Use controlled cord traction (no randomized, controlled data to show that it reduces PPH rates).	III/B	27
No evidence that oxytocin infusion in high risk settings improves outcome.	III/B	90
Treatment		
Initial emergency measures:	—/GPP	—
• Rub-up contraction.		
• Administer intravenous oxytocin (5–10 units) (ergometrine 0.25–0.5 mg IM is an alternative but should be avoided in hypertensive patients).		
• Establish intravenous access.		
• Cross-match blood.		
General management options for major obstetric hemorrhage.	See Chapter 78	
Specific measures:		
• Examine uterus to confirm atony is cause.	—/GPP	—
• Confirm placenta appears intact or perform uterine exploration and removal of placental fragments if suspicion of incomplete third stage.	—/GPP	—
• Bimanual compression is a temporary measure.	—/GPP	—
• Commence IV oxytocin infusion.	III/B	95
• Give further IV bolus of oxytocin.	III/B	95
• Rule out trauma to vagina, cervix, or uterus.	—/GPP	—
• Use uterine packing or balloon tamponade.	III/B	112,116–123
• Prostaglandin options include:		
• 15-Methyl-PGF$_\alpha$ (0.25 mg) IM or PGF$_{2\alpha}$ (0.5–1.0 mg) into uterine muscle.	III/B	97–102
• Rectal misoprostol 1000 µg.	III,Ib/B,A	107,108
• Use B-Lynch sutures or simpler alternatives.	III/B	123–130
• Perform arterial embolization if units have resources and experience.	III/B	141–148
• Perform bilateral uterine artery ligation.	III/B	138,139
• Perform bilateral internal iliac artery ligation.	III/B	132
• Perform bilateral ovarian artery ligation.	III/B	136
• Perform hysterectomy.	III/B	132,151–153
• Consider Cell Saver.	III/B	69

UTERINE INVERSION

Definition

Uterine inversion is the folding of the fundus into the uterine cavity in varying degrees. In first-degree inversion, the wall extends as far as, but not through, the cervix. In second-degree inversion, the fundus prolapses through the cervix but not out of the vaginal opening. Third-degree inversion involves prolapse of the fundus outside of the vagina, and fourth-degree prolapse is the complete prolapse of both uterus and vagina. *Acute* inversion occurs within the first 24 hours after delivery; *subacute* refers to inversion between 24 hours and 30 days after delivery, and *chronic* inversion is inversion after 30 days.

Etiology

Baskett[155] reported on a 24-year series involving 125,081 deliveries. The incidence was 1 in 3737 for vaginal deliveries and 1 in 1860 for cesarean deliveries. Inversion of the uterus is principally a complication of the third stage of labor. The pathophysiology of puerperal inversion requires that there be relaxation of the lower uterine segment and simultaneous downward movement of the fundus. To completely invert the uterus, there must be uterine contractions of sufficient force occurring at the correct time to force the prolapsing fundus through the open cervix. The main predisposing factors for puerperal inversion are a fundally implanted placenta, flaccidity of the myometrium around the implantation site, and a dilated cervix. A number of other associations have been reported. These include intrapartum fundal pressure (Credé's maneuver), morbidly adherent placenta, fundal implantation of the placenta, chronic endometritis, fetal macrosomia, trials of vaginal birth after cesarean delivery (VBAC), intrinsic myometrial weakness/damage, uterine sacculation, precipitate labor, acute tocolysis with potent uterine relaxant or anesthetic drug, and idiopathic factors. Although, in some cases, a short umbilical cord and/or incorrect cord traction with failure to support the uterus during placental delivery may play a role in the inversion, the claim that mismanagement of the third stage is the cause of most inversions is unsubstantiated. In fact, mismanagement may not be a factor in most inversions that occur despite active management of the third stage. Some inversions have occurred without cord traction or through the hysterotomy before placental removal at the time of cesarean section. Almost every vaginal delivery is accompanied by postpartum uterine flaccidity and some degree of cord traction. Fundal implantation is very common and inversion so infrequent that for it to occur must require a number of coincident factors all acting simultaneously.

Diagnosis

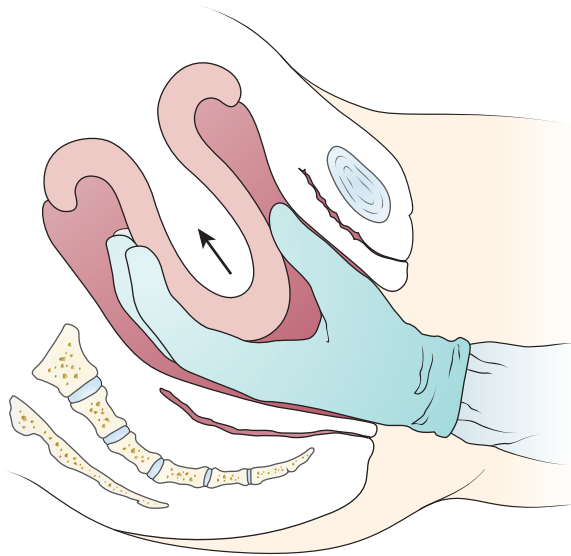
The diagnosis of uterine inversion is established clinically, except in rare cases. Usual observations in a complete inversion include early-onset PPH accompanied by the appearance of a vaginal mass followed by various degrees of maternal cardiovascular collapse. In approximately 60% to 70% of cases, the placenta is still attached at the moment of inversion. The extent of the reported bleeding is variable and depends on the degree of prolapse. Frequently, the degree of shock is reported to be out of proportion to that attributable to the observed blood loss. Theoretically, this may be neurogenic shock due to a parasympathetic outflow from stretching peritoneum or reproductive organs. The underestimation of blood loss at the time of delivery may, however, be an important confounder, and in the absence of hard data in this regard, the proportionate contributions of blood loss and parasympathetic outflow are difficult to assign. In the face of tachycardia, one would be hard-pressed to state that the shock was the result of a parasympathetic discharge. Regardless of the exact mechanism, most cases will respond to prompt uterine replacement and fluid resuscitation. The physical examination in cases of partial inversion (first-degree) can be very misleading. Abdominal or combined abdominopelvic examination often reveals a mass suggestive of a uterine or pelvic tumor. Because the adnexa are compressed together in the midline along with the partially inverted fundus, which is partially collapsed into the lower segment of the uterus, there is a globular and somewhat irregular, central pelvic mass that to the unsuspecting may feel like a poorly contracted 22- to 24-week-sized uterus. The cervix is still palpable and can be visualized (if the bleeding is not too excessive). Often, the only way to make the diagnosis is with ultrasound or if the inversion progresses.

In second-degree inversion, the inverted portion of the fundus remains in the vagina, having passed through the cervix. In such cases, the examiner is unable to palpate the uterine fundus on abdominal examination and cannot see or feel the cervix during pelvic examination.

None of these are pathognomonic signs of inversion, however, because severe uterine atony with heavy vaginal bleeding may preclude observation of the cervix, and a very atonic uterus may difficult to palpate (especially if the patient is obese).

Owing to the potential complexities of presentation, prompt ultrasonographic scanning is the most helpful technique in uncertain cases. If accompanying hemorrhage or shock is sufficiently alarming to prompt immediate surgical exploration, the correct diagnosis may be established only at laparotomy.

Management Options

Management should be tailored to addressing the main risks of inversion, which are hemorrhage and cardiovascular collapse. Institution of aggressive blood product and fluid replacement, replacement of the uterus, and administration of potent uterotonics to keep the uterus contracted and prevent re-inversion are needed. If possible, the placenta should not be removed before uterine replacement because this exacerbates blood loss.[156] Replacement can usually be accomplished manually by placing a hand in the vagina with the fingers placed circumferentially around the prolapsed fundus. The last region of the uterus that inverted should be the first to be replaced (Fig. 75–19). This avoids multiple layers of uterine wall within the cervical ring. Uterine relaxation may be necessary, with β-sympathomimetic agents,


magnesium sulfate, or low-dose nitroglycerine.[157] Caution should be exercised with the use of nitroglycerin, which may exacerbate hypotension and tachycardia.[158] General anesthesia and use of halogenated gases may be needed to provide full uterine relaxation. Intravaginal hydrostatic replacement is an alternative technique that was at one time promulgated but, in our opinion, is difficult and impractical.[159] Improvement of the vaginal seal by use of a Silastic ventouse cup connected to the infusion tubing has been reported.[160] If a tightly contracted cervical ring prohibits vaginal replacement of the fundus, surgical options may have to be exercised. These include incising the ring via a vaginal approach, and both anterior and posterior vaginal incisions have been described with subsequent repair once the fundus has been replaced.[161] If these measures fail, at least two abdominal procedures have been described at the time of laparotomy. The first involves stepwise traction on the funnel of the inverted uterus or the round ligaments, using ring or Allis forceps reapplied progressively as the fundus emerges (Huntington's procedure). If this fails, a longitudinal incision is made posteriorly through the cervix, relieving cervical constriction and allowing traction on the round ligaments as in the Huntington procedure combined with stepwise replacement of the uterus from below with subsequent repair of the incision from inside the abdomen (Haultain's procedure).[162,163] Tews and associates[164] have reported a new abdominal, uterus-preserving approach for such cases. At laparotomy, the bladder is dissected off the cervix and the vagina entered by a longitudinal incision. Two fingers are advanced through this incision, above the invaginated uterine body, and exerting counterpressure with the other hand, the inversion can be reversed. Uterotonic drugs are then given immediately to maintain uterine contraction and to prevent reinversion. Majd and coworkers[165] recently reported a case of recurrent uterine inversion managed with the Bakri SOS balloon catheter. Alternative techniques use a combination of vaginal pressure with counterpressure applied via laparoscopy[166] or the use of the ventouse to extract the fundus at laparotomy.[167]

Once the uterus has been replaced, all uterine relaxant drugs should be stopped and manual removal of the placenta should follow. With early diagnosis and prompt replacement of the fundus, laparotomy and hysterectomy can be avoided.[162,163] In many cases, delay in definitive management is what leads to increased edema, blood loss, and associated morbidities.

Most authorities would recommend antibiotic use after manual replacement, although specific evidence of the utility of this is lacking.

UTERINE RUPTURE

Definition

Uterine rupture (defined here as a full-thickness tear through myometrium and serosa) is an uncommon obstetric complication, which may occur in a previously unscarred uterus or, more commonly, in one with a previous cesarean section or full-thickness gynecologic uterine incision scar. The overall rate varies from 2 to 8 per 10,000 deliveries.[168] Different terms are sometimes used to describe partial separation (dehiscence) or healed defects (windows) of uterine scars. Asymptomatic (bloodless) dehiscence of a previous cesarean section scar may occur during subsequent vaginal delivery or may be seen at the time of repeat cesarean section in women who have not labored. The term "uterine rupture" should be reserved for those cases with complete separation of the wall of the pregnant uterus, with or without expulsion of the fetus, and which may acutely endanger the life of the mother and/or fetus.[169]

Etiology

The approximate incidence of uterine rupture is 0.05%[170] to 0.086%[171] of all pregnancies. Uterine rupture is rarely encountered in developed countries in the absence of previous surgery, but is more commonly seen when iatrogenically caused by the use of oxytocics in the presence of a uterine scar.[172] Taylor and colleagues,[173] in a multicenter study, showed that the risk of uterine rupture in patients undergoing a trial of labor after previous cesarean section was significantly higher when vaginal PGE_2 was used (6/58 [10.3%] vs. 8/732 [1.1%]). In terms of oxytocin and the risk of VBAC, Cahill and associates[174] have recently shown that doses of oxytocin in excess of 20 mU/min increased the risk of uterine rupture fourfold or greater in women attempting VBAC.

Uterine rupture is more frequent when women are left for prolonged periods in obstructed labor. This is more likely to occur in developing countries, although the situation has improved greatly in recent years following improvements in medical facilities, transport systems, organization of medical care, and levels of patient education.[175,176] However, unrelieved obstructed labor remains the major cause of uterine rupture, usually occurring in grand multiparous patients when the fetus is macrosomic or abnormal or when malpresention occurs.

Uterine rupture can occur in nulliparous patients, but the risk is relatively low, accounting for less than 10% of cases, despite the higher incidence of obstructed labor in nulliparous patients compared with multiparae. Maternal and fetal outcomes are usually worse in women with an unscarred uterus than in those with a previous uterine scar whose delivery is planned.[177] If patients with a uterine scar fail to seek medical attention and labor at home, their outcome tends to be worse.[178]

Rupture of an unscarred uterus is frequently related to obstetric intervention. This includes use of uterotonic drugs for induction or augmentation of labor, midcavity forceps delivery, or breech extraction with internal podalic version.[170,171] Prolonged labor in the presence of cephalopelvic disproportion, malpresentation, or malposition may also cause uterine rupture. External trauma may result in uterine rupture at any gestation. Grand multiparity also increases the risk.

Rupture of a previously scarred uterus is more common than rupture of the intact uterus.[170,171] The overall risk of uterine rupture for women attempting a trial of labor following lower segment cesarean section is 0.9% to 1%,[178,179] but higher if the trial of labor is unsuccessful.[179] A previous classic cesarean section has a risk of rupture of 3% to 6%, increased to 12% if a trial of labor takes place. Spontaneous rupture of a classical cesarean section scar has been reported as early as 15 weeks' gestation.[180] Use of uterotonic drugs (prostaglandins, oxytocin, and misoprostol) in the presence of a cesarean section scar is associated with an increased risk of rupture. The risks are difficult to quantify, and their use in patients undergoing VBAC is controversial. Some data indicate that induction of labor and cervical ripening with prostaglandins (PGE_1 and PGE_2) may carry a high risk of uterine rupture.[181] Gynecologic uterine surgery including laparoscopic myomectomy is also considered a strong risk factor for uterine rupture. Rates of rupture after myomectomy have been found to be as high as 1%.[182] Risk of rupture may have been minimized in this series because greater than 50% of these patients underwent cesarean delivery before labor. Although the posterior fundus is considered the weakest part of the uterus, most ruptures occur in the lower anterior segment during labor and at the fundus during prelabor-associated ruptures.[183] Late complications of uterine hysteroscopy include uterine rupture.[184] Spontaneous uterine rupture has been documented in multiparous women with placenta accreta. Although rare, this has also been reported in primiparous women with placenta accreta.[185,186] Congenital uterine anomalies are also a risk factor for uterine rupture, including those related to diethylstilbestrol exposure. In one series, five cases of rupture were discovered in primiparous women with bicornuate uteri.[187]

Some literature suggests that an interdelivery interval of less than 24 months' gestation was associated with a two- to threefold increase in the risk of uterine rupture compared with an interval of greater than 24 months.[188] The same study demonstrated a twofold increase in rupture rates when single-layer closure was used to reapproximate the uterine incision in the previous cesarean delivery. Conversely, other studies demonstrate no difference in maternal or neonatal outcomes with single- or double-layer closure techniques.[189–191] The role of postpartum fever has also been investigated as a risk factor for rupture. In one study, the odds of rupture were four times greater than controls in women with postpartum febrile morbidity.[192] Although fetal macrosomia decreases the likelihood of successful VBAC, multiple studies report no difference in rates of uterine rupture.[193–196] Rupture may occur antenatally or intrapartum and may commonly be first suspected postpartum.

Diagnosis

The most common clinical sign in labor is the sudden onset of fetal decompensation reported in 81% of cases,[168,193]

frequently with prolonged fetal bradycardia.[189] The onset of any fetal heart rate abnormality in a laboring VBAC patient should be regarded very seriously and rupture should be excluded. Abdominal pain, abrupt arrest of contractions, and retraction of the fetal presenting part have also been reported but are less commonly seen as the initial sign of a rupture. Intrauterine catheter monitoring has not proved reliable for prediction of impending uterine rupture, and there is poor correlation between uterine contractility patterns and rupture.[197,198] Bleeding is frequently intraperitoneal or retroperitoneal into the broad ligament rather than revealed vaginally. Over 50% of cases are first diagnosed after delivery, when intractable hemorrhage follows precipitous, spontaneous, or instrumental vaginal delivery. Alternatively, if bleeding is concealed, profound shock may occur before rupture is suspected. Uterine rupture should be considered in every obstetric patient with hemorrhagic shock in whom the cause is not immediately apparent. Vaginal bleeding in a case of obstructed labor is diagnostic but may be hidden above an impacted presenting part.[199] Catheterization of the bladder during labor will frequently reveal blood-stained urine, but fresh arterial blood indicates that the rupture actually involves the bladder.[200]

Once uterine rupture has occurred, the fetus usually extrudes through the defect and placental separation will begin. Immediate maternal cardiovascular collapse is a rare event unless the tear extends into the broad ligament vessels. Usually, maternal condition deteriorates progressively as bleeding continues and eventually leads to collapse only if the situation is left untreated. Examination of the abdomen will most commonly reveal generalized tenderness, easily palpable fetal parts, and absent or agonal fetal heart activity.

Occasionally, the rupture occurs during vaginal delivery of the infant (usually an operative procedure for delay or fetal distress) and presents as a primary PPH. Thus uterine rupture remains a differential diagnosis in PPH, particularly among those with a previous uterine scar.

Management Options

Management options consist of surgical repair and hysterectomy. Published case series, many spanning several decades, vary widely in the reported use of each technique, with hysterectomy rates of 26% to 83%.[168] Most authors consider hysterectomy to be the procedure of choice for uterine rupture.[169,170] Subtotal hysterectomy may be performed if the rupture is confined to the uterine corpus. Evidence has shown that subtotal hysterectomy is associated with decreased operating time, lower morbidity and mortality, and shorter hospital stay compared with surgical repair.[201] Suture repair may be considered when technically feasible and there is a desire for future fertility. However, there is an increased risk of recurrence, which may be fatal. A meta-analysis from 1971 provides the most comprehensive data.[202] This analysis includes 194 women, with a total of 253 pregnancies following uterine rupture; 2 maternal deaths occurred. Overall, repeat rupture occurred in 6% with a previous lower segment rupture, 32% with a previous upper segment rupture, and 14% where the site of previous rupture was unknown. Of note, 3 women in this series had repeated rupture in two or three subsequent pregnancies. Other women had an uneventful pregnancy following uterine rupture, but with a repeat (even fatal) rupture in a subsequent pregnancy.

If suture repair is performed, elective cesarean section has been advocated as soon as evidence of fetal lung maturity is obtained in a future pregnancy. Repair has also been advocated if successful control of hemorrhage can be attained in hemodynamically unstable patients, avoiding further blood loss and prolonged surgery during hysterectomy. Bilateral tubal ligation should be considered in these cases. The need for massive transfusion usually accompanies operative management of uterine rupture. In a study evaluating over 25 peripartum hysterectomies, 98% of cases required multiple units of blood and blood products. Coordination of care with anesthesia and the blood bank is of vital importance when the diagnosis of uterine rupture is suspected.

Puerperal Problems

ANTHONY AMBROSE and JOHN T. REPKE

INTRODUCTION AND GENERAL APPROACH

The puerperium has been referred to as the "fourth trimester" of pregnancy, encompassing the period between delivery and complete physiologic involution and psychological adjustment.[1] Although this component of the human reproductive process does not get the same attention as many other aspects of pregnancy (there is no specific current American College of Obstetrics and Gynecology [ACOG] Practice Bulletin or Committee Opinion, albeit the e-reference UpToDate now publishes an Overview of Postpartum Care),[2] its importance remains indisputable. In both developing countries and the United States, more than 60% of maternal deaths occur in the postpartum period. The first 24 hours postpartum and the first postpartum week are both critical periods, with 45% of postpartum deaths occurring within 1 day of delivery, more than 65% within 1 week, and in excess of 80% within 2 weeks.[3] It is a period of cataclysmic change in which the mother returns to her usual physiology after the dramatic but more gradual adaptations of her pregnancy.

The role of the obstetrician is to conduct the parturient through this period, gradually passing the management of any chronic or lingering problems to her primary care provider.

As patient populations become more ethnically diverse, it is important to realize that postpartum health beliefs and practices, although often similar among cultures, may also differ drastically. Practitioners should make efforts to develop their knowledge regarding the beliefs and traditions of all their patients.[4]

Equally important in this world of too much food and insufficient exercise, maternal obesity contributes to postpartum complications, as reported after a retrospective analysis of data from a validated maternity database system in the United Kingdom. Compared with women with a normal body mass index (BMI), women with a BMI greater than 25 were at increased risk for postpartum hemorrhage (odds ratio [OR] 1 : 1.6), genital tract infection (OR 1 : 2.4), urinary tract infection (OR 1 : 1.7), and wound infection (OR 1 : 2.7).[5]

EXAMINATION OF PLACENTA

Examination of the placenta in the delivery or operating room should be a standard, especially if there are complications. The placenta can provide the clinician with much information regarding the roots of various problems of the mother and newborn. After thorough superficial examination, the decision can be made whether to enlist the assistance of the pathologist for meticulous gross and microscopic examination.[6] In the case of stillbirth, the chances of discovering an etiology is higher in centers that conduct a defined and systematic evaluation of the baby to include careful placental evaluation.[7,8] Pathology reports may be particularly helpful during postnatal and preconception counseling. Indeed, any patient experiencing a less than optimal outcome should be offered the opportunity for counseling before considering another conception.

PRIMARY ACUTE POSTPARTUM HEMORRHAGE

This topic is addressed in Chapter 75.

SECONDARY POSTPARTUM HEMORRHAGE
(See also Chapter 75)

Excessive vaginal bleeding between 24 hours and 6 weeks following delivery is the traditional definition of secondary or late postpartum hemorrhage (PPH).[9,10] It is a major cause of maternal morbidity and potential maternal mortality.[11,12] Calculating its precise incidence is challenging, because definitions in the literature vary; however, it is not unusual, having been reported to complicate between 1% and 2% of deliveries.[13–15]

Secondary PPH is a clinical diagnosis of exclusion, generally presenting as abrupt onset of heavy, sometimes massive (>10% of total blood volume) bleeding 7 to 14 days after delivery.[11] Such bleeding may sometimes represent the initial menstrual period after childbirth, which is often the result of an anovulatory cycle, and thus may be heavy, painful, and prolonged.[12]

Differential Diagnosis

The most common causes of late hemorrhage (Table 76–1) include subinvolution of the placental site, retained products of conception, and infection; previously undiagnosed tumors may rarely present in this fashion.[16] It is often attributed to sloughing of the placental eschar.[11] Subinvolution would seem to be the consequence of failure of obliteration of the vessels underlying the placental site; its mechanism is poorly understood.[17]

Women suffering delayed PPH frequently have retained placental fragments, especially if the bleeding is heavy. This group was noted to have had an increased incidence of

TABLE 76–1

Causes of Secondary Postpartum Hemorrhage

Abnormalities of placentation
  Idiopathic subinvolution of uteroplacental vessels
  Retained placental tissue
  Placenta accreta
Infection
  Endometritis, myometritis, parametritis
  Infection/dehiscence of cesarean scar
Preexisting uterine disease
  Leiomyomata
  Cervical neoplasm
Trauma: rupture of vulvar or vaginal hematoma
Coagulopathy

Modified from Neill A, Thornton S: Secondary postpartum hemorrhage. J Obstet Gynaecol 2002;22:119–122.

complications in prior pregnancies, which might reflect aberrant maternal-trophoblastic interaction, such as in preeclampsia, intrauterine growth restriction, spontaneous abortion, or retained placenta.[18]

Another possible cause of bleeding is endometritis, which should be suspected if the history includes uterine tenderness, fever, or foul lochia. This can be effectively treated with antibiotics without dilation and curettage (to avoid unnecessary trauma). If curettage is undertaken, it is probably wise to give antibiotics for at least 6 to 12 hours before the procedure, to guard against bacteremia, unless the bleeding mandates urgent intervention. In such a case, intravenous antibiotics should be given at the time of the procedure. The combination of exogenous estrogens and progesterone may allow adequate regeneration of the endometrium and may help prevent formation of synechiae.[10] Therefore, in women with secondary PPH, prescribing a progesterone-only contraceptive pill would be unwise, because this would have neither a beneficial effect on the endometrium nor accelerate placental site involution.[12]

Occasionally, relatively earlier secondary PPH (later in the first week) may be related to coagulopathy, especially von Willebrand's disease. Because the level of von Willebrand's factor is physiologically increased in pregnancy, a patient may be well during pregnancy, but develop a problem as she returns to the nonpregnant state; unexpected severe bleeding may occur despite only mildly reduced levels of Factor VIII. All of these women are at risk for both intrapartum and postpartum bleeding. Mild disease usually requires no therapy, especially if Factor VIII levels remain within normal limits. In the case of severe disease (Factor VIII levels < 5%), the risk of bleeding is substantial.[10]

Management Options

In the absence of data from randomized, controlled trials,[14] management of suspected secondary PPH pragmatically and empirically consists of stabilization, investigation to establish a cause for the bleeding, and appropriate treatment. Invasive examination in the office setting (e.g., using endometrial sampling devices) may result in a dramatic increase in the volume of bleeding, and uterine perforation is possible, especially if the uterus or its contents are infected. For this reason, investigation should be performed in a more controlled setting.

Crystalloid and blood products should be given as necessary to maintain intravascular volume and coagulability. The initial treatment of late PPH consists of ecbolic agents plus antibiotics. Pelvic ultrasonography can be helpful in investigating whether there is clot or other debris within the endometrial cavity.[19]

Authors in Belgium evaluated color Doppler and the grayscale sonographic appearance of the uterus after pregnancy.[20] Areas of enhanced vascularity of the uterus, ranging from a focal vascular pedicle to a larger area of the myometrium, were relatively common, predominantly seen in the presence of placental remnants, in the early postpartum period, and after instrumental or manual delivery of the placenta. These investigators felt their results may prove to be of practical value in the management of abnormal uterine bleeding in the puerperium.[20] However, bear in mind that ultrasound cannot reliably differentiate retained placental fragments from retracted blood clots. Thus, diagnoses of retained placental fragments are not always reliable. If significant bleeding persists despite medical therapy, suction or sharp curettage (or both) should be considered, especially if retained products of conception are suspected after ultrasound examination. The use of sharp curettage probably increases the risk of both uterine perforation and Asherman's syndrome. Ultrasonography may be helpful during curettage, allowing visualization of the location of instruments. Although it is probably wise to send evacuated tissue for histologic examination to rule out trophoblastic disease, degenerating chorionic villi and decidua will be also obtained from all postpartum uteri if samples are taken and do not, therefore, necessarily warrant a diagnosis of "significant retained products."

In cases of exceptionally heavy bleeding, before hysterectomy or surgical exploration is undertaken, angiographic embolization by skilled interventional radiologists can be considered.[21,22] Hysterectomy is indicated in the rare patient in whom conservative therapy fails.

SUMMARY OF MANAGEMENT OPTIONS

Secondary Postpartum Hemorrhage (See also Chapter 75)

Management Options	Evidence Quality and Recommendation	References
Clinical features are important in making diagnosis.	III/B	19
Ultrasonography of uterine contents does not distinguish blood clot from placenta; echogenic masses are found in asymptomatic women. Empty uterus on scan may allow a conservative approach.	III/B	19

Management Options	Evidence Quality and Recommendation	References
IV fluids and blood for hemodynamic stabilization may be necessary in some patients; correct coagulation defects.	—/GPP	—
Antibiotics for 12–24 hr prior to surgical evacuation.	—/GPP	—
Uterotonics and antibiotics may reduce need for curettage.	III/B	19
Surgical/suction evacuation of uterus.	III/B	11
Embolization may be tried in persistent bleeding after evacuation before resorting to hysterectomy.	IIb/B	21,22
Send surgical products for histologic examination.	—/GPP	—

GPP, good practice point.

PUERPERAL PYREXIA/INFECTION

Postpartum febrile morbidity has been described as an oral temperature of 38.0° C or higher on any two of the first 10 days of the puerperium, exclusive of the first 24 hours.[2] The parturient demonstrating such a fever should undergo a thorough workup investigating the possibility of an obstetric-specific etiology (to include but not limited to uterine/adnexal infection, wound infection [vaginoperineal and/or abdominal], breast infection, urinary tract infection, thrombophlebitis, hematoma, anesthetic infection [conduction anesthesia site, aspiration]), but also considering the possibility of fever sources that are merely coincident with the recent pregnancy and delivery.

Uterine Infection

Approximately 1% to 3% of women having vaginal delivery will develop what is frequently referred to as "puerperal endometritis," although these infections may more validly be described as "endoparamyometritis," because they often involve more than the innermost tissue layers of the uterus, frequently surrounding structures as well (Table 76–2). Cesarean deliveries performed prior to the onset of labor and rupture of membranes may be associated with an infection incidence of 5% to 15%, and when a cesarean section is performed after lengthy labor or ruptured membranes, the incidence may be in excess of 30%. Rates will vary widely among populations and depending on definitions used.[23]

These infections are generally polymicrobial, caused by organisms present in the normal vaginal flora, now granted access to the upper genital tract, peritoneal cavity, and circulation. The more common pathogenic bacteria include group B, β-hemolytic streptococcus (GBS), anaerobic streptococci, aerobic gram-negative bacilli (usually *Escherichia coli*, *Klebsiella pneumoniae*, and *Proteus*); and anaerobic gram-negative bacilli (generally *Bacteroides* and *Prevotella*).[24] Fatal infections have also been reported with aerobic gram-positive bacilli (*Clostridium*).[25] These etiologic agents too may vary among populations.

Although familiar mostly to students of medical history who read the 1843 paper of Oliver Wendell Holmes, "The Contagiousness of Puerperal Fever,"[26] or readers of Morton Thompson's historical fiction about Ignaz Semmelweis, "The Cry and the Covenant,"[27] group A streptococci (GAS) are not just of historical interest but can still be an important source of postpartum metritis and sepsis. GAS carrier status may occasionally be identified during routine screening for GBS, and this finding may presage serious postpartum infection.[28] A 7-month outbreak of 15 cases of postpartum sepsis due to GAS was traced to a nurse with atopic dermatitis who carried the organism,[29] raising a chilling memory of similar outbreaks that occurred in Budapest and other locales in the mid-19th century.[30] The Centers for Disease Control and Prevention (CDC) hosted a workshop to formulate recommendations for control of GAS disease among household contacts of persons with invasive GAS infections and for responding to postpartum and postsurgical invasive GAS infections.[31]

Risk factors for metritis include young maternal age, cesarean delivery, low socioeconomic status, extended duration of labor, prolonged rupture of membranes, and multiple vaginal examinations.[23] Puerperal pyrexia due to metritis

TABLE 76–2

Differential Diagnosis of Persistent Puerperal Fever

DIAGNOSIS	DIAGNOSTIC TESTS	TREATMENT
Resistant microorganisms	Endometrial and blood culture	Modify antibiotic therapy
Wound infection	Physical examination	Incision, drainage
	Needle aspiration	Antibiotics
	Ultrasound	
Pelvic abscess	Physical examination	Drainage
	Ultrasound, CT, MRI	Antibiotics
Septic pelvic vein thrombophlebitis	Ultrasound, CT, MRI	Anticoagulation antibiotics
Recrudescence of autoimmune disease	Serology	Corticosteroids
Drug fever	Inspect temperature graph, identify eosinophilia	Discontinue antibiotics
Mastitis	Physical examination	Modify antibiotic coverage to cover staphylococci

CT, computed tomography; MRI, magnetic resonance imaging.

typically presents with fever and temperatures in excess of 38°C, between 24 and 36 hours of delivery. Controversy exists as to whether temperature elevations within 24 hours of delivery are pathologic, because they can be due to over-heating of the mother secondary to the efforts of labor, especially if she had an epidural. "Milk fever" can also be a benign cause (see later). Careful evaluation of intrapartum events and observations is necessary to distinguish benign from infectious pyrexia. Other findings and complaints may include tachycardia, pelvic and lower abdominal pain, uterine tenderness, foul lochia, and general malaise.[23]

Patients with such findings or complaints deserve a thorough evaluation, because the differential diagnosis is broad, and metritis should not be assumed. Differential diagnosis includes mastitis, urinary tract infection, atelectasis (especially following cesarean delivery), and bacterial or viral infections virtually anywhere within the respiratory, genitourinary, and gastrointestinal tracts. Examination of the breasts, percussion of the sinuses, inspection of the pharynx, auscultation of the lungs and heart, and other diagnostic techniques may discover a process not related to the uterus. Laboratory tests, with the exception of evaluation of the urine, are not generally helpful initially. Controversy exists as to whether endometrial cultures, leukocyte counts, chest radiograph, and other diagnostic modalities are helpful prior to starting therapy. If endometrial cultures are attempted, some data support the use of multiple-lumen catheters in order to avoid vaginal contamination.[32] Manual examination, plus or minus visual inspection of the vagina and cervix, should always be done, even though this may be uncomfortable for the patient. Discovering a hematoma or abscess is important because it directs appropriate therapy; finding and removing an overlooked vaginal sponge benefits the patient and, at the very least, prevents further embarrassment for the provider who left it behind!

Management Options

Once a thorough examination has been done, and the provider has concluded the uterus is the source of the infection, treatment generally consists of broad-spectrum parenteral antibiotics, to include coverage for β-lactamase–producing anaerobes.[33] In most cases, the combination of clindamycin (900 mg IV q8h) plus gentamicin (1.5 mg/kg IV q8h), with gentamicin levels followed, will be safe and effective, with cure rates of 90% to 97% reported in several studies.[34–43] Parenteral therapy should continue until the patient is afebrile for 24 to 48 hours, and oral antibiotic therapy thereafter is generally not necessary, barring staphylococcal bacteremia.[44]

If the patient does not respond to the initial antibiotic regimen after 48 to 72 hours, modification in therapy may be necessary. In this case, cultures may prove valuable. Resistant organisms such as enterococci are responsible for many treatment failures. Adding ampicillin (2 g IV q4h) may improve the rate of response.[45]

Should the patient still not improve, evaluation should be repeated and extended. Wound infection, pelvic abscess, septic pelvic thrombophlebitis, and drug fever should be added to the differential diagnosis.[33]

A standardized protocol similar to the aforementioned was evaluated with respect to its efficacy against postcesarean endometritis in Alabama. Twenty percent (322) of 1643 patients delivered by cesarean were diagnosed with endometritis and treated with clindamycin and gentamicin; 129 (8%) of these women also received either ampicillin or vancomycin; only 19 of 322 (6%) had persistent fever. Six of these had a wound complication, 1 an infected hematoma, and 12 were suspected as having antimicrobial resistance. Their standardized protocol resulted in a 94% initial cure rate.[46]

A prospective, placebo-controlled, double-blinded study in Tennessee investigated whether once-daily dosing of gentamicin and clindamycin (gentamicin 5 mg/kg and clindamycin phosphate 2700 mg) would be as efficacious as administration every 8 hours.[47] There was no difference in the mean time from starting therapy until becoming afebrile between the groups, and success rates were similar (82% in the daily-dose group, and 69% in the thrice-daily dose group).

Septic Pelvic Vein Thrombophlebitis

Septic pelvic vein thrombophlebitis (SPT) is probably a rather infrequent postpartum complication, occurring in only 1 in 3000 pregnancies. Unfortunately, it is much more likely to occur following cesarean (1 : 800) than vaginal deliveries (1 : 9000); consequently, its overall incidence may be rising.[48] Intrauterine infection may cause seeding of pathogens into the venous circulation, leading to endothelial damage and thrombosis.[49]

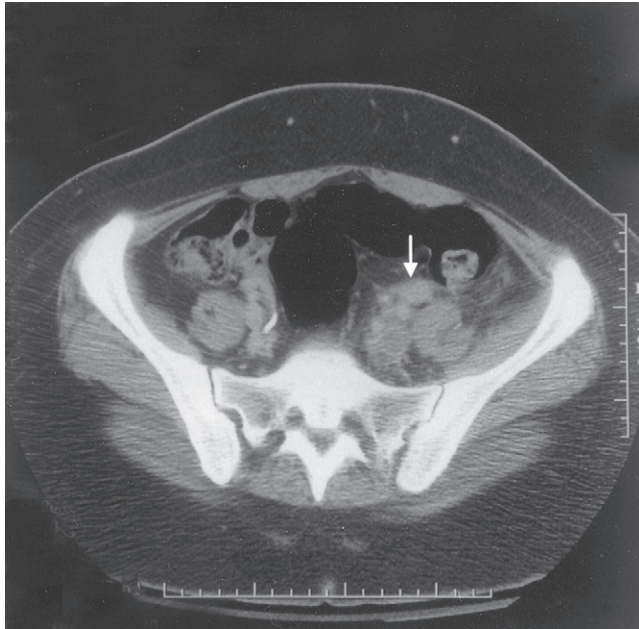
Duff and Gibbs[50] have reported that SPT may occur in two rather distinct forms:
- Ovarian vein syndrome/thrombosis.
- "Enigmatic fever."

More common is ovarian vein syndrome, which is acute thrombosis of one (usually the right) or both ovarian veins.[51] Common findings are moderate fever, pain, gastrointestinal symptoms, and tachycardia. The abdomen is often tender, and the patient may have guarding and decreased bowel sounds. Differential diagnoses include pyelonephritis, renal stone, appendicitis, broad ligament hematoma, adnexal torsion, and pelvic abscess.[49] Ultrasound, computed tomography (CT), and other imaging modalities have been reported to demonstrate extensive thrombosis of an ovarian vein. Medical treatment consists of thrombolytic agents, heparin, and antibiotics.[52]

Less common is so-called enigmatic fever.[53] Patients initially seem to have metritis and receive systemic antibiotics. Initially, there may be some improvement, but patients frequently have temperature instability. Fever and tachycardia may persist. Differential diagnoses include drug fever, viral syndrome, autoimmune disease, and pelvic abscess.[49]

Management Options

Diagnostic imaging (CT, magnetic resonance imaging [MRI]) may help to detect large thrombi. A group in Winnipeg reported the result of a CT scan of the abdomen and pelvis with infused intravenous contrast, which demonstrated a massive thrombosis extending from the superior vena cava to the femoral vein, and which responded to a regimen of clindamycin, gentamicin, and unfractionated heparin (Fig. 76–1).[54]

Infused computed tomography (CT) of the abdomen. The *arrow* indicates left ileofemoral thrombosis. The associated low-density area surrounding the vein represents perivascular inflammation.


However, diagnostic imaging may miss thrombi in smaller vessels. In this case, a favorable response to therapeutic-dose heparin supports the diagnosis.[55,56] Patients generally respond within 2 to 3 days. If there is no response and the patient worsens, consultation with a vascular surgeon may be prudent.[50,55]

Although most would recommend the use of heparin in the treatment of SPT, this is not entirely uncontroversial. A study in Dallas used abdominopelvic CT imaging to search for evidence of puerperal SPT in women diagnosed with pelvic infection and fever that persisted after 5 days of adequate antimicrobial therapy with clindamycin, gentamicin, and ampicillin. Sixty-nine women met the criteria for prolonged infection, and 15 (22%) of these were found to have SPT. Four of these women had delivered vaginally; 11 by cesarean section. Of the 15, all were treated with continued antimicrobial therapy, 6 with the addition of heparin and 9 without. There was no significant difference between the responses of women who were and those who were not given heparin.[48]

Urinary Tract Infections

Factors such as vaginal examinations and urethral catheterization place the just-delivered mother at risk for infection in her urinary tract. This subject is covered in detail in Chapter 49.

SUMMARY OF MANAGEMENT OPTIONS
Puerperal Pyrexia

Management Options	Evidence Quality and Recommendation	References
Uterine Infection		
Prevention:		
• Limit vaginal examinations, intrauterine monitoring, exteriorizing the uterus at CS and manual removal of placenta at CS.	—/GPP	—
• Prophylactic antibiotics at the time of CS.	Ia/A	34–36,43
Management:		
• Gentamycin and clindamycin or extended spectrum β-lactam (e.g., imipenem-cilastatin).	Ia/A	43
• Continue until afebrile for at least 24 hr.	—/GPP	—
• If patient is not responding after 48–72 hr, seek other causes (e.g., retained products of conception, abscess, hematoma, ovarian vein thrombosis), review microbiology and antibiotic regimen.	—/GPP	—
Septic Pelvic Vein Thrombophlebitis		
Diagnosis of exclusion; no localizing symptoms.	IV/C	50
At least 7 days of therapeutic heparin.	Ib/A	48

DISORDERS OF THE BREASTS

The mantra of "breast is best," long a rallying point for many, continues to gather scientific support, to include increasing evidence that breast milk is the single entity that has evolved *with* humans *to nourish* humans.[57,58] A 15-year study of more than 6600 mother-infant pairs revealed that abuse and neglect were much less likely in breast-fed babies.[59] However, for various reasons, many women around the world (approximately half of U.S. women) do not nurse their newborns.[60] Although it is well known that women may experience great discomfort before lactation ceases, precise data about this annoyance are lacking.

Lactation: Suppression and Stimulation

Over the years, a number of nonpharmacologic means have been used to suppress lactation and relieve symptoms of engorgement. These include, but are not limited to, strapping or binding the breasts, forcing fluids, restricting fluids and diet, applying various ointments and other products (e.g., cabbage leaves, ice packs) to the breasts and nipples, narcotics, wearing a tightly fitting brassiere, emptying the breasts by massage or pump, and avoiding expression of milk.[61–65] It is evident that a number of these approaches are contradictory.

In the United States, various pharmacologic methods for lactation suppression were used during most of the 20th century.[66] The natural suppression of prolactin secretion results in breast involution; this was approximated pharmacologically with medicines such as bromocriptine. However, since 1988, the U.S. Food and Drug Administration has recommended against the routine use of pharmacologic methods (save analgesics) for lactation suppression and relief of associated symptoms because evidence from randomized, controlled studies on the safety and efficacy of those drugs for that purpose is lacking.[67,68]

Reports linked bromocriptine with cerebrovascular accident, myocardial infarction, seizure, and other problems in puerperal women. A recent Cochrane review notes "Contrary to a number of case reports, there is insufficient evidence from this review to indicate whether or not bromocriptine is associated with increased risk of major side effects (notably thromboembolism, myocardial infarction

and maternal death) in the first postpartum week."[69] However, largely because of suspected associations with such serious complications, this drug is no longer approved for lactation suppression.[70–75]

Peterson and colleagues at the CDC[68] searched the world literature in 1998 to locate data about the postpartum symptoms experienced by women who do not breast-feed and to review data on the efficacy of nonpharmacologic methods of lactation suppression. Their findings were disappointing: extant data suggested that, in spite of current nonpharmacologic treatment for lactation suppression, as many as one woman in three may experience severe breast pain postpartum. Moreover, they found no studies focusing primarily on the symptoms of such women. They did offer directions for future research, suggesting studies that included treatment groups for wearing a breast binder, wearing a tightly fitting brassiere, pumping breast milk mechanically or manually, applying ice packs to the breasts, applying topical analgesics or other substances to the breasts, and taking only oral analgesics. Between 30% and 50% of nonnursing patients will have engorgement and pain that may persist for up to a week.

Unwanted lactation failure is a rare complication that has been associated with retained placenta, via suppression of prolactin.[76] Prolactin may also be suppressed by ergot, pyridoxine, and some diuretics.

It has been reported that metoclopramide[77] and sulpiride[78] may enhance lactation. Use of oxytocin (which has to be taken as snuff, to avoid first-pass inactivation in the liver) has been demonstrated to improve milk let-down and may help with the successful establishment of breast-feeding in some women, especially those with preterm babies.

Mastitis and Abscess

It is not unusual for the breasts to become distended and firm during the first day or two after delivery; this may be accompanied by a transient temperature elevation.[79] It has been reported that 13% of all postpartum women may demonstrate such "breast fever," which seldom lasts more than 24 hours.[80] When fever develops during the puerperium, however, breast fever should be a diagnosis of exclusion, because it is important not to miss more dangerous pathology.

Puerperal mastitis or breast abscess is the most frequent significant complication of nursing. Fever, localized pain, and erythema, often confined to one or more quadrants, are common findings. Onset is generally in the first or second postpartum week, but it may also develop later. It may be related to an obstruction in the milk ducts. When initiating lactation, the nipple and areolar skin often undergo local inflammation and swelling until the nipple is conditioned to frequent suckling. This swelling causes a relative obstruction to milk flow and can be seeded by bacteria, especially *Staphylococcus aureus*, *E. coli*, and *Streptococci*,[81] leading to bacterial mastitis. There is some evidence that the immediate source of these organisms is the infant's nose and throat. The breast (generally unilaterally and in one quadrant) becomes painful, swollen, warm, and red. An abscess develops in approximately 10% of such women; there may be local fluctuance and pointing.[82,83]

Cultures of the milk are usually unhelpful; infection is almost always with a maternal skin organism. Treatment with antibiotics generally results in prompt resolution of symptoms, and following prompt treatment, the development of abscesses is rare. Dicloxacillin (500 mg PO q6h) may be started empirically.[84] When they do develop, abscesses require surgical incision and drainage[85,86] or aspiration with ultrasound guidance.[87] Continuing to breast-feed may be extremely important: the only women who developed abscesses in a series of 65 woman with puerperal mastitis were among the small group who chose to cease nursing.[88] This is probably because continuing to breast-feed allows the flow of milk to flush infection from the duct system.

A prospective study undertaken in Turkey assessed contributing factors in puerperal breast abscess.[89] Mastitis patients who were treated with antibiotics did not develop breast abscess. Ultrasonography was helpful, allowing needle aspiration; healing times were similar to those in abscess patients treated with incision and drainage. Needle-aspiration patients were reported to have excellent cosmetic results.

SUMMARY OF MANAGEMENT OPTIONS
Breast Problems

Management Options	Evidence Quality and Recommendation	References
Lactation Suppression		
Physical support; evidence for value of other topical measures is poor.	III/B	61–65
Analgesia should be the only pharmacologic agent used.	Ia/A	67,68
Bromocriptine should not be used.	IV/C	70–75
Lactation Enhancement

Culture milk with complicated mastitis or abscess.	—/GPP	—
Continued pumping/expressing and feeding.	IIa/B	88

GPP, good practice point.

OTHER MEDICAL PROBLEMS IN THE PUERPERIUM

During the "fourth trimester," the recently delivered woman must negotiate the dramatic changes from late pregnancy and delivery and return to her normal nonpregnant physiology. Cardiovascular problems are discussed in Chapter 36.

Diabetes (See also Chapter 44)

Women who were diagnosed with gestational diabetes generally do not require treatment following delivery. However, they are at increased risk for developing type 2 diabetes (~50% will do so within 10 yr). Following the traditional postpartum visit at 6 to 8 weeks, they should be directed to follow-up with their primary care providers in 2 to 3 months, at which time they should discuss with their providers provocative testing for diabetes. This may be accomplished by an oral glucose tolerance test, in which a plasma glucose level equal to or more than 200 mg/dL (11 mmol/L) would be sufficient for a diagnosis of diabetes. The test should be performed as described by the World Health Organization (WHO), using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water.[90]

In the case of women with pregestational diabetes, their treatment following delivery depends on their glucose levels as they return to their usual diet and activity levels. Upon discharge from the hospital, they can generally return to a management program similar to the one they observed prior to conception. Coordination with the providers furnishing that management is essential.

Thromboembolic Disease (See also Chapter 42)

Owing largely to the physiologic changes of pregnancy, as well as relative immobilization during the latter parts of pregnancy, venous thromboembolism (VTE) is much more common in the puerperium than during a similar period in women who have not recently been pregnant. Maternal deep vein thromboses (DVTs) are more common (80%–90%) in the left leg, occur usually in the iliofemoral veins, and are often associated with pulmonary embolism. Those with prior DVT and with hereditary thrombophilias are at highest risk.[91]

Women with inherited thrombophilias have an increased risk for VTE, particularly during the puerperium. The overall prevalence of thrombophilic traits in the general population may be 10% or more; the probability of carrying multiple defects is, therefore, not at all rare. Screening for these traits should be done liberally.[92]

In an American College of obstetricians and Gynecologists (ACOG) high risk pregnancy monograph, Lockwood[93] recommended that no matter their past history, asymptomatic pregnant women with antithrombin deficiency and women who are homozygotes or compound heterozygotes for Factor V Leiden or prothrombin (G20210A) mutations are at very high risk for thromboembolic episodes and should have anticoagulant therapy throughout pregnancy and in the puerperium.[94] Following delivery (6–12 hr), heparin therapy should be resumed and warfarin (Coumadin) therapy begun. Until the International Normalized Ratio (INR) has been in the therapeutic range for 2 consecutive days, heparin should be continued. Coumadin should be continued for at least 6 weeks, and longer if there have been prior thromboembolic events.

If a woman developed a VTE during pregnancy, whether or not she was found to have an inherited or acquired thrombophilia, Lockwood[93] recommends full anticoagulation during pregnancy, resumption of heparin after delivery, and establishment and maintenance of therapeutic levels of oral anticoagulation for 6 to 18 weeks thereafter. He is careful to note that, because there are no randomized clinical trials to assess the efficacy of anticoagulation therapy in preventing maternal or fetal complications, recommendations must rely on expert opinion.

Similar recommendations were published by a group in Australia and New Zealand, recommending 6 months of therapy and treatment for at least 6 weeks postpartum for women who experienced VTE either during pregnancy or postpartum.[61] For women who had a previous thromboembolism, they recommend therapy postpartum, with the decision whether to treat during pregnancy based upon whether the index event was spontaneous or provoked, the presence or absence of a family history of VTE, the presence of a

known thrombophilia, and whether there have been multiple episodes of VTE.[61,94]

Women with a past history of a single provoked thrombotic event with an underlying thrombophilia may be treated by careful observation before delivery and 6 weeks of postpartum prophylaxis. Women with recurrent VTE, previous idiopathic VTE, or a previous VTE and strong family history, but no demonstrated thrombophilia are advised to use thrombophylaxis throughout pregnancy and for 6 weeks thereafter.[61,94]

In our own practice, we liberally solicit input from hematologists on a case-by-case basis, because clinical knowledge about the thrombophilias and their role in VTE during and after pregnancy is increasing rapidly.

Finally, the puerperium offers an opportunity to perform or complete a thrombophilia workup, which may have been either delayed or done only partially during pregnancy, because of physiologic changes elevating a number of clotting factors, including Factor VIII, protein S, and protein C.

PSYCHOLOGICAL PROBLEMS IN THE PUERPERIUM

Bereavement

Unfortunately, not all pregnancy outcomes are happy. As many as one woman in five will suffer a perinatal loss through neonatal death, stillbirth, elective abortion, or miscarriage, and as many as one in five of these will suffer some form of prolonged psychological abnormality.[95,96] The birth of an anomalous[97] or severely ill infant can be almost as difficult to bear. Mothers experiencing an emergency hysterectomy for hemorrhage, or even a planned surgical sterilization, can manifest grief.[98] Postpartum depression (PPD) may be more common and more severe when a perinatal loss has occurred.[99]

Interestingly, a recent Cochrane review of the literature for evidence concerning programs of support aimed at encouraging acceptance of loss, specific bereavement counseling, or specialized psychological support or counseling, to include psychotherapy for women and families experiencing perinatal loss, was unable to locate any randomized trials.[95] Conversely, a number of reports of personal and institutional experiences in providing such services exist and arguably provide reasonable support for such programs.[100–102] Tasteful and good-quality photographs of the deceased child, especially, would seem to be valued by parents and families.[103,104]

It is incumbent for the staff of the birthing facility to recognize patients who are in need of bereavement services, and then to provide what is optimally a multidisciplinary approach to assisting the family through the immediate and long-term dilemmas such a loss causes. Many coordinated and formalized programs do this very well. The perceptions of health care professionals about the emotional care needs of families experiencing perinatal loss were significantly increased after attending a formal educational program about bereavement.[105]

In the late 1970s, individuals at Gundersen Lutheran Medical Center in La Crosse, Wisconsin, providing emotional support for families whose babies died during pregnancy or shortly after birth, became increasingly aware of

the pain and grief that families experience when a baby dies. This emotional support effort served as the prototype for *Resolve Through Sharing* (RTS),[106] a perinatal bereavement program formally launched there in 1981, which has subsequently spread nationally and internationally.

Families experiencing perinatal loss grieve for their baby and the loss of an entire lifetime with that child. RTS recognizes that the support, acceptance, and gentle guidance given by professionals upon learning of a loss are important first steps in the journey of grief. The caregiver's knowledge and guidance validate that grief is a normal response to loss, allowing bereaved families to grieve in their own way, in their own time. Families are involved in the decision-making process. Education, consultation, and evaluation are integral parts of the program. The RTS support person remains in touch with the family for a year or more, referring to other health care professionals when additional management support is necessary.[106] The loss of a new sibling may be particularly hard on a brother or sister; a children's picture-book format resource[107] may be particularly helpful in dealing with this.

Psychological Reactions

Even when the overall outcome of pregnancy has been good, a healthy mother may experience psychological problems. Several authors have suggested that women may show specific areas of cognitive changes during and after pregnancy, notably deficits in verbal learning and memory (see also Chapter 55). Mood appears to be affected as well. Steroidal hormones are increasingly recognized as highly relevant in multiple aspects of brain functioning.[108] Although steroid hormones show a pattern of associations with mood during and after pregnancy, no such pattern is evident for cognition.

The postpartum period may represent a time of increased vulnerability to depression for some women.[109] Postpartum "blues" is a transient condition characterized by mild, and often rapid, mood swings, from elation to sadness, irritability, anxiety, decreased concentration, insomnia, tearfulness, and crying spells.[110] Owing largely to inconsistencies in diagnostic criteria, the data regarding incidence conflict. Major depressive disorders are thought to afflict 5% to 9% of women at any time, with a lifetime risk of 10% to 25%.[111] New episodes of depression in the first 4 to 6 weeks after delivery occur three times more frequently than in nonpregnant controls.[112] Depression has been described in up to 30% of women in the first postpartum year.[113–115] Other studies have not confirmed this relation, observing rates of PPD similar to depression diagnosed without relation to pregnancy.[116–118]

Hormonal changes following delivery are often presumed to play a role in the development of PPD; however, the relationship between postpartum changes and the development of depression is not well understood,[119] and there is every reason to assume that PPD results from the interaction between hormonal, genetic,[120] and life-event factors.[109,121] Women may complain of depressive symptoms shortly after delivery, at any time during the following few months, and at cessation of lactation, although it is unclear whether cessation of nursing the child is cause or effect.[122] Moreover, there is good evidence that in many cases, PPD may begin

well before delivery. One study reported that the prevalence of depression at 32 weeks (13.5%) was higher than postpartum (9.1%).[123] In another study, half of all women diagnosed with PPD had onset of symptoms during or even before their pregnancies.[124]

Wickberg and Hwang[125] investigated the use of the Edinburgh Postnatal Depression Scale (EPDS) on a population-based sample of 1655 women who completed the scale at 2 and 3 months postpartum. They also interviewed 128 using the Montgomery Asberg Depression Rating Scale (MADRS) and assessed them according to *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition, revised (DSM-III-R) criteria for major depression. A cutoff score of 11.5 on the EPDS identified all but 2 women with major depression (sensitivity 96%, specificity 49%, positive predictive value 59%).

Thoppil and coworkers[126] reported a multidisciplinary approach to identifying women at risk for depression during pregnancy and postpartum (Table 76–3). Called ISIS (identify, screen, intervene, and support), it was developed and supported by their psychiatry, obstetrics, and social work groups. Social workers educate patients about signs and symptoms of depression at the obstetrics orientation visit. Risk factors for depression are screened for at the first visit with midwife or obstetrician. The EPDS is administered at the 32-week visit. Patients with elevated scores are further evaluated, and consultation and treatment may be initiated by the psychiatry department. In a chart review, they found that 75% of their patients were so screened, with 9.76% of the screened population having a positive score.

Management Options

Psychotherapy is an effective first-line treatment for depression during pregnancy or after the birth of a child.[127]

In some cases, antidepressant treatment may be warranted. The decision to prescribe an antidepressant drug

---

TABLE 76–3

DSM-IV Criteria for a Major Depressive Episode

A. Five or more of the following symptoms must be present daily or almost daily for at least 2 consecutive weeks:
   1. Depressed mood.*
   2. Loss of interest or pleasure.*
   3. Significant increase or decrease in appetite.
   4. Insomnia or hypersomnia.
   5. Psychomotor agitation or retardation.
   6. Fatigue or loss of energy.
   7. Feelings of worthlessness or guilt.
   8. Diminished concentration.
   9. Recurrent thoughts of suicide or death.
B. The symptoms do not meet the criteria for other psychiatric conditions.
C. The symptoms cause significant impairment in functioning at work, school, and social activities.
D. The symptoms are not caused directly by a substance or general medical condition.
E. The symptoms are not caused by bereavement after the loss of a loved one.

* At least one of the five symptoms must be item 1 or 2.
Modified from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 4th ed. Washington, DC, American Psychiatric Association, 2000.

during pregnancy or the postpartum period must be made on an individual basis.[128] Use of pharmacologic therapy in postpartum lactating women must balance the risk of possible deleterious drug effects on the infant via the mother's milk versus the risk of not treating a serious psychiatric condition. All medicines used for this purpose appear in breast milk in varying amounts. The provider must consider such risks to the baby as drug toxicity and the possibility of long-term effects on behavior and neurologic development, which have not as yet been elucidated.[129] Coordination with the baby's pediatrician is essential. Another consideration that must be dealt with before prescribing an antidepressant drug during pregnancy or the postpartum period concerns the matter of which provider will assume responsibility for the patient's treatment once the puerperium has passed.

In one study, 25 women met standard diagnostic criteria for PPD.[130,131] They took 10, 20, or 40 mg/day of paroxetine for at least 4 weeks and no other mood-altering drugs. Researchers studied fresh breast milk, collected within 6 hours of taking the drug, along with maternal and infant blood samples. Even the lowest dosage of paroxetine improved depression in some of the women. There were no differences among groups in the milk-to-plasma ratio, no matter what dosage the women took. Only very small amounts were found in breast milk and the infants' serum. These findings imply that one may treat a nursing woman safely with paroxetine,[130,131] as has been shown in similar studies of fluoxetine and sertraline. Prudence may be important, however; Stowe and colleagues[131] found that in studying infants exposed to paroxetine via mother's milk, the drug was not found in their blood, similar to studies of sertraline and fluoxetine. However, they warn that one cannot assume it was not in the baby's brain, and it may be premature to base safety conclusions on undetectable concentrations in infant serum.

The reader is referred to Chapter 55 for a more detailed discussion of the management options for postpartum blues, depression, and psychosis.

SUMMARY OF MANAGEMENT OPTIONS
Other Medical Problems in the Puerperium

Thromboembolic disease	42
Psychiatric problems	55

OTHER ISSUES IN THE PUERPERIUM

Pain Relief (See also Chapter 70)

The use of epidural analgesia has revolutionized pain management in the immediate puerperium. For patients not having epidurals, evidence about various methods is limited. Prostaglandin synthetase inhibitors, although affording effective control of uterine contractions, may produce excessive bleeding as a side effect. The broad spectrum of perceived pain among women experiencing delivery remains unexplained.

Calvert and Fleming in Glasgow, Scotland,[132] reviewed the literature concerning approaches to dealing with perineal pain following vaginal delivery. They note the dearth of data to support many traditional and apparently efficacious practices and emphasize the need for careful evaluation of damage, use of nontraumatic suture when repair is necessary, and listening carefully to the patient as she describes her pain.

Education: Assuming the Role of the Mother

Many normal psychological changes take place to prepare the mother for her new responsibilities. Any impediment to these changes might result in a lack of emotional response to the infant at delivery. During the immediate newborn period, prenatal preparation needs to be recalled and developed, in addition to many new and often unanticipated tasks as the maternal role is taken on.[133]

Medications

The administration of appropriate medications such as Rh immune globulin, vaccinations, and others must not be overlooked prior to discharge. It should be remembered that dosages of many medications for chronic disease states (e.g., thyroid disease, hypertension, seizure disorders) likely were adjusted (generally increased) during pregnancy because of maternal physiologic adaptations (e.g., the increase in plasma volume or changes in the rate of drug metabolism). During the puerperium, these drug dosages usually need to be restored to prepregnancy levels. The blood levels of antiseizure medications may rise dramatically in the early puerperium if dosages are not adjusted. Coordination with the patient's primary care provider is vital.

General Health Considerations

The puerperium also offers an opportunity for the caregiver to reinforce the healthy lifestyle that many women adopt

during pregnancy. This is the time to intervene to prevent recidivism into unhealthy habits, such as the use of tobacco, excessive alcohol, and other unhealthy substances. The nutrition counseling many women undergo during pregnancy, whether or not they have been diagnosed with gestational diabetes, will serve them well in the nonpregnant state and should be reinforced. Even pregestational diabetics often embrace long-overlooked advice for the sake of the babies they carry; this is an opportunity to bolster that resolve.

Length of Stay

At least eight trials have attempted to compare early discharge (with substantial variation in the definition thereof) of healthy mothers with term infants with standard care in the settings in which the trials were conducted. Investigational problems included high postrandomization exclusions, protocol violations, and failure to use a well-validated standardized instrument to assess PPD. So, although there seems to be no evidence of adverse outcomes associated with policies of early postnatal discharge, methodologic limitations of included studies mean that such complications cannot be ruled out.[134] Indeed, such difficult-to-measure outcomes as fatigue due to sleep deprivation might be affected by length of stay.

Returning to Exercise

As morphologic and physiologic adaptations to pregnancy recede gradually over many weeks, it seems prudent that mothers return progressively to prepregnancy levels of exercise and physical conditioning. Complications associated with the resumption of physical training, even among elite athletes, seem to be rare.[135] Modest weight reduction during lactation appears to be safe and does not seem to compromise infant weight gain in most cases.[136,137] As a general rule, feeding their babies before exercise helps mothers avoid problems associated with breast engorgement and lactic acid accumulation in breast milk.[138,139]

Returning to Work

Returning to work remains a topic replete with opinion but generally unencumbered by data. Although published in the past, ACOG has withdrawn specific written guidelines; a Committee Opinion provides only vague recommendations.[140] A survey was done by *Contemporary OB/GYN* in 1983, in which 803 questionnaires were mailed to readers; 392 responses were received (49%). When asked "How many days should patients wait before returning to work after undergoing, [p. 5] . . . scheduled repeat caesarean section, . . . ?," responses were, on average, 34.7 days (sedentary job), 39.5 days (job that requires standing or walking), and 47.6 days (job that requires heavy physical exertion).[141] Provisions of legislation such as the Family and Medical Leave Act produce a dilemma for the obstetrician, who generally is in no position to objectively assess the capabilities of the patient and has little or no medical evidence on which to rely. The facts that every patient is different and every employment situation is different would seem to demand individualization from the advising provider, but the dearth of evidence-based data to support one's recommendation invites criticism and inappropriate intrusion into the contractual arrangements between employers and employees. In our own practice, we tend to deal with this by informing patient and employer that there are little or no data to support a firm recommendation and advise the patient to return to work, and to do work, according to her comfort level. This allows the patient and her employer to negotiate, compromise, and come to a mutually acceptable arrangement.

OTHER PROBLEMS

Separated Symphysis Pubis

Separated symphysis pubis (SSP) is also known as "subluxation," "incomplete or partial dislocation of symphysis pubis," "diastasis of the symphysis pubis," and "pelvic girdle relaxation." It is a rare condition involving separation of the symphysis pubis in late pregnancy or during delivery. It usually occurs in otherwise healthy pregnancies and is likely to be the result of hormonal or biomechanical factors (or both).

SSP symptoms may present at any time intrapartum or postpartum, with a broad range of symptoms, including pain in the back or pelvic area, difficulty with ambulation, and local manifestation over the symphysis such as tenderness, induration, ecchymoses, and a palpable joint defect.[142] Differential diagnosis is broad and requires exclusion of more serious medical and orthopedic conditions.

Management Options

Successful treatment approaches include analgesia, bedrest, binders, limitation of ambulation, walking in a shuffling style when ambulating, avoiding both adduction and abduction of the hips, injections of local anesthetics, steroids, and other medications. Because of ambulation limitations, DVT becomes a risk, and thromboprophylaxis should be considered. Patient education and emotional support are critical, and follow-up with rehabilitative services, orthopedics, home nursing, and social input may be appropriate.[142]

Obstetric Paralysis

In most cases of maternal obstetric paralysis, symptoms are unilateral, consisting of leg weakness or, in more severe cases, foot drop. Prognosis for recovery from mild injuries is excellent with physical therapy. However, if fatty degeneration of nerve fibers has occurred, in which the nerves have been functionally severed, recovery may take much longer and may never be complete.[143,144]

The incidence of obstetric paralysis is probably between 1 in 7000 and 1 in 14,000 in patients who do not receive regional anaesthesia/analgesia.[143] In the industrialized world, obstetric paralysis is an entity seldom reported unless regional anesthesia/analgesia is involved; neurologic complications that follow childbirth are frequently blamed on epidurals and spinals, even when this is not the case.[145] The mechanisms whereby regional/conduction anesthesia/analgesia may be associated with neurologic damage include neurotoxicity, ischemia, trauma, and compression that may be due to hematomata or abscesses.[145]

Management Options

Prevention includes avoidance, if possible, of prolonged and/or obstructed labor, the use of correct second-stage and lithotomy positions.[145] Specifically, regional analgesia should be avoided when coagulopathy or infection (systemic or local) is present.[143,145]

When neurologic damage follows childbirth, it is important to elucidate the mechanism of its occurrence. It is generally advisable to seek the opinion of a neurologist early in the course of the problem. Management options include splinting, physical therapy, and electrical nerve stimulation. Paraplegia requires immediate MRI. Emergency surgery may necessary for an epidural abscess or hematoma.[144]

Urinary Retention

This is either clinically overt postpartum urinary retention, that is, the inability to void spontaneously after delivery, or

covert urinary retention, identified through measurements of postvoid bladder residual volumes, measured or calculated by either catheterization or bladder imaging.

The physiologic changes of pregnancy, regional anesthesia, instrumental delivery, cesarean delivery, perineal trauma, protracted labor, and primiparity have variously been associated with postpartum urinary retention, as have rare instances of lumbar disk disease, spinal subdural hematoma, postpartum uterine retroversion, and impacted pelvic masses.

Management Options

Evidence would suggest that careful attention to all postpartum women, with prompt catheterization for those who cannot void, will prevent most problems related to urinary retention. If the residual urinary volume is greater than 400 mL, it is suggested the in-dwelling catheter should remain for at least 12 hours if not 24 hours.[146] The majority of women will recover spontaneously. Infection should be excluded. If spontaneous voiding does not follow removal of the catheter, investigation should be considered.[146]

SUMMARY OF MANAGEMENT OPTIONS
Other Puerperal Problems

Management Options	Evidence Quality and Recommendation	References
Pubic Symphysis Separation		
Most resolve with rest, trochanter belts, analgesics, weight-bearing assistance and time.	III/B	142
Consider injection of symphysis with mixture of hydrocortisone and lidocaine (chymotrypsin).	III/B	142

Urinary Retention		
12–24 hr continuous drainage if > 400 mL residual; majority recover spontaneously.	—/GPP	—
Exclude infection.	—/GPP	—
Rarely, intermittent self-catheterization required.	III/B	146
Investigate if self-catheterization required.	—/GPP	—

GPP, good practice point.

CONTRACEPTION

It has been demonstrated that ovulation may occur as early as 27 days after delivery (mean 70–75 days in the absence of lactation).[147,148] Among nursing mothers, the mean time to ovulation is about 6 months.[98] Variables affecting this include frequency of suckling, duration of each suckling period, and amount of supplementation.[149]

Persistently elevated serum prolactin levels appear to be responsible for the suppression of ovulation among lactating women.[150] Levels of prolactin decrease to the normal range by the third week postpartum in nonlactating women, but

remain elevated for several more weeks in lactating patients. Immediately after delivery, levels of estrogen fall in all women and remain low in lactating patients. In women not lactating, estrogen levels begin to rise 2 weeks after delivery and are significantly higher than in lactating women by day 17 postpartum. Follicle-stimulating hormone (FSH) levels are identical in women regardless of whether they are lactating. It is, therefore, assumed that the ovary does not respond to FSH stimulation in the presence of increased prolactin levels.[98]

It is generally advised that vaginal coitus may be resumed when the perineum is comfortable and lochia has slowed.

Desire and willingness to resume vaginal coitus after delivery varies greatly among women—this may depend on several factors, including return of libido, presence of vaginal atrophy because of lactation, and presence and state of healing of incisions and lacerations.[151] Most women have resumed intercourse by 3 months, some much earlier.[152] Conversely, Ryding[153] reported that 20% of women had little desire for sexual activity 3 months after delivery, and an additional 21% had complete loss of desire or aversion to sexual activity.

Abstinence, or more properly, the intention to abstain from vaginal coitus, is not an effective means of postpartum contraception. Even though it is traditional for obstetricians to advise postponing coitus, sometimes until after the traditional 6- to 8-week postpartum examination, and in spite of lochia, which may persist for 3 to 8 weeks, coitus is likely to occur, and it is prudent to have a contraception plan in effect beforehand. ACOG states that contraception is an important topic for discussion and that women should be encouraged to consider their future plans for birth control during prenatal care and be given information that will help them achieve their goals.[154]

Management Options

Choice of Contraceptive Method (See Table 76–4 for Summary of Options)

BARRIER METHODS

In general, barrier methods of contraception have fewer side effects than hormonal methods and, with the exception of cervical caps and diaphragms, are available without prescription. In addition, under some circumstances, they have been shown to provide protection against sexually transmitted diseases. A meta-analysis has shown that regular use of latex condoms decreased the coital transmission of HIV infection by 69%. Epidemiologic studies have shown a decreased risk of genital herpes simplex, gonorrhea, and nongonococcal urethritis in women whose partners faithfully use condoms.[155–157] Unfortunately, the efficacy of barrier methods in preventing both conception and infection depends heavily on the users adhering to manufacturer's recommendations. Most studies have demonstrated a significant difference between method effectiveness and use effectiveness.

HORMONAL CONTRACEPTION

ACOG has recommended that progestin-only methods can be started safely at 6 weeks postpartum in lactating women (Table 76–5) and immediately postpartum in women who do not nurse their infants. Estrogen-plus-progesterone contraception is not recommended for breast-feeding women because of the possible negative impact on lactation, albeit use of combination oral contraceptive pills by well-nourished breast-feeding women does not appear to result in infant development problems; their use can be considered after milk flow is well-established.[158,159] Manufacturers have recommended that their use be postponed until 6 weeks postpartum in breast-feeding women, because very small amounts of progestin are passed into breast milk, although no adverse effects on infants have been noted when these medications have been started earlier.[160]

TABLE 76–4

Contraceptive Techniques. Comparison of Effectiveness in Terms of Number of Pregnancies per 100 Women during the First Year of Use

TECHNIQUE	TYPICAL USE*	PERFECT USE†	RISK REDUCTION FOR SEXUALLY TRANSMITTED INFECTIONS

TABLE 76–5

ACOG Recommendations for Hormonal Contraception if Used by Breast-feeding Women

Progestion-only oral contraceptives prescribed or dispensed at discharge from hospital to be started 2–3 wk postpartum (e.g., the first Sunday after the newborn is 2 wk old).

Depot medroxyprogesterone acetate initiated at 6 wk postpartum (earlier initiation might be considered in certain clinical situations).

Hormonal implants inserted at 6 wk postpartum.

Combined estrogen-progestin contraceptives, if prescribed, should not be started before 6 wk postpartum, and only when lactation is well established and the infant's nutritional status well monitored.

Modified from American College of Obstetrics and Gynecology (ACOG): Breast-feeding: Maternal and Infant Aspects (ACOG Educational Bulletin No. 258). Washington, DC, ACOG, 2000.

INTRAUTERINE CONTRACEPTIVE DEVICES

Copper-containing and hormone-releasing intrauterine devices (IUCDs) have been shown to be effective in preventing conception, with failure rates on the order of 2 to 3 pregnancies per 100 women-years.[161,162] Objections that the principal mode of action of IUCDs was, in essence, the abortion of a viable conceptus have been effectively laid to rest.[163] This concept has been supported by both ACOG and WHO.[98,164] It is important to inform women that, unlike barrier contraceptives, IUCDs do not provide protection against HIV or other sexually transmitted diseases.

NATURAL FAMILY PLANING

Natural family planning (NFP) remains a controversial topic. On the basis of mailing a questionnaire to 840 Missouri physicians (obstetricians/gynecologists, family practice physicians, general practice physicians, internal medicine specialists; 65% response rate), the authors concluded that most physicians underestimate the effectiveness of NFP and do not give information of modern methods to women.[165] NFP methods are based on the prediction of ovulation using temperature, cervical mucus assessment, and timing. They are not reliable in the absence of relatively regular menstrual cycles, which may take some time to reestablish following delivery.[166] Success rates similar to barrier methods have been reported.[167]

NFP methods vary greatly, but all utilize to some extent selective timing of coitus according to some or all of a variety of methods, including periodic abstinence, use of menstrual calendars, ovulation prediction, withdrawal, and lactational amenorrhea (LAM).

LACTATIONAL AMENORRHEA METHOD

Exclusive breast-feeding helps prevent pregnancy for the first 6 months after delivery but should be relied on only temporarily and when it meets carefully observed criteria of the LAM of contraception.[168] The suckling stimulus provides the only truly physiologic signal that suppresses fertility in normally nourished, healthy women. The variability in the duration of lactational amenorrhea between women is related to the variation in the strength of the suckling stimulus, a unique situation between each mother and her baby. Full breast-feeding can provide a reliable contraceptive effect in the first 6 to 9 months. In women, suckling seems to increase the sensitivity of the hypothalamus to the negative feedback effect of estradiol on suppressing the gonadotropin-releasing hormone/luteinizing hormone (GnRH/LH) pulse generator. Practical guidelines for using breast-feeding as a natural contraceptive have been developed, which allows mothers to utilize the only natural suppressor of fertility in women as an effective means of spacing births.[167]

FEMALE STERILIZATION

Tubal sterilization is the most frequently used method of contraception in the United States.[169] More than 600,000 female sterilization procedures and more than 500,000 male sterilization procedures are performed each year in the United States.[170,171] Preoperative counseling should include a clear discussion about risks of, alternatives to, possibility of failure, and planned irreversibility of permanent surgical sterilization.[169]

Complication rates are low, with an overall mortality rate of 1 to 2 deaths per 100,000 sterilization procedures.[172] Long-term effects of tubal sterilization on pelvic pain, menstrual patterns, and the need for subsequent pelvic surgery are controversial and inconsistent.[169]

The findings of the U.S. Collaborative Review of Sterilization (CREST) were published by the CDC in 1996[173]; these present the only available long-term failure rate data in a very large[100] group of women, with 58% still providing follow-up data at 8 to 14 years after their procedures. CREST showed a 10-year cumulative failure rate of 18.5 per 1000 for all sterilization methods combined. During that interval, postpartum tubal ligation and interval laparoscopic unipolar coagulation were the most effective methods (7.5 failures/1000).[173] Sterilization failures are frequently manifested as ectopic pregnancies; CREST showed a 10-year cumulative probability of ectopic pregnancy of 7.3 per 1000. The specific ectopic rate following postpartum partial salpingectomy was the lowest among all methods (1.5/1000).[174]

In 2002, the U.S. Food and Drug Administration (FDA) approved use of Essure, a hysteroscopically inserted transcervical sterilization device.[169] Success rates in excess of 99.7% have been reported,[175] albeit up to 15% of patients will require a second surgery to achieve occlusion of both fallopian tubes,[176] and the procedure should not be performed until 6 weeks postpartum.[177]

In the United States, the strongest indicator of future regret is young age at the time of sterilization, regardless of parity or marital status.[178] Women 20 to 24 years of age at sterilization are twice as likely to experience regret as women 10 years older.[179] Approximately 6% of sterilized women report regret or request information about sterilization reversal within 5 years of the procedure[169]; approximately 1% to 2% of men having vas ligation seek information on reversal.[179,180]

The success of surgical reversal of tubal sterilization would seem to be mainly related to the amount of undamaged fallopian tube remaining for reanastomosis.[181] It is difficult to compare studies concerning the success of sterilization,

because they generally have small numbers and because investigators use different preoperative exclusion criteria; length of follow-up also varies significantly.[182] After a Pomeroy-type procedure was reversed, studies report subsequent term pregnancy rates of 41% to 74% in a total of 198 patients, with ectopic rates of 6% to 9%.[183–185] Following bipolar cautery, reversal success as measured by term pregnancy was 42% to 52% in a total of 137 patients, with ectopic pregnancy rates of 3% to 17%.[181,183,184]

Intrapartum or early puerperium procedures are convenient because the patient is already in the hospital. Cesarean delivery gives excellent access to the fallopian tubes. Following vaginal delivery, an epidural catheter may be left in place and then used to provide anesthesia and analgesia for a procedure later in the day or on the following day. Conversely, waiting another couple of months for an interval procedure allows time to gain confidence in the health of the baby and dispassionately discuss all implications of permanent surgical sterilization.[98]

For years, there have been concerns about a syndrome of poststerilization pain and menstrual disturbances. A large review comparing women who had tubal sterilization with controls showed no consistent differences in outcomes such as levels of hormones and little difference in the characteristics of menses, although there is, understandably, an increase in menstrual flow in women who had previously been using oral contraceptives.[186] Conversely, a cohort study with 6 years of follow-up reported that sterilized women were more likely to be hospitalized because of menstrual disorders, usually to have curettage (relative risk [RR] 2.4).[187] The subgroup of women younger than 30 years of age studied in CREST who had menstrual dysfunction predating their sterilization procedures had more menstrual changes and, ultimately, were more likely to undergo hysterectomy than were controls.[182,187,188]

Transcervical, intrauterine instillation of quinacrine may be a simple, inexpensive, effective, acceptable, and safe method of nonsurgical permanent female sterilization in some populations. A study in Bangladesh reported a 1.9% failure rate using 252 mg of quinacrine with or without adjuvant ampicillin or ibuprofen (or both). No serious complications were reported.[189] A larger study in Vietnam, however, reported higher failure rates (13% in women younger than 35, 6.8% in women older than 35). Moreover, these authors noted that toxicology studies of locally applied quinacrine were thought by WHO to be inadequate.[190] It would seem that more study is needed before this method can be recommended on a wider basis.

Some years ago, there was in the United States enthusiasm for scheduled cesarean hysterectomy as a sterilization procedure.[191] It was thought by some that this might prove to be a life-saving measure in some cases, for example, for women with cervical dysplasia who were either noncompliant with follow-up or had limited access to care. Most studies, however, reported worrisome complication rates, especially regarding the need for blood product replacement. Even though a group in Israel reported an improvement in the need for transfusion from 64% to 17% as their experience increased,[192] the prevailing feeling would seem to be that cesarean hysterectomy without other indications likely has, in most cases, an unfavorable benefit/risk ratio.

Although there is some confidence that tubal ligation protects from recurrent pelvic inflammatory disease, more than 70 cases of salpingitis and almost 40 cases of tubo-ovarian abscess in women who had undergone tubal occlusion have been published.[193] Most cases of salpingitis developed more than a year after either laparoscopic or laparotomy procedures. Tubo-ovarian abscesses developed over a broad interval of time following operation, ranging from weeks to decades.

SUMMARY OF MANAGEMENT OPTIONS
Puerperal Contraception and Sterilization

Management Options	Evidence Quality and Recommendation	References
Contraception		
See Table 76–5 for relative effectiveness of different methods.	IV/C	194
Barrier		
Few side effects, some protection against sexually transmitted disease.	III/B	155–157
Effectiveness totally dependent on user compliance.	—/GPP	—
Hormonal		
Progestin-only preparations for breast-feeding women.	IV/C	160
Relies on user compliance.	—/GPP	—
IUCD		
Main concerns relate to failure to protect against infection.	—/GPP	—
Natural Family Planning		
Main problem as a method in the puerperium is that the method relies on a regular menstrual cycle, which is uncommon initially.	IV/C	166

Management Options	Evidence Quality and Recommendation	References
Lactation Amenorrhea Method		
Much debate in the literature over the value of this method/approach.	III/B	154,167
Sterilization		
Tubal sterilization (Different Techniques)		
Patients must be counseled about		
• The procedure.	—/GPP	—
• The irreversibility (varies with method).	III/B	169,173
• Failure rates (varies with method and timing with respect to delivery).	III/B	172
• Complications (e.g., regret, ectopics, menstrual disturbance, death).	III/B	169
Cesarean Hysterectomy		
Should be considered only in a few selected cases.	III/B	191,192
Chemical Methods		
Not currently advocated; further research needed.	IIb/B	189,190
Vasectomy		
Same counseling as with female sterilization:	III/B	171
• The procedure.		
• The irreversibility.		
• Failure rates.		
• Complications (generally safe, with no evidence of prostate or testicular cancer of cardiovascular disease).		

GPP, good practice point; IUCD, intrauterine contraceptive device.

Major Obstetric Hemorrhage and Disseminated Intravascular Coagulation

STEPHEN W. LINDOW and JOHN ANTHONY

INTRODUCTION

Maternal death from obstetric hemorrhage remains a global problem. In developing countries, it ranks among the leading three causes of maternal death, and industrialized nations continue to report mortality rates in cases in which problems could have been anticipated and prevented.[1,2] In developing countries, postpartum hemorrhage (PPH) accounts for a higher percentage of deaths due to hemorrhage. The combination of uterine atony with retained products of conception leading to hypovolemic shock and coagulopathy are the most common complications giving rise to death from obstetric hemorrhage.

The U.K. Confidential Enquiry into Maternal and Child Health (2002–2005)[2] has emphasized the need to recognize the antenatal woman at risk of obstetric hemorrhage and to ensure that a multidisciplinary consultant–led team including hematologists, anesthetists, and obstetricians is available to provide adequate care. The unpredictability of obstetric hemorrhage is also acknowledged in this report, and the importance of having early warning scoring systems and protocols to deal with massive hemorrhage is stressed.

Major obstetric hemorrhage is the largest cause of severe maternal morbidity in Scotland, accounting for almost 70% of the total from all causes (a rate of 3.66/1000 maternities).[2]

MAJOR OBSTETRIC HEMORRHAGE

Definition

"Major obstetric hemorrhage" is an imprecise term, but it has been defined as an estimated blood loss of greater than 2500 mL, transfusion of 5 or more units of blood, or treatment for coagulopathy.[2] This chapter deals with the risks and management of severe or major obstetric hemorrhage in which there is a risk of hypovolemic shock. Inevitably, there is some overlap with other chapters, which are cross-referenced.

Incidence

The incidence is difficult to estimate because the definition includes all severe episodes of antepartum, intrapartum, primary, and secondary PPH, and these figures are not recorded collectively or statutorily. The incidence is likely to be about 0.5%, with the largest number of cases being due to primary PPH.

Etiology

Major obstetric hemorrhage is generally caused by the following:
- Placental abruption (see also Chapter 58).
- Placenta previa (see also Chapter 58).
- Causes of primary PPH (see also Chapter 75).
- Ruptured uterus (see also Chapter 75).
  However, underlying disease may contribute to the bleeding, including the following:
- Bleeding disorders (e.g., von Willebrand's disease).
- Acquired hemostatic disorders due to liver failure (e.g., fulminant hepatitis, acute fatty liver of pregnancy).
- Severe disseminated intravascular coagulation (discussed in this chapter).
- Platelet dysfunction (e.g., severe preeclampsia, thrombotic thrombocytopenic purpura).
  Antepartum hemorrhage accounts for fewer deaths than PPH in developing countries, although this pattern is reversed in industrialized countries.

Maternal Risks

Death

Deaths due to major antepartum hemorrhage are usually due to placental abruption. Maternal death from placental abruption is attributable to the effects of hypovolemia (see following discussion) combined with the complications that may arise from underlying predisposing conditions such as preeclampsia. The resting uterine tone may be increased (≤25 mm Hg) and labor may be triggered by placental separation with the sudden onset of frequent contractions.[3,4] Although hypovolemic shock and its sequelae may develop as a result of acute blood loss, hypertension may precede or follow abruptio placentae.[5] The coincident occurrence of hypertension due to preeclampsia together with hypovolemia as a result of abruptio placentae increases the risk of renal failure due to tubular necrosis.[6] Up to one third of

pregnancy-related cases of acute renal failure are due to abruptio placentae.[6] Proteinuria is usually found in cases of abruptio placentae, and the pattern of glomerular protein loss is similar to that seen in acute ischemic renal failure.[7] The mother is at risk of severe hypovolemia from placenta previa also, especially as a result of morbidly adherent implantation over a previous cesarean section scar. Placenta previa is also associated with recurrent antepartum hemorrhage and operative delivery.

Severe primary PPH can lead to hypovolemic shock. Other complications are those associated with the treatment of the underlying condition such as from transfusion-related injury and surgical complications of hysterectomy.

The reported risk of maternal death following uterine rupture varies widely, being very low in industrialized countries but up to 38% in developing countries with limited resources.[8–10] Maternal morbidity rates associated with uterine rupture include all the complications that may follow severe hypovolemic shock, postoperative complications, and reproductive sequelae that include loss of fertility and the need for future operative delivery.

Hypovolemic Shock

Shock is a clinical condition characterized by inadequate tissue perfusion due to any one of the following:

- Impaired peripheral circulation because of diminished intravascular blood volume (hypovolemic shock)—only this form of shock is covered in this chapter.
- Left ventricular failure (cardiogenic shock).
- Disruption of vasoregulatory homeostasis as a result of inappropriate peripheral vasodilation (distributive shock).

Hypovolemia leads to a reduction in peripheral blood flow through the splanchnic and cutaneous circulation as a result of selective vasoconstriction mediated by the central nervous system and a baroreceptor sympathetic response. These differential changes in vascular tone allow selective preservation of blood flow to the brain, heart, and adrenal glands. Venous return to the heart is augmented by a reduction in venous capacitance mediated by catecholamine-induced venoconstriction. This sustains cardiac filling pressures, stroke volume, cardiac output, and critical organ oxygenation. Intravascular volume is also replenished by renal conservation of sodium and water triggered by increased formation of angiotensin. The secretion of antidiuretic hormone further contributes to the renal adaptation.

Sympathetic stimulation and an increase in circulating catecholamines both lead to a rising heart rate and increased myocardial contractility that further increase myocardial oxygen demand. Ongoing hemorrhage and the development of anerobic metabolism with acidosis may lead to left ventricular failure and the development of irreversible shock.

The immunologic and metabolic response to injury is characterized by the development of the systemic inflammatory response syndrome (SIRS). This process, triggered by hypovolemia and hypoxia, gives rise to diffuse effects as a result of damage to the vascular endothelium.[11] The initial endothelial response to hypoxia includes the expression of adhesion molecules that bind lymphocytes and leukocytes as well as platelets. The activated white blood cells produce and release a range of proinflammatory cytokines and oxygen free radicals.[12] The latter species augment oxidative stress and promote lipid peroxidation once antioxidant

mechanisms are saturated. Lipid peroxidation of cell membranes is presumed to result in the loss of vascular integrity with increased vascular permeability. This mechanism is the basis for the development of acute respiratory distress syndrome (ARDS) in the lung and also contributes to the development of multiorgan failure.

Reperfusion injury is also implicated in the development of multiorgan failure. When hypoxic cells can no longer sustain anaerobic metabolism because of glycogen depletion, ATP (adenosine triphosphate) levels fall and homeostatic regulation of ionic flux across the cell membrane fails with rising intracellular sodium and calcium levels. Changes in intracellular calcium concentration adversely affect various enzymes, including xanthine dehydrogenase, converting the enzyme to xanthine oxidase. This switch allows the metabolism of accumulating hypoxanthine (derived from purine catabolism) to superoxide anion and hydrogen peroxide once perfusion and oxygenation are restored.[13] The subsequent release of reactive oxygen species and peroxide augments oxidative stress giving rise to further endothelial damage. Reperfusion injury often arises from delayed restoration of flow through the splanchnic circulation even after adequate resuscitation. The ischemic gut contains xanthine oxidase and is able to generate oxygen free radicals that on reperfusion. may overwhelm the hepatic antioxidant defense mechanisms trigerring systemic endothelial damage and contributing to the onset of multiorgan failure. In addition, reduced splanchnic flow alters gut mucosal permeability, allowing the absorption of intestinal bacteria and toxins into the portal circulation.

Disseminated Intravascular Coagulation

Changes in the coagulation system accompany acute blood loss and will vary according to the extent of the blood loss and the underlying pathology associated with bleeding. The acute-phase response elicited by any form of trauma is characterized by increased hepatic synthesis of clotting factors and hyperhomocysteinemia. The resultant hypercoagulability is seldom clinically evident because these effects are usually overwhelmed in women with acute obstetric blood loss by consumptive coagulopathy.

The clotting defect seen in women after obstetric hemorrhage usually develops because of consumption of clotting factors, leading to a bleeding tendency. Disseminated intravascular coagulation (DIC) is frequently also present and develops whenever procoagulant mechanisms promote fibrin formation in the circulation. The hematologic consequences of DIC are often clinically insignificant but are sometimes associated with a profound coagulopathy (typically seen in the anaphylactoid syndrome of pregnancy but also seen in severe sepsis in which liver dysfunction and thrombocytopenia add to the risk of coagulopathy). DIC contributes to the development of organ failure as a result of SIRS, although the management of this complication is the management of the underlying condition rather than the DIC itself. The numerous mechanisms that trigger DIC do so by endothelial or platelet activation and via the release of thromboplastin into the circulation. Hence, procoagulant changes accompany the development of SIRS and are induced by leukocyte activation and endothelial dysfunction.[14] The presence of placental tissue or amniotic fluid in the maternal circulation initiates intravascular coagulation,

and thromboplastin release into the circulation is known to occur in cases of abruptio placentae.

Fibrin formation initiates fibrinolysis, leading to the formation of plasmin and the elaboration of fibrin degradation products (FDPs) that are readily measurable in the peripheral circulation (e.g., quantitative D-dimer levels). Although these breakdown products of fibrin are used to diagnose intravascular coagulation, the protection of vascular integrity during normal pregnancy includes sufficient intravascular coagulation to increase D-dimer levels with an increase in circulating thrombin-antithrombin complexes. Accelerated formation of fibrin stimulates fibrinolysis. Plasmin may stimulate the complement cascade, which further contributes to the development of increased capillary permeability.

The physiologic adaptations of pregnancy protect the mother from the hemodynamic and hemostatic effects of hemorrhage at the time of delivery. These changes include a 30% increase in blood volume as a result of plasma volume expansion combined with an increase in red blood cell mass. These changes are accompanied by physiologic peripheral vasodilation to accommodate the increased blood volume and cardiac output. The combined effects of these changes allow more extensive hemorrhage prior to the development of shock and the net gain of 1 to 2 L of intravascular volume exceeds the estimated blood loss of 500 to 600 mL at the time of normal delivery. Hemostasis is augmented by increased hepatic production of clotting factors, especially fibrinogen, and the anticlotting mechanism is impeded by a reduction in the level of free protein S. Fibrinolysis also diminishes in response to placental production of plasminogen activator inhibitor II.

Clinical Presentation

The development of hypovolemic shock is recognized by a progressive fall in blood pressure and a rising pulse rate. The severity of the blood loss can be classified on the basis of clinical signs alone (Table 77–1).[15]

Hemodynamic monitoring will confirm low ventricular filling pressures (central venous pressure or pulmonary capillary wedge pressure) and a low cardiac output. In addition, measurement of central venous oxygen saturation will confirm increased rates of oxygen extraction (<65%) as cardiac output and peripheral perfusion diminish. In determining the diagnosis of acute hypovolemia, investigations are of limited utility. This is especially true of hemoglobin concentration estimation because the hematocrit will fall only as transcapillary rehydration from interstitial fluid takes place slowly over several hours.

Coagulopathy may be very obvious in the woman who presents with bleeding gums and oozing from all venipuncture sites. In many cases of coagulopathy, however, these signs will not be evident and the diagnosis will depend upon measurement of the International Normalized Ratio (INR), activated partial thromboplastin time (aPTT), and platelet count.

Renal Failure

Acute oliguric renal failure will develop as a consequence of hypovolemic shock. The loss of 15% to 30% of the intravascular blood volume will result in reduced renovascular perfusion and readily reversible changes in urinary output and blood urea and creatinine levels. Ongoing blood loss leads to the development of acute tubular necrosis in which ischemic injury to the tubules results in tubular epithelial cells becoming detached and blocking the tubules. This adds an obstructive component to the renal ischemia that will further reduce glomerular filtration. The development of SIRS may also add an immunologic component to the pathogenesis of renal tubular dysfunction.

Acute Respiratory Distress Syndrome

ARDS develops as part of the systemic inflammatory response syndrome but may also arise as a consequence of multiple blood transfusions. In the latter case, human leukocyte antibodies present in transfused plasma may be responsible for activation of the complement cascade with subsequent pulmonary vascular injury. ARDS is characterized clinically as a form of noncardiogenic pulmonary edema. The underlying pathophysiology is based upon inflammatory changes rather than an accumulation of interstitial edema fluid (usually associated with high pulmonary capillary wedge pressures).

Complications of Blood Transfusion

The immediate complications include incompatible transfusion, hyperkalemia, and citrate intoxication. Hyperkalemia arises because of the leakage of potassium from stored red blood cells and is a potential problem in those who require transfusion despite renal failure. The development of hyperkalemia may be suspected if the electrocardiogram shows peaked T-waves with wide PR and QRS intervals. Citrate intoxication develops because calcium ions are chelated, leading to hypocalcemia (manifest as irritability, hypotension, and a prolonged QT interval on the electrocardiogram). Conversely, the U.K. Confidential Enquiry into Maternal and Child Health has demonstrated that some maternal deaths from major obstetric hemorrhage have resulted from a failure to give sufficient blood replacement.[2]

TABLE 77–1				
Clinical Classification of the Severity of Blood Loss				
CLINICAL SIGN	**BLOOD LOSS < 15%**	**BLOOD LOSS 15%–30%**	**BLOOD LOSS 30%–40%**	**BLOOD LOSS > 40%**
Pulse rate (beats/min)	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Urinary output (mL/hr)	>30	20–30	5–15	<5
Neurologic status	Anxiety	Anxiety	Confusion	Lethargy

From Marino PL: The ICU Book. New York, Williams & Wilkins, 1998, p 209.

Transfusion-related lung injury presents as noncardiogenic pulmonary edema within several hours of transfusion and requires mechanical ventilation for up to 48 hours. Longer-term risks are those related to infection with hepatitis viruses, HIV, and bacterial infection.

Endocrinopathy

During pregnancy, the pituitary gland increases in size severalfold. The blood supply to the anterior pituitary gland is dependent on flow through the superior hypophyseal artery and is susceptible to avascular necrosis. The likely clinical presentation includes failure of lactation, amenorrhea, and loss of secondary sexual characteristics, followed by the evolution of hypothyroidism and adrenocortical insufficiency (Sheehan's syndrome). Sheehan's syndrome may evolve over a lengthy period of time after the precipitating event. The diagnosis should be suspected in the woman who fails to lactate, and confirmatory tests of hypothalamic and pituitary function are carried out. Neuroradiologic investigation will usually reveal an abnormal or empty sella turcica.

Anemia

Anemia may be a late complication of massive hemorrhage. Replenishment of the red blood cell mass will require hematopoiesis dependent on adequate iron stores associated with a normal dietary intake of folic acid.

Fetal Risks

Death

Fetal loss in association with placental abruption is due to hypoxia and prematurity, with perinatal mortality rates as high as 12%.[16] Placental abruption is the leading cause of perinatal death in many countries.[17,18] Fetomaternal hemorrhage is a common occurrence following abruptio placentae.[19]

Major obstetric hemorrhage due to placenta previa less commonly causes perinatal death, but again, this is due to prematurity or fetal hypoxia.[20–22]

The fetal risks following uterine rupture depend on the nature of the rupture and vary from no adverse effects to severe asphyxia and death.

Cerebral Hypoxia

Antepartum or intrapartum hypoxia may result in an infant in poor condition at delivery, with subsequent development of convulsions, intracerebral edema, and hemorrhage. This may lead to conditions such as periventricular leukomalacia and porencephalic cysts and long-term neurologic handicap. Pulmonary hemorrhage and necrotizing enterocolitis may also occur after a hypoxic episode.

Consequences of Prematurity

These complications account for most of the cases of neonatal death if the infant has survived the initial insult, and include respiratory distress syndrome and persistent fetal circulation with patent ductus arteriosus. Complications associated with prolonged neonatal intensive care such as sepsis and bronchopulmonary dysplasia are relatively common.

Management Options (See also Chapters 58 and 75)

Prenatal: Identification of "At-Risk" Patients

ANY BLEEDING

Massive blood loss cannot always be anticipated or prevented. Some high risk patients can be identified more easily, such as those with placenta previa. However, the prediction of such an event in the general obstetric population is poor. If a woman is anemic prior to labor, or states that she will refuse blood products on religious grounds, she is at increased risk should she bleed excessively in association with delivery. It is good practice in such cases for delivery to occur in a large unit with appropriate staff and facilities.

Patients who have had a previous hemorrhage in pregnancy are at risk of recurrence and should be counseled about such risk and delivered in larger obstetric units with full resuscitative measures available. They should be aware of the procedures for urgent admission to the unit and the need to attend with any degree of bleeding. Iron prophylaxis is advisable in this group (although the risk of major hemorrhage is not generally seen as an indication for routine iron therapy).

PLACENTA PREVIA

Advancing age and parity are associated with the development of placenta previa, although the relative importance of these two factors is disputed.[23,24] Uterine scars, previous miscarriages, terminations, and dilation and curettage are reported as predisposing factors, possibly owing to endometrial damage.[25] Placenta previa is more common in multiple pregnancy, owing to increased placental size. Maternal age is an important factor in recurrent placenta previa, and the risk of recurrence is quoted as between 10% and 15%.[26] There is an association between a previous cesarean section and the subsequent development of placenta previa (3%–10%); the risk increases with the number of previous cesarean sections.[23,27] This group of patients is also at risk of placenta accreta (reported as 10%–67%), again increasing with the number of previous cesarean sections. Any patient with a placenta previa and previous cesarean section should be informed of the possible necessity of a hysterectomy. The repeat cesarean section should be booked in an appropriate unit and performed by a senior obstetrician with blood cross-matched and immediately available. Techniques for the antenatal prediction of placenta accreta have not been found to be accurate. The presence of placental lacunae, the border between the bladder and the myometrium, myometrial thickness, the clear space between the placenta and the myometrium, and color-flow Doppler have not shown the necessary sensitivity and specificity to be used as a clinical test. Magnetic resonance imaging (MRI) may prove to be useful with advances in technology, but more evidence is required at present.[28]

Only 15% to 20% of cases of placenta previa have major bleeding episodes.[29,30] It should be stressed to the woman with a placenta previa that she is much more likely not to have a severe hemorrhage than she is to have one, especially as ultrasonographic diagnosis has led to increased detection of asymptomatic placenta previa that may prove to be of uncertain clinical significance.

Although bleeding with a placental previa is assumed to be of maternal origin, it has been suggested that a proportion of the blood loss may be fetal in origin.[24] A denaturation test to detect the presence of fetal cells should be carried out in the presence of hemorrhage if delivery is not planned.[30]

PLACENTAL ABRUPTION

The causative factors are known in only a minority of cases of placental abruption, but an association with increasing parity, smoking, low socioeconomic status, intrauterine growth restriction, and preeclampsia is reported.[31–33]

The importance of maternal factors is shown by the recurrence rate of 6% to 16% after one placental abruption and 20% to 25% after two previous placental abruptions.[31] Interventions in women at risk have not been shown unequivocally to reduce the occurrence or consequences of placental abruption. Thus, maintenance of a normal blood pressure and cessation of smoking might reduce the risk, although this has not been proved in controlled trials. Similarly, both folic acid supplementation and low-dose aspirin therapy, though advocated by some, have not been shown to reduce the risk of recurrent abruption.

RISK OF POSTPARTUM HEMORRHAGE

Any woman having a baby is at some risk of PPH (3%–5% of deliveries), and women contemplating a home delivery should be informed of this because many cases occur unexpectedly. If there has been a previous PPH, the risks of recurrence are increased to approximately 8% to 10%. Women with a history of retained placenta and those with multiple pregnancies are also at risk. Active management of the third stage of labor should be advised.[34]

Prenatal—Active Bleeding: General Management

The essential management of major bleeding is the same, whatever the underlying cause of hemorrhage, and involves the following steps:

- Stop the bleeding.
- Restore the circulating blood volume and oxygen-carrying capacity.
- Correct any coagulation defect.
- Maintain vigilance for and dealing with the consequences of hypovolemia.

MANAGEMENT PROTOCOL

Every obstetric unit should have its own protocol for management of massive hemorrhage available on the delivery unit for all nursing and medical staff. This enables the appropriate clinical and laboratory staff to be summoned early and a clear management strategy to be adopted. An example of a general management protocol for major hemorrhage is given in Table 77–2, and these guidelines should be followed without delay as soon as a major bleeding episode is recognized. This protocol clearly outlines the necessary steps to be taken. Similar guidelines should be drawn up for any obstetric unit, customized to local circumstances.

SITE OF MANAGEMENT

The setting will vary with local resources and established practices. Many units have a high dependency area in which such patients can be managed. However, there will be a stage in the management of these patients at which

---

TABLE 77–2

Sample Major Hemorrhage Protocol

Organization

1. Switchboard operator sends urgently for the following:
   a. Obstetric resident if not present.
   b. Duty obstetric anesthetist.
   c. Obstetric nursing officer to arrange extra staff.
   d. Blood bank technician.
   e. Porter to maternity unit (for transfer of samples).
2. Consultant hematologist and obstetrician are informed of the clinical situation.
3. One nurse to be solely assigned to record keeping:
   a. Patient vital signs, central venous pressure, and urine output.
   b. Amount and type of all fluids the patient receives.
   c. Dosage and types of drugs given.
4. Prepare for theater as soon as possible—most diagnoses require surgical intervention.

Clinical Management

1. Insert two large-bore (preferably 14-gauge) cannulas. Take 20 mL of blood for complete blood count, baseline clotting studies, and cross-matching and order at least 6 units of blood together with 3 units of fresh frozen plasma.
2. Give oxygen via face mask.
3. Commence fluid replacement quickly. (All fluids and blood should be given through a warming device.)
   a. Initially crystalloid and colloid. Hartmann's solution to a maximum of 1.5–2 L.
   b. Uncrossed blood. Rh-negative, matched with the patient's ABO blood group should be given next if cross-matched blood is not ready.
   c. Cross-matched blood given as soon as possible.
   d. Give O-negative blood only if none of the above is available (but it may be life-saving).
4. Insert central venous line and urinary catheter.
5. Stop the bleeding
   a. If antepartum, deliver the fetus (see text).
   b. If postpartum, deliver the placenta if still in utero, commence bimanual compression of the uterus, and give ergometrine 0.5 mg IV. Commence syntocinon infusion of 40 units in 500 mL of Hartmann's solution to run over 4 hr.
   c. If bleeding because of genital tract trauma or retained products, take the patient to theater promptly to explore the uterine cavity and repair damage.
   d. If bleeding continues, consider coagulation failure. Temporary direct aortic compression may give valuable time.
   e. Other surgical measures:
      Direct intramyometrial injection of prostaglandin E_2 0.5 mg, or prostaglandin $F_{2\alpha}$ 0.25 mg.
      Insertion of Lynch suture.
      Ligation of uterine arteries on both sides.
      Ligation of internal iliac arteries.
      Hysterectomy.

---

admission to an intensive care unit is indicated. These indications will also vary with local resources and practices, but an arbitrary list of possible indicators is given in Table 77–3.

MONITORING

The woman bleeding as a result of obstetric hemorrhage may require increasingly invasive monitoring, depending on the extent of the hemorrhage.

- Clinical monitoring should include measurement of blood pressure, pulse rate, and urinary output combined with an estimation of the extent of the blood loss on a half-hourly to hourly basis.

Indications for Intensive Care

1. All patients requiring mechanical ventilation.
2. All patients with ongoing hemorrhage.
3. All patients requiring inotropic support.
4. All patients with organ failure
   a. Renal failure (urine output <30 mL/hr, creatinine >150 mmol/L).
   b. Respiratory distress.
5. All patients with underlying complicating disorders
   a. Preeclampsia/eclampsia/HELLP syndrome.
   b. Acute fatty liver of pregnancy.
   c. Other causes of acute liver failure.
   d. Anaphylactoid syndrome.
6. All patients with invasive monitoring

HELLP, hemolysis, elevated liver enzymes, and low platelets.

- Hypovolemic patients should all have invasive hemodynamic monitoring to assess intravascular volume and ventricular filling pressures (either a central venous pressure line or, in the case of preeclampsia, a pulmonary artery catheter)—see later discussion.
- The extent of the coagulation defect and the hemoglobin concentration must also be assessed, the frequency of which will be determined by the severity and duration of the hemorrhage.
- Organ function may be compromised by massive blood loss and the sequelae associated with resuscitation and massive transfusion. Hence, organ-specific complications such as renal failure and acute lung injury should be considered and laboratory monitoring of renal function, peripheral oxygenation, and chest x-rays may all be required on a daily basis. In high-dependency units, peripheral oxygen saturation is commonly monitored continuously during resuscitation.

FLUID, BLOOD, AND BLOOD PRODUCT REPLACEMENT

Restoration of the circulating blood volume and reperfusion of ischemic organs is an essential priority and needs to be accomplished within 6 hours of developing hypovolemia if inflammatory sequelae are to be avoided.[35] Intravenous fluids must be infused as rapidly as possible until the pulse rate begins to decline. Thereafter, the volume infused should be titrated against a number of clinical parameters, including blood pressure (aiming for mean arterial pressure > 60 mm Hg), peripheral capillary filling, urinary output, and central venous pressure. In the intensive care setting, other indices of tissue oxygenation (oxygen delivery and consumption indices) as well as mixed venous oxygen saturation levels may be used to optimize fluid management.[35,36]

If blood loss is anticipated, blood salvage techniques can be used for autologous transfusion during cesarean section, thus reducing the need for homologous blood transfusions.[37]

The rapid administration of fluids depends upon the viscosity of the fluid chosen and the physical properties of the cannula used to establish the infusion. Acellular fluids (rather than blood or packed red blood cells) can be infused rapidly and should be used to initiate resuscitation. Randomized studies have shown no benefit associated with the use of colloidal solutions; consequently, they should be used only as an adjunct to crystalloids in specific situations in which low oncotic pressure may complicate the presentation (e.g., severe preeclampsia with abruptio placentae). Crystalloids commonly used for resuscitation include lactated Ringer's solution or normal saline. The choice of the cystalloid is probably less important than the volume and the rate at which the solution is given. The rate of fluid infusion is determined by the bore and length of the infusion cannula with short large-bore peripheral cannulas (ideally, two 14-gauge cannulae) being preferable to long central lines. The initial goal of fluid therapy is a fall in pulse rate with a rise in mean arterial blood pressure to above 60 mm Hg. As a rule of thumb, the amount of crystalloid required will be three times the volume of blood lost. Central venous pressure measurement after resuscitation should rise to between 10 and 12 mm Hg and fluid should be administered as a bolus challenge against the central venous pressure until a sustained rise in pressure beyond these values can be demonstrated. If central venous oxygen saturation monitoring is utilized, values of less than 65% are associated with abnormally high rates of oxygen extraction from blood perfusing the peripheral tissues as a result of ongoing hypovolemia and indicate the need for ongoing resuscitation.

Occasionally, severe persistent hypotension despite fluid resuscitation indicates the need for inotropic support to maintain sufficient cardiac output. This can be attained using adrenaline, dopamine, or dobutamine. Vasopressor doses of adrenaline range from 0.01 to 0.1 μg/kg/min and should be titrated against the blood pressure. Dopamine in a dose of 4 to 7 μg/kg/min stimulates β-receptors and increases cardiac output. Dobutamine is primarily a β_1-receptor stimulant and is mostly used for treating left ventricular failure in a dose of 5 to 15 μg/kg/min. Control of hemorrhage and adequate fluid replacement should allow rapid weaning from inotropic support.

Correction of the coagulation defect usually requires the administration of fresh frozen plasma (FFP) in a ratio of 1 unit to every unit of packed red blood cells considered necessary to restore the oxygen-carrying capacity.[38] Each unit of FFP will restore procoagulant activity by about 10% and will also raise the fibrinogen level by 25 mg/dL. Cryoprecipitate contains Factor VIII, fibrinogen, and von Willebrand's factor and should be given when the fibrinogen levels fall below 100 mg/dL. Each adult dose of cryoprecipitate will raise the fibrinogen level by 100 mg/dL. The advice of a hematologist should be sought when correcting the coagulation defect that develops after massive hemorrhage. Platelets do not need to be infused to restore hemostasis until the count falls below 50×10^9 cells/Lm providing the platelets are functionally normal (women with preeclampsia may have qualitative platelet defects as well as thrombocytopenia). Each adult dose of platelet concentrate will raise the platelet count by 20 to 40×10^9 cells/L.[39] Administration of FFP should be continued until the aPTT and INR are measurably normal (Table 77–4).

For the patient with uncontrollable hemorrhage in whom all other measures have failed, evidence is accumulating that recombinant Factor VIIa is proving successful.[40–42]

Correction of the red blood cell mass deficit is guided by the rule that each unit of packed cells will restore

TABLE 77–4

Blood Component Therapy*

	NUMBER OF DONORS	FIBRINOGEN CONCENTRATION	FIBRINOGEN PER UNIT	PLATELETS PER ADULT DOSE	INCREASE IN HEMATOLOGIC PARAMETER (70-KG ADULT)
Packed cells (1 unit)	1	Negligible	–	Negligible	Hemoglobin increase 1 g/dL
Fresh frozen plasma (1 unit)	1	2–5 mg/mL	550–1395 mg (240–300 mL)	Negligible	Fibrinogen increase 0.25 g/L
Cryoprecipitate (1 adult dose)	10	15 mg/mL	3–6 g (200–500 mL)	Negligible	Fibrinogen increase 1 g/L
Platelet Concentrate (1 adult dose)	4	~2 mg/mL	~500 mg	240×10^9	Platelet count increase $20–40 \times 10^9$

* The values are not consistent between different blood transfusion services.
From McClelland DBL (ed): Handbook of Transfusion Medicine, 4th ed. United Kingdom Blood Services. London, TSO, 2007.

hemoglobin concentration by 1 g/dL. There is no consensus regarding what would be generally considered a desirable hemoglobin concentration. Hemoglobin concentrations of 6 g/dL or less probably merit transfusion, and in obstetric patients with ongoing blood loss, a more liberal transfusion policy is necessary. Full cross-match is preferred prior to transfusion, although with massive hemorrhage, type-specific partially cross-matched blood can be used (5-min cross-match). Most labor units will also have a limited supply of type O-negative blood available for obstetric emergencies. Because of the risks associated with transfusion of donated blood, in circumstances in which the need for transfusion may be foreseeable, autologous blood transfusion should be offered and can be accomplished by either predonation or preoperative normovolemic hemodilution.

During resuscitation, supplemental oxygen delivery should be provided by means of a 40% face mask and the patient should be kept warm with space blankets or commercially available pneumatic blanket warming device. Additional intensive care monitoring of blood pressure via a radial artery line is also helpful both to allow continuous monitoring of the systemic pressure and to facilitate repeated hematologic investigation.

Prenatal—Active Bleeding: Specific Management
PLACENTAL ABRUPTION

In severe abruption, the woman is usually in severe pain and may be in shock due to hypovolemia. The amount of vaginal bleeding will vary. Coagulopathy occurs in about one third of cases when the fetus is dead, but is comparatively rare with a live fetus. Labor occurs spontaneously in approximately 50% of patients.

Maternal resuscitation, as described in the previous section, is the immediate priority. Adequate analgesia should be given if required, usually by intravenous narcotics supplemented by nitrous oxide/oxygen mixtures self-administered by mask. Epidural analgesia is contraindicated in any woman who is actively bleeding sufficient to produce hypovolemia, hypotension, coagulopathy, or acute fetal compromise because of the peripheral vasodilation associated with lumbar sympathetic blockade.

The only treatment for continuing severe placental abruption is to empty the uterus as soon as feasible. If the fetus is dead, normal management is to aim for a vaginal delivery, except where there is an obvious obstetric indication for cesarean section, such as transverse lie. In rare situations, uterine contractions cannot be stimulated or maternal shock is uncorrectable. Cesarean section may have to be undertaken in such cases, although there is a significant maternal risk from further blood loss, especially if there is also a coagulopathy. If there is no response to oxytocin, prostaglandins may be administered with appropriate surveillance in an attempt to stimulate uterine contractions. The management of labor in patients with abruptio placentae is uninformed by any randomized evidence, and no clear guidelines are thus available. There is an increased risk of uterine rupture with a large abruption, particularly if there is a Couvelaire uterus.

Determining if the fetus is alive by auscultation might be difficult because of a tender, hypertonic uterus, especially if there is a retroplacental clot and anterior placenta. Accordingly, visualization of the heart using ultrasound is usually the quickest method if a machine is available. If not, it may be necessary to rupture the membranes and attach a fetal electrocardiogram electrode, providing the patient is known to have been screened for HIV infection. Exclusion of placenta previa may be difficult on clinical grounds if the presenting part cannot be palpated, and the two conditions may coexist. Ideally, location of the placental site is checked by ultrasonography before any vaginal examination.

If the fetus is alive, consideration should be given to early delivery by cesarean section for fetal reasons. This will depend on the gestation, because it is extremely improbable that a fetus under 26 weeks will survive such an asphyxial episode. The mode of delivery will also depend on the fetal condition as judged by cardiotocography. If the fetal heart rate pattern is totally normal (which is unlikely), induction of labor with continuous monitoring can be considered. An abnormal cardiotocograph tracing is usually an indication for cesarean delivery, providing that the fetal heart beat is confirmed to be present immediately prior to the cesarean section.

The clinical diagnosis of abruptio placentae in the woman who has had a previous cesarean delivery must lead to consideration of whether the clinical presentation could be due to uterine rupture. Signs of generalized peritonitis, cessation of labor, hematuria, and malpresentation may all indicate uterine rupture; abdominal paracentesis may also reveal hemoperitoneum. A high index of clinical suspicion necessitates laparotomy to exclude the diagnosis.

PLACENTA PREVIA

Massive hemorrhage from placenta previa follows smaller "warning" bleeds in the majority of cases, and the placental site will often already be known. The fetal heart is usually still present, and in addition, there may be evidence of uterine contractions or premature rupture of membranes in about 20% of cases.

Initial management involves maternal resuscitation, as described earlier. A patient with such a severe hemorrhage due to placenta previa will require delivery by cesarean section irrespective of whether the fetus is dead or alive. The cesarean section may need to be performed as resuscitative efforts are under way if the mother's condition cannot be stabilized. Occasionally, vaginal delivery may be contemplated if the fetus is dead or extremely premature. When there is any possibility of placenta previa, a digital examination should occur only in the operating room after the decision has been made to deliver and the diagnosis of placenta previa is in doubt. Cesarean section for placenta previa is often a difficult procedure associated with fetal malpresentation, a poorly developed lower uterine segment, and excessive blood loss that further compromises the condition of the patient. The operation should be performed by a senior obstetrician in association with a senior anesthetist and with extra blood immediately available.

Several aspects of cesarean delivery present additional unresolved dilemmas. These include the choice of anesthesia, the technique by which the amniotic cavity is reached, and the method of delivery of the baby. Regional anesthesia, which is the generally preferred technique of obstetric anesthesia, is associated with peripheral vasodilation that could be deleterious in women who experience massive intraoperative hemorrhage. Reaching the amniotic cavity in women with an anterior placenta previa presents the surgeon with a choice of dissecting the placenta free from the decidua in order to open the amniotic cavity at the edge of the placenta or the alternative choice of transecting the placenta to open the amniotic cavity directly beneath the uterine incision. These techniques have not been subject to randomized comparison, and most practice is informed only by prevailing surgical habit. Delivery of the baby may similarly challenge the surgeon to attempt a potentially difficult cephalic delivery compared with internal podalic version and breech extraction.

Placenta previa accreta may be encountered in about 5% of cases with no previous scar in the uterus and in up to 67% of cases with multiple cesarean sections. Early recourse to hysterectomy may be necessary, but conservative management has been attempted, including oxytocics, uterine devascularization procedures, brace sutures, and catheter compression techniques (see later discussion). PPH is also more common because of the inability of the lower uterine segment to contract efficiently and should be anticipated and similar prophylactic measures taken (see later discussion).

PRIMARY POSTPARTUM HEMORRHAGE
Initial Management

Most cases of massive PPH are primary and occur within the first hour after delivery. It is relatively uncommon for secondary hemorrhage to present with blood loss of more than 1000 mL.

The principles of management are as follows:
- Arrest the hemorrhage.
- Resuscitation (see earlier discussion).
- Definitive management of the underlying problem.

In the labor ward, initial treatment should include rubbing up the fundus to expel clots and to provoke a uterine contraction. Massive hemorrhage in excess of the attainable rate of fluid replacement may lead to rapidly progressive hypovolemia and cardiac arrest. This situation should be recognized when it develops, and temporizing measures are necessary to allow resuscitative measures time to restore circulating blood volume. The temporizing measures employed are those of controlling blood loss by direct pressure on the bleeding vessels. In the case of uterine hemorrhage, this is achieved by bimanual compression of the uterine fundus. The fundus of the uterus is sandwiched between the fist of the obstetrician placed in the anterior vaginal fornix and the abdominal hand that compresses the body of the uterus against the vaginal hand. In desperate circumstances, aortic compression should also be considered. This can be executed by placing the palm of the hand on the abdomen above the umbilicus and applying firm pressure to occlude the aorta.

The cause of the bleeding should be identified early in the management. The main causes are uterine atony (including retained placental tissue), trauma, and coagulation defects.

Management of the Underlying Cause

Few of the necessary interventions can be sustained on the basis of randomized studies. However, the role of oxytocic drugs has been reviewed, and their utility in active management of the third stage of labor is well established.[43]

More than one etiologic factor may be present. The most common cause is uterine atony. Pharmacologic intervention must include a range of oxytocic drugs. First-line treatment requires the use of oxytocin and ergometrine. Oxytocin is administered as a bolus of 5 units intravenously followed by an infusion of 20 units in a liter of Ringer's lactate or normal saline. Ergometrine is given, either in combination with oxytocin (syntometrine) or on its own, in a dose of 0.5 mg intramuscularly or intravenously. This dose may be repeated. Ergometrine may be of limited utility in developing countries with poor facilities for refrigeration and storage away from light.[44,45] There is some evidence that rectal misoprostol may be an effective agent for controlling severe hemorrhage and should be used in combination with oxytocin and ergometrine.[43,46,47] Other pharmacologic options include the use of methylated prostaglandin $F_{2\alpha}$ preparations (Hemabate), although the side effect profile of the prostaglandin $F_{2\alpha}$ analogues include hypertension, bronchospasm, and diarrhea that limits the utility of these agents even if they are effective in controlling uterine hemorrhage.[48]

Persistent uterine hemorrhage unresponsive to pharmacologic manipulation may need to be dealt with surgically in a series of increasingly radical procedures. The choice of procedure will be influenced by the specific individual circumstances that may include bleeding due to retained

products, hemorrhage as a result of persistent uterine atony, bleeding at the time of cesarean section, bleeding from the lower segment following delivery of a placenta previa, and bleeding as a result of trauma. The surgical options include evacuation of the uterus, devascularization of the uterus, compression techniques, and definitive management in the form of hysterectomy.[46,49,50]

Evacuation of the uterine cavity should be preceded by careful examination under anesthesia to exclude uterine rupture. Removal of placental tissue may be achieved by a combination of digital evacuation, the use of Desjardin forceps, and curettage with a large curette (Baum's curette).

Stepwise devascularization of the uterus commences with ligation of the uterine arteries adjacent to the lower segment. This may necessitate opening the leaves of the broad ligament by dividing the round ligaments.[46] The supposition upon which this intervention is based is that a reduction in the perfusing pressures within the uterine circulation may allow the hemostatic mechanism to reassert itself. Failure to control hemorrhage in this way should lead to ligation of the infundibulopelvic vessels, taking care to avoid damage to the fallopian tubes. Devascularization may also be achieved by occluding the internal iliac artery by either ligation or embolization.[46] Ligation of the internal iliac artery requires careful dissection of the retroperitoneal space and identification of the ureter. This technique should not be attempted without adequate surgical experience in pelvic dissection, and the reported success rates vary from a 42% to a 65% chance of avoiding hysterectomy.[51]

Various compression techniques are described. The B-Lynch brace is transfixed through the lower segment with two loops of chromic catgut over the fundus, applying pressure to the body of the uterus in the same way that a pair of braces would be worn.[52] Simpler techniques include sutures that traverse both anterior and posterior walls of the uterus in the form of two parallel sutures inserted into the upper uterine segment.[53]

Bleeding from the lower segment of the uterus after delivery of a placenta previa may be difficult to control because the lower segment does not retract to the same extent as the upper segment. Transcervical catheters with a large bulb (Sengstaken-Blakemore tube) may be used to compress these vessels and have even been advocated as an alternative to uterine packing as a way of controlling PPH.[54] Uterine packing using gauze packs, previously advocated, as a mechanism for controlling blood loss is no longer practiced because of the difficulty of packing the distensible postpartum uterus and because of concerns about infection.

Selective arterial embolization may be useful to control bleeding, however; not all obstetric units would have the specialist facilities and personnel readily available. Using embolization for PPH in shocked patients has been shown to reduce the effectiveness, as has its use following cesarean section. The most effective use was in the treatment of uterine atony (88% successs rate).[55] The exact place of embolization in the range of treatments for PPH has not been determined; however, the early resort to embolization has been recommended.[56] The procedure becomes more difficult technically if the patient is shocked and the bleeding points cannot be identified.

Hysterectomy remains the final resort in controlling intractable uterine bleeding and may be indicated a priori in cases of uterine rupture. Concern about loss of fertility should not deter the surgeon faced with life-threatening hemorrhage from taking this, sometimes unavoidable, step.

SECONDARY POSTPARTUM HEMORRHAGE

Massive blood loss occurring after the first 24 hours following delivery is less common than primary PPH and is usually due to subinvolution of the uterus caused by retained pieces of placenta or membrane and superimposed infection. About 1% of secondary PPH patients will require hysterectomy.

Severe hemorrhage will require maternal resuscitation (see earlier discussion). Definitive treatment comprises exclusion of retained products of conception, treatment for possible sepsis, and the exclusion of underlying trophoblastic disease. None of these interventions has been tested in randomized studies.[57] Antibiotic therapy will generally include a combination of penicillin with an aminoglycoside and anaerobic cover using metronidazole. Alternatives may include the use of cephalosporins or quinolones. Uterine evacuation should be performed if there is any question of retained products or trophoblastic disease.

Pelvic hematoma formation from vulval or vaginal trauma is dealt with conservatively in cases of supralevator retroperitoneal hemorrhage, although this remains a life-threatening source of hemorrhage. Ongoing resuscitation may be required until the bleeding tamponades spontaneously. If this fails to occur, either surgery or radiologic embolization of the traumatized vessel(s) should be considered. The surgical approach may necessitate both hysterectomy and internal iliac ligation. Infralevator hematomas are usually evacuated and either packed for 24 hours or repaired with mattress sutures to obliterate the cavity.

RUPTURED UTERUS AND OTHER GENITAL TRACT TRAUMA

The immediate pre- and postoperative management will include all the previously described principles for dealing with acute hypovolemia and coagulopathy. Experienced anesthetic support is essential.

The suspected diagnosis of uterine rupture necessitates a laparotomy, at which time the decision to repair or remove the uterus will need to be made. These decisions need to be individualized, and few generalizations are possible.

Scar dehiscence can be dealt with by simple repair, but more catastrophic rupture (especially of the unscarred uterus) will require hysterectomy. If contiguous injury to the bladder is identified, urologic assistance will usually be required.

Significant bleeding from other genital tract trauma will require surgical repair. The important principles of management are as follows:
- Prompt and effective resuscitation (see previous discussion).
- Prompt surgical exploration and repair to identify and repair the injury.
- Effective anesthesia.
- Input from other specialists (colorectal, urologic) as indicated.

SUMMARY OF MANAGEMENT OPTIONS
Massive Obstetric Hemorrhage

Management Options (See also Chapters 40, 58, 75, and 78)	Evidence Quality and Recommendation	References
Prenatal—Identification of the At-Risk Patient		
Criteria for risk (though no evidence of measures to prevent/ameliorate bleeding) are as follows:	—/GPP	—
• Anemia.		
• Refusal of blood products.		
• Previous antepartum hemorrhage, PPH, cesarean section, placenta previa.		
Value of prophylactic iron therapy is uncertain.	—/GPP	—
Perform delivery in adequately resourced unit.	—/GPP	—
Provide additional counseling in pregnancy.	—/GPP	—
Preparations/precautions for delivery:		
• Senior obstetrician.	IV/C	1,2
• Cross-match blood.	IV/C	1,2
• Advise active management of third stage with previous primary PPH.	Ia/A	34
Prenatal—Active Bleeding: General		
Have detailed guideline/protocol for unit to include the following guidance:	IV/C	1,2
• Setting/site of management (high dependency area or equivalent).	IV/C	1,2
• Give facial oxygen and warm patient.	—/GPP	—
• Monitoring.	IV/C	1,2
• Fluid, blood, and blood product replacement on basis of clinical condition and laboratory results.	IV/C	38–43
• Recombinant Factor VIIa if all else fails.	III/B	40–42
• Liaison with laboratories and hematologic colleagues.	IV/C	1,2
Prenatal—Active Bleeding: Specific		
Placental Abruption		
General measures (see above).	IV/C	1,2
Adequate analgesia (avoid epidural).	—/GPP	—
Empty uterus—method depends on	—/GPP	—
• Gestation.		
• Fetal condition (Is the fetus alive? Is there possible asphyxia?).		
Placenta Previa		
General measures (see above)	IV/C	1,2
Delivery by cesarean section:		
• Cross-match several units of blood.	IV/C	1,2
• Cell salvage techniques.	III/GPP	37
• Experienced obstetrician.	—/GPP	—
• Experienced anesthetist.	—/GPP	—
See measures under primary PPH (below) for persistent bleeding.	—/GPP	—
Primary PPH		
General measures (see above)	IV/C	1,2

Management Options (See also Chapters 40, 58, 75, and 78)	Evidence Quality and Recommendation	References
Stop bleeding with first aid measures:	—/GPP	—
• "Rub up" a contraction.		
• Bimanual compression.		
• Aortic compression.		
Atony:	Ia/A	43
• Syntocinon bolus and infusion.	Ia/A	43
• Ergometrine.	III/B	44,45
• Prostaglandins.	Ib/A	48
• Misoprostol.	III/B	46,47
Trauma:	—/GPP	—
• Repair trauma.		
• Evacuate retained placenta.		
Persistent bleeding despite the foregoing measures in order:	III/B	49,51,52,54
• Devascularization of uterus.	IV/C	46,50,53
• Uterine compression techniques.		
• Embolization techniques.	III/GPP	55,56
• Hysterectomy.		
Pelvic hematoma (procedure depends on site):	III/B	49,51,52,54
• Evacuate and pack.	IV/C	46,50,53
• Devascularization of uterus.		
• Hysterectomy.		
Secondary PPH		
General measures (see above)	IV/C	1,2
Antibiotics (not specifically tested for secondary PPH in RCTs, hence GPP).	—/GPP	—
	(Ia/A	57)
Evacuate retained products (not specifically tested in RCTs hence GPP).	—/GPP	—
	(Ia/A	57)
Uterine Rupture and Other Genital Tract Trauma		
General measures (see above).	IV/C	1,2
Effective anesthesia.	—/GPP	—
Surgical repair (hysterectomy in extreme).	—/GPP	—
Other specialist surgical input as indicated (e.g., colorectal or urologic).	—/GPP	—

GPP, good practice point; PPH, postpartum hemorrhage; RCTs, randomized, controlled trials.

DISSEMINATED INTRAVASCULAR COAGULATION

Definition

DIC is the widespread activation of intravascular coagulation leading to the deposition of fibrin within the circulation. Consumption of clotting factors usually leads to a bleeding diathesis, although a small percentage of affected individuals may go on to develop widespread thrombosis with peripheral organ ischemia. Some degree of DIC accompanies most forms of obstetric hemorrhage; however, the greater risk of coagulopathy usually arises from consumption of clotting factors and platelets as a result of massive hemorrhage. The combination of massive hemorrhage and coagulation failure is recognized as one of the most serious complications in pregnancy. DIC may arise from a wide variety of clinical situations in obstetrics but is always a

TABLE 77–5

Mechanism of Disseminated Intravascular Coagulation Occurring During Pregnancy

A. **Injury to vascular endothelium**
   Preeclampsia
   Hypovolemic shock
   Septicemic shock

   Phospholipids
   Incompatible blood transfusion
   Septicemia
   Intravascular hemolysis
D. **In many obstetric complications, there may be interaction between several mechanisms and more than one trigger factor present.**

FIGURE 77–1
Once disseminated intravascular coagulation has occurred, there is a potential for a vicious circle, with further consumption of clotting factors and platelets and bleeding until the underlying cause is corrected.

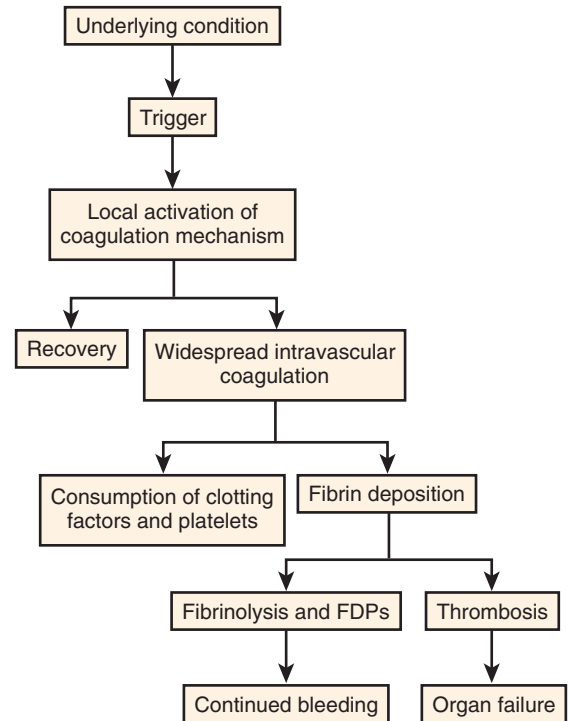
secondary phenomenon following a "trigger" of generalized coagulation activity. The clinical manifestations of coagulation failure can vary from mild disorders detected on laboratory tests only to massive uncontrollable hemorrhage with very low fibrinogen and platelet levels. A failure to anticipate or detect the early stages of DIC is cited as a major deficiency in the care of women who die from obstetric hemorrhage, and despite advances in obstetric care and hematologic services, hemorrhage with associated DIC remains a major cause of maternal death and morbidity.

Mechanisms

DIC is triggered by various mechanisms (summarized in Table 77–5):
- Blood loss itself with transfusion and volume replacement.
- Release of thromboplastic agents into the circulation.
- Endothelial damage to small vessels.
- Procoagulant phospholipids produced in response to intravascular hemolysis.

With obstetric complications associated with coagulation failure, there may be interaction of several mechanisms. Once DIC has occurred, there is a potential for a vicious circle, with further consumption of clotting factors and platelets and bleeding until the underlying cause is corrected (Fig. 77–1).

Risks

The risks to both the mother and the fetus from coagulation failure in terms of death and morbidity are the same as those discussed earlier under "Major Obstetric Hemorrhage." The specific situations in which DIC and coagulation failure may occur and the risks of each underlying condition are considered here.


Placental Abruption

Placental abruption remains the most common cause of coagulation failure in obstetrics and is related to the degree of placental separation and hypovolemic shock. In severe placental abruption with a dead fetus, profound hypofibrinogenemia has been reported in about one third of cases but is much less common if the fetus is alive.[30,58] Earlier stages of DIC are common with mild to moderate abruption but can usually be corrected early if delivery is not delayed.[59] The initial mechanism is due to the release of thromboplastins, but in severe abruption, hypovolemic shock, large volume transfusion, and high levels of FDPs that act as anticoagulants themselves will exacerbate the situation.

Amniotic Fluid Embolism

Amniotic fluid embolism occurs during labor, during cesarean section, or within a short time after delivery. This condition may lead to maternal death as a result of severe pulmonary hypertension following embolization of the pulmonary vessels by fetal squames. If the mother survives this acute event, there may be an anaphylactoid reaction to the presence of the fetal tissues in the maternal circulation associated with cardiovascular collapse, pulmonary edema, seizure activity, and the development of an intractable bleeding diathesis due to severe DIC. The diagnosis is suggested by the detection of fetal squames within the maternal lungs at the time of postmortem, and therefore, the incidence of successfully treated cases is difficult to determine

because the diagnosis is only suggestive and cannot be proved. The incidence of death from amniotic fluid embolism between 1970 and 1987 in England and Wales was 7.1 per million maternities. In most cases, the maternal death was unpredictable and unavoidable, and as obstetric care improves, amniotic fluid embolism has been responsible for an increasing proportion of maternal deaths and is now the fifth most common cause of death in the United Kingdom.

Retention of a Dead Fetus

A gradual reduction in clotting factors occurs following intrauterine fetal death, but these changes are not detectable on laboratory testing for 3 to 4 weeks. Approximately 80% of patients with a retained dead fetus will go into spontaneous labor within 3 weeks, but 30% of patients who remain undelivered for more than 4 weeks will develop DIC, usually of a mild degree.[60] Release of thromboplastic substances from the dead fetus into the maternal circulation is thought to be the trigger mechanism.

Preeclampsia

Preeclampsia is associated with endothelial perturbation currently thought to be due to oxidative stress and the release of reactive oxygen species by the ischemic placenta. The changes in endothelial function predispose to multiorgan systems involvement, including the clotting system.[61]

All preeclamptic patients have an increased rate of platelet turnover, and some develop overt thrombocytopenia. Activation of the coagulation cascade leads to a low-grade DIC that only rarely results in a clinically significant hemorrhage in the occasional patient with severe liver necrosis due to the HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome.[62] Excessive bleeding, which is often observed at the time of cesarean delivery, is more likely to be due to a qualitative platelet defect in thrombocytopenic individuals than any deficit in clotting factors.

Sepsis

Endotoxic shock can be associated with chorioamnionitis, septic abortion, or postpartum intrauterine infection. Gram-negative organisms are the most common isolated, although *Clostridium welchi* and *Bacteroides* species may be encountered, particularly in septic abortion. The bacterial endotoxin produces severe endothelial damage leading to fibrin deposition and DIC. Secondary intravascular hemolysis, which produces hematuria and oliguria characteristic of the condition, then occurs, and microangiopathic hemolysis can also cause purpuric skin lesions. Hypotension and coagulation failure are poor prognostic features in the presence of sepsis.[63,64]

Other Risk Factors

Other rarer conditions of pregnancy that have been associated with DIC and coagulation failure include induced abortion with hypertonic saline, acute fatty liver of pregnancy, and other hepatic disorders.[65,66] Hydatidiform mole and placenta accreta are associated with DIC because of loss of the intact decidua basalis, and passage of amniotic fluid and other thromboplastic substances into the maternal circulation is more likely.[67,68] Incompatible blood transfusions, large fetomaternal hemorrhage, and other causes of intravascular hemolysis, including drug reactions and the use of

other replacement fluids, can also precipitate or exacerbate existing DIC.[69]

Management Options

General

There is a wide spectrum in the manifestation of the process of DIC, but the aims of management are to[70,71]
- Manage the underlying disorder in order to remove the initiating stimulus.
- Maintain circulating blood volume.
- Replace clotting factors and red blood cells.

Management of the underlying disorder will depend upon the specific condition. In the case of placental abruption, delivery will usually lead to rapid recovery once the mother is adequately resuscitated. Amniotic fluid embolism and acute fatty liver of pregnancy will typically result in more resistant coagulopathy that may not be readily corrected despite vigorous attempts at resuscitation.[72]

Laboratory Investigation

If DIC is suspected, blood should be taken and sent for cross-matching and appropriate laboratory tests before commencing definitive treatment (Table 77–6). Blood can be observed for evidence of clotting, but there is little point in performing whole blood-clotting tests at the bedside because they are unreliable and time-consuming.[73] Generally, the laboratory assessment of coagulation requires measurement of the aPTT, the INR, the platelet count, and fibrinogen concentrations together with some estimation of FDPs or D-dimers as an index of intravascuular fibrinolysis.

Fluid Replacement in Coagulation Failure

The management of coagulation failure is often subsidiary to management of massive hypovolemia. The urgent necessity in the initial stages is to maintain circulatory volume and tissue perfusion, and resuscitation with crystalloid and colloid solutions should be undertaken as soon as possible, as outlined previously. Dextran solutions should not be used because they interfere with platelet function and can aggravate bleeding and DIC as well as invalidate the laboratory investigations.[74] Prompt and adequate fluid replacement will also prevent renal failure and help in the clearance of

   Fibrinogen titer (4.5 mL with 0.5 mL citrate anticoagulant)
3. Fibrin degradation products/D-dimers (2.0 mL in special bottle with antifibrinolytic agent)
4. Cross-matching, at least 6 units (10 mL in plain tube) Ideally, 20 mL of blood should be sent, but 10 mL is sufficient for essential tests. The sample should be collected as atraumatically and quickly as possible, and any heparinized IV lines avoided.

EDTA, ethylenediaminetetraacetic acid.

elevated levels of FDPs from the circulation via the liver, aiding the restoration of normal hemostasis.

Replacement of Blood Products

Blood products should be given as soon as available. FFP and stored red blood cells provide all the necessary components in fresh whole blood apart from platelets, and the clotting factors in FFP are well preserved for at least 12 months, provided the sample is stored correctly.[38] The use of fresh whole blood should not be encouraged, because it cannot be screened for possible infections. Furthermore, it is not easily obtained in an emergency. It is occasionally necessary to give extra fibrinogen in the form of cryoprecipitate, although sufficient amounts are usually provided in FFP, which also contains Factors V, VIII, and antithrombin III in higher concentrations. Platelets are not found in FFP, and their functional activity rapidly deteriorates in stored blood. The platelet count reflects both the degree of DIC and the amount of transfused blood given. If there is persistent bleeding and the platelet count is very low (definitions vary but $< 50 \times 10^9$ is often used), the patient may be given concentrated platelets, but these are not usually necessary to gain hemostasis.[73]

Other Treatment Options

Heparin therapy has been used to treat DIC from many different underlying causes, but there is no evidence to suggest that its use confers any benefit over supportive therapy. Heparin is contraindicated if there is hypovolemia, and obviously, this would include that secondary to placental abruption.[75] Heparin therapy has been suggested in the management of amniotic fluid embolism, but in the face of massive coagulation failure and clinical hemorrhage, it is difficult to justify.[72] It has likewise been suggested in the management of sepsis, although the most recent literature suggests that recombinant protein C may have advantages in terms of preventing fibrin deposition and stimulating the immune response.[75–79] Antifibrinolytic drugs have also been used, but there is the risk that their use would prevent the removal of microvascular thrombi from organs such as kidney or brain as the DIC resolves, leading to long-term sequelae.

SUMMARY OF MANAGEMENT OPTIONS
Disseminated Intravascular Coagulation

Management Options	Evidence Quality and Recommendation	References
Remove Insult/"Trigger"		
Empty uterus with major antepartum hemorrhage, retained dead fetus, molar pregnancy.	See Major Obstetric Hemorrhage box (earlier) and Chapters 5, 25, 58, and 78	
Treat uterine atony/repair trauma with PPH.	See Chapter 75	
End pregnancy with preeclampsia.	See Preeclampsia, Chapter 35	
Antibiotics with sepsis.	—/GPP	—
General		
Involve hematologist and support services (e.g., blood transfusion) early.	IV/C	70
Investigations		
See Table 77–6	—/GPP	—
Maintain Circulation		
See Major Obstetric Hemorrhage box	IV/C	70
Colloids (rather than crystalloid) initially but blood ideally.	IV/C	70
Avoid dextran.	III/B	74
Replacement of Blood Products		
Hematologic priorities are to replace blood constituents and coagulation factors (fresh frozen plasma and cryoprecipitate first-line rather than platelets).	III/B	38,76
Other Treatment		
Heparin and antithrombolytic therapy have both been used in DIC to break the cycle of consumptive coagulopathy. Neither has been subjected to controlled trials.	IV/C III/B	70,72 71
Concentrates of anticoagulant proteins such as antithrombin, protein C, and activated protein C are possibly useful in DIC due to severe sepsis.	III/B	76,77
Recombinant activated protein C is very effective in severe DIC due to sepsis outside pregnancy; limited experience in pregnancy.	III/B IV/C	78 79

Critical Care of the Obstetric Patient

JOHN ANTHONY

INTRODUCTION

Maternal mortality accounts for half a million deaths annually.[1] The risk of obstetric mortality varies according to the socioeconomic development of different countries, and many deaths could be avoided with better access to medical care. Industrialized countries, however, continue to focus on maternal deaths because many are associated with substandard care, some of which could be avoided by greater attention to critical care management.[2]

The admission of obstetric patients to critical care facilities is low (published intensive care unit [ICU] admission rates are 0.29% to 1.5% of deliveries in industrialized countries).[1,3] No standardized criteria define the requirement for critical care among pregnant women. The reasons for ICU admission include

- Obstetric complications (e.g., preeclampsia, hemorrhage, and sepsis).
- Medical disorders exacerbated by pregnancy (e.g., cardiac disease and thromboembolism).
- Conditions incidental to pregnancy (e.g., respiratory disease, complications of HIV infection).

Only one dedicated obstetric ICU published its experience several years ago, and the pattern of admissions may be changing in developing countries owing to the evolving HIV pandemic, with a far greater burden of sick patients being admitted as a result of infection and postoperative sepsis.[3]

Provision of critical care to the pregnant woman requires knowledge of intensive care principles as well as relevant aspects of maternal and fetal physiology.

RELEVANT PHYSIOLOGY OF PREGNANCY

Cardiovascular Changes

The dominant cardiovascular change in pregnancy is the increase in cardiac output leading to accelerated delivery of oxygenated blood to the peripheral tissues including the uterus and choriodecidual space. Stroke volume and cardiac output rise by 40%, and blood pressure falls owing to peripheral vasodilation and because the placental circulation functions as an arteriovenous fistula. These changes precede and exceed the fetal and maternal metabolic requirements of pregnancy to such an extent that the difference in arteriovenous oxygen declines in normal pregnancy.[4] Increased cardiac output is achieved largely by a rise in circulating blood volume due to physiologic hyperreninism that increases aldosterone levels 10-fold.[5] This adaptation leads to water and electrolyte retention and a 50% increase in plasma volume.[6,7] Doppler ultrasound has been used to redefine the cardiac changes that accompany the increase in cardiac output. Both filling phases of the left ventricle show increased filling velocities. The peak mitral flow velocity in early diastole (E-wave) and the peak velocity during atrial systole (A-wave) both increase. The increase in early wave velocity occurs by the end of the first trimester, whereas the peak A-wave velocity changes occur in the third trimester. The E/A ratio increases in the first trimester but falls again as the A-wave velocity increases and is accompanied by decreasing left ventricular isovolumetric relaxation time.[8,9] Left ventricular mass increases significantly, whereas fractional shortening and velocity of shortening diminish throughout pregnancy.[10] Systolic function is preserved by falling systemic (including uterine artery) resistance.[8,9] Peak left ventricular wall stress, an indicator of afterload, has been demonstrated in early pregnancy and normalizes as ventricular mass increases in the midtrimester.[10] Geva and colleagues[11] report a 45% increase in cardiac output in normal pregnancy accompanied by an increase in left ventricular end-diastolic volume and increased end-systolic wall stress accompanied by transient left ventricular hypertrophy. These authors also report a reversible decline in left ventricular function during the second and third trimesters.

The pulmonary circulation shows increased flow during pregnancy, with some reduction in vascular resistance without any significant alteration in blood pressure. These changes are evident by 8 weeks' gestation without any subsequent alteration and return to prepregnancy values by 6 months postpartum.[12] Systemic arterial vascular compliance is thought to diminish because of reduced vascular tone.[13]

Plasma volume expansion is matched by enhanced oxygen-carrying capacity brought about by a 14% to 28% increase in red cell mass.[14] Fetal respiration depends on maternal hyperventilation that creates a partially compensated respiratory alkalosis. The partial pressure of carbon dioxide ($PaCO_2$) in a pregnant woman will fall approximately 15% with a reduction in plasma bicarbonate, although arterial pH remains unaltered.[15]

Effective renal plasma flow rises with increasing cardiac output and blood volume, leading to a 50% increase in glomerular filtration.[16] This results in increased fractional excretion of glucose as well as other metabolites and drugs.

Coagulation

The mother is protected against the effects of hemorrhage at the time of delivery by her increased blood volume and also by enhanced coagulation. Coagulation changes include increased estrogen-dependent hepatic synthesis of fibrinogen and Factors VII, VIII, X, and XIII.[17] The anticlotting mechanism is physiologically impaired by reduced levels of protein S. Pregnancy is, therefore, a state of physiologic resistance to the action of activated protein C because free protein S is a necessary cofactor in this reaction. The fibrinolytic system is also impeded by increased levels of both plasminogen activator inhibitor-1 (PAI-1, derived from endothelial cells) and PAI-II, derived from the placenta. Expression of procoagulant activity takes place normally during pregnancy and may be detected by measuring levels of circulating thrombin-antithrombin III complexes.[17]

Effect of Delivery

These physiologic changes in pregnancy are progressive during pregnancy and revert to normal at varying rates during the puerperium. Labor stimulates a further increase in cardiac output, peaking out at 10 L/min as a result of autotransfusion of blood from the choriodecidual circulation during the third stage of labor.[18] Blood pressure fluctuates during pregnancy, falling by 10% to 15% in the midtrimester but rising again toward prepregnancy levels by the end of the third trimester, with a further rise occurring in some patients during labor.

Uteroplacental Effects

Blood flow to the choriodecidual space is determined by both the cardiac output and the dilation of the spiral arteries prior to the 20th week of pregnancy. These dilated vessels cannot vasoregulate blood flow to the placenta, which remains directly proportional to changes in maternal cardiac output and blood pressure. Vasoconstriction in the uterine circulation can develop in response to catecholamines, whereas uterine contractions restrict flow through these vessels by compression of the vessel wall. Transplacental gas exchange takes place by simple diffusion, and even at low partial pressures, fetal hemoglobin binds oxygen avidly because the oxyhemoglobin dissociation curve is shifted to the left. Even minor changes in the partial pressure of oxygen (PaO_2) in the maternal circulation may significantly improve fetal hemoglobin saturation operating on the steep part of the oxyhemoglobin dissociation curve. Fetal well-being is, therefore, critically dependent on maternal cardiac output, uterine blood flow, and maternal PaO_2.

Anatomic Changes

The enlarged uterus compresses the inferior vena cava and aorta. This may lead to supine hypotension as a result of diminished venous return, although the adrenergic response to aortocaval compression tends to maintain or increase blood pressure. Diminished cardiac output can nevertheless critically impair uterine perfusion, especially during labor.

The diaphragm is displaced by the enlarging uterus, resulting in a 10% to 20% reduction in residual volume and functional residual capacity. Under the influence of progesterone, the respiratory center increases chest wall movement, leading to an increase in tidal volume. This leads to respiratory alkalosis and hypocapnia.

METHODS OF MONITORING

Oxygen Saturation Monitoring

Spectrophotometry is the detection of specific light frequencies reflected by a range of molecules. Specific molecules reflect specific frequencies, and their reflective properties differ with changes in molecular conformation. Oximetry is the detection of oxygenated and deoxygenated blood. The oxygenated hemoglobin reflects more light at 660 nm, whereas at 940 nm, deoxyhemoglobin reflects infrared light more strongly. This allows the simultaneous acquisition of peripheral signals from which the ratio of oxyhemoglobin to deoxyhemoglobin can be calculated and expressed as a percentage of oxyhemoglobin saturation.

Oximetry may be based on transcutaneous measurements or can be derived from mixed venous blood via a probe located in a pulmonary artery catheter (PAC). The peripheral pulse oximetry devices rely on detection of pulsed alterations in light transmitted between a transmitter and a photodetector.

Although oximetry is regarded as an effective method of monitoring oxygenation that is widely available and easy to use in practice, some limitations are recognized. They include the assumptions that methemoglobin and carboxyhemoglobin are not present in significant concentrations. Invasive mixed venous oxygen saturation monitoring is less frequently used than peripheral oxygen saturation monitoring. It also shows greater spontaneous variation than peripheral monitors but has a clinical role to play in determining the balance between peripheral oxygen delivery and peripheral oxygen consumption. It is a robust measurement that will reflect changes in cardiac output, hemoglobin concentration, and arterial and venous hemoglobin oxygen saturation. This provides useful clinical information in many clinical circumstances.

Hemodynamic Monitoring of Cardiac Output

Hemodynamic monitoring is an integral part of intensive care management and is especially important in cases of severe hemorrhage, severe preeclampsia, and septic shock. An adequate cardiac output is essential in delivering oxygenated blood to the peripheral tissues. Low output will reflect either hypovolemia or ventricular failure. Knowledge of the cardiac output will determine management and will also allow calculation of other derived hemodynamic values, including vascular resistance and oxygen delivery and consumption indices.

Cardiac output was previously most commonly measured using the Fick principle. This principle states that the amount

of a substance taken up by the body per unit time equals the difference between the arterial and the venous levels multiplied by the blood flow. Hence, oxygen consumption by the body divided by the arteriovenous oxygen difference equals the cardiac output. This principle has been modified to use other markers, including dye dilution techniques and the thermodilution principle of the PAC. In the latter case, iced water is the marker injected into the right atrium, with a probe measuring the temperature of the blood flowing through the pulmonary artery, thus allowing the derivation of the cardiac output from the area under the curve. This technique, although clinically robust, may produce results confounded by variations in catheter position and variations in injectate temperature and volume as well as changes in the rate of saline injection. Despite these limitations, this technology remains the gold standard against which newer techniques are assessed. The need to cannulate peripheral and central vessels has been associated with some risk of injury, and noninvasive techniques of measuring cardiac output have been sought.

Ultrasound in the form of echocardiography allows estimation of cardiac output by measuring changes in left ventricular dimensions during systole measured in the plane below the level of the mitral valve. By assuming that the ventricle is ellipsoid in shape and that the long axis is double the short axis, stroke volume can be calculated from the cube of the change in left ventricular dimension. This measurement is inaccurate when the assumptions on which it is based are no longer true. Hence, the dilated ventricle and the pregnant woman with an increased volume and end-diastolic dimensions violate these assumptions and may overestimate stroke volume and cardiac output. Doppler ultrasound has now added to the utility of echocardiography by allowing an estimation of blood velocity. The Doppler principle measures the frequency of a reflected ultrasound beam striking moving erythrocytes, in which the change in frequency detected is proportional to the velocity of the red cells moving in the axis of the beam. The velocity of a column of red cells multiplied by the period of ejection provides a measure of the distance traveled by a column of blood during systole. The use of ultrasound to measure the diameter of the vessels containing the blood will allow calculation of cross-sectional area with subsequent derivation of stroke volume and cardiac output. The velocity of blood flow can also be related to the pressure gradient down which the blood is moving, providing a way of calculating intracardiac pressure gradients and pulmonary artery pressures.

Doppler probes may be range-gated (pulsed) to allow the measurement of a signal from a given depth of tissue. The pulsed Doppler signal usually allows simultaneous ultrasound imaging and estimation of the angle of insonation between the Doppler probe and the vessel. This latter measurement is important because the calculation of velocity from the reflected Doppler signal requires a knowledge of the angle between the ultrasound beam and the column of blood from which the signal is being reflected. Where the signal is perpendicular to the moving column of blood, no movement will be detected, and the closer the beam moves to being parallel to the vessel, the more completely the reflected vector represents the velocity of the cells in the path of the beam.

The combination of cross-sectional echocardiography and Doppler measurement of flow velocity at specific points in the heart and great vessels allows the determination of volumetric flow. The mitral and aortic valve orifices and the root or arch of the aorta have all been studied using both suprasternal and intraesophageal Doppler probes. Potential for error exists in these techniques, in both the calculation of the insonation angle and the measurement of the cross-sectional area of the vessel. Of the different sites studied, the best correlation between the Doppler technique and thermodilution studies was documented in the aortic valve orifice measurements. Although transthoracic Doppler studies are the most widely accessible tool, transesophageal Doppler allows the posterior structures of the heart to be more clearly imaged with more accurate diagnosis of cardiac pathology and precise alignment to the aortic valve in both the long and the short axis as well as providing long-axis views of the ascending aorta.[19] The use of multiplanar transesophageal echocardiography allows precise measurements of asymmetrical ventricles that cannot be reliably imaged using a transthoracic probe.[20] The probe has particular utility in the diagnosis of aortic dissection and thromboembolism, although the need for esophageal endoscopy limits the application of this technology to specific situations including intraoperative and postoperative care.[21]

Doppler echocardiography has provided a ready means of studying women at risk of developing hypertensive complications during pregnancy. The most detailed study, to date, by Borghi and associates,[22] described detailed cardiac findings among 40 women with mild preeclampsia compared with a control cohort of pregnant women and nonpregnant controls. This study showed a progressive rise in left ventricular mass between nonpregnant women and women with a normal pregnancy, with a further increase in mass among women with preeclampsia. Ejection fraction and fractional shortening decreased in normal pregnancy, though this did not reach statistical significance. However, women with preeclampsia had a significant reduction in both these parameters compared with nonpregnant women. In addition, left ventricular end-diastolic volume rose significantly in preeclampsia. Together with a fall in cardiac output in the preeclamptic group, these findings suggest a compensatory increase in ventricular size to maintain cardiac output against an elevated systemic vascular resistance.

The latter study also showed changes in the peak filling velocities of the left ventricle during diastole.[22] The E/A ratio fell significantly during pregnancy, partly reflecting increased preload. In preeclampsia, further augmentation of the A-wave peak velocity resulted in further significant reduction in the ratio. Collectively, these data support the notion of changes in both cardiac systolic and diastolic function. The authors also measured atrial natriuretic peptide (ANP) levels. In keeping with previous studies, elevated levels of ANP were found in pregnancy, with further increments occurring in preeclampsia. These could not be accounted for by differences in atrial size, although a significant correlation was found between left ventricular mass and volume in women with preeclampsia.

Transesophageal Doppler monitoring of hemodynamic data has been carried out in adult ICUs and found to be equivalent to data derived from PAC measurements.[23] Pregnancy data are few, and only one study has reported the use

of transesophageal Doppler monitoring in pregnancy compared with PACs.[24] That study showed that the Doppler consistently underestimated cardiac output by 40% in women younger than 35 years.[24] This error may be due to the assumptions implicit in the algorithm used to calculate output. These assumptions include a fixed aortic diameter during systole and a fixed percentage of blood perfusing upper and lower parts of the body. Pregnancy physiologic changes probably invalidate these assumptions. The authors nevertheless conclude that esophageal Doppler may contribute to the estimation of trends over time.

Other techniques of measuring cardiac output include impedance cardiography based on changes in transthoracic electrical resistance associated with the ejection of blood into the pulmonary circulation. This technique has been shown to overestimate low cardiac output, with the opposite error in high cardiac output states.

Invasive Pressure Monitoring

Invasive pressure monitoring includes the insertion of lines used for the measurement of intra-arterial pressure and central venous and pulmonary artery pressure.

Intra-arterial lines allow for continuous assessment of systemic blood pressure and also eliminate the need for repeated venesection, often a prerequisite in the management of the critically ill patient. Various noninvasive blood pressure monitors are also available that measure pressure using an oscillometric principle. These monitors have been shown to be significantly inaccurate when measuring blood pressure from women with preeclampsia, consistently underestimating pressures measured by direct arterial line measurement and auscultation.[25]

Central venous pressure (CVP) monitoring is employed as a measure of right ventricular filling pressure and intravascular blood volume. These lines may be inserted as long lines via the antecubital fossa or can be introduced via the internal jugular or subclavian veins. The long-line technique is preferred in any patient with a bleeding diadiesis and also in anyone who cannot tolerate positioning in the Trendelenburg position for internal jugular catheterization (e.g., women with pulmonary edema). CVP in the normovolemic patient should measure between 10 and 12 mm Hg. When managing hypovolemia, fluid should be administered as repeated bolus dose infusions until the CVP shows a sustained rise above 10 to 12 mm Hg over a 30-minute period. Central venous lines allow the withdrawal of mixed venous blood in which estimation of the PaO_2 will indicate the extent of peripheral oxygen extraction. In normally oxygenated and perfused individuals, central venous oxygen saturation should remain above 65%. CVP monitoring should not be used to monitor fluid management in severe preeclampsia because left ventricular diastolic dysfunction in this condition results in left-sided changes in pressure that are not reflected by similar changes in right ventricular filling pressures. Hence, a bolus of intravenous fluid may lead to a rapid increase in pulmonary capillary wedge pressure without any change in CVP.

Pulmonary artery catheterization, although controversial, remains a standard intensive care monitoring technique. Current evidence indicates that PACs do not alter ICU mortality and morbidity, although their utility is recognized in specific patients.[26] In obstetric practice, severe preeclampsia and maternal cardiac disease justify the measurement of left ventricular filling pressures, and measurement of cardiac output allows the calculation of derived hemodynamic parameters such as the systemic vascular resistance and left ventricular stroke work volume. Knowledge of these parameters is a useful guide to appropriate fluid and vasodilator therapy. In preeclampsia, rapid plasma volume expansion has been shown repeatedly to cause a sharp rise in left-sided filling pressures, often without any changes in CVP.[27–29] This occurs despite evidence of normal systolic ventricular function and is a reflection of reduced ventricular compliance during diastole.

PACs, like CVP lines, are inserted either via the internal jugular vein or as a long-line insertion through the antecubital fossa. Catheter placement may lead to a number of complications, especially in inexperienced hands, and should not be undertaken without adequate training and supervision. The incidence of complications may also be lower in pregnant patients than in other ICU populations; the Groote Schuur Obstetric ICU reported no major complications over a 3-year period.[30]

The indications for the insertion of a PAC are similar to those in nonpregnant patients. In addition, severe preeclampsia is recognized to be a condition in which changes in left ventricular diastolic function necessitate monitoring of pulmonary capillary wedge pressure after fluid loading. The Groote Schuur Obstetric ICU audit showed that most catheters were inserted for the management of preeclampsia in patients who also had renal failure (56%), pulmonary edema (32%), or eclampsia (6%).[30]

Although the Pulmonary Artery Catheter Consensus Conference[26] concluded that PAC monitoring did not reduce complications and mortality in patients with preeclampsia, the statement recognized the utility of the catheter in specific circumstances including oliguria unresponsive to fluids, pulmonary edema, and resistant hypertension.

Capnometry

Exhaled gas can be evaluated using an infrared probe and a photodetector set to detect carbon dioxide. This is usually found in the expiratory limb of a ventilator circuit. Expired gas shows a pattern of increasing carbon dioxide concentration related to the sequential expiration of air in the upper airway followed by air from the alveoli. The end-expiratory (or end-tidal) carbon dioxide concentration should approximate the $PaCO_2$ in arterial blood. The development of a gradient between these measurements reflects an increase in anatomic or physiologic dead space. In the latter event, low cardiac output and pulmonary embolism may both affect the measurement. Changes in end-tidal $PaCO_2$ have been correlated to changes in cardiac output and may be used as a means of monitoring the efficacy of resuscitation.

INDICATIONS FOR MONITORING—CAUSES OF CRITICAL ILLNESS IN PREGNANCY

The main causes of critical illness in pregnancy are listed in Table 78–1.

TABLE 78–1

Main Conditions Causing Critical Illness in Pregnancy

Preeclampsia and its variants
 Eclampsia*
 HELLP
Thrombotic thrombocytopenic purpura
Acute fatty liver
Hemorrhage*
Sepsis*
Thromboembolism*
Cardiac problems*
 Arrhythmias
 Cardiomyopathy
Neurologic problems*
Trauma
Metabolic
Anaphylactoid syndrome of pregnancy*
Others

* Indicates conditions that may present with "collapse."
HELLP, hemolysis, elevated liver enzymes, and low platelets.

MANAGEMENT OF CRITICALLY ILL MONITORED PATIENTS

Some would argue that many of the complications reviewed are more appropriately managed exclusively by intensivists, anesthetists, and physicians. However, the pregnant woman presents a unique challenge because of both the physiologic changes that accompany pregnancy and the need to address the requirements of the fetus in a mother who is critically ill. Thus, obstetricians must remain involved in the care of these women if the mother and her unborn child are to receive optimal care. More important, there should be a thorough understanding of those conditions that commonly lead to maternal mortality. Furthermore, substandard care of the critically ill woman arising from ignorance should not be an issue raised by confidential inquiries into maternal mortality.

Severe Preeclampsia (See also Chapter 35)

The preeclampsia syndrome can develop into multiorgan failure (including neurologic, renal, liver, hematologic, and cardiorespiratory disease). Preeclampsia affects 2% to 6% of pregnant women and remains among the leading global causes of maternal mortality.[31–33] Eclampsia with or without evidence of intracranial hemorrhage is the single most lethal complication of preeclampsia/eclampsia. Deaths have also been associated with pulmonary edema; hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome; renal failure; and the development of hypovolemia (commonly due to concurrent abruptio placentae).

The pathogenesis involves chronic placental ischemia that predisposes to an accelerated production of lipid peroxides and oxygen free radicals. Systemic endothelial injury and altered vascular reactivity develop subsequently and are assumed to be a consequence of endothelial damage. The onset of clinical disease is marked by the development of

hypertension, proteinuria, and intrauterine fetal growth restriction. Impaired prostacyclin production and increased release of vasoconstrictors (including thromboxane, endothelin, serotonin, and possibly catecholamines) lead to rising peripheral vascular resistance.[34–38] Endothelial damage leads to expression of cell adhesion molecules that interact with activated leukocytes and platelets.[39,40] Platelet turnover accelerates and may end in thrombocytopenia. Activated platelets also release cytokines that trigger intravascular coagulation.[39,41] Endothelial damage leads to interstitial edema, intravascular dehydration, intensified peripheral vasospasm, and diminished cardiac output. Low cardiac output translates into a critically low rate of oxygen delivery to the peripheral tissues, and multiorgan failure in severe preeclampsia can be attributed to multiorgan ischemia, developing because of vasospasm, low cardiac output, and intravascular coagulation.[28,42]

Management of Renal Failure (See also Chapter 49)

The presentation of renal impairment is commonly that of oliguria (a urine output <30 mL/hr over 4 hr) with or without hematuria. However, this is a common normal occurrence after delivery for the first 24 hours, probably due to renal vasospasm and, if delivery was by cesarean section, antidiuretic hormone production. Thus, if the oliguria persists toward the end of the first 24 hours, provided that the patient is not already in positive fluid balance and does not have pulmonary edema, plasma volume expansion should be attempted. If two fluid challenges (300 mL of colloidal solution) fail to improve the urinary output, low-dose dopamine should be commenced at an infusion rate of 1 to 5 μg/kg/min. Low-dose dopamine is thought to act as a selective renal artery vasodilator, and although of questionable benefit in general critical care, two randomized studies have demonstrated efficacy without adverse effects in the oliguric preeclamptic patient.[43,44] Patients who fail to respond to either of these measures require more intensive monitoring. PACs are a useful adjunct in securing optimal left ventricular preload and afterload. The volume-replete vasodilated patient who fails to pass urine over a 4-hour period should be considered to have intrinsic renal pathology, namely acute tubular necrosis. A single large dose of furosemide (0.5–1 g IV) may convert these patients to high-output renal failure. Should this measure also fail, care must be taken to avoid fluid overload by restricting intravenous fluid administration to output plus 500 mL/24 hr (to allow for insensible loss), and the patient should be prepared for dialysis.

Management of Respiratory Distress

Respiratory distress in the preeclamptic patient can be caused by or associated with
- Upper airway edema.
- Pulmonary edema—secondary to one or more of
  - Low oncotic pressure.
  - Leaky capillaries.
  - Left ventricular dysfunction (diastolic dysfunction cannot be detected without invasive monitoring or access to echocardiography).

- Iatrogenic fluid overload, even with small amounts of fluid.
- Rare causes such as cardiomyopathy and valvular heart disease may be indistinguishable from other causes of pulmonary edema without echocardiography or invasive monitoring.
- Aspiration pneumonia (especially following a cesarean section under general anesthetic) (see also Chapter 37).
- Postoperative atelectasis (it also occurs with the HELLP syndrome from "splinting" of the right hemidiaphragm because of liver pain) (see also Chapter 37).
- Pulmonary embolism (see following discussion and also Chapter 42).
- Acute respiratory distress syndrome (ARDS) (though not a primary complication of preeclampsia, it may follow aspiration pneumonia or prolonged ventilation) (see also Chapter 37). However, the role of ARDS as a cause for maternal mortality in severe preeclampsia has been completely overestimated and the cause for respiratory distress in severe preeclampsia is pulmonary edema in most cases.

The importance of respiratory complications as a cause of maternal mortality in severe preeclampsia has been underestimated. The South African Confidential Enquiry into Maternal Mortality has categorized deaths due to preeclampsia in groups that include those attributable to cerebral complications (presumably mainly cerebrovascular haemorrhage), those related to "cardiac failure," "respiratory failure," and "renal failure."[45,46] Considering that both cardiac failure and renal failure are likely to present with fluid overload and pulmonary edema, it is reasonable to assume that cardiac, respiratory, and renal failure should be grouped into a single entity with respiratory distress as the most likely consequence. Such a grouping challenges the notion that cerebrovascular events are the most common cause for hypertensive deaths. For two consecutive trienniums (1999–2001 and 2002–2004), the South African data indicate that respiratory deaths are the most common cause for maternal mortality (Fig. 78–1).[45,46] These data highlight the
importance of critical care management in women with any evidence of respiratory compromise in the setting of severe preeclampsia. Clearly, patients who present with respiratory distress are a diagnostic challenge. When the diagnosis remains in doubt after clinical examination and special investigation, echocardiography or pulmonary artery catheterization are indicated.

Pulmonary edema will need to be managed according to the hemodynamic findings. Elevated pulmonary capillary wedge pressure may result from high systemic vascular resistance, left ventricular failure, or fluid overload. These complications may require vasodilation with agents such as dihydralazine, the use of diuretics, or a combination of both. Drugs that are negatively inotropic are generally avoided. In the absence of iatrogenic fluid overload, afterload reduction by vasodilation may be the most important aspect of management.

The development of localized lung signs and purulent sputum should alert the clinician to the possibility of aspiration pneumonia. Radiographic findings vary from normal lung fields to unilateral shadowing, atelectasis, and collapse. Bronchoscopy may be necessary if aspiration of particulate matter is suspected. Treatment with broad-spectrum (including anaerobic) antibiotics and physiotherapy would be indicated.

Management of other causes of respiratory distress is covered in the relevant chapters.

Management of Resistant Hypertension (See also Chapter 35)

Hypertension that fails to respond to standard vasodilator therapy has been cited as an indication for invasive hemodynamic monitoring.[47] The purpose of this is to distinguish hypertension due to high cardiac output from that arising from elevated systemic vascular resistance. Treatment aimed at reducing a high cardiac output may seem counterintuitive, but life-threatening hypertension due to this cause should be treated with drugs such as labetalol or a conventional β-blocker such as atenolol rather than the more traditionally used calcium channel blockers and direct-acting vasodilators such as dihydralazine.

Eclampsia (See also Chapter 35)

Eclampsia is the occurrence of generalized tonic-clonic seizures in a pregnant patient with proteinuric hypertension. Most seizures occur prior to delivery, although 40% occur within 24 hours of delivery. Eclampsia may be preceded by prodromal symptoms of headaches and visual disturbances (blurred vision, photopsia, scotomata, and diplopia).[48] The blood pressure at the time of seizure activity varies from levels that are mildly elevated or even normal, although they more commonly have moderate to severe hypertension.[49] Seizure activity is, however, associated with a sharp increase in blood pressure and decreased peripheral oxygen saturation levels. This is important because severe hypertension has been linked to the risk of cerebrovascular hemorrhage.

The differential diagnosis of seizure activity in pregnancy is extensive and includes epilepsy, systemic lupus erythematosus, thrombotic thrombocytopenic purpura (TTP), amniotic fluid embolus, cerebral venous thrombosis, malaria, and

GROUPED CAUSES OF HYPERTENSIVE MORTALITY

FIGURE 78–1
Two consecutive trienniums of the South Africa Maternal Mortality Report (1999-2001 and 2002-2004).[45,46]

cocaine intoxication.[50–52] Late postpartum eclampsia (seizures first developing between 48 hr and 4 wk after delivery) requires neuroradiologic investigation to exclude alternative diagnoses.[53–55]

The critical care management of eclampsia is centered on

- Prevention of recurrent seizures.
- Control of the airway to prevent aspiration pneumonia.
- Control of severe hypertension.
- Management of other organ failure.
- Termination of the pregnancy.

Seizure Prophylaxis

Magnesium sulfate is the drug of choice for seizure prophylaxis. Randomized evidence clearly demonstrates a significantly lower risk of recurrent seizures with magnesium sulfate than with phenytoin and benzodiazepines.[56,57] Magnesium sulfate is a weak calcium channel blocker that regulates intracellular calcium flux through the *N*-methyl-D-aspartate receptor in neuronal tissue and may inhibit ischemic neuronal damage brought about by anion flux through this receptor.[58] Parenterally administered magnesium results in systemic vasodilation and improved cardiac output as well as cerebral vasodilation distal to the middle cerebral artery. Retinal artery vasospasm has been reversed by magnesium sulfate infusion.[59–61] The myocardial effects of parenteral magnesium include slowing of the cardiac conduction times, and in high doses, magnesium is significantly negatively inotropic.[62] Intravenous magnesium sulfate reduces serum calcium levels, possibly as a result of increased renal magnesium and calcium excretion.[63] Falling serum calcium inhibits acetylcholine release at the motor end-plate, the extent of which is directly related to the level of the serum magnesium and inversely proportional to the calcium concentration. This is the origin of magnesium sulfate toxicity leading to neuromuscular blockade and respiratory arrest.[64,65] Dosage regimens vary, but the majority of women in the Collaborative Eclampsia Trial[57] were treated with a 4-g intravenous loading dose followed by a constant infusion of 1 g/hr. Magnesium sulfate is excreted by the kidney, and impaired renal function may lead to toxicity, manifested as weakness, absent tendon reflexes, and respiratory arrest. In practice, monitoring patient magnesium levels as well as clinical features will help minimize the risk of toxicity. Patients with undiagnosed myasthenia gravis may have their disease unmasked by magnesium sulfate, even when the drug reaches only normal therapeutic levels.[66]

Patients who experience recurrent seizures in spite of magnesium sulfate are best treated with intubation and ventilation. Sedation using continuous high-dose benzodiazepine or pentothal infusions will be necessary and will serve to prevent further seizures. Following multiple seizures, these women are likely to have cerebral edema with raised intracranial pressure. Consequently, care should be taken to maintain a mean arterial pressure in excess of 100 mm Hg in order to preserve cerebral blood flow.[67]

Control of the Airway

Clearing the airway is an important first-aid measure accomplished by suctioning and positioning the patient head-down on her side. Endotracheal intubation is indicated in women with recurrent seizures, those who are inadequately oxygenated, and a patient who remains persistently obtunded

more than 30 minutes after the seizure. Ventilatory care should be maintained for a minimum of 24 hours postpartum, until the patient is fully conscious, and any upper airway edema has dissipated.

Obstetric Management

Vaginal delivery, if foreseeable within a short period, may be contemplated in the woman with no complicating features other than a single seizure. Induction of labor should not be protracted, and an arbitrary time limit should be set as a goal for attaining a vaginal delivery.

HELLP Syndrome (See also Chapter 35)

This complication of preeclampsia is due to hepatic ischemia, giving rise to periportal hemorrhage and necrosis along with microangiopathic hemolytic anemia and thrombocytopenia.[68] Patients with the HELLP syndrome present with epigastric pain and, in severe cases, are usually obviously ill because of associated complications including renal failure (characterized by rising urea and creatinine levels and the passage of small quantities of blood-stained or "Coke"-colored urine) and eclampsia. Many women with HELLP syndrome, however, seem to have unremarkable clinical disease.

Liver failure may arise from conditions that mimic preeclampsia, such as TTP and acute fatty liver of pregnancy (AFLP).[69,70] Obstetric cholestasis and viral hepatitis may also enter the differential diagnosis in milder cases of HELLP syndrome. Distinguishing between these conditions may be difficult, but the hallmark of preeclamptic disease is that it resolves after delivery.[71]

Subcapsular liver hematoma is a rare complication of the HELLP syndrome. The surface of the liver is covered in petechial hemorrhages that may coalesce to form one large hematoma. Rupture of this lesion leads to right upper quadrant pain and sudden hypovolemia.

Coagulopathy is uncommon, but thrombocytopenia and impaired platelet function both give rise to impaired coagulation. Prolonged partial thromboplastin times and International Normalized Ratios (INRs) are more likely to occur in association with AFLP than with HELLP syndrome. Hypoglycemia may occur in some cases but is more characteristic of AFLP.

The management of HELLP syndrome is delivery, whereas the associated complications (renal failure, eclampsia, and respiratory distress) might require critical care on their individual merits. Thrombocytopenia should reach a nadir within 72 hours of delivery, and if it is persistent beyond this point, a search for alternative diagnoses should commence (e.g., sepsis, folate deficiency, TTP, systemic lupus erythematosus).

Thrombotic Thrombocytopenic Purpura

TTP is one of a spectrum of microangiopathic hemolytic conditions that include preeclampsia, hemolytic-uremic syndrome (HUS), AFLP, and autoimmune conditions such as systemic lupus erythematosus. TTP is a condition in which multimers of von Willebrand's factor, derived from the endothelium, accumulate in the circulation. Von Willebrand's factor binds platelets to the endothelium, and high

concentrations are associated with peripheral platelet consumption and the formation of platelet microthrombi. Von Willebrand's factor is usually broken down by a specific metalloproteinase but might accumulate if this enzyme is deficient or if endothelial damage provokes excessive release of von Willebrand's factor. The metalloproteinase enzyme deficiency either exists as a hereditary condition or can be acquired as a consequence of autoimmune disease due to a specific immunoglobulin G (IgG) inhibitor of the enzyme. Many factors can precipitate both the congenital and the acquired forms of TTP, including drugs, malignancy, bacterial infection, HIV, and other viral infections. Pregnancy is the precipitating factor in 10% to 25% of cases.[72,73]

TTP presents with a pentad of features:

- Microangiopathic hemolytic anemia.
- Fever.
- Neurologic disturbance.
- Renal impairment.
- Thrombocytopenia.

The neurologic features of the syndrome may be transitory, and mild hypertension and proteinuria may make the condition indistinguishable from HELLP syndrome. TTP does not, however, remit after delivery, whereas HELLP syndrome invariably resolves. Other diagnostic features that may help to distinguish between the two conditions include evidence of marked hemolysis on examination of the peripheral blood smear (this is more characteristic of TTP than HELLP).

Without appropriate management, TTP has a high mortality rate. Treatment consists of plasmapheresis, infusion of fresh frozen plasma, and high-dose steroids.[72] Renal failure and the neurologic manifestations may require appropriate intensive care management.

Acute Fatty Liver of Pregnancy (See also Chapter 47)

Developing in the latter half of pregnancy, AFLP is a condition characterized by microvesicular fatty infiltration of the liver. The incidence is approximately 1 in 12,000 deliveries. Clinical disease severity varies, with some patients having only mild right upper quadrant discomfort associated with prodromal nausea and vomiting. Others develop fulminant liver failure leading to coma. A depressed level of consciousness may arise from either hypoglycemia or the onset of hepatic encephalopathy. Hypoglycemia is a common feature of AFLP and should alert the clinician to the possible diagnosis. More than 50% of affected patients will have mild hypertension and proteinuria, making the distinction from HELLP syndrome difficult. Jaundice is often present at the time of diagnosis. Liver enzymes are increased, and transaminases may rise above 1000 IU/L in severe cases. Liver failure leads to severe coagulopathy and a prolonged partial thromboplastin time and INR. Disseminated intravascular coagulation (DIC) with microangiopathic hemolytic anemia develop together a mild neutrophil leukocytosis.[74,75]

Management principles include delivery of the fetus and treatment of the acute liver failure.[76] Coagulopathy may complicate the delivery and must be corrected beforehand. Management of liver failure also includes maintenance of the blood glucose level, the use of lactulose to limit the effects of intestinal bacteria, and administration of vitamin K to

$Paco_2$, partial pressure of carbon dioxide; WBC, white blood cell count.

mother and baby. Intubation and ventilation might be necessary in the comatose mother who cannot protect her airway. Associated complications of renal failure and pancreatitis need to be managed individually.

Obstetric Hemorrhage

Obstetric hemorrhage occurs as a result of bleeding from the placental site or as a consequence of trauma to the genital tract. These issues, including medical, surgical, and critical care management of shock and coagulopathy, are dealt with in Chapter 77.

Severe Sepsis

The systemic inflammatory response syndrome (SIRS) consists of markers of a systemic immune response (Table 78–2).[77] SIRS may develop from any noxious stimulus including preeclampsia and hypovolemia. When infection causes SIRS, the condition is named "sepsis." Sepsis leading to multiorgan dysfunction is termed "severe sepsis," and severe sepsis plus refractory hypotension is "septic shock." Collectively, infection arising during pregnancy or that resulting from underlying HIV infection is by far the single largest cause of maternal mortality in developing countries. In South Africa, these two entities account for 40% of the maternal deaths: double the number of the next most prevalent cause of mortality.

The sources of sepsis vary. Pelvic infection after delivery, wound sepsis, respiratory infection, and urosepsis are all common and can all lead to life-threatening illness requiring critical care.

Pelvic Sepsis

Pelvic sepsis usually results from infection with gram-negative organisms, although gram-positive organisms and fungi can be implicated. Tuberculosis can also present with abdominal sepsis. Prolonged rupture of the membranes, obstructed labor, instrumentation of the genital tract, retained products of conception, trauma, and operative delivery, together with immunosuppression all contribute to the pathogenesis of sepsis.

Recognition of pelvic sepsis is based on the presence of SIRS together with localizing signs of pelvic infection, including peritonitis, a tender subinvoluted uterus, and malodorous lochia. Coexisting organ dysfunction, such as impaired renal function, gastrointestinal signs (ileus), hyperbilirubinemia or elevated liver enzymes, DIC, ARDS, neurologic dysfunction, and cardiorespiratory disease including

left ventricular failure, will define the syndrome of severe sepsis and will indicate the need for intensive care.

Intensive care principles are self-evident. Supportive therapy will be necessary to maintain organ function by ensuring adequate peripheral perfusion, and the source of sepsis will need to be managed by medical and surgical intervention. Supportive therapy consists of fluid replacement measured against the CVP. Women with distributive shock due to peripheral vasodilation may require large amounts of fluid and blood products. Persistent hypotension due to left ventricular failure may require inotropic support using adrenaline, dopamine, or dobutamine. Coagulopathy due to liver dysfunction and DIC will need to be corrected prior to any surgical intervention, and oxygen-carrying capacity of the blood should be optimized by packed cell transfusion in women who are anemic. Appropriate respiratory support may take the form of face mask oxygen or intubation and ventilation in cases of respiratory distress with inadequate peripheral oxygen saturation or respiratory failure.

Managing the sepsis will require broad-spectrum antibiotic cover tailored to the specific infecting organism if bacteriologic surveillance from blood cultures and pus swabs identify a specific pathogen. Surgical intervention may include evacuation of retained products of conception, drainage of pelvic abscesses, and hysterectomy. The last option is often delayed because of understandable concern about future fertility. However, the woman with multiorgan failure precipitated by sepsis who fails to respond to 24 hours of appropriate antibiotic treatment is at risk of developing septic shock that may progress rapidly and is associated with mortality rates between 20% and 50%.[78] Under these circumstances, hysterectomy to remove the source of sepsis may be a lifesaving procedure.

Respiratory Infection

Respiratory infection may be community acquired (often gram-positive organisms like *Streptococcus pneumoniae*) or nosocomial (usually gram-negatives—e.g., *Pseudomonas, Acinetobacter, Escherichia coli*).

The clinical presentation is that of SIRS together with respiratory symptoms of dyspnea, pleuritic chest pain, cough, sputum production, and clinical signs of pulmonary crepitations or consolidation with bronchial breathing. Radiographic signs may take time to develop, but new pulmonary infiltrates should be identified if the diagnosis of pulmonary infection is correct. Sputum specimens should be routinely examined bacteriologically to identify the infecting organism. Tuberculosis should also be excluded as a diagnosis, especially in areas where there is a high prevalence of HIV infection.

Critical care management must maintain oxygenation while treating the underlying infection. Peripheral oxygen saturation levels will determine the necessary respiratory support, which may include the use of face mask oxygen, the administration of continuous positive airway pressure oxygen or intubation, and ventilation. Generally, respiratory infection has not been regarded as an indication for delivery of the baby, even among ventilated patients. Antibiotic therapy for community-acquired infection is usually a cephalosporin or an aminoglycoside with penicillin, whereas nosocomial infections due to gram-positive organisms will

need treatment with vancomycin. A suspicion of mixed aerobic infection or anaerobic infection may lead to the use of imipenem or a combination of clindamycin/metronidazole with an aminoglycoside. Bacteriologic advice should be sought and treatment adapted to organisms identified from blood and sputum culture.

Sepsis in the Immunocompromised Patient

HIV infection predisposes the affected individual to pelvic, respiratory, and neurologic infection. Respiratory infection may be due to atypical organisms (*Mycoplasma* and *Legionella*), tuberculosis, cytomegalovirus, or the protozoan *Pneumocystis jiroveci* [formerly *carinii*] (PCP). The clinical presentation and radiographic signs may not discriminate between these different disorders, and sputum should be obtained (or bronchoscopic lavage used) to arrive at a bacteriologic diagnosis. Radiologically, PCP may present with patchy changes that progress to a diffuse pattern of bilateral pulmonary infiltrates resembling ARDS. Management consists of supportive treatment including ventilation together with high doses of trimethoprim and sulfamethoxazole (dose 20 and 100 mg/kg/day, respectively, for 21 days) and corticosteroids. The prognosis for women with PCP who require ventilation is poor, with only one in three surviving ventilatory care that extends for more than 2 weeks.[79] Suspected atypical pneumonia requires treatment with erythromycin.

Pelvic and wound sepsis seems to occur more readily in HIV-infected women. Antibiotic prophylaxis against postoperative sepsis should be extended to 48 hours for elective surgery and for 5 days in those having emergency cesarean delivery. In managing puerperal sepsis, surgical intervention, including hysterectomy, has been practiced more aggressively than in immunocompetent women. These approaches are unsubstantiated by randomized evidence but have developed in units faced with a large burden of HIV-infected women.

Thromboembolism (See also Chapter 42)

Thromboembolism is the leading direct cause of maternal mortality in the United Kingdom. The incidence of venous thromboembolism lies between 0.5 and 1 per 1000 deliveries.[80–83] The predisposing factors giving rise to thromboembolism are pregnancy itself, underlying thrombophilia, age, and circumstantial risk factors such as surgery and immobilization. Pregnancy is a procoagulant condition because of increased hepatic synthesis of clotting factors, decreased protein S activity leading to activated protein C resistance, and inhibition of fibrinolysis by placental production of PAI-2. Underlying hereditary or acquired thrombophilias add to the risk. These conditions include deficiencies in protein C, protein S, and antithrombin. The Leiden and prothrombin gene mutations have been described more recently. Hereditary defects also exist in Factor VIII and fibrinogen genes, giving rise to increased concentrations of these clotting factors. Hyperhomocysteinemia is also considered to be a thrombogenic condition, which arises either because of a dietary deficiency in cofactors such as folate, vitamin B_6, and B_{12} or because of enzyme deficiencies. Common mutations affect the enzyme methylene tetrahydrofolate reductase, which is required to convert folate to tetrahydrofolate. The other rarer enzyme defect is linked to

cystathionine β-synthase deficiency. Thrombophilia may also be acquired as part of the antiphospholipid syndrome owing to the presence of the lupus anticoagulant that interferes with the protein C mechanism and also promotes platelet activation through the release of platelet-activating factor by endothelial cells. Finally, the sticky platelet syndrome may increase the risk of clot formation.

Ileofemoral vein thrombosis occurs more commonly in pregnancy; the presenting features of venous thromboembolism are those of a swollen, red, and tender leg. These signs are unreliable, and investigation is sometimes also unhelpful. Compression ultrasound is useful in identifying proximal thrombosis, but venography remains the gold standard against which other investigations are assessed. Pulmonary embolism classically presents with sudden-onset pleuritic chest pain, dyspnea, and hemoptysis. Investigations may confirm hypoxemia and right ventricular strain with an S wave in lead 1 and Q- and T-waves in lead 3 (S_1 Q_3 T_3 electrocardiogram pattern). Radiologic investigation may show no lesion or an elevated hemidiaphragm. Ventilation-perfusion scanning identifies mismatched areas of ventilation and perfusion that may be indicative of embolization. More recently, spiral CT is helpful in diagnosing segmental rather than subsegmental emboli.[84,85] It is notable that measurement of D-dimer concentrations during pregnancy is not a useful way of diagnosing excessive fibrinolysis associated with venous thrombosis because D-dimer levels are normally elevated in pregnancy.

Treatment of thromboembolism consists of anticoagulation to arrest clot propagation until the clot resolves followed by prophylactic doses of low-molecular-weight heparin to prevent further clot formation. The detailed description of how heparin and warfarin are used is covered in Chapter 42. In the critical care setting, unfractionated heparin is given intravenously in a dose of 20,000 units in 200 mL of saline beginning at 13 mL/hr, with the dose titrated against the aPTT to maintain values 1.5 to 2 times the control value. Other supportive therapy may be necessary to maintain oxygenation, up to and including intubation and ventilation.

Cardiac Problems

Arrhythmias (See also Chapter 36)

The patient experiencing cardiac arrest should be resuscitated according to standard protocols, including defibrillation, external cardiac massage, and ventilatory support. The pregnant uterus restricts venous return as a result of aortocaval compression, and cesarean delivery will facilitate resuscitation. If this is to be done, it should take place within 5 minutes of the arrest.

Ventilatory support, when required, should aim for slight hyperventilation to mimic pregnancy physiology in which $PaCO_2$ falls to allow fetal excretion of carbon dioxide down a concentration gradient. Extreme hypocarbia may affect uterine blood flow adversely, and maternal $PaCO_2$ levels must be maintained above 2 kPa. Where pressure considerations permit, tidal volumes of 10 to 15 mL/kg should be used, and the ventilator rate adjusted to achieve an appropriate $PaCO_2$. The maximum ventilatory plateau pressure should (ideally) not exceed 35 cm H_2O.[86]

Arrhythmias occur more frequently in pregnancy and occasionally lead to hypotension. In the critical care setting, the drugs most likely to be used to treat arrhythmias are adenosine, short-acting β-blockers, and amiodarone.[87] Adenosine is used to treat supraventricular tachycardia, Wolf-Parkinson-White syndrome, and arrhythmias involving the atrioventricular node. Because it can cause bronchospasm, it should be avoided in asthmatics. Lignocaine has been used in pregnancy, but there is limited experience. Although β-adrenergic blocking agents given to the mother have been linked to fetal growth restriction, fetal hypoglycemia, and hyperbilirubinemia, short-acting drugs such as esmolol may be used during pregnancy for specific indications such as the treatment of arrhythmias. Amiodarone is a drug with a long half-life (>50 days) and has been linked to a risk of neonatal hypothyroidism. The use of amiodarone should, therefore, be restricted to the treatment of life-threatening arrhythmias unresponsive to other treatment.

Other Cardiac Problems

Arrhythmias were discussed in detail in the previous section but can additionally cause sudden hypotension. Acute pulmonary edema can result from peripartum cardiomyopathy or valvular heart disease, especially thrombosis of a prosthetic valve. Myocardial infarction is rare but can result in cardiogenic shock. Aortic dissection and pulmonary hypertension giving rise to acute right ventricular failure also enter the differential diagnosis. The reader is referred to Chapter 36 for detailed discussion of the management of these conditions.

Neurologic Disorders

Cerebral ischemia or hemorrhage will present with neurologic signs. There may also be a sudden onset of neurogenic pulmonary edema.[88,89] Management should be directed to protecting the airway. Urgent neuroradiologic investigation is required to exclude a surgical remedial cause, and the management of these cases must always take place in consultation with a neurologist. The reader is referred to Chapter 48 for detailed discussion of the management of these conditions.

Trauma

Motor vehicle accidents and assault are the most serious causes of trauma in pregnancy. Pregnancy does not increase the risk of maternal death due to trauma, but the fetus is at exaggerated risk of death due to maternal hypovolemia, placental abruption, and direct trauma to the uterus and fetus.[90]

Direct trauma to the abdomen can lead to placental separation and abruptio placentae, the clinical signs of which may be delayed by up to 6 hours after the event. More forceful blunt trauma has the potential to cause uterine rupture, although this is a rare occurrence among pregnant trauma victims. Other obstetric consequences of blunt trauma are those of premature rupture of the membranes and fetomaternal hemorrhage, which can lead to isoimmunization of babies whose blood groups are incompatible with those of the mother.

Penetrating injury to the abdomen and uterus may lead to direct fetal trauma: Conservative management of penetrating injuries below the level of the uterine fundus has been advocated, but in pregnancies in which the fetus is considered to be viable (usually > 28 wk), many obstetricians would resort to laparotomy and operative delivery in the presence of a penetrating uterine injury.

Resuscitation and critical care should be based on normal trauma guidelines, although monitoring must be extended to include an assessment of the fetal condition. The reader is referred to Chapter 54 for detailed discussion of the management of these conditions.

Metabolic Problems

Hypoglycemia, hyperglycemia, hypocalcemia, and hyponatremia should always be considered in any patient who collapses acutely. Management will be based on the specific cause and diagnosis.

Anaphylactoid Syndrome of Pregnancy

This complication of labor or cesarean delivery gives rise to peripartum collapse as a result of embolization of amniotic fluid and fetal squames into the maternal circulation. The syndrome may be rapidly lethal in women who develop a true embolus of fetal squamae that obstruct the pulmonary circulation, leading to severe pulmonary hypertension and cardiac arrest. However, those who survive for longer periods develop an anaphylactoid type of response to the presence of amniotic fluid in the circulation.[52]

The clinical syndrome is diagnosed in 1 in 8000 to 1 in 80,000 pregnancies. A national registry of cases that has been opened in the United States is currently the most authoritative source of information about this condition.[52] The condition usually presents during labor but may occur at the time of cesarean delivery or immediately after birth. There are no demographic predisposing factors, and obstetric practices such as prior amniotomy and oxytocin administration do not seem to influence the risk of developing amniotic fluid embolus. The onset of the condition is abrupt, and hypotension is universally present. Most patients develop pulmonary edema with cyanosis and a profound coagulopathy, which should immediately give rise to a suspicion of the diagnosis. The single most common initial presenting symptom in antenatal patients is seizure activity, which may be confused with eclampsia. The patients who survive the initial embolus and who develop the anaphylactoid picture have markedly depressed left ventricular function. Cardiac electromechanical dissociation may develop, and there is a high risk of cardiopulmonary arrest. The prognosis is poor; in the U.S. national registry, 61% of the patients died, and only 15% survived neurologically intact.[52]

Diagnosis must be prompt, and continuous vigorous resuscitation will be needed immediately. Intensive care is mandatory and inotropic support necessary from the beginning. Hemorrhage should be anticipated, and hypovolemia is also likely to be a problem as a result of postpartum hemorrhage or bleeding after cesarean section. Continuous transfusion with blood and coagulation factors will be necessary, and obstetric intervention in the form of oxytocic drugs and hysterectomy may be necessary to control bleeding (see also Chapter 77). Intubation and mechanical ventilation along with pulmonary artery catheterization are likely adjuncts to intensive care management.

Other Causes of Acute Collapse

Several other conditions may result in acute collapse requiring emergency intensive care. The same general principles apply to all these cases: namely, secure the airway, maintain respiration and circulation, and then look for and correct the underlying cause.

Respiratory Disorders

Air embolism may develop during delivery as a result of air entering the venous system and becoming trapped in the right ventricle. Paradoxical arterial emboli can develop in any individual with a patent foramen ovale. Presenting features include acute collapse, coronary insufficiency, and cerebral artery occlusion, leading to seizures and a depressed level of consciousness. Specific management is based on the use of hyperbaric oxygen to decrease the volume of the gas.

Other Systemic Disorders

These include thyroid storm, myasthenic crisis, sickle cell crisis, anaphylaxis, and transfusion reactions. The description of these disorders is found in Chapters 38, 43, 45, and 77.

Training for Obstetric Emergencies

TIM DRAYCOTT and DIMITRIOS SIASSAKOS

INTRODUCTION

Labor and delivery are the safest they have ever been in the developed world,[1] yet 1 in 12 labors still ends in an adverse outcome,[2] particularly in emergency situations.[1] Obstetric emergencies are especially high risk: they occur rapidly, are unpredictable, are often unavoidable, and require a rapid, coordinated response by a multiprofessional ad hoc team. Their rarity makes it difficult to learn solely by experience. And although, in the past, training has included didactic lectures combined with arbitrary clinical experiences, this educational paradigm clearly has limitations. The difficulties have been exacerbated by mandatory reductions in working hours worldwide, to the extent that the majority of current obstetric trainees have had no real-life experience leading the management of emergencies like eclampsia, shoulder dystocia, or even the more common postpartum hemorrhage (PPH).[3]

Unfortunately, several Confidential Enquiries have demonstrated that when emergencies do occur, error is far too common, possibly because of these difficulties. Therefore, training—in particular "fire drills"—has repeatedly been recommended,[1,4–8] even though there are precious little data to support it.[9,10] In fact, there is at least one study that demonstrated an increase in poor outcomes after training.[11] More recently, there has been an increasing dataset to support training for obstetric emergencies, and we review the best practices in this chapter.

Training should enable caregivers from a variety of health care professions to provide the best possible clinical care to women as soon as it is required. Training should improve skills, behavior, and attitudes, which in turn should improve the clinical and organizational outcome (modified Kirkpatrick evaluation levels[12]). Face validity should no longer be an acceptable outcome; there is a risk that, although trainees feel more satisfied and confident after training,[9,13–19] entrenched behaviors remain unchanged,[14] and real-life outcomes do not improve[2] and may even deteriorate.[11]

RISKS

Substandard care may lead to adverse outcome with devastating, and sadly potentially avoidable, physical, psychological, and financial consequences.

Maternal Risk

Mortality

Mothers still die in pregnancy and it is a sad indictment of their care that at least 50% of these deaths are avoidable and that percentage has remained static for decades. In the United Kingdom, the Confidential Enquiries into Maternal Death (CEMD) and into Maternal and Child Health (CEMACH) have repeatedly identified poor or absent teamworking as one of the main reasons for substandard care leading to avoidable maternal death. They have recommended that all clinical staff in maternity units be required to undertake regular, documented, and audited training for the management of severely ill women and impending maternal collapse, as well as for the improvement of acute obstetric, life support, and communication skills.[1,4]

Maternal Morbidity

Labor and delivery can result in significant maternal morbidity, rapidly, unexpectedly, and unfortunately often.[2,20] The physiology of pregnancy renders women more susceptible to certain complications, and pregnant women are often younger and fitter than the general medical population. These facts can make it difficult to recognize and preempt potentially serious complications, for example before infection develops into septic shock.

Particularly in developed countries, where maternal mortality is now very low, study into maternal morbidity can also provide insight into avoidable causes of adverse outcome. There was poor recognition of concealed complications in one review of the management of critical obstetric emergencies and intensive care for pregnant women,[1] resulting in suboptimal care for one in three cases. More appropriate management in cases with suboptimal care could have prevented hysterectomy, multiple organ dysfunction, coma, shock, and admission to intensive care.[1] There are similar lessons contained in other reports.[21–24] However, more optimistically, there is indirect evidence that guidance-based management has decreased complications like eclampsia,[24] or death after hysterectomy,[23] and therefore, training may also decrease avoidable maternal morbidity.

Maternal Satisfaction

Maternal dissatisfaction is a significant complication of traumatic birth, but it is often ignored. More than 17% of

women are dissatisfied with labor[25–27] and up to 22% of partners are also dissatisfied with their labor experience.[28] Decreased maternal satisfaction is associated with an increased risk of sexual dysfunction, negative effects on ability to breast-feed and bonding, and negative expectations for future births.[29,30] U.K.-based research showed that over 25% of new mothers were not satisfied with communication by the medical staff, and there was a significant association between satisfaction with communication by medical staff and overall satisfaction with care.[31,32] These negative feelings are more likely when obstetric intervention is necessary for birth[33,34] and may increase the risk of litigation.

Fetal Risks

Perinatal Mortality

Suboptimal team communication, poor teamwork climate, and deficient team training have also been identified as the most common root causes for infant death in developed countries.[5–7] The direction for the future is clear: there is a need for training in perinatal areas that focuses on high risk events like shoulder dystocia, electronic fetal monitoring interpretation, and team-working.

Cerebral Palsy

Cerebral palsy (CP) is a condition with immense physical, psychological problems: lifetime disability for the child, depression for the parents,[35] and costs of around £4 million per case of negligent care for U.K. health organizations.[36] Most types of CP have been associated with factors other than substandard intrapartum care, but spastic quadriplegic and athetoid CP are associated with intrapartum asphyxic events in 45% and 80% of cases, respectively.

The U.K. Department of Health has published its ambition to reduce the rates of avoidable CP by 25% and national guidelines have been developed to facilitate standardized interpretation[37] of electronic fetal monitoring (EFM). Despite these guidelines, birth asphyxia due to misinterpretation of EFM and failure to respond appropriately remains a problem perhaps because the guidelines are not used in the front line of care. It may be that only when maternity staff are trained how to interpret EFM traces using the guidelines, and refer or act on them appropriately,[38] that better outcomes and fewer negligence claims can be achieved without increasing the intervention rate.[39,40]

Neonatal Injury

Another example of a potentially avoidable neonatal morbidity is brachial plexus injury. It is a condition associated with the management of shoulder dystocia[41] that often results in costly litigation for negligent care.[42] Shoulder dystocia is unpredictable and, therefore, unpreventable. Improving management through training may be the most effective method of reducing the associated morbidity,[41] mortality, and litigation.[42] However, a recent study of 450 simulated shoulder dystocia stations revealed that unless training concentrates on the important underlying concepts,[43] confusion and errors result. Another study showed that worse outcomes occurred after the introduction of training in a U.K. unit.[11]

Therefore, it would seem prudent for those designing obstetric training programs to consider the currently available evidence when deciding how best to train. National standards indicate which obstetric situations to target[6,44]: shoulder dystocia, EFM and emergency cesarean section, cord prolapse, neonatal resuscitation, maternal hemorrhage, collapse and shock, preeclampsia and eclampsia.

MANAGEMENT OPTIONS

Scope of Training

In many countries, national bodies mandate[44] or recommend[1,6,7,38] the content of training. However, it is also important to identify local training needs and address them with targeted interventions.[39] Local surveillance systems[45] may provide such information when supplemented by risk management processes, for example, root cause analysis.[39]

Another useful source of information can be reviews of medicolegal cases.[42,46–49] Such reviews can help identify which training interventions are more likely to have a successful impact on litigation frequency and severity.[20,46] Individual staff appraisals, supervisory reviews,[1,50] and safety attitude surveys[51–53] provide another opportunity to identify and address training needs.

Simulation exercises can be used to identify recurrent mistakes. One study in Israel showed that many errors in drug administration, performance of practical maneuvers, resuscitation, and documentation were observed before training for four simulated obstetric emergencies: breech delivery, shoulder dystocia, PPH, and eclampsia.[3] In the study, 84% of participants who had originally expressed being confident of their ability to perform appropriately in obstetric emergencies retracted their statements after simulation and expressed interest in further hands-on practice.[3]

Similarly, a number of performance deficiencies for obstetric residents were identified when 10 labor ward teams were videotaped and externally reviewed managing a simulated amniotic fluid embolism and forceps delivery: poor communication with the pediatric team, not assuming a leadership role during the drill, poor distribution of workload, and lack of practical skills.[54] Moreover, a large regional study in the United Kingdom demonstrated that before training, 39% of teams did not administer magnesium sulfate to women with simulated eclampsia[55] and only 42.9% of caregivers could deliver a baby with simulated shoulder dystocia. Sixty-six percent of staff applied extremely high forces to effect delivery; almost 20% could not perform any internal maneuvers and 11% asked for fundal pressure, a technique currently considered inappropriate. One third did not state what the emergency was, two thirds failed to call a pediatrician/neonatologist to attend the delivery, and almost half the participants did not communicate well with the patient-actor.

It is obvious that there is discrepancy between how good participants *think* they are before training and how good they *really* are when they perform under observation: the need for both individuals[56] and teams[55] to receive practical and communication training is clear and urgent. These deficiencies can be identified and subsequently addressed successfully with simulation.[56]

TABLE 79–1

Examples of Improved Perinatal Outcomes Associated with Evidence-based Management as Detailed in the Summary of Management Options Box

HOSPITAL UNIT	INGREDIENTS OF TRAINING PROGRAM	OUTCOMES BEFORE TRAINING	OUTCOMES AFTER TRAINING
Southmead Hospital, Bristol, UK[41,50,68]	Regular in-house clinical rehearsals for all staff. Integrated teamwork training. Infrastructural changes. Evidence-based protocols. BPI, brachial plexus injury; DDI, decision-delivery interval; HIE, hypoxic ischemic encephalopathy; ICU, intensive care unit; NICU, neonatal intensive care unit.

Incentives

There may be multiple barriers to successful obstetric training, such as cost and time away from work.[57] Those units that have demonstrated direct improvements in perinatal outcomes after training (Table 79–1) have all had financial incentives to train, for example, lower medical malpractice insurance premiums are offered to clinicians and units with regular training in the United States[20] (University of Kansas– and Harvard-affiliated obstetricians) and the United Kingdom[49] via national clinical negligence schemes. These financial incentives may help not always completely altruistic institutions overcome the inhibitory direct costs of training.

Safety Culture

Knowledge, skills, and attitudes are all essential for successful performance in "high-reliability organizations" (HROs): settings that are hypercomplex, are tightly coupled, are time-compressed, and rely upon synchronized outcomes.[58] Maternity units demonstrate all of these characteristics: complex emergencies with frequently two patients to look after (mother and baby); tightly coupled events, when the performance of an emergency cesarean section depends on the actions of every single team member; compressed decision-to-action intervals; and necessity for synchronized actions.

Organizations that provide maternity care should ideally function like HROs. Training should support teamwork and be context-specific. This culture appears not to be ubiquitous. In the Simulation and Fire Drill Evaluation (SaFE) Study,[59] questions regarding the perception of management's role in safety had the lowest scores across professional groups, reflecting a perception of negative attitude

toward risk management. This attitude worsened after training in simulation centers, but not after local training. This may reflect the fact that training in external courses was perceived as paternalistic and driven by managerial targets rather than staff development needs.

Conversely, there was a positive impact of training, particularly if undertaken in the local setting, on job satisfaction and attitudes toward teamwork and stress recognition. After 12 months, the improvement in attitudes toward teamwork was sustained only for health care professionals receiving training locally.[59]

Methods—How Should We Train?
Simulation

Simulation is an educational technique, not a machine or a place, and can be used to bridge the gap between theory and real-life application of skills.[54] It was shown in a randomized trial that postgraduate teams taught using simulation demonstrated larger improvements in clinical management, confidence, communication skills, and knowledge and less anxiety during subsequent emergencies than teams taught with a lecture format.[69] In addition, simulation was deemed more enjoyable. Similar results have been shown for simulation training of both postgraduates and undergraduates, as individuals or in teams.[55,56,61–66]

In-house Rehearsals

In-house training of multiprofessional teams should be the initial training of choice for obstetrics: it is less expensive than external training (Fig. 79–1)[47,50] and appears to offer additional benefits. Assessment of safety and communication as evaluated by a patient-actor has been shown to

In-house rehearsals: a unit's labor ward as simulation center.

be significantly better when training is conducted in local hospitals using patient-actors than when training is conducted at a simulation center using computerized patient mannequins.[61] These improvements do not come at the expense of individual knowledge, skills, or team-working and communication.[55,62] On the contrary, in-house training has been associated with significant improvement in real-life outcomes.[41,50,67]

Local training provides the opportunity for teams to identify local safety problems that can be addressed with targeted interventions. In one study, the patient bed could not pass through the door in two labor rooms, resulting in avoidable delays. This was identified during some of the early rehearsals for cord prolapse simulation training, and the doorframe was widened. The result was a 40% reduction in decision-delivery interval with concurrent improvement in perinatal outcome.[67] Other examples of safety interventions that have been introduced in units in which in-house training was associated with improved perinatal outcomes include eclampsia boxes,[50] streamlined management protocols (Soerensen JL, Copenhagen, Denmark, personal communication), guidelines for specific emergencies, and regular patient handover.[20]

However, there are potential disadvantages to in-house training: it might be difficult to conduct team rehearsals in busy labor wards, whereas external courses allow uninterrupted training. There may also be difficulty in maintaining quality. A study showed that despite the introduction of regular in-house training in 2001, perinatal asphyxia and serious neonatal injury, including brachial plexus injury, significantly increased.[11] This suggests that not all training is equal; other elements might need to be present for improvements in outcome to occur.

Evidence-based Training

A recurrent finding in inquiries and reports is that quality improvement in maternity is always associated with a reduction in the variation of processes and procedures,[40,42] and clinical practice is evidence-based and protocol-driven.[1,6,40,44] However, simply having guidelines available on the labor ward is not sufficient—training is required to implement them. It is necessary to engage multiprofessional teams both in the development of guidelines and in training staff in how to apply them to practice.[20,50] Furthermore, it should be made easy for staff to use them ("make the right way the easiest way"[68]) through innovative practical solutions: miniadhesive proformas ("stickers") that facilitate regular standardized interpretation of EFM traces[50,68]; laminated summaries of guidelines[65]; and perinatal care bundles.[69] Standardized proformas can also help reduce variation, facilitate referral to seniors, and assist communication with women and their birth partners, for example, when an emergency cesarean section is needed for presumed fetal distress based on a pathologic EFM trace.[65]

Interprofessional Teams

Historically, training programs for nurses, midwives, family practitioners, obstetricians, pediatricians, and anesthesiologists have been separate,[10] which may raise the interprofessional barriers associated with poor outcomes for mother and babies—barriers created as early as the undergraduate level.[70] To address this problem, national bodies have recommended the introduction of interprofessional learning strategies.[70] It is important to train in multiprofessional teams. In one of the take-home lessons to emerge from the SaFE study, study teams did not include neonatologists, and after training, there was a trend to forget calling them for help in the event of shoulder dystocia.[62] This trend was even more evident when a high-fidelity mannequin was used,[56] perhaps because the focus was on individual technical skills rather than communication within the team.

The lesson is clear: training has to be inclusive—health care assistants, porters, and other nonclinical staff have a role to play. They can help with rehearsals by becoming trained patient-actors. Their role in achieving good safety culture and optimal teamwork climate is important.[52,53]

Lack of Hierarchy

Training should promote positive attitudes to team-working in interprofessional teams and should take place in a non-threatening environment with the emphasis on constructive criticism. Otherwise, professional marginalization or steep hierarchy can poison the teamwork climate.[71,72] Obstetric nurses and midwives are particularly prone to feeling intimidated during simulation training,[73] but a reduction in the perceived authority gradients can reduce the level.

After each rehearsal, participants, regardless of seniority, can provide feedback to the team using standardized checklists as guides (Table 79–2). Such debriefings encourage juniors to question seniors, midwives to challenge doctors, doctors to feel their expertise is valued, and other staff to feel part of the team. It is noteworthy that in a recent safety attitudes survey with a validated tool,[52,74] the top five scores

TABLE 79–2
Checklist to be Used for Debriefing

Did the first (handover) professional communicate by using SBAR?

DOMAIN	EXPECTED STATEMENT	YES—PLEASE TICK
S Stated which emergency (situation)	Cord prolapse	
B Background history (key points) mentioned	Spontaneous rupture of membranes Not fully dilated	
A Assessment of situation and severity	Fetal bradycardia (need for immediate delivery)	
R Recommendation for initial action	Elevation of presenting part Need to transfer to theatre for caesarean	

FIGURE 79–2
Low-cost props: trousers that "bleed."

in the collaboration scale were given to caregivers belonging to the professions that undergo mandatory interprofessional training and that these good collaboration scores were associated with good safety scores.[53]

Fidelity

ENVIRONMENTAL FIDELITY

Environmental fidelity—that is, conducting rehearsals on labor wards—might be more important in obstetric training than the technology of the equipment used; in the SaFE study, training was more successful, in some aspects, in situ than externally.[61] If mannequins are used, a pregnant abdomen, bra, and female wig add realism to the simulated scenario. In the PROMPT (PRactical Obstetric Multi-Professional Training) course,[75] props are used to increase the realism of the scenarios: blood-stained incontinence sheets, trousers that bleed (Fig. 79–2), a pregnant uterus, life-size copy of O-negative blood bags stuck on to cardboard, and a perineum with a prolapsed cord. With the collection of many low-cost props and a few high-tech models, a "mobile simulation center" (Fig. 79–3) can be used to flexibly train either the trainers or the participants.

HIGH-TECH MODELS

Whereas expensive models are not always necessary, high-fidelity part-task trainers may be best used to train individuals in highly technical skills like internal maneuvers at shoulder dystocia.[62] In the SaFE study, training on a high-fidelity mannequin was associated with a significantly higher chance of successfully managing a simulated shoulder dystocia than training with low-fidelity models.[56]

PATIENT ACTORS AND HYBRID SIMULATION

Obstetric emergencies are unique in that there is significant audience participation; health care team communication with women, their families, and sometimes friends during acute management of the emergency is an essential skill. In medical emergencies, the patient is often conscious and

FIGURE 79–3
Mobile simulation kit: a simulation center anywhere, anytime.

there remains a direct interaction between the patient and the caregivers. Yet, there is acknowledgment that nontechnical skills are often not addressed in obstetric training programs.[76]

Properly trained patient-actors are valuable proxies for assessing communication skills. One study demonstrated that patient-actors working to an agreed protocol are reliable reporters of physicians' practice. Their reports of physicians' quality of care compares well with independent external assessments of audiovisual recordings of patient-doctor interactions.[77]

Computerized mannequins may be less effective: advanced technology allows mannequins to "speak," but in the SaFE study, training with high-tech mannequins did not seem to

Hybrid simulation: a trained patient-actor kneels behind an advanced pelvic trainer model and delivers a standardized script and feedback at debriefing.

improve communication skills as much as training with patient-actors.[61]

Patient-actors are useful not only for the assessment but also for the development of communication skills. The SaFE study demonstrated that training maternity staff in the management of simulated obstetric emergencies improved patient-actor perception of safety.[62,76,78] Another study demonstrated that obstetric intervention for certain emergencies is not detrimental to real-life women's satisfaction with the birth experience[79] when all staff attend regular team communication training with patient-actors.

Integrating a patient-actor with a mannequin ("hybrid" simulation, Fig. 79–4) is a simple, effective, and inexpensive training tool that allows both manual and verbal skills to be learned and practiced simultaneously.[55,56,59,61,75,78] Hybrid simulation can increase the realism of the situation, enhance the communication between team members and women, and lead to improvement in communication scores.[61] To maximize the educational benefit, it may be useful for the patient-actors to provide feedback to the team after each rehearsal.[61]

Human Factors (Teamwork) Training

Teamwork is defined as the combined effective action of a group working toward a common goal. It requires individuals with different roles to communicate effectively and work together in a coordinated manner to achieve a successful outcome.[75] Theories of team effectiveness dictate that the outcome of team-working is related to task clarity and importance (clear outcome-based objectives), group characteristics and size, organizational environment and culture, as well as the intervening factors of teams such as leadership and communication.

Formation of a team is rapid in an emergency and enquiries into poor outcomes clearly show that these ad hoc teams do not always function well.[1] Teamwork training has been recommended to address the problem,[1,6] but isolated teamwork interventions have not been shown to lead to sustainable improvements in outcome.[14] A recent cluster randomized, controlled trial[2] studied the impact of standardized crew

resource management (CRM) ("MedTeams") teamwork training on 11 measures of maternal and neonatal outcome in seven U.S. maternity units. More than 1300 health care professionals were trained, but there was no difference before or after the intervention in any clinical outcome or in 10 out of the 11 process measures used to evaluate the quality of care.

Conversely, clinical training alone might improve teamwork without the need for nonclinical teamwork theories or activities. The SaFE study demonstrated improved simulation performance and team behavior after clinical training in teams. There was no difference in knowledge or clinical performance in rehearsals between learners who received additional teamwork training and those who were randomized to clinical training alone. There was also no difference in overall team performance as measured by global teamwork rating or patient-actor perception of care between the two groups.[55,61,62]

Similarly, in an obstetric emergencies course, pretraining clinical performance was lower for rehearsals requiring multiprofessional team effort (PPH, eclampsia) than for rehearsals focusing on skills of the individual accoucheur (breech vaginal delivery, shoulder dystocia). Simulation performance significantly increased in the former by working in teams: the performance in either eclampsia or PPH was higher for the second pretraining drill than the first, regardless of whether the PPH station followed the eclampsia or vice versa, even before any additional clinical or teamwork training. Subsequent performance improved further with clinical training, even though the scenarios were changed[3]: simply stated, working in teams improves team-working.

It might be that CRM principles can be effective in obstetrics, but perhaps relevant teamwork interventions need to be refined and made directly applicable to labor settings first. In the SaFE study,[59,80,81] content analysis demonstrated that extra teamwork training resulted in increased rate of directed and addressed messages (as opposed to commands called out "in the air"), compared to clinical training alone, but this was not associated with improved simulation performance. Further work is required to determine the components of effective, structured obstetric communication and inform the design of effective nontechnical team training interventions and practical assessment tools.

Documentation Training

An analysis of 189 closed perinatal claims in the United States with a total value of $168 million revealed that theoretical presumption of innocence does not apply to maternity caregivers, who, therefore, must document that their care could not have caused injury. Better documentation was identified as one of the four key interventions that can reduce obstetric litigation.[42] Unfortunately, an evaluation of delivery notes after simulated shoulder dystocia found that notes often lacked critical elements,[82] but participants can achieve better documentation after simulation training including documentation training.[67,83,84] However, training should be supplemented by standardized proformas to assist easy, reliable, and accurate documentation.[82–84]

Frequency of Training

Traditionally, the recommendation has been for annual training, and the existing evidence suggests that this

is reasonable.[78] A study of the management of simulated shoulder dystocia confirmed that there was no deterioration in the performance of basic actions, delivery interval, force application, and patient communication for at least 1 year after training. Those who were proficient before initial training performed best at follow-up, but skill retention was also good in those who learned to deliver during initial training. However, more frequent rehearsal is advisable for those initially lacking competency until skill acquisition is achieved.[78]

Participation

Threat-free Participation

To avoid intimidating authority gradients, a member of the training group can provide feedback to the rest of the team, using specific checklists.[75] Learners often perceive that they have performed very badly, so it is vital that positive actions are emphasized. The lack of formal assessment removes the threat of testing, may promote team ethos, and can enable both 100% staff participation and improved outcomes.[50] Furthermore, it has been shown that informal verbal feedback is as good as feedback based on video recording[85] in improving performance in simulation.

Mandatory Attendance of the Entire Workforce

Units that have reported improvements in perinatal outcomes all achieved full participation in rehearsals.[20,49,50] Poor performers might be less inclined to attend such rehearsals, or more likely to drop out, but they are also the ones likely to show important improvements in performance after training.[59] The solution is to both facilitate threat-free regular participation and, at the same time, mandate and confirm at least annual attendance via appraisal/supervisory schemes and central training databases.[38,50]

Follow-up on Training

Prospective Surveillance of Outcomes

Even with the best of intentions and the best of training, outcomes that improved once may deteriorate again.[39] Systems are needed to detect lapses and address them with targeted training. Monitoring the outcomes of training using routinely collected data and valid tools is a tested and proven solution. It is useful for maintaining the standards of training and supplementing with further safety and quality improvement interventions when necessary.[39,65]

Extension: Undergraduate Training

Postgraduate training can be modified and applied to undergraduate training: simulation with patient-actors, interprofessional learning experiences, practical exercises focusing on fidelity, fun, and evidence-based tools have been successful.[64,66]

Shared Learning

The development, testing, and successful implementation of training interventions are not adequate for quality improvement. Dissemination of the results and the lessons learned is an essential part of the improvement process, if poor outcomes are to be tackled worldwide. It is suggested that individuals and organizations in charge of training program publish explicit reports of their results in accordance with reporting guidelines, share their lessons via public databases (National Institute for Clinical Excellence—Shared Learning database,[68] Institute for Health Improvement—online improvement stories), and make tools freely available via websites.[86]

CONCLUSION

An independent review of maternity care in the United Kingdom stated: "The overwhelming majority of births are safe, but some births are less safe than they could, and should be. 'Safe Teams' are the key to improving the safety of maternity services and teams that work together should also train together, on their labor ward. Simulation-based training including clinical, communication and team skills should be made available for all maternity staff, ideally within their own units."[7]

Obstetric emergencies occur rapidly and unexpectedly and render uncomplicated labors high risk within seconds. Training may be the single most effective way to reduce the potentially avoidable poor outcomes for mothers and their babies. However, not all training is equal or effective. Up until recently, very few data have been available to guide training, but there are significant emerging studies that should inform us what works where. These data should be used to effect the improvements that mothers and their babies deserve.

Resuscitation and Immediate Care of the Newborn

STEPHEN P. WARDLE and NEIL MARLOW

INTRODUCTION

Few newborn babies need any assistance to establish normal respiration and circulation following birth, and of those who do, most require only simple measures. Delivery units base the need for a specialized team to be present at a delivery on preset criteria related to the type of delivery or the presumed condition of the newborn baby. Even with such a policy, unanticipated resuscitation is required in a significant number of deliveries.[1] For example, one study has shown that about 20% of babies who require resuscitation are not predictable from clinical observations made in pregnancy and during labor.[2]

This chapter aims to discuss the stabilization and resuscitation of the newborn in the delivery suite. It does not cover further care that the baby might need in a neonatal intensive care unit (NICU).

Importantly, prompt resuscitation of babies, even of those without apparent signs of life at birth, will result in a significant number of healthy survivors.[3] Hence, wherever babies are delivered, someone must be present who is trained and experienced to commence neonatal resuscitation, and there should be a method of providing expert backup for the complicated resuscitation.

It is important that all staff involved in resuscitation is trained in a systematic way to ensure uniformity of practice. In the United Kingdom, the Neonatal Life Support course (NLS, UK Resuscitation Council) has become the nationally accepted standard for training for staff involved in newborn resuscitation. Guidelines and courses exist in other countries such as the Neonatal Resuscitation Program (NRP) in the United States. Most are part of The International Liaison Committee on Resuscitation (ILCOR), a formal group that coordinates practice between national organizations and includes the production of consensus on neonatal life support. Their recommendations have recently been updated.[4]

All professionals attending delivery must understand the principles of neonatal resuscitation and be able to institute effective respiration with a suitable mask ventilation system or intubation.[5] Generally, the local pediatric or neonatal service provides the necessary expertise for the anticipated resuscitation problem, but other professionals who work in maternity services must be prepared and able to commence resuscitation when it has not been anticipated.

Each delivery unit must ensure that

- There is adequate provision of facilities.
- Staff is adequately trained for resuscitation.
- Staff is available when needed and prepared to institute neonatal resuscitation when required.

PREDICTING PROBLEMS

The need for resuscitation can be predicted before delivery in many cases. Most delivery units set criteria for attendance at delivery by their skilled team. It is important to define criteria appropriately, otherwise an excessive number of deliveries will require attendance. In one study, the attendance rate was decreased from 38.6% to 24.8%[6] by changing criteria following audit. During the same period, the number needing skilled resuscitation and the number of emergency calls did not change, but interestingly, the rate of intubation decreased significantly.

The following are suggested indications for attendance by a skilled and experienced team:

- Fetal compromise (as assessed by the obstetrician/midwife [e.g., pathologic cardiotocography {CTG} or fetal blood sample pH < 7.2]).
- Meconium-staining of the liquor.
- Urgent or emergency cesarean section.
- Elective cesarean section under general anesthesia or for placenta praevia, multiple births, or where admission to the neonatal unit is likely. A skilled resuscitator is not required for elective cesarean section under regional anesthesia.[7]
- Vaginal breech delivery.
- Multiple pregnancy.
- Rotational forceps (e.g., Keilland's forceps) delivery.
- Preterm delivery at less than 34 weeks' gestation.
- Severe fetal growth restriction.
- Maternal insulin-dependent diabetes.
- Maternal myasthenia gravis.
- Known serious fetal abnormality (e.g., diaphragmatic hernia, hydrops fetalis).
- Severe rhesus disease likely to require neonatal intensive care.

GENERAL CARE OF THE BABY AT BIRTH

Optimal Cord Clamping

Modern obstetric practice usually involves division of the cord while the placenta is still in utero. The time of occlusion of the umbilical cord determines the distribution of blood between the baby and the placenta. Optimal distribution has not been clearly defined, but for preterm babies in particular, even a short delay of 30 seconds in cord clamping may produce hemodynamic advantage and results in fewer blood transfusions and a reduced frequency of intraventricular hemorrhage.[8,9] The optimum distribution of blood volume and the least hemodynamic disturbance may be achieved by clamping the cord about 30 seconds after delivery, although some studies have used longer, by which time, the baby usually has taken his or her first breath.

Before division, the cord should be firmly occluded about 2 cm from the umbilicus using a suitable umbilical cord clamp.

Temperature Management

Keeping a newborn baby warm after birth is important to prevent morbidity and is considered a marker of good care.[10] Using warm towels to dry the baby and maintaining the room temperature at around 24°C minimize the heat stress experienced by the baby after birth. Skin-to-skin contact with the mother also helps to maintain temperature. Wrapping and dressing are alternative strategies. Bathing is best avoided immediately after birth because the associated evaporative water loss can reduce a baby's temperature.[11–13]

Attachment and Breast-feeding

When early assessment reveals no immediate problems, including prematurity or significant growth restriction, the baby should be handed at once to the mother. This may be done even before dividing the umbilical cord, but care should be taken to prevent heat loss and to optimize placental transfusion.[13] The baby may be wrapped in a warmed towel or, better, nursed skin-to-skin on the mother's chest, covered with a warm towel. If the mother intends to breast-feed, the baby should be put to the breast. This not only improves the success of lactation but also may aid delivery of the placenta by encouraging the release of endogenous oxytocin. Extra care to avoid cold stress must be taken when a baby is preterm or growth-restricted.

Even when a baby is unwell and needs admission to the NICU, it is important that the mother is given the opportunity to see and, if possible, hold her newborn baby.

Routine Examination

A routine examination of the newborn is recommended as a core component of child health surveillance[14] and can be performed at any stage in the first 72 hours after birth. It does not need to be carried out immediately after birth. However, a routine external examination for major abnormalities is usually carried out by the birth attendant to rule out major congenital anomalies. Early examination facilitates early discharge but may be associated with more false-positive examinations.

Vitamin K

Vitamin K is given as prophylaxis against hemorrhagic disease of the newborn.[15] It can be given as an oral or intramuscular dose, although intramuscular administration gives better vitamin K levels[16] and should be given shortly after birth because bleeding from hemorrhagic disease can present within the first 6 hours after birth.

PHYSIOLOGY

The process of birth, even in a healthy term newborn baby, is associated with relative hypoxia, but newborn babies are able to withstand this surprisingly well. The term "newborn" will demonstrate a particular pattern of physiologic changes during hypoxia,[17–20] and understanding of these processes helps the attendant decide when to initiate resuscitation, assess the baby's responses, and judge the effectiveness of the interventions given.

Acute total hypoxia in animals at delivery results after a few minutes in primary apnea. This is associated with initial tachycardia and a rise in blood pressure, followed by bradycardia. Redistribution of blood flow occurs to essential organs (brain and heart) at the expense of others (skin, gut, and kidneys). If hypoxia persists, deep slow gasping occurs every 10 to 20 seconds before a further final period of apnea occurs, called "terminal apnea." During this phase, hypotension, progressive bradycardia, and decreased cardiac output result in organ damage and death unless active resuscitation is commenced.

A similar sequence of changes seems to occur in the human newborn. During resuscitation, it is not always possible to recognize where in this sequence of events the child is, and it may be difficult to differentiate primary from terminal apnea. A baby in primary apnea will be blue and have a low heart rate, low tone, and apnea, but the appearances are similar in a baby in terminal apnea (Table 80–1). However, a baby in primary apnea will recover quickly following lung inflation (brought about either by the resuscitator or by the onset of gasping respiration) whereas a baby in terminal apnea is unlikely to recover as quickly, even with lung inflation, and will almost always require a longer period of resuscitation before gasping and subsequently normal respiration resumes. A baby in poor condition, therefore, should be assumed to be in terminal apnea, and resuscitation should be initiated without delay.

Lactic Acidosis

Following a period of hypoxia, a baby's tissues quickly switch to anaerobic respiration. This is reflected in the accumulation of lactic acid and, because the baby is not breathing, also carbon dioxide. Therefore, during birth, and particularly during prolonged hypoxia-ischemia, babies become significantly acidotic. Typically, this is associated with redistribution of blood flow away from the skin, and the baby appears pale or white. It is important to note that this does not necessarily indicate hypovolemia or the need for volume replacement unless there is clear evidence of fetal blood loss. Giving excessive volume to an asphyxiated baby could be deleterious in view of cardiac hypoxia.[21]

TABLE 80–1

Physiological Responses to Hypoxia in the Newborn

STAGE	DESCRIPTION	ACIDOSIS	ASSESSMENT				RESPONSE TO RESUSCITATION
			HEART RATE	TONE	BREATHING	COLOR	
1. Initial response	High HR, rise in BP then fall in HR.	No	High/normal	Normal	Breathing	Blue	Increased HR. Normal breathing.
2. Primary apnea	Initial period of apnea. Redistribution of blood flow.	Mild	Low	Low	Apnea	Blue	Increased HR. Normal breathing.
3. Gasping	Deep gasping respiration.	Moderate	Low	Low	Gasping	Blue	Increased HR. Normal breathing quickly takes over.
4. Terminal apnea	Apnea, redistribution of blood flow. Heart rate and BP fall.	Severe	Low/absent	Low	Apnea	Blue/ pale	Increased HR. Gasping then normal breathing.

BP, blood pressure; HR, heart rate.

In addition, although the degree of acidosis may be severe, the administration of alkalinizing agents to correct this is generally not useful. An exception is possibly when the heart rate remains low despite adequate lung expansion and cardiac massage.[22] The level of lactic acidosis may be a useful indicator of the severity of the hypoxic insult. Administration of alkali during resuscitation remains controversial; sodium bicarbonate is a negative inotrope and correction of extracellular acidosis may worsen intracellular pH. However, one unevaluated justification may be the vasodilation of coronary arteries and improvement of adrenaline delivery to the myocardium seen in animal experiments. It is not necessary to correct acidosis fully.

Meconium

The normal breathing efforts of a baby in utero are not sufficient to inhale particulate meconium in significant quantities. Lung aspiration of meconium probably occurs secondary to a hypoxic ischemic insult in a baby who has already passed meconium, during gasping that may commence before or after birth. Subsequent hypoxia and persistent pulmonary hypertension may not be related to the presence of meconium in the lung but to the preceding hypoxia-ischemia. Therefore, the severity of the hypoxic-ischemic insult that has caused the gasping is likely to be as, if not more, important than the meconium itself. As long as meconium is not obstructing the airway, it may be relatively harmless, which is possibly why laryngeal toileting has been shown to have little positive effect.[23]

The Use of Air or Oxygen during Resuscitation

Traditionally, babies have been resuscitated in 100% oxygen. However, there are strong theoretical reasons to believe that this may be harmful, particularly in preterm babies. Following resuscitation with 100% oxygen, there is biochemical evidence of an increase in the generation of oxygen free radicals, which can be harmful to the brain and lungs.[24] In preterm babies, there is additional evidence of significant alterations in cerebral blood flow persisting for some time.[25] Several randomized studies have compared resuscitation with air or oxygen, and these have been subjected to systematic review and meta-analysis.[26] Overall, there was a reduction in mortality in babies resuscitated with room air and no evidence of harm. However, because the number of studies was small and there were some methodologic limitations, the results should be interpreted with caution.

Using air for resuscitation, therefore, appears to be at least as good as using 100% oxygen, but oxygen should also always be available via a mixer system on the resuscitation apparatus for those situations in which it is required.

PREPARATION AND EQUIPMENT

Whenever possible, any individual who expects to initiate neonatal resuscitation should always introduce themselves to the parents and explain what is happening or likely to happen. She or he should obtain as full a history as possible from the mother, midwife, or obstetrician and examine the mother's records to establish

- Gestational age.
- Drugs given to the mother.
- Evidence of fetal distress (e.g., heart rate abnormality, acidosis, meconium).
- Presence of vaginal bleeding.
- Prolonged rupture of membranes.
- Maternal health in labor.[27]
- Number of fetuses.[28]
- Relevant obstetric or medical history.

In addition, the person leading the resuscitation should make sure that appropriate team members are present and check and prepare the necessary equipment. Anyone leading the resuscitation should

- Consider whether they require help and call for it if so.
- Ensure the delivery room is warm (>24°C) and free of drafts.
- Check that equipment is available and in working order.
- Turn on the overhead heater.

- Ensure that warmed towels are available.
- Wash hands, put on gloves, or take other precautions against blood-borne viruses as per hospital policy.

ASSESSMENT OF CONDITION AT BIRTH

Apgar Score

Condition at birth is traditionally assessed using the Apgar score, which was designed as a guide for the need for resuscitation. Measures may be made at 1 and 5 minutes, with further recordings at 5-minute intervals if resuscitation continues. Ideally, the Apgar score should be assessed and recorded at the time of resuscitation (originally this was done by a second observer) because retrospective assignation is fraught with errors. The Apgar score is a poor prognostic guide for later outcome, except that low Apgar scores that persist beyond 15 to 20 minutes are more strongly associated with neurologic deficits.[29] In practice, careful assessment and descriptions of heart rate and respiration, color, and tone are much more meaningful in assessing the physiologic condition of a baby.

Cord Blood Acid-Base

For babies born after fetal distress or for those needing resuscitation, the cord blood pH, base excess, or lactate concentration may indicate the severity of perinatal asphyxia. Blood from both the umbilical artery and vein should be sampled. Some babies have experienced significant intrapartum asphyxia but present with a normal pH. As is true with the Apgar score, extremes of acidosis are most strongly associated with poor outcome. Cord blood acid-base status cannot be used to determine the need for resuscitation but is useful as one of the factors to look at in determining the etiology of a poor condition at birth or a neonatal encephalopathy. Routinely checking cord acid-base balance after delivery can, therefore, be useful and is essential when babies have needed resuscitation.

STABILIZATION AND RESUSCITATION FOLLOWING DELIVERY AT OR NEAR TERM

The following approach is based on the standardized approach taught on the U.K. Resuscitation Council NLS Course (Fig. 80–1)[30]:

- First, the clock should be started.
- The baby should be transferred to the resuscitaire; whatever the condition of the child, prevention of heat loss is a critical priority; the baby should be dried, wet towels removed, and wrapped in a warm towel.
- The condition of the baby should be assessed
  - Color: Assessed by looking at the baby's lips and not peripheries.
  - Tone: Assessed while drying the baby.
  - Breathing: Not breathing, normal respiration, or gasping.
  - Heart rate: Best assessed by auscultation; alternatives are palpation of the umbilical cord or apex beat.
- Following assessment, resuscitation and management should proceed in the following order:

TABLE 80–2

Possible Scenarios during Initial Resuscitation

Scenario 1: A baby who is breathing/crying, heart rate ≥ 100, centrally pink.	The infant should be dried and given to mother. Ideally, these babies should be delivered directly onto their mother's abdomen and dried with a towel. Temperature is then maintained by direct skin-to-skin contact.
Scenario 2: A baby who is blue, apneic, heart rate ≥ 100 with reasonable tone (i.e., not completely floppy).	Because the heart rate is good, this baby will recover. Breathing usually starts spontaneously within a minute of delivery, but healthy babies can take up to 3 min to start breathing after birth.[31] If apnea continues, it will be necessary to open the airway and give inflation breaths.
Scenario 3: A baby who is blue/pale, apneic, heart rate < 60.	Babies with a low heart rate who are not breathing could be in primary or terminal apnea. These infants will, therefore, need further resuscitation, although most will respond to simple measures.

- Airway: The airway must be clear and open in order to allow the lungs to inflate.
- Breathing: Either the baby must be able to breath and inflate its own lungs or this must be achieved by the resuscitator.
- Circulation: The baby's circulation may be compromised and require support.
- Drugs: These are occasionally necessary to facilitate an adequate circulation.

Potential scenarios are set out in Table 80–2.

Further Action if the Baby Is Blue/Pale, Apneic with a Heart Rate less than 60

- The airway should be opened (head in neutral position, jaw thrust) (Figs. 80–2 and 80–3) and the mask placed appropriately (Fig. 80–4).
- Five inflation breaths should be given by mask (30 cm H_2O, 2- to 3-sec inflation time).
- Inflation breaths should be long higher-pressure breaths to remove lung fluid.[32] Until the lungs are inflated, they are filled with fluid and the baby will not improve.
- With each inflation breath, the resuscitator must ensure that the chest moves. If it does not, it will be necessary to reposition the airway (head in neutral position, jaw thrust). If the chest still does not move, then in addition, the following should be considered:
  - Two person jaw thrust, or
  - Insertion of a Guedel airway, or
  - Longer inflation time or increased pressure, or
  - Suction under direct vision: airway obstruction is almost always due to decreased pharyngeal tone, not obstruction.
- If the chest moves well with inflation breaths after five breaths, the baby should be reassessed. If the heart rate is responding, the resuscitator should continue ventilation breaths (0.5-sec inflation time, 40 breaths/min) until the baby is breathing spontaneously. The time at which this

NEWBORN LIFE SUPPORT

Dry the baby, remove any wet cloth and cover

Initial assessment at birth
Start the clock or note the time
Assess: COLOR, TONE, BREATHING, HEART RATE

If not breathing...

Control the airway
Head in the neutral position

Support the breathing
If not breathing – FIVE INFLATION BREATHS (each 2–3 seconds duration)
Confirm a response – increase in HEART RATE or visible CHEST MOVEMENT

If there is no response
Double check head position and apply JAW THRUST
5 inflation breaths
Confirm a response – increase in HEART RATE or visible CHEST MOVEMENT

If there is <u>still</u> no response
a) Use a second person (if available) to help with airway control and repeat inflation breaths
b) Inspect the oropharynx under direct vision (is suction needed?) and repeat inflation breaths
c) Insert an oropharyngeal (Guedel) airway and repeat inflation breaths
Consider intubation
Confirm a response – increase in HEART RATE or visible CHEST MOVEMENT

When the chest is moving
Continue the ventilation breaths if no spontaneous breathing

Check the heart rate
If the heart rate is not detectable <u>or</u> slow (less than around 60 bpm) and NOT increasing

Start chest compressions
First confirm chest movement – if chest not moving <u>return to airway</u>
3 chest compressions to 1 breath for 30 seconds

Reassess heart rate
If improving – stop chest compressions, continue ventilation if not breathing
If heart rate still slow, continue ventilation and chest compressions
Consider venous access and drugs at this stage

FIGURE 80–1
Resuscitation algorithm.
(From Richmond S [ed]: Newborn Life Support, 2nd ed.
London, Resuscitation Council (UK), 2004, p 69.)

AT <u>ALL</u> STAGES, ASK... DO YOU NEED HELP?

In the presence of meconium, remember: Screaming babies > have an open airway
Floppy babies   > have a look

occurs and whether the breaths are gasping or normal should be noted.
- If the heart rate does not respond
  - Ventilation breaths (0.5-second inflation time, 40 breaths/min) should be continued, ensuring that there is good chest movement. If there is not, it will be necessary to go back and recheck the airway as above. If the chest is moving, this ventilation can be continued.
  - The heart rate should be reassessed after 30 seconds to 1 minute.

- If the heart rate remains low **and** the chest is moving:
  - External cardiac compressions should be commenced.
  - The chest should be compressed at a ratio of 3 : 1 with ventilation breaths. If an individual experienced at intubation is present, it is worth intubating to stabilize the airway at this point. If an experienced individual is not present, T-piece/bag-mask ventilation should be continued.
- The most common reason for failure of the heart rate to improve is ineffective lung inflation. Adequacy of chest

movement should, therefore, always be checked before chest compressions are commenced.

- If the heart rate remains low (<60 beats/min) despite adequate chest inflation and external chest compressions, an umbilical vein catheter (UVC) should be inserted. In extreme cases in which attempts at inserting a UVC have failed, intraosseous access may be used.
  - At insertion of the UVC, a baseline blood gas and blood sugar should be obtained.

The techniques of airway opening, suction, mask and T-piece ventilation, bag-and-mask ventilation, intubation, external cardiac compressions, and UVC insertion are described later.

- Table 80–3 lists the drugs that can be given at this stage. There is no good evidence that helps to guide the order in which these drugs should be given. In general, most neonatologists probably choose to give adrenalin (epinephrine) in the first instance, followed by sodium bicarbonate and a second dose of adrenalin (epinephrine).
- After each drug dose is given, ventilation and external cardiac compressions should be recommenced and the heart rate reassessed each time. Once the heart rate responds (>60 beats/min), no more drugs are required and the cardiac compressions can be stopped.
- All drugs should be checked before they are administered and a record of drug administration kept.

A baby may fail to respond to resuscitation for a range of reasons, which are summarized in Table 80–4.
FIGURE 80–2

TABLE 80–3

Drugs Used for Neonatal Resuscitation

DRUG	DOSE	NOTES
Adrenaline	10 μg/kg (i.e., 0.1 mL/kg of 1:10,000 solution) IV followed by a 0.5–1.0 ml normal saline flush.	• If there is likely to be a delay in establishing IV access, then 20 μg/kg of adrenaline can be given via the ET tube if the baby is intubated.[33] Higher doses up to 100 μg/kg have also been suggested,[34] but the safety and efficacy of this have not been determined. This should be given rapidly down a catheter placed to lie just beyond the end of the ET tube and followed by a 0.5–1.0 mL normal saline flush and five rapid inflations. There is little evidence that the tracheal route is effective, and this route should be used only while IV access is being established. It must not be used in preference to IV access. If there is no response to initial doses, give further doses of adrenaline 10 μg/kg IV every 3–5 min if there is no response. An increased dose of 30 μg/kg IV can also be considered in this situation.
Sodium bicarbonate	4.2%–1 mmol/kg (i.e., 2 mL/kg) IV followed by 0.5–1.0 mL normal saline flush.	This dose of sodium bicarbonate is not intended to correct the metabolic acidosis but to increase the pH within the coronary arteries and hopefully increase the action of the subsequent adrenaline.
10% Glucose		During the process of prolonged resuscitation, hypoglycemia (i.e., whole blood glucose <2.6 mmol/L) may occur and this may interfere with adequate resuscitation. 10% Glucose 2.5 mL/kg IV can be given, followed by a 0.5–1.0 mL normal saline flush.
Calcium		No place for this in neonatal resuscitation
Atropine		No place for this in neonatal resuscitation

ET, endotracheal.

Discontinuation of Resuscitation

The decision to cease resuscitative efforts should be taken by a senior and experienced doctor. If there has been no response in heart rate or respiratory efforts by 20 minutes after birth, the outcome is universally poor and resuscitation should be terminated. Termination of treatment should occur, if possible, after discussion with the parents. In term babies, it is important this discussion begins with parents at around 15 minutes, enabling resuscitation to be stopped at 20 minutes. In extremely preterm babies, resuscitation can be stopped following nonresponse well before this time (see later).

Mothers Who Have Received Opiate Pain Relief

If with mask ventilation the baby becomes pink and has a good heart rate but does not breathe spontaneously and if mother has received opiate analgesia more frequently than every hours or within 2 to 4 hours predelivery, naloxone may be given. Bag-and-mask ventilation should not be stopped while naloxone is being administered. Naloxone should not be given to the baby of an opiate-dependent mother because it can cause acute withdrawal.

Meconium-stained Liquor

Meconium staining of the liquor does not necessarily require intervention. If the baby is crying or breathing with a normal heart rate, he or she can be treated as any other baby and unnecessary suction is not indicated.

In the presence of meconium, however, if the baby is not breathing and has a low heart rate, temperature control and assessment of the child should continue, but before giving inflation breaths, the airway should be visualized using a laryngoscope and sucked out under direct vision. If the individual is skilled at intubation, it is appropriate to pass an endotracheal tube and suck directly below the vocal cords, but if not, it is safer to simply suck out the oropharynx under direct vision. There is no place for bronchial lavage with saline because this is known to be harmful.[23] When the airway is clear of meconium, resuscitation should proceed as described previously.

RESUSCITATION OF A PRETERM BABY

The principles of the approach to resuscitation of the preterm baby are the same; however, some significant factors need to be considered that change the approach slightly:
- Optimal cord clamping is probably more important in very immature babies because hypotension may be avoided and respiratory outcomes may be improved; randomized trials are in progress to confirm this.
- Preterm babies lose heat more quickly and hypothermia has harmful effects[10] including an increased likelihood of lung disease due to surfactant deficiency; a different approach is therefore required.
- Preterm babies often do not need formal resuscitation, and excessive handling may worsen their condition; stabilization using gentle support and maintaining close attention to temperature and color should be first-line practice.
- When preterm delivery is anticipated, it is helpful for the parents to have met members of the neonatal team and to have visited the neonatal unit prior to delivery, assuming time allows. For more immature babies, this is critically important so that support can commence prenatally for the women through an emotionally difficult time.

Temperature Control

There is a strong association between a low temperature on admission and mortality rates in preterm babies.[9,37] As a result, alternative methods of maintaining the temperature

TABLE 80–4

Reasons for Failure to Respond to Resuscitation

1. During Mask Ventilation

a. Is the face mask of the correct size?
b. Is there a good seal?
c. Is the head position correct?
d. Do you need a second person to do the jaw thrust?

2. During ET Intubation with Poor or Absent Chest Wall Movement

a. *Is the ET tube in the esophagus?* Poor chest movement will be seen.
b. *Is the ET tube down the right main bronchus?* This should be considered if there is asymmetry of chest movement and breath sounds; inflation and breath sounds will improve as the tube is withdrawn.
c. *Is the inflation pressure adequate?* If the ET tube appears to be in the correct position (i.e., breath sounds present, symmetrical but poor chest wall movement), the most likely problem is that the baby is receiving insufficient pressure to open up the lungs, therefore:
   • Check peak inspiratory pressure on the manometer and increase to 30–40 cm H_2O.
   • Check oxygen flow rate—should be set to 5–8 L/min for mask ventilation, and 3–5 L/min for ET IPPV.
   • If these fail, another option is to increase the inspiratory time.
d. *Does the baby have lung pathology?* For example:
   • Pneumothorax (asymmetry of chest, movement or breath sounds)?
   • Diaphragmatic hernia (scaphoid abdomen or displaced apex beat displaced)?
   • Hypoplastic lungs (signs of Potter's syndrome)?
   • Pleural effusions?
   • Evolving severe lung disease (severe respiratory distress syndrome)?
   • Thoracic dystrophy?

3. During ET Intubation with Good Chest Movement

a. *Has there been fetal hemorrhage?* Suspect if mother has had large antepartum hemorrhage or abruption. Fetal blood loss is rare even with large antepartum bleeding.[35,36] If suspected, then normal saline should be given in a volume of 10 mL/kg, repeated as necessary (uncross-matched O-negative blood or blood cross-matched against mother can also be given cautiously to avoid metabolic problems associated with rapid transfusion such as hyperkalemia).
b. *Is there severe birth asphyxia?*
c. *Does the baby have severe cyanotic congenital heart disease?* Any baby who remains cyanosed following resuscitation needs to be urgently assessed and investigated.

ET, endotracheal; IPPV, intermittent positive-pressure ventilation.

TABLE 80–5

Precut Endotracheal Tube Length and Size for Use in Neonatal Resuscitation

WEIGHT (G)	CUT LENGTH OF ET TUBE (CM)*	LENGTH AT LIPS (CM)†	TUBE SIZE
500	6.5	6.0	2.5
1000	7.0	6.5	2.5
1500	7.5	7.0	2.5/3.0
2000	8.0	7.5	3.0
2500	8.5	8.0	3.0
3000	9.5	9.0	3.5
3500	10.5	10.0	3.5

* Cut ET tube to size indicated. Cut holder so that it is 1 cm long.
† Approximate length of ET tube at lips.

• ≤32 weeks: The baby should be placed directly into a plastic bag without drying,[38,39] ensuring that the head is covered with a hat; the bag should be applied closely to the skin around the neck to prevent water or heat loss.

Respiratory Management

There is debate about the best approach to supporting breathing for the very preterm baby at birth. There is evidence that giving surfactant is effective at reducing mortality and morbidity and that it is best given early ("prophylaxis") rather than after an baby develops established respiratory distress syndrome.[41] One approach is, therefore, to routinely intubate and ventilate in order to give the baby surfactant in the delivery suite prior to admission to the NICU. Because most babies above 29 weeks' gestation will not require intubation during their postnatal course, this approach is generally reserved for those babies born at less than 28 weeks' gestation.[42] Tables of endotracheal tube sizes for different gestational ages should be available on the delivery suite (Table 80–5). If a decision to intubate is made or if respiration is supported by a mask or T-piece system, the use of positive end-expiratory pressure (PEEP) may be of benefit in preterm babies.[43] This can be achieved very simply by using a PEEP valve on the T-piece system, which is one of the advantages of this system over a bag-valve-mask system.

More recently, however, it has been suggested that a less invasive approach may also be successful and avoid intubation and the problems engendered by positive-pressure ventilation. The use of continuous positive airway pressure (CPAP) in the delivery suite as a means of assisting the baby to establish a functional residual capacity has been advocated by some, and there is evolving evidence that this approach may be as successful.[44] This approach also requires a considerable degree of experience with the application and maintenance of CPAP and clinical expertise to manage safely and effectively.

The Extremely Low Gestational Age Baby

The care given for babies born at 25 weeks' gestation or less varies in different societies and health systems. The high

of preterm babies have been investigated. In particular, there is good evidence that the use of occlusive polythene wrapping or plastic bags into which small babies are placed at delivery without drying are effective at improving admission temperature, although there is currently no evidence that this improves survival rates.[38,39] Avoiding drying ensures that the baby is handled less and that 100% humidity is rapidly achievable within the bag, reducing evaporative water and heat loss.

Other methods that have been investigated include the use of chemical gel–heated mattresses, but there is no evidence that the combination of these with the use of polythene wrapping further improves admission temperature.[40]

Current recommendations are
• >32 weeks: The baby should be dried, wet towels removed, and the baby wrapped in a warm towel.

prevalence of mortality and morbidity among survivors is the subject of public and professional debate. The ethical issues associated with this care have been widely debated and many national organizations have developed guidelines, including in the United Kingdom.[45] Key to the provision of appropriate care is the involvement of parents in decision-making and the use of a consistent approach within perinatal teams. Agreed survival and morbidity figures, which reflect population and local practice-based outcomes, should be presented to parents by the team who are responsible for care, neonatologist, obstetrician, and midwife, and within each hospital, guidance as to how this should be approached should be agreed to avoid individual bias. The parents' feelings and responses to that information should be fully appreciated and taken into consideration.

Following extremely premature delivery, the decision to initiate resuscitation must be made carefully in line with this pre-agreed approach. At the delivery, an experienced doctor should be present. Following birth, the baby should be carefully assessed in regard to size, gestational characteristics including fusion of the eyelids, bruising (which anecdotally is a critical determinant of outcome), and heart rate, tone, and breathing movements.

Babies who are considered previable by all these criteria are usually 23 weeks' gestation or less. It must be emphasized that the gestational age is often not precisely known, and all the factors listed previously must be taken into account.

Usually, the previable baby will be white, flaccid, and not making any breathing movements. In this case, the parents, who will have been over all the facts with the neonatologist, will usually want to hold the baby. If they do not wish to do this, the neonatal team can discuss with the midwifery team the most appropriate place to care for the baby. This may be on the labor suite or the neonatal unit.

If the baby is clearly making efforts to establish respiration, this should be supported with endotracheal positive-pressure ventilation. Respiratory support in a viable baby will always result in establishment of a good heart rate. If an inexperienced individual is called unexpectedly to such a delivery and if in any doubt about the viability of the baby, resuscitation is initiated until the arrival of an experienced neonatologist.

Higher-Order Births

The risk of prematurity is very high in this group, and the simultaneous delivery of several immature babies can severely stretch neonatal resources. Close cooperation between obstetrics and neonatology is necessary to ensure that sufficient resources are available for neonatal intensive care at the time of delivery.

At delivery, one resuscitaire and one trained member of the neonatal staff should be available for each baby and supported by an assistant who may be a midwife or a neonatal nurse.

PRINCIPLES OF RESUSCITATION TECHNIQUES

These are summarized in Tables 80–6 and 80–7.

DOCUMENTATION

It is essential for reasons of good clinical care, communication, and clinical governance that the findings at each assessment and the actions taken in resuscitation are fully and accurately documented. In order to do this, it is essential that accurate timings are recorded and that a clock has been started at the commencement of resuscitation. Each event and intervention should be recorded, and the easiest way of ensuring that this occurs accurately is if one individual has the responsibility of recording events, drug doses, and timings. An alternative is the use of a standard resuscitation record. Such a standardized form offers the further advantage of uniform data collection to facilitate study and comparison of resuscitation techniques and outcomes.

Following resuscitation, it is essential that each individual involved records events in which they participated in the case notes, remembering to accurately record the date and time at which they occurred as well as when they were documented.

PARENTS

Prior to the delivery of a baby, members of the team should introduce themselves to the parents of the child and explain what is going to happen, if this is possible. Communication with the parents should continue during resuscitation if it is prolonged; however, it is not always possible for those leading the resuscitation to communicate events directly to the parents, so someone, usually a midwife or neonatal nurse, should explain what is happening.

Immediately after resuscitation, it is essential that the most senior member of the team talks to the parents to explain the events and what has happened. They should explain the implications in terms of prognosis for the baby and what further treatment or interventions will be necessary.

DEBRIEFING

Following resuscitation, at a convenient time, it is extremely useful for the most senior member of the team to gather the resuscitation team together away from the clinical area to discuss events. This helps to identify positive aspects of the resuscitation and any areas of difficulty or particular problems. If there are any particular problems with equipment or systems in place for resuscitation, these should be identified and flagged for attention. Documentation of the events can be reviewed to identify any areas of weakness.

TRANSPORT OF BABIES TO THE NEONATAL INTENSIVE CARE UNIT

How this is best achieved depends on the geography of the delivery unit and NICU and their proximity to each other. Where units are very close, a resuscitaire can be used to move a baby to the NICU. If there is some distance or when units are on different floors of the same building, a transport incubator should always be used.

Before moving a baby from the delivery suite, it should always be ensured that

---

TABLE 80–6

Principles of Resuscitation Techniques

Airway-Opening Techniques

These are important—Mask inflation has no hope of success unless the airway is opened.

a. These should be performed before starting to breathe for the baby. The head should be placed gently into a neutral position (see Fig. 80–2).
b. If the baby is floppy, it may be necessary to use one or two fingers under each side of the lower jaw at its angle to push the jaw forward and outward (jaw thrust) (see Fig. 80–3).
c. A folded towel placed under the neck and shoulders may help to maintain the neutral position.
d. Consider using a Guedel airway.
e. Look, listen, and feel for respiratory effort. If baby is making good respiratory effort but the chest is not moving, consider suction of the nasopharynx under direct vision.
f. Consider suction (see below).

Suction

a. Use a laryngoscope to look into the airway.
b. Use a 10-fg (black) suction catheter or a baby Yankauer sucker or, where there is meconium, use a laryngoscope to look into the airway.
c. The pressure should not exceed 100 mm Hg (13.3 KpA)
d. Beware inserting the catheter too far and producing reflex vagal bradycardia.

Important points:

- No longer than 30 sec should be spent in trying to intubate the infant before recommencing bag and mask or mask and T-piece IPPV, for a minimum of 1 min.
- Never attach the baby directly to either the wall oxygen supply or any supply of oxygen that is not connected to some type of pressure limit valve.

Bag and Mask/Mask and T-piece Ventilation

a. A mask that is big enough to cover the face, from the bridge of the nose to below the mouth, should be chosen (see Fig. 80–4). A good seal must be obtained around the infant's face.
b. When using a mask and T-piece, the oxygen flow rate should be set at 5–8 L/min. The first five inflation breaths should be given at 30 cmH_2O and held for 2–3 sec to establish a functional residual capacity. Once the chest wall is moving, the inflation pressure may be reduced to 15–20 cmH_2O.
c. When using a bag and mask system, only use a 500-mL bag with a blow-off valve set at approximately 45 cm H_2O and an oxygen flow rate of 5 L/min. The oxygen flow rate should be increased as indicated up to a maximum of 10 L/min. The first five inflation breaths should be given slowly, compressing the bag with the fingers for 1–2 sec.
d. Following the first five breaths, ventilation should occur at a rate of 30–40 breaths/min.
e. The chest wall should be observed for equal movement. If there is poor inflation, the airway should be checked to ensure it is not obstructed. The head should be repositioned, making sure that it is not overextended, and other airway maneuvers should be considered (e.g., two-person jaw thrust, Guedel airway). If necessary, suction under direct vision should be carried out.

During prolonged mask ventilation, a nasogastric tube should be passed to deflate the stomach. When a mask and T-piece or a bag, valve, and mask system attached to a reservoir bag is used, the baby will receive the full concentration of oxygen delivered to the circuit.

Chest or External Cardiac Compressions

Chest compressions should be started if the heart rate < 60 beats/min but only if there has been adequate lung inflation. During chest compressions, the relaxation phase is very important because this is the period during which blood can flow into the heart. The inspiratory breath should start only after the compression.

There are two techniques:

- The chest is encircled with both hands so that the fingers lie behind the baby and the thumbs are opposed over the sternum (Fig. 80–5A), or:
- Two fingers are used over the sternum (see Fig. 80–5B).

The thumbs or fingers should be positioned 1 cm below the internipple line. They should be compressed to a depth of 1.5–2 cm at a rate of 120 beats/min and a ratio of three compressions to one ventilation. The quality of the compressions is vital, and the rate and ratio are less important. External cardiac compressions should continue until the heart rate > 60 beats/min and increasing.

In the infant receiving IPPV whose heart rate continues to fall, the most likely cause is inadequate ventilation.

IPPV, intermittent positive-pressure ventilation.

- The parents have had the opportunity to see the baby and had an explanation of why the baby needs to be admitted to the NICU.
- The baby has a stable airway and is breathing satisfactorily. For babies needing respiratory support, this will generally mean that the baby will require intubation but transfer using CPAP may also be possible.

A baby should never be moved while the airway is being managed with a mask.

SOME OTHER NEONATAL PROBLEMS AFFECTING RESUSCITATION

Several neonatal problems require special mention because the approach to resuscitation may be different, particularly when the diagnosis is made prenatally.

Congenital Diaphragmatic Hernia (See also Chapter 19)

In babies in whom a diagnosis of congenital diaphragmatic hernia is made prenatally, the approach to resuscitation needs to be adapted. Bag-and-mask ventilation is contraindicated because this will inflate the stomach and bowel and potentially cause more mediastinal shift and lung compression. Because of this, the approach to resuscitation should include the following:

- Ensuring an experienced team is available for resuscitation.
- Intubating the baby immediately with no mask ventilation.
- Inserting a large-bore nasopgastric tube to decompress the stomach and bowel.

TABLE 80–7
Procedure for Umbilical Venous Catheterization

Equipment

Alcohol swabs
Umbilical tape
Scalpel
5-mL syringe containing 0.9% saline
Size 5 or 6 UVC
Three-way tap

Procedure

Attach the syringe and three-way tap to the catheter.
Flush the catheter with saline.
Loosely tie the umbilical tape around the cord.
Clean the cord with the alcohol swab.
Cut the cord to a length of 1–3 cm.
Identify the umbilical vein and insert catheter. Advance to approximately
    5–6 cm. Confirm that blood can be easily aspirated.
If the UVC fails to advance, apply traction to the cord.
Tighten umbilical tape to secure the catheter.

UVC, umbilical vein catheter.

- Considering early muscle relaxation to prevent breathing and swallowing of air.

Airway Problems

In situations in which potential fetal airway problems are identified, special consideration should be given to how this is managed and to ensuring that individuals with the skills to manage complex airways are available at the delivery. Examples include Pierre Robin sequence, cystic hygroma, or cervical teratoma.

Pierre Robin sequence can usually be managed using airway positioning and/or a nasopharyngeal airway. Intubation in these babies can sometimes be impossible, so this can be a serious problem if they deliver prematurely. In these circumstances, careful use of a nasopharyngeal airway can often be helpful.

Occasionally, airway obstruction may be so severe that there is no prospect of establishing normal respiration without a surgical airway. In these circumstances, the "Exit" procedure has been described[46] in which babies have a surgical airway created after delivery of the head and neck but before clamping the umbilical cord. This technique should be carried out only where specific ear, nose, and throat and airway expertise exist and can be used only when the problem has been identified prenatally.

Fetal Hydrops (See also Chapter 24)

Babies with fetal hydrops may present particular difficulties during resuscitation that require immediate intervention. In particular, large pleural effusions may need to be drained before the chest can be expanded. This can be achieved using needle aspiration, but there may be associated lung hypoplasia that makes resuscitation difficult. In babies in whom hydrops associated with large pleural effusions are suspected, an experienced resuscitator should be present and equipment for emergency aspiration of the chest should be available.

Normal Values

MARGARET RAMSAY

Normal Values

INTRODUCTION

What Is a "Normal" Value?

"Normal" has different meanings. In the context of physical or laboratory measurements, "normal" may mean "average," "disease-free," or "within a given statistical range." However, it is important to know the characteristics of the population yielding "normal" values before deciding whether these values provide an appropriate reference range with which to compare an individual test result. Many laboratories now print reference ranges on their reports and highlight test values that fall outside these values as "abnormal." When the test subject is a pregnant woman, a fetus, or a newborn, and the reference population is composed predominantly of middle-aged men, then comparisons are patently inappropriate. It is important to understand how the physiologic changes of pregnancy affect the results of various tests and measurements before deciding whether an out-of-range result is actually abnormal.

Changes in Pregnancy

Pregnancy results in profound changes in maternal physiology and metabolism, orchestrated by hormonal changes. Thus, physical and laboratory measurements may be very different in the pregnant state compared with the non-pregnant state and may change as pregnancy advances. Similarly, physical, biochemical, hormonal, and hematologic measurements of the fetus change markedly as the fetus increases in size and maturity. Thanks to ultrasound techniques, the fetus, once hidden within the uterus, is now accessible. Fetal structures can be measured, fetal behavior observed, and blood velocity measured with Doppler ultrasound, and a sampling needle can be used to access blood, liquor, urine, and placental and other tissues.

Statistical Terms

The terms used to define normal values depend on the distribution characteristics of data points. The entire range of values encountered in a healthy population may be quoted as reference points, or distribution may be described by terms that express central tendency and scatter. When data are distributed symmetrically around a central value (i.e., normal distribution), mean, standard deviation (SD), and standard error of the mean (SEM) are the appropriate statistics. From these, ranking values, or percentiles, may be calculated (e.g., 5th and 95th percentiles, which encompass the central 90% of data points, with 5% on either side of them). When the data distribution is skewed, median and percentiles should be used. When the data distribution is exponential, median and multiples of the median (MoM) can be used rather than percentiles. Specialized texts provide a more detailed critical appraisal of the statistical analyses used in these studies (Altman, 1991).

Study Methods Used to Derive Normal Values during Pregnancy

Two basic designs are used for studies addressing changes in physical or laboratory values during pregnancy.

1. **Longitudinal studies** follow a group of women sequentially through pregnancy and compare measurements of a particular parameter with those obtained well before or at an interval after the pregnancy. Because these studies are very labor-intensive and require committed research subjects, they usually do not involve large numbers of subjects. They are very effective at showing changes with time, either between the nonpregnant and the pregnant states or with advancing gestation. The variability of the data is small because the same subjects are studied sequentially. These studies are very helpful in showing how pregnancy affects measurement of a particular parameter. This benefit has particular relevance when prepregnancy values are known and the effect of pregnancy must be differentiated from disease-related changes over time. A limitation of longitudinal studies is that a narrow range of "normal" values is defined from a small number of subjects. This narrow range may not correspond to the wider range of values found in a larger group of healthy subjects studied on a single occasion.

2. **Cross-sectional studies** involve large numbers of subjects, each contributing one data point to the study. If the number of study subjects is large enough, then the findings provide a good idea of the true scatter of data points. These studies allow accurate characterization of mean values, SDs, and percentiles. For pregnancy studies, subjects must be evenly distributed throughout gestation and values must not be extrapolated beyond the gestational range actually included. These studies are essential when the ranking of a particular measurement must be determined (e.g., fetal ultrasonic measurement of abdominal circumference for a known gestational age). Most studies of fetal ultrasonic measurements and Doppler waveform indices are of this design, and their statistical methods have been described in detail (Altman and Chitty, 1994).

Opportunistic studies are also used. For example, fetal blood sampling may be done to identify infection or karyotype in a fetus unaffected by the condition. The portion of the blood sample that is not used for specific tests can be used to measure other substances. Much information available about fetal hematologic, biochemical, and endocrine function has been collected in this way. There are obvious ethical concerns about planning studies in normal fetuses requiring invasive sampling because of the risks of fetal injury and loss. However, the selection of fetuses for study after exclusion of a particular problem means that they are not truly normal or representative of the entire fetal population. Opportunistic studies do not cover the entire range of gestational ages. Nevertheless, they provide information that would not be known otherwise.

The pregnancy studies in the literature are of mixed quality in terms of numbers of subjects included, selection criteria for subjects, sampling and laboratory techniques, and statistical interpretation. The best studies found are reported here. The methods used for each study included are described briefly and presented alongside the results. Comment sections provide interpretation of the data or a discussion of the robustness of the statistical methods, and references to the original papers are given for readers who wish to explore in greater detail. Few studies address the possible effect of maternal age, gravidity, or ethnic differences on the parameters under study. Data on many

normal ranges are deficient or limited and are occasionally unreliable.

Use of Normal Ranges in Pregnancy

Some disease states are diagnosed from characteristic symptoms or signs, but others have agreed biochemical definitions. For example, diabetes mellitus is diagnosed with references to fasting blood glucose measurements and those after a known glucose challenge (see Fig. 25). These values represent the upper limits of the normal ranges found in studies of healthy subjects. Differences in blood glucose values in pregnancy led to the suggestion that diagnostic criteria for diabetes should be adjusted in pregnancy.

Disease or organ dysfunction does not always occur at a given value of a physical or laboratory measurement outside its derived normal range. Elevated liver enzyme levels indicative of liver cell dysfunction may be 2, 10, or 50 times the normal values. However, even minimal deviation of pH from its closely clustered normal values may be biologically important.

Another use of normal values is to calculate odds ratios. Assessment of the risk or likelihood of genetic abnormalities (e.g., Down syndrome) is possible from measurement of serum α-fetoprotein, chorionic gonadotropin, or placental protein A (see Figs. 45–47). Measured values of these hormones are compared with expected values at known gestational age (derived from healthy pregnancies). The degree of difference is expressed in terms of multiples of the median values. Absolute values cannot be used for mathematical calculations because these hormonal concentrations change with gestation. For each hormone, multiple regression analysis has shown the relationships between deviations in values and the risk of Down syndrome. Thus, a woman's age-related risk of aneuploidy may be adjusted after measurement of serum hormones (Wald et al, 1996).

Units of Measurement

When possible, both SI (Système International d'Unités) and traditional units are given for ease of interpretation. It is important to check the units of measurement carefully when comparing a physical or laboratory value with a normal range. In SI units, grams (g) and liters (L) are used, whereas traditional units commonly use milligrams (mg) and deciliters (dL). To avoid errors of interpretation, the prefixes d-, m-, μ-, and n-, signifying 10^{-1}, 10^{-3}, 10^{-6}, and 10^{-9} must be observed and used with care.

The terminology milliequivalents (mEq) has not been used because it has been superseded by millimoles (mmol). For monovalent ions (Na^+, K^+, Cl^-), 1 mmol = 1 mEq. For divalent ions (Mg^{2+}, Ca^{2+}, PO_4^{2+}, SO_4^{2-}), 1 mmol = 2 mEq.

WEIGHT GAIN
FIGURE 1
Longitudinal study of maternal weight gain (mean ± SD) in 988 normal women who had uneventful pregnancies. All of the study subjects underwent initial evaluation at less than 20 weeks' gestation and were delivered between 37 and 41 weeks. *Data source*: ref. 1, with permission.

Weight-for-height category	Recommended total weight gain	
	kg	lb
Low (BMI <19.8)	12.5–18	28–40
Normal (BMI 19.8–26.0)	11.5–16	25–35
High (BMI 26.0–29.0)	7–11.5	15–25
Obese (BMI >29.0)	7	15
BMI = weight/height^2		

FIGURE 2
Recommended ranges for total weight gain during pregnancy for women with a singleton gestation, classified by prepregnancy body mass index (BMI). *Data source*: ref. 2, with permission.

Comment: Average total weight gain during pregnancy is approximately 10 kg. Low weight gain during pregnancy in nonobese women has been associated with delivery of small–for–gestational age (SGA) infants.[3] Overweight and obese mothers have increased complications including gestational diabetes, hypertension, large–for–gestational age infants, and difficult deliveries.[4] More women are entering pregnancy with high BMI, and there is evidence that they gain excessive weight during pregnancy and retain it after delivery.[4,5]

NUTRITIONAL REQUIREMENTS

Nutritional requirements		
Nutrient (unit)	Pregnant	Lactating
Energy (kcal)	+300	+500
Protein (g)	60	65
Fat-soluable vitamins		
Vitamin A (μg retinol equivalents)	800	1300
Vitamin D (μg as cholecalciferol)	10	10
Vitamin E (mg α-tocopherol equivalents)	10	12
Vitamin K (μg)	65	65
Water-soluble vitamins		
Vitamin C (mg)	70	95
Thiamin (mg)	1.5	1.6
Riboflavin (mg)	1.6	1.8
Niacin (mg niacin equivalent)	17	20
Vitamin B$_6$ (mg)	2.2	2.1
Folate (μg)	400	280
Vitamin B$_{12}$ (μg)	2.2	2.6
Minerals		
Calcium (mg)	1200	1200
Phosphorous (mg)	1200	1200
Magnesium (mg)	300	355

Selenium (μg)	65	75

FIGURE 3
Recommended daily dietary allowance and energy intake for pregnant and lactating women. These should be used as a guide to nutritional requirements when formulating a balanced diet. *Data source*: ref. 6, with permission.

Comment: The increased requirements for vitamins and minerals during pregnancy can usually be met through the diet. Therefore, routine supplementation with multivitamin preparations is not necessary. However, periconceptual supplementation with folic acid for all women is now advocated in an attempt to reduce the incidence of neural tube defects. Vitamin supplementation should be considered in women with inadequate standard diets, heavy smokers, those who abuse drugs or alcohol, and those with multiple pregnancies. Excessive intake (i.e., more than twice the recommended daily allowance) of fat- or water-soluble vitamins may have toxic effects.

Cardiovascular Function
BLOOD PRESSURE
FIGURE 4

Blood pressure measurements (mean + SD) from a longitudinal study of 226 primigravidae whose first attendance at the antenatal clinic was before 20 weeks' gestation. Their mean age was 24.3 years (SD 4.9). Blood pressure measurements were taken with the London School of Hygiene sphygmomanometer to avoid terminal digit preference and observer bias. Diastolic pressures were recorded at the point of muffling (phase 4). *Data source*: ref. 7, with permission.

Comment: Systolic pressure changes little during pregnancy, but diastolic pressure decreases markedly toward midpregnancy, then rises to near nonpregnant levels by term. Thus, widening of pulse pressure occurs for most of pregnancy.

PULSE RATE
FIGURE 5

Pulse rate (median and interquartile ranges) from a longitudinal study of 20 healthy women recruited in early pregnancy and studied every 2 weeks thereafter. "Nonpregnant" measurements were made 8 to 12 months after delivery. All women finished the study, but not all participated in every visit. *Data source*: ref. 8, with permission.

Comment: The typical increase in heart rate during pregnancy is approximately 15 beats/min, beginning as early as 4 weeks after the last menstrual period.[9]

CARDIAC OUTPUT
FIGURE 6

Cardiac output (median and interquartile ranges) from a longitudinal study of 20 healthy women recruited in early pregnancy and studied every 2 weeks thereafter. "Nonpregnant" measurements were made 8 to 12 months after delivery. All women finished the study, but not all participated in every visit. Cardiac output was measured by an indirect Fick method. *Data source*: ref. 8, with permission.

Comment: Cardiac output increases significantly during the first trimester and remains elevated until the puerperium. When changes in body weight are considered, it is apparent that cardiac output reaches maximal values at 12 to 15 weeks' gestation and then declines gradually toward term.

INVASIVE MONITORING

Invasive monitoring		
	Non-pregnant	Pregnant
Cardiac output (L/min)	4.3 ± 0.9	6.2 ± 1.0
Heart rate (beats/min)	71 ± 10	83 ± 10
Systemic vascular resistance (dyne/sec/cm^5)	1530 ± 520	1210 ± 266
Pulmonary vascular resistance (dyne/sec/cm^5)	119 ± 47	78 ± 22
Colloid oncotic pressure (mm Hg)	20.8 ± 1.0	18.0 ± 1.5
Colloid oncotic pressure—pulmonary capillary wedge pressure (mm Hg)	14.5 ± 2.5	10.5 ± 2.7
Mean arterial pressure (mm Hg)	86.4 ± 7.5	90.3 ± 5.8
Pulmonary capillary wedge pressure (mm Hg)	6.3 ± 2.1	7.5 ± 1.8
Central venous pressure (mm Hg)	3.7 ± 2.6	3.6 ± 2.5
Left ventricular stroke work index (g/min/m^2)	41 ± 8	48 ± 6

FIGURE 7
Findings of a study involving 10 healthy, primigravid women with a singleton pregnancy who were examined at 36 to 38 weeks' gestation and again 11 to 13 weeks postpartum. All women were younger than 26 years old. They did not smoke and were not anemic. Fetal anatomy and growth and amniotic fluid volume were normal. A pulmonary artery catheter was placed through the subclavian vein, and baseline hemodynamic assessment was made in the left lateral position after 30 minutes' rest. Cardiac output was measured with a thermodilution technique. For each subject, the result represented the mean of five independent measurements, with the highest and lowest values excluded. Central pressures were measured over three consecutive respiratory cycles. Results quoted are mean ± SD. *Data source*: ref. 10, with permission.

Comment: Systemic vascular resistance is 21% lower and pulmonary resistance is 34% lower in the late third trimester than in the nonpregnant state. Both colloid oncotic pressure and the colloid oncotic–pulmonary capillary wedge pressure gradient are lower (by 14% and 28%, respectively). Mean arterial pressure, central venous pressure, pulmonary capillary wedge pressure, and left ventricular stroke work index show no significant changes in the third trimester. These results indicate that the systemic and pulmonary vascular beds accommodate higher vascular volumes at normal pressures during pregnancy. The ventricles are dilated, and cardiac contractility does not change significantly. Because the colloid oncotic pressure–pulmonary capillary wedge pressure gradient is reduced in pregnancy, an increase in cardiac preload or an alteration in pulmonary capillary permeability predisposes the patient to pulmonary edema.

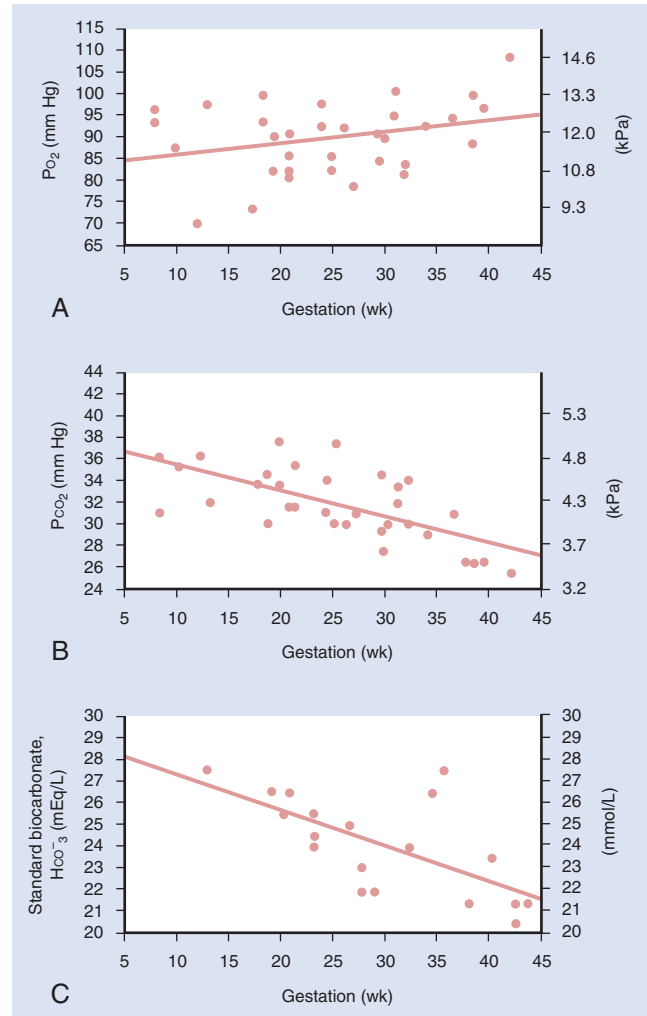
Pulmonary Function and Respiration
ARTERIAL BLOOD GASES


FIGURE 8
Arterial blood gas pressures: Oxygen (Po_2) (*A*), carbon dioxide (Pco_2) (*B*), and standard bicarbonate (*C*) (individual values, with regression lines shown) from a cross-sectional study of 37 women at 8 to 42 weeks' gestation. Blood sampling was done from a cannula inserted into the brachial artery under local anesthesia, after 30 minutes' rest in a quiet, darkened room. *Data source*: ref. 11, with permission of Elsevier Science NL, Amsterdam, The Netherlands.

Comment: Arterial pH was constant (7.47) during pregnancy in this study. Pco_2 and standard bicarbonate levels showed a significant decrease with advancing gestation, but Po_2 levels did not change significantly.

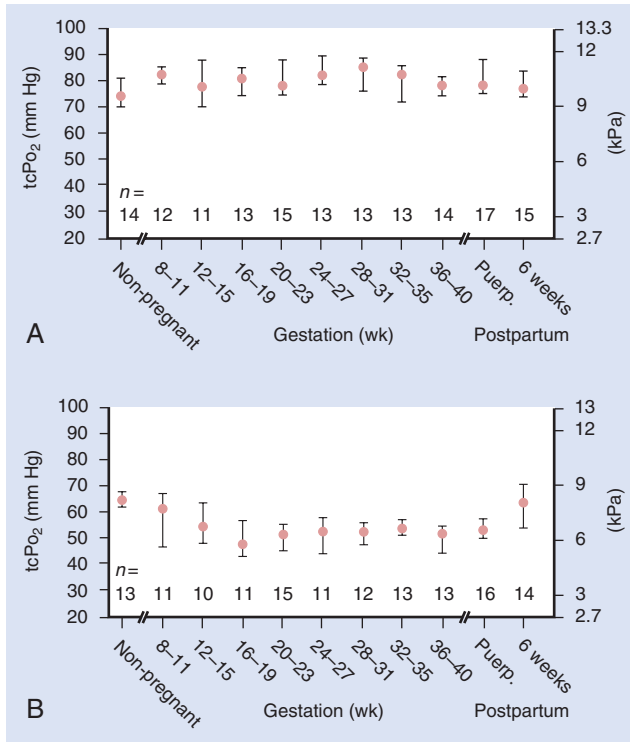
TRANSCUTANEOUS GASES


FIGURE 9
Transcutaneous oxygen (tcPo$_2$) (*A*) and carbon dioxide (tcPco$_2$) (*B*) pressures (median and interquartile ranges) from a longitudinal study of 20 healthy women recruited in early pregnancy and studied every 2 weeks thereafter. Nonpregnant measurements were made 8 to 12 months after delivery. All women finished the study, but not all participated in every visit. *Data source*: ref. 8, with permission.

Comment: tcPCO$_2$ is higher than arterial PCO$_2$ as a result of temperature differences between the skin surface and the blood as well as the addition of CO$_2$ by skin metabolism (conversion factor ~1.4).[8] tcPO$_2$ values in adults are 10% to 20% lower than arterial PO$_2$ values. In this study, the increase in tcPO$_2$ and the decrease in tcPCO$_2$ during pregnancy were significant.

RESPIRATION RATE
FIGURE 10
Respiration rate (median and interquartile ranges) from a longitudinal study of 20 healthy women recruited in early pregnancy and studied every 2 weeks thereafter. Nonpregnant measurements were made 8 to 12 months after delivery. All women finished the study, but not all participated in every visit. *Data source*: ref. 8, with permission.

Comment: The respiration rate is similar in pregnant and nonpregnant women.

TIDAL VOLUME
FIGURE 11
Tidal volume (median and interquartile ranges) from a longitudinal study of 20 healthy women recruited in early pregnancy and studied every 2 weeks thereafter. Nonpregnant measurements were made 8 to 12 months after delivery. All women finished the study, but not all participated in every visit. *Data source*: ref. 8, with permission.

Comment: Tidal volume increases early in pregnancy and continues to rise until term. Overall, a 30% to 40% rise occurs. By 6 to 8 weeks postpartum, tidal volumes return to nonpregnant values. Minute ventilation increases in parallel with tidal volume; typical values are 7.5 L/min in nonpregnant women and 10.5 L/min in late pregnancy.[12]

RESPIRATORY FUNCTION TESTS

Respiratory function tests			
	During pregnancy		After delivery
	10 weeks	24 weeks	36 weeks	10 weeks postpartum
Vital capacity (L)	3.8	3.9	4.1	3.8
Inspiratory capacity (L)	2.6	2.7	2.9	2.5
Expiratory reserve volume (L)	1.2	1.2	1.2	1.3
Residual volume (L)	1.2	1.1	1.0	1.2

FIGURE 12

Respiratory volumes (mean values) from a longitudinal study of eight healthy women 18 to 29 years old who were studied through pregnancy and again at 10 weeks postpartum. All tests were done with the patient in the sitting position. *Data source*: ref. 12, with permission.

Comment: In some women, vital capacity increases by 100 to 200 mL during pregnancy, but the converse is seen in obese women.[1] Anatomic changes (flaring of the lower ribs, a rise in the diaphragm, and an increase in the transverse diameter of the chest) are responsible for alterations in lung volume subdivisions.[13] Forced expiratory volume in 1 second (FEV_1) and peak expiratory flow rate (PEFR) are unaffected by normal pregnancy.[12] The gas transfer factor (i.e., pulmonary diffusing capacity with CO_2) decreases in pregnancy.[12] This decrease has been attributed to altered mucopolysaccharides in the alveolar capillary walls as well as lower circulating levels of hemoglobin.

Chromosomal Abnormalities

Maternal age at delivery (years)	Risk of Down's syndrome

46	55.9			9.1	77.0
47	70.4			11.9	96.0

FIGURE 14

Chromosomal abnormalities by maternal age at the time of amniocentesis performed at 16 weeks' gestation (expressed as rate per 1000). *Data source*: ref. 15, with permission.

Comment: The incidence of chromosomal disorders increases with maternal age but is not affected by paternal age.[15] The prevalence of aneuploidy is higher at earlier gestations. Trisomy 21 (Down syndrome) is the most important numerically of these disorders, with an overall population incidence of 1 in 650 live births. Trisomies 13, 18, and 22 are rare in live births (see Chapter 4, Figure 4–7). Other autosomal trisomies are nonviable and are common in spontaneous abortions.

Biochemistry
Hepatic Function
TOTAL SERUM PROTEIN AND ALBUMIN
FIGURE 15

Total serum protein and albumin (mean + SD) from a longitudinal study of 83 healthy pregnant women (77 of whom were primigravidae) who were recruited at 12 weeks' gestation. Samples were collected every 4 weeks during pregnancy, 7 days postpartum, and again at 6 and 26 weeks postpartum. *Data source*: ref. 16, with permission.

> **Comment:** Decreased total serum protein and albumin concentrations in pregnancy are associated with a decrease in colloid osmotic pressure.[16] Serum immuno-globulin levels change in pregnancy; there is slight decrease in immunoglobulin A (IgA), decreased IgG especially in the third trimester, and increased IgM, especially prior to delivery.[17]

LIVER ENZYMES, SERUM BILE ACIDS, BILIRUBIN, AMYLASE, COPPER, AND ZINC
FIGURE 16

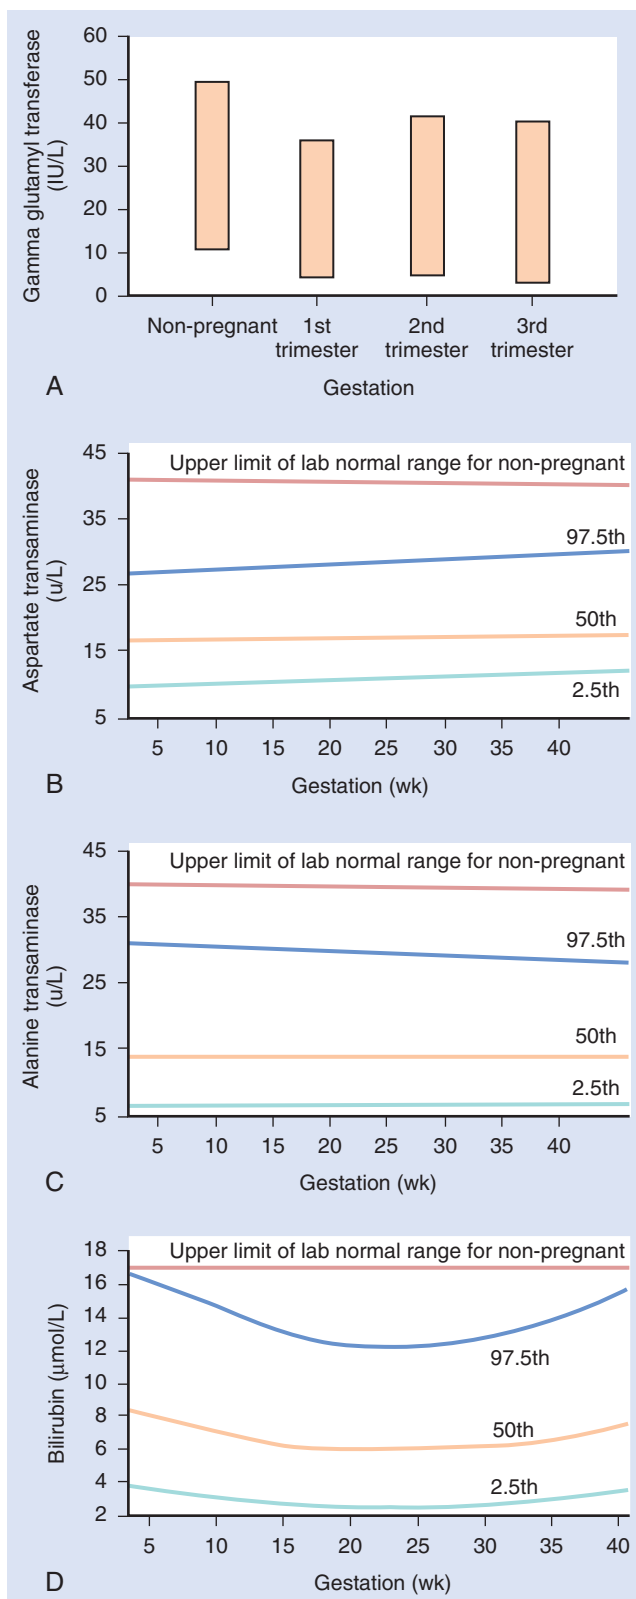
Total alkaline phosphatase levels (mean and SEM) from a cross-sectional study of 108 women attending a hospital antenatal clinic in Nigeria. The nonpregnant control subjects of similar age were patients attending the gynecologic clinic. No patients were clinically anemic, and all were normotensive. *Data source*: ref. 18, with permission.


FIGURE 17

Serum γ-glutamyl transferase (GGT) (*A*), aspartate transaminase (AST) (*B*), alanine transaminase (ALT) (*C*), and bilirubin (*D*) (95% reference ranges) from a cross-sectional study of 430 women with uncomplicated singleton pregnancies. No subjects had hypertension or liver disease, were taking drugs associated with liver dysfunction, or were consuming more than 10 units of alcohol weekly. Data for GGT were not normally distributed, and the results presented are calculated from the nonparametric determination of percentiles. Data for AST, ALT, and bilirubin were normally distributed after logarithmic transformation, allowing gestation-specific percentiles to be calculated. *Data source*: ref. 19, with permission.

Normal Values
FIGURE 18

Serum cholic acid (CA) (*A*), deoxycholic acid (DCA) (*B*), and chenodeoxycholic acid (CDCA) (*C*) (mean + SD) from a longitudinal study of 30 healthy pregnant women. The subjects had uncomplicated pregnancies and no history of hepatobiliary disease. Blood samples were taken after an overnight fast. Most women were recruited at 12 to 17 weeks' gestation and gave blood samples at 18 to 22 weeks, every 2 weeks in the third trimester, and on three occasions up to 35 to 60 days after delivery. Bile acids were measured separately by radioimmunoassay, and the results presented are for total concentrations (i.e., free plus conjugated bile acid). *Data source*: ref. 20, with permission.

Comment: Other recent longitudinal studies of liver function tests[21] confirm that alkaline phosphatase (AP) levels are more than doubled by late pregnancy. Almost half of the total plasma AP in pregnancy is placental AP isoenzyme, but bone AP isoenzyme levels are also markedly increased. Liver AP isoenzyme levels do not change significantly in pregnancy.[18] Serum GGT and transaminase levels overall are lower in pregnancy than in the nonpregnant adult population. There are no significant gestational changes in GGT, AST, or ALT, but all increase after delivery, especially after cesarean section.[22] During pregnancy, bilirubin levels remain within the normal range for adults.[23] Serum concentrations of the primary bile acid, CA, and the secondary bile acid, deoxycholic acid (DCA), do not change during pregnancy, but CDCA levels increase significantly toward term.[20] These minor changes in serum bile acid levels may be caused by changes in bile acid metabolism and excretion as a result of high circulating levels of estrogen and progesterone, but may show a tendency to cholestasis in normal pregnancy. Serum amylase levels remain within normal adult reference ranges during pregnancy.[21] Serum copper levels are increased in pregnancy, but zinc levels are decreased compared with those in nonpregnant women.[24] There are considerable differences between laboratories with regard to liver enzyme assays and resultant variability in "normal ranges" in adults. These differences should be borne in mind when interpreting individual results from pregnant women.

LIPIDS: CHOLESTEROL AND TRIGLYCERIDE
FIGURE 19
Plasma cholesterol and triglyceride levels (mean and SEM) from a longitudinal study of 43 women 20 to 41 years old. Samples were taken after an overnight fast and 10 minutes' supine rest at 4- to 6-week intervals through pregnancy, during labor, and in the puerperium. Samples were also taken 12 months after delivery in 14 of the subjects. The nonpregnant reference samples were obtained from 15 subjects of comparable age. No dietary restrictions were imposed. *Data source*: ref. 25, with permission. *Conversion factors*: cholesterol, mmol/L × 38.5 = mg/dL; triglyceride, mmol/L × 88 = mg/dL.

Comment: During pregnancy, plasma cholesterol doubles and a threefold increase in plasma triglyceride concentration occurs. The lipid content of low-density lipoproteins increases in pregnancy, as does the high-density lipoprotein triglyceride content.[25] Levels of both apolipoproteins A1 and B increase in parallel during pregnancy.[21] Serum lipid levels decrease rapidly after delivery, but cholesterol and triglyceride concentrations remain elevated 6 to 7 weeks postpartum. Lactation does not affect lipid levels.[25]

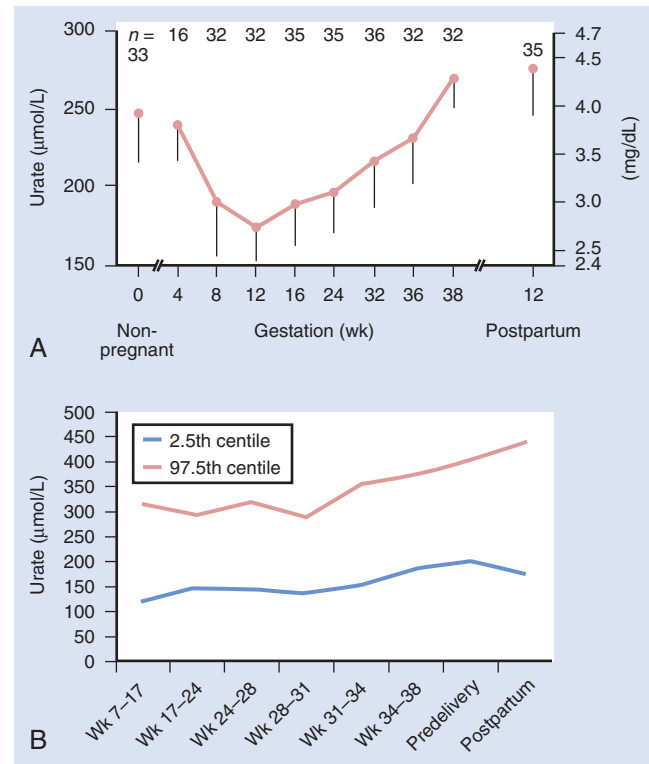
Renal Function
SERUM URATE


FIGURE 20
A, Serum urate levels (mean + SD) from a longitudinal study of 31 healthy women 23 to 37 years old, five of whom were studied during two pregnancies. Subjects were studied preconceptually, at least 3 months after discontinuing oral contraceptives (if used), in the luteal phase of their menstrual cycle, monthly during pregnancy, and again at 12 weeks postpartum. All samples were taken between 9:00 AM and 9:30 AM, after overnight fasting. *Data source*: ref. 24, with permission. *B*, Plasma urate (2.5th–97.5th calculated percentile reference interval) from a longitudinal study of 52 healthy women in Sweden sampled at intervals during pregnancy. At least 40 samples were obtained for each time point; predelivery samples were taken 14 to 0 days before delivery and the postpartum samples 45 to 202 days after delivery. The nonpregnant reference range for plasma urate in this population is 154 to 350 μmol/L. *Data source*: ref. 21, with permission.

Comment: Serum urate levels decrease during the first trimester, as a result of altered renal handling (increased glomerular filtration rate [GFR] and/or reduced proximal tubular resaborption) of uric acid.[26] During late pregnancy, the serum urate level increases to levels higher than nonpregnant values.[21] Levels may remain elevated for 12 weeks after delivery.[26]

SERUM OSMOLALITY
FIGURE 21
Serum osmolality (mean + SD) from a longitudinal study of 83 healthy pregnant women (77 of whom were primigravidae), recruited at 12 weeks' gestation. Samples were collected every 4 weeks during pregnancy, 7 days postpartum, and then 6 and 26 weeks postpartum. *Data source*: ref. 16, with permission.

Comment: Total osmolality decreases by the end of the first trimester to a nadir 8 to 10 mmol/kg below nonpregnant values.

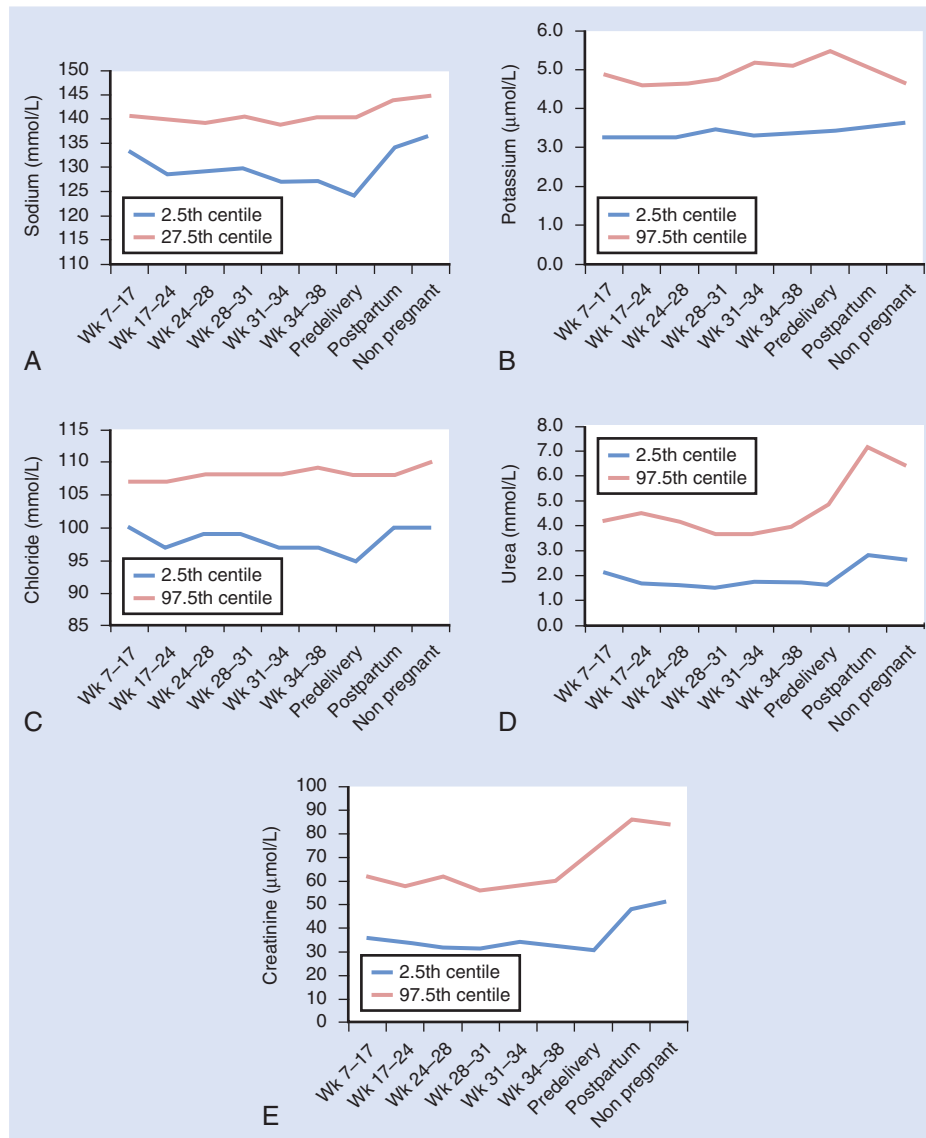
PLASMA ELECTROLYTES, UREA, AND CREATININE


FIGURE 22
Plasma electrolytes (*A–C*), urea (*D*), and creatinine (*E*) (2.5th–97.5th calculated percentile reference interval) from a longitudinal study of 52 healthy women in Sweden sampled at intervals during pregnancy. At least 40 samples were obtained for each time point; predelivery samples were taken 14 to 0 days before delivery and the postpartum samples 45 to 202 days after delivery. The nonpregnant reference ranges are for healthy, fertile women in Scandinavia. *Data source*: ref. 21, with permission. *Conversion factor for urea*: mmol/L × 2.8 = mg/dL.

Comment: Concentrations of the major electrolytes (sodium, potassium, chloride) are almost unchanged during pregnancy. Bicarbonate and phosphate concentrations decrease during pregnancy.[27] Plasma urea and creatinine decrease during pregnancy. Plasma creatinine levels increase from their midpregnancy nadir in the weeks prior to delivery (see also Fig. 23C).[28]

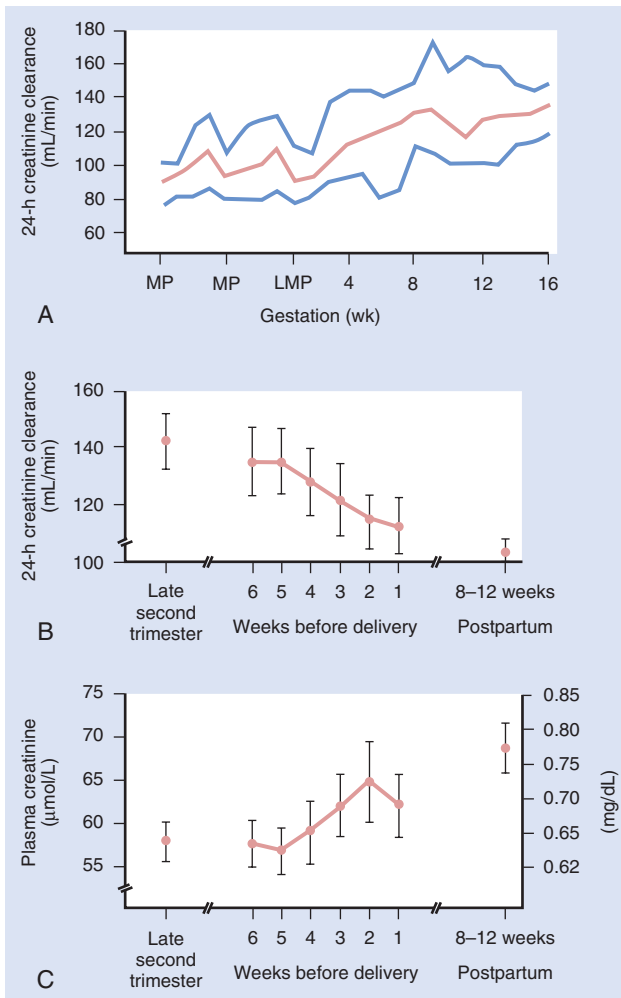
CREATININE CLEARANCE AND PLASMA CREATININE


FIGURE 23
A, Creatinine clearance (mean and range) in early pregnancy from a longitudinal study of nine healthy women who were recruited before pregnancy. Measurements of 24-hour creatinine clearance were made weekly, through the different phases of the menstrual cycle, and up to 16 weeks' gestation. No diet, fluid, or exercise restrictions were imposed. *Data source*: ref. 29, with permission. Creatinine clearance (*B*) and plasma creatinine (*C*) (mean ± SEM) in the second and third trimesters from a longitudinal study of 10 healthy pregnant women. Creatinine clearance was measured once between 25 and 28 weeks' gestation, weekly from 32 weeks until delivery, and once between 8 and 12 weeks postpartum. *Data source*: ref. 30, with permission.

Comment: The GFR and effective renal plasma flow increase in early pregnancy to levels approximately 50% above nonpregnant values. In the third trimester, the GFR decreases by approximately 15%.[30] The 24-hour creatinine clearance measurements mirror these changes. During the menstrual cycle, a 20% mean increase in creatinine clearance occurs between the week of menstruation and the late luteal phase.[29]

URINE COMPOSITION: GLUCOSE, AMINO ACIDS, AND PROTEIN

Comment: Glycosuria is common in pregnant women whose plasma glucose concentrations and glucose tolerance test results are normal. It is believed to arise because of increased glomerular filtration plus decreased tubular resorption of glucose.[31] Aminoaciduria is also reported during pregnancy.[32] Urinary total protein and albumin excretion is significantly increased after 20 weeks' gestation; accepted upper limits of normal are 300 mg/24 hr and 20 mg/24 hr, respectively.[33] Protein-to-creatinine ratio measurements on spot urine samples are increasingly being used in clinical practice, rather than 24-hour total protein collections, as there is close correlation.[34] A threshold value of 30 mg protein/mmol creatinine predicts 300 mg/24 hr[-1] or greater proteinuria.[33]

Carbohydrate Metabolism
FASTING PLASMA GLUCOSE
FIGURE 24
Longitudinal study of plasma glucose levels (mean + SD) after an overnight fast of at least 10 hours in 19 healthy women. The subjects were not obese and had no family history of diabetes mellitus. *Data source*: ref. 35, with permission.

Comment: Other studies confirmed these findings that fasting plasma glucose levels decrease in pregnancy. In most women, the decline occurs by the end of the first trimester.[36] Thereafter, most studies show further decreases in the second and third trimesters.[36] Severely obese women (BMI > 30.0 kg/m^2) studied throughout pregnancy did not show these changes, but had progressively increasing plasma glucose levels.[36] Plasma insulin levels increase in the third trimester.[35,37] Ethnic differences are seen in insulin production (as measured by C-peptide concentrations) and insulin resistance (as indicated by insulin-to-glucose ratios) during pregnancy.[37]

Normal Values

GLUCOSE TOLERANCE TEST

☐ 2nd trimester (14–20 weeks)
☐ 3rd trimester (28–37 weeks)

A   Hours after 75 g glucose load

☐ 1st trimester $n = 93$
☐ 2nd trimester $n = 121$
☐ 3rd trimester $n = 98$

B   Minutes after 100 g glucose load
FIGURE 25

A, Plasma glucose values (median, 2.5th, and 97.5th percentiles) after a 75-g oral glucose load. Cross-sectional study of 111 healthy women younger than 35 years old, weighing less than 85 kg, with singleton pregnancies ($n = 43$ and $n = 168$ in the second and third trimesters, respectively). None had a personal or family history of diabetes mellitus. *Data source*: ref. 38, with permission. *B*, Plasma glucose values (median, 5th, and 95th percentiles) after a 100-g oral glucose load. The study involved 93 women in the first trimester, 121 in the second trimester, and 98 in the third trimester. All were healthy, were not obese, had no family history of diabetes, and had no obstetric complications. *Data source*: ref. 39, with permission.

Comment: Women in the third trimester have decreased glucose tolerance, as judged by criteria used to diagnose diabetes outside pregnancy.[40] There are many different diagnostic criteria for the diagnosis of gestational diabetes. For a 2-hour 75-g oral glucose tolerance test (OGTT), significant findings (accepted by the World Health Organization) are fasting or 2-hour venous plasma glucose values of 7.0 or greater or 7.8 mmol/L or greater, respectively.[41] For the 100-g OGTT, gestational diabetes may be diagnosed when two or more of the following plasma glucose levels are found: ≥105 mg/dL (fasting), ≥181 mg/dL (1 hr), 165 mg/dL (2 hr), and ≥145 mg/dL (3 hr). These values equate to 5.8 mmol/L (fasting), 10.0 mmol/L (1 hr), 9.1 mmol/L (2 hr), and 8.1 mmol/L (3 hr).[41]

SERUM FRUCTOSAMINE AND GLYCOSYLATED HEMOGLOBIN
FIGURE 26

Serum fructosamine (median, 5th, and 95th percentiles) from a cross-sectional study of 1200 pregnant women at different gestational ages, compared with 1650 nonpregnant women 15 to 40 years old. Women with known diabetes or previous gestational diabetes were excluded from the study. *Data source*: ref. 42, with permission.

Comment: Serum fructosamine concentrations are significantly lower in the second and third trimesters than in the first trimester or the nonpregnant state. Decreasing total protein and albumin concentrations in pregnancy may contribute to this reduction.[42] In some studies, values for glycosylated hemoglobin (HbA_1 and HbA_{1c}) during pregnancy in healthy women were lower in the first and second trimesters,[36,43] but in other studies, they were similar to values in nonpregnant women.[44]

AMNIOTIC FLUID INSULIN, GLUCOSE, AND C-PEPTIDE

Amniotic fluid insulin, glucose, and C-peptide					
		Glucose (nmol/L)	Immunoreactive insulin (pmol/L)	C-peptide (pmol/L)	C-peptide/ insulin molar ratio
Early pregnancy	n = 77	3.44 ± 0.22	44.2 ± 2.1	38 ± 2.0	0.97 ± 0.06
Late pregnancy	n = 33	0.72 ± 0.11	45.5 ± 2.6	218 ± 54	4.3 ± 1.2

FIGURE 27
Insulin, glucose, and C-peptide levels in amniotic fluid (mean ± SD) from a cross-sectional study of 110 nondiabetic women who had amniocentesis in pregnancy (mostly for karyotyping). *Data source*: ref. 45, with permission.

Comment: Insulin and C-peptide levels in amniotic fluid can be studied as markers of fetal pancreatic β cell function. C-peptide and insulin are normally secreted in equimolar amounts from β cells. C-peptide may be the more reliable marker because insulin is degraded in the fetal liver and circulating insulin antibodies may be present.[45] In pregnant women with diabetes, concentrations of these substances are greater and third-trimester values are correlated with neonatal complications (macrosomia, hypoglycemia, jaundice, respiratory distress).[46] The mid-trimester insulin concentration in amniotic fluid is also greater in women who subsequently had gestational diabetes.[47]

Antioxidants

Comment: In pregnancy, levels of vitamin E (a free radical scavenger that opposes the effects of lipid peroxides) are increased compared with the nonpregnant state.[48] Vitamin E levels increase progressively with gestation, whereas lipid peroxide levels are constant.[48] Ascorbic acid concentrations in maternal serum during the third trimester and in breast milk during lactation are related to dietary consumption of fruit and vegetables.[49]

Normal Values

Hematology
White Blood Cell Count (Total and Differential)

A
	Week 33 (n = 151)	Week 36 (n = 146)	Week 39 (n = 130)	Postpartum (n = 91)	Non-pregnant range
Total white cell count (WBC) 10^9/L	9.1 (5.7–14)	8.9 (6.1–15)	9.0 (6.0–16)	16 (9.4–25)	(4.0–9.0)
Neutrophils 10^9/L	6.5 (3.5–11)	6.4 (4.1–11)	6.5 (3.7–13)	14 (6.6–23)	(1.8–6.7)
Lymphocytes 10^9/L	1.7 (0.9–2.8)	1.8 (1.1–2.8)	1.8 (1.1–2.9)	1.1 (0.5–2.4)	(0.8–4.0)
Monocytes 10^9/L	0.50 (0.2–1.0)	0.50 (0.3–1.0)	0.50 (0.28–0.90)	0.53 (0.3–1.2)	(0.10–0.90)

Basophils 10^9/L	0.0 (0.0–0.10)	0.03 (0.0–0.10)	0.04 (0.0–0.10)	0.08 (0.0–0.20)	(0.0–0.10)

B

FIGURE 28

A, Total white blood cell (WBC) count (mean + SD) from a longitudinal study of 24 women who were recruited at 12 weeks and were delivered after 37 weeks. Postpartum samples were taken 6 to 8 weeks after delivery. Nonpregnant samples were taken 4 to 6 months after delivery. Samples were analyzed in a Coulter counter. *Data source*: ref. 50, with permission. *B*, Total and differential WBC counts from a semilongitudinal study of 153 healthy pregnant women who were taking iron supplementation. All of the subjects had at least one previous normal pregnancy. Postpartum samples were taken 1 to 3 hours after delivery; samples taken from women who were eventually delivered by cesarean section were excluded from analysis. *Data source*: ref. 51, with permission.

Comment: Supplementation with iron and folate does not affect the total WBC count during or after pregnancy.[50] Other studies have confirmed the high total WBC during pregnancy, with typical reference ranges 6 to 16×10^9/L.[52] No studies reported total WBC values during labor, but in the early postpartum period, very high values ($\leq 25 \times 10^9$/L) may be normal.[51] Pregnancy-related changes in the total WBC count are still present 6 to 8 weeks after delivery.[50] Neutrophils contribute most to the overall higher WBC count; there are more circulating immature forms (myelocytes and metamyelocytes) and their cytoplasm shows toxic granulation.[53] Neutrophil count is relatively constant during pregnancy (3–10×10^9/L), markedly elevated in the hours after delivery ($\leq 23 \times 10^9$/L) and back to non-pregnant values by 4 weeks postpartum (1.5–6×10^9/L).[51,54] Lymphocyte count decreases during pregnancy through the first and second trimesters (typical range 1.1–2.8×10^9/L), increases during the third trimester, but remains low in the early puerperium compared with normal nonpregnant values (0.8–4.0×10^9/L).[54] Lymphocyte count is restored to the normal range by 4 weeks after delivery. Monocyte count is higher in pregnancy, with marked increase in the monocyte to lymphocyte ratio.[51,54] Eosinophil and basophil counts do not change significantly during pregnancy.[51]

Hemoglobin and Red Blood Cell Indices

Red cell indices	Gestation			
	18 weeks	32 weeks	39 weeks	8 weeks postpartum
Hemoglobin (Hb) g/dL	11.9 (10.6–13.3)	11.9 (10.4–13.5)	12.5 (10.9–14.2)	13.3 (11.9–14.8)
Red cell count × 10^{12}/L	3.93 (3.43–4.49)	3.86 (3.38–4.43)	4.05 (3.54–4.64)	4.44 (3.93–5.00)
Mean cell volume (MCV) fL	89 (83–96)	91 (85–97)	91 (84–98)	88 (82–94)
Mean cell hemoglobin (MCH) pg	30 (27–33)	30 (28–33)	30 (28–33)	30 (27–32)
Mean cell hemoglobin concentration (MCHC) g/dL	34 (33–36)	34 (33–36)	34 (33–36)	34 (33–36)
Hematocrit	0.35 (0.31–0.39)	0.35 (0.31–0.40)	0.37 (0.32–0.42)	0.39 (0.35–0.44)

FIGURE 29
Hemoglobin and red cell indices (mean and calculated 2.5th–97.5th percentile reference ranges) from a longitudinal study of 434 healthy Danish women. All delivered normally at term and their infants weighed more than 2.5 kg. All the women had iron supplements (20–80 mg ferrous iron/day) from recruitment to the study until 8 weeks postpartum. Samples were obtained at 18, 32, and 39 weeks' gestation and at 8 weeks postdelivery. *Data source*: ref. 52, with permission.

Comment: Hemoglobin concentration decreases in the first trimester, regardless of whether iron and folate supplements are given.[50] Hemoglobin values of 10.5 g/dL or less suggest anemia in healthy pregnant Caucasian women.[52] Studies done in other ethnic populations find similar ranges for hematologic indices.[55] Pregnancy-induced hematologic changes are still present 6 to 8 weeks postpartum, when compared with values obtained 4 to 6 months postpartum.[50]

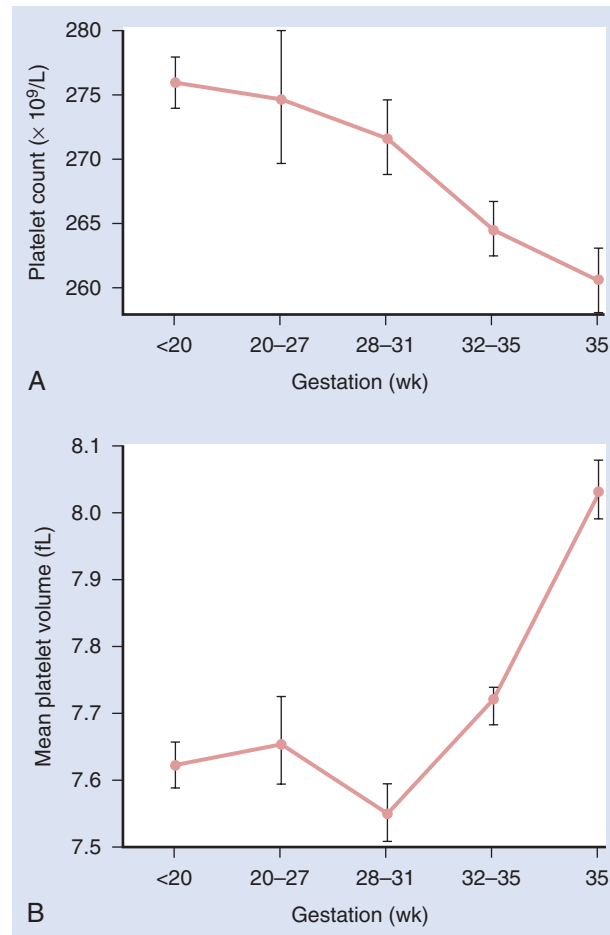
Platelet Count and Indices


FIGURE 30
Platelet count (*A*) and mean platelet volume (*B*) (mean ± SEM) during pregnancy. The study was largely cross-sectional in design (2881 samples from 2114 women). Samples were analyzed in a Coulter counter. At the end of the study, patients who had hypertension were excluded. *Data source*: ref. 56, with permission.

Comment: Hyperdestruction of platelets may occur in pregnancy, with a consequent decrease in platelet life span. Young platelets are larger than old platelets. In a large study of 6770 women in late pregnancy, mean platelet counts were 213 $\times 10^9$/L and the 2.5th percentile value was 116 $\times 10^9$/L.[57] Another, but longitudinal, study with much smaller numbers (*n* = 44) did not find evidence of a significant change in platelet count with gestational age.[58] Platelet closure times (the time required for whole blood to occlude a membrane impregnated with either epinephrine or adenosine 5′diphosphate) are not affected by absolute platelet count in healthy women during pregnancy.[59]

Iron Metabolism

Iron metabolism					
Patients	Hb (g/dL)	Serum iron		Transferrin/ TIBC saturation (%)	Serum ferritin (µg/L)

D

E

FIGURE 31
Mean hemoglobin (Hb) and iron indices (*A*), mean ferritin from a longitudinal study of women recruited in the first trimester (*B*). At the start of the study, 72 were randomized to the no-treatment group, but any whose Hb fell below 11 g/dL were prescribed ferrous sulfate 60 mg three times daily. Only 30 progressed through pregnancy without iron supplements. In all of the subjects studied, serum ferritin levels rose rapidly postpartum, reaching values similar to those found in early pregnancy by 5 to 8 weeks after delivery. No iron supplements were given after delivery. *Data source*: ref. 60, with permission. Plasma iron (*C*), ferritin (*D*), and transferrin (*E*) (2.5th–97.5th calculated percentile reference interval) from a longitudinal study of 52 healthy women in Sweden sampled at intervals during pregnancy, some of whom were taking iron and folic acid supplements. At least 40 samples were obtained for each time point; predelivery samples were taken 14 to 0 days before delivery and the postpartum samples 45 to 202 days after delivery. The nonpregnant reference ranges are for healthy, fertile women in the same laboratory. *Data source*: ref. 21, with permission.

Comment: Iron stores, as indicated by the serum ferritin level, are depleted during pregnancy, regardless of whether iron supplements are given.

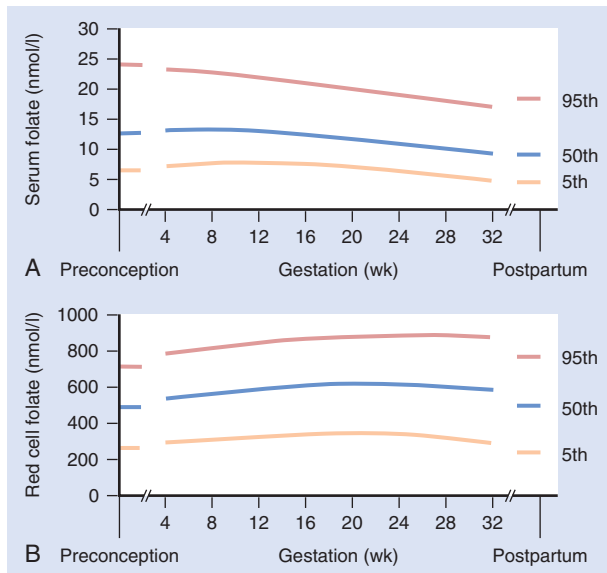
Serum and Red Cell Folate


FIGURE 32
Longitudinal study of serum (*A*) and red cell folate levels (*B*) (5th, 50th, and 95th percentiles) in healthy nulliparous women during an uneventful singleton pregnancy. None of the study subjects took iron or vitamin supplements (*n* = 102). Nonfasting blood samples were taken within 3 months of conception, at 6, 10, 20, and 32 weeks' gestation, and again at 6 weeks postpartum. All women had spontaneous labor at term and had infants of normal size. *Data source*: ref. 61, with permission. *Conversion factor for folate*: nmol/L × 0.044 = μg/dL.

Comment: In other studies, red cell folate levels showed a slight downward trend with advancing gestation,[62] and patients with low red cell folate levels at the beginning of pregnancy had megaloblastic anemia in the third trimester.[63] These differences may relate to dietary folate intake. In a cross-sectional study of 155 women, red cell folate concentration increased with gestation and was significantly higher in subjects who took supplemental folic acid (1 mg daily) than in those who did not (1056 nmol/L vs. 595 nmol/L, respectively).[64] Serum and red cell folate levels are lower in pregnancy in women who smoke.[65] By 6 weeks after delivery, red cell folate levels return toward preconception values, although serum folate levels remain low. Lactation, which is an added folate stress, may be one reason.[66] Serum folate levels may remain low for up to 6 months after delivery.[61]

Homocysteine
FIGURE 33
Plasma homocysteine (mean and 95% confidence interval [CI]) in a cross-sectional study of 155 normal women in the first, second, and third trimesters of pregnancy and in nonpregnant control subjects. Homocysteine concentrations were determined by high-pressure liquid chromatography. *Data source*: ref. 64, with permission.

Comment: Plasma homocysteine levels are significantly lower in all trimesters of pregnancy compared with nonpregnant control values. Longitudinal studies confirm these findings.[61,62] The lowest levels are found in the second trimester. Homocysteine is 70% to 80% albumin-bound, so these gestational changes mirror those of serum albumin (see Fig. 15). Homocysteine is negatively correlated with red cell folate, and lower concentrations are found in women who take folic acid supplements.[64] Hyperhomocysteinemia, which can result from genetic and environmental factors, is associated with deep venous thrombosis, recurrent miscarriage, abruption, stillbirth, and neural tube defects.

Vitamin B₁₂
FIGURE 34
Serum vitamin B₁₂ levels (5th, 50th, and 95th percentiles) in 102 healthy nulliparous women during an uneventful singleton pregnancy. Subjects were those described in Figure 31. *Data source*: ref. 61, with permission.

Comment: Serum vitamin B_{12} levels are approximately 100 pmol/L lower in pregnancy, but recovery occurs by 6 weeks postpartum.[61] Levels tend to be lower in women who smoke.[65] Muscle and red cell vitamin B_{12} concentrations also fall during pregnancy; however, vitamin B_{12} absorption does not change.[66,67] Saturation of vitamin B_{12}–binding proteins decreases steadily during pregnancy.[67] These changes in vitamin B_{12} status do not represent a deficiency state, however, because they are not associated with evidence of reduced red blood cell count or hemoglobin or homocysteine concentrations, once correction is made for serum ferritin concentrations.[67]

Other Vitamins

Comment: Vitamin concentrations during pregnancy are available from a large longitudinal study performed in the Netherlands on women who were not using iron, folate, or other vitamin supplementation. Vitamins studied included retinol, thiamin, riboflavin, pyridoxal 5′-phosphate, and α-tocopherol.[61]

FIGURE 35
Coagulation factors (mean + 2 SD normal ranges) from a cross-sectional study of 239 women, each of whom was sampled only once. Postdelivery samples were taken 3 days after delivery; all samples were anticoagulated with sodium citrate. Following delivery, case records were reviewed to confirm that all pregnancies had remained uncomplicated. *Data source*: ref. 68, with permission.

Comment: Normal pregnancy is a hypercoagulable state associated with substantially increased levels of Von Wille-brand's factor and Factors VIII, X, and fibrinogen as a result of increased synthesis and increased activation by thrombin. The activated partial thromboplastin time, which measures the intrinsic coagulation pathway, is usually shortened in late pregnancy, by up to 4 seconds, due largely to increased Factor VIII. The prothrombin and thrombin times do not change significantly in pregnancy. In a longitudinal study,[69] Factor VII activity increased from the range 60% to 206% (compared with standard) at the end of the first trimester to 87% to 336% by term. The same study found Factors II and V increased in early pregnancy, but then reduced in the thi3rd trimester. The cross-sectional study shown here found a 29% rise in Factor V from 6 to 11 weeks to 36 to 40 weeks' gestation.[68] Factor IX levels increase, whereas factor XI levels decrease.[66,68] There is an increase in fibrinopeptide A during the first-trimester.[69] By 6 to 7 weeks postnatal, coagulation factors have been found to be similar to those in age-matched, nonpregnant women[69]; however, most hematologists would recommend testing at 8 to 12 weeks following delivery to assess true nonpregnant levels.

Naturally Occurring Anticoagulants and Fibrinolytic Factors

No. of patients		41	48	47	66	62	48	61	61

FIGURE 37
Protein S, protein C, and antithrombin III (mean + 2 SD normal ranges) from a cross-sectional study of 239 women, each of whom was sampled only once. The study subjects were described in Figure 35. *Data source*: ref. 68, with permission.

Comment: Total and free (biologically active) protein S levels decrease progressively during pregnancy. In the study shown here, first trimester levels of total and free protein S were lower than the ranges in non–oral contraceptive using women of similar age (64–154 IU/dL and 54–154 IU/dL, respectively).[68] Protein C levels do not change with gestation and are similar to those found outside pregnancy.[68] Antithrombin III levels are stable during pregnancy, decrease in labor, and then increase 1 week postpartum.[66] Fibrinolysis is depressed during pregnancy; fibrinogen and plasminogen levels are elevated, but levels of circulating plasminogen activator are decreased.[70] Lowest levels of plasminogen activator are found during labor and levels increase soon after delivery, as placentally produced plasminogen activator inhibitor-2 ceases to have influence.[70] In late normal pregnancy, D-dimer levels are also elevated, typically 10-fold higher than in early pregnancy or the nonpregnant state.[51,71] FDPs are also found in increased amounts, particularly in late gestation.[69] High levels of FDPs and D-dimers indicate that clot formation and destruction processes are active, and this has been shown particularly to be happening locally in the placental circulation. Clearance of FDPs and D-dimers may also be altered in pregnancy. Levels of FDPs, D-dimers, and soluble fibrin remain high for at least a week after delivery.[69]

Immunology
Complement System and Immune Complexes
FIGURE 38
Complement factors C3 and C4 (mean + SD) from a longitudinal study of 147 healthy women who were normotensive throughout pregnancy. The control population was 32 normal nonpregnant women 15 to 41 years old, 11 of whom were taking oral contraceptives. *Data source*: ref. 72, with permission.

Comment: Levels of C3 and C4 are significantly elevated during the second and third trimesters. Another cross-sectional study showed elevated levels of C4, but not C3, during the first trimester.[73] Levels of circulating immune complexes are low during pregnancy.[73] There is disagreement as to whether levels of C3 degradation products are elevated[73] or normal[74]; no longitudinal studies have been done.

Markers of Inflammation
ERYTHROCYTE SEDIMENTATION RATE AND C-REACTIVE PROTEIN

Comment: The erythrocyte sedimentation rate (ESR) is high in pregnancy (typically > 30 mm in the first hr) as a result of elevated plasma globulins and fibrinogen.[75] Thus, the ESR cannot be used as a marker for inflammation. Levels of C-reactive protein are slightly increased in pregnancy, particularly in the third trimester and early puerperium.[17,51] Other acute-phase inflammatory markers have been studied in pregnancy: α_1-acid glycoprotein decreases, α_1-antitrypsin increases especially in the third trimester, and haptoglobin levels are stable.[17]

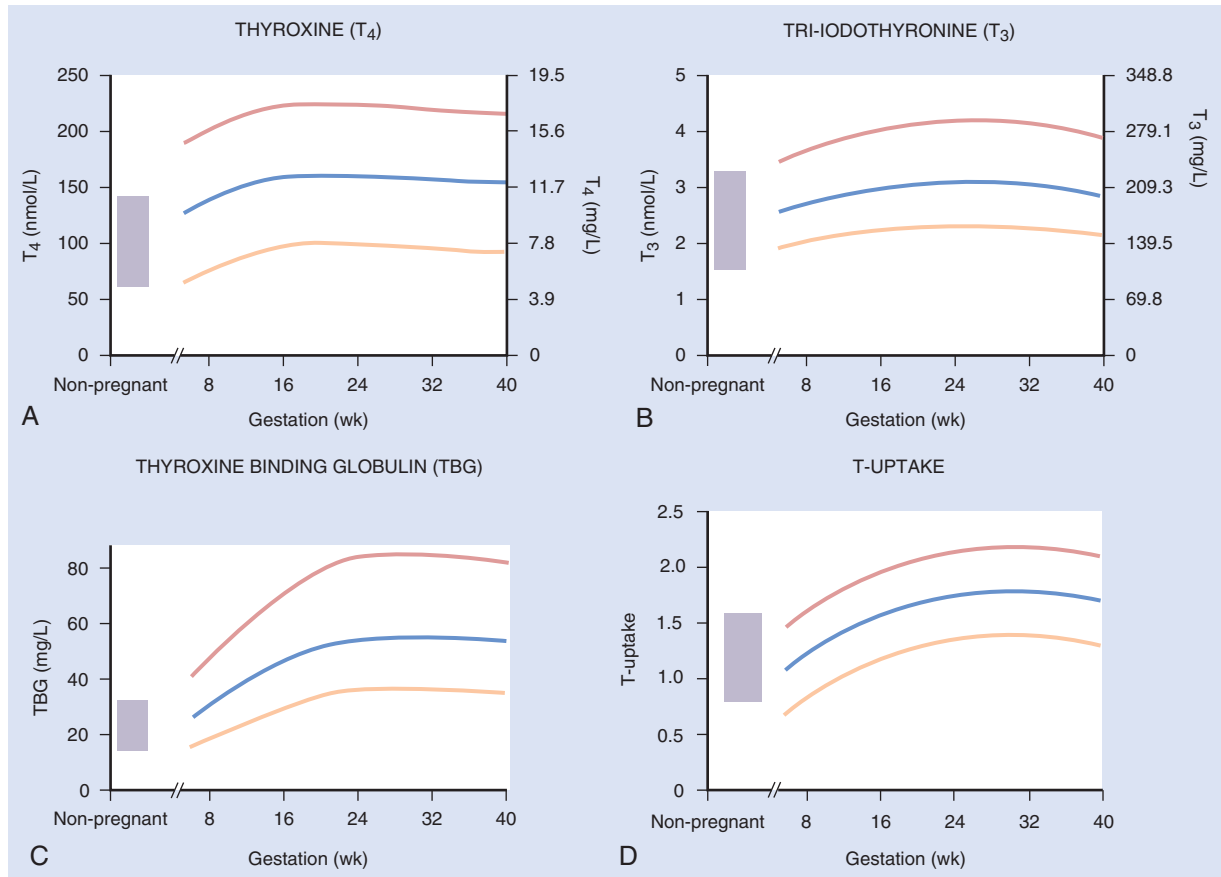
Endocrinology
Thyroid Function
TOTAL THYROXINE, TRIIODOTHYRONINE, THYROID UPTAKE, AND THYROID-BINDING GLOBULIN


FIGURE 39
Total thyroxine (T_4) (*A*), total triiodothyronine (T_3) (*B*), thyroid-binding globulin (TBG) (*C*), and T uptake (*D*) (2.5th, 50th, and 97.5th percentiles) from a longitudinal study of 60 women who each had blood samples three times during pregnancy, once each trimester. Control values were taken from 30 healthy nonpregnant women. *Data source*: ref. 76, with permission.

Comment: Serum total T_4 and T_3 concentrations are elevated in pregnancy. TBG concentrations are doubled by the end of the first trimester, remain elevated throughout pregnancy, and decrease slowly in the 6 weeks after delivery.[77] T_3 uptake is believed to represent total serum thyroxine-binding capacity rather than unoccupied binding site concentration.[76] Other cross-sectional studies found decreased T_3 uptake during pregnancy.[78]

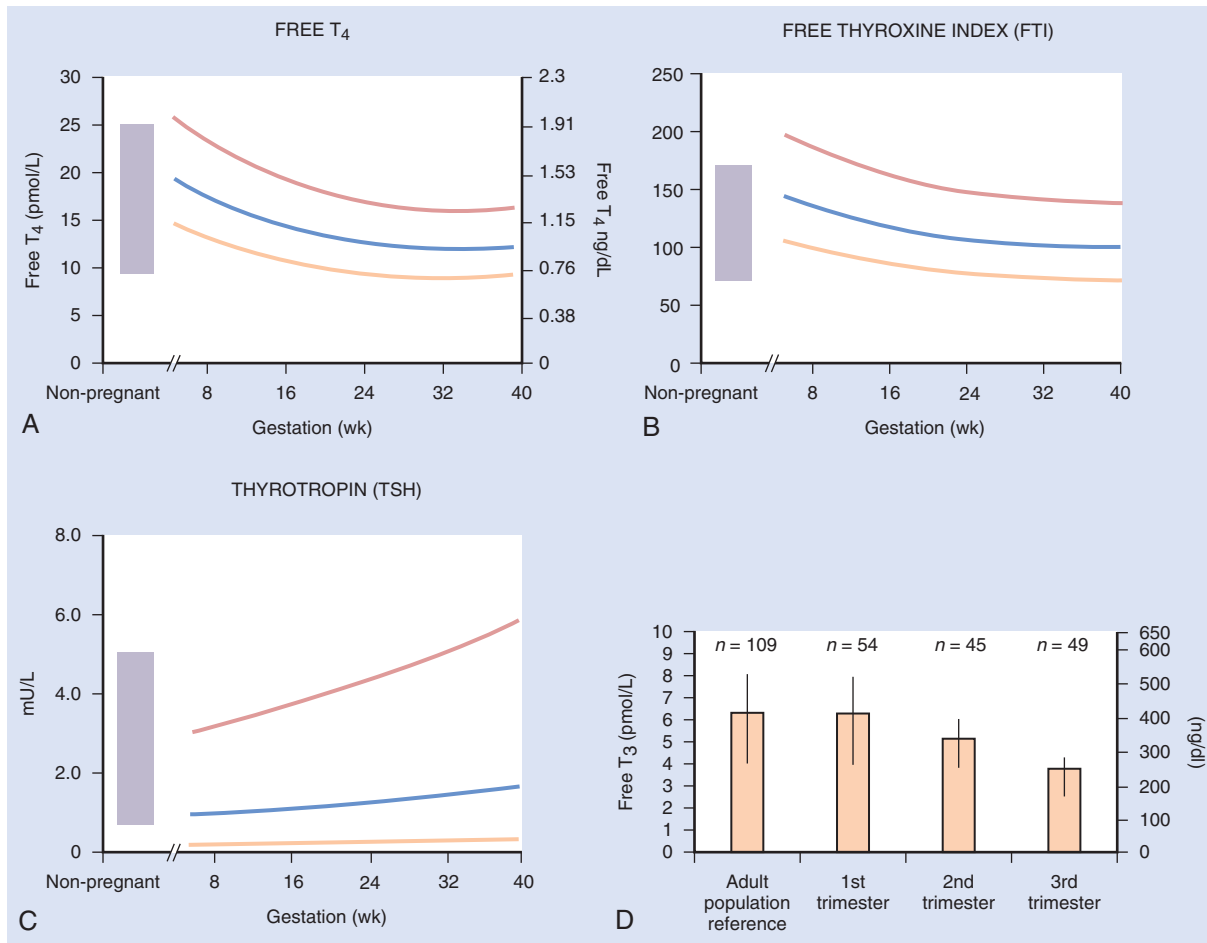
FREE THYROXINE, FREE THYROID-STIMULATING HORMONE, AND FREE TRIIODOTHYRONINE


FIGURE 40

Free T$_4$ levels (A), free T$_4$ index (B), and thyroid-stimulating hormone (TSH) (C) levels (2.5th, 50th, and 97.5th percentiles) from the same study described in Figure 39. *Data source*: ref. 76, with permission. D, Free T$_3$ concentrations (mean ± 2 SDs) from a cross-sectional study of 159 women attending antenatal clinics; none had metabolic illness. The control samples were obtained from 109 patients (male and female) taken from the routine workload of the laboratory (excluding those with thyroid disease, diabetes, cardiac disease, or carcinoma, and postoperative patients). *Data source*: ref. 79, with permission.

Comment: Free T$_4$ and free T$_3$ concentrations, measured directly (rather than derived from resin uptake measurements), decrease during pregnancy but remain within normal nonpregnant ranges.[76,79,80] TSH levels increase with gestation but remain within the reference range for nonpregnant women.[76] Some studies found low TSH levels toward the end of the first trimester in association with the highest circulating concentrations of human chorionic gonadotropin (hCG).[78] The increase in TSH in response to thyrotropin-releasing hormone during early pregnancy is enhanced, similar to responses found in central hypothyroidism.[81]

Adrenal Function
CATECHOLAMINES
FIGURE 41
Epinephrine and norepinephrine concentrations (mean and SEM) from a longitudinal study of 52 women, mean age 28 years, who were normotensive throughout pregnancy; 39 were primigravidae. Samples were taken by venipuncture after 20 minutes' rest in the left lateral position. A radioenzymic method was used for the assays. *Data source*: ref. 82, with permission.

Comment: This study showed a decrease in plasma levels of both epinephrine and norepinephrine as pregnancy progressed. Other studies (in which blood samples were taken from indwelling intravenous cannulas) showed steady levels throughout pregnancy, with no difference between values during pregnancy and those in the early puerperium.[83] In healthy pregnant women, plasma epinephrine and norepinephrine levels show a diurnal pattern, with the lowest levels reported at night.[84] Urinary vanillylmandelic acid (VMA) and catecholamine excretion has not been studied in healthy pregnancies but is likely to be within the normal adult range.

GLUCOCORTICOIDS AND MINERALOCORTICOIDS

Table C

	Plasma cortisol (nmol/L)			Free cortisol index	
	Minimum	Mean (in 24-h period)	Maximum	Minimum (in 24-h period)	Maximum
Pregnant third trimester (n = 7)	197 (25)	581 (28)	1206 (94)	2.2 (0.3)	15.7 (1.7)
Non-pregnant (n = 3)	22 (6)	175 (25)	450 (3)	0.22 (0.05)	5.7 (0.9)

Table D

	Serum cortisol		Salivary free cortisol		Serum aldosterone
	(mg/dL)	nmol/L	(mg/dL)	nmol/L	ng/dL
1st trimester n = 4	9.3 (2.2)	257 (61)	0.21 (0.1)	5.8 (2.8)	8.0 (2.3)
2nd trimester n = 16	14.5 (4.3)	400 (119)	0.36 (0.17)	9.9 (4.7)	13.8 (5.3)
3rd trimester n = 16	16.6 (4.2)	458 (116)	0.47 (0.18)	12.9 (5.0)	25.3 (10.8)
Non pregnant n = 32	9.1 (4.8)	251 (132)	0.22 (0.17)	6.1 (4.7)	3.0 (2.2)

FIGURE 42

A, Adrenocorticotropic hormone (ACTH) and cortisol concentrations (mean and SEM) from a longitudinal study of five healthy pregnant women 17 to 28 years old. Blood samples were taken weekly, from early pregnancy until delivery. Samples were obtained between 8:00 AM and 9:00 AM after an overnight fast. Samples for ACTH measurement were collected improperly from one woman and had to be discarded. Samples were also taken from three of these subjects during labor and on the second postpartum day. *Data source*: ref. 85, with permission. *B,* Mean plasma cortisol levels throughout a 24-hour period from a study of seven primigravidae in the third trimester and three nonpregnant women, two of whom had been studied during pregnancy. The nonpregnant women were at least 3 months postdelivery and were not breast-feeding or using oral contraceptives. Samples were taken every 20 minutes. *Data source*: ref. 86, with permission. *C,* Plasma cortisol and free cortisol index (mean + SD) from a study of seven primigravidae in the third trimester and three nonpregnant women, two of whom had been studied during pregnancy. Subjects were those described in *B. Data source*: ref. 86, with permission. *D,* Serum cortisol, salivary free cortisol, and aldosterone (mean + SD) from a study of 36 healthy pregnant women without previous history of adrenal disease and who had not taken glucocorticoids for the preceding 6 months. Blood samples were taken in a supine position from an intravenous cannula, between 9:00 AM and 10:00 AM. Most of the subjects were ethnically African American. Subjects were studied once during pregnancy, and 32 of them were restudied 11 to 14 weeks postpartum. *Data source*: ref. 87, with permission. *Conversion factor for cortisol*: nmol/L $\times$ 0.036 = µg/dL.

Comment: Total, bound, and free plasma cortisol levels; free cortisol index; and salivary free cortisol are increased in pregnancy compared with the nonpregnant state.[86–88] ACTH levels during pregnancy are variously reported as remaining within the normal range for nonpregnant subjects, increasing, or decreasing,[85,89] but there is agreement that levels increase with advancing gestation. The rise in ACTH during pregnancy is attributed to placental production of the peptide.[89] Despite overall elevated levels, normal diurnal patterns of cortisol are found during pregnancy (i.e., lowest values at 12:00 noon, highest values at 8:00 AM).[86,88] The biologic half-life of cortisol is increased in pregnancy.[86] Cortisol-binding globulin (CBG) concentrations rise steadily during pregnancy, reaching twice the normal values by midgestation.[88,90] The cortisol production rate during pregnancy has been described as depressed[91] or elevated.[86] Urinary free cortisol more than doubles during pregnancy.[92] After 1 mg dexamethasone given orally at 11:00 PM, plasma cortisol levels measured at 8:00 AM are less than 139 nmol/L or 5 µ/dL (a normal response).[93] However, urinary cortisol levels are not suppressed as much in pregnant subjects as in nonpregnant subjects.[89] The cortisol response to an ACTH challenge (250 µg Synacthen test) is unchanged in pregnancy: stimulated serum cortisol levels of 20 µg/dL or greater (550 nmol/L).[87,94] Salivary free cortisol (SaFC) is unaffected by CBG levels and is thus a useful measure in situations in which CBG is high. The calculated lower limit (2.5th percentile) for basal morning SaFC is 0.13 µg/dL (3.59 nmol/L) and 0.19 µg/dL (5.24 nmol/L) in the second and third trimesters, respectively.[87] After a 250-µg ACTH challenge, SaFC levels exceeded 1.06 µg/dL (28.3 nmol/L) and 1.19 µg/dL (32.8 nmol/L) in the second and third trimesters, respectively.[87] Aldosterone levels increase progressively during gestation, and there is an enhanced response to an ACTH challenge.[87]

Prolactin

Comment: Prolactin concentrations increase 10- to 20-fold during pregnancy. The concentrations show a normal circadian rhythm, with a nocturnal rise.[96] In labor, levels decrease acutely, followed by a postpartum surge during the first 2 hours after delivery.[97] These changes are not seen in women undergoing elective cesarean delivery. Prolactin levels approach the normal range 2 to 3 weeks after delivery in nonlactating women, but remain elevated in those who breast-feed their infants.[98]

FIGURE 43
Serum prolactin (10th and 90th percentiles) from a mostly cross-sectional study of 839 women with uncomplicated singleton pregnancies at 8 to 40 weeks' gestation; 980 blood samples were taken. All of the samples were collected between 9:00 AM and 11:00 AM. Women who had a pregnancy complication were rejected from the normal series. *Data source*: ref. 95, with permission.

Calcium Metabolism

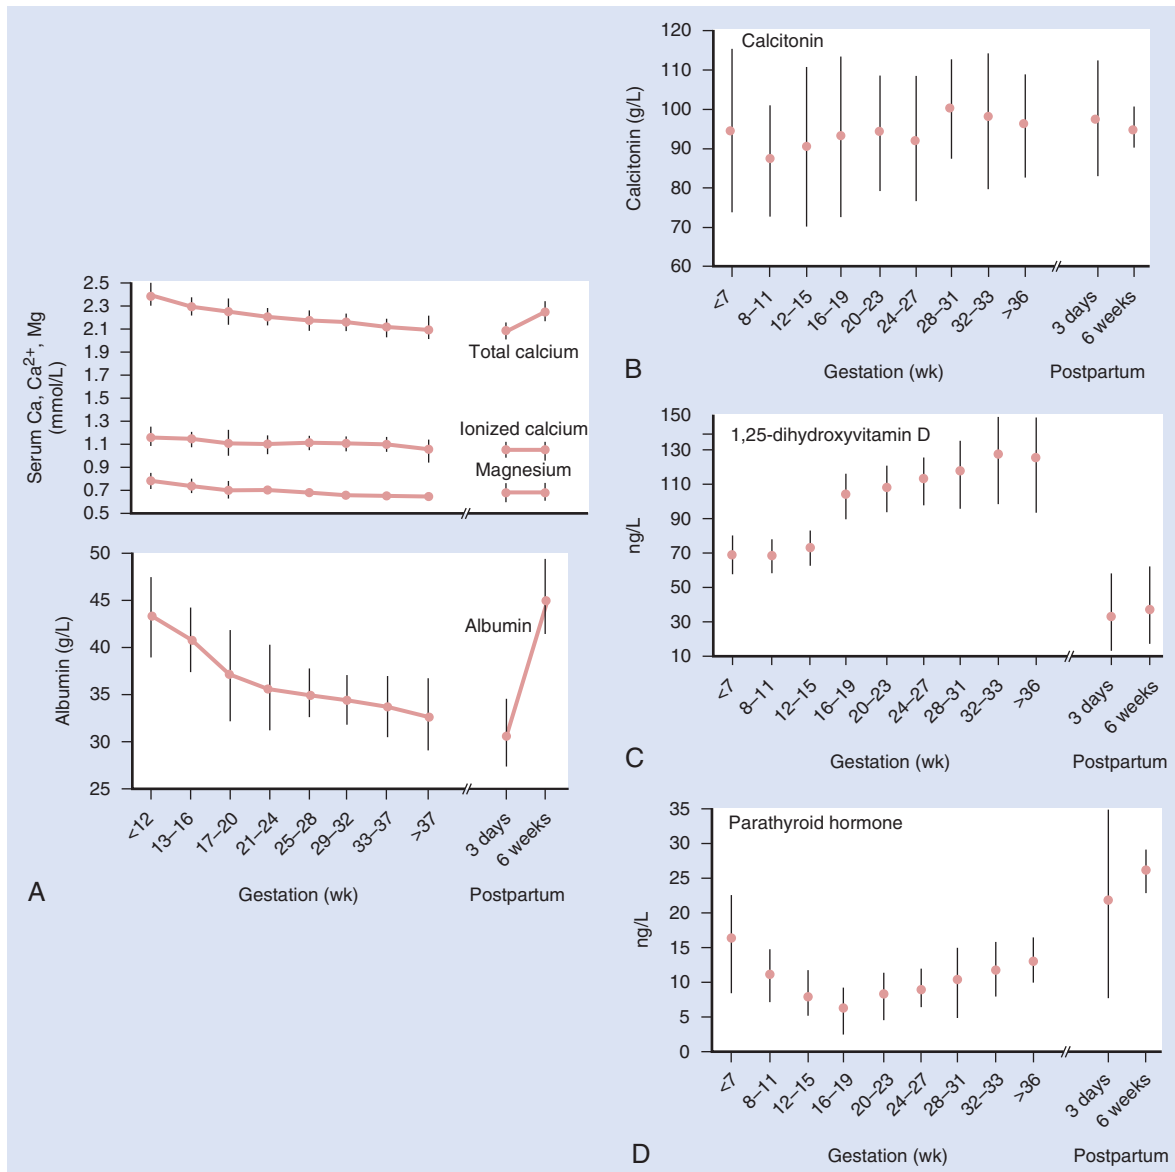
TOTAL AND IONIZED CALCIUM, MAGNESIUM, ALBUMIN, PARATHYROID HORMONE, CALCITIONIN, AND VITAMIN D


FIGURE 44

A, Total and ionized calcium, magnesium, and albumin (mean ± SD) from a longitudinal study of 30 women who were recruited in the first trimester and studied at 4-week intervals. Samples were taken on the third postpartum day and during the sixth postpartum week. Subjects ranged in age from 19 to 33 years; 20 were primigravidae. Samples were collected by venipuncture after an overnight fast. *Conversion factors:* calcium, mmol/L × 4 = mg/dL; magnesium, mmol/L × 2.4 = mg/dL. *Data source:* ref. 99, with permission. Calcitonin (*B*), 1,25-dihydroxyvitamin D (*C*), and parathyroid hormone (PTH) (*D*) (mean ± SD) from a longitudinal study of 20 women 22 to 34 years old, 12 of whom were nulliparous. All had uncomplicated pregnancies of more than 38 weeks' gestation. The only medication they received was ferrous sulfate. Blood samples were taken in the morning after an overnight fast. Samples were collected at 4-week intervals, with the first taken before 7 weeks' gestation. Samples were also taken on the third postpartum day and during the sixth postpartum week. *Data source:* ref. 100, with permission.

Comment: Total serum calcium decreases during pregnancy, in association with the fall in serum albumin; however, ionized calcium levels remain constant. Serum intact PTH levels are lower in pregnancy than at 6 weeks postpartum; they reach a nadir in midpregnancy. A menstrual cyclicity in PTH has also been noted, with higher values corresponding to times of increased estrogen secretion.[99] Calcitonin levels are not significantly altered in pregnancy. 1,25-Dihydroxyvitamin D levels increase with advancing gestation and are significantly higher than during the puerperium. One α-hydroxylation of 25-hydroxyvitamin D in the placenta accounts for this increase and the consequent suppression of PTH.[100]

Placental Biochemistry
PLASMA PROTEIN A
FIGURE 45

Pregnancy-associated plasma protein A (PAPP-A) levels in maternal serum (median 0.5 MoM and 2 MoM) from a cross-sectional study of 379 healthy women at 8 to 14 weeks' gestation. These women had been selected to match 77 women whose fetuses had Down syndrome. Their median age was 39 years (10th and 90th percentiles, 34 and 42 years, respectively). *Data source*: ref. 101, with permission.

Comment: PAPP-A and free β-human chorionic gonadotropin (β-hCG) are useful markers for discriminating pregnancies affected by Down syndrome from normal pregnancies at 8 to 14 weeks' gestation. PAPP-A levels are lower in affected pregnancies than in normal pregnancies (particularly at ≤ 11 wk' gestation).[101,102]

SERUM α-FETOPROTEIN
FIGURE 46

Serum α-fetoprotein (SAFP) (median and interquartile ranges) from a cross-sectional study. Samples from women in labor and samples obtained on the first postpartum day were paired. SAFP was measured by radioimmunoassay. *Data source*: ref. 103, with permission.

Comment: In the second trimester, SAFP increases by approximately 15% weekly.[104] Individual screening laboratories establish reference ranges for SAFP in the second trimester for their own populations. These ranges are usually expressed as MoM for gestation. In twin pregnancies, SAFP levels are approximately twice as high as those in singleton pregnancies.[104] Maternal weight is inversely related to SAFP levels, probably because of the dilutional effect of a larger vascular compartment.[104]

HUMAN CHORIONIC GONADOTROPIN

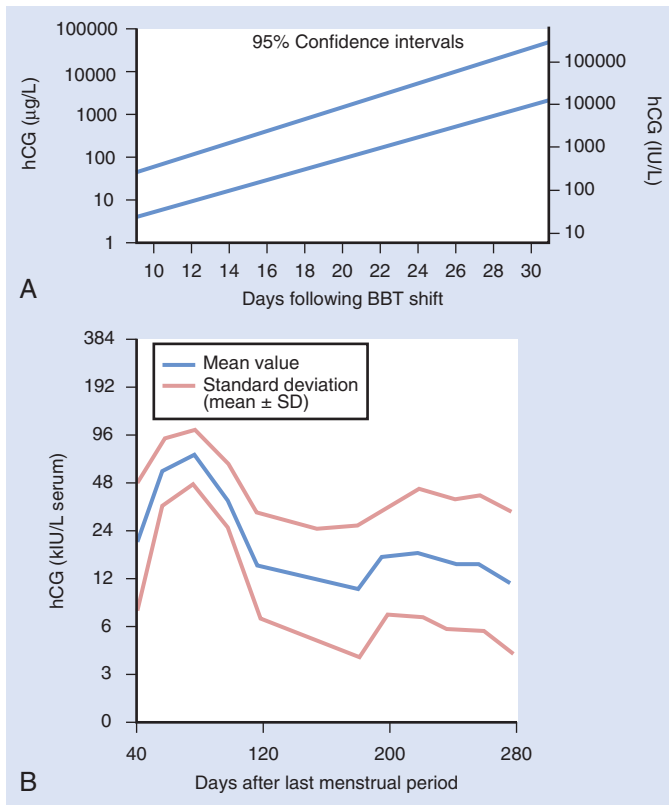
A, Serum values of the β subunit of hCG (95% CI)


FIGURE 47
A, Serum values of the β subunit of hCG (95% CI) measured in 189 women who subsequently had successful pregnancies (total of 280 samples analyzed). The study subjects were patients in an infertility clinic and were keeping basal body temperature (BBT) charts to indicate the timing of ovulation. Some conceptions were spontaneous; other patients were treated with clomiphene citrate, human menopausal gonadotropin, or hCG (a single injection of 5000 IU to induce ovulation). A radioimmunoassay was used for β-hCG. *Data source*: ref. 105, with permission. *B*, Total serum hCG (mean ± SD) from a longitudinal study of 20 healthy women. The first samples were obtained as early in pregnancy as possible, with subsequent samples obtained every 3 to 4 weeks. The last sample was taken during labor. Samples were classified into groups, with a class interval of 30 days. Radioimmunoassay was used to obtain the hCG level; the international hCG standard was used as a reference. *Data source*: ref. 106, with permission.

Comment: The mean doubling time of β-hCG is 2.2 days ± 1.0 (2 SDs).[105] Low hCG values that do not double to within this range are associated with ectopic pregnancy or spontaneous abortion.[105] Women with male fetuses have significantly lower hCG levels than those with female fetuses.[106]

HUMAN PLACENTAL LACTOGEN

FIGURE 48
Serum human placental lactogen (hPL) values (mean ± SD) from a cross-sectional study of 151 normal women with singleton pregnancies attending an antenatal clinic. Radioimmunoassay was used to measure hPL. *Data source*: ref. 107, with permission.
Comment: In women with multiple pregnancies, hPL levels are outside these ranges; however, if values are corrected for predicted placental weight, then they are appropriate for gestational age.[107] Four hours after delivery of the placenta, plasma hPL is virtually undetectable; the half-life of hPL in the plasma is 21 to 23 minutes.[108]
ESTRIOL

FIGURE 49
Plasma estriol (mean and range) from a cross-sectional study in women with uncomplicated pregnancies. Plasma estriol was measured fluorometrically. *Data source*: ref. 109, with permission.

> **Comment:** The normal range of plasma estriol in pregnancy is wide. To assess the significance of values outside this range, trends should be studied over several days.

FETAL VALUES

Physiology

Early Embryonic Structures
FIGURE 50
Ultrasound visualization of the yolk sac, fetal pole, heartbeat, amniotic membrane, and midgut hernia from a longitudinal study of 39 women with known dates of ovulation; most were patients from an assisted conception unit. Once pregnancy was confirmed, patients were scanned with a vaginal probe weekly, starting as early as 18 days after conception. Five subjects had twin pregnancies. *Data source*: ref. 110, with permission.

> **Comment:** Transvaginal ultrasound scanning yields better images in the first trimester than does transabdominal scanning. By 28 days after conception, fetal viability may be confirmed by visualization of a heartbeat. The fetal heart rate increases from 90 beats/min to 145 beats/min by 7 weeks after conception.[110]

Biometry
CROWN–RUMP LENGTH
FIGURE 51
Crown-rump length (CRL) (mean ± 2 SDs) from a cross-sectional study of 334 women who were certain of the date of their last menstrual period (LMP) and had normal, regular menstrual cycles. The study covered the period from 6 to 14 weeks after the LMP. A transabdominal ultrasound technique was used, and the longest length of fetal echoes was found and measured. *Data source*: ref. 111, with permission.

> **Comment:** CRL measurements can be used effectively only in the first trimester. Other studies found similar CRL values; measurements are not affected by maternal age, height, or parity.[112] In a smaller longitudinal study, CRL was significantly lower in female than in male fetuses.[112] No differences in CRL measurements have been found between Asian and European patients.[113]

NUCHAL TRANSLUCENCY
FIGURE 52

Nuchal translucency (NT) measurements (5th, 50th, and 95th percentiles) from a cross-sectional study of 20,217 chromosomally normal fetuses examined at 10 to 14 weeks' gestation. Most examinations were done with transabdominal ultrasound, and all operators were carefully trained in the technique before the study. A sagittal section of the fetus was obtained perpendicular to the ultrasound beam, allowing measurement of CRL and the maximum thickness of the subcutaneous translucency between skin and soft tissue overlying the cervical spine.114 Care was taken to avoid confusion between fetal skin and amnion, both of which appear as thin membranes. *Data source*: ref. 115, with permission.

Comment: Abnormal fluid collections in the cervical region (as shown by increased NT measurements) are strongly associated with chromosomal abnormalities. The upper limit of normal may be set at 2.5 or 3.0 mm when these measurements are used as a screening test.[115,116] However, it is preferable to use the 95th percentile of NT as plotted against CRL, because measurements increase with gestational age.[115]

BIPARIETAL DIAMETER
FIGURE 53

Biparietal diameter (BPD) (3rd, 10th, 50th, 90th, and 97th percentiles) of 594 fetuses from a prospective cross-sectional study of 663 women with singleton pregnancies carried out in London. Each fetus was measured only once between 12 and 42 weeks' gestation for the study. All women had certain menstrual dates, and menstrual and ultrasound ages at 18 to 22 weeks did not differ by more than 10 days. The study population consisted of 75% Western European and 25% African Caribbean women. No women had disease or used medication that was likely to affect fetal growth (e.g., diabetes, hypertension, renal disease). Measurements from 2 fetuses subsequently found to have abnormal karyotypes were excluded from the study. BPD measurements were obtained in the axial plane of the skull at the level where the continuous midline echo is broken by the cavum septum pellucidum in the anterior third. Measurements presented are those from the proximal edge of the skull closest to the transducer to the proximal edge of the deep border (i.e., outer-inner edges of bone). The statistical methods used to derive graphs and tables from the raw data are described in detail. *Data source*: refs. 117 and 118, with permission.

Comment: Other large studies are in close agreement with these measurements.[119,120] Information about growth in BPD is available from a longitudinal study.[121] Charts and graphs are also available for outer-outer BPD measurements,[118] and regression equations are given for both parameters. Racial differences in fetal measurements are likely to be found, so charts or percentile graphs appropriate for the population should be used. A small study found no significant differences between Asian and European women living in the same city.[113]

HEAD CIRCUMFERENCE
FIGURE 54
Head circumference (HC) (3rd, 10th, 50th, 90th, and 97th percentiles) from a prospective cross-sectional study of 594 fetuses, as described in Figure 53. HC was measured directly by tracing around the perimeter of the skull in the same plane used for BPD measurements. *Data source:* refs. 117 and 118, with permission.

Comment: HC measurements as derived from the BPD and the occipitofrontal diameter are also available[118,119] as well as regression equations for each parameter. Other studies yielded similar data, with some differences seen in the late third trimester.[119,122] These differences have been attributed to patient recruitment characteristics (whether only women delivering at term were included in the study) and the numbers of ultrasound operators used to collect data. HC measurements are particularly useful in the assessment of gestational age when the fetal head shape is abnormal (e.g., dolichocephaly).

ABDOMINAL CIRCUMFERENCE
FIGURE 55
Abdominal circumference (AC) (3rd, 10th, 50th, 90th, and 97th percentiles) from 610 fetuses in the prospective cross-sectional study described in Figure 53. The fetal abdomen was measured in a transverse section, with the spine and descending aorta posterior, the umbilical vein in the anterior third, and the stomach bubble in the same plane. Care was taken to ensure that the section was as close as possible to circular, perpendicular to the spine. The circumference was measured by tracing around the perimeter. *Data source*: refs. 117 and 123, with permission.

Comment: Variability in AC increases with gestational age, as shown by widening of the percentiles. Other large studies are in close agreement[120,124,125] with these findings. Studies in which all women delivered at term did not find flattening of the growth velocity curves in late pregnancy.[126,127] Some of the discrepancies are the result of differences in mathematical curve-fitting techniques applied to the experimental data and differences in study design and the numbers of subjects and operators involved. AC is not a good indication of gestational age, but is used to assess fetal size (e.g., in relation to head and limb measurements). A method has been described[124] for assigning Z-scores to measurements, so that deviation from median values can be expressed without graphic presentation of the data. Measurements can also be compared between subjects or between the same subject at different times. Regression equations for AC, both plotted and derived from abdominal diameter measurements, are described.[123,124]

FEMUR LENGTH

Comment: Other cross-sectional studies of FL provide similar measurements,[120,124] although one has wider percentiles in late pregnancy.[129] This difference is likely to be related to a difference in the statistical approach to the calculation of percentiles from the regression line. Regression equations are available.[120,124,128]
FIGURE 56
Femur length (FL) (3rd, 10th, 50th, 90th, and 97th percentiles) from 649 fetuses in the prospective cross-sectional study described in Figure 53. The femur was identified and the transducer rotated until the full femoral diaphysis was seen in a plane at almost a right angle to the ultrasound beam. The measurement was made from one end of the diaphysis to the other, disregarding curvature and ignoring the distal femoral epiphysis. *Data source*: refs. 117 and 128, with permission.

LIMB BONE LENGTHS

FIGURE 57
Lengths of the tibia (*A*), fibula (*B*), humerus (*C*), radius (*D*), and ulna (*E*) (5th, 50th, and 95th percentiles) from a cross-sectional study of 669 healthy women with singleton pregnancies. Women who subsequently delivered an infant with an abnormal karyotype, a significant malformation, or any other disease were excluded from the analysis. In all women, menstrual dating was certain and there was agreement between menstrual age and ultrasound dates at the time of the initial scan. Approximately 20 measurements were obtained for each parameter for each week of gestation from 12 to 42 weeks. *Data source*: ref. 130, with permission.

Comment: All limb bones show linear growth from 13 to 25 weeks' gestation; thereafter, growth is nonlinear. Other studies confirmed these findings.[131] Good agreement has been found between ultrasound and x-ray measurements of limb bone lengths. Tables are available to allow assessment of gestational age from measurement of limb bone lengths.[132] This use of limb bone measurements should be distinguished from tables or graphs of normal measurements at known gestational age that allow assessment of possible skeletal dysplasia.[130,133]

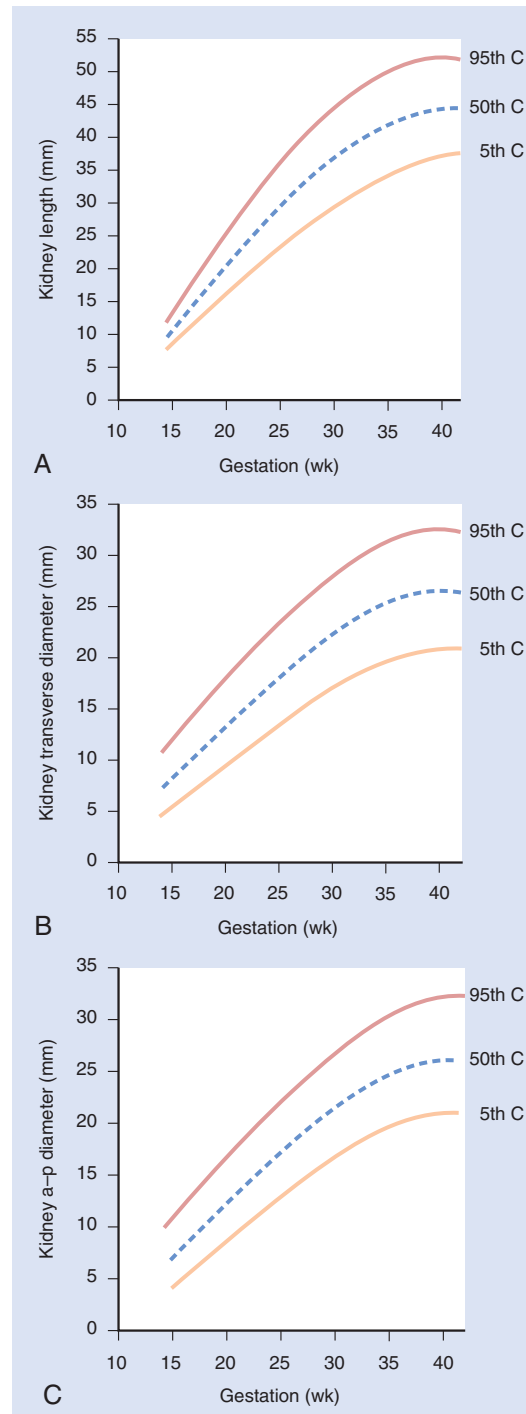
FOOT
FIGURE 58
Length of the foot (5th, 50th, and 95th percentiles) from the cross-sectional study of 669 healthy women with singleton pregnancies described in Figure 57. Approximately 20 measurements were obtained for each variable for each week of pregnancy at 12 to 42 weeks' gestation. *Data source*: ref. 130, with permission.


FIGURE 59
Kidney measurements: length (*A*), transverse diameter (*B*), and anteroposterior diameter (*C*) (5th, 50th, and 95th percentiles) from the cross-sectional study of 669 healthy women with singleton pregnancies described in Figure 57. Approximately 20 measurements were obtained for each variable for each week from 12 to 42 weeks' gestation. *Data source*: ref. 130, with permission.

Comment: The ratio of transverse renal circumference to AC (in a section at the level of the umbilical vein) is a simple way to assess normal kidney size. This ratio is 0.27 to 0.30 from 17 weeks' gestation until term.[134]

ORBITAL DIAMETERS
FIGURE 60
Interorbital distance (mean) from a cross-sectional study of 180 healthy women at 22 to 40 weeks' gestation. The scan plane that was used transected the occiput, orbits, and nasal processes. *Data source:* ref. 135, with permission.

Comment: Outer orbital diameter is closely related to BPD. This measurement is useful when the fetal position precludes accurate measurement of BPD.

CEREBRAL VENTRICLES
FIGURE 61
Ventriculohemispheric ratios (5th, 50th, and 95th percentiles) from a cross-sectional study of 1040 singleton pregnancies at 14 to 40 weeks' gestation, selected from a large database. All women had known LMP dates, with a cycle length of 26 to 30 days. They had no pregnancy complications. Only data from structurally normal fetuses who were liveborn at 37 weeks' gestation or more and who had birth weights between the 3rd and the 97th percentiles for gestation were included. For each week, measurements from 40 fetuses were obtained. Each fetus contributed measurements to the data pool on only one occasion. *A*, Measurement of the anterior horn of the lateral cerebral ventricle was made in a transverse axial plane of the fetal head (as for BPD or HC measurements), from the lateral wall of the anterior horn to the midline. *B*, Posterior horn measurements were made from the medial to the lateral wall of the posterior horn. Hemispheric measurements were made from the midline to the inner border of the skull. *Data source*: ref. 120, with permission.

Comment: The most reliable measurements of the ventricular system are made with the frontal horns of the lateral cerebral ventricles because they are the easiest to identify. In general, ventricular diameter should be less than 10 mm.

CEREBELLUM
FIGURE 62
Transverse cerebellar diameter (5th, 50th, and 95th percentiles) from
the cross-sectional study of 1040 singleton pregnancies described in
Figure 61. Measurements were made in the suboccipitobregmatic plane
of the fetal head. *Data source*: ref. 120, with permission.

Comment: The cerebellum may be visualized as early as
10 to 11 weeks' gestation. Other studies found similar
measurements.[136]

OTHER FETAL MEASUREMENTS

Comment: Normal ranges for many other fetal struc-
tures are described in the literature. Each may be useful
under certain circumstances. Charts of liver length are
useful in the assessment of isoimmunized fetuses, in
which liver length is inversely correlated with fetal Hb
levels.[137] Fetal ear measurements are helpful in the detec-
tion of fetuses with abnormal karyotypes.[138,139]

BIOMETRY IN MULTIPLE GESTATIONS

Comment: A study of ultrasound measurements in twin
pregnancies after 24 weeks' gestation (involving 884 sets
of twins, each of whom contributed only one measure-
ment to the data set) found that the growth pattern for FL
was similar to that of singletons.[140] AC measurements in
twins were lower than those in singletons after 32 weeks;
BPD measurements were greater than those in singletons
before 32 weeks.[140] A longitudinal study of 35 healthy
women with twin pregnancies did not find clinically
important differences between measurements of fetal size
(HC, BPD, limb bone lengths) in twins compared with
singletons.[141,142] Studies in normal triplet pregnancies
found delay in growth patterns after midgestation.[143]

BIRTH WEIGHT
FIGURE 63
Birth weight (10th, 50th, and 90th percentiles) from an analysis of
41,718 singleton births in Nottingham, UK, between 1986 and 1991.
All women had dates confirmed by ultrasound measurements (CRL up to
13 wk and BPD thereafter) before 24 weeks, and they delivered
between 168 and 300 days' gestation. The population was of mixed
ethnicity. *Data source*: ref. 144, with permission.

Comment: This study differs from previous reports[145,146]
(which did not have ultrasound confirmation of gesta-
tional age) in that it found a continued increase, rather
than flattening, of birth weight curves toward term. Birth
weights of preterm infants (≤32 wk' gestation) were
negatively skewed, consistent with the observation that
growth-restricted infants may be born earlier than those
of appropriate size.[144] Birth weight is also dependent on
ethnic origin, altitude, socioeconomic factors, maternal
size, birth order, and maternal cigarette smoking.[144,147,148]
All of the studies described here are for singletons.
Different ranges apply to multiple pregnancies.

WEIGHT ESTIMATED FROM ULTRASOUND MEASUREMENTS
FIGURE 64

Weight estimated from ultrasound measurements (5th, 50th, and 90th percentiles) in a study of 138 women who underwent ultrasound examination within 48 hours of delivery for the measurement of fetal AC. Actual birth weights were compared with AC measurements, and a polynomial equation was derived to describe the relationship. *Data source*: ref. 149, with permission.

Comment: Equations have been derived for estimating fetal weight from various combinations of ultrasonic measurements (AC, BPD, HC, and FL).[150,151] These estimates are reported to be more accurate than those based on AC measurements alone.

Amniotic Fluid
TOTAL VOLUME
FIGURE 65

Total amniotic fluid volume (1st, 5th, 25th, 50th, 75th, 95th, and 99th percentiles). Composite analysis of 12 published reports of amniotic fluid volume in human pregnancy, totaling 705 measurements. Amniotic fluid volume was measured directly at the time of hysterotomy or indirectly with an indicator dilution technique. Only healthy pregnancies were included; any complicated by fetal death or anomaly or by maternal disease were excluded. *Data source*: ref. 152, with permission.

AMNIOTIC FLUID INDEX
FIGURE 66

Amniotic fluid index (AFI) (1st, 5th, 50th, 95th, and 99th percentiles) from a prospective study of 791 patients. Any who did not have a normal pregnancy outcome (i.e., infant born at term, between the 10th and 90th percentiles for birth weight, with a 5-minute Apgar score greater than 6, and without congenital anomaly) were subsequently excluded. Ultrasound imaging was performed, and the uterus was divided into four quadrants along the sagittal midline and midway up the fundus. The AFI was calculated as the sum of the deepest vertical dimension (in millimeters) of the amniotic fluid pocket in each quadrant of the uterus. *Data source*: ref. 153, with permission.

Comment: The volume of amniotic fluid increases to a plateau of 700 to 850 mL between 22 and 39 weeks' gestation. This volume corresponds to an AFI of 140 to 150 mm. After term, amniotic fluid volume decreases significantly.

PRESSURE
FIGURE 67
Amniotic fluid pressure (mean and 95% CI) from a cross-sectional study of 171 singleton pregnancies subsequently shown to have a normal karyotype. Amniotic fluid volume was subjectively assessed as normal, based on ultrasonic appearance. All patients were scheduled to undergo an invasive diagnostic transamniotic procedure or therapeutic termination of pregnancy. Amniotic fluid pressure was measured with a manometry technique referenced to the top of the maternal abdomen. *Data source*: ref. 154, with permission.

Comment: Amniotic fluid pressure increases with gestation, reaching a mid-trimester plateau of 4 to 5 mm Hg. Pressure was not affected by parity or maternal age and was similar in twin and singleton pregnancies.[154]

OSMOLALITY
FIGURE 68
Amniotic fluid osmolality (mean) from a composite analysis of six published reports. *Data source*: ref. 155, with permission.

Comment: In early pregnancy, the composition of amniotic fluid is consistent with a transudate of maternal or fetal plasma.[156] The fetal skin becomes keratinized by midpregnancy, and amniotic fluid solute concentrations decrease as fetal urine becomes more dilute.[156] Thus, there is an osmotic gradient between amniotic fluid and both maternal and fetal plasma.

Cardiac Dimensions
CARDIAC CIRCUMFERENCE
FIGURE 69
Cardiac circumference (mean and 95% CI) from a longitudinal study of 45 healthy women with known menstrual dates that were confirmed by early ultrasound scan. Study subjects were recruited before 20 weeks' gestation and underwent scanning every 4 weeks. Fetal cardiac and thoracic circumference were measured in a transverse plane through the chest, at the level of the four-chamber view of the fetal heart. *Data source*: ref. 157, with permission.

Comment: The cardiac-to-thoracic circumference ratio is normally approximately 0.5 (95% CI at 20 wk, 0.40–0.58; at 30 wks, 0.44–0.60; at 40 wk, 0.46–0.65).[157]

VENTRICULAR DIMENSIONS
FIGURE 70

End-diastolic dimensions of the left ventricle (*A*) and the right ventricle (*B*) (regression line and 95% prediction interval) from a cross-sectional study of 117 normal women at 16 to 41 weeks' gestation. All fetuses were anatomically normal, and gestational age was confirmed by first-trimester ultrasound measurements. A four-chamber view of the heart was obtained in a transverse plane through the fetal chest. The transducer was adjusted so that the intraventricular septum was perpendicular to the ultrasound beam. In this view, transverse endocardial-endocardial dimensions of both ventricles were measured just below the valves, at the end of diastole. *Data source*: ref. 158, with permission.

Comment: This study found narrower CIs for cardiac measurements than those described in earlier reports.[159] This finding was attributed to improved resolution of newer ultrasound equipment and the use of imaging planes perpendicular to the ultrasound plane (which reduces lateral resolution error). Close correlation was seen between measurements made by two observers in this study.

VENTRICULAR AND SEPTAL WALL THCKNESS
FIGURE 71

Thickness of the interventricular septum (regression line and 95% CI) from a study with cross-sectional and longitudinal data (*n* = 100 observations). Subjects were healthy and had their menstrual dates confirmed by ultrasound measurements; all subsequently were delivered at term. Interventricular septal thickness was measured in the four-chamber view of the fetal heart, just below the atrioventricular valves. *Data source*: ref. 159, with permission.

Comment: The thickness of the left or right ventricular wall is similar to that of the interventricular septum.

ASCENDING AORTA AND PULMONARY ARTERY DIAMETER

A

B
FIGURE 72

Diameter of the ascending aorta (*A*) and the main pulmonary artery (*B*) (regression line and 95% prediction interval) from a cross-sectional study of 117 fetuses at 16 to 41 weeks' gestation, as described in Figure 70. The aorta was measured in a long-axis view of the heart, found by moving cephalad from the four-chamber view. Measurements were made between intimal surfaces when the aorta had been aligned perpendicular to the ultrasound beam, just above the sinuses of Valsalva. The main pulmonary artery was measured in a long-axis view, with its vessel walls perpendicular to the ultrasound beam. *Data source*: ref. 158, with permission.

Comment: During intrauterine life, the diameter of the pulmonary artery is slightly larger than that of the aorta. It may not be possible to obtain good views of these vessels in the planes described. However, similar values were reported in other studies in which measurements were made in different scan planes.[159]

Cardiovascular Doppler Indices
DUCTUS VENOSUS
FIGURE 73

Systolic-to-atrial ratio (5th, 50th, and 95th percentiles) from ductus venosus Doppler flow velocity waveforms recorded in a cross-sectional study of 164 fetuses at 16 to 42 weeks' gestation. Fetal size was appropriate for gestational age, and no structural or chromosomal abnormalities were reported. Velocity waveforms were recorded from the ductus venosus at its origin from the umbilical vein, as visualized in a transverse section of the fetal abdomen with color and pulsed Doppler recordings. The angle of insonation of the vessel was kept low; recordings in which this angle exceeded 20 degrees were rejected. Ductus venosus waveforms were recognized by their characteristic biphasic pattern. The ratio between peak systolic velocity and velocity during atrial contraction (nadir of the waveform) was calculated. *Data source*: ref. 160, with permission.
FIGURE 74

Pulsatility index for veins from the ductus venosus (5th, 50th, and 95th percentiles) from a cross-sectional study of 143 women with singleton pregnancies at 20 to 40 weeks' gestation. All fetuses were anatomically normal. Gestational age was calculated from menstrual history and confirmed by fetal measurements made at 20 weeks' amenorrhea. At the time of the study, measurements of fetal head and AC were within the 90% CI for gestational age. Movements, amniotic fluid volume, and umbilical artery Doppler pulsatility index were also normal. All measurements were made in the absence of fetal breathing movements. Flow velocity waveforms were recorded from the ductus venosus and visualized in an oblique transverse plane through the upper abdomen or in a midsagittal longitudinal plane. Good signals were obtained from 134 cases. The pulsatility index for veins was calculated as (peak systolic velocity – minimum atrial velocity/time-averaged maximum velocity). *Data source*: ref. 161, with permission.

Comment: Color-flow mapping Doppler equipment is necessary for correct identification of the ductus venosus. Waveforms from the intrahepatic portion of the umbilical vein and the inferior vena cava are different. The decreasing systolic-to-atrial ratio is interpreted as indicating a relative increase in blood flow during end-diastole (i.e., improved cardiac filling).

INFERIOR VENA CAVA
FIGURE 75

Percentage of reverse flow from the inferior vena cava (mean and linear regression of the 95th CI) from a cross-sectional study of 118 appropriate–for–gestational age fetuses at 18 to 40 weeks' gestation. All pregnancies were singleton and were dated by certain LMP and early second-trimester ultrasonography. All fetuses were structurally normal and of appropriate size for gestation at the time of study. Flow velocity waveforms were recorded with color and pulsed Doppler equipment from the inferior vena cava, which was identified in a sagittal view of the fetal trunk between the entrance of the renal vein and the ductus venosus. Measurements were made in the absence of fetal body or breathing movements. Three components of the waveform were identified: systolic peak (S), diastolic wave (D), and reverse flow during atrial contraction (A). The percentage of reverse flow was calculated as the percentage of the time-velocity intervals during the A-wave, with respect to the total forward time-velocity intervals (S + D). *Data source*: ref. 162, with permission.
FIGURE 76

Pulsatility index for veins from the inferior vena cava (5th, 50th, and 95th percentiles) from the cross-sectional study of 143 women described in Figure 74. Flow velocity waveforms were recorded from the inferior vena cava in a longitudinal section of the fetal abdomen, with the sample volume placed in the portion between the renal and the hepatic veins. Clear signals were obtained from 127 fetuses. The pulsatility index for veins was calculated as (peak systolic velocity – minimum atrial velocity/ time-averaged maximum velocity). *Data source*: ref. 161, with permission.

Comment: Flow velocity waveforms in the inferior vena cava are characteristically triphasic, with reverse velocities found during atrial contraction. These reverse velocities decrease significantly with advancing gestation. This decrease is attributed to a decrease in the pressure gradient between the right atrium and the right ventricle at end-diastole as a result of improved ventricular compliance and reduced end-diastolic pressure. Right ventricular afterload declines with decreasing placental resistance, contributing to the reduction in end-diastolic pressure. In studies in which Doppler waveforms were recorded from the inferior vena cava and ductus venosus in growth-restricted fetuses before cordocentesis, fetal hypoxemia and acidemia were associated with more reverse flow and more pulsatile waveforms.[163,164]

CARDIAC FUNCTION

Comment: Normal ranges have been defined for Doppler flow velocity waveform indices derived from across the mitral, tricuspid, aortic, and pulmonary valves.[161,165,166] These have potential use in the assessment of cardiac function in growth-restricted fetuses and fetuses with structural heart defects. Waveforms from the ductus arteriosus show considerable individual variability[167] and do not appear to be useful in the detection of fetal compromise. Waveforms from peripheral pulmonary arteries show decreasing pulsatility with advancing gestation in healthy fetuses.[168]

CARDIAC OUTPUT
FIGURE 77

Left cardiac output (LCO) (*A*) and right cardiac output (RCO) (*B*) calculated at the level of the outflow tracts (5th, 50th, and 95th percentiles) from a longitudinal study of 26 healthy singleton fetuses studied at weekly intervals. Velocity waveforms were recorded from the ascending aorta and pulmonary artery with the flow parallel to the Doppler beam. Recordings obtained with a beam angle greater than 20 degrees were rejected. Valve diameter measurements were made from videotape images, and valve areas were calculated by assuming a circular cross-section. *Data source*: ref. 165, with permission.

Comment: Cardiac output rises progressively with gestation, with RCO slightly higher than LCO (RCO/LCO ratio ~1.3). Peak flow velocity at both the aortic and the pulmonary valves increases with gestation. This increase is attributed to progressive improvement in cardiac contractility, reduction in afterload, and increase in preload.[165] This type of calculation of volume flow is susceptible to high coefficients of variation because an error in the measurement of diameter (e.g., valve ring diameter) is magnified as the cross-sectional area is computed.

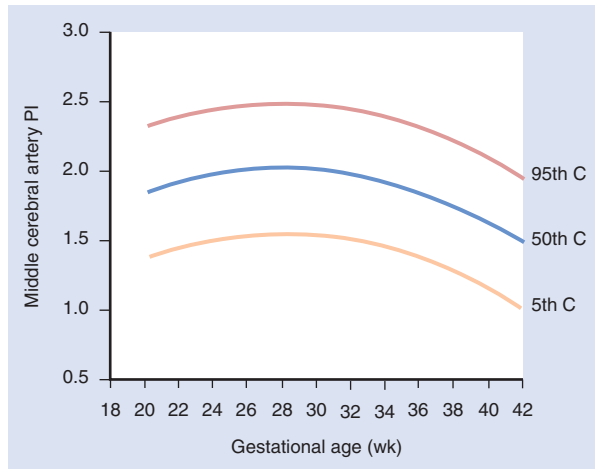
MIDDLE CEREBRAL ARTERY


FIGURE 78

Pulsatility index from the middle cerebral artery (MCA) (5th, 50th, and 95th percentiles) from a cross-sectional study of 1556 fetuses at 20 to 42 weeks gestation. All fetuses were singletons, and gestational age was confirmed by early ultrasound measurement of CRL. Color-flow imaging was used to identify the fetal MCA, and waveforms were recorded at a low angle of insonation. Good signals were obtained from 1467 fetuses. Pulsatility index was calculated (maximum systolic velocity – diastolic velocity/mean velocity). *Data source*: ref. 169, with permission.

Comment: A longitudinal study of MCA Doppler waveforms found that pulsatility index values are higher at 25 to 30 weeks' gestation than those at 15 to 20 weeks, or toward term.[171] Diameter of the fetal MCA increases with gestational age. In one study, calculated volume blood flow in the artery increased from 23 mL/min at 19 weeks' gestation to 133 mL/min at term.[172] Doppler waveforms from the MCA may also be quantitated with a resistance index (maximum systolic velocity – minimum diastolic velocity/systolic velocity).[173] When MCA waveforms are recorded, care must be taken to apply minimal pressure to the maternal abdomen because fetal skull compression may alter MCA flow.[174] Different signals are obtained in the distal portion of the MCA, and most studies have concentrated on the proximal portion, close to the circle of Willis.[175] Changes in MCA Doppler waveforms are noted in growth-restricted fetuses, suggesting that fetal cardiac output may be redistributed to preserve brain blood.[171,174,175] High MCA peak systolic velocities are associated with fetal anemia in pregnancies complicated by maternal alloimmunization.[176,177]

FIGURE 79

Peak systolic velocity from the MCA (5th, 50th, and 95th percentiles) from a cross-sectional study of 331 women at 19 to 40 weeks' gestation. All fetuses were singletons, and none of the pregnancies was complicated by blood group antibodies, hypertension, diabetes, or congenital abnormalities. Only one measurement from each fetus was included in the study. The MCA was identified in an axial section of the fetal brain and insonated at a low angle. The highest point on the waveform (peak systolic velocity) was measured. *Data source*: ref. 170, with permission.

DESCENDING AORTA

FIGURE 80

Descending aorta pulsatility index (5th, 50th, and 95th percentiles) from a cross-sectional study of 1556 healthy pregnancies at 20 to 42 weeks' gestation. All fetuses were singletons, and gestational age was confirmed by early ultrasound measurement of CRL. Recordings from the thoracic portion of the descending aorta were made in the absence of fetal body or breathing movements. Satisfactory recordings were obtained in 1398 fetuses. The pulsatility index was calculated (systolic velocity – diastolic velocity/mean velocity). *Data source*: ref. 169, with permission.

Comment: Unlike in other fetal vessels, no significant change with gestation was seen in the aortic pulsatility index.

UMBILICAL ARTERY
FIGURE 81

Umbilical artery pulsatility index (5th, 50th, and 95th percentiles) from a cross-sectional study of 1556 healthy pregnancies at 20 to 42 weeks' gestation. All fetuses were singletons, and gestational age was confirmed by early ultrasound measurement of CRL. Recordings from the umbilical artery were made in the absence of fetal body or breathing movements. The pulsatility index was calculated (systolic velocity – diastolic velocity/ mean velocity). *Data source*: ref. 169, with permission.
FIGURE 82

Umbilical artery resistance index (5th, 50th, and 95th percentiles) from a cross-sectional study of 1675 pregnancies at 24 to 42 weeks' gestation. Each fetus contributed only one measurement to the study. Signals were recorded from a free-floating loop in the middle of the umbilical cord. Resistance (Pourcelot) index was calculated (systolic diastolic velocity/ systolic velocity). *Data source*: ref. 173, with permission.
FIGURE 83

Systolic-to-diastolic ratio (A/B ratio) calculated from umbilical artery flow velocity waveforms (mean ± 2 SDs) obtained in a longitudinal study of 15 normal pregnancies. Study subjects were scanned every 2 weeks, from 24 to 28 weeks' gestation until delivery. Eight of the study subjects had been recruited at 16 weeks and were also scanned every 4 weeks throughout the second trimester. In all subjects, gestational age was confirmed by ultrasound scanning at 16 weeks' gestation. A range-gated pulsed Doppler beam was guided from the ultrasound image to insonate the umbilical artery. *Data source*: ref. 178, with kind permission from Elsevier Science Ireland Ltd, Co. Clare, Ireland.

Comment: After 16 weeks' gestation, forward flow occurs in umbilical arteries throughout the cardiac cycle, as evidenced by positive Doppler shift frequencies, even at the end of diastole. Decreasing values for the resistance index, pulsatility index, and A/B ratio with gestation are interpreted as indicating decreasing resistance in the placental circulation.

FETAL-PLACENTAL DOPPLER RATIOS

Comment: Various ratios have been suggested to compare fetal cerebral flow velocity waveforms with those from the umbilical artery or aorta. These waveforms may be useful in detecting alterations in fetal cardiac output distribution (e.g., in response to fetal hypoxemia ["brain-sparing" effect]). The placentocerebral ratio[173] describes resistance indices from the umbilical artery and MCA. The cerebroplacental ratio[179] describes resistance indices from the MCA and umbilical artery. The umbilical artery–to–MCA ratio[169] describes pulsatility indices from the umbilical artery and MCA. The descending thoracic aorta–to–MCA ratio[169] describes pulsatility indices from the descending thoracic aorta and MCA.

Cardiovascular and Behavioral Parameters
UMBILICAL VENOUS PRESSURE
FIGURE 84
Umbilical venous pressure (mean and 95% CI) from 27 fetuses referred for assessment of possible intrauterine infection or hemolysis, but subsequently shown to be unaffected. All of the fetuses underwent cordocentesis. After the necessary blood samples were obtained, the needle was connected to a pressure transducer. The transducer was placed at the level of the fetal heart, and the pressure was read at its nadir. The needle was confirmed to be in the umbilical vein by the nonpulsatile pressure tracing that was obtained and by observing the direction of flow of injected saline. As the needle was withdrawn, pressure in the amniotic cavity was recorded. Umbilical venous pressure was calculated by subtracting the amniotic pressure from the measured umbilical venous pressure. *Data source*: ref. 180, with permission.

Comment: Umbilical venous pressure increases with advancing gestation, but remains within a narrow range. Values above the CI are associated with cardiac failure.[181]

MEAN UMBILICAL ARTERIAL PRESSURE
FIGURE 85
Mean umbilical arterial pressure (mean and 95% CI) from 30 normal fetuses referred for assessment of possible infection or hemolysis, but found to be unaffected. The method was identical to that described in Figure 67. It was apparent that the needle tip was in an umbilical artery rather than a vein (because of a pulsatile pressure signal). *Data source*: ref. 182, with permission.

Comment: The normal range of arterial pressure in the fetus is much narrower than the range of umbilical venous pressure. Arterial pressure increases with gestational age.

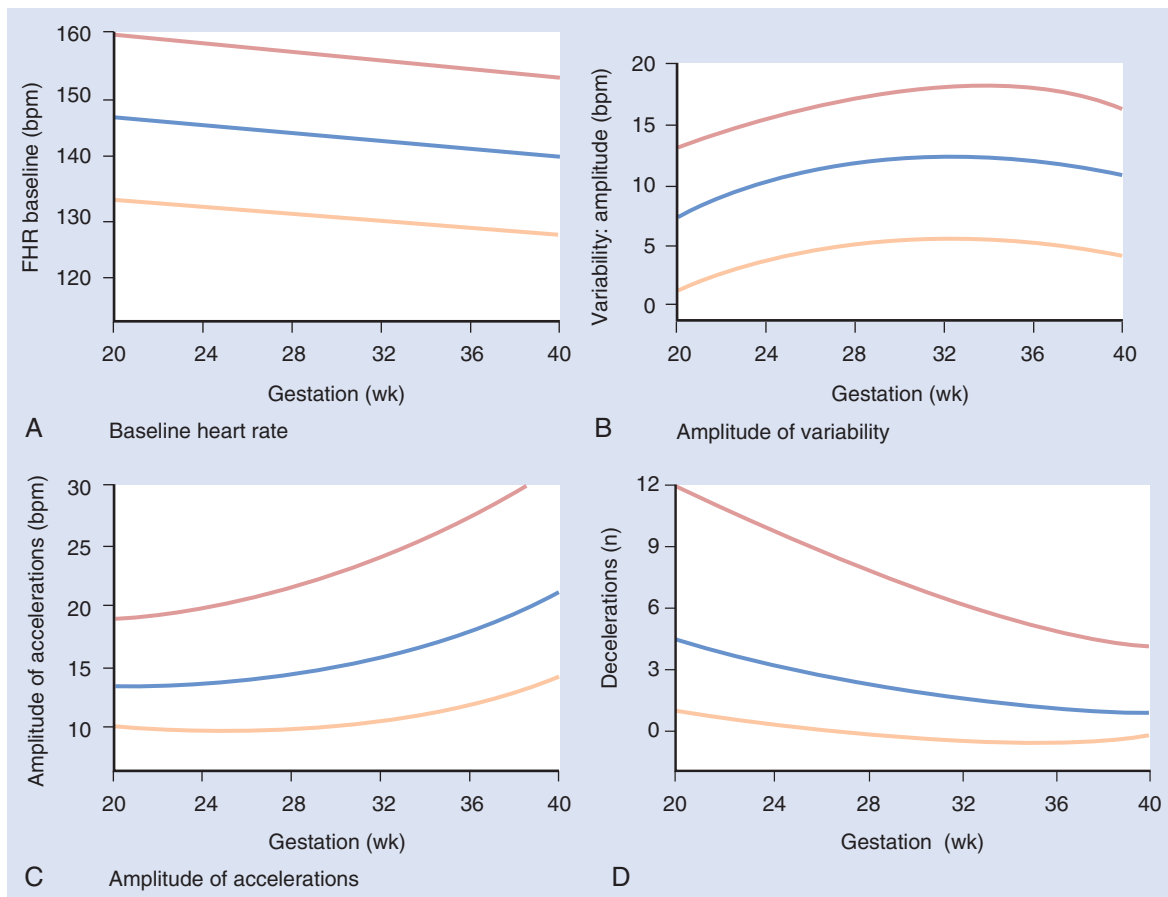
FETAL HEART RATE


FIGURE 86

Fetal heart rate (FHR) parameters (mean and 95% CI) showing the baseline heart rate (*A*), the amplitude of variability (*B*), the amplitude of accelerations (*C*), and the number of decelerations (*D*). Data were obtained from a cross-sectional study of 119 pregnancies at 20 to 39 weeks' gestation. Study subjects were referred for prenatal diagnosis by cordocentesis. In all cases, fetal blood gas values, Hb, and karyotype were subsequently shown to be normal. None of the fetuses had hydrops fetalis or a cardiac defect. FHR monitoring was performed immediately before cordocentesis for 30 minutes, and tracings were examined for baseline heart rate, variability, accelerations, and decelerations. *Data source*: ref. 183, with permission from S Karger AG, Basel.

• At least two accelerations (>15 beats for >15 s) in 20 min, baseline heart rate 110–150 bpm, baseline variability 5–25 bpm, absence of decelerations.

• Sporadic decelerations amplitude <40 bpm are acceptable if duration <15 s, or <30 s following an deacceleration.

• When there is moderate tachycardia (150–170 bpm) or bradycardia (100–110 bpm) a reactive trace is reassuring of good health.

Comment: Baseline FHR decreases with gestation, but the variability of the baseline increases. The number and amplitude of accelerations increase with gestation. Spontaneous decelerations are common in the second and early third trimesters, but rarely in healthy fetuses approaching term. Definitions of the features of normal and abnormal cardiotocograms are available.[185] During labor, criteria for the interpretation of FHR tracings are different (see Fig. 105).

FIGURE 87

Features of a normal antepartum cardiotocogram (nonstress test). *Data source*: ref. 184, with permission.

BIOPHYSICAL PROFILE SCORE

Fetal variable	Normal behavior (score = 2)	Abnormal behavior (score = 0)
Fetal breathing movements	More than one episode of 30 s duration, intermittent within a 30 min overall period. Hiccups count. (Not continuous throughout the observation time)	Repetitive or continuous breathing without cessation. Completely absent breathing or no sustained episodes
Gross body/limb movements	Three or more discrete body/limb movements in a 30 min period. Continuous active movement episodes are considered as a single movement. Also included are fine motor movements, positional adjustments and so on.	Two or fewer body/limb movements in a 30 min observation period
Fetal tone and posture	Demonstration of active extension with rapid return of flexion of fetal limbs, brisk repositioning/trunk rotation. Opening and closing of hand, mouth, kicking, etc.	Only low-velocity movements, incomplete return to flexion, flaccid extremity positions; abnormal fetal posture. Includes score = 0 when FM absent
Fetal heart rate reactivity	Greater than 2 significant accelerations associated with maternally palpated fetal movement during a 20 min cardiotocogram. (Accelerations graded for gestation: 10 beats/min for 10 s before 26 weeks; 15 beats/min for 15 s after 26 weeks; 20 beats/min for 20 s at term)	Fetal movement and accelerations not coupled. Insufficient accelerations, absent accelerations, or decelerative trace. Mean variation <20 on numerical analysis of CTG
Amniotic fluid volume evaluation	One pocket of >3 cm without umbilical cord loops. More than 1 pocket of >2 cm without cord loops. No elements of subjectively reduced amniotic volume.	No cord-free pocket >2 cm, or elements of subjectively reduced amniotic fluid volume definite

FIGURE 88

Scoring system for five fetal biophysical variables (breathing movements, gross body and limb movements, tone and posture, heart rate reactivity, and amniotic fluid volume) developed for the assessment of patients with high risk pregnancies. This scoring system was evaluated in 216 patients who were studied in the week before delivery and whose eventual pregnancy outcome was documented. No perinatal deaths occurred in this study when all five variables were present at the time of examination with ultrasound and cardiotocography (CTG). Low scores (≤6 of 10) were associated with an increased incidence of adverse outcomes (i.e., fetal distress in labor, Apgar scores ≤ 7 at 5 min, perinatal death). More recent studies with greater numbers have demonstrated a significant relationship between low biophysical profile scores (BPSs) and poor fetal acid-base status, intrauterine growth restriction, perinatal mortality, and cerebral palsy. *Data source*: refs. 186–188, with permission.

Comment: Various means of monitoring fetal well-being antenatally have been proposed (i.e., CTG, observation of fetal breathing patterns, measurement of amniotic fluid volume). Scoring systems that consider a combination of behavioral parameters are better able to detect a compromised fetus and allow early delivery.[187] The use of these scoring systems led to improved perinatal mortality rates, even in a high risk group of pregnant women.[188] Fetal behavior is periodic and is affected by external factors (e.g., maternal ingestion of stimulant or depressant drugs, maternal hypoglycemia or hyperglycemia) and by structural or genetic abnormalities. Fetal behavior changes abruptly from a quiescent pattern to an active pattern and vice versa; therefore, ultrasound observation may need to be extended for 30 or 40 minutes to confirm the absence of fetal movements or breathing. Most BPS studies are completed in less than 10 minutes.[186] Acute events may occur that invalidate the predictive accuracy of the BPS (e.g., abruptio placentae, diabetic ketoacidosis, eclampsia).

Biochemistry

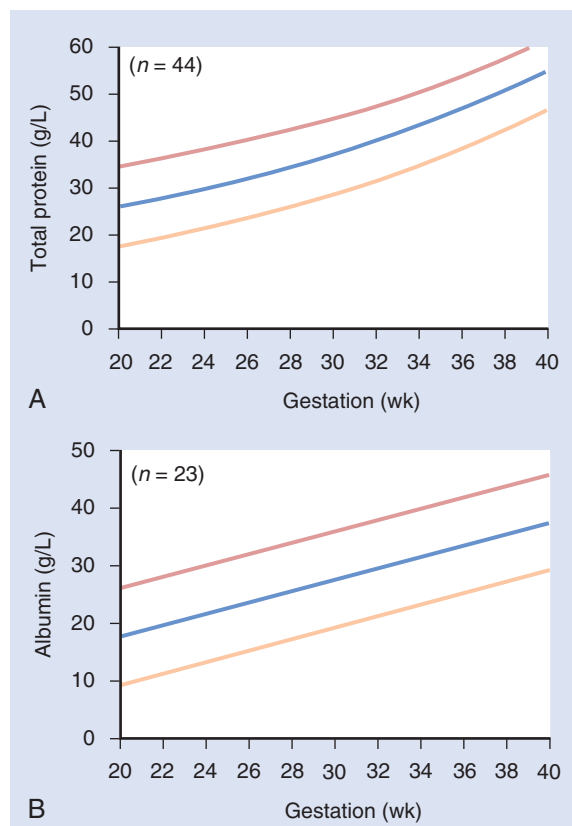
Proteins


FIGURE 89

Total protein (*A*) and albumin (*B*) concentrations (regression curve and 95% CI) from a cross-sectional study of 45 fetuses subsequently shown to be normal at birth. Blood samples were obtained by ultrasound-guided cordocentesis. *Data source*: ref. 189, with permission.

Renal Function Tests, Liver Function Tests, and Glucose

	SI units (mean ± SD)	Traditional units (mean ± SD)
Glucose	4.3 ± 0.6 mmol/L	7.7 ± 1.1 mg/dL
Cholesterol	1.5 ± 0.3 mmol/L	59 ± 11 mg/dL
Uric acid	179 ± 39 mol/L	2.8 ± 0.6 mg/dL
Triglycerides	4.5 ± 1.1 µmol/L	40 ± 10 mg/dL
Total bilirubin	26.3 ± 5.8 µol/L	15 ± 0.3 mg/dL
Alkaline phosphatase	260 ± 65 IU/L	
Gamma glutamyl transferase	60 ± 34 IU/L	
Asparate transaminase	17 ± 6.5 IU/L	
Creatinine	1.8 ± 0.3 µmol/L	0.02 ± 0.003 mg/dL
Calcium	2.3 ± 0.2 mmol/L	9.2 ± 0.8 mg/dL

FIGURE 90

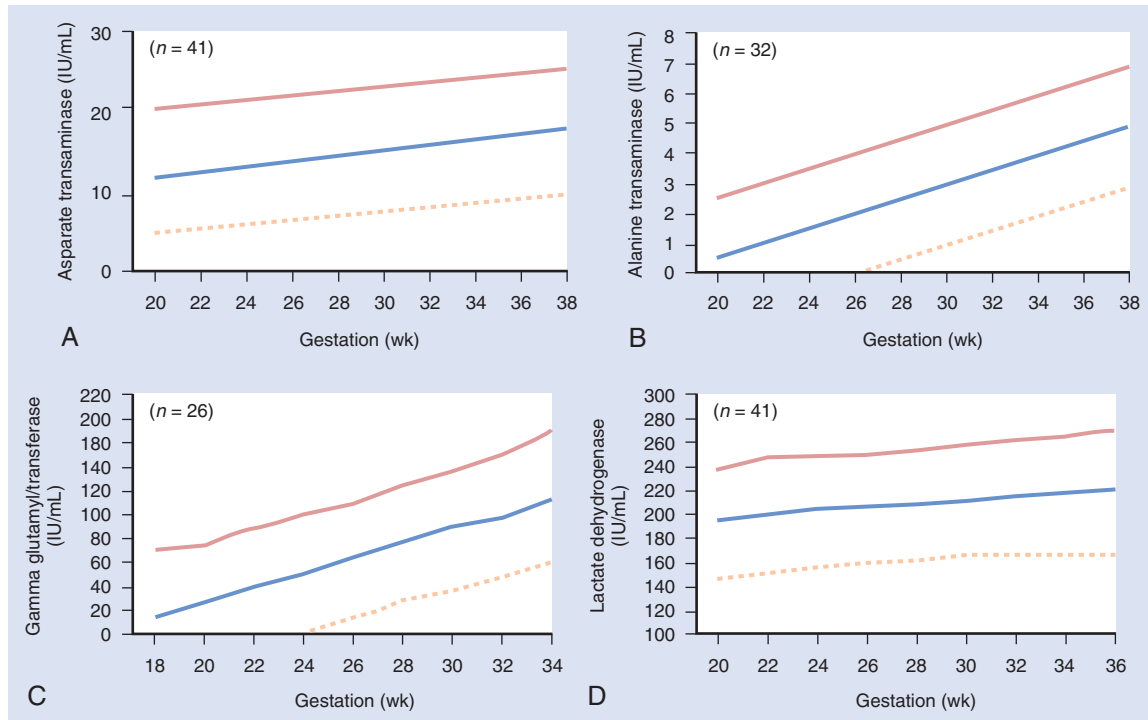
Glucose, calcium, liver function, and renal function test results (mean ± SD) from a cross-sectional study of 78 fetuses at 20 to 26 weeks' gestation; all fetuses were subsequently shown to be healthy at birth. Blood samples were obtained by ultrasound-guided cordocentesis. *Data source*: ref. 190, with permission.


FIGURE 91
AST (*A*), ALT (*B*), GGT (*C*), and lactate dehydrogenase (LDH) (*D*) concentrations (regression line and 95% CI) from a cross-sectional study of 80 fetuses referred for assessment of possible intrauterine infection or hemolysis, but subsequently shown to be unaffected. All study subjects underwent cordocentesis, and blood samples were obtained for liver enzyme assays. Individual graphs show the number of assays performed for each enzyme. *Data source*: ref. 180, with permission.

Comment: Plasma total protein and albumin concentrations increase significantly with gestational age.[189] Little information is available about many other biochemical variables. Triglyceride levels decrease with advancing gestation,[190] bilirubin levels increase,[191] and liver enzyme concentrations (other than LDH) increase.[180] Fetal concentrations of bilirubin are higher and triglyceride and cholesterol concentrations are lower than those in maternal serum.[190] Fetal plasma insulin levels increase with gestation.[192]

	16 weeks	33 weeks
Phosphate (mmol/L)	0.91	0.10
Creatinine (μmol/L)	99.9	172.9
(mean values)		

A

	Mean value	95% confidence intervals (CI)
Potassium (mmol/L)	3.0	0–6.1
Calcium (μmol/L)	0.21	0.04–1.2
Urea (μmol/L)	7.9	2.6–13.1

B

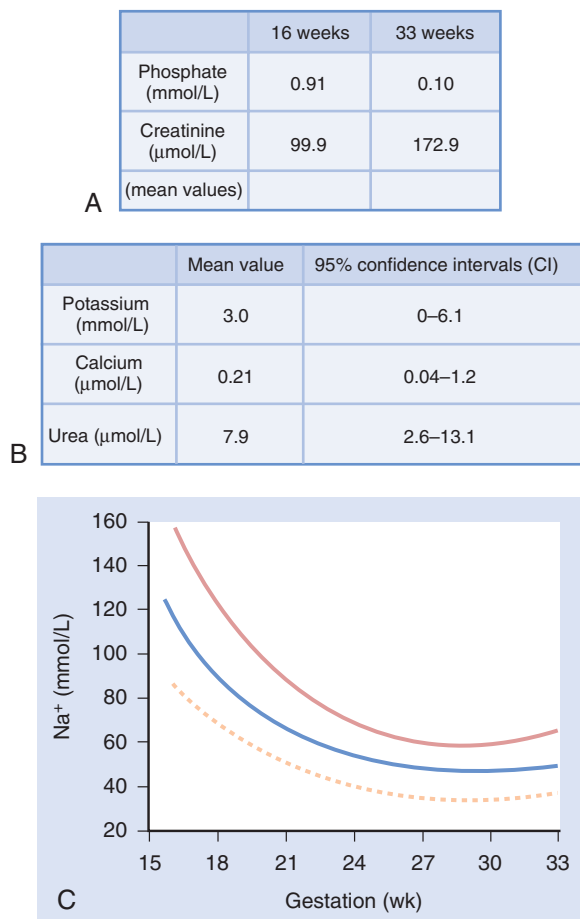
C


FIGURE 92

Urinary electrolytes, including phosphate, creatinine (*A*), potassium, calcium, urea (*B*), and sodium (*C*) (mean and 95% CI, where computed) from a study of 26 women at 16 to 33 weeks' gestation. Amniotic fluid volume and fetal anatomy were normal. Seventeen of the women had pregnancies complicated by Rhesus alloimmunization; in these cases, the fetal bladder was emptied before intraperitoneal blood transfusion. The other women had aspiration of the fetal bladder before therapeutic termination. *Data source*: ref. 193, with permission.
FIGURE 93

Urinary creatinine (5th, 50th, and 95th percentiles) from a study of 20 fetuses with obstructive uropathy and no features of renal dysplasia. All fetuses had normal postnatal renal function. Ultrasound-guided needle aspiration of fetal urine was performed. The fetal bladder was aspirated when it was distended, and both kidneys appeared similar; the renal pelvis was aspirated when unilateral pelvicaliceal dilation was seen. In all cases, the fetal karyotype was normal. *Data source*: ref. 194, with permission.

Comment: Previously, fetal urinary biochemistry had been studied only indirectly from examination of the amniotic fluid.[156] These direct studies found that urinary sodium and phosphate levels decreased significantly with gestational age over the period studied (16–33 wk); creatinine levels increased. Urinary potassium, calcium, and urea did not show gestational changes. The pattern of electrolyte changes suggests parallel maturation of glomerular and tubular function with advancing gestation. Fetuses with obstructive uropathy but normal postnatal renal function[194] had sodium and urea values similar to those shown in Figure 92. However, reference ranges for urinary calcium were calculated as 0.25, 0.95, and 1.65 mmol/L (5th, 50th, and 95th percentiles, respectively).[194] Various groups have suggested urinary electrolyte values that predict an adverse outcome (e.g., sodium level > 100 mmol/L, creatinine level > 150 μmol/L [1.7 mg/dL], calcium level > 2 mmol/L [8 mg/dL], osmolality > 200 mOsm/L). However, these values are not universally accepted.[195,196] These data show that sodium concentration of greater than 100 mmol/L may be normal for fetuses at less than 20 weeks' gestation.

Blood Gases

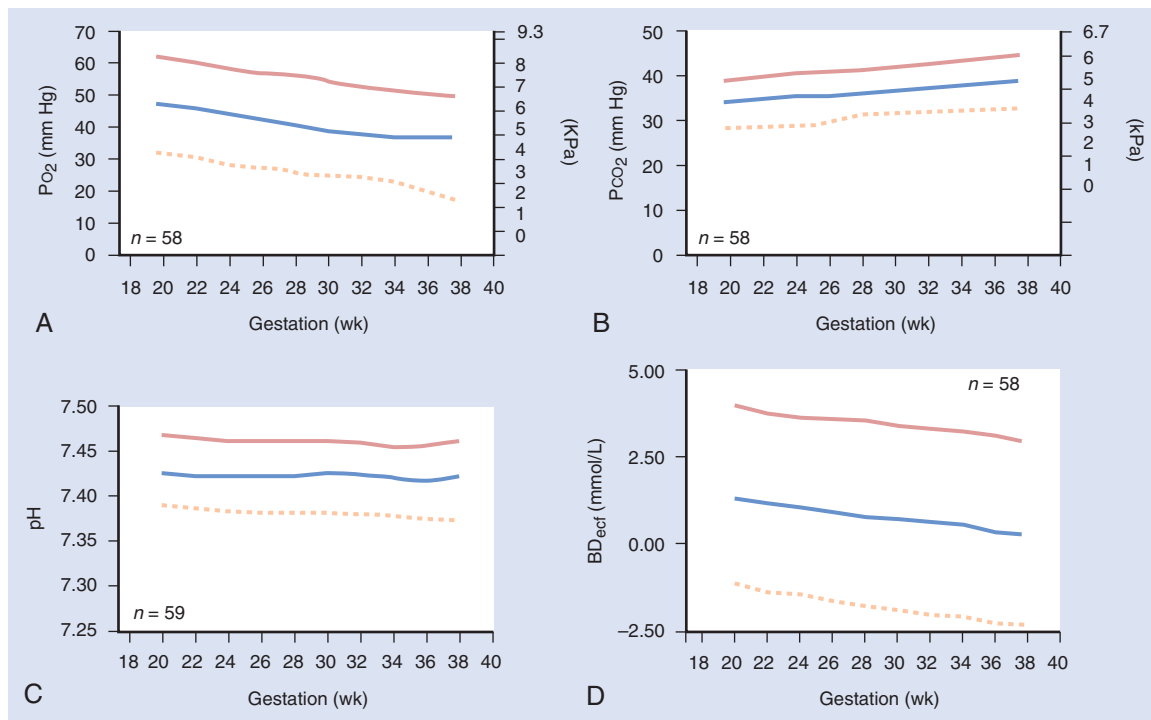
OXYGEN PRESSURE, CARBON DIOXIDE PRESSURE, PH, AND BASE DEFICIT


FIGURE 94

Umbilical venous Po_2 (*A*), Pco_2 (*B*), pH (*C*), and base deficit of the extracellular fluid (*D*) (2.5th, 50th, and 97.5th percentiles) from a cross-sectional study of 59 fetuses referred for assessment of possible intrauterine infection or hemolysis, but found to be unaffected. All were healthy at birth and appropriately grown. *Data source*: ref. 197, with permission.

Comment: Umbilical arterial and venous PO_2 and pH decrease, and PCO_2 increases with gestational age.[198] Concentrations of lactate do not change with gestation; mean (SD) values are 0.99 mmol/L (0.32) for the umbilical vein and 0.92 mmol/L (0.21) for the umbilical artery.[198] Intervillous blood has higher PO_2, and lower PCO_2 than umbilical venous blood, but similar pH and lactate concentrations.[199] The decrease in PO_2 in umbilical venous blood that is seen with advancing gestation is offset by the increasing fetal Hb concentration. As a result, the blood oxygen content remains constant; mean umbilical venous oxygen content is 6.7 mmol/L (0.6).[199]

Hematology
Complete Blood Count

Gestational age (weeks)	WBC (10^9/L)	PLT (10^9/L)	RBC (10^{12}/L)	Hb (g/dL)	MCV (fL)
18–23 ($n = 771$)	4.41 ± 1.2	241 ± 45	2.87 ± 0.2	11.7 ± 0.8	131.2 ± 7.3
24–29 ($n = 407$)	4.6 ± 1.3	267 ± 49	3.38 ± 0.32	12.8 ± 1.1	119.1 ± 5.6
30–35 ($n = 55$)	5.8 ± 1.6	265 ± 59	3.86 ± 0.43	14.1 ± 1.4	114.3 ± 7

FIGURE 95
White blood cell (WBC) count, platelet (PLT) count, red blood cell (RBC) count, Hb, and mean cell volume (MCV) from a cross-sectional study of 1233 normal fetuses at 18 to 36 weeks' gestation (mean ± SD). Study subjects were referred for fetal blood sampling for prenatal diagnosis (mostly toxoplasmosis), but the fetuses were normal and subsequently shown to be healthy at birth. Fetal blood samples were taken by ultrasound-guided cordocentesis. *Data source*: ref. 189, with permission.
FIGURE 97
Fetal reticulocyte count (mean and 95% CI) from a cross-sectional study of 81 fetuses referred for prenatal diagnosis for a variety of indications, but subsequently shown to be unaffected. Ultrasound-guided cordocentesis was performed to obtain blood samples. *Data source*: ref. 201, with permission.

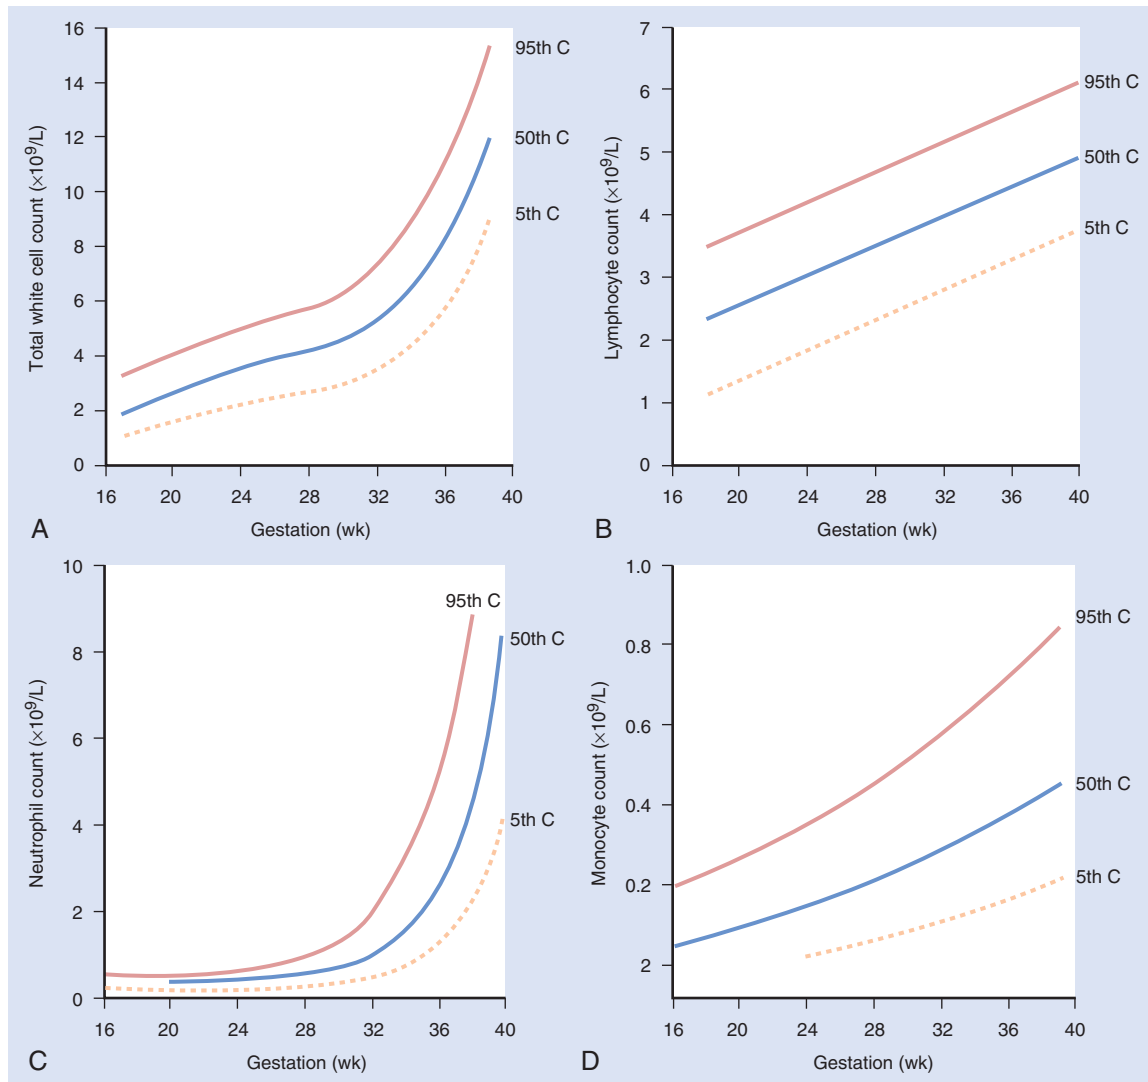
$$Hb = 7.8 + 0.19 \times (\text{weeks gestation})$$
FIGURE 96
Hb (5th, 50th, and 95th percentiles) from a study of 194 fetuses at 17 to 40 weeks' gestation. The fetuses were undergoing prenatal diagnosis, but were unaffected for the condition tested. *Data source*: ref. 200, with permission.
FIGURE 98
Hematocrit (regression line and 95% CI) from a cross-sectional study of 81 fetuses referred for prenatal diagnosis for a variety of indications, but subsequently shown to be unaffected. Ultrasound-guided cordocentesis was performed to obtain blood samples. *Data source*: ref. 201, with permission.


FIGURE 99
Total WBC (*A*), lymphocyte (*B*), neutrophil (*C*), and monocyte (*D*) counts (5th, 50th, and 95th percentiles) from umbilical cord blood samples obtained at cordocentesis (*n* = 316) or elective cesarean delivery (*n* = 11) from fetuses at 18 to 40 weeks' gestation. Cordocentesis was performed for karyotyping, prenatal diagnosis, evaluation of infection, or blood typing, but all fetuses included in the study were unaffected by the condition being studied. The fetuses studied at the time of elective cesarean delivery were normal and appropriately grown. The indication for cesarean delivery was breech presentation or uterine scar. *Data source*: ref. 202, with permission.

Comment: Fetal RBC count and total Hb increase linearly, reticulocyte count decreases linearly, and erythroblast count decreases exponentially with gestation.[200–202] PLT count does not change.[190] Lymphocytes form the main population of white cells in the fetus until 37 to 38 weeks' gestation.[202] From 32 weeks onward, neutrophils become more plentiful, and by term, they form approximately 60% of the total WBC count.[202] Natural killer cells are the main type of circulating WBC in the first trimester.[202,203] Interferon-γ concentrations (5th–95th percentiles) are high in the first trimester (0.4–3.1 U/mL) and decrease to 0.2 to 1.7 U/mL in the third trimester.[203] Fetal Hb decreases with advancing gestation, from more than 80% of total Hb in midpregnancy to approximately 70% by term.[190]

Coagulation Factors

Coagulation factors	%	Inhibitors	%
VIIIC	40 ± 12	Fibronectin	40 ± 10
VIIIRAg	60 ± 13	Protein C	11 ± 3
VII	28 ± 5	α2-Macroglobulin	18 ± 4
IX	9 ± 3	α1-Antitrypsin	40 ± 4
V	47 ± 10	AT III	30 ± 3
II	12 ± 3	α2-Antiplasmin	61 ± 6
XII	22 ± 3		
Preallikrein	19 ± 2		
Fibrin-stabilizing factor	30 ± 5		
Fibrinogen	40 ± 15		
Plasminogen	24 ± 15		

FIGURE 100
Coagulation factors (percentage of normal adult values; mean ± SD) from a cross-sectional study of 103 fetuses at 19 to 27 weeks' gestation. All fetuses were subsequently shown to be healthy. Blood samples were obtained by ultrasound-guided cordocentesis. *Data source*: ref. 190, with permission.

Comment: No changes in the level or activity of the various coagulation factors and their inhibitors were observed through the 8 weeks of gestation studied.

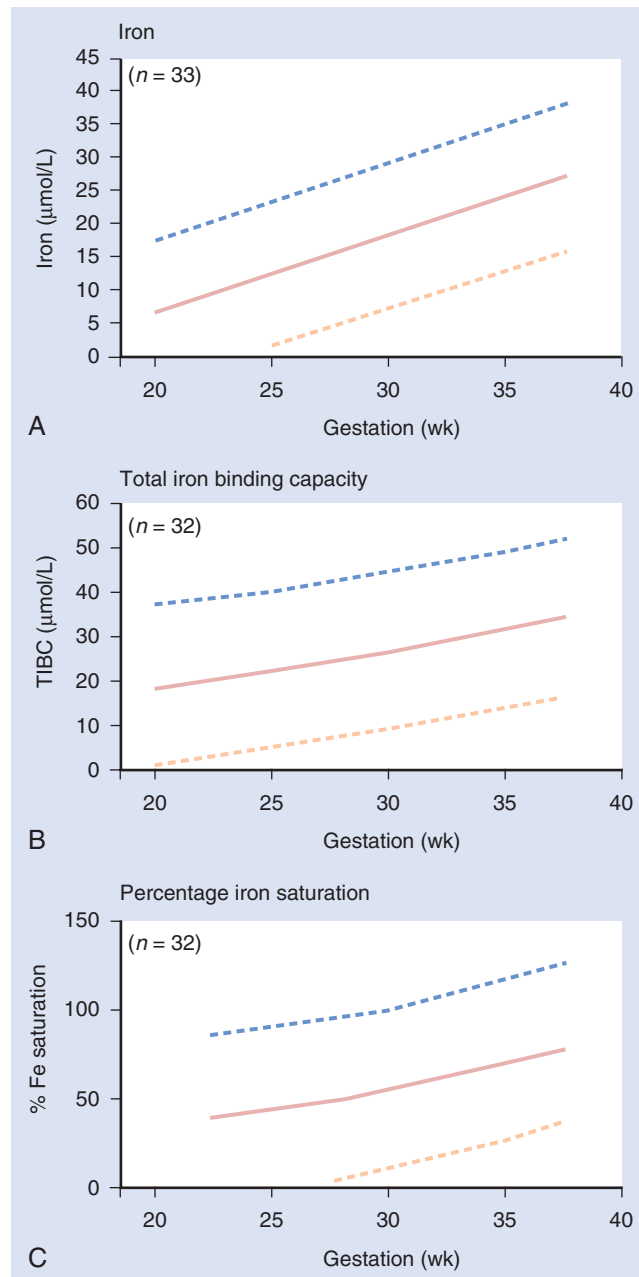
Iron Metabolism


FIGURE 101
Fetal iron (*A*), total iron-binding capacity (TIBC) (*B*), and percentage of iron saturation (*C*) from a cross-sectional study of 33 fetuses referred for prenatal diagnosis for a variety of indications, but subsequently found to be unaffected. Blood samples were taken by ultrasound-guided cordocentesis. *Data source*: ref. 204, with permission.

Comment: Fetal iron, TIBC, and percentage of iron saturation increase with advancing gestation.

Amniotic Fluid Bilirubin
FIGURE 102   Amniotic fluid bilirubin ΔOD450 (mean ± 2 SDs) from 475 samples of amniotic fluid obtained from pregnancies at 16 to 36 weeks' gestation. The pregnancies were not complicated by fetal hemolysis. Amniotic fluid samples obtained at fetoscopy or by amniocentesis were placed in darkened containers to protect against photodecomposition and centrifuged to remove vernix and cellular debris. The bilirubin concentration was measured spectrophotometrically by the deviation in optical density of the amniotic fluid at a wavelength of 450 nm. *Data source*: ref. 205, with permission.

Comment: The normal range of liquor ΔOD450 does not change between 16 and 25 weeks' gestation, but values decrease during the third trimester and are widely scattered.

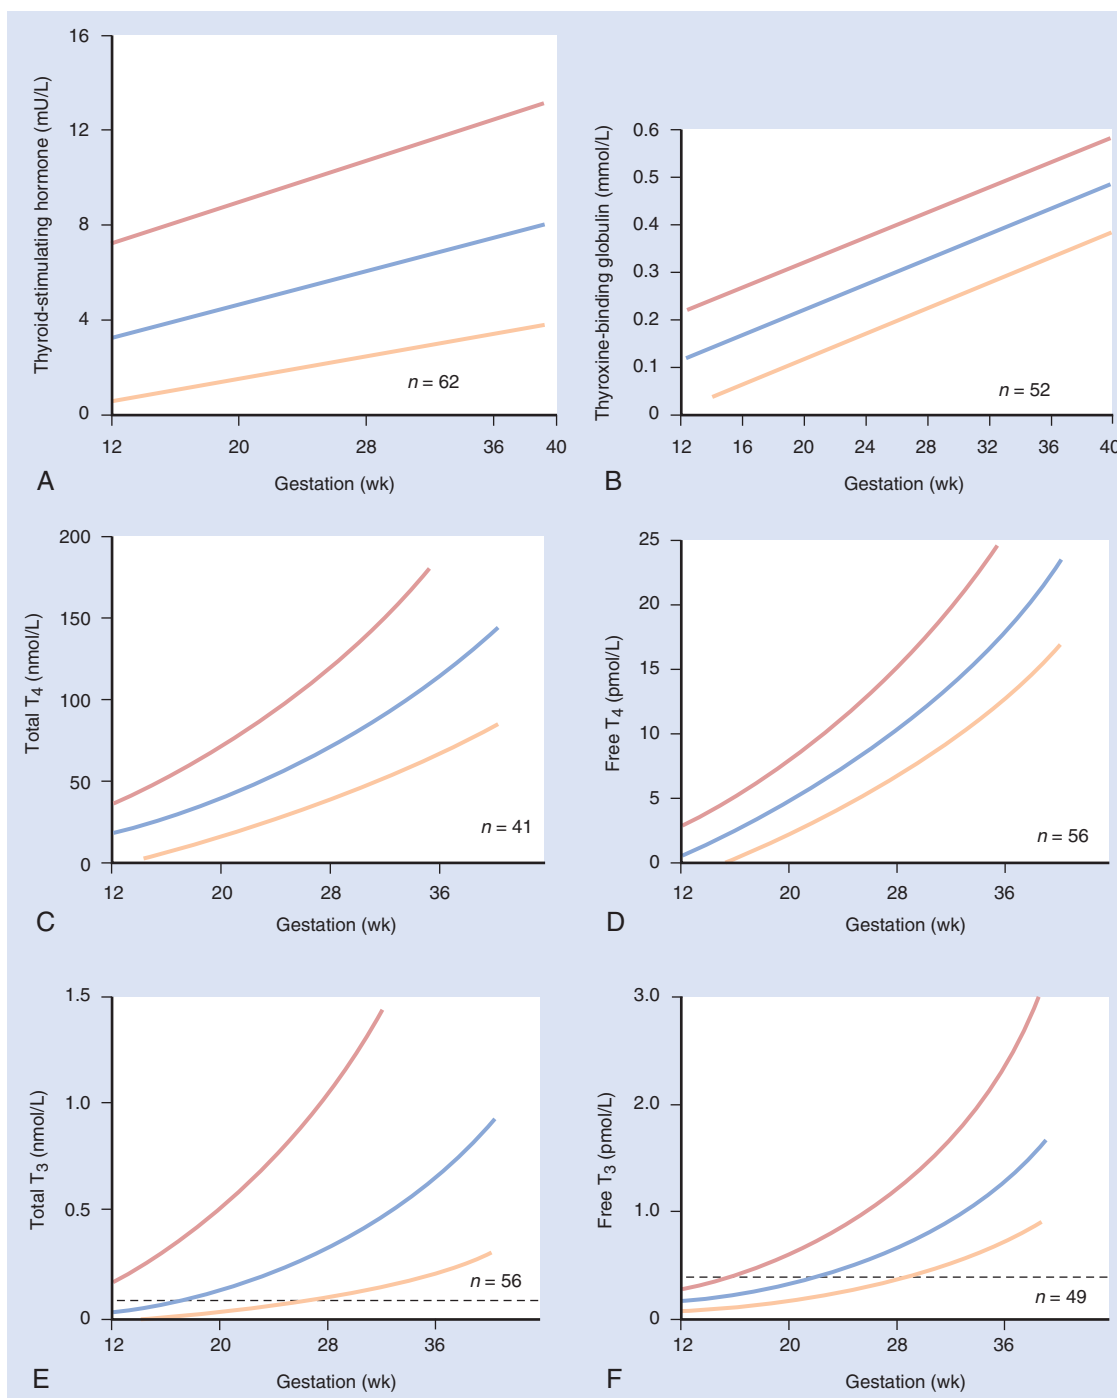
Endocrinology
Thyroid Function


FIGURE 103

TSH (*A*), TBG (*B*), total T_4 (*C*), free T_4 (*D*), total T_3 (*E*), and free T_3 (*F*) from a study of 62 women who underwent cordocentesis or cardiocentesis for prenatal diagnosis. Fetuses were subsequently found to be normal (mean, 5th, and 95th percentiles). The *cross-hatched area* is the lower limit of sensitivity of the assay. *Data source*: ref. 206, with permission.

Comment: No significant associations have been found between fetal and maternal thyroid hormones and TSH concentrations, suggesting that the fetal pituitary-thyroid axis is independent of the maternal axis.[206] Fetal TSH levels are always higher than maternal levels. Fetal free and total T_4 levels and TBG levels increase throughout pregnancy and reach adult levels by 36 weeks' gestation; however, fetal free and total T_3 levels are always substantially lower than adult levels. The increase in fetal levels of TSH, thyroid hormones, and TBG during pregnancy indicates independent and autonomous maturation of the pituitary, thyroid, and liver, respectively.[206] There does not appear to be feedback control of pituitary secretion of TSH by circulating thyroid hormones in utero.

LABOR

Progress of Labor
FIGURE 104

Mean cervimetric progress of white primigravidae (A) and white multigravidae (B) from a study of 3217 consecutive women in labor, from which a group of 1306 who had normal labor were identified (i.e., women with a cephalically presenting fetus who did not have epidural block, receive oxytocic drugs, or require instrumental delivery). The progress of labor was followed by vaginal examination to establish cervical dilation. The first examination was performed soon after admission to the labor suite. The onset of the second stage was confirmed when full cervical dilation was found on routine examination or when the patient was beginning to bear down. *Data source*: ref. 207, with permission.

Comment: This study found that mean cervimetric progress from 1 to 7 cm was faster in white multiparae than in primiparae, but thereafter, progress in the two groups was similar. No significant differences in the cervimetric progress of labor between women from different racial groups has been found.[207] The mean duration of the second stage of labor is approximately 42 minutes in primiparae and 17 minutes in multiparae,[207] although the precise onset of full cervical dilation is difficult to establish.

Fetal Heart Rate Parameters by Cardiotocography

Admission test CTG
- At least two accelerations (>15 beats for >15 s) in 20 minutes.
- Baseline heart rate 110–150 bpm.
- Baseline variability 5–25 bpm.
- Absence of decelerations.
- Moderate tachycardia/bradycardia and accelerations.

First stage intrapartum CTG
- At least two accelerations (>15 beats for >15 s) in 20 minutes.
- Baseline heart rate 110–150 bpm.
- Baseline variability 5–25 bpm.
- Early decelerations (in late first stage of labor).

Second stage intrapartum CTG
- Normal baseline heart rate, normal baseline variability and no decelerations, both periodic and scattered.
- Baseline heart rate 110–150 bpm and baseline variability 5–25 bpm or >25 bpm, with or without early and/or variable decelerations.

FIGURE 105
Features of the normal cardiotocogram in labor. *Data source*: ref. 184, with permission.

Comment: Guidelines defining the parameters for normal CTG have been established by working groups, but are based on opinion and clinical experience rather than research evidence. The definitions here are taken from the International Federation of Obstetricians and Gynecologists (FIGO). Different interpretations are available from the Royal College of Obstetricians and Gynaecologists (RCOG) in Britain[208] and the American College of Obstetricians and Gynecologists (ACOG) in the United States.[185] There are differences in the range of baseline heart rates accepted as normal (lower limit 110–120 beats/min; upper limit 150–160 beats/min) and the definitions of variability. Decelerations that are considered abnormal if identified antepartum (see Fig. 87) often occur intrapartum. Early decelerations (i.e., synchronous with contractions) are common toward the end of the first stage of labor. During the second stage of labor, both early and variable decelerations can be normal findings. Accelerations and normal baseline variability are important features of a normal CTG finding.

Umbilical Cord Blood Sampling

FIGURE 106
Umbilical arterial and venous blood gas values (pH, Po$_2$, Pco$_2$, and extracellular base deficit) from a 2-year-long study in a university hospital in the Netherlands, where cord blood samples were taken from all deliveries (95% CI). A piece of umbilical cord was isolated as soon as possible after delivery, and arterial and venous samples were taken into two heparinized syringes. Samples were analyzed within 75 minutes of delivery by an automated blood gas machine. If the difference between pH values in the umbilical artery and the vein was not at least 2 pH units, the arterial sample was rejected. Thus, 4667 arterial and 5151 venous pH samples were obtained. Smaller numbers of samples also had Po$_2$ and Pco$_2$ values measured. *Data source*: ref. 209, with permission.

Comment: The overall distribution of pH values was negatively skewed. This data set was large enough to allow for subanalysis. Values for pH were lower after cesarean section or breech delivery than after spontaneous vertex delivery. The 10th percentiles for pH in these groups were 7.12, 7.11, and 7.15, respectively. Optimal cases (no problems antenatally or during labor, spontaneous labor, second stage lasting < 30 min, vertex presentation, and a normally grown infant in good condition at birth) had 10th percentile pH values of 7.17. There were only small differences in pH between samples obtained from premature, mature, and postmature infants. Guidelines are available for optimal collection and analytical techniques.[197] In another study, significant changes in cord blood gas values were found between samples taken immediately after delivery, at 45 seconds, and 90 seconds in a study in which the umbilical cord was not clamped and continued to pulsate.[210]

Lactate

> **Comment:** Median umbilical artery lactate levels at term were found to be 4.4 mmol/L (3rd–97th percentile range 2.0–9.5 mmol/L) in a study of more than 10,000 vigorous newborns after vaginal delivery.[211] Lactate was higher in umbilical arterial than in venous samples and increased somewhat over the gestational range 34–42 weeks; numbers of samples were small for earlier gestations. Another study found lower values after elective caesarean than spontaneous vaginal delivery.[212]

Complete Blood Count

Complete blood count			
Analyte	25th centile	50th centile	75th centile
Red cell count ($\times10^{12}$/L)	4.13	4.40	4.62
Hemoglobin (mmol/L)	9.5	10.0	10.7
(g/dl)	15.3	16.1	17.2
Hematocrit (%)	45.2	47.9	50.9
Mean cell volume (fl)	107.4	109.8	113.3
Mean cell hemoglobin (fmol)	2.2	2.3	2.4
(pg)	35.4	37.1	38.7
Reticulocyte count ($\times10^9$/L)	145.8	170.0	192.6
Platelet count ($\times10^9$/L)	237	270	321
Total white cell count ($\times10^9$/L)	11.1	13.3	16.2
Neutrophil ($\times10^9$/L)	5.4	7.4	8.8
Lymphocyte ($\times10^9$/L)	3.3	3.8	5.1
Monocyte ($\times10^9$/L)	1.2	1.6	2.3
Eosinophil ($\times10^9$/L)	0.23	0.39	0.54
Basophil ($\times10^9$/L)	0.04	0.06	0.09

FIGURE 107
RBC count, hemoglobin, hematocrit, MCV, mean cell Hb, reticulocyte count, PLT count, and differential WBC count (25th, 50th, and 75th percentiles) from a study of 89 women who had been healthy during pregnancy and were nonsmokers. All were delivered after 34 weeks' gestation, and their infants were of normal birth weight and had umbilical cord pH greater than 7.20. Umbilical venous samples were taken and analyzed within 3 hours. *Data source*: ref. 213, with permission.

> **Comment:** In this study, infants of smokers had lower reticulocyte and neutrophil counts.[213] Reticulocyte counting was done by flow cytometry, which is more precise than manual counting. Full-term cord blood has more immature reticulocyte forms than does adult blood.[214] Another study found similar blood counts[215] and recommended that the lower limit for normal Hb be designated as 12.5 g/dL for term newborns.

Biochemistry

Analyte	Cord arterial (n = 179)	Cord venous (n = 390)	Adult
Na$^+$ (mmol/L)	135–143	135–143	136–146
K$^+$ (mmol/L)	3.7–6.4	3.8–6.8	3.6–4.8
Cl$^-$ (mmol/L)	102–111	102–112	96–110
Glucose (mmol/L)	2.3–6.7	2.9–7.4	4.4–6.1
Urea (mmol/L)	1.8–5.6	1.8–5.4	2.5–8.5
Creatinine (µmol/L)	45–96	51–97	65–125
Urate (µmol/L)	186–480	200–456	150–480
Phosphate (mmol/L)	1.23–2.14	1.31–2.18	0.80–1.60
Ca^{2+} (mmol/L)	2.16–2.94	2.32–2.99	2.10–2.60
Albumin (g/L)	26–40	30–41	35–48
Total protein (g/L)	43–67	46–68	60–80
Cholesterol (mmol/L)	0.8–2.5	0.9–2.5	<5.2
ALP (U/L)	77–285	87–303	36–135 (20–55 years) 37–160 (55–74 years) 50–200 (>75 years)
ALT (U/L)	4–24	4–27	5–40
AST (U/L)	16–63	17–59	10–30
CK (U/L)	71–475	82–528	10–180
LD (U/L)	206–580	201–494	90–230
CO$_2$ (mmol/L)	13–29	15–28	24–30
GGT (U/L)	20–302	27–339	8–50 (male) 6–50 (female)
Triglyceride (mmol/L)	0.10–1.04	0.13–0.97	0.55–1.7
Mg^{2+} (mmol/L)	0.49–0.80	0.50–0.79	0.6–1.0

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; LD, lactate dehydrogenase

FIGURE 108
Clinical chemistry analytes (95% CI) from umbilical arterial and venous blood compared with adult blood values. Samples were taken into heparinized tubes from the umbilical cords of 397 infants delivered at 37 to 41 weeks' gestation, before placental expulsion from the uterus. There were 310 vaginal deliveries and 87 cesarean deliveries. All infants included in the study had 5-minute Apgar scores of 8 or greater. Samples were stored at 40°C until analysis. Complete biochemistry profiles were obtained from 390 venous plasma and 179 arterial plasma samples. These were compared with the adult reference ranges from the institution (Ottawa Civic Hospital, Ottawa, Canada). *Data source*: ref. 216, with permission.

> **Comment:** All cord blood chemistry values were significantly different from adult values. No male-to-female differences were identified. Cord creatine kinase concentrations were very high, although they were similar in infants after vaginal or cesarean delivery, suggesting that this change did not relate to physical trauma.
