FOURTH EDITION

Senior Editor
David James, MA, MD, FRCOG, DCH
Emeritus Professor of Fetomaternal Medicine, Foundation Director of Medical Education
Queen's Medical Centre, Nottingham, United Kingdom

Editors
Philip J. Steer, BSc, MD, FRCOG, FCOGSA (hon)
Emeritus Professor
Faculty of Medicine
Imperial College London
Chelsea and Westminster Hospital
London, United Kingdom

Carl P. Weiner, MD, MBA, FACOG
K.E. Krantz Professor and Chair
Department of Obstetrics and Gynecology
University of Kansas School of Medicine
Kansas City, Kansas

Bernard Gonik, MD, FACOG
Professor and Fann Srere Chair of Perinatal Medicine
Department of Obstetrics and Gynecology
Wayne State University School of Medicine
Detroit, Michigan

Associate Editors
Caroline A. Crowther, MD, FRANZCOG, FRCOG, Cert MFM
Professor
Discipline of Obstetrics and Gynaecology
The University of Adelaide
Women's and Children's Hospital
North Adelaide, South Australia, Australia

Stephen C. Robson, MD, MRCOG, MBBS
Professor of Fetal Medicine
Institute of Cellular Medicine
University of Newcastle upon Tyne
Newcastle upon Tyne, United Kingdom

HIGH RISK PREGNANCY: MANAGEMENT OPTIONS ISBN: 978-1-4160-5908-0

Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

www.manaraa.com

Anthony Ambrose, MD
Associate Professor, Maternal-Fetal Medicine, Penn State University College of Medicine; Staff Physician, The Milton S. Hershey Medical Center, Hershey, Pennsylvania
Puerperal Problems

Janet I. Andrews, MD
Assistant Professor, University of Iowa, Iowa City, Iowa
Hepatitis Virus Infections

John Anthony, MB, ChB, FCOG, MPhil
Professor, Department of Obstetrics and Gynaecology, University of Cape Town; Groote Schuur Hospital, Cape Town, South Africa
Major Obstetric Hemorrhage and Disseminated Intravascular Coagulation; Critical Care of the Obstetric Patient

Domenico Arduini
Professor and Chairman, Department of Obstetrics and Gynecology, Università Roma Tor Vergata; Department of Obstetrics and Gynecology, Ospedale Fatebenefratelli Isola Tiberina, Rome, Italy
Fetal Cardiac Anomalies

Vincent T. Armenti, MD, PhD
Administrative Course Director, Human Form and Development, Professor of Pathology, Anatomy and Cell Biology, and Professor of Surgery, Jefferson Medical College, Philadelphia, Pennsylvania; Thomas Jefferson University, Philadelphia, Pennsylvania
Pregnancy after Transplantation

George Attilakos, MD, MRCOG
Consultant in Obstetrics and Fetal Medicine, St. Michael's Hospital, University Hospitals Bristol NHS Foundation Trust, Bristol, United Kingdom
Invasive Procedures for Antenatal Diagnosis

Marie-Cécile Aubry, MD
Department of Obstetrics and Gynaecology, Port Royal Hospital, Paris; Department of Obstetrics and Gynaecology, Antoine Beclere Hospital, Clamart, France
Fetal Genitourinary Abnormalities

Loraine J. Bacchus, PhD, MA, BSc
Lecturer, Gender Violence and Health Centre, Department of Public Health and Policy, London School of Hygiene & Tropical Medicine, London, United Kingdom
Domestic Violence

May Backos, MBChB, MRCOG
Consultant in Obstetrics and Gynaecology, West Middlesex University Hospital, Isleworth, Middlesex, United Kingdom
Recurrent Miscarriage

Mert O. Bahtiyar, MD
Assistant Professor, Department of Obstetrics and Gynecology, Yale University School of Medicine, New Haven, Connecticut
Fetal Cardiac Arrhythmias: Diagnosis and Therapy

David Allan Baker, MD
Professor, Department of Obstetrics, Gynecology and Reproductive Medicine, Health Sciences Center, Stony Brook University Medical Center, Stony Brook, New York; Director, Division of Infectious Diseases, Department of Obstetrics and Gynecology, Kantonsspital Schaffhausen, Schaffhausen, Switzerland
Cytomegalovirus, Herpes Simplex Virus, Adenovirus, Coxsackievirus, and Human Papillomavirus

Imelda Balchin, BSc, MBChB, MSc, MFFP, MRCOG
Academic Clinical Fellow, University College London Institute for Women's Health; Honorary Research Fellow, CEMACH, London, United Kingdom
Prolonged Pregnancy

Ahmet Alexander Baschat, MD, MB, BCh, BAO
Professor, University of Maryland School of Medicine, Baltimore, Maryland
Fetal Growth Disorders

Marie H. Beall, MD
Clinical Professor of Obstetrics and Gynecology, David Geffen School of Medicine at UCLA, Los Angeles; Vice Chair, Harbor-UCLA Medical Center, Torrance, California
Abnormalities of Amniotic Fluid Volume

Michael A. Belfort, MD, PhD
Professor (tenured), Department of Obstetrics and Gynecology, University of Utah, Salt Lake City, Utah; Director of Perinatal Research, Director, HCA Fetal Therapy Program, and Director, HCA Obstetric Telemedicine Program, Hospital Corporation of America, Mountain Star Division, Nashville, Tennessee
Postpartum Hemorrhage and Other Problems of the Third Stage

Ron Beloosesky, MD
Faculty of Medicine, Technion Israel Institute of Technology; Rambam Medical Center, Haifa, Israel
Abnormalities of Amniotic Fluid Volume

Susan Bewley, MD, FRCOG, MA
Honorary Senior Lecturer, Kings College London; Consultant Obstetrician, Kings Health Partners, London, United Kingdom
Domestic Violence

Joseph R. Biggio, Jr., MD
Director, Division of Maternal Fetal Medicine, Medical Director, Obstetric Services, and Associate Professor, Department of Obstetrics and Gynecology and Department of Genetics, University of Alabama at Birmingham, Birmingham, Alabama
Fetal Tumors

Ralph B. Blasier, MD, JD
Professor of Orthopaedic Surgery, Wayne State University; Residency Program Director, Detroit Medical Center, Detroit, Michigan
Spine and Joint Disorders

Renee A. Bobrowski, MD
Director of Maternal Fetal Medicine and Women and Children's Services, Saint Alphonsus Regional Medical Center, Boise, Idaho
Trauma

D. Ware Branch, MD
H.A. and Edna Benning Research Chair, and Professor, Obstetrics and Gynecology, University of Utah Health Sciences Center; Medical Director, Women and Newborns Clinical Program, Intermountain Healthcare, Salt Lake City, Utah
Autoimmune Diseases

Anneke Brand, PhD, MD
Professor, Department of Immunohaematology and Blood Transfusion, and Specialist, Hematology – Internal Medicine, Leiden University Medical Center, Leiden, The Netherlands
Fetal Thrombocytopenia

Christopher S. Bryant, MD
Fellow, Division of Gynecologic Oncology, Wayne State University/Karmanos Cancer Center, Wayne State University School of Medicine, Detroit, Michigan
Malignant Disease

Catalin S. Buhimschi, MD
Director, Perinatal Research, Yale University, New Haven, Connecticut
Medication

David J. Cahill, MD, MRCPI, FRCOG
Reader in Reproductive Medicine, and Head of the Academic Unit of Obstetrics and Gynaecology, University of Bristol, St. Michael's Hospital, Bristol, United Kingdom
Bleeding and Pain in Early Pregnancy

J. Ricardo Carhuapoma, MD
Assistant Professor, Department of Neurology, Neurosurgery and Anesthesiology and Critical Care Medicine, Johns Hopkins University School of Medicine; Faculty, Department of Neurology, Neurosurgery and Anesthesiology and Critical Care Medicine, The Johns Hopkins Hospital, Baltimore, Maryland
Neurologic Complications

Frank A. Chervenak, MD, MMM
Given Foundation Professor and Chairman, Weill Cornell Medical Center, New York, New York
Fetal Craniospinal and Facial Abnormalities

Lyn S. Chitty, BSc, PhD, MROCG
Professor of Genetics and Fetal Medicine, UCL Institute of Child Health; Consultant in Genetics and Fetal Medicine, University College London Hospitals NHS Foundation Trust, London, United Kingdom
Fetal Skeletal Abnormalities

Joshua A. Copel, MD
Professor, Obstetrics, Gynecology and Reproductive Sciences and Pediatrics, Yale University School of Medicine, New Haven, Connecticut
Fetal Cardiac Arrhythmias: Diagnosis and Therapy

Caroline A. Crowther, MD, FRANZCOG, FRCOG, Cert MFM
Professor, Discipline of Obstetrics and Gynaecology, The University of Adelaide, Women's and Children's Hospital, North Adelaide, South Australia, Australia
Multiple Pregnancy

Peter Danielian, MA, MD, FRCOG
Honorary Senior Lecturer, Department of Obstetrics and Gynaecology, Aberdeen University Medical School; Consultant Obstetrician, Aberdeen Maternity Hospital, NHS Grampian, Aberdeen, United Kingdom
Fetal Distress in Labor

John Maelor Davies, MA, MD, FRCP, FRCPath
Consultant Haematologist, Western General Hospital, Edinburgh, United Kingdom
Malignancies of the Hematologic and Immunologic Systems

John M. Davison, BSc, MD, MSc, FRCOG
Professor, Newcastle University, Newcastle upon Tyne, United Kingdom
Pregnancy after Transplantation

Gustaaf Dekker, MD, PhD, DCOG, FRANZCOG
Professor, Obstetrics and Gynaecology, The University of Adelaide; Director, Women's and Children's Division, Lyell McEwin Hospital, Adelaide, South Australia, Australia
Hypertension

Isaac Delke, MD
Professor, Department of Obstetrics and Gynecology, University of Florida College of Medicine; Chief, Division of Maternal-Fetal Medicine, and Medical Director, Obstetric Services, Shands Jacksonville Medical Center, Jacksonville, Florida
Induction of Labor and Termination of the Previable Pregnancy

Jeff M. Denney, MD
Clinical Instructor, Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, University of Wisconsin, Madison, Wisconsin; Physician/Research Consultant, Division of Adolescent Medicine, Department of Pediatrics, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Autoimmune Diseases

Jan Deprest, MD, PhD
University Hospitals Leuven, Leuven, Belgium
Fetal Problems in Multiple Pregnancy

Jan E. Dickinson, MD, FRANZCOG, DDU, CMFM
Professor, Maternal Fetal Medicine, School of Women's and Infants' Health, The University of Western Australia, Perth; Maternal Fetal Medicine Specialist, King Edward Memorial Hospital, Subiaco, Western Australia, Australia
Cesarean Section

Gary A. Dildy III, MD
Clinical Professor, Department of Obstetrics and Gynecology, Louisiana State University School of Medicine, New Orleans, Louisiana; Director of Maternal-Fetal Medicine, Hospital Corporation of America, Mountain Star Division, Nashville, Tennessee
Postpartum Hemorrhage and Other Problems of the Third Stage

Jodie M. Dodd, MBBS, FRANZCOG, Cert MFM
Professor, Discipline of Obstetrics and Gynaecology, The University of Adelaide, Women's and Children's Hospital, North Adelaide, South Australia, Australia
Multiple Pregnancy; Threatened and Actual Preterm Labor Including Mode of Delivery; Prelabor Rupture of the Membranes

Marc Dommergues, MD
Professor, Groupe Hospitalier Pitié Salpêtrière; Université Pierre et Marie Curie, Paris, France
Fetal Genitourinary Abnormalities

Tim Draycott, MD, MRCOG
Senior Clinical Lecturer in Obstetrics, University of Bristol; Consultant Obstetrician, Southmead Hospital, Bristol, United Kingdom
Training for Obstetric Emergencies

Joseph M. Ernest, MD
Clinical Professor, Department of Obstetrics and Gynecology, University of North Carolina, Chapel Hill; Chair, Department of Obstetrics and Gynecology, Carolinas Medical Center, Charlotte, North Carolina
Parasitic Infections

Peter A. Farndon, MSc, MB BS, MD, FRCP, DCH
Professor of Clinical Genetics, University of Birmingham; Consultant Clinical Geneticist, West Midlands Regional Genetics Service, Birmingham, United Kingdom
Genetics, Risks of Recurrence, and Genetic Counseling

Roy G. Farquharson, MD, FRCOG
Consultant Gynaecologist, Liverpool Women's Hospital NHS Foundation Trust, Liverpool, United Kingdom
Recurrent Miscarriage; Thromboembolic Disease

Tom Farrell, MBChB, MD, FRCOG
Consultant Obstetrician and Gynaecologist, Jessop Wing, Royal Hallamshire Hospital, Sheffield, United Kingdom
Diabetes

Albert Franco, MD
Assistant Clinical Professor, Department of Obstetrics and Gynecology, University of North Carolina, Chapel Hill; Assistant Director, Division of Maternal Fetal Medicine, Carolinas Medical Center, Charlotte, North Carolina
Parasitic Infections

Robert Fraser, MBChB, MD (Sheffield), FRCOG, DCH
Reader in Obstetrics and Gynaecology, University of Sheffield; Honorary Consultant in Obstetrics and Gynaecology, Jessop Wing, Royal Hallamshire Hospital, Sheffield, United Kingdom
Diabetes

Harry Gee, MD, FRCOG
Consultant Obstetrician, and Retired Head of West Midlands Postgraduate School of Obstetrics and Gynaecology, Birmingham Women's Hospital, Birmingham, West Midlands, United Kingdom
Dysfunctional Labor

Robert B. Gherman, MD
Head, Division of Maternal/Fetal, Prince George's Hospital Center, Cheverly, Maryland
Shoulder Dystocia

Paul S. Gibson, MD
Associate Professor, University of Calgary, Calgary, Alberta, Canada
Respiratory Disease

Joanna Girling, MA, MRCP, FRCOG
Consultant Obstetrician and Gynaecologist, West Middlesex University Hospital, Isleworth, Surrey, United Kingdom
Hepatic and Gastrointestinal Disease

Francesca Gotsch, MD
Research Fellow, Perinatology Research Branch, NICHD, NIH, DHHS, Bethesda, Maryland, and Detroit, Michigan
Intrauterine Infection, Preterm Parturition, and the Fetal Inflammatory Response Syndrome

Michael Greaves, MBChB, MD, FRCP, FRCPath
Professor of Haematology, and Head of School of Medicine and Dentistry, University of Aberdeen, Aberdeen, United Kingdom
Thromboembolic Disease

David R. Griffin, MD, FRCOG
Consultant Obstetrician and Gynaecologist, West Herts Hospital HMS Trust, Waterford, Hertfordshire, United Kingdom
Fetal Skeletal Abnormalities

Rosalie M. Grivell, BSc, BMBS, FRANZCOG
Senior Lecturer, Discipline of Obstetrics and Gynaecology, The University of Adelaide, Women's and Children's Hospital, North Adelaide, South Australia, Australia
Multiple Pregnancy

A. Metin Gülmezoglu, MD, PhD
Coordinating Editor of the World Health Organization Reproductive Health Library, Department of Reproductive Health and Research, World Health Organization, Geneva, Switzerland
Global Maternal and Perinatal Health Issues

Christina S. Han, MD
Clinical Instructor, Department of Obstetrics, Gynecology and Reproductive Sciences, Yale University School of Medicine; Clinical Instructor, Yale-New Haven Hospital, New Haven, Connecticut
Clotting Disorders

Roger F. Haskett, MD

Professor of Psychiatry, University of Pittsburgh School of Medicine; Psychiatrist, Western Psychiatric Institute and Clinic of UPMC Presbyterian, Pittsburgh, Pennsylvania
Psychiatric Illness

Robert Hayashi, MD

J. Robert Wilson Professor Emeritus, University of Michigan, Ann Arbor, Michigan
Assisted Vaginal Delivery

Darren Travis Herzog, MD

Orthopaedic Surgery Resident, Detroit Medical Center, St. John's Providence Hospital, Detroit, Michigan
Spine and Joint Disorders

G. Justus Hofmeyr, MRCOG

Consultant, East London Hospital Complex, East London, Eastern Cape, South Africa
Global Maternal and Perinatal Health Issues

Elizabeth Helen Horn, MD, FRCP, FRCPath

Royal Infirmary of Edinburgh, Edinburgh, United Kingdom
Thrombocytopenia and Bleeding Disorders

Jonathon Hyett, MBBS, MSc, MD, MRCOG, FRANZCOG

Clinical Professor, Faculty of Obstetrics and Gynaecology, Central Clinical School, University of Sydney; Clinical Professor, RPA Women and Babies, Royal Prince Alfred Hospital, Sydney, New South Wales, Australia
Screening for Spontaneous Preterm Labor and Delivery

Robin B. Kalish, MD

Associate Professor, Weill Cornell Medical College; Attending Physician, New York Presbyterian Hospital, New York, New York
Fetal Craniospinal and Facial Abnormalities

Humphrey H. H. Kanhai, MD, PhD

Leiden University Medical Center, Leiden, The Netherlands
Fetal Thrombocytopenia

Lucy H. Kean, BM, BCh, DM, FRCOG

Consultant in Fetal and Maternal Medicine, Nottingham University Hospitals NHS Trust, Nottingham, United Kingdom
Malignancies of the Hematologic and Immunologic Systems; Thrombocytopenia and Bleeding Disorders

Rohna Kearney, MD, MRCOG, MRCPI

Consultant Gynaecologist, Subspecialist in Urogynaecology, Addenbrooke's Hospital, Cambridge University Hospitals Trust, Cambridge, United Kingdom
Perineal Repair and Pelvic Floor Injury

Anna P. Kenyon, MBChB, MD, MRCOG

Clinical Training Fellow, Elizabeth Garrett Anderson Institute for Women's Health, University College London, London, United Kingdom
Thyroid Disease

Mark D. Kilby, MD, FRCOG

Professor of Fetal Medicine, Head of Reproduction, Genes and Development/Deputy Head of School of Clinical and Experimental Medicine, College of Medical and Dental Sciences, University of Birmingham; Head of Fetal Medicine Centre, Birmingham Women's Foundation Trust, Edgbaston, Birmingham, United Kingdom
Genetics, Risks of Recurrence, and Genetic Counseling

Justin C. Konje, MD, FWACS, FMCOG (NIG), FRCOG

Professor of Obstetrics and Gynaecology, Reproductive Sciences Section, Department of Cancer Studies and Molecular Medicine, University of Leicester and University Hospitals of Leicester, Leicester, United Kingdom
Bleeding in Late Pregnancy

George Kroumpouzos, MD, PhD, FAAD

Clinical Assistant Professor of Dermatology, Brown Medical School, Providence, Rhode Island
Skin Disease

Juan Pedro Kusanovic, MD

Assistant Professor, Department of Obstetrics and Gynecology, Wayne State University, Detroit, Michigan; Perinatology Research Branch, NICHD, NIH, DHHS, Bethesda, Maryland, and Detroit, Michigan
Intrauterine Infection, Preterm Parturition, and the Fetal Inflammatory Response Syndrome

Mark B. Landon, MD

Professor and Interim Chair, College of Medicine, and Director, Division of Maternal Fetal Medicine, Department of Obstetrics and Gynecology, The Ohio State University, Columbus, Ohio
Pituitary and Adrenal Disease

Tze Kin Lau, MD

Professor, Department of Obstetrics and Gynaecology, Faculty of Medicine, The Chinese University of Hong Kong, Hong Kong, SAR
Prenatal Fetal Surveillance

Steven R. Levine, MD

Professor and Vice Chair, Neurology, and Associate Dean for Clinical Research and Faculty Development, The State University of New York Health Science Center - Brooklyn; Chief of Neurology, University Hospital of Brooklyn, Brooklyn, New York
Neurologic Complications

Liesbeth Lewi, MD, PhD

Professor, School of Medicine, Catholic University; Consultant, University Hospitals Leuven, Department of Obstetrics and Gynecology, Leuven, Belgium
Fetal Problems in Multiple Pregnancy

Stephen W. Lindow, MB, ChB, MMed (O&G), MD, FCOG (SA), FRCOG

Senior Lecturer in Perinatology, University of Hull, Hull, East Yorkshire, United Kingdom; Honorary Associate Professor of Obstetrics and Gynaecology, University of Cape Town, Cape Town, South Africa; Honorary Consultant in Obstetrics and Gynaecology, Women and Childrens' Hospital, Hull Royal Infirmary, Hull, East Yorkshire, United Kingdom
Assisted Vaginal Delivery; Major Obstetric Hemorrhage and Disseminated Intravascular Coagulation

Charles J. Lockwood, MD

Anita O'Keefe Young Professor and Chair, Department of Obstetrics, Gynecology and Reproductive Sciences, Yale University School of Medicine; Director of Obstetrics and Gynecology, Yale-New Haven Hospital, New Haven, Connecticut
Clotting Disorders

Pisake Lumbiganon, MD, MS

Professor, Khon Kaen University, Khon Kaen, Thailand
Global Maternal and Perinatal Health Issues

Ian Z. Mackenzie, MD, FRCOG, DSc

Reader in Obstetrics and Gynaecology, University of Oxford; Honorary Consultant Obstetrician and Gynaecologist, John Radcliffe Hospital, Oxford, United Kingdom
Unstable Lie, Malpresentations, and Malpositions

Kassam Mahomed, MD (Bristol), FRCOG (UK), FRANZCOG

Associate Professor, Department of Obstetrics and Gynaecology, University of Queensland; Senior Staff Specialist, Department of Obstetrics and Gynaecology, Ipswich Hospital, Ipswich, Queensland, Australia
Abdominal Pain; Nonmalignant Gynecology

Melissa S. Mancuso

Instructor/Fellow, Maternal-Fetal Medicine and Medical Genetics, University of Alabama at Birmingham School of Medicine, Birmingham, Alabama
Fetal Tumors

Neil Marlow, DM, FMedSci

Professor of Neonatal Medicine, UCL Elizabeth Garrett Anderson Institute for Women's Health, University College London; Honorary Consultant Neonatologist, University College London Hospitals NHS Foundation Trust, London, United Kingdom
Resuscitation and Immediate Care of the Newborn

Anthony J. Marren, BMed (Hons), MMed (R. H. & H. G.)

Registrar, Department of Obstetrics and Gynaecology, Royal Prince Alfred Hospital for Women and Babies, Sydney, New South Wales, Australia
Screening for Spontaneous Preterm Labor and Delivery

Alec McEwan, BA, BM, BCh, MRCOG

Consultant in Obstetrics and Fetal Medicine, Department of Obstetrics and Gynaecology, Nottingham University Hospitals NHS Trust, Nottingham, United Kingdom
Video Editor

Michael J. Moritz, MD

Professor of Surgery, Penn State College of Medicine, Hershey; Chief, Transplantation Services, Lehigh Valley Health Network, Allentown, Pennsylvania
Pregnancy after Transplantation

Adnan R. Munkarah, MD

Professor, Wayne State University School of Medicine; Chairman, Women's Health, Henry Ford Health System, Detroit, Michigan
Malignant Disease

Kimta Nanhornguè, MD

University of Padova; Medical Resident in Gynecology, Department of Gynecological Sciences and the Human Reproduction, University of Padua School of Medicine, Padova, Italy
First-Trimester Screening for Fetal Abnormalities

Osric B. Navti, MBBS, MRCOG

Consultant in Fetal and Maternal Medicine, University Hospitals of Leicester NHS Trust, Leicester, United Kingdom
Bleeding in Late Pregnancy

Catherine Nelson-Piercy, MA, FRCP, FRCOG

Consultant Obstetric Physician, Guy's and St. Thomas Foundation, Queen Charlotte's and Chelsea Hospital, Imperial College Healthcare Trust, London, United Kingdom
Thyroid Disease

Robert Ogle, FRANZCOG, FHGSA

Director, Royal Prince Alfred Hospital, Sydney, Australia
Screening for Spontaneous Preterm Labor and Delivery

Colm O'Herlihy, MD, FRCPI, FRCOG

Professor, University College Dublin; Consultant Obstetrician/Gynaecologist, National Maternity Hospital, Dublin, Ireland
Perineal Repair and Pelvic Floor Injury

Michael J. Paidas, MD

Associate Professor, Co-Director, Yale Women and Children's Center for Blood Disorders, and Co-Director, National Hemophilia Foundation - Baxter Clinical Fellowship at Yale, Yale University School of Medicine; Attending Physician, Yale-New Haven Hospital, New Haven, Connecticut
Clotting Disorders

Robert C. Pattinson, MD, FRCOG, FCOG (SA), MMed (O&G)

Professor, Obstetrics and Gynaecology, University of Pretoria, Pretoria, Gauteng, South Africa
Global Maternal and Perinatal Health Issues

Zoë Penn, MD, FRCOG

Consultant Obstetrician, Chelsea and Westminster Hospital, London, United Kingdom
Breech Presentation

Troy Flint Porter, MD, MPH

Director, Maternal-Fetal Medicine, Intermountain Healthcare; Associate Professor, University of Utah Health Sciences, Salt Lake City, Utah
Autoimmune Diseases

Raymond O. Powrie, MD

Senior Vice President, Quality and Clinical Effectiveness, Women & Infants Hospital of Rhode Island; Associate Professor of Medicine and Obstetrics and Gynecology, The Warren Alpert Medical School of Brown University, Providence, Rhode Island
Respiratory Disease

Susan M. Ramin, MD

Professor and Chair, Department of Obstetrics, Gynecology and Reproductive Sciences, University of Texas Health Science Center at Houston, Houston, Texas
Renal Disorders

Margaret Ramsay, MB, BChir, MA, MD, MRCP, FRCOG

Consultant in Fetomaternal Medicine, Nottingham University Hospitals, Queen's Medical Centre Campus, Nottingham, United Kingdom
Appendix: Normal Values

Lesley Regan, MD

Professor, Consultant Obstetrician and Gynaecologist, Imperial College London, St. Mary's Hospital, London, United Kingdom
Recurrent Miscarriage

John T. Repke, MD

University Professor and Chairman, Department of Obstetrics and Gynecology, Penn State University College of Medicine; Obstetrician-Gynecologist-in-Chief, The Milton S. Hershey Medical Center, Hershey, Pennsylvania
Puerperal Problems

Laura E. Riley, MD

Assistant Professor, Obstetrics and Gynecology and Reproductive Biology, Harvard Medical School, Cambridge; Medical Director of Labor and Delivery, Massachusetts General Hospital, Boston, Massachusetts
Rubella, Measles, Mumps, Varicella, and Parvovirus

Giuseppe Rizzo, MD

Professor, Università Roma Tor Vergata; Department of Obstetrics and Gynecology, Ospedale Fatebenefratelli Isola Tiberina, Rome, Italy
Fetal Cardiac Anomalies

Jeffrey S. Robinson, BSc (Hons), MB ChB, BAO (Hons), FRCOG, FRANZCOG

Emeritus Professor, Discipline of Obstetrics and Gynaecology, School of Paediatrics and Reproductive Medicine, Faculty of Health Sciences, The University of Adelaide, Adelaide, South Australia, Australia
Threatened and Actual Preterm Labor Including Mode of Delivery; Prelabor Rupture of the Membranes

Stephen C. Robson, MD, MRCOG, MBBS

Professor of Fetal Medicine, Institute of Cellular Medicine, University of Newcastle upon Tyne, Newcastle upon Tyne, United Kingdom
Fetal Thyroid and Adrenal Disease

Roberto Romero, MD

Department of Obstetrics and Gynecology and Center for Molecular Medicine and Genetics, Wayne State University, Detroit, Michigan; Chief, Perinatology Research Branch, and Program Director for Obstetrics and Perinatology, *Eunice Kennedy Shriver* National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland, and Detroit, Michigan
Intrauterine Infection, Preterm Parturition, and the Fetal Inflammatory Response Syndrome

Thomas Roos, MD

Assistant Professor, University of Regensburg Medical School, Regensburg, Germany; Chief, Section of Obstetrics, Department of Obstetrics and Gynecology, Kantonsspital Schaffhausen, Schaffhausen, Switzerland
Cytomegalovirus, Herpes Simplex Virus, Adenovirus, Coxsackievirus, and Human Papillomavirus

Michael G. Ross, MD, MPH

Professor of Obstetrics and Gynecology, David Geffen School of Medicine at UCLA, Los Angeles; Professor of Public Health; UCLA School of Public Health; Los Angeles,Perinatologist, Harbor-UCLA Medical Center, Torrance, California
Abnormalities of Amniotic Fluid Volume

Rodrigo Ruano, MD

Research Fellow, Université Paris V; Consultant, Hôpital Necker Enfants Molades, Paris, France
Fetal Genitourinary Abnormalities

Jane M. Rutherford, MBChB, DM, MRCOG

Consultant in Fetomaternal Medicine, Nottingham University Hospitals, Nottingham, United Kingdom
Anemia and White Blood Cell Disorders

Luis Sanchez-Ramos, MD

Professor, Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, University of Florida College of Medicine, Jacksonville, Florida
Induction of Labor and Termination of the Previable Pregnancy

Veronica L. Schimp, DO

Associate Professor, M.D. Anderson Cancer Center Orlando, University of Central Florida College of Medicine, Orlando, Florida
Malignant Disease

Dimitrios Siassakos, MBBS, MRCOG, MSc, DLSHTM

Clinical Lecturer in Medical Education, University of Bristol; Research Fellow in Obstetrics, Southmead Hospital, Bristol, United Kingdom
Training for Obstetric Emergencies

Gordon C. S. Smith, MD, PhD

Professor and Head, Department of Obstetrics and Gynaecology, University of Cambridge; Honorary Consultant in Maternal Fetal Medicine, Addenbrooke's Hospital, Cambridge, United Kingdom
Delivery after Previous Cesarean Section

John S. Smoleniec, MD, FRCOG, FMS, FRANZCOG, CMFM, DDU

Associate Professor, University of New South Wales, Sydney; Director, Maternal Fetal Medicine, Liverpool Hospital, Sydney South West Area Health Service, New South Wales, Australia
Fetal Hydrops

Peter W. Soothill, BSc, MD, MBBS, FRCOG

Emeritus Professor of Maternal and Fetal Medicine, Medical School, University of Bristol; Consultant in Fetal Medicine, Fetal Medicine Unit, St. Michael's Hospital, University Hospitals Bristol NHS Foundation Trust, Bristol, United Kingdom
Invasive Procedures for Antenatal Diagnosis

Philip J. Steer, BSc, MD, FRCOG, FCOGSA (hon)

Emeritus Professor, Faculty of Medicine, Imperial College London, Chelsea and Westminster Hospital, London, United Kingdom
Prolonged Pregnancy; Fetal Distress in Labor

Peter Stone, BSc, MBChB, MD (Bristol), FRCOG, FRANZCOG, DDU, CMFM

Professor of Maternal Fetal Medicine, Department of Obstetrics and Gynecology, University of Auckland; Professor of Maternal Fetal Medicine, National Women's Hospital, Auckland Hospital, Auckland, New Zealand
Fetal Gastrointestinal Abnormalities

Jane Strong, MBChB, MRCP, FRCPath

Consultant Pathologist (Haematology), Leicester Royal Infirmary, Leicester, United Kingdom
Anemia and White Blood Cell Disorders

John M. Svigos, MB BS, DRCOG, FRCOG, FRANZCOG

Associate Professor, Discipline of Obstetrics and Gynaecology, School of Paediatrics and Reproductive Medicine, Faculty of Health Sciences, The University of Adelaide, Adelaide; Senior Visiting Medical Specialist, Maternal Fetal Medicine Unit, Women's and Children's Hospital, North Adelaide, South Australia, Australia
Threatened and Actual Preterm Labor Including Mode of Delivery; Prelabor Rupture of the Membranes

Rebecca Swingler, MSc, MRCOG

Academic Clinical Lecturer, University of Bristol, St. Michael's Hospital; Senior Registrar in Obstetrics and Gynaecology, St. Michael's Hospital, Bristol, United Kingdom
Bleeding and Pain in Early Pregnancy

Mark W. Tomlinson, MD

Regional Director of Obstetrics, Providence Health System, Providence St. Vincent's Hospital, Portland, Oregon
Cardiac Disease; Neurologic Complications

Lawrence C. Tsen, MD

Associate Professor in Anaesthesia, Harvard Medical School; Co-Editor in Chief, International Journal of Obstetric Anesthesia; Director of Anesthesia, Center for Reproductive Medicine, Brigham and Women's Hospital, Boston, Massachusetts
Neuraxial Analgesia and Anesthesia in Obstetrics

Frank P. H. A. Vandenbussche, MD, PhD

Professor of Obstetrics and Fetal Medicine, Radboud University Medical Center, Nijmegen, The Netherlands
Fetal Thrombocytopenia

Alex C. Vidaeff, MD, MPH

Professor of Obstetrics and Gynecology, Department of Obstetrics, Gynecology and Reproductive Sciences, Maternal-Fetal Medicine Division, University of Texas Health Science Center at Houston, Houston, Texas
Renal Disorders

Yves Ville, MD

Professor, Descartes University, GHU Necker-Enfants-Malades, Paris, France
First-Trimester Screening for Fetal Abnormalities

Anthony M. Vintzileos, MD

Professor of Obstetrics, Gynecology and Reproductive Medicine, Stony Brook University School of Medicine, Stony Brook; Chairman, Department of Obstetrics and Gynecology, Winthrop-University Hospital, Mineola, New York
Second-Trimester Screening for Fetal Abnormalities

Ann M. Walker, MBChB

Prescribing Doctor for Pregnancy and Parenting Team, Leeds Partnership NHS Foundation Trust, Leeds, West Yorkshire, United Kingdom
Substance Abuse

James J. Walker, MBChB, MD, FRCP (Edin), FRCPS (Glas), FRCOG

Professor of Obstetrics and Gynaecology, University of Leeds; Consultant, Obstetrics and Gynaecology, St. James University Hospital; Chairman of Perinatal Research Group, Leeds Institute of Molecular Medicine, Leeds, West Yorkshire, United Kingdom
Substance Abuse

Peter G. Wardle, MD, FRCS, FRCOG

Honorary Senior Lecturer, University of Bristol; Consultant Gynaecologist and Subspecialist in Reproductive Medicine, and Lead Consultant for Fertility Services, North Bristol NHS Trust, Southmead Hospital, Bristol, United Kingdom
Bleeding and Pain in Early Pregnancy

Stephen P. Wardle, MB, ChB, FRCPCH, MD

Consultant Neonatologist, Nottingham University Hospitals, Nottingham, United Kingdom
Resuscitation and Immediate Care of the Newborn

D. Heather Watts, MD

Medical Officer, Pediatric, Adolescent, and Maternal AIDS Branch, Center for Research on Mothers and Children, Eunice Kennedy Shriver National Institute of Child Health and Human Development, Bethesda, Maryland
Human Immunodeficiency Virus

Bevin Weeks, MD

Assistant Professor of Pediatrics, Yale University School of Medicine; Director for Pediatrics, Yale Fetal Cardiovascular Center, New Haven, Connecticut
Fetal Cardiac Arrhythmias: Diagnosis and Therapy

Carl P. Weiner, MD, MBA, FACOG
K.E. Krantz Professor and Chair, Department of
   Obstetrics and Gynecology, University of Kansas
   School of Medicine, Kansas City, Kansas
   Fetal Hemolytic Disease; Fetal Death; Medication

Hajo I. J. Wildschut, MD
Consultant in Obstetrics and Gynecology, Erasmus
   University Medical Center, Rotterdam, The Netherlands
   *Constitutional and Environmental Factors Leading to a High Risk
   Pregnancy*

Catherine Williamson, MD, FRCP
Professor, Imperial College London, London, United
   Kingdom
   Hepatic and Gastrointestinal Disease

Lami Yeo, MD
Associate Professor, Department of Obstetrics and
   Gynecology, Wayne State University School of
   Medicine, Detroit, Michigan; Director of Fetal and
   Maternal Imaging, Perinatology Research Branch,
   NICHD, NIH, DHHS, Bethesda, Maryland, and
   Detroit, Michigan
   Second-Trimester Screening for Fetal Abnormalities

Mark H. Yudin, MD, MSc, FRCSC
Assistant Professor, University of Toronto; Attending
   Physician, Department of Obstetrics and Gynecology,
   St. Michael's Hospital, Toronto, Ontario, Canada
   Other Infectious Conditions

One of the most popular features of the first thee editions of *High Risk Pregnancy—Management Options* were the 'Summary of Management Options' (SOMO) Boxes. The SOMO Box was placed at the end of each chapter or section within a chapter and presented the reader with an *aide memoire* of the main points regarding the management options for a specific condition discussed in detail in the preceding chapter. For the third edition, we included an evidence based approach in the SOMO Boxes.

We continued this approach for the fourth edition. The following is the evidence based scoring system for the SOMO Boxes that we asked contributors to use.

SCORING SYSTEM FOR SUMMARY OF MANAGEMENT OPTIONS BOXES

Quality (level) of Evidence

Ia	Evidence obtained from meta-analysis of randomized controlled trials
Ib	Evidence obtained from at least one randomized controlled trial
IIa	Evidence obtained from at least one well-designed controlled study without randomization
IIb	Evidence obtained from at least one other type of well-designed quasi-experimental study
III	Evidence obtained from well-designed non-experimental descriptive studies, such as comparative studies, correlation studies and case studies
IV	Evidence obtained from expert committee reports or opinions and/or clinical experience of respected authorities

Strength (grade) of Recommendation

A	At least one randomized controlled trial as part of a body of literature of overall good quality and consistency addressing the specific recommendation (Evidence Levels Ia or Ib)
B	Well-controlled clinical studies available but no randomized clinical trials on the topic of the recommendations (Evidence Levels IIa, IIb or III)
C	Evidence obtained from expert committee reports or opinions and/or clinical experiences of respected authorities. Indicates an absence of directly applicable clinical studies of good quality (Evidence Level IV)
GPP	Good Practice Point: recommended best practice based on the clinical experience of the chapter authors and editors

The fourth edition of *High Risk Pregnancy: Management Options* brings growth and change while remaining true to the original vision of an evidence-based user friendly text. Good clinical practice should be a universal goal, and we have sought to produce a truly International Postgraduate Textbook. There are over 150 contributors who reflect expertise from around the world with 20 countries represented. The third edition was sold in over 80 countries in four different versions—English, Chinese, Turkish and an English language adaptation for the Indian market. It is now a standard text used in the qualifying examinations of many countries. The book continues to grow in popularity with the third edition being the best-seller yet.

As the complexity of medicine continues to increase, so has the burden on the editors to review and process the material so it remains relevant to the reader. To that end, we are delighted that Caroline Crowther, an international leader in clinical design, performance and analysis of clinical trials, and Stephen Robson, a world recognized perinatologist have joined the original editorial team. In addition, we are most grateful to our contributors for their enormous efforts (and often those of their secretaries). We are especially indebted to Dee Simpson from Elsevier who has kept the project on course.

Each chapter in the fourth edition has been revised and where indicated, new ones added to reflect new developments. As reassuring as the traditional textbook is to hold, the fourth edition is published with a greatly expanded electronic version providing easy access to references and expanded figures. In addition, the website not only includes these electronic features, but also has video clips (edited by Alec McEwan), each making learning dynamic. Other changes to the fourth edition include:

- A major overhaul and revision of the book's appearance to further enhance readability including the transfer of the full reference list for each chapter to the accompanying complementary electronic publication so that only 10 key references ('Suggested Reading') are retained in the printed text.
- A clearer presentation of the text while keeping to the original layout style of
  - "Introduction"
  - "Risks (Maternal and Fetal)"
  - "Management Options (Prepregnancy, Prenatal, Labor and Delivery, Postnatal)"
  - "Summary of Management Options" Box
- The Summary of Management Options Box includes a simplified evidence-based scoring system for each management strategy proposed. It illustrates how strong the evidence is for each option.
- All chapters were written or updated to reflect the current management options and to incorporate changes in practice since the last edition. Twelve chapters are either new or rewritten by new authors to bring a fresh view [1, 2, 6, 10, 12, 35, 44, 49, 65, 67, 75, 77].
- One feature that deserves special mention in the Preface is Margaret Ramsay's popular and valuable Appendix on 'Normal Values'. This section has had its own separate publication (both written and electronic) in the past and these publications will be updated in the future.

As in prior editions, we have appreciated the comments of readers and reviewers and sought to respond to them wherever possible in this edition.

Previous editions of *High Risk Pregnancy: Management Options* were popular because readers have found them relevant to their daily clinical practice; in other words the book is a manual for the management of problem pregnancies. We hope that the fourth edition will uphold and enhance that reputation and will prove even more valuable to busy clinicians.

David James
Philip J. Steer
Carl P. Weiner
Bernard Gonik
Caroline A. Crowther
Stephen C. Robson

This new international textbook in obstetrics will, we believe, be of major value to all practicing clinicians, be they trainees or established in practice.

It aims to assist with the questions: How do I manage this patient? or How do I perform this procedure?

It presents a wide range of reputable management options. Unlike many traditional texts, based on a single individual's experience and view, all the contributors to each section were asked to give their preferred management in all areas of their section. Each resulting chapter reflects that wide range of acceptable practice. This means you will have a *choice* about which option or combination of options suits you and your patient.

This book is designated to be practical. It addresses those difficult questions which arise in practice, which often stem not only from the medical facts, but from the constraints of time, facilities, finance, and patient acceptability. Moreover, we have standardized the presentation of each topic as far as possible (while still allowing the personality of the original authors to shine through!) to enable the reader to become familiar with the format.

We have deliberately chosen a panel of contributors who are both leaders in their field and who can represent practice in the USA, Europe, and Australasia and this we feel gives the text a unique universality.

Finally it is our intention that the book is comprehensive. We hope that we will have something to say on all the important problems you come across. If you find any exceptions, please let us know, with your comments, in time for the next edition.

Global Maternal and Perinatal Health Issues*

A. METIN GÜLMEZOGLU, ROBERT C. PATTINSON, G. JUSTUS HOFMEYR, and PISAKE LUMBIGANON

INTRODUCTION

In 2000, 189 member states of the United Nations signed up to the Millennium Development Declaration committing themselves to ambitious health and development goals to be achieved by 2015. Agreement on these important goals within the Declaration was later translated into a structured framework of Millennium Development Goals (MDGs) with measurable targets and indicators. This MDG framework is the most significant global public health event since the 1990s. It has encouraged many donors to prioritize their funding on specific areas linked to the MDGs. Three of the eight MDGs (4, 5, and 6) relate directly to maternal and perinatal health (Table 1–1).

The MDG process has had several positive effects so far. By highlighting the areas of largest disease burden, the MDGs have not only improved resource flows to low- and middle-income countries toward effective practices such as antiretroviral treatments in sub-Saharan Africa but also led to better ascertainment of the causes of morbidity and mortality and improved evaluation of interventions likely to have an impact on health outcomes.

Since 2000, there has been an increase in the number of analytical studies of the global burden of sexual and reproductive ill health, including the monitoring and evaluation of care, and these have improved our understanding of the barriers to improvement. For example, in 2003, a group of scientists initiated the "Countdown to 2015 Initiative," tracking coverage levels for health interventions that have been shown to reduce maternal, newborn, and child mortality (http://www.countdown2015mnch.org/). In 2008, this group reported the coverage, equity, financing, and policy progress on those interventions.[1] These analyses represent important advances on our ability to measure and report key global maternal and perinatal health markers.

THE MEASUREMENT CHALLENGES

In the past, data on maternal and perinatal mortality and morbidity have been lacking in many parts of the world.[2]

However, since 2000, the number of studies on maternal and perinatal mortality and morbidity has increased significantly, in terms both of primary studies such as Demographic and Health Surveys (DHS) collecting representative data at the national level and the number of systematic reviews synthesizing such data to assess current status and monitor trends.

Confidential inquiries into maternal deaths are accepted as the relevant gold standard audit tool. In the United Kingdom, implementation of the confidential inquiry methodology and the consequent uptake of the recommendations from it are thought to have been a driver of the reduction in maternal deaths in this country over the past 50 years.[3] More recently, India, Jamaica, Sri Lanka, South Africa, and Tunisia have all successfully implemented either confidential inquiries into maternal deaths or specific surveillance systems to capture the number and causes of maternal deaths.[4–8] The 2005 Maternal Mortality estimates developed by the World Health Organization (WHO), United Nations Children's Fund (UNICEF), United Nations Population Fund (UNFPA), and the World Bank represent a methodologic advance in an area that has often been controversial. Maternal mortality estimates for countries are sometimes contentious because of adjustments for underreporting, and modeling estimates for countries that do not have data from methodologically sound studies. However, the results of such studies are a big improvement on having no data at all, and more recent estimates have used improved methodology, including an analysis of trends. A systematic review of the global causes of maternal death was published in 2006, presenting for the first time a synthesis of population-based representative data on studies reporting the major causes of maternal death,[9] and our current picture is much more robust compared to the 1990s.

MATERNAL MORTALITY AND SEVERE MORBIDITY

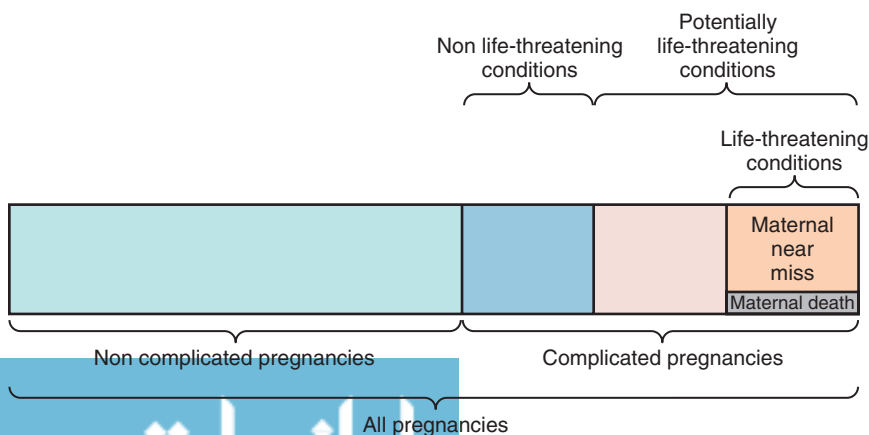
About 99% of all maternal deaths occur in developing countries, and current estimates suggest that 536,000 women die every year during pregnancy or within the 42 days following completion of the pregnancy. Deaths in sub-Saharan Africa and southern Asia accounted for 86% of global maternal deaths. The trend analysis indicates a global reduction of

less than 1% annually, which is way behind the 5.5% required to reach MDG 5.[10]

The majority of maternal deaths in Africa and Asia are due to obstetric hemorrhage (Fig. 1–1).[9] In Latin America and the Caribbean, hypertensive disorders are responsible for the largest proportion of direct obstetric deaths (26%). Unsafe abortion is an important cause of maternal death and probably one of the most preventable.

In developed countries, the most common causes of death are direct causes such as thromboembolism and indirect causes such as cardiac disease. Maternal deaths in these countries are now rare, and the events that lead to death are often multifactorial, but this does not mean that pregnancy is entirely safe. Waterstone and coworkers[11] reported that in the 1990s in the South East Thames region of the United Kingdom, there was a severe obstetric morbidity rate of 12.0 per 1000 births, and a "severe morbidity to mortality" ratio of 118 : 1. Say and colleagues[12] conducted a systematic review of reports of severe acute morbidity worldwide up to 2004, using organ system–based criteria and unselected groups of women, and concluded that its incidence varied between 0.3% and 1.08%. Recently, the concept of maternal morbidity as a continuum ranging between healthy pregnancy and death has attracted much interest (Fig. 1–2). "Maternal severe morbidity" and "near-miss" are terms often used to identify women who experience a severe event during pregnancy, labor, or the postpartum period. Although there are currently no internationally agreed criteria, maternal near-miss can usefully be defined as "a woman who nearly died from a complication but survived." The WHO Working Group on Maternal Mortality and Morbidity Classifications has recently proposed clinical, laboratory, and management criteria based on earlier studies and audit data from Brazil, Canada, and South Africa (Table 1–2).[13]

Maternal near-miss estimates can be regarded as a valid proxy for maternal death and have practical value. In an individual facility, the number of maternal deaths will usually be too few to be useful for monitoring progress and highlighting areas that require action. Maternal near-misses occur more frequently than mortality and allow identification of inadequate care in a way similar to confidential inquiries into maternal death. The criteria proposed by the WHO Working Group have been developed taking into consideration the lack of resources in low- and middle-income countries. The criteria have been validated in Latin American countries but still require validation in other parts of the world.[14]

It is widely acknowledged that poor and socially disadvantaged sections of our communities share the highest burden of ill health. The equity analysis conducted by the Countdown 2008 Equity Analysis Group[15] found that the poorer quintiles of the communities are less likely to receive effective, guideline-recommended interventions. As expected, the equity gap has large variations within and between countries. Maternal and newborn health interventions represented an area of greater than average inequity, with a mean difference of 27.5% between the wealthiest and the poorest quintiles.


PERINATAL MORTALITY

The MDGs identified a reduction in the mortality of children younger than 5 years of age as a priority (MDG 4), and within that group, reducing early neonatal deaths (~40% of the total) is a priority. It is estimated that around 4 million newborn babies die every year.[16] In addition, stillbirths occur in about 1% to 3% of all births, amounting to more than 3 million perinatal deaths annually at a global level.[17,18]

Measuring and classifying perinatal deaths is not easy. Several classification systems exist, suggesting that no classification system is optimal.[19–22] Kramer and associates[23] suggest that antepartum, intrapartum, and early neonatal deaths should be reported separately.

Global modeling estimates based on data from 45 countries suggest that preterm birth (28%), severe infections (36%, including pneumonia [26%], tetanus [7%], and diarrhea [3%]), and complications of asphyxia (23%) account

for most neonatal deaths.[24] In sub-Saharan Africa, 1.16 million babies die in the neonatal period, and another million babies are stillborn every year. In South Africa, in-depth analyses of perinatal deaths have been conducted since 1999 through the "Perinatal Problem Identification Programme" (PPIP) (http://www.ppip.co.za/savbab.htm). Each year about 22,000 babies die in South Africa. The Sixth Perinatal Care Survey of South Africa is a comprehensive report on causes of perinatal deaths, avoidable factors, and recommendations.[25] Unexplained stillbirths and preterm-related deaths constitute the largest groups (Table 1–3). The top three causes of perinatal deaths in all birth weight categories were unexplained stillbirth, spontaneous preterm labor, and intrapartum asphyxia and birth trauma.

Perinatal death rates in industrialized countries are generally much lower than in developing countries, and preterm births and congenital abnormalities tend to play a more prominent role.[26] In 2006, in England, Wales, and Northern Ireland, the stillbirth rate was 5.3 (95% confidence interval [CI] 5.1, 5.5) per 1000 total births, the neonatal mortality rate was 3.4 (CI 3.3, 3.6) per 1000 live births, and the perinatal mortality rate was 7.9 (CI 7.7, 8.1) per 1000 total births. However, in the United Kingdom, the perinatal mortality rate is rising in the growing numbers of births to immigrant mothers, and immigration is increasing rapidly in many developed countries because of the need to rebalance the age pyramid (the indigenous population is aging owing to low birth rates).

STRATEGIES TO IMPROVE MATERNAL AND PERINATAL HEALTH

Public Health and Political Context

A comprehensive evaluation of global, regional, and national strategies to reduce maternal and perinatal mortality and morbidity is beyond the scope of this book. Broad population-level strategies have been summarized by the World Bank (Table 1–4).[27]

TABLE 1–2

The WHO Near-Miss Criteria

A woman presenting any of the following life-threatening conditions and surviving a complication during pregnancy, childbirth, or within 42 days of termination of pregnancy should be considered a near-miss case.

DYSFUNCTIONAL SYSTEM	CLINICAL CRITERIA	LABORATORY MARKERS	MANAGEMENT-BASED PROXIES
Cardiovascular	Shock[a] Cardiac arrest[b]	pH <7.1 Lactate >5 mEq/mL	Use of continuous vasoactive drugs[i] Cardiopulmonary resuscitation
Respiratory	Acute cyanosis Gasping[c] Respiratory rate >40 or <6 bpm	Oxygen saturation <90% for ≥60 min Pao_2/Fio_2 <200 mm Hg	Intubation and ventilation not related to anesthesia
Renal	Oliguria nonresponsive to fluids or diuretics[d]	Creatinine 300 μmol/L or ≥3.5 mg/dL	Dialysis for acute renal failure
Hematologic/coagulation	Failure to form clots[e]	Acute severe thrombocytopenia (<50,000 platelets/mL)	Transfusion of ≥5 units of blood/red cells
Hepatic	Jaundice in the presence of preeclampsia[f]	Bilirubin >100 μmol/L or >6.0 mg/dL	
Neurologic	Any loss of consciousness[g] lasting >12 hr Stroke[h] Uncontrollable fit/status epilepticus Total paralysis		
Alternative severity proxy			Hysterectomy following infection or hemorrhage

[a] Shock is a persistent severe hypotension, defined as a systolic blood pressure < 90 mm Hg for ≥ 60 min with a pulse rate at least 120 despite aggressive fluid replacement (>2 L).
[b] Cardiac arrest refers to the loss of consciousness AND absence of pulse/heartbeat.
[c] Gasping is a terminal respiratory pattern and the breath is convulsively and audibly caught.
[d] Oliguria is defined as an urinary output <30 mL/hr for 4 hr or <400 mL/24 hr.
[e] Clotting failure can be assessed by the bedside clotting test or absence of clotting from the intravenous site after 7–10 min.
[f] Preeclampsia is defined as the presence of hypertension associated with proteinuria. Hypertension is defined as a blood pressure of at least 140 mm Hg (systolic) or at least 90 mm Hg (diastolic) on at least two occasions and at least 4–6 hr apart after the 20th week of gestation in women known to be normotensive beforehand. Proteinuria is defined as excretion of 300 mg or more of protein every 24 hr. If 24-hr urine samples are not available, proteinuria is defined as a protein concentration of 300 mg/L or more (≥1 + on dipstick) in at least two random urine samples taken at least 4–6 hr apart.
[g] Loss of consciousness is a profound alteration of mental state that involves complete or near-complete lack of responsiveness to external stimuli. It is defined as a Coma Glasgow Scale <10 (moderate or severe coma).
[h] Stroke is a neurologic deficit of cerebrovascular cause that persists beyond 24 hr or is interrupted by death within 24 hr.
[i] For instance, continuous use of any dose of dopamine, epinephrine, or norepinephrine.
Fio_2, fractional concentration of oxygen in inspired gas; Pao_2, arterial oxygen pressure.

Prerequisites for Saving Lives

Saving lives is mainly dependent on two aspects of health care: whether effective interventions are available to all and the quality of care with which that intervention is implemented. Without patients having access to the specific interventions, lives cannot be saved, and providing the intervention in an inadequate way also inhibits the effect of that intervention (Fig. 1–3). Full access in turn requires that the community has a basic knowledge of when to use the

Maternal mortality reduction should be taken as a national priority and actions planned accordingly. There is a need to act on various levels at the same time. The confidential inquiry system is useful to concentrate efforts on avoidable causes of deaths and assess new interventions. Such strategies are inevitably context-specific.

RESPONSIBILITY
FOR ACTIONS   ACTIVITIES   IMPACT

FIGURE 1–3
Factors associated with and the relationship between coverage and quality of care in saving lives.

health care facilities, and health care managers/planners must ensure that health facilities are accessible to the community. Such facilities must have the equipment, drugs, and staff to provide the intervention effectively and the staff must have the appropriate skills.

Community-Based versus Facility-Based Care

There is an ongoing debate internationally regarding which are the most effective strategies to reduce maternal deaths and that, therefore, deserve promotion at a national or provincial level. Some suggest that ensuring that skilled attendants are at all births within central facilities should be the priority, whereas others advocate embarking on community-level interventions because most births currently occur outside such facilities. In our opinion, a one-size-fits-all approach will not work and will be difficult to implement if the context is not appropriate. It is likely that a combination of strategies, including those at community level, utilizing best evidence on antenatal, intrapartum, and postpartum care, will be needed in many countries for the foreseeable future. Complete access to facility-based obstetric care may be the best practice but is likely to be many years away, and even then, it will not be acceptable or accessible to all.[28] It is plausible that community-level interventions could improve outcomes either by increasing the standard of out-of-facility care through training or education or by improving care-seeking behavior and access to facility-level care.

In a systematic review of community-based interventions, two important large randomized controlled trials implemented in Nepal and Pakistan were identified.[29] These trials have produced valid policy-relevant evidence to show that neonatal and perinatal mortality can be reduced by community-level interventions to improve perinatal care practices. Such interventions, directed at improving maternity services, are likely to influence both maternal and perinatal outcomes. Since this review was completed, two other trials on the topic have been published. Baqui and coworkers[30] evaluated the effects of antenatal and postnatal home visits by female community health workers in rural Bangladesh. In this study, the home visit package was significantly more effective than community-level group sessions and resulted in a 34% reduction in neonatal mortality (95% CI 7–53). The second trial was conducted in rural India, in the Shivgarh district of Uttar Pradesh state.[31] The intervention was a package of basic newborn care interventions consisting of birth preparedness, clean delivery, cord care, thermal care, breast-feeding promotion, and danger sign recognition. The neonatal mortality risk was reduced by 54% (95% CI 40–65) in this trial.

All these community-level trials have used the same strategic approach but delivered carefully constructed and contextualized interventions that are different in each trial. Unfortunately, these impressive improvements in perinatal outcome were not reflected in maternal outcomes; although the Pakistan trial showed a reduction in maternal mortality, it was not statistically significant. In another study, a community-based nutritional supplementation of vitamin A suggested an impressive reduction in maternal mortality, but those findings have not been replicated to date.[32]

The presence of such high-quality community-based studies with consistent results is encouraging to those wishing to pursue such activities both as research projects and as program implementation where appropriate.

Community strategies, however, need to be backed up by facility-based care as much as possible, and the presence of one does not mean the other is not needed. Even minor

obstetric life-saving interventions, such as manual removal of a retained placenta, are best delivered in a health facility. Internationally, WHO, UNICEF, and UNFPA recommend that there should be at least four facilities offering basic emergency obstetric care (EmOC) for every 500,000 people. Basic EmOC includes the administration of uterotonics, parenteral antibiotics, and magnesium sulfate and provision of manual removal of the placenta.

Clinical Interventions

Appropriate clinical interventions are presented and discussed in detail in specific chapters of this book. The effects of clinical interventions to reduce maternal and perinatal mortality and morbidity have been evaluated through systematic reviews published in the *Cochrane Library* and other journals. Although we know of some interventions that address the main causes of mortality and morbidity, we badly need innovation and new technologies relevant to resource poor as well as rich countries. Tsu and colleagues[33,34] reported on some new and underused technologies to reduce maternal mortality in 2003 and in 2008. Some emerging promising technologies in obstetrics and gynecology have recently been described by Papageorghiou and El-Toukhy.[35] Unfortunately, some well-established effective practices such as magnesium sulfate for preeclampsia and eclampsia and oxytocin or misoprostol to limit postpartum hemorrhage are not implemented as widely as they should be.

SUMMARY OF MANAGEMENT OPTIONS
Some Recommended Practices for Improved Maternal and Perinatal Survival

	Evidence Quality and Recommendation	Reference
Maternal		
Postpartum hemorrhage		
• Active management of the third stage of labor, including administration of uterotonic agents.	Ia/A	39
Hypertensive disorders		
• Magnesium sulfate for women with eclampsia	Ia/A	40
• Calcium supplementation for women with low dietary calcium intake	Ia/A	41
• Labor induction using extra-amniotic saline infusion or very low dose misoprostol for severe cases	Ia/A	42
Obstetric sepsis		
• Clean birth practices	GPP	
HIV		
• Primary prevention (lifestyle changes, condom use)	III/B	43
• Antiretroviral treatment for immunocompromised women	Ia/A	44
Perinatal		
Unexplained intrauterine death		
• Community education on monitoring fetal movements in developing countries	GPP	
Preterm birth		
• Steroids for women at risk of preterm birth	Ia/A	45
• Kangaroo mother care	Ia/A	46
• Nasal continuous positive airway pressure (in settings with no access to mechanical ventilation)	IV/C	47
Intrapartum asphyxia and trauma		
• External cephalic version for breech presentation	Ia/A	48
• Cesarean section for breech delivery	Ia/A	49
• Vacuum extraction	Ia/A	50
• Access to cesarean section	IIb/B	51
• Symphysiotomy	III/B	52
HIV		
• Antiretroviral prophylaxis for mother-to-child transmission of HIV	Ia/A	53
Childhood infections and malnutrition		
• Exclusive breastfeeding for 6 months	Ia/A	54
General		
Prevention of unplanned pregnancy	GPP	

GPP, good practice point.

There are currently no new drugs in the offing that are likely to have an impact on maternal and perinatal survival in the near future, and the pharmaceutical industry has not brought a new effective drug into use since the 1980s.[36]

Some clinical interventions that should be achievable in many resource-poor settings and are likely to reduce the important causes of maternal and perinatal mortality are listed and evidenced in the Summary of Management Options box. These recommendations are based on critical incident audits conducted in South Africa and have been shown to be effective. A tool has been developed to prioritize the interventions for implementation. Choice of the most appropriate interventions for a particular setting can be calculated by estimating the number of lives saved by the introduction or expansion of the intervention to cover 95% of the population using the Lives Saved Tool (LiST).[24,37] Although these methods may not be very precise, they could nevertheless be useful in prioritizing and focusing policy and program decisions.

Reducing the Know-Do Gap: Implementing Best Practices

Reducing maternal mortality and morbidity is complex and involves political commitment and organized persistent action at the health systems and community services levels. In recent years, it is increasingly acknowledged that the implementation of effective practices is often patchy and interventions that are ineffective and harmful remain entrenched in practice. A major cause of this so-called know-do gap is the lack of access to reliable information, although even when this is available, traditional practices can be difficult to change. Since the late 1980s, systematic reviews of effects of maternal and perinatal interventions have greatly increased our knowledge about practices that are more likely to be beneficial than harmful. There is however, a great need to transfer this knowledge widely and in formats that are accessible and user-friendly. Since 1997, WHO has published *The WHO Reproductive Health Library* (RHL)[38] including selected *Cochrane* reviews with commentaries on the relevance of the review results to underresourced country settings. RHL provides access to information from the *Cochrane* reviews and their interpretation to more than 30,000 health workers every year. It is published in Chinese, French, Spanish, and Vietnamese as well as English, which enhances its reach to many settings in which most health workers do not speak English. *The Cochrane Library* is available in English and partially in Spanish. Access to the *Cochrane Library* and more than 2000 periodicals from low- and middle-income country institutions has been made possible through the WHO Access to Research Initiative (HINARI) project (http://www.who.int/hinari/en/).

CONCLUSIONS

At a clinical level, there are many important interventions likely to reduce maternal and newborn mortality. However, many of these interventions are not implemented in the places where they are needed most. The implementation of effective practices varies substantially between and within countries. Since 2000, our knowledge about the effectiveness of implementation strategies has increased substantially. Many strategies such as educational outreach, audit, and feedback, active dissemination through seminars and interactive workshops, have only modest to moderate positive effects. Barriers to the adoption of evidence-based practices exist at multiple levels; tradition is often a major stumbling block. Although there is no single intervention or strategy that can be recommended for every situation, several have been shown to have positive effects. What is clear is that waiting passively for the best practices to be brought into use will be inadequate and active implementation strategies are usually needed.

Reducing maternal mortality and morbidity is possible as several countries have shown. However, for this to happen, all the various stakeholders (politicians, health care workers, and the community at large) need to agree on a concerted plan of action.

Constitutional and Environmental Factors Leading to a High Risk Pregnancy

HAJO I. J. WILDSCHUT

DEFINITION OF A HIGH RISK PREGNANCY

Pregnancy should be considered a unique, physiologically normal episode in a woman's life. However, preexisting disease or unexpected illness of the mother or fetus can complicate the pregnancy. *Risk* is defined as the probability of an adverse outcome or a factor that increases this probability. A pregnancy is defined as *high risk* when the probability of an adverse outcome for the mother or child is increased over and above the baseline risk of that outcome among the general pregnant population (or reference population) by the presence of one or more ascertainable risk factors, or indicators. This classification does not take into consideration the magnitude of risk or the importance of the risk to the health outcome of the pregnant population at large.

CONSTITUTIONAL RISK

Ethnicity

Race and ethnicity are complex, controversial sociologic issues that are difficult to measure accurately. Race and ethnicity are often considered surrogate measures for standard of living and lifestyle. However, both between and within ethnic populations, marked variations occur in cultural beliefs and practices, language, household structure, sexual behavior, contraceptive patterns, general health, perception of illness and disease, childbirth and child-rearing practices, postnatal customs, dietary habits, housing, education, employment, economic status, level of assimilation, stress, and access to health care services. Some of these attributes have little to do with health or disease, whereas others may be important factors. In clinical research, the terms *race* and *ethnicity* are often defined inadequately, if at all. Therefore, epidemiologic associations with health problems should be interpreted cautiously.

Risks

Ethnicity is one of the factors that is most strongly associated with low birth weight.[1–6] Low birth weight is closely related to infant mortality and childhood morbidity rates.[7] In the United States, preterm birth rather than growth restriction is implicated as the most important cause of low birth weight in black women. Given the high rates of preterm delivery, crude survival rates for black infants are less favorable than those for white infants.[5,8,9] The biologic explanation for the high preterm delivery rate among black women is unclear. The excess birth weight–specific mortality in black infants may be compounded by a failure to seek or receive optimal medical care.[10]

Many diseases and problems that occur during pregnancy have both ethnic and geographic distributions. The risks are summarized in Table 2–1. Uterine fibroids occur more often in black women than in white women.[11] Nonengagement of the fetal head late in pregnancy is not uncommon in black primigravidae.[12] The available data on ethnic differences in the frequency of dysfunctional labor are inconclusive.

MANAGEMENT OPTIONS

Information, screening, and appropriate counseling services should be made available for communities that are considered at risk for specific diseases (see Table 2–1 and other relevant chapters).

PRENATAL

Communication is often a problem because of language barriers. Video displays and informative pamphlets or brochures written in several languages should be made available.[13] Standard information should include guidelines for lifestyle and nutrition as well as preparation for parturition and parenthood, preferably in keeping with sociocultural features of the relevant ethnic communities. The use of interpreters, either in person or by telephone, is advisable for dealing with specific problems.[13]

Once prenatal care has been initiated, women at risk for specific diseases, such as hemoglobinopathies, may be selected for further testing or treatment.[14,15] In parous women, it is important to obtain all necessary information about the course and outcome of previous pregnancies.

TABLE 2–1

Risks in Pregnancy Associated with Certain Ethnic Groups

ETHNIC GROUP	RISKS
Mediterranean islands, parts of the Middle East, Southeast Asia, and parts of the Indian subcontinent	Beta-thalassemias: Minor: Anemia in pregnancy, treated with oral iron and folate, but not parental iron Major: Rare to survive to reproductive age, but those who do often have pelvic bony deformities and problems with labor and delivery; also iron overload with subsequent hepatic, endocrinologic, and myocardial damage Major/minor: Possible risk of inheriting the disease, requiring prenatal counseling and diagnosis Alpha-thalassemias: Minor: Usually asymptomatic Major: Rare, but a spectrum of presentation: in adults, usually manifests as a hemolytic anemia of variable severity Major/minor: Possible risk of inheriting the disease, requiring prenatal counseling and diagnosis; homozygous alpha-thalassemias in the fetus can manifest as hydrops fetalis and associated severe preeclampsia in the mother
Afro-Caribbean, Mediterranean, Middle East, India	Sickling disorders (especially HbSS, HbSC): Maternal: Infection, sickling crises, preeclampsia, renal compromise, jaundice; although HbSC tends to be a milder disease (Hb levels usually within normal limits), it can cause massive sickling crises if the diagnosis has not been made; HbAS (carrier state) mothers are rarely at risk for sickling crises with, for example, anoxia, dehydration, or acidosis Fetus: Possible risk of inheriting the disease, requiring prenatal counseling and diagnosis; growth restriction is a risk with HbSS and HbSC
Mediterranean, American Blacks	Glucose-6-phosphate dehydrogenase deficiency: Mother: Hemolytic anemia Fetus: Risk of inheriting the disease, requiring prenatal counseling and diagnosis; fetal hydrops
Far East	Hepatitis B (chronic carriers): Risk of transmission to the fetus or neonate and health care workers
Africa, Caribbean, Hawaii	HIV infection: Risk to the mother of symptomatic infection; risk to the fetus and health care workers of acquiring the infection
Africa (especially Horn of Africa), developing countries	Female circumcision: Problems with vaginal delivery (dystocia, trauma, hemorrhage) Varied effects of endemic infection on the mother or fetus

Hb, hemoglobin; HbAS, hemoglobin AS; HbSC, hemoglobin SC; HbSS, hemoglobin SS.

Immunization status should be checked, and fetal growth should be monitored.

LABOR AND DELIVERY

The continuous presence of a supportive female companion during labor and delivery benefits maternal well-being by improving her emotional status, shortening labor, and decreasing the need for medical intervention.[16] Psychosocial support may also improve mother-infant bonding. It is unlikely that ethnicity in itself affects the duration of labor and delivery.

POSTNATAL

Breastfeeding should be encouraged.[17] Contraceptive advice should take into account individual sociocultural norms and values.[18,19]

Socioeconomic Status

The importance of maternal social factors on the health and well-being of the offspring is well known. However, caution should be exercised in interpreting studies of the effect of social conditions on pregnancy outcome because of variations in definitions and practices in time and geographic area, availability of reliable data, and interpretation of the findings.[21–23]

Various measures of social status are used, some of which tend to be crude and meaningless. In England and Wales, for example, the maternal social class index is traditionally derived from the Registrar General's Classification, which is based on the occupation of the father of the child (Table 2–2). Other criteria of categorization include educational attainment, income, type of health care, employment, legitimacy, family affluence, and household characteristics.[23] Although there is a strong association between social class, however defined, and infant mortality, this observation does not explain why some infants die and others do not.

Social adversity probably represents a wide range of behavioral, environmental, medical, and psychological factors that are causally related to pregnancy outcome, some of which are more amenable to intervention than others. In scientific research, correlations with socioeconomic status should be the impetus for further investigation, rather than the endpoint of an analysis.[24]

Risks

Lower socioeconomic status is associated with an increased risk of various adverse pregnancy outcomes, including perinatal mortality, preterm birth, and low birth weight. Smoking has been suggested as the key factor underlying socioeconomic differences in low birth weight and infant mortality.[6,23,25–27] Differences in care along the social strata may

SUMMARY OF MANAGEMENT OPTIONS
Pregnancy in Women from Different Ethnic Backgrounds

Management Options	Evidence Quality and Recommendation	References

IIIb	Skilled workers, manual
IV	Semiskilled workers
V	Unskilled workers

also account for some of the extra risks. The contribution of poor nutrition is discussed in the next section.

Management Options

PRENATAL

Socially disadvantaged women are less likely to seek prenatal care and also have more pregnancy complications. Some claim that apart from recognizing the increased risk associated with socioeconomic disadvantage, there is little to do in terms of prevention. Social support, however, benefits women psychologically, although the effect of social intervention on mean birth weight, low birth weight, and preterm delivery is limited.[16]

LABOR AND DELIVERY

Intrapartum management need not be substantially modified if no other risk factors are present.

POSTNATAL

Women of higher socioeconomic status tend to breast-feed more often and longer than women of lower socioeconomic status. Breast-feeding should be encouraged and social support provided, when indicated.[28] Contraception must be discussed.[19]

Parity

Incidence

In western societies, nulliparous women constitute approximately half of all pregnant women.

Definitions

Parity is the number of times a woman has given birth to an infant, dead or alive. However, the gestational threshold may vary between countries (e.g., 23 completed weeks' gestation vs. 27 completed weeks' gestation).

Risks

Parity is closely correlated with maternal age and with socioeconomic status to a certain extent. On the whole, the risk of adverse outcome with parity does not show a consistent pattern. Mean birth weight for infants born to nulliparous women is consistently lower than that for infants born to multiparous women, and this accounts for most of the differences in mortality risk in the offspring of nulliparous and multiparous women.[32,33] Differences in the mean birth weight of infants born to women of different parity are partially explained by differences in maternal weight. Nulliparity is associated with an increased risk of pregnancy-induced hypertension, which in turn is strongly related to low birth

SUMMARY OF MANAGEMENT OPTIONS
Pregnancy in Women of Low Socioeconomic Background

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Recommend health education measures specifically directed at smoking cessation and family planning.	Ib/A	29
Prenatal		
Encourage patients to seek preconception care.	III/B	30
Provide specific and directed social support.	Ia/A	16
Look for clinical evidence of poor fetal growth.	III/B	25
Labor and Delivery		
No additional measures are needed on the basis of adverse socioeconomic factors alone.	—/—	—
Postnatal		
Encourage breast-feeding.	Ib/A	28
Provide specific and directed social support.	Ib/A	31
Discuss contraception.	III/B	19

weight. Further, in nulliparous women, there is an increased risk of perineal trauma as a result of either episiotomy or spontaneous tear.

Women of high parity tend to receive inadequate obstetric care owing to delays in seeking care and poor attendance. Moreover, it is assumed that women with a history of rapid or precipitated childbirth have an increased risk of unattended out-of-hospital delivery. High parity is associated with an increased likelihood of abnormal fetal presentation and obstetric hemorrhage.[34] Parity, however, does not have a significant effect on the incidence of Down syndrome when the effect of maternal age is taken into account.[35]

Management Options
PRENATAL

Nulliparity is a nonspecific risk factor and no specific precautions need to be taken.

In parous women, it is of fundamental importance to obtain all clinically relevant details of previous pregnancies, which will guide patient specific care. Provision of child care facilities may facilitate prenatal care.

LABOR AND DELIVERY

There is a difference in the normal labor patterns of nulliparous and multiparous women. In practice, however, the duration of the second stage of labor is highly variable. In both nulliparous and multiparous women, policies for imposing limits on the length of the second stage of labor tend to be subjective and are usually based on uncontrolled observational data. If the maternal and fetal condition are satisfactory and progress is occurring, with descent of the presenting part, obstetric intervention is not warranted. Cephalopelvic disproportion, however, must be considered when progress in labor is slow. For women with a history of rapid or precipitated delivery, timely admission to the hospital and elective induction of labor are often considered, although there is no evidence that this approach is beneficial.

POSTNATAL

Discussion of long-term contraception is recommended.[36,37]

Age
Adolescent Pregnancy
DEFINITIONS

Epidemiologically, a distinction is often made between pregnancy rates among adolescents aged 15 to 19 years and those among adolescents aged 10 to 14 years.[38–42] *Reproductive age* is the interval from the age of menarche to the chronologic age at conception, whereas *gynecologic age* is the time span from the age of menarche to the chronologic age at delivery. With the improvement of socioeconomic conditions, the median age of menarche has shown a downward trend. The median age of menarche in developed countries is currently 12.5 years.[38] Conception or delivery within 2 years after the onset of menarche represents the lower

SUMMARY OF MANAGEMENT OPTIONS

Discuss long-term contraception.	III/B	36,37

extreme of the distribution of both reproductive and gynecologic age.

INCIDENCE

The incidence of teenage pregnancy varies by country. In England and Wales, the teenage (15–19 yr) pregnancy rate is 45/1000, the abortion rate is 19/1000, and the birth rate is 26/1000.[38] In the United States in the mid-1990s, the comparable figures were 84/1000, 29/1000, and 54/1000.[43]

RISKS

Teenage pregnancy is associated with both social and medical problems.[44] Many teenage mothers originate from working-class families and ethnic minorities. Many are themselves the children of teenage or very young parents.[45] Many teenage pregnancies are unplanned and unwanted. Consequently, in western societies, abortion rates among adolescents range from 30% to 60%.[46]

Reports on adolescent pregnancy complications are contradictory because of the confounding effects of adverse social circumstances and poor attendance for prenatal care. However, one risk factor for poor outcomes in adolescent pregnancy is a maternal history of adverse childhood experiences (e.g., emotional, physical, or sexual abuse; living with someone with substance abuse or mental illness or involvement in criminal activity; divorced or separated parents). These experiences are associated with subsequent sexual risk behaviors, smoking, alcohol consumption, and mental health problems such as depression.[47]

Medical complications associated with adolescent pregnancy include preterm birth and low birth weight, perinatal mortality, short interval to next pregnancy, and sudden infant death syndrome. Adolescents who become pregnant are at particular risk for nutritional deficiencies, anemia, HIV infection, and other sexually transmitted diseases.[38] The increased incidence of pregnancy-induced hypertension is largely explained by nulliparity.[39] It has been suggested that competition for nutrients between the fetus and the mother could affect pregnancy outcome in adolescents by interrupting the normal growth process.[48] However, biologic "immaturity" does not affect reproductive performance in terms of length of labor and route and mode of delivery.[38]

MANAGEMENT OPTIONS
Prevention and Prepregnancy Management

Primary prevention includes sexual education in schools and includes information about values, responsibilities, and the right to say "no."[49–51] Teenagers should be encouraged to discuss the realities of pregnancy and parenthood openly.[52] Secondary prevention is directed at sexually active women through a flexible approach to the use and provision of contraceptives for both males and females.[50] Teenagers require different but sensitive approaches.[51] Tertiary prevention involves adolescents who become pregnant. They are encouraged to seek early adequate prenatal care and to discuss options for the resolution of pregnancy.[53–55]

Prenatal

Compliance with prenatal care can be poor, especially among teenagers in their second pregnancy. Strategies for intervention should be focused on individual medical and social risk factors, in particular, poor nutritional status, adverse health habits, and perceived isolation. Pregnant adolescents should be offered social support when feasible, preferably in close cooperation with the family physician, an empathetic midwife, or a social worker.[16,47] Information on pregnancy, delivery, and child-rearing should be made available.

SUMMARY OF MANAGEMENT OPTIONS
Pregnancy in Adolescence

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Education and advertising directed toward sexual behavior and family planning.	IIa/B	49,50
Emphasize self-referral for care when pregnant.	III/B	53–55
Prenatal		
Encourage early referral for routine prenatal care and regular attendance.	III/B	53,54
Confirm gestation with early ultrasonography.	III/B	53
Provide advice about diet and adverse habits (e.g., smoking).	III/B	56
Mobilize social support.	III/B	55
Labor and Delivery		
Ensure adequate psychological support.	Ia/A	16
Schedule delivery in a special unit if dystocia is anticipated.	III/B	58
Postnatal		
Provide advice and support for maternal and child care.	III/B	57
Discuss contraception.	III/B	50,51

Labor and Delivery

Continuous emotional support during labor should be provided by a professional (e.g., nurse, midwife) or nonprofessional caregiver (e.g., spouse, friend, relative).[16]

Postnatal

Infant feeding practices, infant growth, and infant safety should be reviewed. Social and financial concerns should be discussed.[55] Teenage girls should be encouraged to continue secondary education.[52] Effective contraception should be implemented. A large percentage of teenagers who give birth before the age of 17 years have a repeat pregnancy before they are 19 years old.[56,57] Home visitation programs by public health nurses can have a positive effect on the health of the adolescent mother and her child.[56,57]

Advanced Maternal Age
INCIDENCE

In the last decades, there has been a trend toward deferred childbearing, especially among healthy, well-educated women with career opportunities, although the proportion of pregnant women aged 35 years and older varies from country to country. Formerly, pregnant women aged 35 years and older tended to have several unplanned children, whereas today, the proportion of first births to such women is growing.[59–63]

RISKS

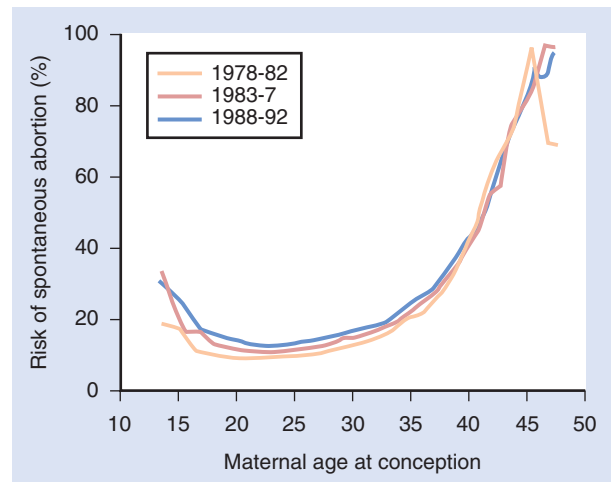
Advanced maternal age is a risk indicator for several pregnancy complications, including spontaneous miscarriage


FIGURE 2–1

Risk of spontaneous abortion according to maternal age at conception, stratified according to calendar period, based on Danish civil registry data from 1978–1992. During this period, a total of 634,272 women had 1,221,546 pregnancies, of which 126,673 ended in fetal loss, 285,022 in an induced abortion, and 809,762 in a live birth.
(From Andersen A-MN, Wohlfahrt J, Christens P, et al: Maternal age and fetal loss: Population-based register linkage study. BMJ 2000;320:1708–1712, with permission.)

(Fig. 2–1)[64]; ectopic pregnancy; stillbirth; chromosomal abnormalities (see Chapter 4); twins; uterine fibroids; hypertensive disorders; gestational diabetes; prolonged labor; cephalopelvic disproportion necessitating operative delivery; bleeding disorders, including placenta previa; low birth

weight; antepartum and intrapartum fetal loss; and neonatal mortality.[62–65] However, most reports of pregnancy outcome in elderly nulliparous women have not taken into account effects other than age, such as details of general health, smoking habits, and reproductive history (including a history of miscarriage or infertility and its treatment).[61] Information about whether the first pregnancy was postponed deliberately is often lacking.

Maternal age has no effect on the incidence of birth defects of unknown etiology.[66] Advanced paternal age has little or no independent effect on the risk of autosomal trisomies.[67]

MANAGEMENT OPTIONS
Preconception and Prenatal

The main focus for discussion is the risk of chromosomal abnormalities. This should include careful distinction of the risks at different stages of pregnancy, the options for screening, and the risks of miscarriage from invasive procedures and advanced maternal age itself.[67–71] These issues are also discussed in Chapters 4, 7, 8, and 9.

Although medical and obstetric complications tend to be more common in women aged 35 years and older, in practice, normal prenatal care is not modified unless another specific risk factor or complication is identified.

Labor and Delivery

Elderly women are usually advised to be delivered in a specialized unit because of the risk of dystocia during labor. However, there is no evidence that intrapartum care should be modified because of the extremes of maternal age. Nonetheless, the woman's age often contributes strongly to decisions to intervene.[63]

Postnatal

Discussion of long-term contraception is recommended.[36,37]

Nutrition
Risks
GENERAL

Nutritional conditions in pregnancy are a major determinant of health in later life.[72,73] Conditions such as type 2 diabetes, hypertension, and coronary heart disease are considered to be the result of fetal programming of physiology and metabolism.[72,74] Studies of the Dutch famine of 1944–1945 showed a relative increase in placental weight in infants whose mother's nutrition was compromised around conception or in the first trimester.[74] The increase in the placenta weight–to–birth weight ratio is interpreted as a compensatory mechanism after reduced caloric intake in early pregnancy.[75,76] An increased ratio is also seen with maternal anemia, tobacco use in pregnancy, and births at high altitude.[75] Fetal cardiovascular adaptations are a recognized feature of intrauterine growth restriction and divert nutrient-rich, highly oxygenated blood to spare the growth of the brain and other critical organs. Furthermore, reduced availability of micronutrients may affect fetal body composition. The relative amounts of fetal bone and lean and fat mass influence the risk of adult obesity and type 2 diabetes.[72] When undernutrition during early development is followed by improved nutrition, many animals and plants have accelerated compensatory growth.[72] However, in animals, this compensatory growth may reduce life span.[73]

SUMMARY OF MANAGEMENT OPTIONS		
Advanced Maternal Age		
Management Options	**Evidence Quality and Recommendation**	**References**

Discuss risks, but they should be put into perspective.	III/B	62,63
Spontaneous miscarriage risk increased.	III/B	64
Discuss prenatal diagnosis of chromosomal abnormalities.	III/B	69,71
Advanced paternal age has little or no independent effect on the risk of autosomal trisomies.	III/B	71
Multiple pregnancy risk increased.	III/B	65
Prenatal		
Discuss options for aneuploidy screening and prenatal diagnosis with invasive procedures.	III/B	70
Labor and Delivery		
Delivery in a unit that can manage dystocia and other complications.	III/B	62
Postnatal		
Discuss long-term contraception.	III/B	36,37

CAFFEINE

Caffeine consumption in pregnancy is a controversial topic. Reports of teratogenicity from animal studies led the U.S. Food and Drug Administration (FDA) to advise pregnant women to eliminate caffeine from their diets.[77] Subsequent epidemiologic studies showed inconsistent results. Moreover, cigarette smoking may confound the association of caffeine consumption with pregnancy outcomes.[77]

VITAMINS

The current reference daily intakes (RDIs) for vitamins are summarized in Table 2–3.[78] Pregnancy may increase vitamin requirements. Mechanisms underlying vitamin deficiency include inadequate dietary intake and abnormal metabolism.

FOLATE

Folate is a water-soluble vitamin and is found mainly in polyglutamated form. Folic acid (folacin) is the synthetic form present as a monoglutamate in vitamin tablets and fortified foods. Folate is important for the biosynthesis of DNA and RNA. It also plays an important role in the conversion of homocysteine to methionine, an essential amino acid. An adequate level of folate should be established before conception and maintained during the first trimester to reduce the risk of neural tube defects. Fruits, green vegetables, beans, nuts, and bread are the primary sources of folate. Cooking may destroy some forms of dietary folate. In pregnancy, folate requirements are usually increased. A low-folate plasma concentration could be caused by inadequate dietary intake or the use of anticonvulsant drugs, such as phenytoin, phenobarbital, and carbamazepine, which are known folate antagonists. Moreover, folate deficiency could be the result of inherited metabolic disorders, associated, for instance, with methylenetetrahydrofolate reductase (MTHFR) gene polymorphism. MTHFR is a key enzyme in homocysteine metabolism.[79] The homocysteine plasma concentration is considered a sensitive biomarker of the levels of folate and vitamins B_6 and B_{12}. In pregnancies complicated by a fetal neural tube defect, maternal plasma homocysteine levels are elevated and plasma folate concentration is decreased, suggesting a defect in the folate-dependent homocysteine metabolism. Hyperhomocystinemia is also associated with various conditions characterized by placental vasculopathy, such as preeclampsia and abruption, and with recurrent pregnancy loss.[80]

OTHER VITAMINS

Vitamin A is a member of the family of fat-soluble *retinoids*.[78] Isotretinoin, a derivative of vitamin A, is a powerful prescription drug for the treatment of severe recalcitrant nodular acne. Doses of vitamin A at three times the daily allowance can cause birth defects (e.g., heart defects, craniofacial anomalies). Thus, isotretinoin has been labeled as pregnancy category X, meaning it should not be used during pregnancy. Another derivative of vitamin A, etretinate, is a prescription drug for the treatment of psoriasis. This drug is also contraindicated in pregnant women. In adults, vitamin A toxicity results in hepatotoxicity and visual changes.[78] Xerophthalmia, night blindness, and increased susceptibility to disease characterize vitamin A deficiency.

Vitamin B_6 (pyridoxine, pyridoxal, and pyridoxamine) is water-soluble and found in various plant and animal products. Vitamin B_6 is involved in many enzymatic reactions. Deficiency is uncommon.

Vitamin B_{12} (cyanocobalamin) is water-soluble and found in animal products only. Cyanocobalamin must be converted to a biologically active form (methylcobalamin or adenosylcobalamin). Methylcobalamin is an essential cofactor in the conversion of homocysteine to methionine.[79] When this reaction is impaired, hyperhomocysteinemia occurs and folate metabolism is deranged. The cobalamins are involved in fat and carbohydrate metabolism, protein synthesis, and hematopoiesis. Deficiency can result from poor intake, including strict veganism, malabsorption from the absence of intrinsic factor, and rare enzyme deficiencies. Vitamin B_{12} deficiency results in macrocytic anemia and neurologic abnormalities. There are no consistent reports of adverse effects from high intake.[78]

Vitamin C (ascorbic acid) is water-soluble and a cofactor in hydroxylation reactions required for collagen synthesis. It is also a strong antioxidant. Vitamin C deficiency leads to bruising and easy bleeding (scurvy). Large doses (≤ 2000 mg) of vitamin C are generally well tolerated.

Vitamin D (calciferol) is not a true vitamin because humans can synthesize it with adequate sunlight exposure. Vitamin D deficiency is associated with rickets in children. In adults, vitamin D deficiency leads to secondary hyperparathyroidism, with subsequent bone loss and increased fracture risk. There is evidence that genetic polymorphisms strongly affect fracture risk.[78] Inadequate vitamin D intake is more common than previously believed, particularly among housebound women of specific ethnic minority groups.[78] There is no documented evidence of vitamin D deficiency and adverse pregnancy outcome, apart from neonatal hypocalcemia. Given the relatively high prevalence of vitamin D deficiency in certain communities, vitamin D supplementation at a dosage of 0.01 mg (400 IU) is advocated. High intake of vitamin D (>0.05 mg or 2000 IU) results in hypercalcemia and soft tissue calcification.[78]

TABLE 2–3
Current Reference Daily Intakes for Vitamins

VITAMIN	DAILY VALUE
Vitamin A	1500 µg (5000 IU)
Vitamin C	60 mg
Vitamin D	10 µ (400 IU)
Vitamin E	20 mg (30 IU)
Vitamin K	80 µg
Vitamin B_6	2 mg
Vitamin B_{12}	6 µg
Folate	400 µg
Thiamin	1.5 mg
Riboflavin	1.7 mg
Niacin	20 mg

From Fairfield KM, Fletcher RH: Vitamins for chronic disease prevention in adults: Scientific review. JAMA 2002;287:3116–3126.

Vitamin E is a family of eight related compounds, the tocopherols and the tocotrienols. The only reported perinatal effect of dietary vitamin E deficiency has been hemolytic anemia and retinopathy in preterm infants, However, genetic deficiencies in apolipoprotein B or α-tocopherol transfer protein lead to severe vitamin E deficiency syndromes, with symptoms including hemolytic anemia, muscle weakness, and brain dysfunction.[78] With doses of 800 to 1200 mg/day, antiplatelet effects and bleeding may occur.[78] Because of its antioxidative properties, vitamin E is believed to prevent diseases associated with oxidative stress, such as cardiovascular diseases, cancer, chronic inflammation, and neurologic disorders. It is assumed, but not proved, that vitamin E requirements increase during pregnancy. It is uncertain whether supplementation with vitamins C and E help prevent preeclampsia (see Chapter 35).[81]

Vitamin K is fat-soluble and essential for normal clotting, especially for the production of prothrombin, factors VII, IX, and X, and protein C and S. Vitamin K has two subtypes,

vitamin K_1 and K_2. Vitamin K_1, or phylloquinone, is found in most vegetables and dairy products. Vitamin K_2, or menaquinone, is synthesized by the intestinal flora and absorbed only in small amounts.[82] Vitamin K deficiency occurs when dietary intake is inadequate or intestinal bacteria, which synthesize vitamin K, are altered. Newborn infants are at risk for vitamin K deficiency because of poor placental transfer, lack of intestinal bacteria, and low content in breast milk.[82] The risk of vitamin K deficiency is higher in the breast-fed infant because breast milk contains lower amounts of vitamin K than modern formula or cow's milk.[82] A single dose of either oral or intramuscular vitamin K, 1 mg, to all infants is advocated to prevent hemorrhagic disease of the newborn in the first week after birth.[82] Pregnancy women using antiepileptic drugs, including phenytoin, carbamazepine, and phenobarbital, are particularly at risk for vitamin K deficiency in their offspring. They are advised to take oral vitamin K, 10 mg daily, from 36 weeks to prevent neonatal hemorrhagic disease.[83]

SUMMARY OF MANAGEMENT OPTIONS
Nutritional Preparation for Pregnancy

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Offer counseling to women at risk for nutritional deficiency.	III/B	88,89
Recommend folate supplements (0.4 mg/day) for all women contemplating pregnancy.	Ia/A	90
Offer continuing folate supplementation (0.4 mg/day) to all women at increased risk for neural tube defects in pregnancy.	Ia/A	90
Prenatal		
The decision to recommend supplements is based on individual requirements.	Ia/A	91
Routine iron supplementation is warranted in populations in which iron deficiency is common.	Ia/A	92
Avoid excess vitamin A (i.e., more than the daily allowance).	III/B	78
Advise supplemental vitamin K (10 mg/day from 36 weeks' gestation) to women who take antiepileptic drugs to prevent neonatal hemorrhagic disease.	IIa/A	83
Advise women to avoid large amounts of caffeine (>600 mg daily, which is equivalent to six 10-oz cups of coffee).	III/B	73
Labor and Delivery Postnatal		
Give a single dose (1 mg) of either intramuscular or oral vitamin K to the newborn to prevent classic hemorrhagic disease. Vitamin K prophylaxis improves biochemical indices of coagulation status at 1–7 days.	Ib/A	82

IODINE AND ZINC

Trace minerals, such as iodine and zinc, are needed in greater quantities during pregnancy. Deficiencies have been implicated in low birth weight, perinatal mortality, mental retardation, childhood hearing and speech disorders, and birth defects.[84]

IRON

In Europe, iron deficiency is an important nutritional disorder, affecting large fractions of the population, particularly children, menstruating women, and pregnant women. Moreover, vegetarians, vegans, and patients with malabsorption are at increased risk for iron deficiency. A reduction in body iron is associated with a decrease in the level of functional compounds, such as hemoglobin (see also Chapter 38).

Management Options

GENERAL

From an overview of randomized controlled trials, no firm conclusions could be drawn about the implications of nutritional advice to prevent or treat impaired fetal growth.[76] Most physicians agree that RDIs, except those for iron and folic acid, can be obtained through a proper diet. Pregnant teenagers, smokers, drug users, alcohol drinkers, and strict vegetarians tend to be deficient in various vitamins.[85–87] Multivitamin supplements can be of value.

To reduce the incidence of neural tube defects, most countries advocate folic acid supplementation in a dosage of 0.4 mg/day to all women from at least 4 weeks before until 8 weeks after conception.[77]

Large quantities of caffeine consumption should be avoided.

Maternal Weight and Weight Gain

Body mass index (BMI), also known as Quetelet's index (weight [kg]/height [m]^2), is the most commonly used measure. Naeye[90] classified pregnant women into four BMI categories: "thin," less than 20; "normal," 20 to 24; "overweight," 25 to 30; and "obese," greater than 30. In clinical practice, however, these can be difficult to apply because prepregnancy weight is usually unavailable at the first prenatal visit.[93]

Underweight Women

Nutritional deprivation may arise as a result of starvation, dieting, or chronic eating disorders, such as anorexia nervosa and bulimia. Eating disorders are a public health concern in affluent societies.[85]

Anorexia nervosa is a syndrome characterized by severe weight loss, a distorted body image, and an intense fear of becoming obese.[85,94] Anorexia nervosa is not synonymous with bulimia, although bulimic symptoms may occur in women with anorexia nervosa. *Bulimia* is characterized by recurrent episodes of secretive binge eating followed by self-induced vomiting, fasting, or the use of laxatives or diuretics.[85] Depression and alcohol and drug abuse are also prominent features of this disorder.[95] Patients show frequent weight fluctuations but are not likely to have significant weight loss, as seen in women with anorexia nervosa. Both syndromes, which primarily affect adolescents and young adults from middle-class and upper-middle-class families, are often associated with oligomenorrhea and amenorrhea.[85] Despite menstrual irregularities, women with chronic eating disorders may become pregnant.

SUMMARY OF MANAGEMENT OPTIONS
Underweight Women

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Advise women with an eating disorder wishing to become pregnant to wait until the disorder is in remission.	III/B	89
Use a multidisciplinary approach for eating disorders.	III/B	85
Prenatal		
Check for fetal growth restriction.	III/B	89,97
Provide multidisciplinary treatment for women with eating disorders not yet in remission.	III/B	94,97
Labor and Delivery		
Provide continuous electronic fetal heart rate monitoring if the fetus is small.	IIa/B	98
Postnatal		
Monitor signs of maternal depression, and provide treatment if indicated.	III/B	94

RISKS

Underweight women are more likely than women of normal weight to give birth to infants who are small for gestational age.[90,96,97] Poor fetal growth may result in birth asphyxia and complications, such as neonatal hypoglycemia and hypothermia.[98] Underweight women my be more susceptible to anemia. In "thin" women (Quetelet's index < 20), the perinatal mortality rate is increased.[90]

The outcome of pregnancy in women with anorexia and bulimia varies. If the eating disorder is in remission, then an uneventful pregnancy and outcome can be anticipated. However, expectant women with active anorexia nervosa or bulimia at the time of conception may have a number of severe health problems, including electrolyte imbalances, dehydration, depression, social problems, and poor fetal growth. Appropriate psychiatric treatment is warranted.[89,94]

MANAGEMENT OPTIONS

Prepregnancy

Women who have anorexia or bulimia and wish to become pregnant are advised to wait until the eating disorder is in remission.[89] The treatment of underweight women with anovulatory infertility should be focused on restoration of weight by an integrated multidisciplinary approach rather than on ovulation induction.[85]

Prenatal

Prenatal care should focus on early detection of impaired fetal growth.[94] However, the beneficial effects of dietary advice, with or without specific food supplements, are controversial.[76,85,99]

Labor and Delivery

If fetal growth restriction is suspected, the patient should be admitted to a specialist unit. Continuous electronic fetal heart rate monitoring is advised.[97] Emergency neonatal services should be readily available for resuscitation.

Postnatal

Approximately 40% of women with eating disorders have a history of affective disorders, which also puts them at risk for postpartum depression.[94] No additional specific management strategies need to be considered. Treatment with antidepressant drugs may be warranted.

Overweight Women

According to the World Health Organization, "overweight" is defined as a BMI between 25 and 30 kg/m^2 and "obesity" is defined as a BMI of 30 kg/m^2 or greater.[100] The degree of obesity is classified into three categories: class I (BMI 30.0–34.9 kg/m^2), class II (BMI 35.0–39.9 kg/m^2), and class III (BMI > 40 kg/m^2; "morbidly obese"). For an online BMI calculator, see www.nhlbisupport.com/bmi. There are also BMI percentiles, which are age-, gender-, and population-specific.[101] The prevalence of obesity in industrialized countries is increasing rapidly.[102]

RISKS

Hypertensive disorders, including preexisting hypertension and pregnancy-induced hypertension, are more common in women with excess weight, although reported prevalence varies widely (7%–46%).[102,103] Gestational diabetes is also more frequent, affecting 7% to 17% of obese women.[103] Other problems associated with obesity include gallbladder disease, shortness of breath, fatigue, hiatus hernia, raised cholesterol levels, urinary tract infections, postnatal hemorrhage, and possibly thrombophlebitis.[102,104,105] Controversy exists regarding the association between obesity and congenital malformations. Watkins and coworkers[106] explored the association between several birth defects and obesity in a population-based case-control study. They concluded that obese women (BMI ≥ 30) were more likely than average-weight women (BMI 18.5–24.9) to have an infant with spina bifida (unadjusted odds ratio [OR] 3.5; 95% confidence interval [CI] 1.2–10.3), omphalocele (OR 3.3; 95% CI 1.0–10.3), heart defects (OR 2.0; 95% CI 1.2–3.4), and multiple anomalies (OR 2.0; 95% CI 1.0–3.8). The biologic mechanism behind obesity and birth defects is unknown.

There is conflicting evidence about the effect of obesity on perinatal mortality. Obese women are more likely to give birth to large-for-gestational-age infants. Increased maternal weight is independently associated with poor labor progression and increased risk of cesarean delivery.[102,104,105] Overall, the increased need for abdominal delivery in obese women can be attributed mainly to the relatively high rates of prenatal complications and to factors such as advanced age and high parity. When surgical delivery is required, obese women are more prone to wound infection than nonobese women.[103,107]

The risks of anesthesia are increased in obese women including failed epidural, difficult intubation, inability to identify landmarks, difficulty in placing the regional block, and erratic spread of anesthetic solution.[102] Management of the airway in morbidly obese patients can be extremely difficult. They have an increased risk of aspiration because of a larger volume of gastric fluid and increased intra-abdominal pressure with a higher incidence of gastroesophageal reflux.[108] The anesthetic problems can be compounded by coexistent cardiovascular and respiratory problems. Finally, transportation of the grossly obese patient can be extremely difficult.

MANAGEMENT OPTIONS

Prepregnancy

Ideally, an obese woman should be encouraged to lose weight before or after pregnancy. However, data on the efficacy of numerous dietary programs are limited.[109–111] Dietary manipulation should not be advocated during pregnancy because it is difficult to achieve, offers no benefit to the mother, and may have ill effects on fetal weight and health after birth.[112,113] Behavior modification including daily exercise programs is probably the key to weight loss[100,109,114] (see "Physical Activity," later). However, if a woman insists on severe caloric restriction for weight reduction, the problem of maintaining reduced weight for prolonged periods should also be addressed. The recurrence rate of obesity after weight reduction is high.[114]

Bariatric surgery encompasses the various surgical procedures performed to treat obesity by modification of the gastrointestinal tract to reduce nutrient intake and/or absorption. It is considered with morbid obesity when all other

treatments have failed.[115] The majority of patients are women.[116] The three most common surgical procedures currently performed worldwide are laparoscopic gastric bypass, laparoscopic adjustable gastric banding and open gastric bypass. Sixty-three percent of bariatric surgery is now performed laparoscopically.[117] A recent *Cochrane* review concluded that bariatric surgery resulted in greater weight loss than conventional treatment and led to improvements in quality of life and obesity-related diseases such as hypertension and diabetes. However, the comparative safety and effectiveness of the surgical procedures remain unclear.[118] A systematic review concluded that women who had bariatric surgery before pregnancy had lower rates of a number of adverse maternal and neonatal outcomes when compared with rates in pregnant women who did not have surgery for morbid obesity.[119] Most pregnancies after bariatric surgery appear to have a benign course.

Prenatal

Prepregnancy weight and maternal height should be documented routinely at the first visit. Weight is usually recorded at each prenatal visit, using calibrated scales, although the value of this is uncertain. Blood pressure should also be monitored with an appropriately sized cuff to minimize the artificially high recordings that might result when a standard cuff is used.[120]

In obese women, it can be difficult to assess fetal growth and presentation clinically. Ultrasonography is helpful in resolving problems of presentation. However, poor ultrasound visualization in obese women lessens the accuracy of measurements and assessment of fetal anatomy.[121] Tissue harmonic imaging improves the quality of ultrasound images of the fetal heart.[122] Anesthetic consultation is advisable. This has greater urgency if patient has medical problems

such as hypertension, diabetes mellitus, or pulmonary dysfunction. Obese women should be evaluated for gestational diabetes at the first prenatal visit and at the start of the third trimester (see Chapter 44).

Ultrasound screening for fetal macrosomia is commonly undertaken in pregnancy.

Labor and Delivery

Fetal macrosomia is strongly associated with problems in labor, including poor progress as a result of cephalopelvic disproportion, shoulder dystocia, and birth asphyxia.[123] Attempts to derive a prediction score to identify large-for-gestational-age infants have been unsuccessful because of unacceptably high false-positive rates.[124]

Cesarean section in obese women requires specific considerations. Regional anesthesia has advantages over general anesthesia.[104,125] As with all cesarean sections, obese patients should receive prophylactic antibiotics and thromboprophylactic measures.[125,126] Evidence about the most appropriate surgical technique is limited[127] (see also Chapter 74). Gross[128] reviewed the benefits and risks of the two common operative approaches (Pfannenstiel and midline vertical) in obese women. He concluded that the favorable aspects of the Pfannenstiel incision are (1) less postoperative pain and early ambulation; (2) a more secure closure; (3) less adipose tissue to incise; and (4) better cosmetic results. However, the potential adverse effects of the Pfannenstiel incision are (1) greater likelihood of wound infection; (2) potentially restricted access to the infant; and (3) more difficult exposure of the upper abdomen. Exteriorization of the uterus is of no proven benefit.[129] Naumann and colleagues[130] tested the hypothesis that closure of the subcutaneous fat decreases the incidence of wound disruption after cesarean section. There was no significant difference in the incidence of wound infections between the two study groups. However, there was a significantly lower incidence of wound disruption in the subcutaneous closure group (relative risk [RR] 0.5; 95% CI 0.3–0.9). A recent multicenter randomized trial concluded that the additional use of a subcutaneous drain does not prevent of wound complications in obese women being delivered by cesarean section.[131] There is no conclusive evidence about how the skin should be closed after cesarean section.[132]

Postnatal

Prophylactic administration of anticoagulants should be continued until the patient is fully mobilized. Early mobilization appears to improve maternal outcome.

In newborn infants born to grossly obese women, especially those that are large for gestational age, the blood glucose levels should be monitored during the first hours of life. From a systematic review, it was concluded that breastfeeding seems to have a small but consistent protective effect against obesity in children.[133]

Weight Gain in Pregnancy

The total weight gain of a healthy nulliparous woman eating normally is approximately 12.5 kg (27.5 lb).[92] However, large variations in weight gain are seen with normal outcomes.[92,135] In western societies, average total weight gain ranges from 10 to 16 kg (22–35 lb).[136] In healthy, well-nourished women with uncomplicated pregnancies, the proportional weight gain (i.e., total weight gain at term expressed as a proportion of prepregnancy weight) is 17% to 20%.[88] The increase is mainly due to an increase in total body water (~7.5 kg [16.4 lb] when no edema is present) and body fat mass (~2.2–3.5 kg [5.0–7.7 lb]).[92,136,137] The remainder (~0.9 kg [2 lb]) is caused by an increase in protein content, half of which is fetal. Mean weight gain in pregnancy, from conception to birth, does not show a linear trend. In the normal, lean nulliparous woman, weight gain during the first trimester is 0.65 to 1.1 kg (1.4–2.4 lb).[90,137] In the second trimester, average weekly weight gain is 0.45 kg (1 lb), and 0.36 kg (0.8 lb) thereafter.[92] Weight loss or failure to gain weight over a 2-week interval in the third trimester is not uncommon in both nulliparous and parous women. The maximum rate of weight gain occurs between 17 and 24 weeks.[135]

After delivery, the most rapid weight loss, mainly as fluid, occurs between 4 and 10 days. Subsequently, weight loss is more gradual, at 0.25 kg (0.55 lb) per week due to mobilization of fat stores.[138] The average woman eventually loses most of the weight she gained during pregnancy.[92,139] Breastfeeding for longer than 60 days has a favorable effect on the rate of postpartum weight loss.[140]

RISKS

Inadequate weight gain during pregnancy is associated with low–birth weight and small-for-gestational-age infants. Excessive weight gain during pregnancy does not necessarily enhance fetal growth and has been consistently found to contribute to postpartum weight retention and later obesity.[141] The magnitude of the association between inadequate maternal weight gain and low birth weight depends on prepregnancy weight. Thus, women of low prepregnancy weight with little weight gain during pregnancy are more likely to give birth to a low–birth-weight infant than overweight women with a similar overall weight gain. Net weight gain in underweight women is strongly related to birth weight. In overweight women, net weight gain is only marginally related to birth weight.[141,142] The optimum weight gain in terms of minimum perinatal mortality is 7.3 kg (16 lb) for overweight women, 9.1 kg (20 lb) for women of normal weight, and 13.6 kg (30 lb) for underweight women.[112] The possibility of an eating disorder should be considered in women who do not gain appropriate weight or who have intractable vomiting.[89]

MANAGEMENT OPTIONS
Prenatal

Despite the risks previously discussed, evidence that interventions based on poor weight gain improve outcome is lacking and many units no longer weigh pregnant women regularly through pregnancy. Those that do often check for abnormal fetal growth in such women, consider physical and organic causes, and if the abnormal weight gain is thought to be dietary, offer advice about improving diet and lifestyle.[113,124,138,142–144] Advice on reducing weight is not helpful.

Labor and Delivery

Important considerations were discussed in the previous sections.

Physical Activity

Definition

Physical activity can be
- Daily activities (domestic, occupational, and commuting).
- Leisure activities (sports and exercise).

It accounts for 15% to 40% of total energy expenditure. The magnitude of the physiologic response is determined by age, fitness, body weight, body position, concurrent physical adaptations to pregnancy, and psychological factors.[145]

Risks

GENERAL HEALTH

Physical activity, diet, and health are linked, especially through obesity.[100] However, physical inactivity is an independent risk factor for type 2 diabetes, hypertension, cardiovascular disease, and stroke.[100]

PREGNANCY

Physically and emotionally demanding work during pregnancy is associated with an increased risk of hypertension, low birth weight, and preterm birth[146] (see "Occupational Factors"). Regular recreational exercise in pregnancy, including aerobics and competitive sports, improves the outcome for both mother and fetus, in terms of maternal cardiovascular reserve, placental growth, and functional capacity.[145–150] Activities with a high risk of abdominal trauma should be avoided.[147] Scuba diving should be discouraged throughout pregnancy, because the fetus is not protected from decompression problems and is at risk for malformation and gas embolism after decompression disease.[147,149]

Management Options

A woman's overall health, including obstetric and medical risks, should be evaluated before an exercise program is prescribed. The American College of Obstetricians and Gynecologists (ACOG) recommends that healthy pregnant women engage in 30 minutes or more of moderate exercise daily, provided there are neither medical nor obstetric complications.[147] Healthy pregnant women are allowed to exercise vigorously or take part in competitive sports, provided there are no noticeable health hazards to themselves or their infants.[147,149,150]

SUMMARY OF MANAGEMENT OPTIONS
Exercise in Pregnancy

Management Options	Evidence Quality and Recommendation	References

Regular exercise carries no demonstrable harm to the mother or fetus.	Ia/A	149

ENVIRONMENTAL RISK

General

Some environmental risk (such as infection, prescribed drugs, drugs of abuse) is covered in other chapters.

It is difficult to ascertain the clinical importance of each of these environmental influences on reproductive health because of lack of evidence and the existence of confounding variables.

Chemicals

Polychlorinated Biphenyls

Polychlorinated biphenyls (PCBs) have been used in pesticides, surface coatings, inks, adhesives, flame retardants, paints, and old electrical equipment.[152] Many countries have severely restricted or banned the production of PCBs.

Highly chlorinated PCB congeners persist in the environment, the air, drinking water, and food, particularly meat, fish, and poultry. They are rapidly absorbed from the intestinal tract and distribute to and accumulate in the liver. They also cross the placenta and are excreted in breast milk. Formula milk is free of PCBs. Much concern exists that PCBs transferred to the fetus across the placenta may induce long-lasting neurologic damage.[153] The beneficial effects of breast-feeding, however, outweigh the potentially adverse effects of PCB exposure from breast milk.

Dioxins

Dioxins are a heterogeneous mixture of chlorinated dibenzo-*p*-dioxin and dibenzofuran congeners. Dioxins are emissions of industrial incineration processes. They accumulate in the food chain to result in human exposure.[154] Few data are available on the effects of dioxins on female reproductive health. In animal models, dioxin has an antiestrogenic effect. Environmental chemicals have been implicated in the temporal decline in the age of onset of puberty, the development of polycystic ovarian syndrome, and shortened lactation. Reports of cryptorchism and hypospadias need more careful study, particularly because they are linked to testicular cancer. The effects of environmental chemicals on sperm quality are inconsistent. Because of methodologic shortcomings in epidemiologic studies, it is unknown whether dioxins affect spontaneous abortion rates or fetal growth restriction.

Pesticides

Pesticides (e.g., fungicides, herbicides, insecticides, and rodenticides), often found in commercially available food products, are a reproductive health concern in many countries. However, the almost universal exposure to low concentrations of these compounds makes it very difficult to determine the effect of pesticides on the incidence of fetal abnormalities. Occupational exposure to pesticides has been implicated in increased birth defect rates.[155,156]

Occupational Risk

Risks

With the rising number of women in paid employment in both developing and developed countries,[157] exposures to unsafe and unhealthy conditions, such as toxic chemicals, radiation, and physically or mentally demanding work, have become more common. Because women's occupations are multidimensional and risk exposure perhaps subtle, a simple guide for establishing specific health risks is not always possible.[156,158] However, the adverse effects of poor working environment can be magnified by problems of isolation, stress, tiredness, and depression. Physical violence is a major contributor to women's health risks, either in the home or in the formal workplace (see Chapter 3).

Occupational exposure to risk can be specific such as anesthetic agents, laboratory chemicals, organic solvents, and pesticides (see earlier).[159,160] A meta-analysis of studies of working conditions in pregnancy concluded that physically demanding work is significantly associated with preterm birth (OR 1.22; 95% CI 1.16–1.29), fetal growth restriction (OR 1.37; 95% CI 1.30–1.44), and hypertension or pre-eclampsia (OR 1.60; 95% CI 1.30–1.96). Other occupational exposures significantly associated with preterm birth include prolonged standing (OR 1.26; 95% CI 1.13–1.40) and shift and night work (OR 1.24; 95% CI 1.06–1.46).[161] It appears that interventions to reduce physical exertion among pregnant women could improve birth outcomes.[161–164] Exposure to magnetic fields emitted by video display

Work and Pregnancy

Management Options	Evidence Quality and Recommendation	References
Precautions to protect women against specific occupational risks (e.g., toxic chemicals or radiation).	IV/C	157
Avoid long hours of standing and walking.	Ia/B	157
Avoid excess lifting and exercise.	Ia/B	161
Patients can continue to work if they wish and are not unduly tired.	Ia/B	161,163
There is no evidence that video display units (VDUs) are associated with adverse pregnancy outcome.	III/B	165,166

SUMMARY OF MANAGEMENT OPTIONS
Air Travel in Pregnancy

Management Options	Evidence Quality and Recommendation	References
Long-distance air travel is safe in normal pregnancy.	IV/C	167,171
Long-distance flights are not recommended for women <36 weeks' gestation with singleton pregnancies and <32 weeks' gestation with multiple pregnancies.	IV/C	171
Air travel is not recommended for infants younger than 7 days.	IV/C	167
Update travelers on routine immunizations, including tetanus, diphtheria, polio, measles, mumps, rubella, hepatitis A and B, and influenza vaccines. Other immunizations are based on geographic risk.	IV/C	180
Travel is not recommended during pregnancy for women with medical or obstetric problems that could result in emergencies.	IV/C	171
Preventive measures (e.g., supportive stockings, periodic movement of lower extremities) minimize thromboembolic risk. Additional prophylaxis is advised in those with increased thromboembolic risk (see Chapter 42).	Ib/A	171,177
Travelers should take steps to prevent mosquito bites in malarial endemic areas.	Ia/A	182
Antimalaria prophylaxis in pregnancy significantly reduces the likelihood of severe maternal anemia and low birth weight.	Ia/A	183
Malaria should be suspected in all patients who have symptoms after traveling to an area where malaria is endemic.	III/B	184
See also Chapter 32 for Malaria.		

---

terminals is not a risk to the reproductive health of women or their children.[165,166]

Management Options

A careful workplace history should be taken, including level of activity, hazardous exposures, and ease of workplace modification.[162] Precautions should be taken to protect women from specific occupational health risks, such as exposure to toxic chemicals or radiation.[157] Women whose work is physically or emotionally demanding should be monitored carefully throughout pregnancy for evidence of hypertension, intrauterine growth restriction, and symptoms of preterm labor.[161] It is important for health care professionals, family members, and employers to recognize the potential negative effect of adverse working conditions on pregnancy outcome.

The ultimate decision on continuation of employment during pregnancy should be made by the pregnant woman after careful counseling by her physician, involving the company medical officer and the employer, when indicated.

Air Travel in Pregnancy
General

Little evidence exists on this topic, and recommendations are typically based on common sense rather than scientific evidence.[167]

Risks
RADIATION EXPOSURE

The annual exposure dose limit for a member of the general public is 1 millisievert (mSv). The occupational limit is 5 mSv. Cosmic radiation exposure during high-altitude flight is less than 0.005 mSv/hr.[168] Thus, it takes about 200 flight hours to reach the annual dose limit for the general public. There is less exposure with shorter flights and lower altitudes. Airlines usually restrict commercial airline crew members from long-haul flights once pregnancy is diagnosed.

FETAL AND MATERNAL HYPOXIA

On long-distance commercial high-altitude flights (~32,000 ft), cabin pressure is set at the equivalent to an altitude of 6000 feet.[167] Acute ascent to 6000 feet produces transient cardiovascular and pulmonary adaptations (decreased heart rate, increased blood pressure, decreased aerobic capacity and partial oxygen pressure).[169,170] These changes should not affect women with uneventful pregnancies, but it may affect those with oxygen-dependent conditions. Such pregnant women either should not travel or should receive supplemental oxygen during air travel.[167,171]

VENOUS THROMBOSIS

There is a link between long-distance air travel and deep venous thrombosis and the risk is not confined to those

TABLE 2–4

Vaccination in Pregnancy

VACCINE	USE IN PREGNANCY	COMMENTS
Bacille Calmette-Guérin	No	
Cholera	Yes, administer if indicated	Avoid unless high risk
Hepatitis A	Yes, administer if indicated	Safety not determined
Hepatitis B	Yes, administer if indicated	Safety not determined
Influenza	Yes, administer if indicated	Consult a physician
Japanese encephalitis	Yes, administer if indicated	Avoid unless high risk
Measles	No	
Meningococcal disease	Yes, administer if indicated	
Mumps	No	
Poliomyelitis	Yes, administer if indicated	Normally avoided
Rubella	No	
Tetanus and diphtheria	Yes, administer if indicated	
Rabies	Yes, administer if indicated	
Typhoid	Yes, administer if indicated	Avoid unless high risk
Varicella	No	
Yellow fever	Yes, administer if indicated	Avoid unless high risk

From World Health Organization: International travel and health. Vaccine-preventable diseases. Available at www.who.int/ith/chapter06_16.html; and Thomas RE: Preparing patients to travel abroad safely: Part 2. Updating vaccinations. Can Fam Physician 2000;46:646–652, 655–656.

traveling in economy. The risk, however, appears small and is largely confined to those with additional risk factors.[172–176] There are insufficient scientific data on which to base specific recommendations for prevention, other than leg exercise and the use of elastic compression stockings.[177]

PRETERM LABOR

Air travel does not increase the risk of preterm labor, however, ACOG recommendations suggest that pregnant women with evidence of preterm labor or who are at increased risk for preterm birth should avoid long-distance air travel on empirical grounds.[171]

SEAT BELTS

Advice for airline seat belt use is the same as that for cars. One study showed that the likelihood of adverse pregnancy outcome among belted pregnant women who were involved in a passenger car accident is comparable with that of those who were not pregnant.[178] Because air turbulence cannot be predicted and this risk of trauma is not trivial, pregnant women are advised to use their seat belts continuously while seated.[171]

VACCINES

Live vaccines carry the greatest fetal risk. The World Health Organization advises that administration of live attenuated measles, mumps, rubella, bacillus Calmette-Guérin, and yellow fever virus vaccines should be avoided in pregnancy (Table 2–4).[179,180] Otherwise, the risks and benefits of vaccination should be examined in each case.[181]

MALARIA PROPHYLAXIS

This is addressed in Chapter 32.

Domestic Violence

LORAINE J. BACCHUS and SUSAN BEWLEY

INTRODUCTION

Since the late 1990s there has been growing awareness of the importance of domestic violence as a public health issue. Obstetricians, gynecologists, and midwives have a key role in identifying women who are experiencing domestic violence; documenting the abuse; and ensuring that appropriate advice, support, and interventions are offered. Domestic violence is one part of a spectrum of human rights abuses against women and girls. It includes rape and sexual abuse, sexual harassment and intimidation at work, "honor killings," female genital mutilation, trafficking of children and women for prostitution, and systematic rape as a tool of war. Gender-based violence is predominantly inflicted by men upon women and girls. It reflects and reinforces inequalities between men and women and adversely affects the health, dignity, safety, and autonomy of those affected.

"Domestic abuse" is defined by the U.K. Home Office as "Any incident of threatening behaviour, violence or abuse (psychological, physical, sexual, financial or emotional) between adults who are or have been intimate partners or family members, regardless of gender or sexuality."[1] Throughout this chapter. the terms *domestic violence* and *domestic abuse* are used interchangeably on pragmatic grounds. Both terms have been used by academics and health professionals in their work on the topic both inside and outside the United Kingdom.

Domestic violence is rarely an isolated incident and the abusive behavior often begins insidiously, growing more oppressive and harmful with time.[2] In most cases, violence is directed toward a woman by her male partner.[3] Women are more likely than men to sustain physical injuries, experience repeated assaults, report fear and emotional distress, and seek medical attention as a result of the violence.[4] This chapter deals with violence by men against female partners in pregnancy.

PREVALENCE

The 2006/2007 British Crime Survey reported that 28% of women had experienced domestic abuse at some point in their lives, with 21% threats or force and 24% sexual assault. The prevalence of any partner abuse in the past year was 5.9%.[5] Similar rates have been reported in surveys from Canada[6] and the United States.[7] Higher rates of domestic violence (≤40%) have been reported in clinical settings.[8,9]

In most cases of domestic violence that are identified in pregnancy, there is preexisting violence that continues throughout the pregnancy and following the baby's birth.[10] However, domestic violence may also begin pregnancy.[11] The prevalence of domestic violence in pregnancy is reported to be between 3%[12] and 33.7%,[13] with the greatest risk occurring during the postpartum period.[14,15] Higher rates of violence during pregnancy have been found among pregnant teenagers.[16,17] Thus, domestic violence is more common than many obstetric complications such as preeclampsia.

Domestic violence also contributes to maternal mortality—either directly or indirectly, for example, by impeding access to care. The 2003–2005 Confidential Enquiries into Maternal Deaths in the United Kingdom[18] reported the deaths of 19 pregnant or recently delivered women who were murdered. Seventy of 295 women who died from all causes (i.e., 14% of all maternal deaths) had documented features of domestic abuse, including 4 women with genital mutilation or cutting.

RECOGNITION

Significant associations with domestic violence include:

Psychosocial Factors

- Mental health issues such as depression, suicidal ideation, self-harming, post-traumatic stress disorder, and anxiety.[19–24]
- Alcohol and substance misuse is associated with both the experience and the perpetration of domestic violence.[14,25,26]

Behavioral Factors

- Unwanted pregnancy or rapid repeat pregnancy (within 24 months).[27,28]
- Increased parity and younger age at first pregnancy.[29,30]

Contact with Health Services

- Frequent use of health care services, requiring treatment for injuries and symptoms resulting from the violence.[31–33]
- Late initiation of antenatal care.[34]

Interactions with Partner Indicative of a Controlling Relationship

- The partner may accompany the woman to all her antenatal appointments, taking a keen interest, holding the maternity notes, or answering questions directed at her, or may appear reluctant to leave the woman alone with a health professional.[35]
- Noncompliance with treatment regimens, lack of independent transportation, and difficulties in communicating by telephone.[35]
- Where domiciliary care is available, health professionals can experience difficulties in gaining access.[36–38]

Clinical Presentations

- The woman's explanation for how an injury occurred seems implausible.
- Forced sex that can lead to infection of perineal sutures and delay the healing process.[39]
- Difficulties occurring while conducting pelvic examinations prenatally or during labor, with the woman becoming distressed, withdrawn, or even hostile. This may be significant when a woman requests a female health professional for such examinations.

Although the presence of these risk factors and indicators may raise a health professional's index of suspicion, no single factor will accurately identify which women are likely to be affected by domestic violence. Abused women may present with a range of these symptoms and behaviors or none at all (Table 3–1).

RISKS

Maternal Risks

Women who experience domestic violence have significantly poorer health outcomes than nonabused women including

- Chronic pain[40] (e.g., headaches, backaches, pelvic pain), hearing or vision problems,[41] sleep disturbance, poor appetite,[42] and gastrointestinal disorders such as irritable bowel syndrome.[43] These effects may be caused directly by recurrent physical or sexual injury or indirectly from underlying stress.[44]
- Gynecologic problems (e.g., sexually transmitted infections, urinary tract infections, pelvic inflammatory disease, vaginal bleeding, menstrual irregularities, genital irritation, and pain during intercourse).[44,45]
- Depression,[46] especially after delivery when domestic violence may get worse.[14,15,47]

Fetal and Neonatal Risks

These include

- Low birth weight babies.[48,49]
- Trauma to the abdomen may result in placental abruption, premature rupture of membranes, preterm labor, miscarriage, and fetal death.[50–52]
- Bruising, fractures, hemorrhaging, and deformity.[53]

MANAGEMENT OPTIONS

General

In recognition of the serious health implications of domestic violence, in the United Kingdom, the Royal College of Midwives[35] and the Royal College of Obstetricians and Gynaecologists[54] have published guidelines for the identification and support of women affected by domestic violence. The Department of Health[55] has also produced a domestic abuse handbook for health care professionals in which they recommend that "all Trusts should be working towards routine enquiry and providing women with information on domestic abuse support services. It is important to take the initiative and be proactive." Similarly, the American Medical Association[36] and the American College of Obstetricians and Gynecologists[56] have developed guidelines for health practitioners in North America. The 2003–2005 Confidential Enquiries into Maternal Deaths in the United Kingdom recommend that "once multi-agency support services are in place … routine enquiries should be made about domestic abuse, either when taking a social history at booking, or at another opportune point during a woman's antenatal period."[18]

TABLE 3–1	
Physical Signs and Injuries Associated with Domestic Violence	
Head, neck, or facial injuries	Multiple bruises or lacerations in various stages of healing
Back, chest, or abdominal pain or tenderness	Patterned injuries that show the imprint of the object used
Injuries to the breasts, abdomen, or genitals	Burns from cigarettes, appliances, rope, or friction
Vaginal bleeding or discharge, sexually transmitted infections, genital injuries	Scalding from boiling water
Dizziness, black outs	Strangulation marks
Numbness	Fractures
Injuries to the extremities	Broken bones
Delay in seeking treatment	Knife wounds
Premature removal of and infection of perineal sutures	Dental injuries (e.g., broken or lost teeth)
Distress, aggression, or withdrawn behavior during pelvic examinations, labor, and delivery	Hair loss consistent with hair pulling
Partial loss of hearing or vision	Bite marks or scratches

SUMMARY OF MANAGEMENT OPTIONS
Domestic Violence

Management Options (Any Stage of Pregnancy or the Postpartum)	Evidence Quality and Recommendation	References
Stage 1: Awareness and Recognition		
Increase awareness and recognition of domestic violence and its health effects through training and education.	III/B	70,72,73
Develop guidelines for identifying and supporting women affected by domestic violence, in conjunction with other health professionals and community groups.	IV/C	55,73
Stage 2: Provision of Safe Environment		
Provide the woman with a safe and private environment away from partners, family, or friends.	IV/C	35,55,73
Stage 3: Identification and Aiding Disclosure		
When language translation is required, arrange for independent professional interpreters, preferably female.	IV/C	35,55
Ask direct questions about domestic violence, routinely.	III/B	61,74,75
Adopt a supportive and nonjudgmental response.	IV/C	35,55,73
Stage 4: Documenting the Abuse		
Document the abuse and any interventions offered in the confidential maternity record.	IV/C	35,55,73
Stage 5: Safety Assessment, Information Giving, and Ongoing Support		
Offer referral information about advocacy organizations that provide immediate and long-term support to women and children affected by domestic violence.*	Ib/A	62,63*
Assess the immediate safety of the woman and any children.	IV/C	35,55
Provide ongoing support and monitoring at subsequent appointments, ensuring continuity of care wherever possible.	IV/C	35,55
Display and disseminate information about local and national domestic violence organizations and other helpful agencies so that it is accessible to users and providers of maternity services.	IV/C	35,55
Work in partnership with local multiagency domestic violence initiatives.	IV/C	35,73

* Little experimental work on interventions in health care settings, but one community-based randomized controlled trial in a nonpregnant population showed a reduction in violence, decreased difficulty in obtaining community resources, and a higher quality of life at 2 years in the intervention group that received advocacy compared with the control group.[62,63]

Five key stages to the clinical management of domestic violence are applicable to any stage of the pregnancy and postpartum period[35,55]:

- Awareness and recognition of domestic violence.
- Provision of a safe and quiet environment.
- Identification and aiding disclosure.
- Documenting the abuse.
- Safety assessment, information giving, and ongoing support.

Stage 1: Awareness and Recognition of Domestic Violence

All health professionals providing care for pregnant women should be aware of the potential indicators (see earlier) of domestic violence and the maternal and fetal risks. Women may present with a range of physical and emotional indicators or none at all. Although these indicators may increase the index of suspicion, if abuse is suspected, inquiry about domestic violence should be made using stages 2 and 3.

Stage 2: Provision of a Safe and Quiet Environment

The woman should be provided with a safe and quiet environment before any inquiry about domestic violence takes place. Maternity services must have management policies and guidelines that ensure women will have confidential time with health professionals, both at booking and during other stages of pregnancy. Strategies for creating individual private consulting time may include requesting to see the woman alone as a routine procedure, asking the partner to

wait outside at the end of the appointment to conduct a physical examination, or taking the woman to another part of the clinic for a urine sample, blood test, or weight check. In suspicious cases, for example, a "check up" after "a fall" with an overbearing accompanying partner, admission for observation might be suggested to ensure private time. Issues of safety and confidentiality should be paramount when working with women experiencing domestic violence. Anecdotally, children as young as 2 years may report back to the partner or family members that abuse was discussed. The woman should be reassured that any information she provides will not be shared with her partner, family members, or friends. However, the woman must be advised about the limitations of confidentiality with regards to sharing information with other professionals involved in her care. If the woman does not feel safe discussing the violence in depth with her partner waiting nearby, it may be preferable to make another appointment at a time when the partner is unable to attend. Health professionals working in the community could offer to meet women at the clinic or at the home of a trusted friend or family member. If a woman has hearing difficulties or her first language is not English, arrange for an independent professional interpreter, preferably female, to be present. Family or friends should never be asked to translate when discussing domestic violence.

Occasionally, a health professional may become aware that a child or other vulnerable person living with the abused woman is also at risk of harm. Child protection procedures should be followed. The other exceptional circumstance in which confidentiality may be breached is when the health professional becomes aware that a victim of domestic violence is at risk of serious harm or death from a violent partner (see "Safety Assessment, Information Giving, and Ongoing Support," later). Any referrals to social services should be discussed with the mother and her consent and cooperation sought.[57] Much more is likely to be achieved by working openly with the woman and reassuring her that social services are able to support her in protecting herself and her children. Any information disclosed to a third party without consent should be the minimum necessary to secure the best interests of the woman and her children.[57]

Stage 3: Identification and Aiding Disclosure

Studies conducted in a range of health care settings have shown that the use of direct questions about domestic violence, asked routinely of all patients, increases the rate of detection.[58] Evidence shows that the majority of women find routine inquiry for domestic violence during health care appointments acceptable.[8,9]

A woman's willingness to discuss the abuse will partly depend on the approach of the health professional, and disclosure is more likely if a sensitive and nonjudgmental manner is adopted. Simply asking about domestic violence can be an important intervention in itself, by reducing the stigma attached to it and directing women to sources of help.[59,60] Important principles are to listen and offer validation of the woman's experiences, to acknowledge the seriousness of the situation, and to emphasize that she does not have to deal with it by herself.

It is recommended that the health professional begin by asking a few open-ended questions before following up with specific questions about abuse. For example:

"How are things at home?"

"Are you getting the support you need?"

"Is there anything you are unhappy about?"

This will help to establish some degree of rapport with the woman.[35,54] Women often talk tangentially around the issue of domestic violence, for example, referring to feeling "stressed," overwhelmed, not coping, financial worries, or housing problems. When asking directly about domestic violence, the question should be framed in a way that conveys you recognize domestic violence is an important health issue and difficult to talk about. For example:

"Many women I see experience some form of emotional or physical abuse from their partner, but find it difficult to bring the subject up themselves, so I ask everyone about it."

This can be followed up with one or more direct questions appropriate to the situation. For example:

"Do you ever feel afraid of your partner?"

"Do you and your partner argue or fight? Do the arguments get physical?"

"I've noticed a number of bruises/cuts/scratches; has someone at home hurt you?"

"Some women tell me that their partners are cruel, sometimes emotionally and sometimes physically hurting them—is this happening to you?"

"Does your partner ever treat you badly such as shout at you, constantly call you names, push you around, or threaten you?"

If a woman makes a disclosure of abuse, stages 4 and 5 should be followed. If a woman tells you that she has not been abused, it is important to accept her response even if you suspect otherwise because this conveys respect. However, it is important to allow the opportunity for future disclosure by reminding her that she can talk to you about any concerns or problems at home at any time. It has been demonstrated that repeated inquiry about domestic violence increases the detection rate and can facilitate detection of violence that begins later in pregnancy.[61]

Robust evidence regarding the potential benefits and harmful outcomes of interventions based in health care settings is limited and what evidence does exist originates from North America. One U.S. randomized controlled trial found that domestic violence advocacy intervention can reduce the levels of violence up to 2 years postintervention[62] and lead to improvements in social support and quality of life[63] up to 3 years postintervention. However, with the exception of a few studies conducted in antenatal settings,[64–66] most of the evidence is based on samples of women who had already disclosed partner violence and were actively seeking help from professional services.[67,68] In a recent systematic review of the evidence for screening interventions, the authors state that although there is enough evidence to justify access to advocacy services for survivors of partner violence in general, the evidence is weakest for women who are identified through screening by health professionals.[67]

Health professionals have a key role in providing women with information about services and options available to them, assessing current and future risk, and documenting the

abuse. Maternity services can raise public awareness of domestic violence as an important health issue and convey the message that violence of any kind is unacceptable. Posters and leaflets about domestic violence and support services should be placed in clinic waiting rooms and areas where women will be able to access the information safely (e.g., the toilets, baby-changing rooms). These should be available in a range of languages that reflect the local community.

Stage 4: Documenting the Abuse

The medical records of treatment for any injuries or symptoms resulting from the violence are important documents. Women experiencing domestic violence are often required to provide evidence of the abuse when seeking help from agencies (e.g., housing, divorce proceedings, obtaining injunctions, or prosecution of the perpetrator), and medical evidence can be important to support her statement. Documentation is also important to ensuring the flow of information to other health professionals involved in the woman's care, which will facilitate ongoing support and monitoring. Inform the woman of the benefits of documentation, even if she does not wish to take immediate action.[35,54] To maintain the woman's safety and confidentiality, domestic violence should never be recorded in places accessible to her partner (e.g., in hand-held maternity records) but placed in a separate record that is kept in the clinic or hospital.[35,55] An agreed plan of action that can be followed up by the midwife or doctor at a later date may also be useful. Without a follow-up plan, the woman may feel that she has not been listened to.[35] Clear and accurate notes are important, including

- Date and time that the abuse took place.
- Where the incident occurred.
- Name and relationship of the perpetrator to the woman.
- Any new or old injuries sustained including psychological symptoms; information, advice, or treatment offered; and whether the woman accepted this.
- A body map picture can be used to indicate the location of any injuries sustained.[69] Alternatively offer the services of medical photography in the hospital.

Injuries consistent with domestic violence that are explained implausibly should also be documented in the confidential records. Records should be signed and dated by the health professional. Remember to check and gain the woman's permission to share the information with other relevant health professionals, emphasizing that information will be shared only on a "need to know" basis.

Stage 5: Safety Assessment, Information Giving, and Ongoing Support

The immediate safety of the mother and her children should be assessed by asking whether it is safe for her to return home. Inform the woman of her options and of the specialist domestic violence services in and out of her area that can provide emergency help and long-term support.[55] Provide written information about domestic violence organizations and other support services, after confirming that it is safe for her to take the information away with her. Discreet

credit-sized cards may be preferable. The woman may prefer to use a telephone in a private room to contact the agencies herself, if she cannot do this at home. It is always best to encourage the woman to talk to the agencies herself so that she is in control of her sources of help and gains confidence in explaining her situation and asking for help. Health professionals can best facilitate the woman's exploration of her options by maintaining a supportive position but avoiding personal and emotional investment in the choices she makes.

A variety of emotional and situational factors make leaving an abusive relationship difficult, and women often return to their partners several times before terminating the relationship. Isolation from friends and family, lack of self-esteem, self-blame, financial hardship, inappropriate accommodation, and living in constant fear of retaliation by the partner are just some of the challenges women encounter when ending an abusive relationship. Other factors that may undermine the woman's capacity to initiate change or increase her dependence on her partner include alcohol and substance misuse, mental health issues, pregnancy, having dependent children, and cultural or religious values that emphasize family and marriage over the woman's well-being.[27]

It is suggested that each woman is provided with a mutually agreed safety plan that can be modified over time.[35,55] However, each item on the safety plan should be achieveable. This may include

- Making a list of important phone numbers, including emergency numbers that can be called at any time of the day or night (e.g., emergency housing, National Domestic Violence Helpline).
- Identifying a trusted friend or family member that the woman can stay with in an emergency.
- Leaving a bag packed with clothes, medicines, other essential items with a trusted friend or family member.
- Having money for bus, train, cab fares.
- Getting an extra set of house and car keys.
- Taking original copies or photocopies of any important legal and financial papers (e.g., passport, birth and marriage certificate, bank book, rent book, credit cards).

If the woman agrees to being referred to a specialized domestic violence service, the health professional can offer to speak to someone from the organization to make an introduction, give basic details of the situation, and identify any needs. It is good practice to ensure that, wherever possible, the woman is given the option of seeing the same health professional at subsequent appointments.[35] Reconciliation work with the couple should not be attempted, because this may jeopardize the safety of both the woman and the health professional.

CONCLUSION

Domestic violence is a complex issue, and health professionals should not work in isolation because many local and national initiatives offer expertise on the subject. Therefore, health professionals should equip themselves with the skills and knowledge necessary to provide an informed response to women affected by violence by requesting and accessing opportunities for training and education.

Genetics, Risks of Recurrence, and Genetic Counseling

PETER A. FARNDON and MARK D. KILBY

INTRODUCTION

An abnormal fetal phenotype can be caused by environmental factors, chromosomal anomalies, specific genes, or more complex genetic mechanisms.

Because families with single-gene disorders or parental chromosomal anomalies are at the greatest risk, it is important to identify couples from such families before they undertake pregnancy. An assessment of a couple's probability can often be made by a combination of pedigree analysis, precise clinical diagnosis, and genetic testing, which is available for a large number of conditions.

Particular pointers that might suggest that a couple is at increased probability of having a child with an anomaly include

- A previous child affected with a single-gene disorder.
- A family history of a single-gene disorder.
- A parent with a chromosomal anomaly.
- Structural anomalies found on ultrasound examination.

DETERMINING THE GENETIC BASIS OF A CONDITION

To ensure that a family receives accurate genetic information, it is recommended that the following steps are undertaken:

- Record and examine the family tree to detect a pattern of inheritance.
- Refine and confirm the diagnosis by clinical examination and testing.
- Perform karyotype analysis or DNA testing, as appropriate.
- Assess the genetic risks to family members.
- Explain the genetic information to the family (*genetic counseling*).
- Discuss the available options.
- Support the family while they make decisions appropriate to their situation.

IDENTIFYING FAMILIES WITH AN INCREASED PROBABILITY OF A GENETIC CONDITION

The couple may have realized that the family tree suggests a genetic condition and volunteer this information. In other cases, a high risk is appreciated only when a formal history is taken.

The best and easiest way to record genetic information is to draw a pedigree. The standard notation is shown in Figure 4–1. Guidelines include

- Create the tree from the "bottom," starting with the affected child and siblings, including the names of the children and their dates of birth, in order of age.
- Choose one parent (usually the mother) and ask about her siblings and their children, and then her parents, moving from generation to generation.
- Add information about the paternal side of the family.
- Use clear symbols (e.g., circles for females, squares for males). Fill in the symbol if the person is affected.
- Put a sloping line through the symbol (from the bottom left to the top right corner) if the person has died.
- Record all names, dates of birth, and maiden names.
- Ask about miscarriages, stillbirths, or deaths in each partnership: "How many children have you had?" "Have you lost any children?" "Have you had any previous partners?"
- Note parental occupations, medical and drug history, and pregnancy and birth history, especially when a child has a dysmorphic syndrome.
- Record at least basic details for both sides of the family, even when it appears that a condition is segregating on one side.
- Ask about consanguinity: "Are you and your partner related?" "Are there any surnames in common in the family?"
- Date and sign the pedigree.

PEDIGREE SYMBOLS

FIGURE 4–1
Symbols used in drawing a pedigree.

When the mode of inheritance is certain from the diagnosis (e.g., a known autosomal recessive condition), it may not be necessary to record personal details about all family members in as much detail as would be required for an unknown condition.

It is strongly recommended that the couple's consent is obtained and documented to share their medical information and test results with professionals and family members, should this be helpful for other family members in the future.

Interpretation of the Genetic Family History

The precise pattern of members with the condition may suggest dominant, recessive, or X-linked inheritance, as discussed later. Inherited chromosomal anomalies may show a pattern of unaffected members having children with multiple anomalies and/or several pregnancy losses (Table 4–1).

Although consanguinity in a family may support the likelihood of an autosomal recessive mode of inheritance, care must be taken to consider and exclude the other modes of inheritance. Sometimes, there may be no family history, but the person who appears to be an isolated case can still have a genetic cause.

Confirmation of the Diagnosis

Accurate genetic information requires a precise diagnosis, which may need to be confirmed by a specialist, who may be able to identify clinical subtypes with different modes of inheritance. Confirmatory documents, such as specialists' letters and laboratory or necropsy results, may also be required. Apparently unaffected individuals may need to be assessed to exclude mild or early disease, especially in autosomal dominant conditions, such as neurofibromatosis, tuberous sclerosis, myotonic dystrophy, retinitis pigmentosa, and adult polycystic kidney disease.

Genetic Counseling

Harper[1] defined genetic counseling as "the process by which patients or relatives at risk of a disorder that may be hereditary are given information about the consequences of the disorder, the probability of developing and transmitting it and the ways in which it may be prevented or ameliorated."

Providing Genetic Counseling

The provision of clinical genetic services varies between countries. In the United Kingdom, medically trained clinical geneticists, supported by a team of genetic counselors, are usually based in tertiary referral centers, but most have clinics in district hospitals.

As part of clinical care, most obstetricians give genetic information about common chromosomal trisomies found at prenatal diagnosis, for instance, but seek advice from a clinical geneticist for DNA diagnosis, familial chromosomal conditions, single-gene disorders, and malformation syndromes.

Giving Genetic Information

Genetic information should be given in a nondirective manner, presenting facts, discussing options, and helping

---

TABLE 4–1

Establishing the Mode of Inheritance

Autosomal Dominant Inheritance

Males and females affected in equal proportions.
Transmitted from one generation to next ("vertical transmission").
All forms of transmission are observed (i.e., male to male, female to female, male to female, and female to male).

Autosomal Recessive Inheritance

Males and females affected in equal proportions.
Individuals affected in a single sibship in one generation.
Consanguinity in the parents may provide further support.

X-Linked Recessive Inheritance

Males affected almost exclusively.
Transmitted through carrier females to their sons ("knight's move" pattern).
Affected males cannot transmit the condition to their sons.

X-Linked Dominant Inheritance

Males and females are affected but affected females occur more frequently than affected males.
Females are usually less severely affected than males.
Affected females can transmit the condition to male and female children, but affected males transmit the condition only to their daughters, all of whom are affected.

Inherited Chromosomal Anomalies

May give a pattern of unaffected family members having children with multiple anomalies with growth and developmental retardation.
The hallmarks of chromosome anomalies are multiple organ systems affected at different stages in embryogenesis.
May give a pattern of multiple pregnancy losses.

Mitochondrial Inheritance

If all the children of affected mothers are affected, but no children of affected fathers, consider the possibility of mitochondrial inheritance.

An Apparently Isolated Case

Could be caused by a
- Phenocopy (caused solely by environmental factors).
- New dominant mutation.
- More severe expression in a child of a dominant condition in a parent.
- Recessive condition.
- X-linked condition (if a male).
- Chromosome anomaly (either inherited or spontaneous).
- A combination of environmental influences acting on a genetic predisposition.

---

couples and families to reach their own decisions. It may not be easy to be completely nondirective because the professional's views can affect the tone and manner of presentation of the information. There is no "right" or "wrong" decision; a couple must make a decision that they believe is right for them. Whenever possible, the partners should be seen together when discussing genetic information or anomalies found at prenatal diagnosis.

Timing

Couples who consider themselves to be at potentially high risk for a genetic condition and who have sought genetic information before embarking on a pregnancy have time to decide which option is the most appropriate.

The diagnosis of a serious genetic condition or malformation syndrome during pregnancy may require difficult management decisions to be made relatively quickly. The family may have little time to understand the severity and consequences of the condition, identify the options (including available treatments), and discuss the genetic implications. Families want to know whether the condition is lethal or severely disabling, whether there is a high risk that a future pregnancy will be affected, and whether specific prenatal diagnosis would be available.

Genetic information may play an important role in the consideration of options for future pregnancies and clinical management of the current pregnancy. Options include
- Having no further children.
- Accepting the risk.
- Undertaking prenatal diagnosis, if available.
- Seeking adoption.
- Accepting gamete donation.
- Seeking preimplantation diagnosis.

A couple's choice will depend on many factors, but social, economic, moral, and practical factors appear particularly important.

DETERMINING THE PROBABILITY OF RECURRENCE

The mathematical *risk of recurrence* can usually be derived with certainty for a single-gene (mendelian) condition. For other conditions, empirical figures must be used (see later).

Genetic Risk: Burden and Probability

A genetic *risk* figure has two components: the probability that the condition will occur and the burden of the

condition. Families may view the same mathematical figure entirely differently. For example, for autosomal dominant conditions with a "1 in 2" risk, the family may view the effect of the condition as mild (e.g., brachydactyly) or very severe (e.g., Huntington's disease). Their view may also be affected by whether screening and treatment are available (e.g., bilateral retinoblastoma, adenomatous polyposis coli). Families usually want to discuss such issues during the genetic consultation.

Explaining Risks (See also Chapter 2)

Although some people perceive probabilities only as "high" or "low," most wish to understand how a figure has been reached, and so a discussion about modes of inheritance and mechanisms of genetic disease may be helpful. Expressing a risk figure as a fraction (e.g., 1 in 2, 1/2), as odds (50:50), or as a percentage (50%) is less likely to lead to confusion. The perception of what constitutes a "high" or "low" probability varies with the individual. Some families find it easier to

understand probabilities when they are presented as odds, whereas others prefer to discuss these figures as percentages. Most clinical geneticists use both odds and percentages during a consultation, concentrating on the one that the patients find easiest to understand. The decision as to what constitutes an "acceptable" risk varies with the condition and the individual. However, providing some reference points (Table 4–2) may be helpful.

TYPES OF GENETIC CONDITIONS: MECHANISMS AND PROBABILITIES

Humans have approximately 23,000 genes arranged on 23 pairs of chromosomes that allow their physical transmission from cell to cell and generation to generation. Generally, alteration of gene function is the underlying mechanism for single-gene disorders, and alteration of copy number underlies chromosomal conditions. Many isolated congenital anomalies are the result of multifactorial inheritance in

TABLE 4–2

Examples of Approximate Reproductive Risks in Developed Countries

REPRODUCTIVE OUTCOME	RISK	
	ODDS	%
Infertility	1 in 10	10.0
Pregnancy ending in a spontaneous miscarriage	1 in 8	12.5
Perinatal death	1 in 30 to 1 in 100	1.0
Birth of a baby with a congenital abnormality (major and minor)	1 in 30	3.3
Birth of a baby with a serious physical or mental handicap	1 in 50	2.0
Death of a child in the first year after the first week	1 in 150	0.7

which the condition occurs in individuals with a liability above a particular threshold. The liability is composed of *environmental* components that act with a genetic predisposition caused by the summation of the effects of several genes.

CONDITIONS WITH MENDELIAN INHERITANCE: SINGLE-GENE DISORDERS

General

Single-gene (mendelian) disorders behave as though they are under the control of only one pair of genes. They have high probabilities of recurrence. Mendelian inheritance is usually recognized by a combination of clinical diagnosis and the pattern of affected people in the family.

Probabilities of recurrence can usually be determined from knowledge of the mode of inheritance of a particular condition. However, some conditions, such as retinitis pigmentosa, have dominant, recessive, and X-linked forms, so care is needed.

For many mendelian conditions, DNA tests are available for presymptomatic diagnosis, carrier detection, and prenatal diagnosis. Up-to-date information should be sought from a clinical genetics department because advances are too rapid for published literature to remain current. In addition, access to online databases is helpful (see Appendix). Prenatal diagnostic possibilities may have changed by the time a couple is considering having another child.

Autosomal Dominant Inheritance (Fig. 4–2)

A dominant trait manifests in a heterozygote (a person with both the altered and the usual alleles) and is usually transmitted from one generation to the next (*vertical transmission*). Each offspring of a parent with an autosomal dominant condition has a 1 in 2 chance of inheriting the altered allele. Because autosomal dominant traits can exhibit variable expressivity, reduced penetrance, and sex limitation, it may be more difficult to predict the clinical severity in a fetus than would be suggested by the simple probability of 1 in 2 of inheriting the altered allele.

In dominant conditions with variable expression, careful physical examination may be needed to detect the minute

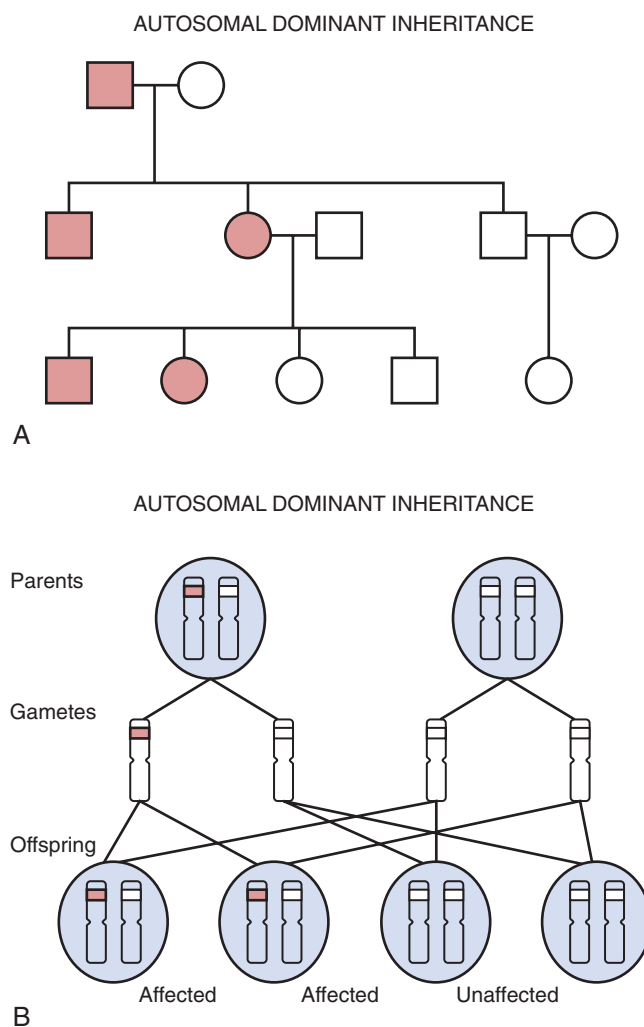
FIGURE 4–2

Single-gene disorders: examples of pedigrees and modes of inheritance. *A,* Autosomal dominant inheritance. Three generations are affected, and male-to-male transmission is shown. *B,* Autosomal dominant inheritance. If one parent has a dominant condition, each offspring has a 50% (1 in 2) probability of inheriting the altered gene.

AUTOSOMAL DOMINANT INHERITANCE

A

AUTOSOMAL DOMINANT INHERITANCE

B


signs that a parent has the altered gene. For example, axillary freckling may be the only sign of neurofibromatosis. Variable expression can also result in a fetus having more severe manifestations of the condition than the affected parent. For example, in myotonic dystrophy, a mother with mild signs can have a child with the severe congenital form of myotonic dystrophy due to an increase in size during maternal transmission of the trinucleotide repeat associated with the condition. In contrast, some dominant conditions show no variation in expression, resulting in all people with the condition having the same phenotype (e.g., achondroplasia).

Very rarely, a person who carries an altered gene for an autosomal dominant condition (with an affected parent and an affected child) has no physical signs of the condition. The allele is said to be *nonpenetrant* in the person who has no clinical signs of the condition.

Some autosomal dominant conditions appear to occur sporadically. If both parents are found to be unaffected after appropriate examinations and investigations, then the child's

condition is likely to be the result of a new mutation causing the dominant condition. The probability of recurrence in further children of the parents is low, but not zero, because there is a small probability that a parent of a child with an apparently new dominant mutation has gonadal mosaicism. Gonadal mosaicism—in which a parent has two populations of gonadal cells, one population containing the mutation and one with the normal gene—can explain the rare cases in which unaffected parents have two children with the same autosomal dominant condition.

Autosomal Recessive Conditions (Fig. 4–3)

Autosomal recessive conditions are manifest only in the homozygous state: the affected person has two copies of the

Affected

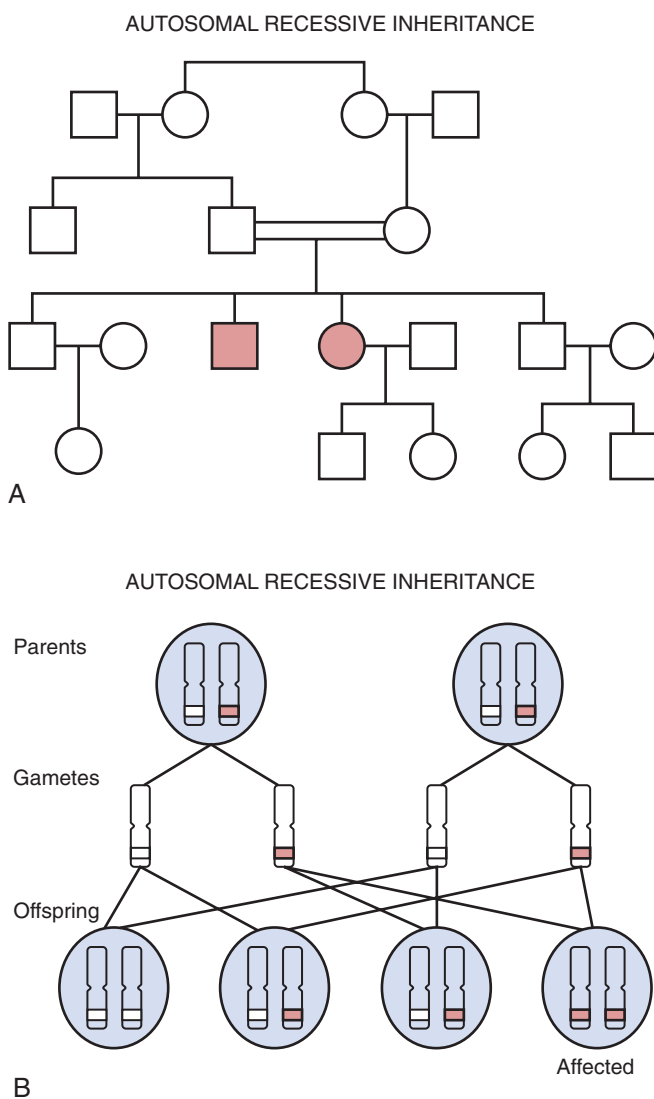
B


FIGURE 4–3

Single-gene disorders: examples of pedigrees and modes of inheritance. *A*, Autosomal recessive inheritance. Siblings in only one generation are affected. In this family, the parents are first cousins. *B*, Autosomal recessive inheritance. If both parents carry the same altered gene for a recessive condition, each offspring has 25% (1 in 4) probability of inheriting the altered gene from both parents and, therefore, of having the condition.

altered gene. Heterozygotes (carriers) are healthy. When both parents are heterozygous for the same autosomal recessive condition, each child has a 1 in 4 chance of inheriting the condition. An unaffected sibling of an affected person has a 2 in 3 chance of being a carrier. When someone with an autosomal recessive condition has children, offspring will be at risk of inheriting the condition only if the partner is a carrier for the same autosomal recessive condition.

Carriers for some inborn errors of metabolism can be identified by biochemical tests. Unfortunately, for many conditions, the range of results for carriers overlaps with the range of results for noncarriers; test results generate a probability of being a carrier rather than giving a definitive answer. DNA techniques allow diagnosis of the carrier state for some autosomal recessive conditions in some families. This *genetic testing* is offered when other evidence (usually being closely related to an affected person or a known carrier) suggests that the prior probability is increased.

For some conditions, genetic testing can be offered to populations in which there is a high incidence of carriers, particularly where there are a few common mutations. This *genetic screening* may detect carriers with no known family history and is discussed in more detail later.

Unless the condition is very common or unless consanguinity is present, the probabilities for half-siblings, children of affected individuals, and especially children of unaffected siblings are minimally increased over those of the general population. The precise probability depends on the frequency of heterozygotes in the population and can be calculated using mendelian principles.

If a couple requests sterilization after the birth of a child with a very severe autosomal recessive condition, it is important to discuss sensitively that other forms of contraception are available. This is because, if in the future, either parent were to have children with a new, unrelated partner, the probability of recurrence would likely be very low.

X-Linked Recessive Inheritance (Fig. 4–4)

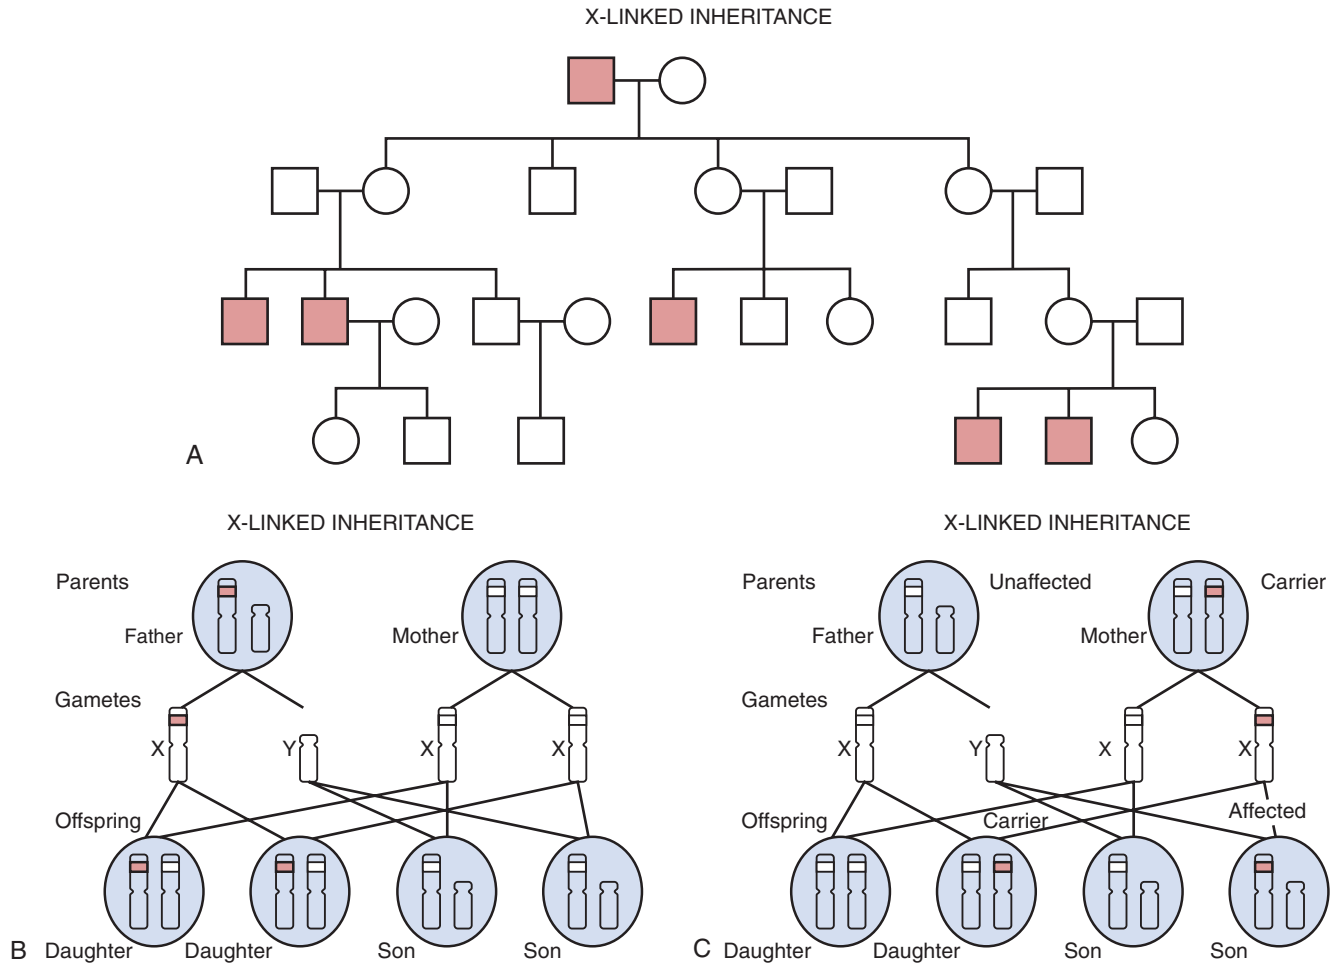
Although males and females have similar sets of the 22 pairs of autosomes, the sex chromosome pair is different. Females have two X chromosomes, whereas males have one X chromosome and a Y chromosome. X–Linked recessive traits usually manifest only in males because males have a single copy of the genes on the X chromosome. Although females have two copies of the X chromosome, one is inactivated at random early in gestation to ensure equal amounts of gene products from the X chromosome in males and females. In an individual female cell, the genes on either the paternal or the maternal X chromosome are active and most of the genes on the other X chromosome are silenced. Therefore, a female who is heterozygous for an X-linked condition will be a mosaic of cells in which the normal or the altered gene is active, the numbers of each type in a given tissue related to the chance pattern of X inactivation. Carrier detection in X-linked recessive conditions may, therefore, be difficult. For example, approximately 30% of known carriers of Duchenne muscular dystrophy have biochemical carrier test results within the normal range, because, by chance, relatively few of their muscle cells express the altered gene. Reliable techniques for carrier detection are particularly important to determine whether apparently isolated cases of

FIGURE 4–4

Single-gene disorders: examples of pedigrees and modes of inheritance. *A*, X-Linked inheritance. In this family, the grandfather has a nonlethal X-linked condition (e.g., hemophilia). Males affected in several generations are linked through unaffected females. Daughters of affected men are obligatory carriers. *B*, X-Linked recessive inheritance in which a father is affected. If a father has an X-linked condition, all of his daughters will be carriers, but none of his sons will be affected. (Sons inherit his Y chromosome; that is why they are male!) *C*, X-Linked recessive inheritance in which a mother is a carrier. If a woman carries a gene for a recessive condition on one of her X chromosomes, each of her sons has a 1 in 2 probability of being affected and each of her daughters has a 1 in 2 probability of being a carrier.

X-LINKED INHERITANCE

X-LINKED INHERITANCE

X-LINKED INHERITANCE


X-linked recessive conditions are the result of a new mutation or whether the mother is a carrier. Fortunately, DNA techniques may be able to answer these questions, either by direct detection of a mutation or by gene tracking (discussed later).

Each son of a woman who is heterozygous for an X-linked recessive condition has a 1 in 2 chance of inheriting the altered allele from his mother and of being affected (see Fig. 4–4*C*). Each daughter has a 1 in 2 chance of inheriting the altered allele, and so of being a carrier, but would be expected to be unaffected. (Women who are carriers for the fragile X mental retardation syndrome can have daughters who are mentally handicapped; because of the complexities involved, patients should be referred for genetic counseling.)

As daughters of males with an X-linked condition inherit their father's X chromosome, they are obligate carriers (see Fig. 4–4*B*).

Rarely, females show signs of an X-linked recessive trait or condition because they are homozygous for the allele (e.g., color blindness), have a single X chromosome

(Turner syndrome), have a structural rearrangement of an X chromosome, or are heterozygous with skewed or nonrandom X inactivation.

If male-to-male transmission is observed in a family, then X linkage is excluded.

Unusual Patterns of Inheritance

Unusual inheritance patterns can be explained by phenomena such as genetic heterogeneity, mosaicism, anticipation (i.e., an earlier age at onset in successive generations), imprinting, uniparental disomy (UPD), mitochondrial mutations, and on occasion, mistaken paternity.

GENETIC SCREENING AND TESTING

Genetic screening is a term used when members of a particular population are offered a test for a condition or carrier status when there is no prior evidence of its presence in an individual.

The potential benefits of genetic screening include identifying treatable genetic conditions at an early stage and allowing couples to make informed choices about parenthood. Potential disadvantages include whether or not to communicate information to the family and, when screening is performed in pregnancy, the urgency of deciding about prenatal diagnosis and considering the options available. In the future, it may be possible to identify people who have a genetic susceptibility to common complex conditions, but the advantages of early identification will need to be weighed against possible adverse effects.

Guidelines for genetic screening programs have been recommended by several organizations.[2–5] These are helpful in determining the aims, limitations, scope, and ethical aspects of a genetic screening program as well as considerations for the storage and registration of data or material, the need for follow-up (including social consequences), and the risk of side effects.

People undergoing genetic investigations are entitled to receive sufficient information about what is proposed and about substantial risks in a way they can understand. They should be given time to decide whether or not to agree to what is proposed. They must be free to withdraw at any time.

Specifically, they should receive information about the following:

- Nature of the medical condition.
- Mode of inheritance.
- Reliability of the screening test.
- Procedures for giving results.
- Implications for their future, their existing children, and family members if the result is positive.
- Possibility that genetic screening may result in unexpected information being revealed (e.g., nonpaternity).

The debate in the United Kingdom over population screening for carriers for the autosomal recessive condition cystic fibrosis (CF) illustrates many of these points. The condition is common, with 1 in 25 of the white population in the United Kingdom being a carrier. Routine DNA tests can identify approximately 85% of carriers; these people have the common mutations. A "negative" result for commonly tested mutations does not exclude a member of the population from being a carrier, but greatly reduces the probability. This is in contrast to DNA testing for sickle cell disease which detects all carriers of the altered sickle cell hemoglobin (HbS) allele.

The current program for screening newborns for CF in England focuses on identifying affected individuals. Positive results from screening based on serum immunoreactive trypsinogen measurement are followed by direct gene analysis; the combination of tests has proved to be highly effective.[6] *Cascade genetic testing* for the mutations identified in the family can then be offered to the relatives of people with CF. Compared with other methods, offering testing to relatives of an affected person produces a high ratio of positive test results.

Cascade screening is up to 10 times more powerful than unfocused population screening in detecting carriers.[7] The uptake of CF carrier tests when offered to anyone interested in the general population has been shown to be low, but a high uptake (>70%) did follow an invitation by an interested health professional to be screened during pregnancy.

However, screening during pregnancy might not allow people to be fully informed or couples at high risk to have the choice of all options.[8] A "two-step" approach in pregnancy has been studied,[9] in which the woman was tested first and then testing offered to those men whose partner was found to be a carrier. However, considerable anxiety may occur when the woman is shown to be a carrier and the man is not. An alternative procedure is to regard the couple as the screened unit and to provide information on carrier status only when both partners are carriers.[10]

As illustrated in the CF example earlier, the term *genetic testing* is used when an individual is tested for a condition or genetic status that other evidence suggests may be present. This may be to confirm a diagnosis or to test for carrier status within a family. Although the same laboratory procedure is likely to be used for both genetic screening and genetic testing, there are important clinical conceptual differences. Those undergoing genetic testing are likely to have more knowledge about the genetic implications because of their family history. This is unlikely to be the case in a genetic screening program, in which education and information have been shown to be key factors in successful programs (e.g., a carrier screening program for thalassemia in Cyprus, screening for Tay-Sachs disease in Montreal).

Experience shows that the optimal timing of the testing procedure changes as a community becomes more informed. For example, a screening program designed to detect newborns with a recessive condition so that treatment may be instituted might have the effect of encouraging relatives to undergo carrier testing. This can increase awareness of the benefits of antenatal screening and may lead to an offer of testing to couples or individuals in the general population[4] before pregnancy. Some communities encourage individuals leaving school to be tested.[5]

It is widely accepted that genetic testing of children may be offered to confirm a diagnosis or assist treatment in childhood, but that children should not be tested for adult-onset genetic conditions (unless specific preventive measures are available) nor for carrier status until they are old enough to decide whether to undergo testing.[11]

DNA TECHNIQUES AND CLINICAL PRACTICE

Online databases that list DNA tests provided by genetic laboratories are increasingly available. To ensure clinical reliability and validity, it is important to confirm that laboratories that offer testing are part of recognized quality control programs and to ask about the experience of the laboratory with the particular test.

Although recent advantages in DNA sequencing offer the possibility of determining the mutation responsible for a single-gene condition in a family, it is important to tailor the ordering of DNA tests to those clinical situations in which the result is likely to influence management. Such situations include

- Confirmation of the diagnosis, especially when the clinical features can be equivocal.
- Confirmation that a family member has not inherited the condition.
- Carrier testing, especially when biochemical testing is not available or the results are equivocal.

- Presymptomatic diagnosis so that surveillance can be instituted (e.g., familial adenomatous polyposis coli, some types of breast cancer).
- Prenatal diagnosis, especially for conditions for which biochemical or hematologic testing or ultrasound detection of associated structural anomalies were formerly the only possibilities.

DNA diagnosis for some conditions still relies on family studies to "track" the allele for the disease through the family. This may be necessary where the chromosomal location of the gene responsible for the condition is known but the gene itself has not yet been identified. Some genes have a structure that makes direct DNA sequencing more difficult, and until technological difficulties are overcome for these genes, gene tracking may be useful for families. "Gene tracking" is discussed later.

Identifying Families Who May Benefit from DNA Diagnosis

Families are often identified from the pattern of affected members or when a precise diagnosis is made. Each family must be assessed individually because some techniques rely on the family structure and availability of the necessary DNA samples. Therefore, DNA diagnosis may require considerable time. Families are best referred to a clinical genetics unit before pregnancy for completion of the steps outlined in Table 4–3.

The Principles of Diagnosis Using DNA

The Regional Clinical Genetics Service will be able to advise whether gene tracking or sequencing is available for particular conditions.

TABLE 4–3

Practice Points* for Prenatal Diagnosis by DNA Techniques for Single-Gene Conditions

Identify families through:
- Previously affected child
- Carrier screening programs for autosomal recessive conditions
- Family history

Do they wish to proceed to further testing?

Consider the techniques available for prenatal diagnosis:
- Biochemical assays
- Ultrasound
- DNA diagnosis

Is DNA diagnosis possible? Consult the regional Genetics Services. Check before each pregnancy because of the rate of advances.
- Is the clinical diagnosis secure?
- Has the gene been localized or cloned?
- Is the family structure suitable, and are samples available for testing?
- Is sufficient time available for testing?

Explain procedures and the accuracy of results to family.
Collect appropriate samples.
Order laboratory testing:
- Gene tracking
- Direct mutation detection

Explain the results and options.
Proceed with diagnostic testing

* A clinical genetics unit can advise and arrange for much of these. The genetics of some single-gene conditions may be complicated (e.g., retinitis pigmentosa can be inherited as autosomal dominant and autosomal and X-linked recessive).

Following the Inheritance of Genes in a Family to Predict Genetic Status (Gene Tracking)

The aim of gene tracking is to follow the inheritance through a family of a "marker" piece of DNA which is known (from research studies) to be in close physical proximity to the gene causing the condition. These marker sequences of DNA vary naturally in the population (polymorphisms). Markers used include those which vary at one base position (single-nucleotide polymorphisms) and those with a set of alleles each of which varies in length (CA repeat markers). The latter are detected by their different positions on a gel after electrophoresis, as shown in Figure 4–5.

Figure 4–6 shows an example of gene tracking for an autosomal recessive condition. It should be noted that for gene tracking, DNA from the affected person and family studies are required. The fragment "tracking" with the disease allele can be identified by observing which fragment pattern is common to affected family members. There is an error rate associated with the use of linked markers because recombination may occur between the DNA marker and the disease gene. To minimize the risk of misdiagnosis, markers that show no more than 1% recombination with the disease gene are used whenever possible.

Detection of Mutations and Copy Number Variants

The definitive diagnostic test is to show a change in DNA that is predicted to disrupt gene function, and thus cause disease. When a mutation is predicted to cause truncation of the protein product (usually through a frameshift mutation or the introduction of a stop codon), this is strong evidence that the mutation is pathogenic. Other sequence changes may be more difficult to interpret, especially missense mutations that result in replacement of one amino acid by another. Additional genetic studies may be needed to determine the likelihood of pathogenicity. These may include testing members of the population to determine whether this is a polymorphism or performing a family study to determine whether the DNA change is being inherited with the condition.

In some conditions, certain mutations occur at a high frequency (e.g., δ-F508 mutation in CF, G380R mutation in achondroplasia). For most conditions, however, the precise mutation must first be identified in an affected person in the family. This may take months, depending on the structure of the gene and the laboratory techniques used. DNA sequencing is used to detect variants in the coding sequence, but other techniques need to be used to detect deletions or large rearrangements. After the mutation is identified, other family members can be offered definitive diagnosis. Even when the DNA sequence of a gene is known, gene tracking may have to be used if technical constraints make direct mutation testing impractical.

Microarrays and Their Use in Prenatal Diagnosis

Clinical cytogenetics is being transformed by widespread implementation of array comparative genomic hybridization (array CGH). This technique represents arguably the most

DNA diagnosis of an autosomal recessive condition by gene tracking. In this family, both parents have two detectable fragments (*1* and *2*) but their son, who is affected with an autosomal recessive condition, shows only one (*2*). Therefore, the altered alleles must be located on the parental chromosomes that give the fragment labeled *2*. In the next pregnancy, the fetus had two fragments, *1* and *2*, and therefore is predicted to be a carrier, but is not affected with the condition.

powerful direct application of the human genome mapping project in medicine today, both in terms of design of microarrays to interrogate the human genome in one assay (at previously unthinkable resolution) and in terms of establishing very accurate phenotype-genotype correlations from the results obtained.

The technique involves differentially labeling patient and reference DNA with fluorochromes and co-hybridizing the samples onto a glass slide or chip that is spotted either with genomic clones (bacterial artificial chromosome [BAC] probes) or, increasingly, synthetic oligonucleotide probes. Hybridization occurs relative to the amount of patient and reference DNA competing for any individual spot or feature. After hybridization and washing, the microarrays are scanned with a laser scanner and the resulting raw data are then extracted using sophisticated software that plots fluorescent ratio relative to each feature's position in the genome and calls regions as potentially aberrant via user-defined thresholds. In this way, copy number imbalances (loss or gain) can be detected in patient DNA relative to normal copy number DNA. Array CGH has substantial advantages over conventional chromosome analysis.

Conventional cytogenetics at highest resolution can detect imbalances of 3 to 5 to 10 Mb. Array CGH using the highest resolution oligonucleotide arrays is capable of detecting changes in the order of 1 Kb, which is significantly smaller than the average gene. Resolution at this level is not in routine clinical use and not yet appropriate for prenatal

diagnosis. Current applications in clinical use typically aim for a resolution of between 200 Kb and 1 Mb, and this has led to a major step change in detection rate over conventional cytogenetics. Of particular note, studies of children with learning difficulties and congenital malformation with previously normal cytogenetics have revealed pathogenic copy number imbalances in 10% to 20% of cases, which represents a fourfold increase in detection rate over conventional cytogenetics. International collaborations with the pooling of results from microarray analysis and phenotypic data through initiatives such as the DECIPHER consortium (https://decipher.sanger.ac.uk/) has led to the rapid establishment of several new microdeletion syndromes, such as the 17q23.1 microdeletion syndrome.

One of the current challenges to the application of microarrays in the clinical setting is determining whether a given copy number imbalance is de novo and likely to be causative or inherited and likely to be benign. Up to 12% of any individual's genome is likely to exhibit normal copy number variation (CNV), and there is emerging evidence of a huge degree of structural complexity within these CNV regions. In addition, limited data exist on the prevalence of CNVs between different ethnic populations. High-resolution studies using 500 K single nucleotide polymorphism (SNP) arrays analysis of patient-parent trios have showed previously unreported or "private" inherited CNVs in up to 30% of individuals. Interpretation of data at this resolution in the setting of prenatal diagnosis would be challenging, given the necessity for parental samples for rapid follow-up by microarray analysis and demands for unambiguous and robust reporting. In addition, reporting a novel CNV as benign, even if inherited from a phenotypically normal parent, would not be recommended, because some causative CNVs have been well documented to exhibit highly variable penetrance between generations. On a technical level, DNA yield from prenatal samples (amniotic fluid and chorionic villous) is usually lower than that from blood samples, and array design and protocols need to reflect the importance of this. Fundamental array design can be adapted to meet these criteria. There is little doubt that this cytogenetic technological advance may lead to the identification of subtle differences in DNA in fetuses that appear both phenotypically normal and abnormal. This raises a host of ethical considerations that need discussion and consensus view before such technology is applied widely.

CHROMOSOMAL ANOMALIES

The Karyotype Report: Nomenclature

Karyotyping is labor-intensive because high-resolution (extended) chromosome preparations reveal more than 850 bands. These bands are usually analyzed by light microscopy, although computer imaging is beginning to have a major effect. Occasionally, only limited analysis may be possible because of poor elongation of the chromosomes.

The human chromosome composition is reported in an internationally agreed format that gives a precise description of an anomaly. The format has three parts that are separated by a comma: the total number of chromosomes seen, the sex chromosome constitution, and normal variants or anomalies.

- The first figure gives the total number of chromosomes (e.g., 46, 45, 47).
- The second part gives the sex chromosome complement (e.g., XX, XY, X, XXY).
- The third part describes normal variants or anomalies affecting the following:
  - Whole chromosomes.
  - Arms of chromosomes.

The short arm of a chromosome is designated "p" (for *petit*), and the long arm is designated "q" (the next letter in the alphabet). Each arm is further subdivided into bands and subbands.

Breakpoints involved in structural rearrangements are described according to the arm involved, the region of the arm, and then by band and subbands within that region. For example, the location Xq27.3 is found on the long arm of the X chromosome, in region 2, band 7, and subband 3. Further examples are given in Table 4–4.

Molecular Cytogenetic Techniques

Some syndromes are caused by submicroscopic deletions of chromosomal material. Molecular techniques (usually

46,XX,add(20)(p13) Additional material of unknown origin attached to band p13 on one chromosome 20

fluorescence in situ hybridization [FISH]) can be used for diagnosis when the loss or gain of material is beyond the limit of light microscopy. This technique is also helpful for determining the origin of chromosomal material.

This method can also be applied to interphase nuclei to determine the numbers of copies of specific chromosomes, particularly as a rapid screening test for common trisomies (array CGH).

A Parent with a Chromosome Anomaly

Chromosomal Translocations

During the formation of a translocation during cell division, breaks will have occurred in chromosomes from different pairs with rejoining in an unusual pattern. Chromosomal material normally found on a particular chromosome will now be placed on a different chromosome. If the exchange results in no loss or gain of DNA, the individual is clinically normal and is said to have a "balanced translocation." A translocation carrier is, however, at risk of producing chromosomally unbalanced gametes, which may result in a baby with multiple congenital anomalies, miscarriages, stillbirth, or infertility depending on the origin and amount of chromosome material involved. It may be possible to determine the relative probabilities of each of these outcomes, depending on the particular translocation involved, by consulting the cytogenetic literature of previous cases, and by using special formulas—both of which require consultation with clinical genetics or cytogenetics services.

For most couples, however, understanding the precise probability is not the overriding consideration because they choose to undertake fetal karyotyping in future pregnancies. It is important to offer carrier testing to other family members because of the potentially high risks of having offspring with unbalanced forms of the translocation. Referral to a clinical genetics service is recommended for contacting and counseling family members.

There are two types of translocations: reciprocal and robertsonian.

RECIPROCAL TRANSLATIONS

Reciprocal translocations are characterized by the exchange of chromosomal material distal to (i.e., beyond) the breaks in two chromosomes. The long or short arms of any pair of chromosomes may be involved. Approximately 1 in 500 people is a carrier of a reciprocal translocation.

When a fetus has inherited an apparently balanced reciprocal translocation from a clinically normal parent, there appears to be no increased incidence of phenotypic abnormality in the child, especially if the translocation is present without effect in several family members. A cryptic unbalanced complement is more likely if a translocation is de novo (see later).

ROBERTSONIAN TRANLOCATION ("CENTRIC FUSION")

A *robertsonian translocation* ("centric fusion") is one in which effectively all of one chromosome is joined end-to-end to another. Robertsonian translocations involve the acrocentric chromosomes (13, 14, 15, 21, and 22) and are among the most common balanced structural rearrangements in the general population, with a frequency in newborn surveys of approximately 1 in 1000.

Centric fusion may arise from breaks at or near the centromere in two acrocentric chromosomes, with the two products fusing together. This usually results in the production of a single chromosome and most frequently involves chromosomes 13 and 14. Next in frequency are chromosomes 14 and 21. Clinically, the most important fusions are those involving chromosome 21, which give rise to familial Down syndrome.

For female carriers of a robertsonian 14;21 translocation, the observed probability of having a liveborn infant with Down syndrome is approximately 10%. The risk is approximately 1% for a male carrier. A robertsonian translocation involving both copies of chromosome 21 is rare, but all children of a carrier will have Down syndrome.

Where a robertsonian translocation involves chromosome 15 and a balanced translocation karyotype is detected at prenatal diagnosis, it is appropriate to test for UPD. This is to exclude Angelman's syndrome or Prader-Willi syndrome in the fetus caused by UPD for chromosome 15. This can occur by postzygotic "correction" of trisomy 15 when one parental chromosome 15 that is not involved in the robertsonian translocation is lost during mitosis.

Deletions and Duplications of Chromosomal Material

When a person with partial autosomal monosomy or trisomy has children, the probability that a child will inherit the parental chromosomal anomaly is theoretically 50%, because the parent passes on either the normal homologue or the chromosome with the deletion or duplication.

Inversions

An inversion (inv) affects just one chromosome, with a segment between two breaks inverted and reinserted. A pericentric inversion has one break in the short arm and one in the long arm. A paracentric inversion has both breaks in the same chromosome arm.

A carrier of a pericentric inversion is usually phenotypically normal, but the inversion may cause chromosomally unbalanced gametes. For the normal and inverted chromosomes to pair at meiosis, they have to adopt an unusual physical configuration so that if a crossover occurs in the inverted segment, unbalanced products will result. In theory, the larger the inverted segment, the greater the likelihood of recombination occurring and liveborn children with congenital anomalies and developmental problems. In practice, this is uncommon when the inverted segment is less than one third the length of the chromosome.

The overall probability of having a child with problems is approximately 1% when there is no family history of the recombinant form, but the individual probability depends on the precise inversion. For instance, there are also common pericentric inversion variants of chromosomes 1, 9, 16, and Y that are not associated with an increased risk. If, however, a family is identified through the birth of an individual with problems due to a recombinant chromosome, then the probability of having a liveborn child with problems increases to 5% to 10%.

A carrier of a paracentric inversion (involving only one chromosome arm and not the centromer) is usually phenotypically normal, and empirical data suggest a very low risk

of having a child with an unbalanced form of the inversion.

A Parent with Trisomy 21

Few data are available, but a literature review of about 30 pregnancies gives an empirical figure of approximately 1 in 3 of a woman with trisomy 21 having a child with trisomy 21. In addition, the probability of a chromosomally normal fetus having a congenital anomaly or mental handicap could be as high as 30%.[12]

Fetal Chromosomal Anomaly Found on Karyotyping during Pregnancy

Aneuploidies

Most structural chromosomal anomalies are aneuploidy, numeric abnormalities that involve the loss or gain of one or two chromosomes, or even the gain of a whole set. These anomalies are most commonly caused by nondisjunction, a process that is more common with increased maternal age. Fraser and Mitchell[13] noted a lack of hereditary factors but an association with advanced maternal age in cases of Down syndrome. Subsequently, in a study of 350 cases, Shuttleworth[14] reported a considerable proportion of affected infants born to women approaching the climacteric. Bleyer[15] proposed an association with degeneration of the ovum. Antonarakis and associates[16] examined DNA polymorphisms in infants with Down syndrome and showed that 95% of nondisjunction trisomy 21 is maternal in origin.

In the late 1970s and early 1980s, when prenatal diagnosis was in its infancy, eight large studies were carried out to assess the age-specific prevalence of trisomy 21 in live births.[17–24] Some of these studies had incomplete ascertainment and little information about the distribution of maternal age and the effect of selective abortion after prenatal diagnosis.

However, two studies[19,22] had nearly complete ascertainment. Cuckle and colleagues[25] combined the data from these eight surveys on a total of 3,289,114 births to determine the prevalence of trisomy 21 at each maternal age. Regression analysis was applied to smooth out fluctuations in the observed data.

In the 1970s and 1980s, genetic amniocentesis at 16 to 20 weeks was offered to women 35 years of age or older. This group was considered to be at increased risk for aneuploidy. Similarly, these groups were targeted for chorionic villus sampling between 9 and 14 weeks.

Data from these prenatal studies confirmed that the prevalence of trisomy 21 increased with maternal age and that the prevalence was higher during pregnancy than at birth.

Combined data from two multicenter studies of amniocentesis (one in the United States and one in Europe) showed that the prevalence of trisomies 13, 18, and 21 was approximately 30% higher at 16 to 20 weeks than at birth.[26,27] Similarly, data from fetal karyotyping by chorionic villus sampling showed that the prevalence of these aneuploidies was approximately 50% higher between 9 and 14 weeks than at birth (Fig. 4–7).[28]

Ultrasound studies have demonstrated that major chromosomal defects are often associated with multiple fetal

FIGURE 4–7

The prevalence of trisomy 21 (*A*), trisomy 18 (*B*), and trisomy 13 (*C*) at 9 to 14 weeks' gestation (*triangles*) and the prevalence of these trisomies at 16 to 20 weeks (*squares*) compared with the prevalence of live births affected with trisomy 21 (*dashed line*) in women 35 to 42 years old.
(From Snijders RJM, Nicolaides KH: Assessment of risk in ultrasound markers for fetal chromosome defects. In Nicolaides KH [ed]: Frontiers in Fetal Medicine. London, Parthenon, 1996.)
abnormalities. Conversely, in a fetus with multiple abnormalities, the frequency of chromosomal defects is high and the relative risk increases with the number of anomalies identified. However, prenatal karyotyping is often performed because the prognosis for the baby may be dictated not only by the combination of structural anomalies identified but also by marked neurodevelopmental morbidity associated with aneuploidy. The frequency of chromosomal defects, such as aneuploidy, increases with maternal age. Traditionally, counseling of patients about the risk of fetal chromosomal defects depends on the provision of live birth indices of trisomy 21. However, with ultrasound screening, the prevalence must be established for all chromosomal defects that are associated with structural and biometric anomalies.

Chromosome anomalies differ in the rate of intrauterine attrition, and it is important to establish maternal and gestational age–specific risks for each of the common aneuploidies. Data from a subgroup of women 35 to 42 years old have been used to examine the radiance of regression lines that describe the relationship between maternal age and the prevalence of aneuploidy. For trisomy 21 (see Fig. 4–7*A*), trisomy 18 (see Fig. 4–7*B*), and trisomy 13 (see Fig. 4–7*C*), the increase in frequency is nearly parallel, suggesting that there are no maternal age–related differences in the rate of intrauterine loss. If the prevalence of each of the common trisomies in live births is considered to be 1, then the relative prevalence of other gestational ages can be calculated and relative prevalence curves calculated.

The identification of fetal structural abnormalities leads to a stepwise increase in prevalence risk with each additional abnormality. A detailed discussion is beyond the scope of this chapter, but may be found elsewhere (see Snijders and Nicolaides, listed in Suggested Readings). Since the late 1990s, the use of first-trimester scanning to measure nuchal translucency (as related to fetal crown–rump length), combined with maternal serum free β-human chorionic gonadotropin (β-hCG) and pregnancy-associated plasma protein A, has been used to screen for aneuploidy (see Chapter 7).

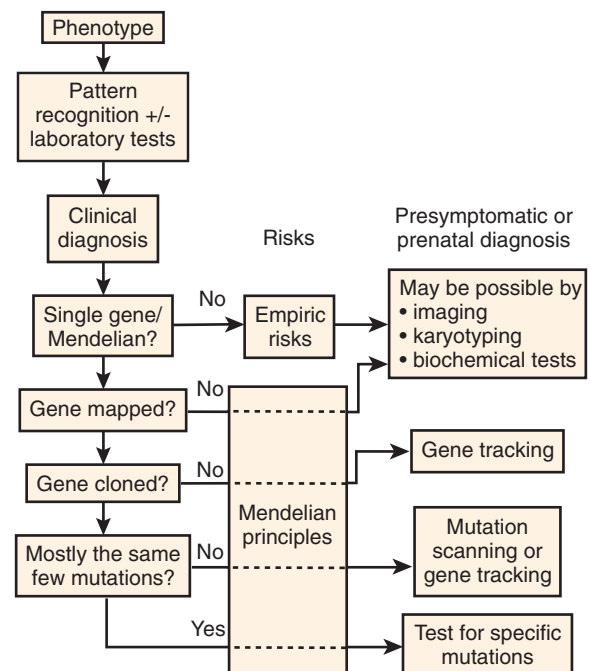
Triploidy

Survival to term of fetuses with triploidy is rare, and those born alive die shortly after birth. Most have partial hydatidiform mole, and the rest are nonmolar, with a normal or hypoplastic trophoblast. It is reasonable to offer prenatal karyotyping in future pregnancies. The phenotypes of the fetus and placenta depend on whether the additional set of chromosomes is paternally or maternally derived. The overall recurrence risk is usually low, but diandric triploidy associated with partial hydatidiform mole has a 1% to 1.5% risk of recurrence, and some women appear to have a predisposition for digynic triploidy.

Structurally Abnormal Chromosomes

When an unexpected structural chromosomal anomaly is found, the first step should be to examine the parental chromosomes. If the structural anomaly is present in a parent who is otherwise normal, it is unlikely that a similar chromosome anomaly in the child will cause severe problems. Exceptions may occur when chromosomes known to be imprinted are involved, principally chromosome 15, and genetic advice should be sought. If neither parent has the chromosomal anomaly, it is likely to have occurred during gamete formation. If chromosomal material has been duplicated or deleted during its production, this may cause severe clinical effects (Fig. 4–8).

De Novo Apparently Balanced Structural Rearrangements

The concern is that there could be a submicroscopic abnormality, either deletion, duplication, or gene disruption, involving the breakpoints. Molecular techniques, such as comparative genomic hybridization or the use of arrays, may be able help to determine whether there is cryptic gain or


loss of material in apparently de novo rearrangements found at prenatal diagnosis.

De Novo Apparently Balanced Reciprocal Translocation

In a very large study, Warburton[29] found that serious malformations were detected in 6.1% of pregnancies at elective termination or in liveborn infants, which is approximately 3% greater than the background risk of malformation that applies to all pregnancies. No prospective data on the risks of cognitive impairment or mental retardation are available, but an overall figure of 5% to 10% is often used to include not only malformations but also neurologic and developmental deficiencies. Whereas a detailed scan may give reassurance about the absence of malformations, there remains a risk of an adverse cognitive outcome. If, however, malformations are found on ultrasound, this is a strong indication that chromosomal imbalance is likely to be present.

De Novo Robertsonian Translocation

Because the formation of robertsonian translocations does not disrupt coding sequences, the risk of phenotypic abnormalities is low. When a robertsonian translocation involves chromosome 14 or 15, fetal UPD studies may be indicated to exclude the small probability that the fetus has inherited both copies of chromosome 14 or 15 from the same parent, resulting in dysmorphic and developmental features because of imprinting effects (see later).

De Novo Apparently Balanced Inversions

The risk of phenotypic anomaly is increased if the inversion is de novo. Empirically, the risk appears to be approximately 9%. Figures for cognitive impairment are not available.

Structurally Abnormal Additional Chromosomes ("Marker Chromosomes")

If a structurally abnormal extra chromosome (marker, supernumerary, accessory chromosome) or a ring chromosome is discovered, parental karyotyping should be performed urgently. Further advice should be sought because specialized genetic tests (e.g., painting with chromosome-specific fluorescent probes, array technology) may be able to determine whether the fetus is at high or low risk by determining the chromosomal origin and nature. Mosaicism (discussed later) with a normal cell line often accompanies the finding of a cell line with a marker chromosome and can make clinical interpretation even more difficult. The size of the marker and the ratio of cell lines in tissue used for prenatal diagnosis cannot be used prognostically. There is no accurate information relating to the residual risk of mental handicap when ultrasound examination shows no fetal anomalies.

De Novo Duplications and Deletions

During meiosis, the two chromosomes of a particular pair naturally swap genetic material between themselves, by breaking and rejoining, thereby producing different combinations of genes to pass on to offspring. Sometimes, repair of the breaks can be faulty or unusual pairing of chromosomes can occur. This may result in deletion or duplication of genetic material in the gamete. When fertilization occurs with a normal gamete, the fetus will have half the usual amount of gene products from that segment where a deletion is present, and one and a half times the normal amounts in duplications. The altered amounts of gene products affect development, resulting in congenital malformations and mental retardation. The precise features depend on the amount of chromosomal material involved and the chromosome from which it was derived.

Duplications are more common than deletions and generally result in a less severe phenotype. Specific syndromes are associated with certain deletions, but fewer phenotypes associated with duplications have been given names.

Further information about the likely clinical effects may be available from similar cases reported in the literature, or from online databases (such as DECIPHER) which are attempting to catalogue information from array studies in patients with structural chromosome anomalies.

The recurrence risk for a de novo deletion or duplication is very low, but not zero. Rare recurrences are likely to be caused by parental mosaicism, which is not usually detected by routine karyotyping. Although recurrence is extremely rare, many couples request prenatal diagnosis for reassurance. When the deletion/duplication is caused by an unbalanced product from a familial translocation, the risk of recurrence can be high.

Fragile Sites

Hereditary fragile sites can occur on several chromosomes, giving the appearance of breakage at a specific point. On autosomes, they appear to be harmless. However, a fragile site near the end of the long arm of the X chromosome at Xq27.3 is a marker for fragile X syndrome, an X-linked mental retardation syndrome. Because of the high risks and complex genetics of this single-gene disorder, families should be referred to the clinical genetics department.

Mosaicism

Mosaicism occurs when an individual's tissues or organs contain more than one genetic line of cells. One line of cells may contain a chromosomal anomaly or sometimes a single gene containing a mutation. The phenotype can be difficult to predict: depending on the number and disposition of cells with the genetic anomaly, the clinical effects will lie between those of the full condition and those of a normal individual. Testing other tissues (chorionic villi, amniotic cells, fetal blood) might be helpful. Even so, the proportion of cells with the genetic anomaly in one tissue might not be the same as the proportion elsewhere.

As mosaicism occurs postzygotically, the probability of recurrence in another pregnancy of normal parents is low.

A parent who is known to have mosaicism can have a child with the full features of the chromosome or single-gene condition, if the gamete making the child contains the anomaly, which will then be present in all the child's cells. It is not possible to give an exact figure for the child inheriting the condition because this depends on the numbers and disposition of cells in the gonads. Most parents, therefore, request prenatal diagnosis.

Although placental mosaicism with a chromosomally normal fetus is a well-recognized phenomenon (see Chapter 9), mosaicism involving chromosomes 13, 18, and 21 often predicts fetal abnormality and especially so when mosaic trisomy 9 or mosaic trisomy 22 is found. Mosaicism for a structurally abnormal additional chromosome appears to carry a greater risk than autosomal trisomy mosaicism. However, another concern when autosomal trisomy mosaicism is found at prenatal diagnosis is that a trisomic fetus may have "lost" one of the three copies of the chromosome in some cells to "correct" the imbalance. If both remaining copies of the chromosome originated from the same parent (UPD), this too could give an abnormal phenotype (see next section).

OTHER MECHANISMS OF GENETIC ANOMALY: UNIPARENTAL DISOMY AND GENOMIC IMPRINTING

Uniparental Disomy

The genomic stimulus for fetal growth is affected by the constant constraints of maternal size, placental function, and nutritional sufficiency. However, the expression of certain genes in both the fetus and the placenta is probably crucial to growth potential. It is probable that the placenta can control not only its own size but also, through a variety of mechanisms, that of the fetus. Few studies of the genetic control of fetal and placental growth have been done. However, UPD may be a cause of abnormal fetal growth, especially when it occurs without classic risk factors.

Abnormal growth in utero predisposes the fetus to increased perinatal and neonatal morbidity and mortality. In

mammals, reproduction requires the fusion of two haploid chromosome sets, one paternal and the other maternal. The fertilized egg then contains two copies of each chromosome. It is usual, and previously has been assumed invariable, for one member of each chromosome pair to be derived from each parent. However, in UPD, one homologous chromosome pair comes from the same parent (in isodisomy, the chromosomes are identical, but in heterodisomy, the two different maternal or paternal chromosomes are inherited). Catanach and Kirk in 1985[30] showed UPD in mice that resulted in specific abnormal phenotypes associated with growth disturbance. The progeny of mice with maternal disomy of chromosome 11 were smaller than their normal litter mates. Those with paternal disomy 11 were considerably larger than their litter mates.

Cases have been described in human pregnancies in which UPD for specific chromosomes has caused a clinical condition. The first example was an individual with maternal isodisomy 7 and homozygosity for the CF gene.[31] A similar case was subsequently described by Vosse,[32] the progeny showing phenotypically short stature.

Other conditions may be associated with UPD and show the following characteristics:
- Occurrence that is usually sporadic.
- No consistent cytogenetic abnormalities.
- Abnormal growth patterns and rates of growth.

Three separate mechanisms have been postulated for UPD:
- Chromosomal duplication in a monosomic somatic cell after postzygotic loss of a homologous chromosome.
- Fertilization of a nullisomic gamete by a disomic gamete.
- Loss of a supernumerary chromosome from a trisomic cell, leaving two homologues from the same gamete (trisomic rescue).[33]

Supporting the evidence for this has been provided in several publications.[34,35] The paper by Purves-Smith reported a confined placental mosaicism for trisomy 15, but an apparently normal karyotype on amniotic fluid cytogenetic and postnatal blood analysis.[35] However, at the age of 2 years, Prader-Willi syndrome was diagnosed clinically and maternal disomy 15 confirmed on molecular studies. The second study reported confined placental mosaicism for trisomy 16 in four fetuses with severe intrauterine growth restriction.[36] Subsequent skin karyotyping and molecular studies showed a normal karyotype with maternal disomy of chromosome 16.

Alternatively, postzygotic mitotic recombination could result in "mosaic" UPD. This phenomenon was recently identified in four patients with Beckwith-Wiedemann syndrome.[33]

Further mechanisms for UPD include gamete complementation or monosomic zygote correction; the latter has supporting evidence from some isodisomy cases of Angelman's syndrome when no evidence of recombination between chromosome 15 was found.[37] Whatever the mechanism, UPD may play an important role in unresolved genetic syndromes that affect growth.

Similarly, we carried out pilot chromosomal studies of 11 babies born with idiopathic growth restriction. The fetuses had prenatal diagnosis performed before 26 weeks' gestation. In the 11 cases, we showed 5 instances of placental

chromosomal mosaicism. The chromosomal abnormalities identified varied from trisomies for chromosomes 7 and 8 to structural abnormalities and deletions. In a further 6 pregnancies in which chromosomal mosaicism was detected prenatally after first-trimester chorionic villus sampling, 3 cases occurred involving chromosome 7, 1 chromosome 8, and 2 chromosome 15 for uteroplacental disomy. In 1 of these 6 cases, UPD was found and this was for chromosome 15. Maternal heterodisomy was detected and would have resulted in Prader-Willi syndrome if the pregnancy continued.[37]

About 100 well-documented pregnancies have been reported as having intrauterine growth restriction or fetal death associated with confined placental mosaicism. To date, only 12 chromosomes have been involved: 2, 3, 7, 8, 9, 13, 14, 15, 16, 18, 22, and X.[35] Trisomy 16 is the most common trisomy associated with pregnancy loss and confined placental mosaicism in intrauterine growth restriction. A prospective study investigated the incidence of UPD associated with growth restriction in 35 infants born between 25 and 40 weeks.[38] However, only 2 fetuses were born before 28 weeks, and both had chromosomal UPD of chromosome 16 plus confirmed placental mosaicism. No other UPD was found for the 12 chromosomes tested. It was concluded that UPD for the chromosomes tested did not explain the etiology of most cases of intrauterine growth restriction. However, many of these cases occurred after 32 weeks, and a higher detection rate is likely in fetuses with severe intrauterine growth restriction before 28 weeks.

Genomic Imprinting

The concept that male and female genomes do not contribute equally to mammalian development derives from observations made in mice in the late 1980s.[39] In those experiments, the development of uniparental diploid embryos was severely disrupted. Pathogenetic conceptuses developed embryos up to the 25-cell stage but showed only very rudimentary extraembryonic tissues. Androgenic conceptuses were characterized by relatively well-developed extraembryonic membranes and severely perturbed embryos. These reciprocal uniparental phenotypes probably resulted from disruption of the normal parental-specific expression patterns of a subset of imprinted genes. A detailed discussion is outside the scope of this chapter (see Suggested Readings, Georgiades and coworkers, 2001).

MALFORMATION SYNDROMES

The Pathogenesis of Malformation Syndromes

The term *dysmorphology* has been applied to the study of birth defects occurring in recognizable syndromic combinations. The cellular pathways involved in the pathogenesis of some malformation syndromes are being delineated and key genes identified. An increasing number of syndromes is being shown to be associated with mutations in specific genes, raising the possibility of prenatal diagnosis by DNA analysis.

Structural Malformations Found at Ultrasound Examination

A detailed screening fetal ultrasound examination may reveal a pattern of major anomalies that suggests a specific diagnosis (see Chapters 7 and 8). Recognizable patterns are most likely to be caused by chromosomal anomalies, but rare single-gene or dysmorphic syndromes may be diagnosed in utero in the absence of a history of the syndrome. In addition to major structural anomalies, careful evaluation of the fetus may show other dysmorphic features that are not commonly sought in a routine "screening" ultrasound examination. These include micrognathia and anomalies of eye spacing and of the hands (e.g., clinodactyly) or feet (e.g., sandal gap of the toe). Careful evaluation of the fetal posture or attitude when the fetus is stationary and moving may also give important diagnostic information.

Evaluation of the features with a clinical geneticist or perinatologist with a special interest in fetal dysmorphology may aid in the prospective diagnosis of a dysmorphic syndrome. The use of computer databases (see Suggested Readings) may be helpful, but it is important to compare the features of patients with a suspected diagnosis with photographs in original reports. A written description of dysmorphic features may suggest a match, but comparing photographs may be needed to confirm or refute the diagnosis.

As with all aspects of genetic counseling, accuracy of the diagnosis is paramount. Information obtained prenatally should be supplemented by information from postnatal examination or from a detailed examination by a perinatal pathologist if the couple wishes to end the pregnancy or if the fetus is stillborn. Photographs of the main features are helpful when seeking the diagnostic advice of a clinical geneticist.

Probability of Recurrence of a Syndrome

For many common conditions, empirical risk tables are available (see Suggested Readings and especially Harper, 2004). If the diagnosis is not clear or no accurate data on which to base a recurrence risk are available, it is advisable to refer the case to a clinical geneticist.

ISOLATED ORGAN AND SYSTEM ANOMALIES

Many conditions involving a single organ system appear to have a genetic or inherited component but show no clear pattern of mendelian inheritance or identifiable chromosomal abnormality. The term *multifactorial* has been used to describe this group. In some cases (e.g., Hirschsprung's disease, congenital heart disease), the condition is not a single entity but a heterogeneous group of indistinguishable conditions. Some of these may be inherited in a mendelian fashion, others may result from interplay of an inherited component and environmental factors, and others may be "acquired" in the sense that environmental factors are largely influential. Empirical risk data, obtained from observing recurrences in population studies, are available for many of these conditions (see Suggested Readings), but a clinical geneticist should be consulted.

SUMMARY OF MANAGEMENT OPTIONS
Counseling Points for Common Conditions

Management Options	Evidence Quality and Recommendation	References
Mendelian Inheritance		
High recurrence risks.	IV/C	1
Establish an accurate diagnosis and the mode of inheritance before counseling.	IV/C	1
Seek the latest information about carrier detection tests.	IV/C	1
Plan invasive procedures requiring DNA methods in consultation with the laboratory.	IV/C	1
Autosomal Dominant Conditions		
Each offspring of an affected parent has a 50% probability of inheriting the condition	IV/C	1
Potential pitfalls in conditions with variable expression	IV/C	1
Autosomal Recessive Conditions		
Each offspring of a couple in which both parents are carriers has a 25% probability of being affected with the condition.	IV/C	1
Prenatal diagnosis is possible for some.	IV/C	1
Donor gametes may be an acceptable therapeutic option for some; much discussion is required.	IV/C	1

SUMMARY OF MANAGEMENT OPTIONS
Counseling Points for Common Conditions—cont'd

Management Options	Evidence Quality and Recommendation	References
X-Linked Recessive Conditions		
Male-to-male transmission does not occur.	IV/C	1
All daughters of an affected male are carriers.	IV/C	1
For female carriers, each son has a 1 in 2 risk of being affected and each daughter has a 1 in 2 risk of being a carrier; affected homozygous females are rare.	IV/C	1
Chromosome Anomalies		
Refer families with translocations to a clinical geneticist so that family studies can be performed and to quantify the risk of an unbalanced karyotype (which may lead to miscarriage or a child with anomalies).	IV/C	1
With an unexpected structural chromosome abnormality, examine the parents' chromosomes.	IV/C	1
Duplication or deletion of chromosomal material can result in congenital anomalies or mental retardation.	IV/C	1
Predicting the clinical effects of mosaicism is difficult; karyotyping of other tissues may be required.	IV/C	1
De novo chromosomal conditions have a low probability of recurrence; offer fetal karyotyping for reassurance.	IV/C	1
Check karyotype reports with a laboratory if the meaning is in doubt.	IV/C	1
Clarify whether probabilities quoted in laboratory reports relate to "at amniocentesis" or "at delivery."	IV/C	1
Specific Syndromes		
Ensure the accuracy of diagnosis and recurrence risks.	IV/C	1
Empirical risk figures are available for some conditions (see "Suggested Readings").	IV/C	1
Prenatal diagnosis is available for some conditions with a biochemical basis, in which the gene responsible has been identified, or in which a microdeletion or duplication is the cause.	IV/C	1
If the diagnosis or probabilities are in doubt, refer the patient to a clinical geneticist.	IV/C	1
Organ and System Anomalies		
For many conditions, obtain information from a clinical geneticist.	IV/C	1
Empirical risk figures for siblings and children are available for some conditions (see "Suggested Readings").	IV/C	1

Bleeding and Pain in Early Pregnancy

DAVID J. CAHILL, REBECCA SWINGLER, and PETER G. WARDLE

INTRODUCTION

Complications arise more frequently during the first trimester than at any other stage of pregnancy. Most present with bleeding, pain, or both. Vaginal bleeding occurs in about 20% of clinically diagnosed pregnancies.[1] It causes considerable anxiety for the woman and her partner. In the vast majority of cases, no intervention alters the outcome. The main aim of clinical management is a prompt and accurate diagnosis, with reassurance if the pregnancy is appropriately developed and viable, or appropriate intervention if not. The differential diagnoses are shown in Table 5–1.

Approximately 15% to 20% of clinically recognized pregnancies miscarry.[2] When bleeding occurs in the first trimester, about 30% of pregnancies will miscarry, 10% to 15% will be an ectopic pregnancy, approximately 0.2% will be a hydatidiform mole (HM), and about 5% of women will have a termination of pregnancy. The remaining 50% will continue beyond 20 weeks.[3]

Ectopic pregnancy is the most important cause of maternal mortality in the first trimester of pregnancy in the United Kingdom[4] and other western countries[5] and is the single largest cause of death in pregnancy among blacks. The most recent U.K. Confidential Enquiry into Maternal Mortality reported 11 deaths due to ectopic pregnancies (in contrast to 1 women who died following spontaneous miscarriage and none from sepsis).[4]

Understanding the psychological effects of early pregnancy loss has lagged behind that of perinatal bereavement.[6] However, there is now greater recognition of the psychological and psychiatric sequelae and the consequent need for support that should be part of the management of couples who suffer early pregnancy loss.[7]

INITIAL MANAGEMENT

Resuscitation and Triage

Heavy bleeding in early pregnancy should be assessed urgently. The rate and amount of blood loss should be assessed as accurately as possible, including a speculum examination to estimate any additional concealed loss from intravaginal blood and clot. Most women with first-trimester bleeding will be young and fit and will be able to maintain their blood pressure even after substantial blood loss. When the woman's initial blood pressure is low, it is important to visualize the cervix carefully and remove any products of pregnancy, which may be lying within the cervical canal. It is important to differentiate between

- "Cervical shock," which will respond rapidly to this removal of retained products of conception, and
- Vascular decompensation, due to catastrophic hemorrhage requiring rapid resuscitation.

If the patient is clinically shocked and there are no products of conception in the cervical canal, she should be managed as if there has been a major blood loss, irrespective of the amount of revealed bleeding.

When severe blood loss is evident or suspected, adequate staff should be available for resuscitation. Pulse and blood pressure should be recorded frequently and a large-bore intravenous access should be established. Blood should be taken for a full blood count, a clotting screen, and blood grouping and to cross-match blood. A minimum of 4 units of blood would be required for a patient who is clinically shocked. The woman should be rapidly assessed from her clinical history and examination while resuscitation is proceeding. If this assessment suggests a catastrophic intraperitoneal hemorrhage from a ruptured ectopic pregnancy, it is unlikely that resuscitation will render her clinically stable. Under those circumstances, an emergency laparotomy should be arranged.

If the woman responds promptly to appropriate resuscitation, or if she is not clinically shocked (the vast majority of patients), a careful history and examination should be undertaken and investigations arranged.

Diagnosis (see Table 5–1)

History

The date of the woman's last menstrual period, her usual menstrual cycle length, and any variation of this and the date of her first positive urinary pregnancy test should define her likely gestational age. The severity of any early pregnancy symptoms, particularly nausea and breast discomfort, may be of diagnostic value. Nausea and vomiting in the first trimester are more frequently associated with a positive pregnancy outcome,[8] even among women presenting with a threatened miscarriage.[9] The loss of early pregnancy symptoms around the time of any vaginal bleeding is a

bad prognostic sign. Increased early pregnancy symptoms are associated with molar pregnancies and multiple pregnancies.

The outcome of previous pregnancies should be noted and is an important indicator of the risk of miscarriage, ectopic pregnancy, or gestational trophoblastic disease. Primigravidae and women with previous live births have a lower risk of miscarriage. Miscarriage risk increases cumulatively according to the number of previous miscarriages.[10,11] Similarly, women with a previous ectopic pregnancy are at substantially increased risk of a further ectopic pregnancy.[12] There is about a 10-fold increased risk of repeat HM in women with a history of a previously affected pregnancy.[13]

The nature and distribution of any associated pain can be helpful. Unilateral pelvic pain is not necessarily related to an ectopic pregnancy and may simply be due to ovarian capsule distention from a corpus luteum of pregnancy, particularly if the pain radiates to the anterior thigh from irritation of the adjacent cutaneous nerves. Shoulder tip pain suggests diaphragmatic irritation from intra-abdominal bleeding. Although more likely with an ectopic pregnancy, this can also occur with retrograde bleeding from a miscarriage. The extent of first-trimester vaginal bleeding gives a useful prognostic guide. Pregnancy is rarely successful if the loss is equivalent to, or greater than, a woman's normal menstrual blood loss.[14] One of the more common exceptions to this is when there is loss of one of a twin pregnancy, although spontaneous reduction to a single pregnancy is often not accompanied by bleeding; the so-called vanishing twin phenomenon.[15]

Examination

The aims of examination should be to differentiate between an early pregnancy complication and a coincidental abdominal pathology and to identify women who need surgical intervention promptly. The woman's pulse and blood pressure should be monitored frequently to identify early any

developing clinical shock. On inspection, the abdomen may be distended because of intraperitoneal bleeding or bowel dilation. Rarely, Cullen's sign (a bluish tinge of the periumbilical skin or an umbilical "black eye") may be present in cases of ruptured ectopic pregnancy. Generalized lower abdominal guarding or rebound tenderness on abdominal palpation may suggest intraperitoneal bleeding. Localized unilateral iliac fossa tenderness may be present with an unruptured ectopic pregnancy but can also be caused by a physiologic corpus luteum cyst of pregnancy.

A vaginal examination with a Cusco speculum should identify any local cause of bleeding due to trauma or any cervical cause due to a polyp or physiological ectropion (in which bleeding can frequently be related to coitus). An open cervical os suggests either an incomplete or an inevitable miscarriage. Blood loss through the cervical os and whether this is fresh or "old" should be noted. If products of conception are extruding through the cervix, these can be removed with sponge forceps, which may relieve pain and correct any reflex shock due to cervical distention. In general, removed products of conception should be sent for histologic assessment.

Bimanual examination should assess any cervical dilation and identify whether cervical excitation tenderness is present (see later) as a clinical sign of an ectopic pregnancy. The size and shape of the uterus should be assessed. If larger than expected from the menstrual dates, this may suggest a multiple pregnancy, an HM, or coincidental uterine pathology, most frequently fibroids. Adnexal palpation may identify a tender mass, which might be either an ectopic pregnancy or a normal corpus luteum cyst.

Special Investigations

A urinary β-human chorionic gonadotropin (β-hCG) pregnancy test should always be done, if not previously checked. Currently available commercial tests are now very sensitive and specific and can be expected to yield a positive result even 2 or 3 days before a missed period. If positive, the critical and complementary diagnostic investigations are a transvaginal pelvic ultrasound scan (TVUS) and quantitative serum β-hCG measurements.

The Role of Ultrasound, β-Human Chorionic Gonadotropin, and Progesterone Levels in the Investigation of Early Pregnancy Problems

The key purpose of an ultrasound scan and/or measuring hormones is to predict or differentiate an ectopic pregnancy from a normal intrauterine pregnancy. The ultrasound scan findings that predict an ectopic pregnancy include a living extrauterine pregnancy, an extrauterine gestational sac containing a yolk sac or embryo, an empty "tubal ring," or any adnexal mass other than a simple cyst. In both pooled retrospective data and prospective cohort data, the criterion that performed best in sensitivity, specificity, and predictive value was the presence of any adnexal mass other than a simple cyst.[16,17]

Transvaginal Ultrasonography

This generally provides more immediate information than hCG levels but is unhelpful in women who are less than 7

days past their missed period (conventionally taken to be 4 weeks after the first day of the last period). Rapid changes occur in appearance between 4 and 7 weeks of amenorrhea (Table 5–2). At 5 weeks' gestation from the woman's last menstrual period (assuming a regular 28-day cycle), a gestation sac of 2- to 5-mm diameter should be visible. However, this can often be difficult to differentiate from a pseudogestational sac associated with an ectopic pregnancy, in which there is simply a small collection of fluid secretions within the uterine cavity, or a decidual cast, in which the pregnancy has failed and decidual separation from the basal endometrium has occurred. A genuine intrauterine gestation sac should have two recognizable concentric decidual rings surrounding it, whereas a decidual cast or pseudogestational sac will have only one.

Confirmation of an intrauterine sac can be secure when the yolk sac or fetus becomes visible. The yolk sac is the first structure that becomes identifiable within the gestation sac, usually by 5$\frac{1}{2}$ weeks (Fig. 5–1). It will usually measure 2 to 5 mm in diameter. Initially, up to about 6 weeks, it will be larger than the fetus. However, an excessively large yolk sac (>5.6-mm diameter) is often an early sign of impending miscarriage.[18] Other early indicators of an almost certain miscarriage are when the gestation sac diameter exceeds 20 mm without any visible yolk sac or exceeds 25 mm without a visible fetus.

When an intrauterine pregnancy is clearly visible, a useful formula to calculate approximate gestational age (in days from the last menstrual period) is

$$\text{Gestational age (days)} = \text{mean sac diameter (mm)} + 30^{19}$$

This formula is valid up to 9 weeks. A second, more accurate but more complex, formula and that is valid to at least 12 weeks is

$$\text{Mean sac diameter (mm)} = 0.986 \text{ (days after ovulation/conception)} - 17.1^{20}$$

The presence of an intrauterine pregnancy with a live fetus is a good prognostic finding. When a live embryo or

fetus is seen on ultrasound, the pregnancy is likely to continue in over 95% of cases.[21,22] As well as ultrasound structures, fetal circulation becomes evident at 5½ weeks and is visible in all viable pregnancies by 6 weeks.[20] Initially, the fetal heart rate is slower than normal, but it increases over time, from 85 to 90 beats/min at 6 weeks to levels of up to 180 beats/min at 9 weeks.[23] Rates persistently slower than 100 are more likely to be associated with a poor outcome.[23]

Measurement of Human Chorionic Gonadotropin

Serum β-hCG concentrations complement the information available from TVUS in assessing early pregnancy problems. For this chapter, β-hCG values and ranges relate to the Third International Reference Preparation (3rd IRP). Absolute levels may be helpful in recognizing when a normal intrauterine pregnancy should be seen at TVUS. Levels of β-hCG greater than 1500 to 2000 IU/L (depending on local laboratory variations) should almost always be associated with the finding of a gestational sac in the uterus if the pregnancy is intrauterine.[24] If it cannot be seen in the uterus, it should be assumed there is a pregnancy elsewhere (Fig. 5–2). However, caution should be exercised when women have had assisted conception treatment (by in vitro fertilization or ovulation induction). In these situations, more than one embryo might be present and, therefore, an intrauterine and extrauterine pregnancy might coexist (i.e., a heterotopic pregnancy) or two intrauterine pregnancies might exist, giving rise to higher β-hCG levels (≤20 times normal) without a pregnancy yet being visible on TVUS. Excessively high serum β-hCG levels are also found with gestational trophoblastic disease and levels up to twice normal can be found in pregnancies affected by Down syndrome. Generally, β-hCG levels will be lower at any given gestational age with ectopic pregnancies than with normal intrauterine pregnancies. However, the overlap in values between the two clinical conditions is too great for this to be a diagnostic criterion.

Changes in β-hCG levels are more useful clinically. Usually, β-hCG values are best tested at intervals of 48 hours or longer. A falling β-hCG concentration in the first few weeks identifies a pregnancy as abnormal. If the β-hCG falls by more than more than half within 48 hours, it suggests that residual trophoblastic activity has ceased and that the pregnancy is likely to resolve without intervention. With a viable intrauterine pregnancy, previous data supported the view that β-hCG values should increase by at least 66% in 48 hours.[25] However, more recent and more accurate data for viable pregnancies support a view that the slowest rise at 1 day was 24% and 53% at 2 days; median increases in hCG at 1 day and 2 days were 50% and 124% (considerably

lower than previously thought).[26] In addition, a β-hCG doubling time of more than 7 days is never found in a normal pregnancy.[25]

Measurement of Progesterone

In both natural conceptions and in pregnancies arising from assisted conception, progesterone has been assessed in its role to determine the health of a pregnancy, particularly with reference to the site of that pregnancy. Levels of 30 to 45 nmol/L (10–15 ng/mL) suggest a healthy ongoing pregnancy. However, low levels are poor at differentiating miscarriages from ectopics (though combining with hCG measurements may help).[27–29]

SPONTANEOUS ABORTION OR MISCARRIAGE

Definition

Now used synonymously, the terms *spontaneous abortion* and *miscarriage* imply the natural loss of a pregnancy before independent viability of the fetus. Until recently, the term "abortion" was generally used in professional communication and "miscarriage" was used in discussion with patients. However, because this was not an exclusive definition, and as the term "abortion" (which many patients find offensive) has pejorative connotations of "elective termination of pregnancy," there has been an overall shift away from using "abortion" to describe the spontaneous loss of a pregnancy.[34] *Viability* implies the ability of the fetus to survive extrauterine life. This is generally taken to be around 24 weeks, and rarely, fetuses born before that will survive for a short while or at least show some signs of life. The cutoff point for the use of the term "miscarriage" might lie at 22 weeks (154 days), therefore, as recommended by the World Health Organization (WHO).[35] The WHO also includes in this a baby's weight (the value being < 500 g). In the United Kingdom, the legal definition changed in 1992 to 24 weeks (168 days) whereas in North America, the gestational age limit for a miscarriage is 20 weeks.[36]

In addition to these changes in terminology, there has been a marked alteration in the way in which early pregnancy problems of bleeding and pain are managed. Much of this is attributable to the

- Availability of rapid access to serum β-hCG estimations.
- High-resolution TVUS.
- Introduction of fast-track referrals to early pregnancy assessment units/clinics (EPU/EPC).

In EPCs, access to integrated evaluation by ultrasonography, serum sampling for β-hCG, and the presence of experienced timetabled medical and nursing staff has permitted women to be managed more as outpatients or in the office, providing a more streamlined service.

A summary of requirements for an EPC service is provided in Table 5–3. EPCs have improved the quality of care and produced savings in financial and staff resources. However, as a tool in patient management, EPC services have not yet been fully evaluated.[37] Management of women through an EPC service is not without its drawbacks. Inappropriate delays in diagnosis of true ectopic pregnancies and overmanagement by laparoscopy of suspected ectopic pregnancies both occur, despite rigid adherence to protocols.

TABLE 5–3

Requirements for an Early Pregnancy Assessment Clinic

- Appropriate resources for rostering of ultrasonographic, medical, and nursing staff (exact calculation of time required is not evidence-based; experience suggests that for a hospital with a delivery rate of 5000 deliveries/yr, 3 hours of patient contact time for all disciplines and 1 hour of telephone contact time later in the day is reasonable).
- Dedicated clinic space with rooms for ultrasonography, clinical assessment and investigation, counseling, and a waiting area.
- Good quality ultrasound machines with transvaginal facility.
- Availability of same-day hCG estimation.
- Responsibility for development of guidelines and resolution of conflicts and problems should be the responsibility of a designated senior member of the clinical staff.

hCG, human chorionic gonadotropin.

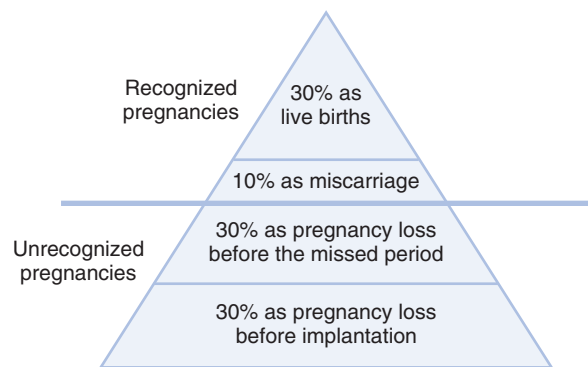
PROPORTION OF UNRECOGNIZED PREGNANCIES LOST TO RECOGNIZED MISCARRIAGES AND LIVE BIRTHS (AFTER CHARD, 1991)


FIGURE 5–3
Proportion of unrecognized pregnancies lost to recognized miscarriages and live births.
(From Chard T: Frequency of implantation and early pregnancy loss in natural cycles. Baillieres Clin Obstet Gynecol 1991;5:179–189.)

A pregnancy loss may be clinically evident, following presentation with bleeding or pain, or be clinically silent, identified at routine ultrasound scan. The introduction of almost routine scanning to confirm gestational age has had a dramatic effect of the management of early pregnancy loss. Bleeding occurs in a fifth of recognized pregnancies before 20 weeks. It is likely, however, that a far greater unrecognized pregnancy loss is present in the background, with more pregnancies being lost before the pregnancy has been suspected, recognized, or confirmed (giving rise to the term "pregnancy loss iceberg"'; Fig. 5–3).[38,39] In one study, 12% of pregnancies in which bleeding occurred went on to miscarry.[40] Other studies have reported higher rates (≤16%),[40] but these studies do not include those women who did not know they were pregnant (≤22%)[41] or those who did not seek medical advice about their bleeding, knowing they were pregnant (~12%).[40]

Risks

The maternal risks are blood loss, infection, and the psychological effects of the loss of the pregnancy.

Presentation and Diagnosis

Most women will present to a hospital, family doctor, or EPC in a number of ways:

- Bleeding without pain,
- Bleeding with pain (with possible passage of pregnancy tissue vaginally).
- Bleeding with pain with symptoms and signs of blood loss.
- Absence of bleeding with pregnancy symptoms diminishing.

The amount of bleeding can vary and has some prognostic value. Bleeding without pain is more likely to be associated with a threatened miscarriage. Presentations to an EPC service will frequently be for painless bleeding. Once the pregnancy is confirmed on ultrasound to be ongoing, this situation can be dealt with by reassurance. Most of these cases will be due to bleeding from local causes such as physiologic changes in the cervix. The additional presence of pain is often associated with cervical opening or distention as a result of tissue or blood clot passing through and is a painful process. Blood loss can give rise to symptoms in itself, and the passage of tissue through the cervical os can promote a vagal response causing shock, which is rapidly relieved if the products are removed from the os.

Management Options

Threatened miscarriages are managed expectantly. If the bleeding is slight and not associated with pain, then the woman can be reassured that the pregnancy is likely to continue. For all pregnancies in which bleeding occurs, more than 50% will continue.[3] If the bleeding occurs at 10 weeks more than 90% will continue; at 13 weeks, 99% will continue.[42] If the menstrual/gestational age is 6 weeks or older, then ultrasound may show a healthy ongoing pregnancy. In such cases, the likelihood of pregnancy loss is less than 3%.[22] Ultrasonography before 6 weeks is less likely to be helpful. If a patient needs the reassurance of an ongoing pregnancy by ultrasound scan, then this should be undertaken after 6 weeks.

The management options for the loss of an early intrauterine pregnancy are

- Expectant.
- Medical.
- Surgical.

Cases of complete spontaneous miscarriage can be managed expectantly. Most difficulty in the management of early pregnancy bleeding concerns cases of missed or incomplete miscarriage.

In most western countries, historically, the surgical approach ("evacuation of retained products of conception" [ERPC]) has been the most common emergency gynecologic procedure. The procedure was traditionally carried out with ovum forceps and curettage and evolved to vacuum aspiration. Vacuum aspiration is associated with less blood loss and pain and a shorter procedure than surgical curettage.[43]

Expectant management avoids a surgical procedure and allows the woman to continue in her normal daily routine. It is more acceptable to women and has less impact on quality of life.[44] It is an approach that has been adopted readily in primary care without hospital admission.[45]

Many reported studies compare two of the three modalities of treatment (expectant, medical, and surgical). Some are included in the Summary of Management Options at the end of this section. However, current management of miscarriage should now be based on published meta-analysis and randomized, controlled trial (RCT) papers, together with both economic and quality of life data, which these studies have also produced. The advice from these is not entirely in harmony. This is partly because the meta-analysis attempted to synthesize data from disparate studies comparing two modalities of treatment, whereas the RCTs compared all three modalities in a randomized approach. The RCTs were published after the meta-analysis.

In their meta-analysis, Sotiriadis and colleagues[46] suggest that surgical management appears most likely to achieve success and expectant management least so. The largest RCT combining all three modalities (the miscarriage treatment [MIST] trial) recruited 1200 women in approximately equal proportions to the three modalities of treatment.[47] In that study, there were no differences in rates of infection, hemoglobin or hematocrit levels, incidence in surgical complications, sick leave, or scores in hospital anxiety and depression questionnaires between the three modalities. Compared with expectant and medical management, those patients managed surgically had fewer unplanned admissions and unplanned surgical curettages, no blood transfusion (compared with 1%–2%), and less analgesia.

A second much smaller RCT (40 patients) had broadly similar results but was stopped early because of failure to recruit to randomization.[48] Data from the MIST study on women's preferences for treatment suggested that women particularly value alternatives being offered to expectant management[49]—clearly an important consideration when planning service provision. The level of pain experienced appeared to be the most important determinant for preference for an alterative treatment, and to a lesser extent, time to return to normal activity, number of days of bleeding, and likelihood of complications. When costs are analyzed, expectant management was least expensive and medical treatment was 40% and surgical treatment 50% more expensive.[50] One other large study analyzed medical and surgical modalities for quality of life and acceptability, finding no differences.[51]

For practical purposes, expectant management is well tolerated, cost-efficient, and safe and should be used for women in the first instance, providing that they are hemodynamically stable. It appears difficult to predict for which women expectant management will be effective.[52] Patients need to understand that they will bleed for slightly longer[53] and have a risk of needing surgical evacuation[47] so they need to have ready access to hospital services if needed. Medical management is not much more effective than expectant, but it is more expensive and, therefore, its role is less clear as a management option. Expectant and surgical seem to be the practical options—no intervention if possible, and then surgical if required.

Vacuum aspiration is preferable to surgical curettage, being safer, less painful, and quicker to undertake.[43] Whether any women should electively have surgical treatment rather

than any other is not clear, though in terminations, women of high parity (>para 3) are more likely to have a complete abortion following surgical management.[54]

Ideally, tissue should be sent from all miscarriages for histologic examination. However, there are obvious practical problems in achieving that goal if medical and expectant management are undertaken. It certainly should be requested on all those having surgical curettage. Ultrasound findings suspicious of trophoblastic disease are an indication for surgical rather than medical management.

Some have suggested that the optimum management option can be determined on the basis of ultrasound and biochemical evaluation. The volume of tissue remaining in the uterine cavity on ultrasound may be a useful guide in management. No intervention is required in the absence of tissue or if products of conception are present with a mean diameter less than 15 mm. Medical or expectant management may be considered if the tissue mass is between 15 and 50 mm, and an ERPC is probably required if tissue diameter is greater than 50 mm.[55] More complications (37% vs. 3%) occurred when women with significant intrauterine tissue (an intrauterine sac >10 mm in diameter) were managed expectantly compared with surgically.[56] Tissue volume has not been used in the evaluation of the data in the three-modality RCTs[47,48] or the meta-analysis,[46] so further clarification is still awaited.

Evidence regarding the value of serum β-hCG levels[56,57] or progesterone[58] to determine the need for surgical intervention is insufficient. When color Doppler imaging of uterine blood flow and of the intervillous space was examined in missed miscarriages,[59] uterine blood flow could not differentiate between those women whose miscarriage resolved spontaneously and those who required an ERPC. Intervillous space blood flow was associated with an 80% chance of spontaneous resolution compared with 23% in those for whom flow was absent.[59] Although this technique shows promise, it requires validation. At present, these adjuvant techniques are of little value in determining which women should be managed expectantly or otherwise.

Should women undergoing surgical evacuation of uterus have *Chlamydia* screening in line with other invasive interventions in the uterine cavity? One inadequately powered randomized trial showed no benefit, but because the intervention reduces infection in induced abortion, it is probably worth continuing until evidence suggests otherwise.[60]

Much of the management of early pregnancy bleeding may remain within the remit of general practitioners[45] or midwives,[1] but accurate diagnosis of ectopic pregnancies[56] and molar pregnancies[52] remain particular concerns. Rapid access to ultrasound and β-hCG assays should remain as a fundamental part of the management of early pregnancy bleeding.

ECTOPIC PREGNANCY

The management of ectopic pregnancy has changed over the past 20 years because of several important developments:

- Recognition of high risk individuals (Table 5–4).
- Increased sensitivity of home pregnancy tests.
- Early referral to dedicated EPCs in hospital settings.
- Development and refinement of high-resolution TVUS.
- Accurate and rapid estimation of serum β-hCG.
- Laboratory techniques allowing 24-hour access to auto-mated sample processing.

However, there is no room for complacency with regard to ectopic pregnancy management. The most recent report on maternal deaths in the United Kingdom shows an increase in ectopic pregnancy rates over the previous 20 years, from 8.6/1000 pregnancies in 1985 to 1987, to 11.1/1000 pregnancies in 2003 to 2005.[69] Deaths from ectopic pregnancies in that report are no better than 20 years previously: 4.7 compared with 4.8 deaths/1,000,000 maternities. Although the death rate expressed as a proportion of ectopic pregnancies in that time span (6.1 compared with 3.5 /1000 ectopic pregnancies) is an apparent fall, in real terms, there have been about 10 deaths in each triennium from 1985 to 2005.

A major recommendation from the most recent report on maternal deaths suggests that every unit should have clear guidelines for the management of pain and bleeding in early pregnancy because "there are persisting failures to recognise these conditions [ectopic pregnancies] promptly."[69]

Definition

An *ectopic pregnancy* is one that occurs in a site outside the uterine cavity, but usually in an adjacent site. In over 98% of ectopic pregnancies, the primary site is in the fallopian tube and the remainder will be in the abdominal cavity, the ovary, or the cervix. In the fallopian tube, about 80% of the pregnancies will occur in the ampullary region. Given these relative frequencies, this chapter deals largely with sites in the extrauterine fallopian tubes.

Risks

These are blood loss and its consequences, implications for future reproductive performance (see later), and psychological effects of the loss of the pregnancy.

Diagnosis

Symptoms

Diagnosis of an ectopic pregnancy can be difficult. Some, all, or none of the following symptoms may be elicited in a woman presenting with an ectopic pregnancy:

- Amenorrhea.
- Abdominal pain.
- Vaginal bleeding.
- Fainting.
- Shoulder tip pain.

Signs

At presentation to an EPC, many women with an ectopic pregnancy may have few or no signs. Unilateral iliac fossa pain is more in keeping with ectopic pregnancy, but bilateral pain is not uncommon. Guarding, rigidity, and signs of peritonism may be elicited on abdominal palpation. Guarding may be reduced if the knees are drawn up to relax the abdominal muscles.

On vaginal examination, it may be possible to elicit tenderness on the affected adnexal side by manipulating the cervix laterally ("cervical excitation") or by direct adnexal palpation. Because the uterus moves in the opposite direction owing to rotation around the fulcrum of the transverse cervical ligaments, there is increased tension on the side where the ectopic pregnancy is sited. The uterus may be softer and even enlarged slightly in the presence of an ectopic pregnancy owing to the softening effect of increased levels of progesterone on the endometrium and myometrium.

It is now rare in U.K. practice for women with an ectopic pregnancy to present with hypovolemic shock or in severe pain. The practical implications of this change in practice means that greater clinical acumen is required in managing those women presenting with pain and bleeding in early pregnancy.

Investigations

The diagnosis of ectopic pregnancy needs to be differentiated from other causes of lower abdominal pain in a woman of reproductive years (see Table 5–1).

Critical to the diagnosis of ectopic pregnancy are TVUS, and serum β-hCG, and to a lesser extent, serum progesterone. Confirmation of the diagnosis by laparoscopy is not always necessary. Laparoscopy is indeed not even the absolute answer, having a false-negative rate of 3% to 4% (being done too early) and a false-positive rate of 5% (owing to retrograde uterine bleeding).[70]

The complementary roles of TVUS and β-hCG measurements were discussed earlier. Serum progesterone is also considered to have a role in the differentiation of an ectopic pregnancy. Its use is not as widespread as β-hCG and TVUS. Serum progesterone concentrations well into the normal range for early pregnancy (>80 nmol/L) are associated with a high probability of the pregnancy being normal and intrauterine in site.[31] Conversely, values lower than 15 nmol/L are highly likely (98%) to be associated with a nonviable pregnancy.[71] Most ectopic pregnancies have progesterone concentrations between these values, making the test of little value at present for routine clinical practice. Algorithms have been devised with and without the use of serum progesterone and can be referred to and integrated into local practice guidelines if considered appropriate.[24,72] Figure 5–4 shows an example of such a practical algorithm.

The patient presenting acutely with obvious intra-abdominal bleeding will be diagnosed without difficulty. The less acute clinical scenario in which a women presents

with little or no pain, vague symptoms, slowing rising β-hCG levels, and nonspecific findings on ultrasound is more challenging.

Management Options

Management of the acutely ill woman differs from the more common presentation of a woman who is clinically stable, in which situation there are a number of treatment options.

The acute presentation with hypotension, tachycardia, pain, and other signs of shock, usually, though not always, associated with amenorrhea is generally dealt with by laparotomy. The acute symptoms are usually due to fallopian tube rupture and/or significant intraperitoneal bleeding. Surgical treatment usually requires partial or total salpingectomy, securing hemostasis and removing blood and products of conception from the abdominal cavity.

In the less acute situation, there are several treatment options, which include expectant, medical, and surgical (conservative and radical) management. The gradation of quality of evidence is presented in the Summary of Management Options box (later). The algorithm in Figure 5–4 shows the critical criteria that influence appropriate management, namely, the trend in serum β-hCG level and the findings on TVUS. Serum β-hCG rising above a critical threshold in the absence of an intrauterine gestation sac will usually be an indication for surgical intervention. Whether by

laparoscopy or laparotomy will depend on the patient's past surgical history, the TVUS findings, and the absolute level of β-hCG and its rate of rise.

Expectant Management

As shown in Figure 5–4, this management is most appropriate when the woman is hemodynamically stable, with no symptoms of pain. Some authors have suggested that this approach should not be undertaken with a gestational sac size greater than 4 cm and/or the presence of a fetal heartbeat on TVUS.[73] Certainly, expectant management is more likely to be effective if the initial serum β-hCG concentration is less than 1000 IU/Ll and falls thereafter and if a gestational sac is not seen on TVUS.[73] The serum β-hCG level, both the initial level and the trend, is generally the most important predictor of successful expectant management.[73] Some publications suggest that of vaginal bleeding, endometrial thickness, serum β-hCG, and serum progesterone, the most useful modality to predict spontaneous resolution was serum progesterone with a cutoff level of less than 20 nmol/L.[74]

In practice, expectant management involves establishing a reliable diagnosis of early extrauterine pregnancy failure, informing the patient of other treatment options, and obtaining consent that this method of management is acceptable. Having done so, serum β-hCG levels should be monitored every 3 to 4 days until they fall to less than 10 to 15 IU/L.[71]

Success rates for this approach range from 70% to 75% for β-hCG levels of less than 1000 IU/L[73,74] falling to 25% with levels greater than 2000 IU/L.[75]

Medical Management

Current methods of medical management focus on the use of methotrexate, generally as a single dose, although multiple-dose regimens are less commonly used. Adjunctive mifepristone is only of additional benefit in improving success rates when the serum progesterone is greater than 10 nmol/L.[76]

Methotrexate is a folic acid antagonist (inactivating dihydrofolate reductase and depleting tetrahydrofolate, required for RNA and DNA synthesis) and, as a chemotherapeutic agent, is active against rapidly dividing tissues such as those in the placental trophoblast. Methotrexate can produce side effects through its actions on other tissues in the body such as the gastrointestinal tract (stomatitis, gastritis, diarrhea, transient liver enzyme disorders), and rarely, the hematologic system (bone marrow suppression).[77] A single dose can produce symptoms, though less than multiple doses (daily or alternate-day), including gastrointestinal symptoms (31% single vs. 41% multiple [$P < .04$]), abdominal pain (22% vs. 26% [nonsignificant]).[77] Folinic acid (leucovorin) is given to counteract this (0.1 mg/kg). Folinic acid is not required when doses are given at more than weekly intervals.[78] Medical management is particularly appropriate when surgical intervention would be difficult (e.g., cervical and interstitial pregnancies). Medical treatment has been available since the mid 1980s[79] but has not been adopted extensively. This is lamentable because studies involving large series of women show success rates around 90%.[80] Predictors of success of medical treatment include sac size, presence of fetal cardiac activity, and serum β-hCG concentration. β-hCG is the most important of these.[80] For values of 2000 to 5000 IU/L, the likelihood of success is 92% (86%–97% 95% confidence interval [CI]), but higher when less than 1000 IU/L (98%, 96%–100% 95% CI).[80] Compared with conservative laparoscopic surgery, methotrexate use is associated with a shorter in-hospital stay but a longer return to normal β-hCG levels.[81] Given that in U.K. practice, one might expect most women to attend an outpatient EPC for diagnosis, this is not a particular advantage. Opinions vary on the effect of medical therapy on quality of life: one study found higher well-being scores in women managed medically[82]; another failed to confirm this.[83] However, future reproductive expectations are better with methotrexate, with higher intrauterine pregnancy and lower ectopic rates subsequently.

The dose of methotrexate used in clinical practice varies. Given systemically, and usually intramuscularly, the dose is either 1 mg/kg or 50 mg/m^2. These doses seem to be equally effective, and most favor the easier dose calculation of the former with a minimum total dose of 50 mg.[84] When single-dose therapy is planned, most women will only require one dose (85%). When multiple-dose therapy is planned, most (90%) will have at least two doses, and 54% will have four.[77]

Surgical Management

Salpingectomy has long been considered the gold standard treatment for ectopic pregnancy. In situations of emergency care and rupture of the fallopian tube, this may still be unavoidable. However, considerable recent emphasis has been placed on conservation of the fallopian tubes where possible and debate now focuses on:

- When is it appropriate to conserve a fallopian tube?
- Does fallopian tube conservation significantly affect subsequent fertility rates?

WHEN IS IT APPROPRIATE TO CONSERVE A FALLOPIAN TUBE?

The Royal College of Obstetricians and Gynaecologists recommends that surgical treatment by laparoscopic salpingectomy is the preferred method of treatment for an ectopic pregnancy when the fallopian tube on the other side is normal.[85] However, the majority of women in the United Kingdom were having open surgery, not laparoscopic surgery, for the management of their ectopic pregnancy until recently.[86] Furthermore, open surgery may be the more appropriate route as concluded by a meta-analysis, based on the combined results of three studies, involving women with unruptured tubal pregnancies, which showed laparoscopic conservative surgery had more failures (defined as persistence of trophoblastic tissue and raised hCG levels) than an open surgical approach (odds ratio [OR] 0.28; 95% CI 0.09–0.86).[87] Laparoscopic salpingotomy is, however, less costly.[87]

There is insufficient evidence from RCTs to answer the questions raised in the salpingectomy/salpingotomy debate and opinions vary. In the management of an ectopic pregnancy, removal of the fallopian tube (salpingectomy) is considered to be the safest,[88] most clinically effective,[89] and most cost-effective technique.[90] A meta-analysis of nine well-designed comparative studies showed similar intrauterine pregnancy rates whether salpingectomy (49%) or salpingotomy (53%) was used.[84] That paper and a separate meta-analysis showed higher subsequent ectopic pregnancy rates after salpingotomy (15% vs. 10%).[84,91] There is general agreement that salpingectomy would be appropriate if a women desired no further children, if a second ectopic occurred in the same fallopian tube, if bleeding could not be controlled, or if the tube was severely damaged by the ectopic pregnancy. If salpingotomy is undertaken, further quantitative β-hCG monitoring is required to confirm successful treatment because persistence of the ectopic pregnancy occurs in 8% to 19% of cases.[84,92] We would expect that the ongoing multicenter randomized, controlled ESEP (salpingostomy versus salpingectomy for tubal ectopic pregnancy) trial will address whether the advantages of salpingostomy outweigh the disadvantages when compared with salpingectomy.[93]

In the woman with a solitary fallopian tube who has a salpingostomy in her single remaining tube, it has been reported that 54% of women achieved a subsequent intrauterine pregnancy but 21% of the remainder had a further ectopic pregnancy.[84]

The details of the techniques used to undertake these surgical techniques are beyond the scope of this chapter. Salpingectomy may be undertaken laparoscopically or by open surgery. Open surgery is more likely to be undertaken if the woman is shocked or otherwise showing signs of being hemodynamically unstable. Laparoscopic salpingectomy techniques include resection using diathermy and scissors, loop ligatures, or single-use proprietary stapling instruments. Conservative surgery generally involves a linear incision along the antimesenteric border of the fallopian tube over the site of the ectopic pregnancy. The pregnancy is removed by flushing with high-pressure hydrodissection, and hemostasis is achieved by (bipolar) diathermy. In two small studies, prophylactic vasopressin was used in 40

hemodynamically stable women with a small unruptured ectopic pregnancy[94] and diluted oxytocin in 25 similar women.[95] These interventions reduced the need for electrocoagulation for hemostasis (relative risk [RR] 0.36; 95% CI 0.14–0.95) without side effects, resulting in a significantly shorter operation time, reduced intra- and postoperative blood loss, and easier removal of the tubal pregnancy without side effects. However, neither study showed any benefit in reducing the likelihood of persistent trophoblastic disease. Suturing of the incision in linear salpingostomy had no benefit in reducing adhesion formation or subsequent pregnancy rate.[96]

FERTILITY AFTER SURGERY

After salpingectomy, in the presence of a normal fallopian tube on the contralateral side, the likelihood of an intrauterine pregnancy is greater than 50%.[97] After salpingotomy, the likelihood of an intrauterine pregnancy is approximately 65%.[84,98]

Any study that looks at fertility after radical or conservative treatment must take account of the fact that there is a higher chance of salpingectomy if the initial ectopic had ruptured. In studies that took this factor into account, no appreciable difference was found in the subsequent intrauterine pregnancy rates.[99] Factors that did alter the likelihood of conception included the woman's age, previous tubal damage, and infertility.[99] This holds true even if the previous ectopic pregnancy had ruptured.[100] The reported likelihood of a future ectopic pregnancy after 3 years is 18% to 23% after conservative treatment and 28% after radical treatment.[99,101]

On economic and fertility outcome grounds, there is no clear indication whether salpingectomy or salpingotomy is more appropriate for women who have both fallopian tubes.

Future Advice and Appropriate Treatment

The likelihood of a further ectopic pregnancy varies little with the management of the index case. Previous tubal rupture does not appear to have a detrimental effect on future fertility. Smoking is an independent risk factor for fertility and the likelihood of a future intrauterine pregnancy appears to be increased by stopping smoking.[99] Future

SUMMARY OF MANAGEMENT OPTIONS		
Ectopic Pregnancy		
Management Options	**Evidence Quality and Recommendation**	**References**
Diagnosis		
Accurate and rapid β-hCG estimation and high-resolution transvaginal ultrasound are key to the management	III/B	24
Expectant		
Suitable for some ectopic pregnancies if β-hCG levels are low and falling (<1000 IU/L)	Ib/A	102–104
Medical		
Valid option with no fetal heartbeat, β-hCG < 5000 IU/L, patient is asymptomatic and willing to have serial β-hCG estimations	III/B	80
Methotrexate local	Ib/A	102
Methotrexate systemic	Ib/A	102,105
Hyperosmolar glucose	Ib/A	102
Prostaglandins and methotrexate	Ib/A	102
Methotrexate and mifepristone	Ib/A	76
Single and multiple doses of methotrexate	Ia/A	77
Surgery—General		
Laparotomy has higher success rates	Ib/A	102
Salpingectomy is marginally better than salpingotomy; subsequent fertility rates are no different	III/B	84,101
Use agents preoperatively to reduce bleeding	Ib/A	94,95
Surgical—Laparoscopy		
Salpingotomy/salpingectomy	Ib/A	87
Surgical—Laparotomy		
Salpingotomy/salpingectomy	Ib/A	87

Suturing salpingostomy edges does not improve subsequent fertility	Ib/A	96

β-hCG, β-human chorionic gonadotropin.

fertility also decreases if the women is older (>35 yr)[100] or has had previous tubal damage or infertility.[99] For these women, perhaps, assisted conception may offer a better chance of an intrauterine conception. The risk for a further ectopic is strongly increased (three to four times) if the woman was previously nulliparous, if this was not her first ectopic, if she has had previous tubal surgery,[101] or if there are adhesions around either fallopian tube.[99]

If a woman has had a previous ectopic, any subsequent pregnancy is more likely to be ectopic again. Under these circumstances, early review by high-resolution TVUS in a specialist EPC is advisable so evaluation can be made of the site and viability of the pregnancy as soon as possible. This will provide reassurance if appropriate or allow timely intervention if not.

GESTATIONAL TROPHOBLASTIC DISEASE AND NEOPLASIA

Gestational trophoblastic disease (GTD) is an uncommon cause of vaginal bleeding in the first half of pregnancy. The disease encompasses a wide range of conditions that vary in their clinical presentation; their propensity for spontaneous resolution, local invasion, and metastasis; and their overall prognosis. These conditions include complete hydatidiform mole (CHM) or partial hydatidiform mole (PHM) and the malignant conditions invasive mole, choriocarcinoma, and placental site trophoblastic tumors.[106–109] The worldwide incidence of GTD is approximately 0.6 to 2.3/1000 pregnancies. Most cases are CHMs or PHMs.[110–112] The most invasive form of GTD, choriocarcinoma, has an incidence of 0.2 to 2.0/10,000 pregnancies.[113]

The incidence of all types of GTD in Asia and Africa is reported to be higher than that in Europe.[113,114] However, these regional differences may in part be due to differences in histologic classification of GTD, methodologic difficulties in the studies, or possibly, dietary differences.[115] The woman's age is a consistently demonstrated risk factor for HM. Compared with women aged 25 to 30 years, there is approximately a 6-fold excess risk in women who become pregnant before 15 years of age and approximately a 300-fold excess risk in women who become pregnant after 45 years of age.[110,116] This age association is much greater for CHM, rather than PHM.[116–118] However, because women at these extremes of reproductive age represent such a small proportion of all pregnancies, more than 90% of molar pregnancies still occur in women aged 18 to 40 years. A history of a previous molar pregnancy is also a risk factor. Women with a history of one HM have at least a 10-fold greater risk of a repeat molar pregnancy, usually the same type of mole as in the preceding pregnancy, which equates to an incidence of approximately 18/1000 pregnancies.[114,119] This risk appears to be independent of chemotherapy exposure. Although maternal A and AB blood groups are associated with an increased risk of a woman developing GTD, no plausible explanation for this association has been proposed yet.

HM is classified as a CHM or a PHM on the basis of histopathologic features and karyotype. A CHM is usually diploid and entirely androgenetic in origin. Most have a 46XX karyotype; a few have a 46XY karyotype. There is a rare form of CHM in which a haploid set of maternal and paternal chromosomes are present but failure of maternal imprinting causes only the paternal genome to be expressed.[120] It appears to be inherited as an autosomal recessive trait and women can present with recurrent molar pregnancies.[121,122] A mutation of a gene (NALP7/NLRP7) on chromosome 19 is thought to be the cause of the disease.[123,124] A complete molar pregnancy consists of diffuse hydropic chorionic villi with trophoblastic hyperplasia, forming a mass of multiple vesicles. There is usually no evidence of a fetus and minimal embryonic development.

A PHM is usually triploid, with one maternal and two paternal haploid sets, either from dispermic fertilization or from fertilization with an unreduced diploid sperm. There is usually a fetus and a large placenta. The hydropic villi show a less florid appearance than is seen with a CHM and are interspersed with normal chorionic villi. The fetus usually dies within a few weeks of conception, and a review by Petignat and coworkers[125] did not identify any case in which a fetus of paternal (diandric) origin survived to term. Occasionally, a PHM pregnancy develops with two maternal and one paternal haploid set (digynic). In these cases, the placenta is small, the villi show minimal hydropic changes, and the fetus is growth-restricted.[126] Some of these pregnancies have been reported to result in live births, with subsequent early neonatal death.[127] One study suggested that diandric PHM pregnancies have a greater malignant potential than digynic PHM pregnancies. Of 3000 women with PHMs, 0.1% had a choriocarcinoma. All were genetically diandric.[128]

The term GTD generally refers to the premalignant forms of trophoblastic disease. When the term *gestational trophoblastic neoplasia (GTN)* is used, it refers to persistent GTD and to the malignant forms of trophoblastic disease (invasive moles, gestational choriocarcinomata, placental site trophoblastic tumors). Further details on the histologic classification and macroscopic appearance of these subgroups is beyond the scope of this chapter but available from the Trophoblastic Tumour Screening and Treatment Centre website (Charing Cross Hospital, London, UK).[158] GTN is much more common with a CHM pregnancy than with a PHM. The incidence of these complications is approximately 15% and 0.5%, respectively, compared with a risk of approximately 1:50,000 after a full-term pregnancy.[128]

Diagnosis
Presentation and Clinical Features

Historically, women with molar pregnancy presented in the second trimester with an enlarged uterus, vaginal bleeding, passing vesicles per vagina, and systemic symptoms such as hyperthyroidism, anemia, and respiratory distress (Table 5–5). However, the advent and accessibility of routine TVUS in the first trimester has changed the clinical presentation of molar pregnancy,[129,130] with most women in the developed world presenting before 12 weeks as early pregnancy failure with or without vaginal bleeding.[131] A recent large retrospective study demonstrated that pre-evacuation ultrasound identifies 44% of HMs (80% of CHMs and 30% PHMs).[132] The ease with which CHMs are detected increases after 14 weeks when the characteristic "snowstorm"

TABLE 5–6

Clinical and Pathologic Differences between Complete and Partial Hydatidiform Moles

	COMPLETE MOLE	PARTIAL MOLE
Clinical		
Features	Often severe and early.	Often mild, similar to miscarriage, fetal tissue may be passed.
Diagnosis	Usually suspected from clinical and ultrasound features.	Often missed clinically and on ultrasound, diagnosed from histology of conception products.
Persistent trophoblastic disease/tumor	15% of cases.	0.5% of cases.
Pathologic		
Macroscopic appearance	"Grapelike" vesicles often recognized. No fetal tissues.	Often normal or suspected hydropic miscarriage. Fetal tissue may be seen.
Microscopic appearance	Diffuse hydropic villi. Trophoblastic proliferation.	Focal hydropic villi. Variable mild trophoblastic proliferation. Often focal. Microscopic diagnosis sometimes difficult.
Karyotype	Usually diploid. Paternal chromosomes only.	Usually triploid. Diploid paternal and haploid maternal contribution.

From Seckl MJ, Fisher RA, Salerno G, et al: Choriocarcinoma and partial hydatidiform moles. Lancet 2000;356:36–39.

appearance of mixed echogenicity, representing hydropic villi and intrauterine hemorrhage, is seen (Fig. 5–5).[132] At earlier gestations, a mole often shows a fine vesicular or honeycomb appearance on scan. The ovaries often contain multiple large theca-lutein cysts as a result of increased ovarian stimulation by excessive hCG. Ultrasound diagnosis of a PHM is more difficult. The fetus may still be viable but may show signs consistent with triploidy, such as unusually early growth restriction or developmental abnormalities. There may be only scattered cystic spaces within the placenta, and ovarian cystic changes are usually much less pronounced. When there is diagnostic doubt, the scan should be repeated after 1 to 2 weeks.

The quantitative serum β-hCG level is higher than expected in women with a CHM, often exceeding 100,000 IU/L. This is much less likely in women with a PHM; in these women, the level is often within the wide range associated with normal pregnancy. Partly as a result of the elevated β-hCG, early pregnancy symptoms are usually more severe and present earlier in a CHM than in a PHM in which the symptoms and signs can be mild enough to be missed. These women more often have a missed miscarriage or a spontaneous miscarriage, with the passage of a recognized fetus. Consequently, the gold standard for detection of a molar pregnancy remains at present histologic examination of the products of conception from early pregnancy failures. The clinical and pathologic differences between CHMs and PHMs are summarized in Table 5–6.

Investigations

Investigations directed at disease assessment include a complete blood count, measurement of creatinine and electrolytes, liver function tests, thyroid function tests, and a baseline quantitative β-hCG measurement. A careful pelvic and abdominal ultrasound scan should be undertaken to look for evidence of an invasive mole, exclude a coexisting pregnancy, and look for possible metastatic disease. Computed tomography (CT) or magnetic resonance imaging (MRI) of the thorax, abdomen, and pelvis may provide supplementary information. Chest radiography or CT should be considered if there are symptoms that suggest pulmonary metastases. CT or MRI of the brain should also be considered. If cerebrospinal metastases are suspected despite normal findings on imaging, a lumbar puncture may be done to measure β-hCG levels in the cerebrospinal fluid. A

plasma–to–cerebrospinal fluid ratio for β-hCG of greater than 1:60 is strongly suggestive of occult cerebral metastases.[133,134]

Risks

Risks include hemorrhage, persistent trophoblastic disease, malignant changes, psychological problems related to the loss of pregnancy, and the risks and need for follow-up of persistent or malignant disease.

Management Options

An algorithm for the management of GTD is shown in Figure 5–6.

Evacuation of Molar Pregnancy

CHM and PHM pregnancies are managed differently. For CHM pregnancies, suction curettage is the method of choice for uterine evacuation. A suction catheter of up to 12 mm in diameter is usually sufficient because of the absence of fetal parts. It is best to avoid prior cervical preparation, the routine use of oxytocic drugs and sharp curettage, or medical evacuation with a CHM to minimize the risk of dissemination of tissue leading to metastatic disease.[135,136] Oxytocic agents and prostaglandin analogues are best used only after uterine evacuation when there is significant hemorrhage. Data for the use of mifepristone are limited. Evacuation of CHM pregnancy with this agent should be avoided because it increases the sensitivity of the uterus to prostaglandin.

In PHM pregnancies that are recognized before uterine evacuation, again suction curettage is the method of choice. However, when pregnancy is more advanced and the size of any fetal parts may reduce the chance of complete suction evacuation, medical termination can be used.

Total abdominal hysterectomy, with the molar pregnancy in situ, can be considered for older women whose families are complete. This approach reduces the risk of persistent trophoblastic disease by up to 50%.[137]

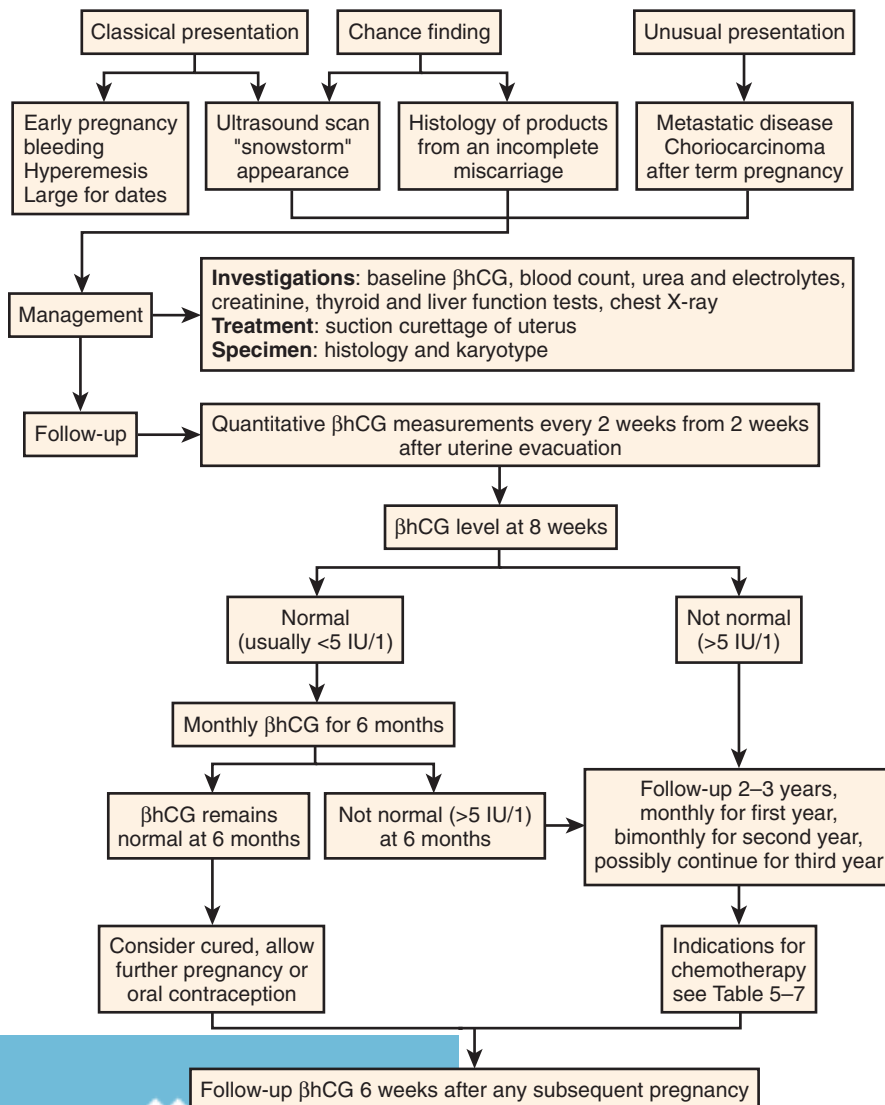
ALGORITHM FOR THE MANAGEMENT OF GESTATIONAL TROPHOBLASTIC DISEASE


FIGURE 5–6
Algorithm for the management of gestational trophoblastic disease. βhCG, β-human chorionic gonadotropin.

Follow-up after Uterine Evacuation

The aims of follow-up are to confirm successful treatment and to identify women with GTN. GTN can occur after molar pregnancy or nonmolar pregnancy irrespective of the site and gestational age. GTN begins as a molar pregnancy or an abortus that fails to completely regress. Proliferation of the residual trophoblast results in an enlarging uterine mass that may embolize and spread to the vagina, lungs, liver, or brain. Continued vaginal bleeding, an enlarged uterus, and rising β-hCG are the most common clinical features.[138] Continued elevation of serum hCG, measured using an assay that detects all the different forms of the hormone seen in cancer, has a sensitivity and specificity of virtually 100% for malignant GTD.[139,140] The approach to follow-up and the criteria for initiating chemotherapy vary around the world. The most effective systems are based on regional or national registries that involve experienced specialist oncologists.

Clinical follow-up and β-hCG surveillance after uterine evacuation of a molar pregnancy also vary according to the different prognosis for GTN between CHMs and PHMs with chromosome analysis predicting prognosis more precisely than histology.[141] The clinical course for women who have had a PHM is almost always benign after uterine evacuation. Persistent disease occurs in 1.2% to 6% of cases; metastatic disease occurs in only 0.1% of cases.[131,142,143] In CHMs, these risks are approximately five times greater after treatment with uterine evacuation and two to three times greater after treatment with hysterectomy.[137,144] The risk of persistent or recurrent GTN is greatest in the first 12 months after evacuation, with most cases evident within 6 months.

In North America, current recommendations for surveillance after uterine evacuation of a molar pregnancy are for β-hCG monitoring 48 hours after surgery and then weekly until three normal levels (<5 IU/L) have been obtained. Levels of β-hCG are monitored at 2-week intervals for 3 months and monthly for 6 and 12 months for PHM and CHM pregnancies, respectively.

In the United Kingdom, there is a central registry for patients with molar pregnancies. Monitoring is supervised by a small number of screening centers. Monitoring of β-hCG levels usually begins 2 weeks after uterine evacuation. The frequency and duration of monitoring are dependent on serum or urinary β-hCG levels. If the β-hCG falls to normal (<5 IU/L) within 8 weeks of evacuation, the monitoring can be stopped at 6 months postevacuation. If the β-hCG falls more slowly, monitoring can stop at 6 months after the first normal value. After normalization of the serum β-hCG, monitoring is done by urinary β-hCG monthly. If β-hCG levels remain normal for 6 months, the risk of malignant GTD is very small (~1:300) and the woman can consider a further pregnancy from that point.[145]

There is a debate about the use of a combined oral contraceptive pill (OCP) after treatment. Limited data from the United Kingdom suggest that it slows the rate of decrease of the β-hCG level and may increase the risk of persistent GTD, and the advice is to avoid the OCP until β-hCG levels have returned to normal. However, data from other countries suggest the combined OCP is safe,[146] and because the risk associated with an unplanned early pregnancy is greater,

the use of oral contraception is considered acceptable by some North American clinicians.[131,144]

Adjuvant chemotherapy may be required in approximately 10% of women after uterine evacuation. The indications for chemotherapy are shown in Table 5–7. In 2002, the International Society for the Study of Trophoblastic Diseases adopted the revised WHO/FIGO (International Federation of Gynecologists and Obstetricians) scoring system for GTN (Table 5–8).[147] It differentiates women with low risk disease from those with high risk disease. Women with low risk disease are usually treated with a single agent, most commonly methotrexate and folinic acid rescue.[148] This is still the recommended approach, although a recent systematic review concluded that "pulsed" dactinomycin is superior to weekly parenteral methotrexate in achieving primary cure, without significantly increasing toxicity.[138] Single-agent chemotherapy will cure only 31% of patients classified as high risk.[149] These women are best given multiagent chemotherapy with etoposide, methotrexate, and actinomycin D [EMA], alternating with cyclophosphamide and vincristine [CO]). The remission rate with this regimen is reported to be 80% to 95%.[150]

After chemotherapy is completed, serial β-hCG measurements are usually assessed twice-weekly for 1 year, monthly for a second year, with decreasing frequency over the next 3 years, and then a 6-monthly urinary β-hCG for life. Cure rates are high, sometimes with the need for additional salvage surgery, and women with a history of GTN can anticipate normal reproductive outcomes, with no increase in the risk of fetal abnormalities, miscarriage, ectopic pregnancy, premature delivery, or stillbirth, compared with the normal population.[151–155] Monitoring of β-hCG is advisable after any subsequent pregnancy, regardless of gestational age or outcome, to exclude recurrent GTD.

In a subsequent pregnancy after chemotherapy for GTN, an ultrasound scan should be performed at 8 weeks' and 14 weeks' gestation. The risk of further GTN is 1.4% to 2.4%.[154] Monitoring of β-hCG levels should be performed 6 weeks and 3 months after delivery.

Although there is a very high cure rate with GTN, it is not surprising that many women experience psychosocial sequelae, such as depression, marital and sexual dysfunction, and concerns about future pregnancy.[156] It is, therefore, important to offer support and counseling to these women.

TABLE 5–7

Indications for Adjuvant Chemotherapy in Gestational Trophoblastic Disease[158]

Serum hGC levels > 20,000 IU/L more than 4 weeks after uterine evacuation
Static or rising hCG levels at any time after uterine evacuation
Raised hCG level 6 months after uterine evacuation
Metastases in liver, lung, brain, or gastrointestinal tract
Histologic diagnosis of choriocarcinoma
Pulmonary, vulval, or vaginal metastases unless hCG concentrations are falling
Heavy vaginal bleeding or evidence of gastrointestinal or intraperitoneal hemorrhage

hCG, human chorionic gonadotropin.

SUMMARY OF MANAGEMENT OPTIONS
Gestational Trophoblastic Disease and Neoplasia

Management Options	Evidence Quality and Recommendation	References
Presentation		
Complete moles cause more exaggerated symptoms and signs than partial moles	III/B	157,158
Partial moles are often missed clinically and by ultrasound scan and are often diagnosed histologically after uterine evacuation of an incomplete miscarriage	IV/C	159
Surgical Evacuation		
Primary treatment of choice for all moles	III/B	160
Suction curettage for uterine evacuation is safer (lower risk of metastasis) than sharp curettage, particularly for evacuation of complete moles	IIb/B	161
Oxytocics, cervical preparation, and medical termination are better avoided, particularly for evacuation of complete moles	IV/C	145
Medical (for Partial Moles)		
Methotrexate	III/B	148
Actinomycin-D	III/B	148
Combination therapy	III/B	162,163
Follow-up		
If β-hCG levels remain normal 8 weeks to 6 months after evacuation, a woman can be considered cured and further pregnancy allowed	—/GPP	—
β-hCG should be measured 6 weeks after any subsequent pregnancy because of the risk of further trophoblastic disease	—/GPP	—
Gestational Trophoblastic Neoplasia		
(See Table 5–8 for categorization of risk)		
Low risk disease management: methotrexate or actinomycin-D	III/B	148
High risk disease management: multiagent chemotherapy (EMA alternating with CO) and if recurrent disease (cisplatin and etoposide with EMA)	III/B	145,159

β-hCG, β-human chorionic gonadotropin; CO, cyclophosphamide and vincristine; EMA, etoposide, methotrexate, and actinomycin-D; GPP, good practice point.

SUMMARY OF MANAGEMENT OPTIONS
Rhesus Prophylaxis

Management Options	Evidence Quality and Recommendation	References
Bleeding associated with threatened miscarriage before 12 weeks' gestation does not require anti-D	IV/C	164
Anti-D is required for an incomplete miscarriage only when surgical evacuation is required	III/B	165
Anti-D Ig should be given to all nonsensitized RhD-negative women who have an ectopic pregnancy	IV/C	165
Trophoblastic cells express RhD factor, so RhD-negative women should receive anti-D at the time of evacuation	IV/C	169,170

RHESUS PROPHYLAXIS

Guidelines from the Royal College of Obstetricians and Gynaecologists and the British Blood Transfusion Society[164,165] recommend that women who have a miscarriage after 12 weeks' gestation should be given anti-D. Between 12 and 20 weeks' gestation, a Kleihauer test to quantify fetomaternal hemorrhage is not required. Treatment with 250 IU anti-D immunoglobulin is adequate.

For miscarriages and ectopic pregnancies earlier than 12 weeks' gestation, the evidence to guide decision-making is poor. There is general consensus that complete spontaneous miscarriages without surgical intervention do not require anti-D prophylaxis.[164] When surgical evacuation of the uterus is required, even before 12 weeks' gestation, it is associated with a higher chance of transfer of fetal cells to the maternal circulation.[166] Under these circumstances, 250 IU anti-D immunoglobulin should be given to all Rhesus-negative women.[165]

With a threatened miscarriage before 12 weeks' gestation, anti-D is generally not required. However, Rhesus prophylaxis may be prudent empirically if the patient has very heavy bleeding or considerable abdominal pain. If a threatened miscarriage occurs later than 12 weeks, anti-D ($\geq$ 250 IU) should be given. If bleeding is persistent, this may be repeated at intervals of no more than 6 weeks. The half-life of anti-D is 2 weeks. Prophylaxis may be needed at 2-week intervals if bleeding is heavy or if it is indicated by the results of a Kleihauer test.[164]

Most religious groups who have concerns about the use of blood products do not object to the use of anti-D prophylaxis.

If it is indicated, anti-D prophylaxis should be given within 72 hours of the sensitizing episode.[167] A 250-IU dose is sufficient for fetomaternal hemorrhage before 12 weeks. The use of anti-D immunoglobulin in Rhesus-negative women in later pregnancy is addressed in Chapter 58. For Rhesus negative women with trophoblastic disease, Anti-D should be given at the time of evacuation or as soon as possible afterwards. Even though fetal red blood cells ought not to be present in a complete mole, nonetheless the consensus view is that it is more prudent to give Anti-D (P. Savage, Imperial College, personal communication).[169,170]

Recurrent Miscarriage

LESLEY REGAN, MAY BACKOS, and ROY G. FARQUHARSON

INTRODUCTION

A *miscarriage* is the spontaneous loss of a pregnancy before the fetus has reached viability. In the United Kingdom, viability was historically taken to occur at 28 weeks, but with improvements in neonatal care, the transition was changed to 24 weeks. In developing countries, where gestation at birth is often uncertain, the World Health Organization (WHO)[1] recommends that the criterion of viability should be a birthweight of 500 g or more. In the United Kingdom, therefore, miscarriages include all pregnancy losses from the time of conception until 23 completed weeks of gestation. Miscarriage is the most common complication of pregnancy, and epidemiologic data have demonstrated that the fate of a fertilized egg is "precarious." Approximately 50% of all conceptions are lost, the majority of which are unrecognized clinically. Furthermore, 15% (almost one in six) of all clinically recognized pregnancies end in miscarriage.[2–4]

There are two distinct types of miscarriage—sporadic and recurrent. The lifetime chance of a woman having a sporadic miscarriage (each pregnancy has a risk of miscarriage that is unrelated to the previous pregnancy history) will depend on the number of pregnancies she has. If each clinically apparent pregnancy carries a one in six (16.7%) risk of miscarrying, then the chance of a woman experiencing at least one miscarriage with two pregnancies is 31%, 42.5% with three pregnancies, 52.1% with four pregnancies, 60.1% with five pregnancies, 67% with six pregnancies, and so on. The chance of two consecutive sporadic miscarriages is 1 in 36 and of three is 1 in 216.

In the majority of cases, the pregnancy loss is due to a random fetal chromosomal abnormality,[5,6] the risk of which rises with increasing maternal age.[7] The vast majority of miscarriages occur early in pregnancy, before 12 completed weeks of gestation (first trimester). The incidence of late miscarriage (second-trimester pregnancy loss, from 13 to 23 completed weeks) is estimated at 2%.[8]

Recurrent miscarriage (RM), the accepted definition of which is three or more consecutive pregnancy losses, affects 1% of couples.[9] As can be seen from the previous calculation of the likelihood of sporadic miscarriages, this is about twice the incidence that would be expected by chance and, therefore, indicates the likelihood of additional pathology. However, some clinicians argue that couples who have had two or more losses should be included in the definition, to avoid the trauma of a third loss before undergoing diagnostic evaluation, in which case, the scale of the problem increases from 1% to 5% of all couples trying to achieve a successful pregnancy.[10] Such a reduction in the stringency of diagnosis will inevitably have large resource implications because of the cost of investigations.

As explained earlier, the incidence of RM is higher than that expected by chance alone (0.34%)[11,12]; hence, a proportion of couples must have a persistent underlying cause for their recurring pregnancy losses. Several additional strands of evidence support the view that RM may be a distinct clinical entity rather than one that occurs by chance alone:

- A woman's risk of miscarriage is not the same with each successive pregnancy, but is related to the outcome of her previous pregnancies.[13–16]
- Women with a history of RM are more likely to have reproductive characteristics (demographics, physical attributes) associated with a poor prognosis for future pregnancy outcome than women suffering sporadic miscarriage.[17–20]
- In contrast to women with sporadic miscarriage, those with RM are more likely to lose pregnancies with a normal chromosome complement[5,21]; in observational terms, fewer of their miscarried fetuses are chromosomally abnormal.

EPIDEMIOLOGY

Maternal Age

The risk of miscarriage increases with advancing maternal age, secondary to an increase in chromosomally abnormal conceptions[22] together with a decline in uterine and ovarian function. Previous miscarriages and multigravidity are also well-recognized risk factors that are strongly correlated with maternal age. A large prospective register linkage study has demonstrated that maternal age at conception is a strong and independent risk factor for miscarriage, irrespective of previous pregnancy outcome. The overall incidence of miscarriage in this study was 13.5%, but the risk of fetal loss classified by maternal age at conception increased steeply with age, rising from 9% at 20 to 24 years to over 70% at 45 years[16] (Table 6–1). The rate of increase in risk escalates

TABLE 6–1

Miscarriage Rates Stratified by Maternal Age at Conception

AGE (YR)	TOTAL NO. OF PREGNANCIES	MISCARRIAGE RATE (%)
20–24	350,395	9
25–29	414,149	11
30–34	235,049	15
35–39	93,940	25
40–44	25,132	51
≥45	1865	75

Overall risk of miscarriage for 634,272 women = 13.5%

@ 22 yr = 8.7%

@ 35 yr = 23.5%

@ 42 yr = 54.5%

@ 48 yr = 84.1%

After Nybo Andersen AM, Wohlfahrt J, Christens P, et al: Maternal age and fetal loss: Population based register linkage study. BMJ 2000;320: 1708–1712.

sharply after 35 years of age, and the chance of a successful pregnancy in women aged 40 years or more is poor. The risks of ectopic pregnancy and stillbirth show similar increases.

Significant changes in reproductive behavior have occurred in our society during recent decades. Many women delay childbearing for social and professional reasons. According to U.K. census data, the number of babies born to mothers aged 35 years or older doubled between 1985 and 2001 from 8% to 16%, and more recent data show a continuing rise. The wider availability of assisted fertility treatments and donor gametes will undoubtedly accelerate this trend. Although no comparable miscarriage figures are available, it is logical to conclude that the incidence of miscarriage has also increased owing to the increase in maternal age at conception. Advanced paternal age has also been identified as a risk factor for miscarriage. A large multicenter European study reported that the risk of miscarriage is highest for couples in which the woman is 35 years of age or older and the man is 40 years of age or older.[23]

Reproductive History

Reproductive history is an independent predictor of future pregnancy outcome. One prospective study reported that a woman's risk of miscarriage is affected by her obstetric history, the single most important factor being a previous miscarriage.[14] Primigravidae and women with a history of a live birth in the immediately previous pregnancy have a significantly lower (5%) risk of miscarriage than women whose last pregnancy ended in miscarriage (19%).[14] Both retrospective[15] and prospective[14,16] studies have reported that the risk of a further miscarriage increases after each successive pregnancy loss, reaching 45% after three and 54% after four consecutive pregnancy losses. These observations are partly explained by reproductive compensation because women who miscarry tend to embark on further pregnancies at progressively later ages, until they achieve their desired family size and partly because they tend to get pregnant again very quickly (an interpregnancy interval of less than 18 months increases the risk of a miscarriage). However, it is important to be aware that a previous live birth does not preclude women from experiencing RM in the future.[18,24]

It is not just first-trimester miscarriage that increases the risk of subsequent early pregnancy loss. In a large study of 500 consecutive couples attending a specialist RM clinic, a previous stillbirth or neonatal death was noted in 6%, termination of pregnancy for fetal abnormality in 2%, an episode of second-trimester (late) miscarriage in 25%, and an ectopic gestation in 5%. Among the 45% of couples with a living child, obstetric complications such as premature delivery and low–birth weight infants were common. In addition, one third of this population had a history of conception delays and previous subfertility investigations.[20]

RISK FACTORS FOR RECURRENT MISCARRIAGE

RM is a heterogeneous condition. Historically, the causes have been grouped into genetic, anatomic, infective, endocrine, immune, environmental, and unexplained categories. Our recent understanding that thrombophilic disorders play an important part in the etiology of recurrent pregnancy loss at various gestations has widened the scope of investigations and management options for this distressing condition.

Genetic Factors

Fetal aneuploidy is the most important cause of miscarriage before 10 weeks' gestation.[25] Chromosomal abnormalities of the embryo account for at least 50% of first-trimester sporadic miscarriages[26] and 29% to 57% of further miscarriages in couples with RM.[16,27] However, most published studies have used conventional cytogenetic analysis, which can identify only gross chromosomal aberrations and depends on tissue culture before karyotyping can be performed. Consequently, the results are limited by external contamination, potential culture failure, and selective growth of maternal cells.[28] When miscarriage tissues are analyzed by comparative genomic hybridization, it appears that the contribution of chromosomal abnormalities to first-trimester miscarriage is almost 70%.[29] Knowledge of the karyotype of a miscarriage may help to predict future pregnancy outcome and informs clinical investigation. Women who miscarry a euploid (normal chromosome complement) embryo have a greater risk of RMs than women whose lost pregnancy is aneuploid.[9,30]

Parental Chromosomal Rearrangement

In approximately 3% to 5% of couples with RM, one partner carries either a balanced reciprocal translocation, in which there is an exchange of two terminal segments from different chromosomes, or a robertsonion translocation, in which there is centric fusion of two acrocentric chromosomes (Fig. 6–1).[20,31,32] Although carriers of a balanced translocation are usually phenotypically normal, abnormal segregation at meiosis leads to 50% to 70% of their gametes, and hence embryos, being unbalanced. These pregnancies are at increased risk for miscarriage and may result in a live birth

of a child with multiple congenital malformations or mental handicap. This justifies offering chorionic villus sampling (CVS) or amniocentesis to assess the chromosomal status of the fetus.[32] (The reproductive risks conferred by chromosome rearrangements differ both according to the type of rearrangement[33] and whether the rearrangement is carried by the female or the male partner.[34]) Until recently, little could be offered to such couples other than referral to a genetic counselor for advice regarding the prognosis for a future pregnancy and the offer of CVS or amniocentesis for established pregnancies. This has changed with the introduction of in vitro fertilization and preimplantation genetic screening (PGS), in which fluorescent in situ hybridization (FISH) is used to infer the genetic status of an embryo from a single cell biopsied 3 days after fertilization.[35,36] However, the live birth rate among couples with a structural chromosome abnormality who conceive spontaneously is significantly higher (50%–65%)[33,37] than that currently achieved after IVF + PGS (38% per embryo transfer[38]), and so couples may still prefer to go down the CVS/amniocentesis route, with the option of termination of pregnancy if the baby is found to be abnormal.

Fetal Aneuploidy and Polyploidy

The vast majority of human aneuploidies arise from errors in the first meiotic division of the oocyte, which is initiated prenatally and is not complete until ovulation. In contrast to females who are born with their complete complement of oocytes, meiosis in males begins only at the time of puberty, new spermatazooa being produced continuously with an average life span of 70 days. Although an increased incidence of sperm chromosome abnormalities in couples with RM has been reported,[39,40] only 7% of fetal trisomies arise from paternal meiotic errors.[41]

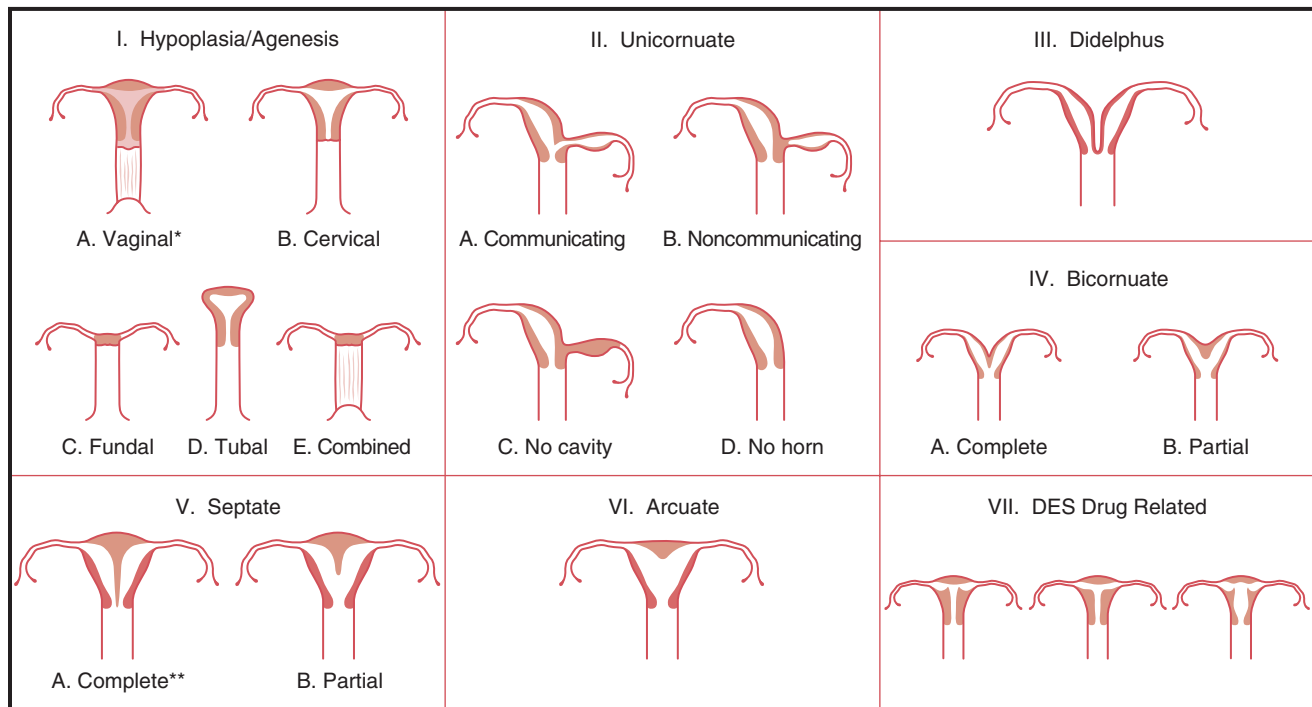
The meiotic error may lead to an extra chromosome (trisomy) or the deletion of a chromosome (monosomy). Triploidy, in which there is a complete set of extra chromosomes, usually arises from fertilization of the oocyte by two spermatozoa, whereas tetraploidy (four times the haploid number) is usually caused by failure to complete the first zygotic division. In couples with RM, conventional

cytogenetic analysis reports the incidence of trisomy, polyploidy, and monosomy X in miscarriage tissue as 30%, 9%, and 4%, respectively.[5,6] Most trisomies are the result of meiotic error associated with advanced maternal age.[42] In one study from the United States, the rate of trisomy in miscarriages rose from 22% to 42% from the 1980s to the early 2000s as mean maternal age rose from 29 to 34 years.[43] However, gonadal mosaicism and sperm aneuploidies also increase the risk of trisomic conceptions. The risk of sex chromosome monosomy and polyploidy conceptions does not increase with maternal age.[22] Some couples with a history of RM are at risk for recurrent aneuploidy and may be prone to heterotrisomy, a recurrence of trisomy involving different chromosomes.[44]

Single-gene mutations leading to abnormalities of embryonic development (particularly placental and cardiac lesions) together with skewed X chromosome inactivation (preferential expression of maternal or paternal X chromosome in maternal cells) are more common in women with RM than in controls.[45] Transcervical embryoscopy has demonstrated that the disordered growth and development seen in aneuploid embryos may also be present in some 18% of euploid pregnancies that have ended in miscarriage.[46]

Anatomic Disorders

Congenital Uterine Malformations

Congenital uterine malformations (Fig. 6–2) are the result of disturbances in müllerian duct development, fusion, canalization, and septal reabsorption. In the most extreme form, the uterus is duplicated in its entirety (uterus didelphus), and in the least severe form, it is only slightly indented at the fundus (arcuate uterus). The contribution of congenital uterine anomalies to recurrent pregnancy loss is unclear because the true prevalence and reproductive implications of uterine anomalies in the general population are unknown. In patients with RM, the reported frequency of uterine anomalies varies widely, from 1.8% to 37.6%.[47–49] This variability is due to differences in the criteria and imaging techniques used for diagnosis and the fact that women with a history of two, three, or more miscarriages at both early and


* Uterus may be normal or take a variety of abnormal forms.
** May have two distinct cervices.

late stages of pregnancy have been included in the studies. The prevalence of uterine anomalies appears to be highest in women with a history of late miscarriages, which probably reflects the greater prevalence of cervical incompetence in women with uterine malformation.[50] However, a large prospective study that employed three-dimensional ultrasound as a diagnostic tool reported that the frequency of uterine anomalies was 23.8% in women with first-trimester RM (three or more consecutive pregnancy losses) compared with a frequency of 5.3% in low risk women who were referred for ultrasound for a variety of reasons unrelated to reproductive outcome.[49] By contrast, a recent literature review of uterine anomalies in early and late RM patients reported a prevalence of 16.7% (96% confidence interval [CI] 14.8–18.6).[51] A retrospective review of reproductive performance in patients with untreated uterine anomalies suggested that these women have high rates of miscarriage and preterm delivery and a term delivery rate of only 50%.[47] Open uterine surgery is associated with postoperative infertility and carries a significant risk of scar rupture during pregnancy.[52] These complications are probably less likely to occur after hysteroscopic surgery,[53] but no randomized trial assessing the benefits of open or hysteroscopic surgical correction of uterine abnormalities on pregnancy outcome has been performed.

Cervical Incompetence (Insufficiency or Dysfunction)

Cervical incompetence is defined as the inability of the cervix to retain a pregnancy, owing to a functional or structural defect, in the absence of contractions or labor. The term is outdated and is probably better described as cervical insufficiency or dysfunction. It is a well-recognized cause of late miscarriage and the diagnosis is often made retrospectively after a woman has had a second-trimester loss. Cervical incompetence occurs along a spectrum of severity, severe incompetence leading to mid-trimester miscarriage, lesser degrees underlying some cases of preterm delivery.[54] The true incidence of cervical incompetence is unknown because the diagnosis is essentially clinical and there are no objective tests to reliably identify women with cervical weakness in the nonpregnant state.

Epidemiologic studies suggest an approximate incidence of 0.5% in the general obstetric population[55] and 8% in women with a history of previous mid-trimester miscarriages.[8] Although some cases involve mechanical incompetence (e.g., congenital hypoplastic cervix, previous cervical surgery, or extensive trauma), many women with a clinical diagnosis of cervical incompetence have normal cervical anatomy. When considered as a continuum, premature cervical ripening may represent a final common pathway of a variety of pathophysiologic processes, such as infection, immunologically mediated inflammatory stimuli, and subclinical abruptio placentae together with a hormonal or genetic predisposition.[56,57] The cervix is the main mechanical barrier separating the pregnancy from the vaginal bacterial flora, and many patients who have asymptomatic mid-trimester cervical dilation also have evidence of subclinical intrauterine infection.[58] It is unclear whether this high rate of microbial invasion is the result or the cause of premature cervical dilation. When cervical incompetence is associated with mechanical weakness, supportive measures such as cerclage may prevent ascending infection and,

hence, may prolong pregnancy. In contrast, if cervical changes result from nonmechanical processes, then cerclage would be less effective, and even harmful in some cases, because of possible inflammatory, prothrombotic, and infectious complications. Some surgical approaches, for example, the use of double sutures (one suture at the internal os and another to close the external os [occlusion suture]), are not primarily mechanical but aim to trap cervical mucus and thus improve the barrier against ascending infection.[59] The efficacy of this approach is unknown and is currently being assessed by a large multicenter prospective, randomized controlled trial.[60]

Fibroids

Uterine fibroids have long been associated with a variety of reproductive problems, including pregnancy loss. Although the exact mechanisms are unclear, the presumed theories of pathophysiology include mechanical distortion of the uterine cavity, abnormal vascularization, abnormal endometrial development, endometrial inflammation, abnormal endocrine milieu, and structural and contractile myometrial abnormalities,[61] any or all of which may impede embryonic implantation. The expression of HOX10, a gene that controls differentiation and is involved in implantation, has been shown to be lower in uteri with fibroids.[62] Evidence of the association between uterine fibroids and RM is retrospective[63] and insufficient to determine differences in pregnancy outcome or assess the effect of the size and location of the fibroids. Data from patients with infertility suggest that only fibroids with a submucosal or an intracavitary component are associated with a reduced implantation rate and an increased rate of miscarriage.[64] Subserous fibroids have no deleterious effect, and the role of intramural fibroids that do not distort the cavity is controversial.[65]

Intrauterine Adhesions

Intrauterine adhesions (Asherman's syndrome, an acquired uterine defect of varying severity) result from intrauterine trauma after vigorous endometrial curettage or evacuation of retained products of conception. Intrauterine adhesions have been associated with RM. The presumed mechanisms are decreased uterine cavity volume and fibrosis and inflammation of the endometrium that predispose the patient to defective implantation, abnormal placentation, and pregnancy loss. However, evidence of the association is mostly retrospective[66] and conflicting,[67] with no robust prospective evidence to confirm a causal relationship. Despite the advances in hysteroscopic surgery, pregnancies following surgical treatment remain at high risk of complications.[68]

Endocrine Factors

Historically, a variety of endocrine disorders have been suggested as causal in RM, but few have withstood critical scrutiny.

Systemic Endocrine Factors

Diabetes mellitus and thyroid disease have been associated with sporadic miscarriage, but there is no direct evidence that they contribute to RM. The prevalence of both endocrinopathies in women with RM is similar to that expected in the general population.[20] Women with diabetes who have high hemoglobin A1c levels in the first trimester are at risk for miscarriage and fetal malformation.[69] In contrast, well-controlled diabetes mellitus is not a risk factor for RM,[70] nor is treated thyroid dysfunction.[71] A meta-analysis has reported an association between the presence of thyroid autoantibodies, a history of one or two miscarriages, and outcome of the next pregnancy.[72] Women with RM are no more likely than fertile control subjects to have circulating thyroid antibodies.[73] The presence of thyroid antibodies in euthyroid women with a history of RM did not affect future pregnancy outcome in a prospective observational study.[74] However, thyroxine therapy for euthyroid women with antithyroid antibodies was reported to improve pregnancy outcome in a general population, including a reduction in pregnancy loss.[75]

Prolactin is involved in both ovulation and endometrial maturation. It has been reported that hyperprolactinemia is a cause of RM and that treatment with bromocriptine, which suppresses prolactin secretion by the anterior pituitary, significantly reduces the miscarriage rate.[76] Lack of expression of endometrial prolactin during the luteal phase of the menstrual cycle has also been reported to be associated with RM in one small study.[77]

Luteal Phase Defect and Progesterone Deficiency

A functional corpus luteum is essential for the implantation and maintenance of early pregnancy, primarily through the production of progesterone, which is responsible for the conversion of a proliferative endometrium to a secretory endometrium suitable for embryonic implantation. Luteal phase defect, in which insufficient progesterone production results in retarded endometrial development, has long been associated with RM. However, standard diagnostic criteria required to assess the true incidence and effect of luteal phase defects are lacking.[78] Diurnal variations and pulsatile secretion make serum progesterone measurements unreliable, and the interpretation of the results of endometrial biopsy is susceptible to sampling and interobserver variation.[79] In addition, serum progesterone levels are not predictive of pregnancy outcome; low progesterone levels in early pregnancy appear to reflect a pregnancy that has already failed. Moreover, no convincing studies show that treatment of luteal phase defect improves pregnancy outcome in women with RM,[80,81] although a Cochrane meta-analysis suggested that progesterone supplementation in early pregnancy may be of benefit for some women.[82] A recent review of the literature suggests that progesterone has an important immunoregulatory role in altering maternal cytokine production and natural killer (NK) cell activity and regulating human leukocyte antigen (HLA)-G gene expression in pregnancy, prompting a call for further therapeutic intervention studies.[83] The Medical Research Council (MRC) recently funded a multicenter randomized placebo-controlled trial of progesterone treatment in early pregnancy for women with a history of unexplained RM (the PROMISE trial). The results of this are eagerly awaited and will inform clinical practice.

Polycystic Ovary Syndrome, Hypersecretion of Luteinizing Hormone, and Hyperandrogenemia

Polycystic ovaries and the various endocrinopathies associated with polycystic ovary syndrome (PCOS), high

luteinizing hormone (LH) levels and hyperandrogenemia, have been linked to infertility and miscarriage for several decades. Although polycystic ovaries are found significantly more often among women with RM than among parous control subjects, polycystic ovaries themselves do not appear to predict future pregnancy outcome in ovulatory women with RM.[84] A high level of LH or testosterone does not correlate with pregnancy outcome in ovulatory women with RM.[85] Further, a prospective, randomized placebo-controlled trial[86] reported that prepregnancy suppression of high LH did not improve the live birth rate—the outcome of pregnancy in women in the placebo group was similar to that of women with a normal LH level.

More recently, the association between PCOS and insulin resistance leading to compensatory hyperinsulinemia has come under scrutiny as a risk factor for RM. The mechanism underlying this relationship may be through impairment of the fibrinolytic response, which is important in the tissue remodeling that accompanies embryonic implantation. The 4G/5G polymorphism in the plasminogen activator inhibitor-1 (PAI-1) gene promoter influences plasma concentrations of fibrin. Homozygosity for the 4G/4G polymorphism, which is associated with hypofibrinolysis, is found significantly more often among women with PCOS and a history of RM than among those with normal ovarian morphology. Of particular interest is the fact that there is an insulin response element in the promoter region of the PAI-1 gene. Hence, hyperinsulinemia is associated with impairment of fibrinoylyis, which in turn, is associated with miscarriage.

Insulin resistance is associated with a higher rate of miscarriage among women with PCOS undergoing ovulation induction than among those who are not insulin resistant,[87] and the prevalence of insulin resistance is increased among women with RM.[88] Metformin treatment for women with PCOS during induction of ovulation and early pregnancy may improve endometrial receptivity and implantation, thereby reducing the risk of future miscarriage.[89,90] However, the role of insulin resistance and the efficacy and safety of metformin in women with polycystic ovaries and RM remain to be established in prospective controlled trials.

Infective Factors

The evidence for a role of infection in recurrent early miscarriage is weak. Any severe infection that leads to bacteremia or viremia can cause an early sporadic miscarriage. However, for an infective agent to be implicated in the etiology of repeated early pregnancy losses, it must persist in the genital tract and avoid detection or cause insufficient symptoms to disturb the woman. Toxoplasmosis, rubella, cytomegalovirus, herpes, and *Listeria* infections do not fulfill these criteria, and routine screening for these disorders has been abandoned.[91] A recent study has reported that positive immunoglobulin G (IgG) serology for *Chlamydia trachomatis* is associated with early but not late miscarriage.[92] The authors suggest that even in the absence of a detectable organism, previous *Chlamydia* infection increases the miscarriage risk, possibly by triggering chronic inflammation.

The evidence of an association between endometritis and first-trimester miscarriage is inconsistent.[93,94] However, the presence of bacterial vaginosis in the first trimester has repeatedly been reported as a risk factor for second-trimester miscarriage and preterm delivery.[95,96] Two randomized controlled trials conducted in low risk obstetric populations found that the incidence of late miscarriage and preterm birth was reduced by screening and treating women for bacterial vaginosis in early pregnancy with oral clindamycin[97] or alternatively with a combination of oral erythromycin and metronidazol.[98] However, the results from another eight randomized trials concluded that there is no benefit in screening and treating all pregnant women for bacterial vaginosis in order to prevent preterm birth and its consequences.[99] By contrast, a Cochrane review suggested that detection and treatment of bacterial vaginosis early in pregnancy may reduce the risk of preterm delivery, but only in women with a history of mid-trimester miscarriage or preterm birth.[100] These findings, coupled with the recent report of long-term outcomes from the ORACLE II study that observed an increase in the incidence of cerebral palsy in the children of women in threatened preterm labor given erythromycin, co-amoxyclav, or both,[101] suggest that the empirical use of antibiotics in pregnancy should be avoided.

Thrombophilic Factors

The hemostatic system plays a crucial role in both the establishment and the maintenance of pregnancy. The fibrinolytic pathways are intimately involved in ovulation and the implantation of the fertilized egg into the uterine decidua. Once pregnancy has been established, an intact placental circulation is maintained by a dynamic balance between the coagulation and the fibrinolytic systems. Pregnancy is a hypercoagulable state secondary to an increase in the levels of some coagulation factors, a decrease in the levels of anticoagulant proteins, and an increase in fibrinolysis.[102]

A thrombophilic defect is an abnormality in the coagulation system that predisposes an individual to thrombosis. The first studies of the prevalence of coagulation abnormalities in women with adverse pregnancy outcome appeared in the mid 1990s.[103,104] Numerous studies of the prevalence of individual coagulation defects in women with RM have since reported very variable findings, but the role of antiphospholipid syndrome (APS), an acquired thrombophilic defect, has become an established and treatable cause of RM and the potential role of other thrombophilic defects (acquired or inherited) has been extensively explored. The presumed hypothesis is that some cases of RM and later pregnancy complications are caused by an exaggerated hemostatic response during pregnancy, leading to thrombosis of the uteroplacental vasculature and subsequent fetal demise.

Antiphospholipid Syndrome

APS is now recognized to be the most important treatable cause of RM.[9] Antiphospholipid antibodies (aPLs) are a family of heterogeneous autoantibodies (numbering approximately 20) directed against phospholipids-binding plasma proteins. In the etiology of pregnancy morbidity, the two most clinically important aPLs are lupus anticoagulant (LA) and anticardiolipin antibodies (aCLs) of the IgG and IgM subclass. APS, as originally defined, refers to the association between aPLs and either RM, thrombosis, or thrombocytopenia.[105] "Primary APS" affects patients with no identifiable

underlying systemic connective tissue disease, whereas APS in patients with chronic inflammatory diseases, such as systemic lupus erythematosus, is referred to as "secondary APS." APS is associated with fetal loss in every trimester of pregnancy, and the clinical criteria thought to suggest it have now been extended to include (1) three or more consecutive unexplained miscarriages before the 10th week of gestation, (2) one or more deaths of morphologically normal fetuses after the 10th week of gestation, and (3) one or more preterm births before the 34th week of gestation as a result of severe preeclampsia, eclampsia, or placental insufficiency.[106]

APS can be associated with pregnancy loss in any trimester, but because the vast majority of miscarriages occur early, numerically it has the greatest impact before 12 weeks.[107] It is generally accepted that the prevalence of APS in women with RM is about 15%[108] and the fetal loss rate in untreated future pregnancies is as high as 90%.[109] However, the prevalence of APS in a highly selected cohort of late miscarriage sufferers has been reported to be over 40%.[110] By comparison, the prevalence of APS in women with a low risk obstetric history is less than 2%.[111] The mechanisms by which aPLs are thought to cause adverse pregnancy outcome are varied, reflecting in part their heterogeneity. Historically, the suggested pathogenesis of aPL-related pregnancy loss focused on placental thrombosis and infarction,[112,113] but it is important to note that these findings are neither specific nor universal.[114,115] Advances in our understanding of early pregnancy development and the biology of aPLs have provided new insights into the mechanisms of aPL-related pregnancy failure. In vitro studies report that aPLs.

- Impair signal transduction mechanisms controlling endometrial cell decidualization.[116]
- Increase trophoblast apoptosis.[117]
- Decrease trophoblast fusion.[117,118]
- Impair trophoblast invasion.[115,119]

Interestingly, the effects of aPLs on trophoblast function are reversed, at least in vitro, by low-molecular-weight heparin (LMWH).[117,119–121] Elegant experiments in mice have highlighted the pivotal role that complement plays in the pathogenesis of aPL-induced fetal damage. aPLs activate the classical complement pathway, generating the potent anaphylotoxin C5a, which in turn, recruits and activates inflammatory cells leading to tissue damage in the placenta and fetal death or growth restriction.[122,123] Heparin prevents aPL-induced fetal loss by inhibiting complement activation,[124] which raises the possibility that complement inhibitory therapies targeted to the placenta might be a useful treatment option for prevention of miscarriage in the future.

Inherited Thrombophilic Defects

Inherited thrombophilic defects are a well-established cause of systemic thrombosis, but their association with obstetric morbidity is more recent and less clearly understood. The publication of retrospective prevalence studies of thrombophilic disorders such as activated protein C resistance, protein C, protein S, and antithrombin III deficiencies in women with a history of fetal loss and later pregnancy complications was followed swiftly by the identification of three common thrombophilic mutations—factor V Leiden (FVL) G1691A, factor II prothrombin G20210A, and methylene tetrahydrofolate reductase C667T.

Since then, a plethora of studies have reported that individual defects are as or more frequent in women with RM as they are in control subjects. However, these prevalence data are compromised by the small sample size of individual studies, ascertainment bias, and poor matching of cases and controls owing to racial heterogeneity. Nonetheless, two meta-analyses have confirmed an association between RM and both the FVL and the prothrombin gene mutations.[125,126] The meta-analysis by Rey and coworkers[126] using pooled data from 31 retrospective studies suggested that carrying the FVL mutation (which gives rise to the inherited form of activated protein C resistance) is associated with a history of both early and late recurrent fetal loss and late nonrecurrent fetal loss. Carrying the prothrombin gene mutation is associated with early recurrent and late nonrecurrent fetal loss, whereas protein S deficiency is associated with late nonrecurrent fetal loss only. Methylenetetrahydrofolate mutation, protein C, and antithrombin III deficiencies are not significantly associated with fetal loss. Regrettably, there are little prospective data on the outcome of untreated pregnancies among women with genetic thrombophilic defects. One small prospective study showed that women with unexplained first-trimester RM who carry the FVL mutation are at significantly increased risk for further miscarriage compared with those with a normal factor V genotype (live birth rates 37.5% vs. 69.5%: odds ratio 3.75, 95% CI 1.3–10.9).[127] An equally important finding from this study was that carrying the FVL mutation did not preclude an uncomplicated pregnancy delivered at term, but at the present time, we have no means of reliably predicting those women with FVL mutation who are destined to miscarry and those who will have a successful outcome.

It may well be that "multiple hits" are necessary to substantially increase the likelihood of adverse pregnancy outcome in carriers of weakly prothrombotic genotypes. Indeed, one European cohort study identified a 14-fold increased risk of stillbirth in patients with combined thrombophilic defects.[103]

Global Markers of Hemostatic Function

The limitations of individual genetic thrombophilic defects in predicting pregnancy outcome has led to the introduction of "global tests" of hemostatic function in the assessment of women with RM. Using such tests, it has been reported that these women are in a prothrombotic state outside pregnancy.[128–130] This may result not only in an exaggerated hemostatic response during pregnancy, leading to thrombosis of the uteroplacental vasculature and subsequent fetal loss[131,132] but also confer an increased risk of ischemic heart disease in later life.[133]

Vincent and colleagues[130] reported that the levels of thrombin-antithrombin (TAT) complexes, a marker of thrombin generation, were significantly higher among women with a history of RM compared with age-matched fertile parous controls. This finding was independent of the gestation at previous miscarriage and unaffected by the woman's aPL status. Using alternative global markers, it has also been reported that women with RM suffer from a chronic state of endothelial activation,[134] and abnormally high levels of procoagulant particles have been reported in the circulation of women with a history of hitherto unexplained early and late pregnancy miscarriage.[128,135] In addition to their direct effect on the coagulation cascade, these

circulating microparticles may be exerting a proinflammatory or proapoptotic action resulting in a disturbance in the implantation process and subsequent impairment of fetal growth.

Further evidence for an inherent prothrombotic state outside of pregnancy in women with RM has been demonstrated using thromboelastography. The thromboelastogram (TEG) is a cheap but effective tool that assesses the kinetics, strength, and stability of whole blood coagulation.[136] A variety of parameters scoring different stages of clot formation are registered, ranging from the initial platelet-fibrin interaction, through platelet aggregation, clot strengthening, and fibrin cross-linkage to clot lysis. Among women with RM, the maximal clot amplitude (MA)—a measure of the absolute strength of the fibrin clot formed—is significantly greater than among parous controls.[129] Moreover, the prepregnancy MA has also been found to be predictive of future pregnancy outcome, being significantly higher in those RM women whose next pregnancy ends in a further miscarriage than in those having a live birth. Once pregnancy is confirmed, serial TEG testing during the first trimester is capable of identifying increases in the MA that predate the clinical evidence of impending miscarriage by several weeks.[129]

Immunologic Factors

Maternofetal Alloimmune Disorders

The hypothesis that successful pregnancy depends on maternal immunologic tolerance of the semiallogeneic fetus suggests that fetal survival is dependent on suppression of the maternal immune response that would normally be expected against paternal antigens expressed by the fetus. However, the hypothesis that some cases of RM result from failure of maternal alloimmune recognition of the pregnancy has never been substantiated. No alloimmune mechanisms have been shown unequivocally to cause RM in humans. Further, there is no clear evidence to support the hypothesis that HLA incompatibility between couples, the absence of maternal leukocytotoxic antibodies, or the absence of maternal blocking antibodies is related to RM. Tests of such parameters should not be offered routinely to women with RM. Although it is clear that lymphocyte function does indeed change during pregnancy, there is no generalized suppression of the maternal immune response. Indeed, the concept that maternal immunization with paternal white blood cells, third-party donor leukocytes, trophoblast membranes, and intravenous immune globulin (IVIG), in order that she may mount a protective immune response to prevent rejection of the genetically dissimilar fetus and improve the live birth rate, has been refuted repeatedly by randomized therapeutic studies, summarized in two Cochrane systematic reviews.[137–140]

Furthermore, immunotherapy is expensive and has potentially serious side effects, including transfusion reaction, anaphylactic shock, and hepatitis. U.K. and U.S. current recommendations are that immunotherapy should no longer be offered to women with unexplained RM outside the context of approved clinical research projects.[141]

Contemporary concepts in reproductive immunology are now focused on the cooperative nature of the interaction between individual cells and molecules of the immune system with the fetus in determining pregnancy outcome.[142] In particular, interest is currently focused on the relationship between natural killer (NK) cells and reproductive failure. NK cells are lymphocytes that form part of the innate immune system and are found in both peripheral blood and the endometrium. There are, however, important phenotypic and functional differences between NK cells present at the two sites.[143] Microarray analysis combined with flow cytometric and reverse transcriptase polymerase chain reaction (RT-PCR) studies have demonstrated that the phenotype of uterine natural killer (uNK) cells ($CD56^{bright}$ $CD16^-$) is different from that of peripheral blood NK cells (PBNK) ($CD56^{dim}$ $CD16^+$).[142] In addition, uNK cells have an immunoregulatory potential that PBNK cells do not demonstrate.[143] More recently, it has been demonstrated that there is no relationship between PBNK and uNK cell levels and that PBNK cell levels are not predictive of pregnancy outcome among women with unexplained RM. The value of peripheral blood NK cell testing in the evaluation of women with RM is, therefore, questionable.[144]

The temporal and spatial distribution of uNK cells suggest that they play a role in controlling trophoblast invasion. Increased numbers of CD56+ NK cells have been documented in preconceptual decidual biopsies from women with RM compared with controls and those women with the highest levels of CD56+ cells had a higher rate of miscarriage in future untreated pregnancies.[145,146] However, although a recent study confirmed an increase in peri-implantation uterine NK cells in women with a history of RM, this did not have any useful prognostic value for the outcome of a subsequent pregnancy.[147] At the present time, there is no justification for the measurement of uNK cells in routine clinical practice. Furthermore, the use of systemic immunomodulatory drugs to suppress NK cell numbers in an attempt to improve pregnancy outcome has no logical basis.

The cytokine response at the maternofetal interface, to which uNK cells contribute, is currently under investigation. In general terms, the cytokine response may be divided into either a predominantly T helper-1 (Th-1) type (characterized by the production of interleukin 2 [Il-2], interferon, and tumor necrosis factor-α [TNF-α]) or a Th-2 type response (characterized by the production of Il-4, -6, and -10). It has been suggested that normal pregnancy is the result of a Th-2 type cytokine response that allows the production of blocking antibodies to mask fetal trophoblast antigens from immunologic recognition by a maternal Th-1 cell-mediated cytotoxic response.[148] In contrast, women who recurrently miscarry tend to produce a predominantly Th-1 type response both in the period of embryonic implantation and during pregnancy.[149–151]

These observations support the view that disturbances of immune tolerance of the fetus may account for some cases of RM. Future studies should be aimed at (1) identifying the subgroup of women with RM who produce a dominant Th-1 cytokine profile at the maternofetal interface during pregnancy and (2) the effect of immunomodulatory interventions aimed at shifting the balance toward Th-2 dominance.

Autoimmune

The prevalence of a variety of autoantibodies is reported to be increased among women with RM,[152,153] but this

association is inconsistent and depends on which tests are employed and the population studied. Prospective data on the outcome of untreated pregnancies of autoantibody-positive compared with antibody-negative women is also conflicting, but the majority of studies demonstrate no association.[74,73,154,155] Furthermore, a placebo-controlled randomized study has reported that the use of steroids to suppress autoantibody titers does not improve the live birth rate but is associated with an increased risk of preterm delivery.[156]

Environmental Factors

Most data on environmental risk factors have concentrated on sporadic miscarriage rather than RM. The results have been conflicting and are undoubtedly biased by difficulties in controlling for confounding factors, the inaccuracy of exposure data, and the measurement of toxin dose. However, some environmental factors have been shown to affect pregnancy outcomes. Cigarette smoking has an adverse effect on trophoblast invasion and proliferation and is associated with a dose-dependent increased risk of miscarriage,[157] although these findings have been challenged.[158] Alcohol has adverse effects on fertility and fetal development and even moderate consumption of 5 or more units per week appears to increase the risk of sporadic miscarriage.[159] (In the UK, a unit of alcohol is defined as 10 ml [or approximately 8 g] of ethanol [ethyl alcohol].) Caffeine consumption is associated with a dose-dependent increased risk of miscarriage with the risk becoming significant when intake exceeds 300 mg (3 cups of coffee) daily.[158,160] Some forms of occupational exposure, such as working with or using video display terminals, does not appear to increase the risk of miscarriage,[161] and evidence of an adverse effect of anesthetic gases among surgical workers is contradictory.[162,163] Obesity has become a major health problem worldwide and in the United Kingdom affects 25% of the female population. Compelling evidence is accumulating that obesity is a risk factor for infertility, sporadic miscarriage and RM,[164,165] late pregnancy complications, and perinatal morbidity.[166] A recent review has highlighted the adverse impact that obesity exerts on every aspect of obstetric practice and outcome.[167] Concerns have also arisen that an increased risk of miscarriage is associated with the use of nonsteroidal anti-inflammatory drugs and some antidepressants during the periconceptual period.[168]

Psychological Factors

Miscarriage is a stressful life event: depression, anxiety, denial, anger, sense of loss, inadequacy, and marital disruption have all been reported in female and male members of couples experiencing pregnancy loss. RM may seriously affect a woman's mental health.[169] One study indicated that a third of women with RM were clinically depressed and 21% had levels of anxiety that were equal to or higher than those in typical psychiatric outpatient populations.[170] Animal data indicate that stress may induce miscarriage.[171] A small prospective study indicated that among 14 psychological parameters studied, only a high depression scale affected the miscarriage rate in women with a history of two previous miscarriages.[172] Larger prospective studies are needed to address the scope of psychological disorders and their contribution to RM.

MANAGEMENT OPTIONS

"Prepregnancy" When the Third Miscarriage Occurs

A detailed history of the previous miscarriages is essential. When the third miscarriage occurs, it is important to consider the following factors:

- The underlying causes of first-trimester miscarriage are different from those responsible for mid-trimester loss. Therefore, it is important to accurately determine gestational age, confirmed by ultrasound whenever possible, at the time of the miscarriage.
- In cases of first-trimester miscarriage, one should determine whether the loss was at a very early stage (biochemical evidence of pregnancy only), anembryonic (blighted ovum), embryonic (6–8 wk), or fetal (>8 wk). Different pathologic factors affect the various stages of early pregnancy. For example, biochemical and anembryonic losses are more likely to be associated with chromosomally abnormal embryos.
- Note whether fetal heart activity was detected before the miscarriage. Many first-trimester miscarriages associated with APS occur after the establishment of fetal heart activity.
- When surgical evacuation of the products of conception is performed, it is important to document suspected uterine abnormalities, such as a bicornuate or subseptate uterus or fibroids. Tissue should be collected and sent for both histologic examination (to confirm pregnancy and exclude trophoblastic disease) and fetal karyotyping (Table 6–2).
- In the event of a second-trimester miscarriage, note whether the pregnancy loss was preceded by intrauterine fetal death, spontaneous rupture of the membranes, vaginal bleeding, painful uterine contractions, or painless cervical dilation. This information is particularly useful in identifying or excluding a presumed diagnosis of cervical incompetence. The couple should be encouraged to consent to a full fetal postmortem examination, fetal karyotyping, and placental histologic examination.
- Coexisting pathology is a frequent finding in cases of second-trimester miscarriage. If the fetal karyotype and morphology are normal, the search for evidence of anatomic problems (including cervical weakness) should always be accompanied by a detailed thrombophilia and infection screen.
- Ensure that a follow-up appointment is scheduled for the couple.

Prepregnancy Assessment and Counseling after the Third Miscarriage

The loss of a pregnancy at any stage is a tragic event, and sensitivity is required in assessing and counseling couples with RM. A specialist miscarriage clinic is a better environment in which to provide this care than a busy postnatal or general gynecology clinic. Ideally, the couple should be seen together and offered information to facilitate decision-making about future pregnancies (see "Risk Factors for Recurrent Miscarriage"). Wherever possible, the couple should be given written information to take home.

TABLE 6–2

Chromosome Analysis of the Products of Conception—Tissue Collection

General	It is good practice, and in some countries a legal requirement, to obtain patient consent prior to tissue collection for diagnostic testing. Ensure aseptic technique in tissue handling.
Collection—first-trimester miscarriage	Collect all fetal tissues and placental villi.
Collection—second-trimester miscarriage	Obtain a small piece of full-thickness fetal skin samples with subepidermal layers. In cases of intrauterine fetal death and macerated fetus, it is particularly important to send a placental biopsy in addition to a fetal sample, because fetal karyotyping is often unsuccessful. Placental biopsies should be a wedge from the cord insertion site and include membranes.
Container	Sterile universal container containing sterile saline or transport media provided by the cytogenetics laboratory. **DO NOT ADD FORMALIN**. Transport media should be regularly renewed.
Labeling	Patient's details including name, date of birth, and hospital number should be recorded on the sample container label and accompanied by a completed referral form. Samples should be prebooked with the laboratory.
Transport and storage	Send samples immediately after collection to the laboratory; transport at room temperature. Sample can be refrigerated at 4°C if not sent until the following day. **DO NOT FREEZE**.
Causes for rejection	Gross contamination, necrotic tissue, specimen in formalin fixative.
Limitations	Some products of conception may contain only maternal tissues. Trophoblast cells may contain mosaicisms or aneuploidy not present in the fetus.

History

A comprehensive history should be obtained from both partners, noting their ages and obstetric, gynecologic, medical, surgical, social, psychological, and family histories. Seeking the cooperation of the patient's family doctor and other physicians may be necessary to obtain relevant information.

Physical Examination

The physical examination should include height, weight, blood pressure, and a general assessment for signs of endocrine disease. Pelvic examination should assess signs of previous cervical trauma or surgery, genital tract anomalies, and uterine size.

Investigation of Recurrent Miscarriage (Table 6–3)

Testing should include

- Parental karyotyping of both partners to determine abnormal chromosome rearrangements, translocations, or inversions.
- Two-dimensional pelvic ultrasound to identify polycystic ovaries and assess the uterine anatomy. Suspected uterine anomalies may require further studies using hysterosalpingography (HSG), hysteroscopy, laparoscopy, or three-dimensional pelvic ultrasound.
- Early follicular phase (days 2–4 of menstrual cycle) LH, FSH, and testosterone levels are measured to exclude LH hypersecretion, hyperandrogenemia, and possible high FSH levels.
- All women with RM should be screened for aPLs before pregnancy. A diagnosis of APS requires at least two positive test results for either LA or aCLs IgG or IgM antibodies in samples obtained 6 weeks apart. Women with one positive test result and a second negative test result should have a third aPL test to confirm or refute the APS diagnosis. The detection of aPL is subject to considerable variation between laboratories because of

TABLE 6–3

temporal fluctuation of aPL titers in individual patients, transient positivity as a result of infection, suboptimal methods of sample collection and preparation, and lack of standardization of laboratory tests for their detection.[173] Therefore, laboratory assays should be performed according to international guidelines.[174] Because maternal aPLs might be down-regulated during pregnancy,[175] tests are best performed preconceptually. Testing for aPLs other than LA or aCLs is uninformative.[174] The dilute

Russell viper venom time test, together with platelet neutralization procedure, is a more sensitive and specific test for the detection of a LA than either the activated partial thromboplastin time or the kaolin clotting time test.[107] aCLs are detected with a standardized enzyme-linked immunosorbent assay.[175]

- Screening for APC resistance should include coagulation tests for both unmodified and modified APC resistance and factor V genotyping. Factor II (prothrombin) genotyping should also be undertaken. Additional thrombophilia tests may be requested on the basis of positive findings on history, examination, and laboratory tests. Table 6–3 shows a complete list of possible tests. In the majority of cases of RM, an underlying systematic cause will not be identified.[176]

- Thromboelastography is not widely available. However, this method of assessing whole blood hemostasis is a useful tool for identifying evidence of prothrombotic and impaired fibrinolytic parameters among women with RM in whom the more conventional hemostasis tests are normal.[129] It has the great advantage of being cheap and reproducible with results that are available within a few hours. Because pregnancy may trigger proinflammatory hemostatic changes, it is helpful to repeat TEG testing in early pregnancy. Abnormal results may help to inform decisions regarding the use of variable-dose aspirin.

Prepregnancy Treatment Options

General Considerations

Couples should be treated sensitively and sympathetically. The management of couples with RM has traditionally been based on anecdotal evidence, personal bias, and the results of small uncontrolled studies.[136] As our knowledge of early pregnancy development increases, it is incumbent upon us to reject such customs and embrace evidence-based practice. It is important to avoid recommending unproven treatments.

Epidemiologic Factors

Advanced maternal age and the number of previous miscarriages are two important independent risk factors for further miscarriage that should be considered (see Table 6–1).

Genetic Factors

When a parent carries a balanced chromosome rearrangement, the risk of producing chromosomally unbalanced offspring depends on the specific chromosomes involved, the size of the segments involved in the rearrangement, and the sex of the transmitting parent. The risk of miscarriage in couples with reciprocal translocation is approximately 50%, whereas in robertsonian translocation, the risk is approximately 25%.[177] Most couples with balanced chromosome rearrangements have healthy children; however, homologous robertsonian translocations always result in fetal aneuploidy. The finding of an abnormal parental karyotype warrants genetic counseling. Genetic counseling offers the couple a prognosis for future pregnancies, prenatal diagnostic options, and the opportunity to perform familial chromosomal studies if desired.

If a subsequent miscarriage occurs, karyotyping of the products of conception is essential, regardless of the parental karyotype. Table 6–2 summarizes the procedure for collecting the products of conception for chromosome analysis. Traditionally, reproductive options in couples with chromosomal abnormality have included proceeding to a further natural pregnancy, with or without prenatal diagnostic tests, CVS, or amniocentesis; gamete donation[178]; and adoption. Preimplantation genetic diagnosis has been explored as a treatment option for translocation carriers[179,180] and couples with unexplained RM.[181,182] Preimplantation genetic diagnosis is a technically demanding procedure and requires the couple to undergo in vitro fertilization to produce embryos. Therefore, couples with proven fertility must be made aware of the high financial cost and low implantation and live birth rates per cycle after in vitro fertilization. In summary, aneuploidy screening does not improve the live birth rate for couples with RM,[182] and in women aged between 35 and 41 years, it significantly lowers the live birth rate.[183]

Anatomic Considerations

As a screening test for uterine anomalies, noninvasive two-dimensional pelvic ultrasound assessment of the uterine cavity, with or without sonohysterography,[20,184] when performed by skilled and experienced staff, is as informative as invasive HSG. Three-dimensional ultrasound offers additional accuracy in the diagnosis and classification of uterine malformations[185,186]; hence, its use might obviate the need for hysteroscopy and laparoscopy. Minor defects rarely warrant surgical correction. Historically, abdominal metroplasty was advocated for a uterine septum. However, open uterine surgery has not been assessed in prospective trials, is associated with postoperative infertility, and carries a significant risk of scar rupture during pregnancy.[52] These complications are less likely to occur after transcervical hysteroscopic resection of uterine septa, and experience from case series appears promising.[187] These procedures must be performed by clinicians with appropriate training and experience in hysteroscopic surgery. Metroplasty has been traditionally advocated for bicornuate uterus and uterus didelphys, even though it is of unproven benefit and carries a significant risk of morbidity. Unicornuate uterus is rare and has limited treatment options. Cervical cerclage has been proposed, but is of uncertain value.[188] Uterine anomalies resulting from in utero diethylstilbestrol exposure are rarely amenable to surgical correction, but prophylactic cervical cerclage has been advocated.[189] Intrauterine adhesions can be corrected by hysteroscopic lysis, placement of an intrauterine device, and administration of cyclic estrogen and progesterone after surgery.[68] Occasionally, abdominal or hysteroscopic myomectomy is warranted for RM associated with significant submucous fibroids that distort the uterine cavity or occupy a large subendometrial area. A 3-month course of a GnRH analogue preoperatively facilitates surgery by reducing the size and vascularity of the fibroids. More recently, percutaneous thermal ablation of uterine fibroids under real-time magnetic resonance control has been pioneered and appears to be a safe and effective therapy that offers the advantage of preserving fertility.[190–192]

Traditionally, the diagnosis of cervical incompetence has relied on a clinical history of late miscarriage preceded by spontaneous rupture of the membranes or painless cervical

dilation. This clinical diagnosis has not been evaluated in terms of its ability to predict future pregnancy outcome. Although HSG and painless passage of an 8 Hegar dilator have been used to make the diagnosis before pregnancy, neither procedure has been studied prospectively. There is no satisfactory objective test to identify nonpregnant women with cervical incompetence.

Experience with prepregnancy abdominal cerclage is limited and of unproven value. It has been advocated in women with a history of mid-trimester loss and previous failed cervical vaginal cerclage and for those with a very short or scarred cervix in which the transvaginal approach would be difficult. Transabdominal cerclage has been associated with a lower rate of perinatal death or delivery at less than 24 weeks' gestation, but is accompanied by a higher risk of operative complications, particularly hemorrhage and damage to the bladder or bowel.[193,194] Necessarily, the procedure commits the woman to two major operations: (1) a laparotomy for placement of the suture either before or in early pregnancy and (2) cesarean delivery.

Endocrine Factors

There is no value in performing glucose tolerance tests in women with RM who have no history suggestive of diabetes mellitus. In women with established diabetes, poor glycemic control increases the risk of pregnancy loss. Consequently, these women require prepregnancy counseling with the aim of obtaining optimal periconceptual glycemic control.[195] The contribution of luteal phase defect to RM is controversial, and a review of pregnancy rates after hormonal treatments for luteal phase deficiency concluded that the benefits are uncertain[81] and that standardized diagnostic criteria are lacking.[76] A multicenter placebo-controlled study of human chorionic gonadotropin (hCG) supplementation in early pregnancy showed no benefit in pregnancy outcome.[196] Subsequently, a small placebo-controlled study suggested that the benefit of hCG is confined to a small subgroup of patients with RM and oligomenorrhea.[197] One meta-analysis based on three small studies reported that progesterone support for pregnancy in women with RM may have a beneficial effect.[80] This could be explained by the immunomodulatory action of progesterone in shifting the proinflammatory Th-1 cytokine response to a more favorable Th-2 response. Prepregnancy suppression of high LH levels with an LH-releasing hormone analogue followed by low-dose ovulation induction in ovulatory women with RM does not improve pregnancy outcome.[86] Further, the live birth rate without pituitary suppression is excellent. The role of insulin resistance and the safety and effectiveness of metformin treatment in women with RM and polycystic ovaries require further study. Metformin should be used only in the context of prospective controlled trials.

Infections

All women with RM should be screened routinely to establish their rubella antibody status and be offered immunization if not immune before the next pregnancy. The empirical use of antimicrobial drugs in the treatment of women with recurrent pregnancy loss cannot be justified and might increase the risk of neonatal neurologic problems, according to the results of a recently published long-term follow-up study.[101]

Antiphospholipid Antibodies

aPLs are associated with a wide spectrum of pregnancy complications, including RM, late fetal loss, fetal growth restriction, preeclampsia, placental abruption, preterm birth, and maternal thromboembolic disease.[107,198,199] Several treatment modalities including aspirin, steroids, IVIG, and heparin have been used in an attempt to improve the pregnancy outcome of these women. However, a meta-analysis shows that only a combination of low-dose aspirin and low-dose (i.e., prophylactic rather than therapeutic) heparin significantly improves the live birth rate in women with RM and APS (Fig. 6–3).[200] This treatment enhances pregnancy outcome by 54%, to achieve a live birth rate of 70% or more in women with the syndrome.[108,201] Since this meta-analysis was published, two small trials have suggested that aspirin alone is sufficient to improve pregnancy outcome in women with APS.[194,202] In one study, 25% of the participants switched treatment group.[194] The use of steroids during pregnancy leads to significant rates of maternal and fetal morbidity and does not improve pregnancy outcome compared with other treatment modalities.[203,204] Further, a randomized trial found that aspirin plus heparin is superior to IVIG,[205] and a recent systematic review of IVIG[140] concluded that this treatment has no place in the management of women with aPL-related pregnancy loss. Because heparin does not cross the placental barrier, it is not teratogenic and does not cause fetal hemorrhage. Unfortunately, heparin is associated with significant maternal complications, including bleeding, hypersensitivity reactions, heparin-induced thrombocytopenia, and when used long term, osteopenia and vertebral bone fractures. However, two prospective studies showed that the loss in
FIGURE 6–3

Meta-analysis of treatments for antiphospholipid antibody (aPL)–associated pregnancy loss.
(Modified from Empson M, Lassere M, Craig JC, Scott JR: Recurrent pregnancy loss with antiphospholipid antibody: A systematic review of therapeutic trials. Obstet Gynecol 2002;99:135–144.)

bone mineral density at the lumbar spine associated with long-term, low-dose heparin therapy is similar to the loss that occurs physiologically during normal pregnancy,[206,207] although whether it is equally reversible has not been established. A combination of these two effects might be more serious than either alone, and it is probably wise to warn women of the possible sequelae of osteopenia. Nonetheless, risk-benefit assessment of aspirin plus heparin treatment supports its use in women with APS. After the diagnosis of APS is made, women should be advised to start aspirin and heparin treatment after confirmation of their next pregnancy (at 4–5 wk). No evidence suggests that preconceptual treatment of APS improves pregnancy outcome.

Hereditary Thrombophilia

The pregnancy outcome for women with a history of RM associated with FVL mutation is poor if no pharmacologic treatment is offered during pregnancy.[127] The efficacy of thromboprophylaxis during pregnancy in women with RM and inherited thrombophilic defects, who are otherwise asymptomatic, has not been assessed in prospective, randomized controlled trials, but uncontrolled studies suggest that heparin therapy may improve the live birth rate in these women.[208,209] Until further evidence becomes available, the poor pregnancy outcome associated with FVL mutation, coupled with the maternal risks during pregnancy, probably justifies routine screening for FVL and antenatal thromboprophylaxis for those with the FVL mutation or evidence of placental thrombosis. Full anticoagulation may be required throughout pregnancy and puerperium in some patients with a personal or family history of thromboembolism (see Chapter 42).

Maternofetal Alloimmune Disorders

None of the proposed alloimmune theories have been substantiated, and no immunologic tests have been identified to predict pregnancy outcome. It is of concern that some women with RM are being treated with a variety of agents—IVIG, anti-TNF-α drugs, and/or glucocorticoids—in order to dampen an "excessive immune response." Not only is there no evidence base for these interventions, they are also potentially associated with significant morbidity.

IVIG is a pooled blood product and is associated with anaphylactic reactions, fever, flushing, muscle pains, nausea, and headache.[210] Anti-TNF-α agents have been reported to be associated with the development of lymphoma, granulomatous diseases such as tuberculosis, systemic lupus erythematosus–like syndromes, demyelinating disease, and congestive cardiac failure.[211] Of equal concern is that whereas TNF-α has traditionally been viewed as a cytokine involved in triggering immunologically mediated pregnancy loss, it is also involved in antiapoptotic signaling pathways and has a regulatory role in cell proliferation. Indeed, studies in TNF-α knock-out mice suggest that this cytokine may play an important role in embryo development and the prevention of structural abnormalities.[212] These abnormalities might not, of course, be unmasked until later in life. Glucocorticoids during pregnancy are associated with an increased risk of preterm delivery secondary to rupture of membranes and the development of preeclampsia and gestational diabetes.[156] Immunotherapy should be offered to women with RM only in the context of prospective controlled trials.

Unexplained Recurrent Miscarriage

Despite extensive testing, in approximately 50% of couples with RM no cause is identified.[20] Although the mechanism is unclear, several nonrandomized studies suggest the benefit of supportive care and attendance at a dedicated early pregnancy clinic. The prognosis for a successful future pregnancy in women with unexplained RM who receive supportive care alone is in the region of 60% to 70%; this figure is lower with increasing maternal age and number of previous miscarriages. Two studies have reported that aspirin does not improve the live birth rate in women with unexplained RM.[213,214] The use of aspirin and other nonsteroidal anti-inflammatory agents has been associated with an increased rate of miscarriage[215,216] and both a case-controlled study[217] and a meta-analysis[218] have reported a two- to threefold increased risk of gastroschisis in mothers taking aspirin during the first trimester of pregnancy. These data suggest that empirical treatment in women with unexplained RM is unnecessary and should be avoided. A prospective placebo-controlled trial would be needed to establish the efficacy of heparin in the treatment of women with unexplained RM.[219] General advice about stopping smoking, avoiding excessive alcohol and caffeine intake, dietary balance, and weight loss for obese women is important. Taking folic acid (400 µg/day) for at least 2 months before attempting conception should be advised to prevent neural tube defects.

Management during Subsequent Pregnancy, Delivery, and Puerperium

Strategies for management during a pregnancy following a miscarriage differ according to the underlying cause of miscarriage. The risk of repeated miscarriage increases with each successive pregnancy loss and with advancing maternal age. Even when the pregnancy progresses beyond 24 weeks' gestation, evidence suggests that women with RM are at risk for late pregnancy complications such as preeclampsia, intrauterine fetal growth restriction, preterm delivery, perinatal loss, and operative delivery.[19,198,201] Close antenatal surveillance and delivery in a unit with specialized obstetric and neonatal intensive care facilities are indicated.

First Trimester

Couples with RM are understandably anxious and need support and reassurance throughout the first trimester. Ultrasound is valuable in the management of early pregnancy to confirm viability and, after fetal heart activity has been detected, to provide ongoing maternal reassurance. Using transvaginal ultrasound, an intrauterine gestation sac will be visible at 5 weeks, a yolk sac at approximately 5.5 weeks, and fetal heart activity at 6 weeks. Thereafter, a scan to check fetal heart activity may be obtained every week or every 2 weeks until the end of the first trimester. The demonstration of normal sequential fetal growth and activity is very reassuring for many couples.

Women with APS should be offered aspirin and heparin treatment. Low-dose aspirin (75 mg/day) should be commenced as soon as the patient has a positive urinary pregnancy test result. Subcutaneous low-dose heparin therapy in the form of LMWH (enoxaparin [Clexane] [Lovenox]

20 mg/day or dalteparin [Fragmin] 2500 units/day) or unfractionated heparin ([Calciparine] 5000 IU twice daily) should be started as soon as an intrauterine pregnancy is confirmed by ultrasound scan (gestational sac and a yolk sac within the uterine cavity). Some clinicians prefer to commence the heparin therapy as soon as the pregnancy test is positive. Although unfractionated heparin is equally beneficial, LMWH offers the advantage of once-daily injection owing to its longer half-life and increased bioavailability. A platelet count should be done at the start of treatment and repeated 2 weeks later to exclude the rare complication of heparin-induced thrombocytopenia. Despite significant improvement in live birth rates, pregnant women who have APS and are treated with aspirin plus heparin until 34 completed weeks of gestation remain at risk for later pregnancy complications, including preeclampsia, intrauterine growth restriction, placental abruption, and preterm delivery.[199] Some clinicians prefer to continue treatment until the time of delivery in the belief that this reduces the risk of these late pregnancy complications, but there is no hard evidence to support this view. Indeed, the randomized controlled trial by Rai and associates[108] emphasized that the main benefit of combination therapy with aspirin and heparin is to improve the quality and depth of embryonic implantation during the first trimester of pregnancy. After 13 weeks' gestation, the number of pregnancies ending in live births did not differ significantly by treatment group.

Second Trimester

When cervical incompetence is suspected in pregnancy, transvaginal ultrasonic assessment of the cervix is a noninvasive and objective means of assessing cervical length and shape and predicting preterm birth in high-risk populations.[220–222] The three ultrasound signs that suggest cervical incompetence are shortening of the endocervical canal, funneling of the internal os, and sacculation or prolapse of the membranes into the cervix, either spontaneously or as a result of fundal pressure (Fig. 6–4). A short cervix (<25 mm)
FIGURE 6–4
Transvaginal ultrasound scan of the cervix shows cervical shortening and funnelling. *A*, Total cervical length. *B*, Length of distal cervical segment. *C*, Depth of cervical funnel.

is the best independent predictor of spontaneous preterm birth before 34 weeks' gestation. Cervical cerclage is a recognized treatment for cervical incompetence. However, a meta-analysis of four randomized controlled trials found no conclusive evidence that prophylactic cervical cerclage reduces the risk of pregnancy loss and preterm delivery in women at risk for preterm birth or mid-trimester loss because of cervical factors.[223] Further, the procedure was associated with an increased risk of minor morbidity, but no serious morbidity. A small decrease in the number of deliveries before 33 weeks' gestation was noted in the largest trial.[224] The benefit was greatest in women with three or more second-trimester miscarriages or preterm births. There was no significant improvement in neonatal survival. The same meta-analysis assessed the role of therapeutic cerclage in women with a short cervix seen on ultrasound.[223] The pooled results from two small randomized controlled trials showed no reduction in mid-trimester pregnancy loss and preterm delivery before 28 and 34 weeks in women assigned to undergo ultrasound-indicated cerclage.[57,225] However, the numbers of women randomized were too small to allow firm conclusions to be drawn. A recent trial of elective cerclage inserted on the basis of historical risk factors versus cerclage inserted after detection of cervical length shortening using ultrasound showed no difference in pregnancy outcome, but a higher rate of cerclage (32% vs. 19%, relative risk 1.66; 95% CI 1.07–2.47) and its associated morbidity in the ultrasound-monitored group.[226] This suggests either that cerclage made no difference in either group or that ultrasound monitoring overdiagnoses women at risk of preterm labor. Based on this evidence, it would seem reasonable to divide women with a history of mid-trimester miscarriage that suggests cervical incompetence into two groups, with the therapeutic approach tailored accordingly.

The first group includes women at high risk for second-trimester miscarriage, including those with two or more second-trimester miscarriages without bleeding or clear signs of labor preceding the miscarriage. These women may benefit from prophylactic cervical cerclage at 13 to 16 weeks, with removal at 37 to 38 weeks. Several adjuvant measures may be considered to minimize the risk of infection or other complications at the time of suture insertion including a short course of antibiotics and bed rest for 24 hours (although there is no randomized controlled trial evidence to suggest that either of these precautions is necessary). Before prophylactic cerclage, women should be offered ultrasound examination to assess fetal viability and exclude apparent fetal anomalies. This will avoid inserting a suture in a pregnancy in which there is no possibility of improving the outcome.

The second group, considered at medium risk, includes women with a history of one second-trimester miscarriage and those with evidence of other factors predisposing to preterm delivery such as infection and thrombophilic disorders, both of which should be treated aggressively. These women can be offered serial transvaginal cervical ultrasound scanning beginning at 12 weeks and performed every 2 weeks until 23 weeks to measure cervical length and exclude funneling of the upper cervical canal. Therapeutic cervical cerclage may be offered to women with ultrasound signs of cervical shortening (<25 mm) or with progressive

funneling in the absence of uterine activity or signs of chorioamnionitis, although it must be emphasized that currently there is no randomized controlled trial evidence that such "rescue cerclage" is beneficial.[227]

CERVICAL CERCLAGE FOR RECURRENT MID-TRIMESTER PREGNANCY LOSS

There is a lack of good epidemiologic data on the incidence of mid-trimester loss; however, a commonly quoted figure is 2%. It is important to remember that many cases are multifactorial, and demonstration of cervical weakness does not exclude the coexistence of other causes. Thus, screening for causes such as APS or thrombophilia should also be carried out, in addition to planned cerclage.

Factors in the history suggestive of cervical incompetence include a painless mid-trimester delivery (characteristically the mother presents fully dilated, not having realized she was in labor), previous major cervical surgery (e.g., conization, including large loop excision), documented trauma to the cervix in a previous birth, in utero exposure to diethylstilbestrol (taken by the woman's mother to try to prevent miscarriage—this was still in clinical use as recently as the mid-1970s), or prelabor preterm rupture of the membranes.

As stated by the Euro-Team Early Pregnancy Protocol,[228] there is no agreed definition of cervical weakness by absolute measurable and reproducible criteria. It is important that before cervical weakness is diagnosed, appropriate diagnostic criteria are applied and other causes excluded, because management is invasive and carries a significant risk of an adverse outcome. The diagnosis is made in the absence of other causes of preterm delivery such as uterine anomaly, fibroids, or infection, and in which only singleton pregnancies are included.[229] As has been written as the premise for a randomized controlled trial, "the overuse of prophylactic cerclage is a manifestation of our inability to diagnose cervical incompetence with any degree of reliability on the basis of historical criteria alone."[230] More recently, this message has been underlined and it has been emphasized that "prophylactic and reactive interventions remain largely unevaluated or ineffective."[231]

McDonald Suture

As explained previously, there is currently no good evidence for the effectiveness of rescue cerclage, and thus whenever possible, if cerclage is indicated by the history, it should be planned at the end of the first trimester, following a reassuring scan. The most common suture employed is that first described by McDonald.[232] This is a simple purse-string suture placed around the cervix at the vault of the vagina, just below the reflection of the vaginal skin onto the cervix. Mersilene tape or nylon can be used. Knots are usually tied anteriorly to make removal easier at about 37 weeks' gestation (the uterus anteverts as pregnancy progresses, making access to the posterior aspect of the cervix difficult). The anterior knot is easily visualized with a speculum, grasped with a tenaculum, and the suture cut at the side of the knot, allowing it to slide out. With a good light and the correct instruments (e.g., long-handled scissors), this can be done in the clinic or office, with the woman lying in the left lateral position. There is no need to leave large loops of suture material in the vagina; indeed, these can cause maternal discomfort and excessive discharge. There is no evidence that tocolysis or an overnight stay is necessary, provided the insertion is straightforward. Some advocate use of a sharp needle, taking multiple small bites to encircle the cervix, whereas others use a large-diameter curved needle passed in the subcutaneous tissues, a plane that can be found by its relative lack of resistance.

Despite the attraction of the McDonald suture as a simple procedure, initial, prospective, randomized controlled trials failed to demonstrate benefit.[233,234] However, a much larger trial (including > 1200 subjects), carried out under the auspices of the Medical Research Council (United Kingdom) and the Royal College of Obstetricians and Gynaecologists and reported in 1993, recruited women with borderline indications for cerclage. Results showed that after cerclage, delivery prior to 32 weeks' gestation occurred in 13% of women as opposed to 17% in the control group ($P < .03$). This can either be taken to mean that the procedure needs to be performed 25 times to prevent one case of very preterm birth or that it reduces preterm labor by 25%, depending on whether one is an enthusiast or a skeptic.[224]

Shirodkar Suture

Often, the cervix is short, making it difficult to insert a McDonald suture containing a significant amount of cervix. In such cases, it is necessary to incise the skin over the anterior cervix and dissect under the skin in order to push the bladder up and allow access to the upper part of the cervix. The bladder is most easily pushed up using a gauze swab over a gloved finger. Defining the position of the bladder and the internal os is made much easier by the use of simultaneous ultrasound visualization. This is most conveniently done via a suprapubic transducer because a vaginal probe makes it difficult to insert the suture. The basics of the technique were first described by Shirodkar in 1955[235] and so the procedure is usually called a "Shirodkar suture." There have been no randomized controlled trials of this technique, but if it is thought that a suture is justified, then it is necessary to use this approach if the cervix is too short for a McDonald suture. Some authorities recommend opening the posterior fornix, but if a large-diameter blunt needle is used, it can often be passed high behind the cervix without colpotomy, provided care is taken to ensure the needle stays in contact with the cervix and does not enter the peritoneal cavity. One important attribute of the Shirodkar suture is that the knot is buried, which means much less vaginal discharge than with the McDonald. However, this also means it needs to be removed using an anesthetic.

Transabdominal Cervicoisthmic Cerclage (Fig. 6–5)

The concept of placing a suture at the internal os via an abdominal approach was introduced by Benson and Durfee in 1965.[236]

Transabdominal cervicoisthmic cerclage. A, Lateral view. B, Anterior view.

A

Uterine
artery

B
The indications for a transabdominal suture are[237]
- Previous failed vaginal suture.
- Traumatic or surgical damage making a vaginal approach difficult.
- Severe scarring or chronic cervicitis.
- Cervicovaginal fistula.

A preconceptual interview is ideal, allowing full disclosure and explanation regarding risks of failure and complications of insertion following previous surgery (e.g., classic cesarean delivery); damage to the cervix and adjacent major vessels, bowel, or bladder; and the need for two major operations (insertion of the suture and subsequently delivery by cesarean section). All these factors need to be addressed, ideally by a second counseling interview when consent can be obtained. The patient has by then received all the relevant information before conception and understands that abdominal cerclage should be seen as a last resort.

The technique is ideally carried out at 12 weeks' gestation, with prior ultrasound screening for fetal anomaly as previously described. It can be carried out earlier, but this increases the risk that there will be fetal demise or abnormality diagnosed subsequently. It can also be carried out later, up to 24 weeks, but the increasing size of the uterus makes it technically more difficult and there is a requirement for a larger abdominal incision. At 12 weeks, a Pfannenstiel incision is usually appropriate. Placement of abdominal sutures using minimal access techniques (laparoscopic transabdominal cervicoisthmic cerclage) has been described, but the series are small and it is not yet a generally used technique.[238,239] The use of the technique may be accelerated by the use of robotic surgery.[240]

The procedure is performed under general anesthesia. The bladder should be emptied and the catheter left in situ during the operation. Packing the vagina before laparotomy can elevate the uterus with improved access to the cervicoisthmic region. The patient is placed in the Trendelenburg position. A low transverse abdominal incision is made and packs used to keep bowel away from the operative field.

Scanning directly onto the uterus using an ultrasound probe covered in a sterile sleeve enables precise visualization of the internal os, which can then be identified externally using an opposed finger and thumb on either side (fore and aft) of the broad ligament. The finger and thumb can also be used to identify the ascending branch of the uterine artery by feeling it pulsate and drawing it laterally, forming an avascular space of about 2 mm^2 in the broad ligament just lateral to the cervix and about 2 mm below the internal os through which to pass the needle mounted with the encircling tape. The suture is traditionally passed from anterior to posterior using a blunt needle. Mersilene tape and double-stranded nylon are both commonly used. It is traditional to tie the knot posteriorly to avoid the knot irritating the bladder (which may need to be dissected clear of the lower segment and pushed down before the suture is inserted; again, its location can be determined using ultrasound). A posterior knot allows removal of the suture via a posterior colpotomy in the event of fetal demise, so that vaginal birth can be achieved. However, it is easier to tie the knot anteriorly, and some recommend this as routine as it avoids intraperitoneal exposure of the surgical knot and prevents adhesion formation to bowel and its attendant complications.[241]

Scanning also allows the confirmation of fetal life, and intact membranes, before closure of the abdomen. A single dose of intraoperative antibiotics is commonly given. Nonsteroidal anti-inflammatory agents (diclofenac sodium suppositories 100 mg) may be prescribed for pain relief and uterine quiescence over the following 72 hours. Preoperative thromboprophylaxis is recommended, using LMWH.

Delivery by cesarean section is necessary, usually carried out at 38 weeks' gestation. The suture is commonly left in place in case of a further pregnancy. Whether it should eventually be removed once childbearing is complete is uncertain.

As explained previously, there are no randomized trials of transabdominal cerclage. However, 13 individual series have been published, reporting the results of 332 pregnancies, with 279 resulting in a live birth (84%). These encouraging figures may result from a positive reporting bias (series with lower success rates are less likely to be submitted for publication). However, the personal series of the authors and the editor are consistent with a favorable outcome in 85% of pregnancies (Table 6–4).

TABLE 6–4

Results of Published Series of Transabdominal Cervicoisthmic Cerclage

FIRST AUTHOR	YEAR OF PUBLICATION	NUMBER OF PATIENTS	NUMBER OF PREGNANCIES	LIVE BABIES	SUCCESS PER PREGNANCY (%)

Insertion of Transabdominal Cerclage prior to Pregnancy

Insertion of a transabdominal cervicoisthmis cerclage is technically much easier when it it done before the woman is pregnant, and it is therefore probably less dangerous, but difficulties with the technique include difficulty in the precise identification of the internal os and accidental inclusion of the uterine artery, which may restrict blood flow in a later pregnancy. In addition, it is an unnecessary procedure if the woman never subsequently conceives, and it can complicate evacuation of the uterus in the event of early pregnancy failure. The personal experience of the authors and editor is limited to a few cases in which prepregnancy laparotomy was indicated for other reasons. Published series are very small. Prepregnancy screening for thrombophilia and bacterial vaginosis is increasingly used as the presence of either may double the risk of preterm delivery before 34 weeks.[241]

Further Pregnancy Management

Uterine artery Doppler ultrasonography at 22 to 24 weeks may be useful in predicting preeclampsia and intrauterine growth restriction in APS pregnancies. Women with circulating LA or high titers of IgG anticardiolipin antibodies are at increased risk for these complications.[242] A glucose tolerance test at 28 weeks may be prudent for women with PCOS because of the increased risk of gestational diabetes. Although the 2008 National Institute for Clinical Excellence (NICE) guidelines[243] recommended that there was no evidence that management of gestational diabetes improved outcomes for the mother and fetus, this has been challenged because the Australian Carbohydrate Intolerance Study in Pregnant Women (ACHOIS) trial[244] reported that treatment of gestational diabetes mellitus reduces serious perinatal morbidity and may also improve the woman's health-related quality of life.

Third Trimester

During the third trimester, serial fetal growth scans and umbilical artery Doppler recordings are advisable. The risk of intrauterine growth restriction is increased in women with a history of RM, particularly those with APS or inherited thrombophilia (see Chapters 41–43). Those women with a cervical suture in situ will need to be admitted for removal of suture under regional anesthesia between 37 and 38 weeks' gestation.

Delivery and Puerperium

If the pregnancy is progressing well, a history of RM is not an indication for any specific interventions. However, many women with a history of RM will become anxious toward the end of the pregnancy and request early delivery, either by induction of labor or by elective cesarean section. The obstetrician will wish to consider this sympathetically, but needs to bear in mind the increase in iatrogenic morbidity for the child, ranging from an increased incidence of respiratory distress (especially at < 39 wk) to the long-term increases in the risk of asthma and diabetes (among other problems) associated with elective cesarean section. In women receiving heparin, it is important to plan regional anesthesia to minimize the risk of epidural hematoma, and coordination with the anesthetist is required. Current guidelines[245] recommend that regional techniques should not be used until at least 12 hours after the previous prophylactic dose of LMWH and 6 hours after a dose of unfractionated heparin. Heparin should not be given for at least 4 hours after the epidural catheter is removed. There are no prospective data on the risk of systemic thrombosis to determine the optimal management of asymptomatic women with inherited thrombophilia. Current Royal College of Obstetricians and Gynaecologists guidelines based on expert opinion recommend that postnatal thromboprophylaxis is indicated for women with known inherited thrombophilias (e.g., FVL and

prothrombin gene mutations), but individual assessment will be guided by the type of thrombophilia and the presence of other thrombotic risk factors. Similarly, in women with APS and no symptoms other than RM, there is no evidence to justify routine postnatal thromboprophylaxis. In women with APS without additional thrombotic risk factors, postnatal thromboprophylaxis is not recommended.

SUMMARY

The management of RM requires a combination of sensitivity and a systematic approach to care. The goal is to identify a cause and implement appropriate treatment whenever possible. Of the many risk factors, parental karyotype abnormalities, APS, activated protein C resistance, and cervical incompetence are the only established causes of RM. Of the many treatment options for couples with RM, only aspirin plus heparin treatment in women with APS has proven benefit. Despite detailed studies, in more than 50% of couples with RM, no cause is found. However, even without pharmacologic treatment, the prognosis is good and supportive care appears to play an important role. Empirical treatments for women with RM should be avoided, and new treatments should be introduced only after their benefit has been assured through properly designed prospective controlled trials.

SUMMARY OF MANAGEMENT OPTIONS — Recurrent Miscarriage		
Management Options	**Evidence Quality and Recommendation**	**References**
Prepregnancy Assessment Options		
At the Time of the Third Miscarriage		
Document pattern and trimester of the pregnancy loss and whether a live embryo or a fetus was present. Clinical and ultrasound features.	III/B	14
Carefully document any suspected uterine abnormality at surgical evacuation.	—/GPP	—
Send products of conception for histology or autopsy and karyotype with consent of patient as appropriate (see Table 6–2).	II/B	5
General approach is important (e.g., see couple together, sympathy, sensitivity).	II/B	5
Offer follow-up assessment and counseling.	IV/C	9,20
Prepregnancy Assessment and Counseling after the Third Miscarriage		
History and Examination for Causative and Associated Factors		
Obstetric history to confirm true diagnosis of "recurrent miscarriage" (pattern of losses, gestation of former losses, previous confirmation of pregnancy: biochemical, ultrasonographic and/or histologic).	III/B	14
General medical history: • Features associated with autoimmune disease (e.g., joint pains, skin rash, allergy). • Features related to APS (e.g., migraine, epilepsy, vascular thrombosis, joint pain, Raynaud's). • Features related to thrombophilic disorders (e.g., personal or family history of vascular thrombosis). • Exposure to environmental toxins or drugs. • Surgery to cervix, uterus, ovary.	—/GPP	—
Family history of recurrent miscarriage, PCOS, diabetes, genetic disorders, thrombophilia, early-onset cardiovascular disease or stroke (<50 yr).	—/GPP	—

Management Options	Evidence Quality and Recommendation	References
Physical examination: identify signs of endocrine or gynecologic disease, opportunistic screening (BP, cervical cytology, breast palpation), assess any specific risk factors raised by history.	—/GPP	—
Routine Investigations on All Cases (see Table 6–3)		
Karyotype		
• Both partners.	III/B	5,7,20,27,29,31,32
• Miscarried tissue (with consent as appropriate).	III/B	
Pelvic ultrasound.	III/B	20,48,49,50,184–186
Anticardiolipin antibodies (IgG and IgM).	III/B	106,107
Lupus anticoagulant	III/B	106,107
Early-follicular phase LH, FSH, testosterone	III/B	20,84
Thrombophilia screening:	IIa/B	126,127
• Activated protein C resistance/factor V Leiden and factor II (prothrombin) gene mutation only indicated in all cases.	III/B	126
• Antithrombin III, factor XII, factor VIII, protein C, protein S, MTHFR reserved for cases with high personal or family history of thrombophilia.		
• Thromboelastography—if available.	III/B	129
Prepregnancy opportunistic screening:	—/GPP	—
• Serology for rubella status.		
• Blood group and rhesus type.		
Others determined by positive features in history or examination (see Table 6–3).	—/GPP	
Counseling with the Following Key Principles/Guidelines		
See couple together, dedicated miscarriage clinic, sympathetic approach.	—/GPP	—
The true rate of recurrent miscarriage is affected by a reproductive compensation effect.	IV/C	14–16
After three consecutive losses, intensive investigation will identify a probable cause in less than 50% of couples.	III/B	9,20
The majority of cases are due to repeated fetal chromosome abnormalities occurring consecutively by chance.	III/B	5,21,27
Advanced maternal and paternal age and previous reproductive history are important risk factors for a further miscarriage.	III/B	9,14–16,23
Parental chromosomal rearrangements, anatomic defects of the uterine fundus and cervix, phospholipid antibodies, activated protein C resistance, factors V and II gene mutations also play a role.	III/B	20,37,41,51,67,103, 107,126,127,131
Progesterone deficiency, hypersecretion of LH, infective agents, and immune rejection are not currently considered causes of recurrent miscarriage. Empirical treatment with progesterone, high LH suppression, or immunotherapies are of no proven benefit.	Ia/A	80,81,84–86, 137–141
Subclinical thyroid disorders or diabetes mellitus are rare.	III/B	20,73

SUMMARY OF MANAGEMENT OPTIONS
Recurrent Miscarriage—cont'd

Management Options	Evidence Quality and Recommendation	References
Recurrent miscarriage is associated with significant psychological morbidity.	III/B	9,169–172
Role of psychological stress is unclear.	IV/C	9,171
Even after three miscarriages, the chance of success without treatment is approximately 60%, except for women with antiphospholipid syndrome and those with activated protein C resistance in which success rates are lower.	III/B IIa/B	9,14,15,24 109,127
Prepregnancy Treatment Options		
Do not advocate "unproven" treatments.	—/GPP	—
Parental translocations:		
• Genetic counseling couple and relatives.	IV/C	20,37
• Proceed to a further pregnancy with or without prenatal diagnosis (amniocentesis or chorionic villous biopsy).	III/B	38,177–181,183,184
• Gamete donation.		
• Artificial insemination by donor sperm.		
• In vitro fertilization by donor egg.		
• Preimplantation genetic diagnosis with in vitro fertilization.		
• Adoption.		
Uterine abnormalities:		
• Uterine septum: GnRH analogue and hysteroscopic septal resection and temporary intrauterine device.	III/B	47,52,53
• Intrauterine adhesions: hysteroscopic division and temporary intrauterine device; postoperative course of cyclic estrogen and progesterone therapy.	III/B	66
• Fibroids: GnRH analogue and myomectomy.	III/B	63,191
Management during Subsequent Pregnancy, Delivery and Puerperium		
Psychological support, reassurance, and the like.	III/B	18,24
Do not advocate "unproven" treatments.	—/GPP	—
There is no evidence that any immunologic therapy is of benefit.	Ia/A	138
Offer low-dose aspirin and heparin to women with APS.	Ib/A	108,200,205
Offer low-dose heparin to women with activated protein C resistance (or other thrombophilia).	IIb/B	127,208,209
Patients with diabetes mellitus: good metabolic control.	IIb/B	61,195
First trimester:		
• Transvaginal USS to confirm fetal viability.	—/GPP	—
• Serial scans for reassurance.	—/GPP	—

Management Options	Evidence Quality and Recommendation	References
Second trimester:		
• Options with suspected cervical incompetence:		
• Serial cervical ultrasonography with insertion of cervical suture with evidence of shortening/funneling.	Ib/A	225,226
• Primary cervical cerclage.	Ib/A	224
• Serial vaginal swabs for pathogens.	—/GPP	—
• Uterine artery Doppler studies in selected cases.	III/B	241
• Consider prophylactic maternal steroids at 28 wk in selected cases.	—/GPP	—
• Consider formal GTT at 28 wk in selected cases	—/GPP	—
Third trimester:		
• Vigilance for fetal growth restriction, preeclampsia and preterm labor in selected cases.	III/B	198,199
Labor/delivery:		
• Consider elective LSCS/IOL at term in some cases.	III/B	199

First-Trimester Screening for Fetal Abnormalities

KIMTA NANHORNGUÈ and YVES VILLE

Videos corresponding to this chapter are available online at www.expertconsult.com.

INTRODUCTION

The screening for and diagnosis of fetal abnormalities in the first trimester are characterized by the confidentiality surrounding parental decisions. Early termination of pregnancy has proven medical and psychological benefits for women compared with late termination. The early first-trimester ultrasound examination is also an opportunity to identify a family history of genetic syndromes or anomalies that warrant more frequent or detailed ultrasound assessments (see Chapter 4).

The goals of first-trimester screening were until the mid-1980s limited to localization of the pregnancy, assessment of viability and diagnosis of miscarriage, determination of gestational age (GA), and identification and typing of multiple pregnancies. However, prenatal diagnosis has rapidly shifted over the last two decades from the second to the first trimester owing to the development of high-resolution abdominal and transvaginal ultrasound. As a result, a significant amount of information can be garnered about the fetus as well as the obstetric management.[1] The 11- to 14-week window of GA is the best compromise to assess GA, to screen for fetal aneuploidy based on the measurement of nuchal translucency (NT), and to obtain a potentially detailed anatomic survey.

ULTRASOUND EXAMINATION AT 11 + 0 TO 13 + 6 WEEKS

Localization of the Pregnancy

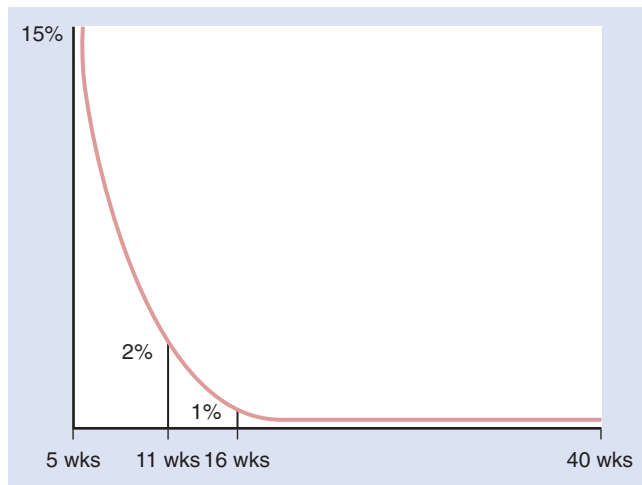
The evaluation of an intrauterine pregnancy requires the exclusion of ectopic pregnancy, bearing in mind the incidence of heterotopic pregnancy is about 1 in 4000 spontaneously and as high as 1 in 100 after assisted conception. For gestations greater than $5\frac{1}{2}$ weeks, a transvaginal ultrasound examination should identify an intrauterine pregnancy with a close to 100% accuracy.[2] Because of the inaccuracies of pregnancy dating, β-human chorionic gonadotropin (β-hCG) is often used as a surrogate for GA. Sequentially, structures become visible by transvaginal ultrasonography, including a gestational sac ("double decidual sign" at $4\frac{1}{2}$–5 wk after the last menstrual period [LMP]), yolk sac (at 5 wk), and fetal pole with later cardiac motion (at

$5\frac{1}{2}$–6 wk). A pseudosac is a collection of fluid within the endometrial cavity that results from bleeding of the decidualized endometrium when an extrauterine gestation is present. Although it may sometimes be mistaken for a gestational sac, it can be distinguished by its central location, filling the endometrial cavity itself.[3] However, the identification of a presumed pseudosac on ultrasonography is not diagnostic of ectopic pregnancy because it has a high false-positive rate.[4]

Critical to the diagnosis and management of suspected ectopic pregnancy is the concept of the *discriminatory cutoff* of β-hCG, defined as that level of β-hCG at which a normal intrauterine pregnancy can be reliably visualized by ultrasonography.[5] It is now accepted that a normal intrauterine pregnancy should always be visualized above the discriminatory cutoff of 1500 to 2500 IU/L using transvaginal ultrasonography, and its absence implies an abnormal gestation.[6] The discriminatory cutoff should be set by each institution based on that hospital's success in identifying ectopic pregnancies, based mostly on the equipment used and the expertise of the sonographers. Varying the discriminatory cutoff will affect the sensitivity (positively identifying an ectopic gestation) and specificity (correctly excluding an ectopic when none exists). A decrease in the cutoff will increase the risk of misclassifying a developing intrauterine pregnancy as an abnormal gestation, and increasing the value provides "extra" reassurance that lack of visualization of an intrauterine pregnancy did not miss an early viable gestation, but may delay the diagnosis of an ectopic pregnancy leading to tubal rupture.[3]

Identifying a Viable Pregnancy, Predictors of Adverse Outcome, and the Diagnosis of Miscarriage

An ultrasound examination between 11 to 13 + 6 weeks is often the first opportunity to diagnose early pregnancy failure (Fig. 7–1). The prevalence of early pregnancy failure (EPF) in one screening study of 17,870 women 10 to 13 weeks was 2.8% (501 cases), including 313 (62.5%) embryonic deaths and 188 (37.5%) anembryonic pregnancies.[7] The accurate diagnosis of EPF is paramount in being able to counsel patients appropriately about their pregnancy management options.[8] There are key chronologic landmarks in

Risk of spontaneous miscarriage.


the normal development of an embryo that can be identified by transvaginal ultrasound scan, facilitating the distinction between normal and abnormal pregnancy. Stringent diagnostic criteria are required to avoid an incorrect diagnosis in those women who have irregular cycles, who are unsure of their dates, or whose initial ultrasound findings do not correspond with the expected gestation.[9] An intrauterine pregnancy can first be diagnosed sonographically by visualization of a gestational sac. GA can be estimated either by measurement of the mean sac diameter (MSD) or the embryonic pole/crown-rump length (CRL). A true "crown" and "rump" should be visible with a MSD greater than 18 mm; before then, only an embryonic pole (the long axis of the embryo) can be seen.[10] A yolk sac should be visible transvaginally when the MSD is greater than 8 mm and an embryonic pole should be visualized with a MSD greater than 16 mm.[11] A gestation sac with a MSD of 20 mm and no evidence of a yolk sac is highly suggestive of early embryonic demise.[12,13] If the gestation sac is greater than 15 mm, a second scan should be performed at least 7 days later. If an embryo of more than 6 mm is present and heart activity is not observed, the scan should be repeated again in another 7 days.[13] The diagnosis of early fetal demise can be made with certainty if cardiac activity is still not seen. Some authors advocate the use of a 10-mm cutoff [12] when looking for cardiac activity in the embryo, because approximately one third of embryos with a CRL of less than 5 mm have no demonstrable cardiac activity at the time of initial scan.[13] A recent study suggests that the improved sonographic technology allows for the detection of embryonic demise with a CRL less than 5 mm. In particular, the absence of cardiac activity with a CRL of 3.5 mm or greater had, under ideal conditions, 100% positive predictive value and specificity.[14] If the gestational sac is smaller than expected, the possibility of incorrect dates should be considered and caution exercised, especially if there has been no pain or bleeding. However, in cases of a normal CRL, if the gestational sac volume is 2 or more standard deviations (SDs) below normal, the

prediction of subsequent miscarriage can be made with a high sensitivity.[15] Likewise, early embryonic demise may be signified by absent cardiac activity, a CRL greater than 6 mm, and an excessively large gestation sac compared with the CRL.[15,16]

A fetal heart rate less than 120 beats/min in the first trimester is associated with pregnancy loss (sensitivity 54%, specificity 95%). The specificity rises to 100% when the fetal heart rate is greater than 85 beats/min.[17] However, caution is recommended before diagnosing impending early embryonic demise based on a bradycardia, especially a single recording. A continued reduction in heart rate over a few days is more likely to be associated with miscarriage.[18]

Dating the Pregnancy

First-trimester aneuploidy screening using NT and maternal biochemistry depends upon the reliable pregnancy dating. As consequence, ultrasound dating in the first trimester is now recommended for all women with spontaneous pregnancies, even those with certain menstrual dates owing to misclassification bias that occurs because of both incorrect memory of the LMP and oligo- and polyovulation. An increasing number of pregnancies are now dated in the late first trimester during aneuploidy risk assessment, which is typically performed at 11 to 13 + 6 weeks' gestation.[19] Dating a pregnancy by menstrual history can be unreliable. Up to 40% of women are uncertain of their menstrual dates, and even when they are certain, GA is often overestimated compared with ultrasound findings.[20] Although early ultrasound systematically underestimates the GA of smaller fetuses by approximately 1 to 2 days, this bias is relatively small compared with the large error introduced by LMP estimates of gestation, as evidenced by the number of implausible birth weight-for-gestation.[21] In one study of 165,908 women comparing LMP with ultrasound estimates, the prevalences of preterm birth were 8.7% versus 7.9% (<37 wk), 81.2% versus 91.0% for term (37–41 wk) birth, and 10.1% versus 1.1% for post-term (≥42 wk birth). The sensitivity of the LMP-based preterm birth estimate was 64.3%, and the positive predictive value was 58.7%. Overall, 17.2% of the records had estimates with an absolute difference of greater than 14 days.[21] Early GA dating is more accurate and affects pregnancy management. There seems little logic to support routine dating in the mid to late second trimester.

The maximum embryonic length and the fetal CRL can be used to accurately determine GA in a normal first-trimester pregnancy to within 3 to 5 days. The CRL is measured excluding the inferior limbs and without correction for body flexion. Transvaginal ultrasound can be used for measurements earlier than transabdominal ultrasound. The original Robinson[22] curve used for dating pregnancies is still valid in most cases.[23]

The gestation sac is always visible by 4 weeks. The yolk sac is the first sonographically evident embryonic structure within the gestational sac. Its size correlates to GA and is usually visible between the 5th and the 12th weeks as a round anechoic area. Rarely, it can be seen until the end of pregnancy. Before 6 weeks, dating is done by description and measurement of the gestation sac.[24,25] In 95% of cases, the yolk sac is present by 5 weeks, and in all cases, it is present

by 6 weeks. The fetal heart is seen beating in 86% of cases by 6 weeks, and always by 7 weeks.

Of all of the available measurements, the maximum embryo length between 6 and 10 weeks and the CRL up to 14 weeks are the most accurate for determining GA. The random error is 4 to 8 days at the 95th percentile.[22,26–28] The largest study using a strict dating method is that of Wisser and Dirscheld,[28] who highlighted potential pitfalls of earlier studies and reported a predictive interval of 4.7 days (SD) in 160 patients who underwent in vitro fertilization, including 21 with multiple pregnancies.[28] All charts are concordant before 60 mm (predictive interval 3 days [SD]), but differ significantly thereafter.

Another recent study suggests that gestational sac and amniotic sac volumes assessed during the first trimester by transvaginal three-dimensional ultrasonography (3DUS) also have excellent correlation with the GA and CRL and hence may be used for determining GA.[29] Though this result was not confirmed,[30] larger studies are needed to determine the importance of these volumes in predicting normal pregnancy outcomes and whether these volumes can be used in the management of pregnancies at risk for spontaneous abortion.

When the CRL is greater than 60 mm, other biometric parameters are more useful for dating the pregnancy up to 20 weeks.[31] These parameters include the biparietal diameter, head circumference, femur length, and abdominal circumference. First-trimester fetal biometry is underused to diagnose or characterize abnormal fetal development. Fetal growth during the first trimester was previously considered relatively uniform, but increasing evidence shows that anthropometric differences and other growth abnormalities are expressed in the first trimester. Maternal factors (multiparity, diabetes, small stature, and high prepregnancy body mass index [BMI]) and fetal factors (chromosomal abnormality and female fetus) have been reported to be associated with a greater difference between expected and observed fetal size in 46,514 women with both early ultrasound and menstrual estimations of GA.[32] One study of 464 women undergoing 1063 ultrasound assessments between 5 and 14 weeks' gestation observed that embryonic and fetal growth rates increased with maternal age and was higher in fetuses of black than of white or Asian women.[33] Fetal gender has also been suggested to influence fetal growth, with male fetuses being larger than female in two series at 7 weeks.[34]

Detecting Multiple Pregnancies and Determining Chorionicity (See also Chapters 23 and 59)

Twin pregnancies constitute 2% of all pregnancies (Table 7–1).[35] Two thirds of these are dizygotic, and one third are monozygotic. An important task of the first-trimester scan is to diagnose twin pregnancy and determine chorionicity. For obstetricians, the management of multiple pregnancies relies mainly on chorionicity owing to the fact that the prevalence of prenatal and perinatal complications differs by chorionicity. It is estimated that monochorionic twins have a three- to sixfold increase in perinatal morbidity compared with dichorionic twins.

The relationship between chorionicity and zygosity can be kept simple. Two thirds of dichorionic pregnancies (two placentas) are dizygotic, but one third of them are monozygotic. The only way to determine zygosity is through invasive testing, with chorionic villus sampling, amniocentesis, or cordocentesis to analyze the fetal DNA. In 2% of cases, monozygotic twins share organs (Siamese, or conjoined, twins).

The first trimester is the best time to determine chorionicity. Dichorionic twins have two placentas, but in most cases, the placentas are adjacent, making the diagnosis of chorionicity difficult. Sonographic determination of chorionicity and amnionicity carried out at 11 to 14 weeks is based on the number of placental sites, the visualization of and the characteristics of an intertwin membrane, and the identification of the "lambda" (Fig. 7–2)[36] or "twin-peak" sign on the one hand or the "T" sign on the other enables accurate categorization compared with placental histology.[37,38] The lambda sign is formed by the triangular tissue projection at the base of the intertwin membrane. It is an extension of the two chorion layers within the intertwin membrane that is present only in dichorionic pregnancy. In monochorionic pregnancies, there is no layer of chorion between the two

TABLE 7–1

Types of Monozygotic Twins and Time of Division after Fertilization

CHORION	AMNION	TIME OF DIVISION (DAY)	FREQUENCY (%)
Dichorionic	Diamniotic	0–3	33%
Monochorionic	Diamniotic	4–8	65%
Monochorionic	Monoamniotic	>8	2%
Monochorionic	Monoamniotic (Siamese)	>13	Rare

FIGURE 7–2
Dichorionic diamniotic twin pregnancy and the lambda sign.

layers of amnion, and the lambda sign is absent. This sign can be seen during transvaginal ultrasound examination as early as 7 to 9 weeks and has high agreement with the 11- to 14-week scan.[39] Note that the chorion disappears with advancing gestation, and the lambda sign becomes progressively more difficult to identify. By 16 weeks and 20 weeks, respectively, the lambda sign, or twin-peak sign, is present in 98% and 87% of cases.[40]

Although the twin-peak sign is the current standard of care in ultrasound assessment of chorionicity, other methods have been proposed. Carroll and coworkers[37] used a combination of signs (number of placental sites, lambda and T sign, thickness of intertwin membrane) in 150 twin pregnancies scanned between 10 and 14 weeks' gestation to demonstrate that the most reliable indicator for dichorionicity was two separate placentae, and when there was a single placental mass, the presence of the lambda sign (sensitivity 97.4%, specificity 100%). For monochorionicity, of the single best marker was the T sign (sensitivity 100%, specificity of 98.2%). This study supports the observation of others that whereas the presence of the lambda sign indicates dichorionicity, its absence does not rule it out. Shetty and Smith[41] suggested a monochorionic placenta that appears to be two separate placentas is bilobed or has a succenturiate lobe in 97.7%. Moon and colleaguesl[42] sought chorionicity in first trimester of 306 diamniotic twin pregnancies directly by depiction of the amnion and chorion, describing three patterns of intertwin membranes (Fig. 7–3): pattern 1, two relatively thin layers of even thickness, which indicate no layer of the chorion and two layers of the amnion; pattern 2, one relatively thick and two relatively thin intertwin membranes, which indicate one layer of the chorion and two layers of the amnions; pattern 3, one relatively thick and one relatively thin intertwin membrane, which indicate one layer of the chorion and one layer of the amnion. The twin pregnancies with pattern 1 were considered monochorionic diamniotic twin pregnancies, and pattern 2 and 3 were considered dichorionic diamniotic twin pregnancies. They concluded it was possible to determine the chorionicity in the majority of the twin pregnancies between 11 and 14 weeks' gestation (92.9%) and all of the determined chorionicities corresponded correctly with the ultimate chorionicity confirmed postnatally on histologic evaluation (a predictive accuracy of 100%).

Identifying Normal Sonographic Features in the First Trimester

Prenatal diagnosis of fetal structural malformations during either the first or the second trimester has helped reduced perinatal morbidity and mortality by decreasing the prevalence of congenital anomalies at birth. Although many major fetal defects are diagnosable in the first trimester, the diagnostic accuracy is significantly higher in the mid-second trimester owing to the larger size and more advanced development of the fetus. Conversely, the second trimester scan is generally considered less reliable as a screening tool.

Several studies have assessed the ability of sonographers and sonologists to detect fetal structural malformations by first-trimester ultrasound. It is widely accepted that the measurement of NT to screen for aneuploidies should be combined with a search for detectable malformations. This approach requires standardization and quality control. Most fetal structures can be visualized in the first trimester using either vaginal or abdominal ultrasound (Table 7–2).[43] Whereas some structures such the posterior fossa, cerebellum, genitalia, and sacral spine are less reliably seen in the first trimester[44] than in the second and third trimesters (see also Chapter 8), other findings are characteristic of the first trimester. Visualization of normal fetal anatomy in the first trimester provides the patient reassurance and reduces anxiety. Earlier detection of fetal structural malformations also allows for timely referral to a tertiary care facility and coordination of care among appropriate subspecialists. Some may argue, however, that the first-trimester anatomic survey adds cost and burden to the health care system. It is, however, feasible to continue to perform a single ultrasound examination at 11 to 14 weeks of gestation to measure the fetal NT and assess the fetal anatomy. There are additional costs that will accompany widespread use of the first-trimester anatomic survey just as there are for later screening. Though aneuploidy screening is now accepted in most industrialized countries, the benefit of first-trimester anatomic screening needs to be demonstrated in the research arena before performing a cost-benefit analysis of first-trimester screening in clinical practice.[44]

The fetus should be sonographically evaluated in three planes:

FIGURE 7–3

CRL, crown-rump length.
* Anatomy check I includes all organs except the heart.
† Anatomy check II includes all organs including the heart.
From Souka AP, Pilalis A, Kavalakis Y, et al: Assessment of fetal anatomy at the 11–14-week ultrasound examination. Ultrasound Obstet Gynecol 2004;24:730–734.

- A strict midsagittal plane for measurement of CRL and examination of the abdominal wall and cranial and caudal fetal extremities. The NT measurement is performed in this plane.
- An axial view of the skull to identify the cranial contour, the midline of the brain, and the posterior fossa.
- A cross-section of the abdomen to identify the abdominal cord insertion site and the intra-abdominal position of the stomach. The presence of four limbs with three segments is also verified.

Fetal anatomy should be examined as previously described[43]:

- Skull and brain: completeness of the skull, the presence of the falx, and the butterfly shape of the choroid plexuses.
- Face: presence of orbits and lenses and the view of the fetal profile.
- Spine: alignment of the vertebrae and the skin covering the spine from the cervical to the sacral regions.
- Heart: four-chamber view (visualization of the two atria and ventricles, the crux, and the atrioventricular valves) and the three-vessel view of the great vessels (visualization of the cross-sectional view of the pulmonary artery, aorta, and superior vena cava).
- Stomach: visualization of the stomach as a hypoechoic structure in the left upper abdomen.
- Abdomen: examination of the abdominal wall and the umbilical cord insertion.
- Kidneys: visualization of the kidneys as hyperechoic structures with a hypoechoic center lateral to the spine.
- Bladder: visualization of the bladder as a hypoechoic structure in the fetal pelvis; add color flow to demonstrate arterial flow on both sides indicative of a two-vessel cord.
- Extremities: examination of the long bones and fingers.

External Features

- Ossification begins at approximately 11 weeks with the occipital bone. The skull appears regular and hyperechogenic compared with the underlying tissues.[45]

Central Nervous System

From 9 weeks onward, the outline of the lateral ventricles, the echogenic choroid plexus, and the midline echo are visible. By 10 to 11 weeks, the third and fourth ventricles become visible, and from 14 weeks onward, the cerebellum and thalami are seen. The ventricles occupy most of the cerebral hemispheres. The choroids plexus should fill the lateral ventricles completely. Choroid plexus cysts are more common in the first trimester than in the second (incidence 5.7% vs. 1.4%)[46,47] and are not associated with fetal abnormalities.

The width of the third ventricle becomes narrow toward the end of the first trimester. The corpus callosum is not visible at the end of the first trimester, though the area where it will develop can be identified. The cerebellar hemispheres seem to meet in the midline during weeks 11 to 12. At the end of the first trimester, the choroid plexuses lie close to the caudal border of the cerebellum. Successively, the ossification of the spine appears.[48]

3DUS imaging has made it possible to obtain images of the developing embryonic brain in planes not previously available.[49] The lack of skull ossification allows visualization of the brain in any plane, which is not the case during the second and third trimesters. 3DUS is particularly helpful because volumes acquired with a transvaginal transducer can be easily rotated to evaluate the anatomy, which is not possible with the limited motion of a transvaginal transducer.[50] Geometric visualization of brain cavities including the choroid plexuses by manual segmentation shows the form and shape and enables volume calculation that has provided new insights into embryonic development not obtainable from aborted specimens.[49] Recently, a study using the "inversion-rendering" mode revealed 3-dimensional development of the ventricles of the brain in early pregnancy, from 6 to 13 weeks, providing a reference for early diagnosis of central nervous system anomalies such as hydrocephalus and holoprosencephaly.[51]

Heart

Abnormalities of the heart and great arteries are the most common congenital defects and account for about 20% of all stillbirths and 30% of neonatal deaths due to congenital defects. The position, axis, four-chamber view, and symmetry of the heart can be seen in the first trimester. Smrecek and associates[52] found it was impossible evaluate the fetal heart at 10 weeks. The success rates rose to 45% at 11 weeks and 90% between 12 and 14 weeks' gestation. Huggon and coworkers[53] found that a highly trained cardiologist could obtain transabdominally informative images under 14 weeks in 84% of cases. With less specialized operators, the four-chamber view was imaged successfully in 76% and 95% of cases transabdominally and transvaginally, respectively, at 12 to 13 weeks' gestation.[54] Whitlow and Economides[55] observed that the four-chamber view was seen in 83% at 11 weeks and in 98% from 13 weeks onward. Souka and colleagues[43] reported the visualization of heart anatomy according to CRL measurement (Table 7–3).

Interest in early examination of fetal heart is related to the significant clinical impact of early detection of cardiac problems. Early cardiac scanning should be offered to high risk

pregnancies in specialized centers because fetal echo-cardiography in the first trimester has been proved to be accurate in defining major cardiac anomalies when performed by a specialist, but the degree of assessment of the early cardiovascular system that is possible and the lack of operators who are trained specifically makes its application questionable for routine scanning of the fetal heart in the first trimester of low risk patients by the first-level operator.[56] This could produce apparent contradictions in light of prevalence[57] of cardiac defects, the association with both chromosomal anomalies and genetic syndromes,[58] and the assessment of cardiac anatomy at this stage of gestation.[59,60] Because the prevalence of congenital heart disease (CHD) in fetuses with increased NT thickness (discussed later) is between 5% and 10%,[61–63] a detailed fetal cardiac examination should be recommended only in these cases (see later).

Stomach

The stomach bubble is seen as a small, sonolucent cystic structure in the upper left quadrant of the abdomen, below the heart by 8 weeks in 31%[64] and in all cases by 12 to 13 weeks. Fluid production by the intestinal epithelium is the most likely explanation for visualization of a stomach because fetal swallowing movements are not seen until 11 weeks onward.[64,65] The relationship of this structure to the diaphragm should be noted.

Abdominal Wall

Physiologic hernia of the midgut into the umbilical cord is part of embryonic intestinal development.[64] It is a large, hyperechogenic mass that retracts into the abdominal cavity between 10 weeks and 4 days and 11 weeks and 5 days. Fetuses older than 11 weeks and 5 days should not show herniation.[64] At that point, a differential diagnosis of omphalocele and gastroschisis should be considered.

Bladder and Kidneys

The fetal kidneys are visible in most cases at 12 to 13 weeks and appear more echogenic than the rest of the intra-abdominal contents. Renal echogenicity decreases as excretory function develops.[55] As a result, the fetal bladder is seen in 80% of fetuses[66] by 11 weeks and in more than 90% by 13 weeks. The sagittal long axis of the bladder is less than 6 mm in the first trimester. In one study of 300 pregnancies between 10 to 14 weeks' gestation, the fetal bladder was always visualized when the CRL was greater than 67 mm. The fetal bladder was visualized in 90% of fetuses with a CRL of 38 to 67 mm.[67]

Skeleton

All three parts of the long bones are consistently seen from 11 weeks onward, although measurement of the long bones before 14 weeks seems clinically irrelevant. All long bones are similar in size at 11 to 14 weeks, ranging from approximately 6 mm at 11 weeks to 13 mm at 14 weeks.[68] Body and limb movements are seen from 9 and 11 weeks onward, respectively.

Fetal Gender

Fetal gender assessment should not be considered part of a screening ultrasound during the first trimester and care should be taken not to communicate gender impressions. However, an ultrasound determination of the fetal sex can benefit decision-making regarding invasive testing in pregnancies at risk for sex-linked genetic abnormalities, and several techniques have been proposed.

In one, the angle of the genital tubercle to a horizontal line extending through the lumbosacral skin surface is measured (accomplished in 99.6% of males and 97.4% of females). The fetus is assigned male gender if the angle is greater than 30 degrees, and female if the angle is parallel or convergent (<10 degrees) to the horizontal line. Gender cannot be determined if intermediate (10–30 degrees). The accuracy of male assignment is unaffected by the CRL,[69] whereas the accuracy of female assignment increases with increasing CRL.

In another technique, a "caudal acute angle" between the axis of the ventral surface of the fetus and the long axis of the clitoris is interpreted to mean female genitalia, whereas a "cranial acute angle" between the axis of ventral surface of the fetus and the long axis of the penis indicates male genitalia.[70] Other proposed methods either combine the sagittal and transverse views of the genitalia[71] or use only the transverse plane in order to assign sex with better accuracy. These techniques indicate that males are recognizable by the presence of a third echogenic point in addition to two echogenic points or lines that are present in both sexes on this plane.[72] 3DUS is also used for first-trimester fetal gender determination. Michailidis and associates[73] reported that a correct prediction of fetal gender can be achieved in 85% of cases. Mazza and coworkers[70] found gender could be correctly assigned in 95% to 99% with a biparietal diameter (BPD) of 20 mm and 99% to 100% with a BPD of 22 mm. They concluded fetal sex assignment should not be undertaken below a BPD of 22 mm, especially in cases in which fetal sex is not relevant.

Uterine Artery Doppler Ultrasound

As first-trimester ultrasound became more popular for aneuploidy screening, attention turned to the development of a risk profile predictive of other adverse pregnancy outcomes. The concept underlying uterine artery Doppler measured flow is that it reflects impedance of uterine artery blood flow, which normally decreases with increasing gestation. A high vascular resistance continues in pregnancy disorders associated with suboptimal placental function.[74] The high resistance is thought to promote endothelial cell injury, disruption of vascular integrity, vessel occlusion, and placental ischemia.[75] Women with first-trimester uterine artery resistance indices above the 75th percentile are 5.5 times more likely to experience this outcome.[76] It also appears that first-trimester uterine artery Doppler resistance measurements can aid the identification of women at risk for early, severe preeclampsia or growth restriction.[77,78] Currently, uterine artery Doppler interrogation in the first trimester does not perform well as a screening test despite documented associations. The role of Doppler studies in the first trimester for adverse pregnancy risk outcome assessment is being studied in conjunction with biomarkers including pregnancy-associated plasma protein A (PAPP-A), free β-hCG, and placental protein 13 (PP13).[74]

Nuchal Translucency

Definition

Nuchal translucency (NT) is the ultrasound term for the physiologic collection of fluid underneath the nuchal skin extending for a variable distance over the fetal head and back at 11 to 14 weeks. For unclear reasons, the amount of fluid at this gestation is highly sensitive to fetal problems. An anteroposterior measurement of this layer of fluid with the fetus in a longitudinal view provides an accurate and reproducible measurement, provided it is done in a standardized fashion. NT thickness normally increases with CRL between 44 and 85 mm.[79–81] Therefore, GA can influence the risk calculation significantly (Fig. 7–4). The 50th percentile values for NT thickness are 1.2 mm and 1.9 mm for a CRL of 45 mm (11 wk) and 85 mm (13 wk and 6 days), respectively, and the 95th percentile values are 2 mm and 2.8 mm, respectively.

Because of the need to standardize the measurement process, initial attempts to differentiate the NT from cystic hygroma have been abandoned. However, cystic hygroma can be clearly differentiated from an increased simple NT, and further efforts to assess the prognosis of these fetuses are needed. When the NT thickness is greater than 3.5 mm, thin septations are typically seen. The typical ultrasonographic appearance of cystic hygroma is that of two dilated jugular lymphatic sacs seen on a transverse scan at the level of the neck and separate from the NT (Fig. 7–5).

Measurement

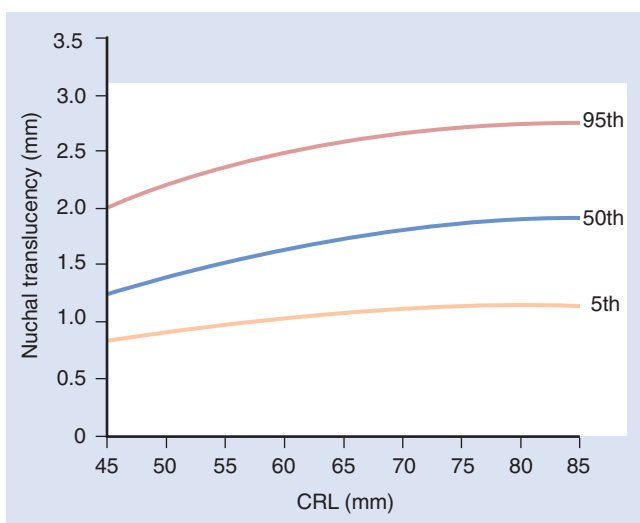
Standardization and quality control in NT measurement is best served by the Fetal Medicine Foundation initiative. This initiative established a process for certification in the 11- to 14-week scan to ensure those performing the examination are adequately trained and maintain an appropriate level of performance through continuing education and audit


FIGURE 7–4

Changes in nuchal translucency with gestational age, as expressed by crown-rump length (CRL).

(Adapted from Pandya PP, Snijders RJM, Johnson SJ, et al: Screening for fetal trisomies by maternal age and fetal nuchal translucency thickness at 10 to 14 weeks of gestation. Br J Obstet Gynaecol 1995;102:957-962.)

(www.fetalmedicine.com).[82] Local branches for certification have been established in numerous countries to enhance efficiency.

To obtain a reliable measurement of fetal NT, the following steps are needed (Fig. 7–6):

- All sonographers who perform fetal scans must be appropriately trained. The ability to measure NT reproducibly improves with training; good results are typically achieved after approximately 100 scans. Intraobserver and interobserver differences in measurements are less than 0.5 mm in 95% of examinations.[83,84]
- The ultrasound equipment must be of good quality, with a video-loop function. The calipers should be able to provide measurements to 0.1 mm.
- NT can be measured successfully by transabdominal ultrasound in approximately 95% of pregnancies; in the rest, transvaginal sonography is required.
- The minimum fetal CRL should be 45 mm and the maximum, 84 mm, because the optimal GA for the measurement of NT is 11 weeks to 13 weeks and 6 days.
- Gestation must be taken into account when determining whether a given NT increases risk because the fetal NT thickness increases with CRL.
- A good sagittal section with the fetus in the neutral position is needed for accurate measurement of the CRL and NT.
- The magnification should be such that each increment in distance between calipers is 0.1 mm.
- Care must be taken to distinguish between the fetal skin and the amnion. Both structures appear as thin membranes at this gestation. This distinction is made by waiting for spontaneous fetal movement away from the amniotic membrane or by "bouncing" the fetus off of the amnion with a maternal cough or by tapping the maternal abdomen.
- More than one measurement is taken and the maximum technically acceptable measurement is recorded.
- A nuchal umbilical cord (Fig. 7–7) may falsely increase the NT measurement and is present in approximately 5% of scans. In such cases, the NT measurements above and below the umbilical cord are different. It is more appropriate to use the average of the two measurements in the calculation of risk.[84]

Screening for Fetal Aneuploidies

FETAL NUCHAL TRANSLUCENCY AND TRISOMY 21

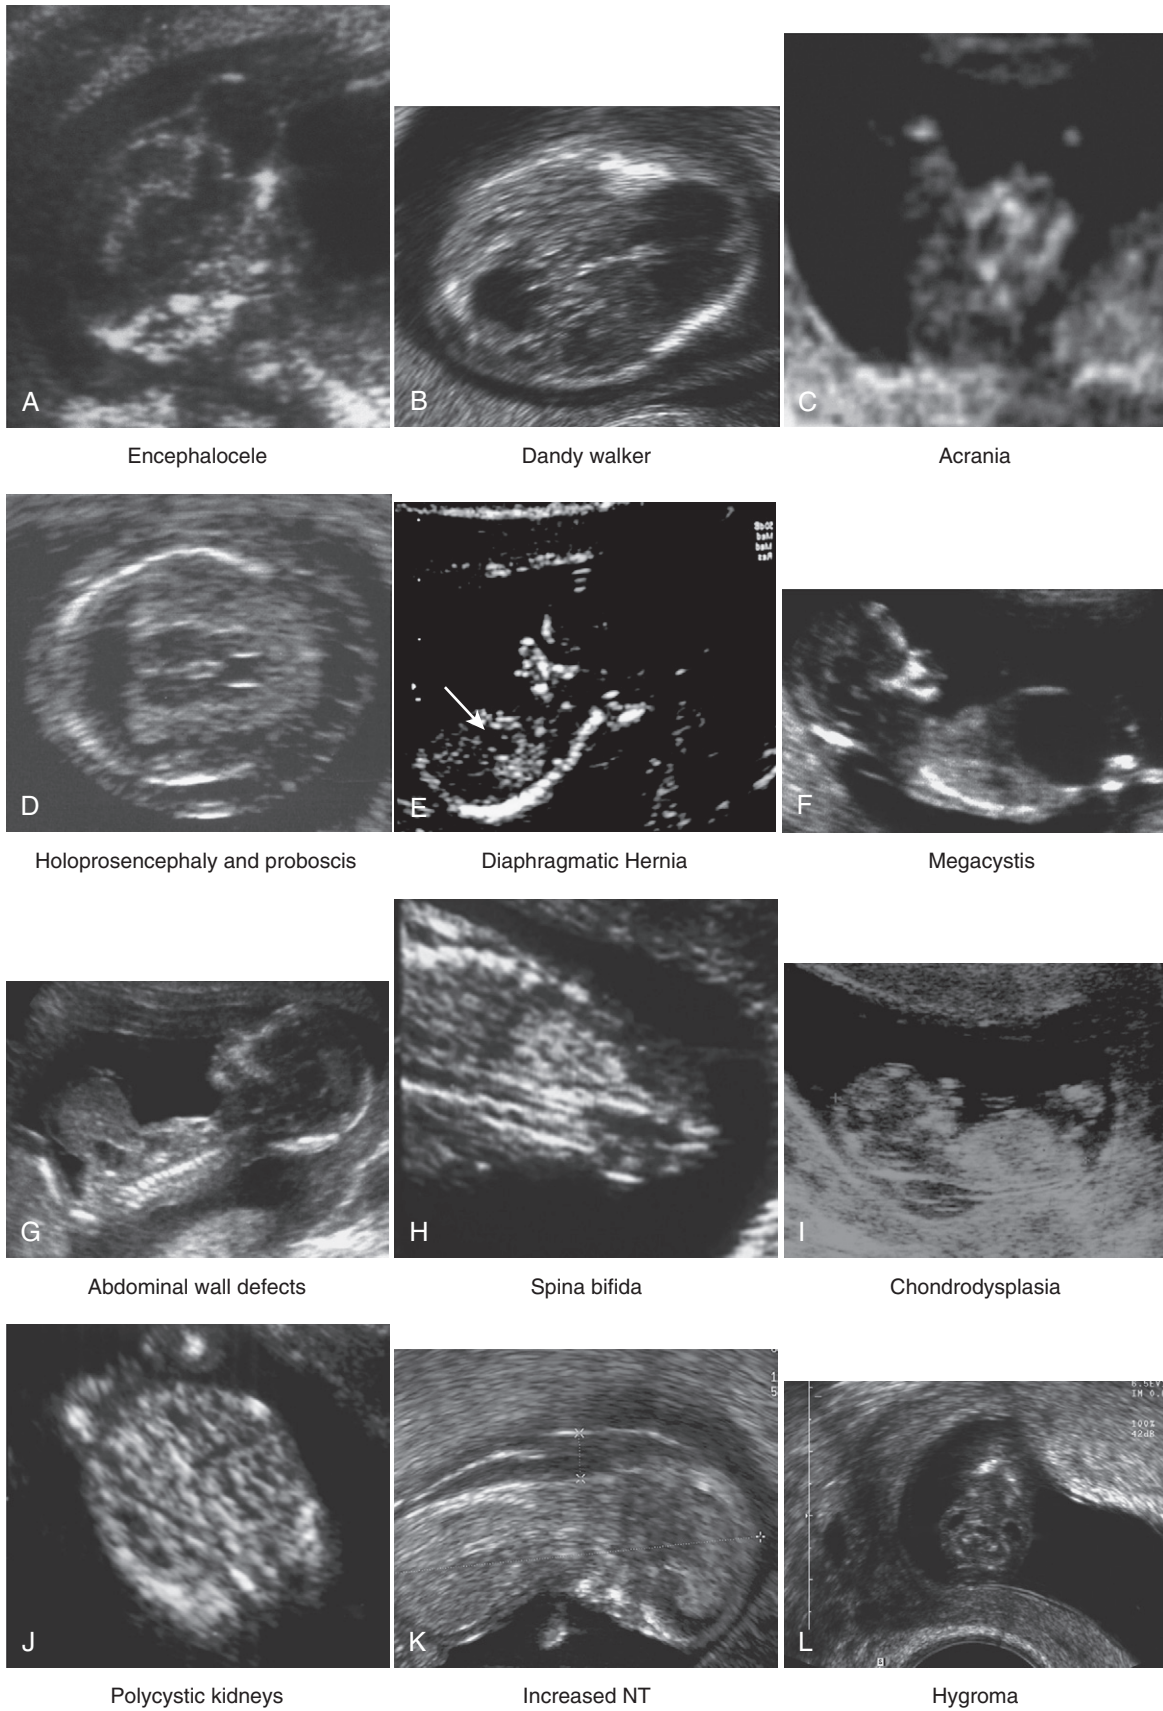
Down syndrome is the most common chromosomal abnormality in liveborn children, and every woman is at risk for having an affected fetus. This pervasive risk justifies the screening programs that have been established worldwide. A woman's risk of having a fetus with Down syndrome depends on her age, the GA, and her history of chromosomal defects. These three factors establish the background risk or a priori risk. A 33-year-old woman at 10 weeks' gestation has a 1 in 352 risk of having a fetus with trisomy 21. Because the risk decreases with advancing gestation as a result of the spontaneous death of fetuses with chromosomal abnormalities, the risk decreases to 1 in 547 at 40 weeks. NT measurement at 11 to 14 weeks, combined with maternal age, provides an effective method of screening for trisomy 21.


FIGURE 7–5

FIGURE 7–8

Likelihood ratios for trisomy 21 in relation to the deviation in fetal nuchal translucency thickness from the expected normal median for crown-rump length. (From Snijders RJM, Nicolaides KH: Assessment of risks. In Ultrasound Markers for Fetal Chromosomal Defects. Carnforth, UK, Parthenon, 1996, pp 63–120.)
An association between NT thickness and chromosomal abnormalities has been recognized since the early 1990s.[79,83–97] The average reported detection rate with NT measurement is 77%, for a false-positive rate of 4.7%. The false-positive rate is the percentage of karyotypes potentially performed because of a positive screening test result. This detection rate represents the combined results of 14 prospective studies on NT measurement for chromosomal abnormalities involving 174,473 patients, including 728 with trisomy 21 (Table 7–4).[79,83–98] In comparison, screening by maternal age only using a cutoff age of 37 years has a detection rate of 30%, for a false-positive rate of 5%, The detection rate is approximately 60% with second-trimester maternal serum markers using the same false-positive rate.[99]

Whenever a screening test is performed, the background risk is multiplied by the test factor to calculate a new risk. Thus, the NT measurement in a fetus with a given CRL is converted to a likelihood ratio that is multiplied by the background risk to provide a new risk (Fig. 7–8).[79,100,101] A woman's risk of having a fetus with trisomy 21 is higher if the NT measurement is large and lower if it is small (Figs. 7–9 and 7–10).[36,100] The median NT thickness is approximately 2.0 mm in fetuses with trisomy 21. However, because NT thickness increases with gestation, the use of a cutoff value rather than a continuous assessment with CRL and maternal age leads to a 5% loss in sensitivity.[102]

NUCHAL TRANSLUCENCY AND CHROMOSOMAL DEFECTS OTHER THAN TRISOMY 21

Less prevalent chromosomal abnormalities are also associated with an increased NT thickness. In these fetuses, other characteristic sonographic findings are associated with increased NT measurements.

In trisomy 18, early-onset intrauterine growth restriction (IUGR) often occurs and may cause an error in dating the pregnancy. In approximately 30% of these cases, other anomalies, such as omphalocoele, are seen after 11 weeks.[103]

Trisomy 13 may also cause early-onset IUGR and severe brain anomalies, mainly holoprosencephaly, in up to 30% of cases at 11 to 14 weeks.[104]

Turner's syndrome is characterized by fetal tachycardia in approximately 50% of cases. These fetuses often have large cystic hygromas.[105]

In triploidy, there is early-onset, but asymmetrical IUGR, with an almost normal-sized head. Other severe anomalies are present in approximately 40% of cases, and molar changes in the placenta are seen in approximately one third of cases.[106]

INCREASED NUCHAL TRANSLUCENCY AND NORMAL KARYOTYPE

By definition, 5% of fetuses screened at 11 to 14 weeks have an NT measurement greater than the 95th percentile. Most of these fetuses are chromosomally and anatomically normal antenatally and at birth.[79,107,108] Fetuses with increased NT thickness but a normal karyotype are at increased risk for major cardiac defects as well as other structural anomalies, rare genetic syndromes, and other unfavorable outcomes (Table 7–5).[109–113] Because an increase in the amount of this

fluid is associated with a number of apparently unrelated fetal problems, it is safe to assume there are multiple mechanisms underlying the increased thickness. It is also likely that more than one mechanism is involved in some circumstances. These include cardiac dysfunction, abnormalities of the heart and great arteries, venous congestion of the head and neck, altered composition of the extracellular matrix, failure of lymphatic drainage due to abnormal or delayed development of the lymphatic system or impaired fetal movements, fetal anemia, and congenital infection.[114]

Souka and colleagues[109] looked at pregnancy outcome in 1320 chromosomally normal fetuses with NT thickness greater than 3.5 mm in the first trimester. The chance of a live birth and no structural defects was 86% when the NT thickness was 3.5 to 4.4 mm, 77% when the NT thickness was 4.5 to 5.4 mm, 67% when the NT thickness was 5.5 to 6.4 mm, and 31% when the NT thickness was greater than 6.5 mm. Thus, parents should be counseled that even if the NT thickness exceeds 6.5 mm, there is a one in three chance that the pregnancy will end with the live birth of an infant with no major defects.[109]

CARDIAC DEFECTS

Increased NT in a fetus with a normal karyotype is associated with a greater risk of CHD.[61–63,115] The prevalence of congenital cardiac defects in fetuses with increased NT thickness is between 5% and 10%.[116] Moreover, although NT may be increased in fetuses with CHD and a normal karyotype, the median NT is significantly higher when the karyotype is abnormal for almost any given diagnosis of CHD. A meta-analysis of studies examining the screening performance of NT thickness for the detection of cardiac defects in fetuses with normal karyotype concluded the detection rates were about 37% and 31% for the respective NT cutoffs of the 95th and 99th percentiles[62] Some 60% of CHD in the chromosomally abnormal group and 23% of CHD in the chromosomally normal fetuses will be identified by applying the 99th percentile.[63] The policy regarding referral for NT between the 95th and the 99th percentiles is much less consistent, and probably only a portion in this group gets to see a fetal cardiologist specifically because of the increased NT. Another recent meta-analysis concluded that about half the cases of CHD could be prenatally identified with an NT cutoff of 1.7 multiple of the median (MoM) and a 5% false-positive rate.[117] Fetal echocardiography is recommended as early as the first trimester because it would identify one major cardiac defect in every 16 patients examined for all chromosomally normal fetuses with NT above the 99th percentile.[62]

The performance of screening by increased NT does not vary with the type of cardiac defect. The NT is increased in all types of heart defects: left as well as right heart lesions, septal defects, outflow tract disorders, laterality disorders, and complex heart lesions.[63] Other first-trimester sonographic markers of trisomy 21 have been proposed as part of a two-stage assessment of risk.[118] With the exception of the nasal bone (NB), these markers are related to the cardiovascular system, and include tricuspid regurgitation (TR) and increased impedance to flow in the ductus venosus (DV). These may be explained in part by the theory of dysfunctional or abnormal angiogenesis in aneuploidy.[119]

DIAPHRAGMATIC HERNIA

In a study of 19 fetuses with diaphragmatic hernia, NT thickness was increased in 37%, including 83% of those who died in the neonatal period as a result of pulmonary hypoplasia. Only 22% of the survivors had an increased NT measurement. Increased NT thickness may reflect venous congestion in the head and neck as a result of mediastinal shift or compression and impaired venous return.[120]

OMPHALOCOELE

The prevalence of omphalocoele is approximately 10 times higher in fetuses with a normal karyotype and an increased

NT measurement compared with the general population.[108,121] Other structural defects are associated with increased NT thickness and a normal karyotype.[108]

Miscellanous Associations

An increased NT measurement (>3.5 mm) with a normal karyotype is an indication for detailed, follow-up ultrasound examinations.[122] An anomaly scan should be performed at 14 to 16 weeks to determine the evolution of the NT to nuchal edema and to diagnose or exclude most fetal defects.[109] Nuchal edema is diagnosed when subcutaneous edema is noted in the midaxial plane of the neck and tremors occur if the uterine wall is tapped or if the edema measures more than 6 mm.[123] If no obvious abnormalities are seen during the 14- to 16-week scan, echocardiogram should be performed at 20 to 22 weeks, when further genetic testing may be indicated (Fig. 7–11).[109]

An adverse outcome may be expected in about one out of five fetuses with persistent, unexplained nuchal edema at 20 to 22 weeks,[109] including progression to hydrops, genetic syndromes detected at birth, and cardiac defects (one third) that could have been detected, but were missed antenatally.

Based on combined data from two studies that included 4540 chromosomally normal fetuses with increased NT and no obvious structural defects, the incidence of miscarriage or fetal death increased from 1.3% in those with NT between the 95th and the 99th percentiles to about 20% for NT of 6.5 mm or greater.[108,109] Another study of 6650 pregnancies undergoing NT screening reported that in chromosomally normal fetuses, the incidence of miscarriage or fetal death was 1.3% in those with NT below the 95th percentile, 1.2% for NT between the 95th and the 99th percentiles, and 12.3% for NT above the 99th percentile (3.5 mm).[124] The authors concluded that once aneuploidy is ruled out, the risk of fetal mortality does not statistically increase until the NT reached 3.5 mm or above. The majority of fetuses that die do so by 20 weeks, progressing from the increased NT to severe hydrops fetalis. Chromosomally and structurally normal fetuses with history of thickened NT found to be alive and well at 20 weeks with no evidence of nuchal fold thickening or nonimmune hydrops are no longer considered at an increased risk for perinatal or long-term morbidity and mortality.

The prevalence of neurodevelopmental delay in the group with normal findings on follow-up scans is 0.4%, but rises to 1.2% in those with persistent nuchal edema. Other studies report a 3.2% to 5.6% prevalence of residual neurodevelopmental delay in fetuses with increased NT thickness.[125,126] Methodologic issues make it difficult to compare the prevalence of mental retardation in infants with increased NT measurements with the general population, which ranges from 0.5% to 2%.[127] Etiologies include chromosomal abnormalities in 25% of cases and genetic syndromes in 7% to 10% of cases. Mental retardation is unexplained in 30% to 50% of cases,[127] or less than 1% of the population. Children with an isolated NT measurement in utero of greater than 3.5 mm should be followed jointly by pediatricians and geneticists to allow enhanced prenatal counseling (Table 7–6).[107,109,128,129] Elucidation and integration of these data are essential if the counseling is to be balanced. Otherwise, counseling may resemble this confusing statement: "The good news is that the karyotype is normal, and the bad news is the karyotype is normal."[128,129] Such uncertainty is potentially lethal, particularly when announced in the first trimester in countries in which pregnancy termination is an option at 14 weeks, but is challenged or forbidden at a later GA.

The association between increased NT thickness and a wide range of structural abnormalities and genetic syndromes indicates the need for long-term follow-up of these children, even when they appear normal at birth. Hiippala and associates[122] followed 50 chromosomally normal children 2.4 to 7.1 years of age who had NT thickness greater than 3 mm at 13 to 15 weeks' gestation. Their growth was within normal limits, but 1 in 12 had a previously unrecognized cardiac defect. One child had Noonan's syndrome, 1 had cleidocranial dysplasia, and a third had developmental delays and an undefined syndrome. Webbing was seen in the neck region of 2 children who were otherwise free of associated pathology.

Nuchal Translucency in Multiple Pregnancies

First-trimester NT thickness measurement in combination with maternal age is an efficient technique for trisomy 21 screening in multiple gestation. Sebire and coworkers[130,131] reported that it has a performance comparable with that in singletons, although with a slightly higher false-positive

rate. Fetus-specific risk estimation helps select the best invasive technique for diagnostic testing.

In dichorionic multiples, the risk of aneuploidy depends on the number of fetuses, because each additional fetus proportionally increases the risk of aneuploidy per pregnancy. In monochorionic multiples, which are always monozygotic, the maternal age–related risk for chromosomal abnormalities is the same as in singleton pregnancies, and in the vast majority of cases, both fetuses are affected. The findings of a retrospective study of 769 monochorionic twin pregnancies suggests that effective screening for trisomy 21 is best provided by using the average of NT measured in the two fetuses. If the fetus with the smaller NT is considered, the detection rate of trisomy 21, for any given false-positive rate or risk cutoff, is substantially lower than using the average NT measured in the two fetuses.[132] Moreover the false-positive rate of NT screening (13% per pregnancy) is higher than in dichorionic twins, because increased NT in at least one of the fetuses is an early manifestation of twin-twin transfusion syndrome (TTTS; see next section for additional details).[132]

Increased Nuchal Translucency Measurement and Twin-Twin Transfusion Syndrome

A NT measurement above the 95th percentile for CRL between 11 to 14 weeks is associated with a fourfold increase in the risk of severe TTTS in a study of 132 monochorionic twin pregnancies[133] (see also Chapters 23 and 59). Another study of 287 monochorionic twin pregnancies, including 43 that developed severe TTTS at 16 to 24 weeks, reported that the NT was above the 95th percentile in at least one of the fetuses in 28% of the TTTS group at 11 to 13 + 6 weeks compared with 10% in the non-TTTS group.[134] Although the positive predictive value of this screening test is low, it is important to follow these pregnancies closely for the early diagnosis of TTTS. A recent evaluation of 512 monochoronic twin pregnancies revealed that a NT discordance of 20% or more was found in about 25% of cases and that in this group, the risk of developing TTTS was more than 30%.[135]

Other Fetal Measurements as Markers for Fetal Aneuploidy

Nasal Bones

In the combined data from nine studies, the NB was absent in 176 of 12,652 (1.4%) chromosomally normal fetuses and in 274 of 397 (69.0%) fetuses with trisomy 21, yielding a likelihood ratio for absent NB of 49.3.[136–144] The prevalence of absent NB (Fig. 7–12) reflects ethnicity (it is highest in individuals of African origin), NT thickness (it increases as the NT measurement increases), and the CRL measurement (it decreases with GA). Therefore, likelihood ratios for trisomy 21 must also be adjusted to account for these factors.[137,138] Methodologic problems surrounding that part of the first-trimester scan can generate a high false-positive rate, together with significant interoperator and intraoperator variability.[139]

Ductal Blood Flow

A high proportion of fetuses with trisomy 21 and other chromosomal abnormalities have increased impedance to flow in the DV at 11–13 weeks' gestation (Fig. 7–13). In combined data from seven studies, ductal blood flow with an absent or reversed a-wave was observed in 5.2% of euploid fetuses, and 70.8%, 89.3%, 81.8%, and 76.9% of fetuses with trisomies 21, 18, and 13 and Turner's syndrome, respectively.[145] In combined data from six studies, abnormal ductal flow was observed in 273 of 5462 (5.0%) chromosomally normal fetuses and in 108 of 131 (82.4%) fetuses with trisomy 21, and therefore the likelihood ratio for abnormal ductal flow was 16.5.[146–151] There may be an association between increased fetal NT and the presence of abnormal ductal flow, but it appears weak. These findings suggest that Doppler evaluation of the DV flow can be combined with NT screening.[149–151] Ductal flow measurement requires skilled operators because the interference from adjacent vessels is commonly encountered.

Blood Flow across the Tricuspid Valve

Regurgitant flow across the tricuspid valve (TR), determined by pulsed wave Doppler, is a common finding in trisomy 21 fetuses at 11 + 0 to 13 + 6 weeks' gestation (Fig. 7–14).[152,153]
FIGURE 7–13
Reversed a-wave in the ductus venosus in a fetus with trisomy 21 at 12 weeks of gestation.
(From Maiz N, Valencia C, Kagan KO, et al: Ductus venosus Doppler in screening for trisomies 21, 18 and 13 and Turner syndrome at 11–13 weeks of gestation. Ultrasound Obstet Gynecol 2009;33:512–517.)
FIGURE 7–14
Holosystolic regurgitation on pulsed Doppler examination of the tricuspid valve in a fetus at 12 weeks' gestation.
(From Huggon IC, DeFigueiredo DB, Allan LD: Tricuspid regurgitation in the diagnosis of chromosomal anomalies in the fetus at 11–14 weeks of gestation. Heart 2003;89:1071–1073.)

A study performed by experienced fetal cardiologists revealed that the prevalence of TR in fetuses with trisomy 21 at this GA approximates 74% whereas only 7% of chromosomally normal fetuses have this finding.[153] The prevalence of TR decreases with CRL in both normal and trisomic fetuses. In studies performed by the Fetal Medicine Foundation Center, TR was present in 72 of 1394 (5.2%) chromosomally normal fetuses and in 109 of 162 (67.3%) fetuses with trisomy 21.[118] An additional benefit of this measurement is a high association between TR and cardiac defects, suggesting that the high prevalence of TR in the chromosomally abnormal fetuses can be partly attributed to the coincidence of cardiac defects.[152] Like the DV examination, the assessment of tricuspid flow necessitates specialist training.

It is questionable whether NB, abnormal ductal blood flow, and TR can be routinely combined with the other first-trimester sonographic and biochemical markers of chromosomal abnormalities to improve the performance of first-trimester screening. The complexity of the assessment of these procedures and the rigor required to maintain the skills, together with the potential for a subjective assessment, are limitations for their implementation as a one-step risk procedure performed at the time of NT measurement. However, these markers have the characteristics to be a second-line screening that can be performed in early pregnancy, resulting in a major reduction in the need for invasive testing. It is likely their use will grow in fetal medicine laboratories with added experience.

Other Markers of Aneuploidy

Several other measurements in the first trimester are more common in chromosomally abnormal fetuses than in the chromosomally normal population.

A novel method for evaluating the relative position of the fetal maxilla with respect to the forehead was introduced in the first trimester to investigate the location of the front of the maxilla in relation to the forehead in fetuses with trisomy 21.[154] A three-dimensional volume of the fetal head was obtained before karyotyping in 100 fetuses with trisomy 21 and 300 euploid fetuses. The *frontomaxillary facial (FMF) angle* (Fig. 7–15), defined as the angle between the upper surface of the upper palate and the frontal bone in a midsagittal view of the fetal face, was measured. The FMF angle was significantly larger in the trisomy 21 (mean 88.7 degrees, range 75.4–104 degrees) than in the euploid fetuses (mean 78.1 degrees, range 66.6–89.5 degrees). The FMF angle was more than 85 degrees in 69% of the trisomy 21 fetuses and in 5% of the euploid fetuses. There was no significant association between the FMF angle and the NT measurement. The authors postulate that measurement of FMF angle will be a useful adjunct in screening for trisomy 21. Unfortunately, it is more cumbersome to measure than all other sonographic markers.

Other fetal measurements potentially affected in chromosomally abnormal fetuses include the fetal heart rate,[155] maxillary length,[156] ear length,[157] femur length,[158] and humeral length,[158] and in general, fetal growth (see later). Even though statistical differences between trisomy 21 and euploid fetuses exist, the differences are small, limiting their clinical utility.[1]

Lethal skeletal defects

Ultrasound Diagnosis of Fetal Abnormalities

The majority (80%) of common fetal malformations develop before 12 weeks' gestation; therefore, a good visualization of the fetus at this stage should be able to detect these malformations. Most fetal structures can be seen at 12 to 13 weeks, and this GA offers the earliest opportunity for screening for fetal abnormalities. Though the available reports of detection rates in the first trimester for fetal structural defects other than those associated with increased NT thickness are confined mostly to high risk or selected populations (Table 7–7),[159–162] there is increasing evidence that early detailed ultrasonography is technically feasible as a screening test for fetal structural defects in low risk pregnancies.[162] The most frequently detected first-trimester anomalies involve the central nervous system, such as anencephaly, encephalocele, and holoprosencephaly.[163]

Lethal, incurable, or curable severe abnormalities with a high risk of residual handicap are defined as *major structural abnormalities*. The diagnosis of spina bifida is a challenge because the indirect sonographic signs that are characteristic later in gestation are usually missing prior to 14 weeks.[89] Omphalocoele, gastroschisis, and megacystis are also commonly diagnosed in the first trimester. There are case reports of the first-trimester diagnosis of a wide range of severe skeletal defects (see Fig. 7–5). The remaining cases of less severe or benign abnormalities, of no cosmetic or functional significance, constitute the group of minor structural abnormalities. A review[44] analyzed several studies reporting first-trimester detection rates that are comparable with those achieved in the routine second-trimester anatomic survey at 18 to 22 weeks (Table 7–8).[159,162,164–183]

Central Nervous System Defects

The development of the fetal central nervous system is not completed at the end of the first trimester and the anomalies reported differ from those described later in pregnancy. In first-trimester studies, the vast majority of defects described are lethal or severe major structural anomalies. Empty or enlarged brain cavities or abnormal contours of the head and spine are important diagnostic markers for the detection of central nervous system anomalies in the very early pregnancy.[48]

ACRANIA, EXENCEPHALY, AND ANENCEPHALY

Anencephaly can be diagnosed reliably on routine 11- to 14-week ultrasound examination. Acrania is the main feature of anencephaly in the first trimester. Fetuses with acrania may have a normal brain or one that shows varying degrees of disruption.[184,185] In one large, multicenter study, screening for fetal abnormalities was performed in 53,435 singleton and 901 twin pregnancies. Eight of the 47 fetuses with anencephaly were missed.[185] The sonographers were then instructed to look specifically for the cranial vault and at brain organization. All subsequent cases of anencephaly were identified at the 11- to 14-week scan.

ENCEPHALOCELE

Encephalocele appears as a bony defect in the skull, with brain tissue protruding. It is associated with Meckel-Gruber syndrome.[186,187] In most cases, the lesion arises midline in the occipital area. The main alternative diagnosis is cystic hygroma. Once the diagnosis is suspected, the prognosis usually cannot be ascertained before the late second trimester.

HOLOPROSENCEPHALY

Holoprosencephaly results from incomplete cleavage of the forebrain. The most severe forms, alobar and semilobar, are amenable to first-trimester ultrasound diagnosis. They are characterized by a monoventricular cavity and fusion of the thalami. One study suggests that failure to identify both choroid plexuses (the "butterfly" sign) is a first-trimester warning sign of holoprosencephaly.[188] These forms are often associated with facial abnormalities.[189,190] The most common related chromosome abnormality is trisomy 13.

Detection Rates of First-Trimester and Second-Trimester Ultrasound Screening for Fetal Structural Malformations

Different authors have used the 3DUS "inversion rendering" mode to described abnormal brains.[51] Inversion rendering of early fetal brain ventricles is feasible and should be attempted if additional information is needed.[191]

SPINA BIFIDA

The sonographic diagnosis of spina bifida aperta is difficult prior to 14 weeks. The diagnosis of hydrocephaly is also difficult to establish in the first trimester because of the large relative proportions of the lateral ventricles to the calvarium. Therefore, in the absence of cranial signs in the first trimester, the sensitivity of detection of spina bifida is unlikely to be as high as in second-trimester scanning. At this early gestation, indirect signs, such as sacral irregularities, the lemon (frontal bone scalloping) and banana signs (abnormal curvature of the cerebellar hemispheres), are usually absent.[163,192] Other signs, such as a flattened occiput, parallel peduncles, a straight metencephalon, and the acorn sign (frontal bone narrowing), are not consistently present.[163,192] Blaas and colleagues[193] studied high risk pregnancies prospectively and identified three first-trimester fetuses with lumbosacral myelomeningocele characterized by an irregularity in the caudal part of the spine before 10 weeks. 3DUS examination might be helpful but is not necessary to make the diagnosis.

Heart Defects

See the detailed discussion of NT thickness of greater than 3.5 mm and heart defects, earlier. The prevalence of major cardiac defects increases with NT thickness, from 5.4 per 1000 with an NT measurement of 2.5 to 3.4 mm, to 233 per 1000 with an NT measurement of greater than 5.5 mm. The sensitivity of NT is 15% to 56% for the diagnosis of major cardiac defects.[102,110–112] Early fetal echocardiography is recommended and can be performed reliably by trained operators from 14 weeks onward.[58,59,194] Care should be taken not to extrapolate the results of these studies to low risk populations.

Omphalocoele

Reduction of the physiologic midgut hernia ends by 11 weeks and 5 days.[195] An abdominal defect, especially omphalocoele, should be suspected if the herniation continues after 12 weeks. This defect is sporadic, having a birth prevalence of approximately 1 in 4000. Omphalocele is commonly associated with other abnormalities such as aneuploidy, most commonly trisomy 18.[196] Because trisomy 18 has such a high rate of mortality, its association with an omphalocele decreases significantly with GA: 61% at 11 to 13 + 6 weeks' gestation, 30% in the second trimester,

and 15% at term.[197] There are many reports of first-trimester ultrasound diagnosis of omphalocele,[196,198] gastroschisis as well as body stalk anomaly, pentalogy of Cantrell, and ectopia cordis.[44]

Megacystis

Megacystis is defined as a bladder with a longitudinal diameter of 7 mm or more at 10 to 14 weeks' gestation. It is found in approximately 1 in 1500 pregnancies.[67] One study of 145 fetuses with megacystis observed a 25% aneuploidy rate, mainly trisomies 13 and 18.[199] In 75% of fetuses with chromosomal abnormalities, the NT was also increased, possibly the result of thoracic compression. Ninety percent of chromosomally normal fetuses had spontaneous resolution, with no obvious adverse effects on the development of the urinary system. The risk of a chromosomal abnormality when the longitudinal diameter is more than 15 mm is actually lower, approximately 11%.[200] Here, there is a strong association with progressive obstructive uropathy.[199] Favre and associates[200] reported a high prevalence of aneuploidy in fetuses with megacystis and a longitudinal diameter of 9 to 15 mm. Parents can usually be reassured when the megacystis is between 7 and 15 mm and the karyotype is normal that 90% of abnormalities will resolve and renal function will be normal. Vesicoamniotic shunting in midgestation has no benefit and there is no experience with first-trimester decompression.[201] It is interesting to note that megacystis is associated with an increased NT regardless of the karyotype.[199]

Renal Anomalies

Bilateral renal agenesis, hydronephrosis, and multicystic dysplastic kidney have been diagnosed by ultrasound in the first trimester.[165,202,203]

Skeletal Defects

Skeletal dysplasias complicate approximately 1 in 4000 births. Twenty-five percent of affected fetuses are stillborn, and 30% die in the neonatal period. In some skeletal dysplasias, growth impairment is not apparent until later in gestation. However, first-trimester diagnosis of isolated cases has been reported, mainly because they were associated with an increased NT.[204,205]

Two-Vessel Cord

The finding of a two-vessel cord in the first trimester is not associated with an increased prevalence of trisomy 21, but it increases the risk of trisomy 18 approximately sevenfold.[206]

Variation in First-Trimester Growth

First-trimester growth in normal pregnancy is influenced by maternal and fetal factors. Early fetal growth restriction is demonstrable in many pregnancies that subsequently end as a first-trimester loss. However, slow growth occurs prior to miscarriage in both chromosomally normal and abnormal pregnancies. Serial growth assessment of ongoing viable pregnancies and those that subsequently fail suggests that whereas they have significantly different growth rates, those that miscarry also fall broadly into two groups: those that have antecedent growth restriction and those that do not.[33] It is potentially easy to overlook early growth delay by misdating an abnormal pregnancy.[207] The assessment of growth restriction in the first trimester using the cross-sectional studies described relies on an accurate recall of menstrual age and a regular menstrual cycle so that expected fetal size can be calculated. Functional linear discriminant analysis (FLDA) using serial measurements of CRL or MSD was found to differentiate normal from abnormal early pregnancy growth, predicting a spontaneous loss with a sensitivity of 60.7% and a specificity of 93.1%.[32] In contrast, a single CRL more than 2 SD below expected has a sensitivity of only 53.6% and a specificity of 72.2%.[33]

In pregnancies that continue, various studies have shown some chromosomal abnormalities such as trisomy 18 as well as triploidies,[207] but not trisomy 21, trisomy 13, monosomy X (Turner's syndrome), or sex chromosome triploidies[208] are associated with poor growth. The spectrum of aneuploidy associated with growth restriction and first-trimester miscarriage includes a wider range of trisomies, commonly 7, 16, and 22.[209]

Several studies document that slow growth in the first trimester (absent chromosomal abnormality or miscarriage) is associated with adverse late pregnancy outcomes.[23] Smith and coworkers[210] reviewed 30,000 pregnancies and concluded that a CRL 2 to 6 days smaller than expected is associated with an increased risk (compared with a normal or slightly larger than expected CRL) of a birth weight less than 2500 g (relative risk [RR] 1.8), a birth weight less than 2500 g at term (RR 2.3), a birth weight below the 5th percentile for GA (RR 3.0), and delivery between 24 and 32 weeks' gestation (RR 2.1). In a prospective study of 976 assisted reproduction pregnancies, increased size for gestation in the first trimester was associated with higher birth weight, with the risk of of a small-for-GA newborn diminishing with increasing first-trimester embryonic/fetal size.[34] Thus, adverse outcomes in late pregnancy may at least in part be predicted by early pregnancy growth assessment using ultrasound.[23]

Variation in Growth in Twin Pregnancies

Twins provide a particularly useful model for assessing first-trimester growth. In cases in which there is a discrepancy in size between the two embryos or fetuses, the normally growing twin can be used as a control for the other. The incidence and significance of early intertwin growth discrepancy are controversial. In a study of 182 twin pregnancies (20 monochorionic and 162 dichorionic),[207] the authors observed that up to 95% of twins show discordance in CRL of up to 9.8 mm at 11 to 14 weeks, but there was no indication for further investigation should the fetal anatomy appear normal. In such cases, it may be more appropriate to date the pregnancy based on the smaller twin. Moreover, the risk of significant weight difference or poor outcome is not increased and discrepancy may simply reflect different growth patterns of two normal fetuses. In contrast, a discrepancy in the CRL greatly exceeding the 95th percentile is likely to reflect major growth delay in one twin, which is often aneuploid, and thus has the same significance as that in singletons.[207] In another large study of 200 monochorionic diamniotic twin gestations, the authors concluded that those who ultimately develop TTTS (see also Chapters 23 and 59) can exhibit intertwin differences in growth as early as 11 to 14 weeks.[211] The earlier the discordance, the earlier the manifestation of TTTS.[211]

Three-Dimensional Ultrasound

3DUS is increasingly being used in obstetric practice. The method offers several advantages during the first trimester because it allows visualization of planes that are otherwise difficult to obtain with two-dimensional scanning (2DUS). It could potentially minimize scan time and provides an excellent way to store scanned data for later study. However, no randomized controlled trials of 3DUS versus 2DUS have been published, and the benefits of 3DUS scanning remain speculative. If the 2DUS images are of poor quality, the resulting 3DUS images will be of little clinical use. As shown by Michailidis and colleagues,[124] 2DUS seems the best way to examine the first-trimester fetal anatomy. In some 94% of cases, a complete anatomic survey can be achieved with 2DUS. However, the examination was adequate in only 81% of cases with 3DUS ($P < .001$).

Several feasibility studies of NT measurement with 3DUS have been conducted.[212–215] Theoretically, an NT measurement could be performed regardless of the fetal position, significantly shortening examination time. Moreover, tomographic examination of the three-orthogonal sectional images should make it easy to distinguish fetal skin from the amnion. Paul and associates[212] concluded that reslicing of stored 3D volumes can be used to replicate NT measurements, but only if the nuchal skin is clearly seen on the 2DUS. When the fetus is lying in a position that precludes clear visualization of the nuchal area, 3DUS is unlikely to help.[212] Whereas Paul and associates[212] could repeat the NT measurement in only 60% using a 3D random volume, a number of other studies using 2D and 3D sonography for the measurement of NT show a good correlation between these two techniques at any position. Moreover, several investigators have observed benefit combining 3D with 2D scanning in the form of decreased acquisition time and an improvement in image resolution.[124,213–218] As a result, some authors have suggested 3DUS may be useful in scanning fetuses in a suboptimal position.[218,219] Chung and coworkers[215] and, more recently, Shaw and colleagues[219] demonstrated in pilot studies that the acquisition of 3D volumes can be a most effective and reproducible method of measuring NT. 3DUS also minimized scanning time and provided views not easily obtained using the strict NT guidelines.[219]

MATERNAL SERUM MARKERS AT 11 TO 14 WEEKS

Median serum concentrations of α-fetoprotein, estriol, and β-hCG (total and free) are independent of maternal age and can be combined in the second trimester to refine the risk of trisomy 21. This testing allows for the identification of approximately 60% of fetuses with trisomy 21 (compared with 30% based on maternal age alone) with a 5% invasive testing rate.[99,220]

Free β-hCG is even more discriminant in the first trimester (11–14 wk), and when combined with PAPP-A and maternal age, it provides an estimated detection rate of 60%, with a 5% invasive testing rate.[221]

Free β-Human Chorionic Gonadotropin

The maternal serum concentration of free β-hCG is higher in fetuses with trisomy 21 than in chromosomally normal fetuses. The MoM in pregnacies affected with trisomy 21 is approximately 2. First-trimester measurement of free β-hCG alone allows for the detection of 35% of fetuses with trisomy 21, with a 5% invasive testing rate. The detection rate is increased to 45% if the findings are integrated with maternal age.[221] The maternal serum free β-hCG level is decreased if the fetus has trisomy 13 or 18.[222,223] It is usually normal in women whose fetus has a sex chromosomal abnormality.[224]

Pregnancy-Associated Plasma Protein A

The PAPP-A level increases with gestation and is lower in pregnancies in which the fetus is affected with trisomy 21. The median value in trisomy 21 is approximately 0.5 MoM. When used alone in the first trimester, PAPP-A allows for the detection of 40% of fetuses with trisomy 21, with a 5% invasive testing rate. The detection rate increases to 50% when the findings are integrated with maternal age.[221] The maternal serum PAPP-A level is also decreased if the fetus has trisomy 13 or 18 or sex chromosomal abnormalities.[222–224]

Free β-Human Chorionic Gonadotropin and Pregnancy-Associated Plasma Protein A

When maternal age is combined with first-trimester maternal serum PAPP-A and free β-hCG levels, the estimated detection rate for trisomy 21 approximates 60%, with a 5% invasive testing rate.[221,225,226] These rates are similar to those obtained in the second trimester. Screening with a combination of fetal NT measurement and maternal levels of serum PAPP-A and free β-hCG allows the detection of approximately 90% of these chromosomal abnormalities, with a 5% invasive testing rate (Table 7–9).[1,227–235]

TABLE 7–9

Detection and False-Positive Rates of Screening Tests for Trisomy 21

SCREENING TEST	DETECTION RATE (%)	FALSE-POSITIVE RATE (%)
MA	30 (or 50)	5 (or 15)
MA + serum β-hCG + PAPP-A at 11–14 wk	60	5
MA + fetal NT at 11–14 wk	75 (or 70)	5 (or 2)
MA + fetal NT + NB at 11–14 wk	90	5
MA + fetal NT + serum β-hCG + PAPP-A at 11–14 wk	90 (or 80)	5 (or 2)
MA + fetal NT + NB + serum β-hCG + PAPP-A at 11–14 wk	97 (or 95)	5 (or 2)
MA + serum biochemistry at 15–18 wk	60–70	5
Ultrasound for fetal defects and markers at 16–23 wk	75	10–15
MA + serum β-hCG + PAPP-A at 11–14 wk ± DV, TR, NB (individual risk-oriented two-stage)	90	2–3

β-hCG, β-human chorionic gonadotropin; DV, ductus venosus; MA, maternal age; NB, nasal bone; NT, nuchal translucency; PAPP-A, pregnancy-associated plasma protein-A; TR, tricuspid regurgitation.

Logistic and Organizational Issues

There is no significant relationship between the NT measurement and the maternal serum free β-hCG or PAPP-A levels whether or not the pregnancy is affected by aneuploidy. Therefore, ultrasonographic and biochemical markers can be combined in the first trimester to provide more effective screening than either method individually. The same is true for NT measurement and second-trimester biochemical markers.[236] Many European countries have adopted first-trimester screening for chromosomal abnormalities with a combination of ultrasound NT measurement and maternal serum testing.[237,238]

In 1997, the 32nd Study Group of the Royal College of Obstetricians and Gynaecologists concluded that the evidence in favor of first-trimester screening for trisomy 21 by NT measurement or biochemical testing was sufficiently well developed to justify moving out of the research phase and into routine practice. They also concluded that ultrasound in early pregnancy is superior to biochemical screening in the second trimester. Several large studies support these conclusions.[98,237–241] Spencer and associates[242] studied 12,339 women with singleton pregnancies who were screened by the measurement of NT and maternal serum markers at 11 to 14 weeks in a one-stop clinic for assessment of risk (OSCAR).[242] These authors too concluded it was time to shift the screening for trisomy 21 from the second to the first trimester.[242]

Fetal Nuchal Translucency Measurement and Maternal Serum Free β-Human Chorionic Gonadotropin and Pregnancy-Associated Plasma Protein A (Combined Screening Test)

Spencer and coworkers[235] concluded that the most effective method of screening for trisomy 21 was achieved by a combination of maternal age, fetal NT, and maternal serum free β-hCG and PAPP-A concentrations at 11 + 0 to 13 + 6 weeks' gestation. The detection rate for trisomy 21 was 92% (23 of 25) for a 5% screen-positive rate, a rate far superior to that achieved with maternal age alone (30%) or by maternal age and second-trimester serum biochemistry (65%). This combined method for first-trimester screening also identified 94% of all other major chromosomal defects, such as trisomies 13 and 18, triploidy, and Turner's syndrome, and 60% of other chromosomal defects, such as deletions, partial trisomies, unbalanced translocations, and sex chromosomal aneuploidy other than Turner's syndrome.[98] Wapner and colleagues[240] achieved similar results in a prospective study of 8514 patients (detection rate 78.7%, 5% screen-positive rate) (Table 7–10).

In twin pregnancies, the combination of first-trimester NT and maternal serum biochemistry is less effective than in singleton pregnancies because placental products from the normal twin can mask the abnormal levels of the affected twin. Further, an abnormal result cannot distinguish which twin is affected.[243] As consequence, the combination of first-trimester NT and maternal serum biochemistry is less effective than in singleton pregnancies and not at present recommended. NT screening alone, however, provides similar detection and false-positive rates in multiples as in singleton pregnancies. There may be new options in the future. The authors of one large study concluded that twin pregnancy screening requires an adjustment of the calculated MoM to account for the presence of two fetuses. In general, this should be by dividing the observed corrected MoM by 2.023 for free β-HCG. Two different correction factors are required for PAPP-A, 2.192 in dichorionic twins and 1.788 in monochorionic twins.[244] Further, the distribution of PAPP-A in monochorionic twins is lower than in dichorionic twins, as previously suggested.[245] Such corrections require an accurate diagnosis of chorionicity. Alternative strategies have been proposed[246] that use estimated distributions of markers in twins rather than making correction for twins and the calculation of a singleton equivalent or pseudorisk. The problem with this approach is the sparse data available to determine the distribution of markers in twins concordant or discordant for trisomy 21.

Individual Risk-Oriented Two-Stage First-Trimester Screening

Studies from fetal medicine centers demonstrate that in addition to NT, other highly sensitive and specific first-trimester sonographic markers of trisomy 21 can be used to enhance screening. They include the absence of the NB and increased impedance to flow in the DV and TR.[136,143,152] The addition of these new ultrasound markers to the combined screen (NT and free β-hCG and PAPP-A) requires a sufficient degree of independence among the markers, and this has been shown for NB,[137] TR,[147] and DV.[151] A prospective study of more than 75,000 pregnancies examined the potential impact of a new individual risk-oriented two-stage approach to screening.[118] After undergoing combined fetal NT and maternal serum free β-hCG and PAPP-A screening, patients were assigned to either a high risk category with a risk estimate of 1 in 100 or more, a low-risk category with a risk estimate of less than 1 in 1000, or an intermediate-risk category with a risk estimate of between 1 in 101 and 1 in 1000. Those in the intermediate-risk category had further assessment of risk by first-trimester ultrasound to determine the presence/absence of the NB, normal/abnormal Doppler velocity waveform in the DV, or the presence/absence of TR. Chorionic villus sampling was offered if their adjusted risk became 1 in 100 or more.[118] The results of this study demonstrate that individual risk-oriented two-stage screening for trisomy 21 can potentially identify in the first trimester of pregnancy more than 90% of affected fetuses with a screen-positive rate of 2% to 3%. However, the accurate examination for these markers is time-consuming and requires skilled operators. Although it is unlikely this assessment will be incorporated into the routine first-trimester scan, it is likely to be used in fetal medicine centers across the board or to evaluate the risk in patients with intermediate risk after screening by fetal NT and maternal serum biochemistry.

FETAL NUCHAL TRANSLUCENCY MEASUREMENT AND MATERNAL SERUM MARKERS AT 14 TO 17 WEEKS

Sonographic and biochemical screening methods evolved independently. As a result, many women undergo sequential two-stage screening, even if the NT screen result is negative. Each method is designed to generate a 5% invasive testing rate, and the two-stage screening paradigm has a cumulative rate. Thus, the proportion of patients undergoing invasive prenatal diagnostic testing can be as high as 10%, or even higher in countries that offer invasive prenatal diagnosis to women older than 35 years, regardless of the screening result. This illogical approach increases the iatrogenic loss rate of normal pregnancies and all related costs. The rate of invasive testing for fetal karyotyping is indeed an important public health issue that must be controlled. When the combined first-trimester test is not available, one approach is to combine NT measurement and second-trimester maternal serum screening into a single risk assessment and not to consider the results independently (integrated screening) (Table 7–11).[236] At least in that instance, the screen-positive rate remains around 5%.

TABLE 7–11

Definitions

TERM	DEFINITION
Combined screening	Nuchal translucency measurement + first-trimester serum markers
Fully integrated screening	Nuchal translucency measurement + first-trimester serum markers + second-trimester serum markers
Serum integrated screening	Pregnancy-associated plasma protein-A + second-trimester serum markers
Sequential screening	Successive independent risk assessments, leading to cumulative false-positive rates
Individual risk-oriented two-stage first-trimester screening	Nuchal translucency measurement + first-trimester serum markers ± NB, DV, TR

DV, ductus venosus; NB, nasal bone; TR, tricuspid regurgitation.

In women undergoing second-trimester biochemical testing after first-trimester NT screening (with or without maternal serum testing), the background risk must be adjusted to take into account the first-trimester screening results. Otherwise, it should not be done. For example, a 41-year-old woman whose age-related background risk of having a fetus with trisomy 21 is 1 in 50 has reduced risk (e.g., 1 in 200) after a thin NT. If the risk then after second-trimester screening with serum markers is 1 in 100, this woman has an integrated risk of 1 in 400 because the NT measurement allowed a fourfold reduction of the background risk and maternal serum testing has done so by twofold. Use of both tests, therefore, divided the background risk by 8. Because first-trimester combined screen can identify almost 90% of pregnancies affected by trisomy 21, second-trimester serum testing identifies, at best, an additional 6% of affected pregnancies (60% of the residual 10%), but doubles the overall invasive testing rate from 5% to 10%. It is theoretically possible to use various statistical techniques to combine NT measurement with different components of first- and second-trimester serum testing.[133] One hypothetical model combines the first-trimester NT measurement and PAPP-A testing with second-trimester free β-hCG, estriol, and inhibin A testing (fully integrated test), claiming a potential sensitivity of 90%, for a 5% false-positive rate.[241] This offers no advantage over comprehensive first-trimester screening.

In a multicenter interventional study,[236] NT was measured at 12 to 14 weeks' gestation in 9444 women. Maternal serum markers were measured between 14 weeks and 1 day and 17 weeks' gestation. Karyotyping was delayed until after maternal blood was obtained. A combined risk for NT measurement and maternal serum markers was estimated retrospectively. The invasive testing rate generated by sequential two-stage screening was 8.6%, which means that 8.6% of patients underwent amniocentesis because of an increased risk generated by any of these tests. Twenty-one fetuses (0.22%) had trisomy 21. Adjusting for a 5% invasive testing rate, the detection rates would have been 55% and 80% for NT measurement alone and NT measurement combined with second-trimester serum marker testing, respectively. The results of the study suggest a 25% increase in the

detection rate with a combination of NT measurement at 12 to 14 weeks and serum marker studies between 14 weeks and 1 day and 17 weeks, with a 5% invasive testing rate and a modest increase in cost. Four other studies reported screening with a combination of fetal NT measurement in the first trimester and maternal serum marker testing in the second trimester, with similar results.[236–239]

Sequential (but not integrated) screening programs also increase the invasive procedure–related pregnancy loss rate. This increased rate is an important issue in populations in which the prevalence of Down syndrome is less than 1 in 1000 births. In these populations, an invasive testing rate of 8.6% might be considered unacceptably high in women who are at relatively low risk,[236] compared with the 5% rate

generated by a single-test screening program. A single risk assessment that integrates the results of NT measurement, free β-hCG levels, and α-fetoprotein levels with maternal age is possible. Here, it would be possible to keep the sensitivity as high as that obtained with combined screening while maintaining an invasive testing rate as low as 5%. However, the cost is also significant because the 25% increase in the detection rate would delay risk calculation and invasive testing by 2 to 4 weeks. Such information should be included in genetic counseling, especially when termination for fetal abnormality is an issue. Further, screening strategies in the first trimester are cost-effective compared with the use of second-trimester biochemical markers.[236]

SUMMARY OF MANAGEMENT OPTIONS
First-Trimester Screening for Fetal Abnormalities

Management Options	Evidence Quality and Recommendation	References
General Approach		
Prerequisites:	See also Chapter 4	
• Details of the history, examination, and routine tests completed and known relevant risk factors identified		
• Prescan interview, discussions, and counseling		
Screening is performed ideally between 11 and 14 wk.	III/B	235
Ultrasound is considered safe in both the short and the long terms.	Ib/A	243
First-Trimester Screening—Benefits		
Confirm viability.	III/B	7,10
Dating the pregnancy by crown-rump length before 14 wk is the most accurate method and decreases the risk of post-term pregnancy.	III	22,24–28, 207
Screening for fetal aneuploidy:		
• NT measurement, combined with maternal age and maternal serum markers for trisomy 21, has a detection rate of 80%–90%, for a 5% false-positive rate.	IIa/B	235,236
• Other chromosomal abnormalities are also more likely with increased NT thickness.	III/B	103–106
Detection of structural abnormalities:		
• Some major structural anomalies are detectable as early as 12 wk. These include anencephaly, holoprosencephaly, abdominal wall defects, and major limb defects.	IIb/B	71,109,113
• Detection rates are dependent on sonographer experience.	III/B	162
Multiple pregnancy:		
• Chorionicity is optimally determined by either visualization or absence of the lambda sign.	III/B	40
• Twin–twin transfusion syndrome is more likely in monochorionic pregnancies with increased NT thickness.	III/B	133
Examine the uterus and adnexal structures.	GPP	

GPP, good practice point; NT, nuchal translucency.

Videos corresponding to this chapter are available online at www.expertconsult.com.

INTRODUCTION

Every pregnant woman desires a healthy child who is free of anomalies. In the general population, the overall risk of having a child with a major malformation is 3% to 5%. As a greater proportion of women delay childbirth, the shortened reproductive window has increased the pressure on all for a successful outcome and rendered the increasing sophistication of ultrasonography and biochemical testing for fetal abnormalities of growing importance to obstetricians and their patients. We find that genetic sonography is a patient-driven service. This chapter focuses on noninvasive modalities of screening for fetal abnormalities in the second trimester.

In the early 1970s, the only method available to screen for fetal Down syndrome was based on maternal age; amniocentesis was offered to all women above a certain age, typically 35 years or older. However, maternal age proved a very inefficient screening tool with less than one third of fetuses with trisomy 21 identified by this means. In the 1980s, a new screening method incorporated second-trimester maternal serum biochemical markers in addition to maternal age. In the 1990s, screening for Down syndrome by combining maternal age and fetal nuchal translucency (NT) thickness in the first trimester was introduced (see Chapter 7). Subsequently, maternal serum biochemical markers of value in the first trimester were identified. In the recent past, three-dimensional sonography entered the arena of screening.

Invasive tests, such as amniocentesis, chorionic villus sampling, and cordocentesis, are diagnostic tools and not screening tests. They allow for essentially 100% accuracy in the diagnosis of fetal aneuploidy but carry a real risk of pregnancy loss. Thus, many women choose biochemical and ultrasound screening modalities for aneuploidy detection because the test efficiency (percentage of abnormal fetuses identified) is so much higher than that based on maternal age alone, even though they have a relatively high invasive testing rate (the so-called false-positive rate), typically set at 5%. Based on the result of the screening test, a decision is made as to whether an invasive test for diagnosis is indicated and acceptable to the patient. The combination of screening and diagnostic tests allows the maximum number of women to gain accurate information about their individual risk status.

SECOND-TRIMESTER BIOCHEMICAL SERUM MARKER SCREENING

Maternal serum testing in the second trimester for the screening of women at low risk for fetal aneuploidy, neural tube defects, and other fetal anomalies remains a standard of care in many countries. Screening for trisomy 21 in low risk patients (women < 35 yr) was initiated in the mid-1980s with the observation that the mean maternal serum concentration of α-fetoprotein was 0.7 multiple of the median (MoM) in affected pregnancies.[1-3] Subsequently, it was recognized that human chorionic gonadotropin (hCG) levels were higher (2.04 MoM) and unconjugated estriol levels were lower (0.79 MoM) in pregnancies with trisomy 21.[4-7] By using the relative risks derived from maternal serum levels, the maternal age–related risk can be modified and a "triple-screen" risk can be derived for each woman.

Triple-marker screening has been the preferred screening modality in some locales for the detection of fetal trisomy 21 in women younger than 35 years.[7-10] In this group, the triple-marker screen identifies approximately 60% of pregnancies affected by trisomy 21 as being at risk, with a 5% screen-positive rate (Table 8–1). In the population of women 35 years and older, the triple-marker screen identifies 75% or more of pregnancies affected by trisomy 21 and some other aneuploidies.[11] Because the maternal age–related risk of trisomy 21 is the basis of the serum screening protocol, both the trisomy 21 detection rate and the screen-positive rate increase with maternal age.[12] Different laboratories use different screen-positive cutoffs. For example, some use the midtrimester risk of trisomy 21 in a 35-year-old woman (1 in 270). Others apply a screen-positive cutoff that provides an acceptable balance between the detection rate and the screen-positive rate (usually 1 in 190 or 1 in 200).

Maternal serum screening can be performed between 15 and 20 weeks but is most accurate between 16 and 18 weeks. Similarly to first-trimester screening, the pregnancy must be dated accurately because an error will affect the assigned risk, causing false-negative and false-positive results. It is important to recalculate the results if the dates are found to be in error or to have a new sample drawn if the original sample was obtained before 15 weeks. Other factors that are

incorporated into the risk calculation include the number of fetuses, maternal weight, race, and diabetes.

Serum screening is used primarily to detect trisomy 21, and it does not efficiently detect other fetal aneuploidies, except for possibly trisomy 18. Thus, serum screening misses both lethal (e.g., trisomy 13) and sex chromosomal abnormalities that are not associated with severe physical or developmental limitations or profound mental retardation.

During the first trimester, the free beta subunit of hCG (β-hCG) is superior as a marker to the intact hCG molecule, but this has not been proved in the second trimester. In 1992, the potential use of a fourth analyte (inhibin) in second-trimester screening for Down syndrome was first suggested by Van Lith and coworkers.[13] The median value of the maternal inhibin A level is increased at 1.77 MoM in Down syndrome pregnancies. However, inhibin A is not used in the calculation of risk for trisomy 18.[14] Dimeric inhibin A has emerged as the most promising analyte and is used by many commercial laboratories in combination with the three traditional analytes. This four-analyte combination ("quad screen") detects 67% to 76% cases of fetal trisomy 21 in women younger than 35 years, with a screen-positive rate of 5% or less.[15,16] In 2003, Benn and colleagues[17] screened over 23,000 women for Down syndrome using the quadruple test. They found the sensitivity to be 85.8% for an initial false-positive rate of 9% (which was further reduced to 8.2% after correction for major gestational age errors).

Diagnostic options are limited for screening multiple gestations in the second trimester. In dizygotic twins, the risk of trisomy 21 is calculated by considering the maternal age–related risk and the probability that one or both fetuses will be affected. Thus, the midtrimester risk of trisomy 21 in at least one fetus of a twin gestation in a 33-year-old woman approximates the risk in a singleton pregnancy of a 35-year-old woman.[18]

FETAL ANATOMIC SURVEY ON SECOND-TRIMESTER SONOGRAPHY

The introduction of two-dimensional (2D) static scanning in the early 1970s allowed physicians to view the fetus for the first time. In the late 1970s and early 1980s, real-time B-mode imaging emerged as a widespread clinical tool. The major advantage of ultrasound is the lack of a demonstrable adverse fetal effect[19] because the image is generated with sound waves and not ionizing radiation. It quickly became the preferred method during pregnancy. Despite its apparent safety, some believe fetal sonography should be used only when there is a clear indication. However, most complicated pregnancies are unexpected and occur in low risk women, and ultrasound examinations are routine throughout pregnancy in many countries. We agree that all pregnant women should have access to expert obstetric sonography given that 90% of infants with congenital anomalies are born to women with no risk factors.[20] Ultrasound resolution has improved dramatically, and a detailed examination of the fetus for both structural anomalies and markers of aneuploidy is possible. The diagnosis and management of specific congenital fetal abnormalities are discussed in other chapters. We focus here on the elements of a complete sonographic fetal anatomic survey.

The sonographic examination should be systematic and thorough. Normal findings provide reassurance to patients, and the examination should detect most fetal malformations, along with abnormalities in fetal growth, the placenta, amniotic fluid, and the cervix. We also examined the value, from a patient's perspective, of a targeted ultrasound examination performed after an abnormal karyotype was discovered.[21] All women valued the scan because it helped them to visualize the fetal anomalies and accept the diagnosis of aneuploidy, which, in turn, affected their plans for pregnancy management. All patients considered the effect of the ultrasound greater than that of the chromosomal diagnosis alone, and all believed that ultrasound should be used for patients in similar clinical situations.

The American Institute of Ultrasound in Medicine (AIUM) first published standards for the performance of obstetric ultrasound in 1994.[22] The most recent AIUM *Practice Guideline for the Performance of Obstetric Ultrasound Examinations* was published in 2007.[23] Although it describes indications for second- and third-trimester ultrasound examinations, it notes that the list is by no means inclusive. Imaging parameters for a standard fetal examination in the second and third trimester include (1) fetal cardiac activity, number, presentation (multiple gestations require additional documentation); (2) qualitative or semiquantitative estimate of amniotic fluid volume; (3) placental location, appearance, and relationship to the internal cervical os; (4) imaging of the umbilical cord, and the number of vessels in the cord should be evaluated when possible; (5) gestational (menstrual) age (via biparietal diameter, head circumference, femoral diaphysis length, abdominal circumference, or average abdominal diameter); (6) fetal weight estimation; (7) maternal anatomy (uterus, adnexal structures, cervix); (8) and fetal anatomic survey.[23] The fetal anatomic survey, as described by the AIUM, involves the following areas of assessment: head, face, and neck, chest (including four-chamber view of the fetal heart), abdomen, stomach,

kidneys, bladder, abdominal cord insertion site, spine, extremities, and sex.[23] They note that the basic cardiac examination includes a four-chamber view of the fetal heart; however, if technically feasible, views of the outflow tracts should be attempted as part of the cardiac screening examination.[23]

Amniotic fluid
Cervix and lower uterine segment

This was a compromise document, and we suggest the current state of the art requires a more detailed examination than that described by the AIUM for optimal diagnostic accuracy of fetal abnormalities (Table 8–2). Moreover, sonographer training must be focused and audited to ensure these detailed examinations are done appropriately. The sonographer must be familiar with normal fetal anatomy, sonographic landmarks, and normal variants. An adequate examination requires proper equipment. The highest-frequency transducer should be used to maximize the resolution of the fetal anatomy.

The entire uterus is scanned transversely and longitudinally to determine the fetal position, amniotic fluid volume, and placental location. Accurate determination of the right and left sides of the fetus is crucial. Factors that may limit visualization (Table 8–3) include equipment quality, fluid abnormalities, maternal body habitus (discussed later) or tissue density, and other scanning characteristics. Techniques to improve visualization include changing the maternal position (to effectively change the fetal position) and using different scanning probes (including transvaginal). The timing of the second-trimester ultrasound varies with the center and physician preference. Repeating the examination later may aid the resolution of anatomic detail of some structures (e.g., heart) but hinder visualization of others (e.g., extremities). This is not to infer that scanning, even late in pregnancy, cannot provide important information and be highly sensitive for fetal anomalies whose diagnosis will alter pregnancy management. We recommend that the fetal anatomy survey be performed at 18 to 22 weeks to optimize the assessment of anatomy while leaving an adequate window for invasive testing, if necessary. Scans performed during this window are less likely than earlier scans to end incompletely and trigger the need for a repeat examination. In addition to evaluating the fetal anatomy, the number and position of fetuses should be determined. The placental appearance, thickness, echogenicity, and location are important to document, along with amniotic fluid volume. Amniotic fluid abnormalities may indicate an

anomalous fetus (e.g., anhydramnios is associated with renal agenesis and polyhydramnios with esophageal atresia). The fetal echocardiogram is best performed between 22 and 24 weeks, when the cardiac structures are larger.

Content of the Fetal Anatomic Survey

The examination begins with the fetal head and proceeds caudally. Imaging the fetal intracranial anatomy is extremely important because central nervous system anomalies can have a devastating effect on perinatal morbidity and mortality. The calvarium can be identified from the late first trimester onward. It should be well mineralized (hypomineralization may indicate a skeletal dysplasia) and elliptical in shape by the second trimester. Brachycephaly (anteroposterior shortening) suggests fetal trisomy 21 or 18 ("strawberry" head). A "lemon"-shaped head suggests a neural tube defect. Tangential imaging shows cranial sutures (hypoechoic spaces between bones) that are best visualized early in gestation. Premature closure of the sutures occurs in many syndromes (e.g., craniosynostosis) and with several skeletal dysplasias.

The transthalamic view is an axial view through the brain at the level of the thalami (Fig. 8–1). It is here that the biparietal diameter and head circumference measurements are obtained. Biparietal diameter is measured from the outer margin of the near calvarium to the inner margin of the far calvarium (with cranial bones perpendicular to the ultrasound beam). The head circumference is measured circumferentially at the outer margin of the calvarium (see Fig. 8–1). Other structures that are visualized in the transthalamic view include the cavum septum pellucidum (a fluid-filled midline structure anterior to the thalami), midline falx, third ventricle (between the thalami), and frontal horns of the lateral ventricles. A normal cavum suggests proper midline brain formation; its absence may signal abnormalities, such as holoprosencephaly, septo-optic dysplasia, or agenesis of the corpus callosum. The transventricular view is just superior to the transthalamic view and includes the lateral ventricles that contain sonolucent cerebrospinal fluid. Within this lies the echogenic choroid plexus that normally

fills the atrium and may contain cysts (a potential marker for trisomy 18) (Figs. 8–2 and 8–3). The cerebral ventricle is measured through the atrium in an axial plane and is normally less than 10 mm. The transcerebellar view contains the cerebellum and vermis, cisterna magna (between the dorsum of the cerebellar hemispheres and inner calvarium), and nuchal fold (Fig. 8–4). Visualization of this area is important to exclude spina bifida; obliteration of the cisterna magna and a banana-shaped cerebellum typically occur with this disorder. This view is also used to exclude Dandy-Walker malformation or variant, occipital encephalocele, and cerebellar agenesis or hypoplasia. The nuchal fold should be less than 6 mm, although with a breech presentation, an extended head onto the neck, or increased pressure by the transducer over the fetal head, this may create a false-positive thickening. The transcerebellar diameter provides a useful estimate of gestational age because it is relatively spared by fetal growth disturbances, including intrauterine growth restriction.[24] Sometimes, the fetal head is low in the pelvis, blocking access to the intracranial structures; in this case, transvaginal scanning is often useful.
FIGURE 8–2

FIGURE 8–5
Coronal view of the fetal face shows the nose, and upper and lower lips (*arrows*).
FIGURE 8–7
Profile of a fetus with Down syndrome shows frontal bone, but absent nasal bone.

The facial structures should be examined routinely because they are especially important for the diagnosis of genetic disorders or syndromes. This is accomplished with coronal (Fig. 8–5), sagittal (profile) (Fig. 8–6), and axial views. A combination of these planes is often optimal. Structures important to image include the chin (for micrognathia), nasal bone (NB; absent or shortened) (Fig. 8–7), nose, lips, anterior palate (to exclude cleft lip or palate), orbits (and diameters, if necessary, to exclude hypertelorism or hypotelorism), and ear (which may be shortened in aneuploid and nonaneuploid fetuses) (Fig. 8–8).

Next, the fetal spine is imaged in sagittal (Fig. 8–9), transverse, and coronal views, when possible. The overlying skin should be intact to exclude open spina bifida and masses or tumors. Each normal vertebral segment consists of three echogenic ossification centers (two located posteriorly and one located anteriorly that is the vertebral body) lying in a symmetrical, triangular configuration. In the transverse plane, the posterior processes appear angled in the same way as the roof of a house; if they are splayed, a neural tube defect should be sought (Fig. 8–10). Sagittal and coronal views are useful to observe how well the ossification centers

FIGURE 8–8

align to exclude hemivertebrae that cause disorganization or absence of ossification centers. The sacrum should curve gently upward.

The ribs, clavicles, and scapulae are examined next. A normal appearance excludes some types of skeletal dysplasia.

FIGURE 8–9
Normal sagittal view of the fetal spine. The overlying skin is intact, and the features of the spinal centers are parallel.

FIGURE 8–12
Apical four-chamber view of the fetal heart shows a single, bright, echogenic focus in the left ventricle (HELV).

Abnormal lung tissue or echogenicity (e.g., cystic adenomatoid malformation) or pleural effusions may be seen. The thoracic circumference is measured to exclude pulmonary hypoplasia, and the diaphragm is examined for evidence of a hernia.

A detailed fetal cardiac examination is perhaps the most challenging task for the sonographer. The cardiac rate and rhythm (normally 120–150 beats/min and regular), size (one third of the fetal thorax), axis and position (apex points to the left at an angle of 45 ± 20 degrees relative to the midline), and situs should be established (liver on the right, stomach on the left). Alterations in position, axis, or both suggest malposition or an intrathoracic mass causing mediastinal shift. Multiple planes and views are used in real time to exclude cardiac defects. Routine imaging of the outflow tracts increases detection sensitivity and should be part of the standard fetal cardiac examination. When screening for cardiac defects, the examination should include, minimally, the four-chamber apical (Fig. 8–11) and subcostal views, outflow tracts, longitudinal parasternal arches (aortic and ductal), inferior and superior venae cava, valves, and atria and ventricular septa. The chambers are roughly equal in size. The pulmonary veins should enter the left atrium; the two atrioventricular valves and septa should be visualized in

their entirety, and the rate and rhythm documented as well as the axis, position, and size of the heart. The great vessels should cross each other, and there should be no dependent pericardial fluid. Some recommend routine color, M-mode, or pulsed Doppler sonography to assist in the visualization of the heart and great vessels and to exclude significant valvular stenosis or regurgitation (see Chapter 16 for a discussion of specific cardiac abnormalities). An echogenic focus is commonly seen, typically in the left ventricle. It is caused by specular reflection from the papillary muscles and chordae tendineae (Fig. 8–12).[25]

Identifiable intra-abdominal organs include the liver (occupying most of the upper abdomen), spleen (solid organ posterior to the stomach), gallbladder (teardrop-shaped organ in the right upper quadrant, at the inferior edge of the liver), stomach, bowel, umbilical vein, and umbilical cord insertion site. The abdominal circumference is the single most sensitive fetal growth parameter. It is measured at the transverse level, where the umbilical vein joins the right portal venous system (Fig. 8–13), which should "curve" away from the stomach. If the curve is toward the stomach, persistence of the right umbilical vein is suspected. The stomach and spine should be imaged in this axial plane; the stomach should always be located below the diaphragm. An absent

FIGURE 8–13

or small stomach, despite prolonged scanning to allow for filling, suggests esophageal atresia, with or without tracheo-esophageal fistula, or a diaphragmatic hernia (stomach located within the chest). Most of the abdomen is bowel-filled, and the appearance varies with gestational age. In the second trimester, the bowel appears as midlevel to increased echogenicity filling the abdomen. Hyperechoic bowel is associated with aneuploidy, infection, cystic fibrosis, and bowel abnormalities, and may also be seen with intrauterine growth restriction. In the third trimester, prominent hypoechoic loops of colon may be seen. More dilated loops of bowel may reflect atresia or another cause of obstruction. The umbilical cord insertion and the adjacent ventral abdominal wall should be visualized to exclude ventral wall defects (e.g., omphalocele, gastroschisis). There should be no fetal ascites.

Next visualized is the genitourinary tract, which is a common site for fetal anomalies. The kidneys are bilateral, hypoechoic, paraspinal structures that include the urine-containing renal pelvis. Abnormal findings include dilation of the renal pelvis, calix, or ureter; renal masses; cysts within the parenchyma; hyperechogenicity; and enlargement or absence of the kidneys. Color or power Doppler imaging is useful to identify the renal arteries, especially when the kidneys cannot be seen in their usual location. It is important to distinguish between pyelectasis (dilated renal pelvis) and hydronephrosis (pyelectasis plus upper tract dilation). The bladder is a urine-filled structure located midline, anterior, and low in the fetal pelvis. Absence of the fetal bladder (bladder exstrophy) or a very enlarged bladder (lower obstructive uropathy) should be excluded. The sonographer should confirm that the two umbilical arteries course around the fetal bladder. This image all but excludes a two-vessel cord. Gender is assigned by imaging the genitalia, and not by the lack of an image. Ambiguous genitalia should be excluded. The fetus is male if both the penis and scrotum are seen. The testicles are echogenic and usually descend into the scrotum around 28 weeks. The labia appear as several parallel linear echoes.

All extremities (including hands and feet) should be surveyed because they might provide important diagnostic information. The five fingers should extend fully (Fig. 8–14). Movement and tone should be normal, and the middle
phalanx of the fifth digit should be visualized. Persistently clenched hands with overlapping digits are a highly sensitive (95%) sonographic feature for trisomy 18.[26] The long bones (femur, humerus, radius and ulna, tibia and fibula) should be well mineralized and of normal length. Absence, fractures, contractures, or bowing of these bones is abnormal. The ulna extends farther into the elbow than the radius, and the tibia extends farther into the patella than the fibula. The length of each long bone is measured. Images are obtained with the diaphysis located horizontally in the image (Fig. 8–15) because vertical measurements can falsely "shorten" the length. Multiple images are measured and the longest technically adequate image is the optimal measurement. The lower extremities should not be clubbed, nor should the plantar surface appear "rocker-bottom." There should be five toes (Fig. 8–16), and they should not appear dysplastic. The foot length can also be measured.

Finally, the umbilical cord is examined. There should be two arteries and one vein. Once the umbilical vein enters the fetal abdomen, it should turn superiorly, enter the liver, and communicate with the portal vein. The umbilical vein continues into the ductus venosus and then into the inferior vena cava and right atrium.

Third-trimester fetal foot shows five toes present.
Second-Trimester Ultrasound Screening for Structural Abnormalities

There are many accepted indications for ultrasound examination during pregnancy, and 60% to 70% of all pregnant women in the United States undergo an examination at some stage during pregnancy.[27] The rate is much higher in most other industrialized countries. One of the first studies to quantify the diagnostic accuracy of ultrasound in high risk pregnancies was performed in the United Kingdom in the late 1970s and early 1980s; 95% of malformations were correctly diagnosed.[28] Subsequently, many studies examined the efficacy of routine screening ultrasound. Published sensitivities range from 13.3% to 82.4%,[29] with the collaborative world experience approximating 50%.[30] We suggest that much of the variation reflects differences in the quality of training because there are huge differences among countries in the skill level of accredited sonographers. In light of the wide variations in detection rates, it is understandable why the reliability and utility of sonographic screening for fetal malformations have been challenged. Even among those who recommend routine ultrasound screening, the number and timing of scans are debated. Because 75% of patients with abnormal fetuses are considered low risk, it is important we review the literature to assess the effect of routine sonography.[29]

The antenatal diagnosis of a fetal abnormality has many advantages. It may trigger additional testing to refine the diagnosis or prognosis, alter pregnancy management (e.g., termination, intrauterine therapy, early delivery, and delivery in a tertiary care center), prepare the parents for an adverse pregnancy outcome, and alert the clinician to the possibility of other malformations. For many patients, the benefits of sparing social and psychological costs are also very important. However, the fact that no one contests is that sonographic screening performed by inexperienced individuals increases the costs of health care and generates high false-negative and false-positive rates, with serious consequences, such as termination of an actually normal fetus.

Many biases and problems explain much of the variation in sensitivity.[29] They include technical issues (e.g., fetal positioning, obesity), lesions that resolve over time, and the undetectability of certain anomalies by ultrasound. Selection bias may play an important role, depending on whether the patient population served is derived from a hospital or an office practice. The most important bias is the variation in sonographic skills, capability, and experience of individuals performing the ultrasound examination. In the Helsinki study, which incorporated patient populations from two hospitals, the sonographic sensitivity for detecting anomalies was twofold higher in the university hospital than in the city hospital (77% vs. 36%).[31] A systematic and almost compulsive approach to each examination is necessary, with attention paid to all structures. Each center has different criteria as to what constitutes a detailed ultrasound examination. The less detailed the examination, the lower the sensitivity. Patient selection is also important. Screening high risk women (e.g., those with a prior ultrasound suggestive of congenital anomalies, positive family history, or teratogen exposure) is likely to be more effective because sonographers tend to be more focused, expecting to find an anomaly. One group noted an average sensitivity of 55% in a low risk population and 92% in a high risk population.[29]

Gestational age at screening also affects sensitivity because various anomalies may appear at different gestational weeks. Some are seen only later in gestation (e.g., duodenal atresia). The more scans a patient undergoes, the greater the anomaly detection rate. Levi[29] reported that the average sensitivity of studies that included only scans performed once before 20 weeks was 45%. The sensitivity increased to 60% if the scanning was performed several times during the pregnancy. The type of congenital anomaly plays a role in the detection rate of congenital abnormalities on sonography. For example, a complex cardiac defect is more likely to be detected than a small atrial septal defect.

The prevalence of specific malformations within a population can significantly affect the sensitivity of ultrasound screening. Studies that exclude certain anomalies because they are considered either minor or undetectable can dramatically alter the sensitivity compared with a calculation that includes all anomalies. A 1996 study found that the sensitivity of ultrasound for diagnosing both minor and major anomalies was only 8.7%; however, if only major anomalies detectable by ultrasound were included, the sensitivity rose to 75%.[30]

Finally, other factors may affect the reported fetal anomaly detection rates, such as a lack of autopsies (the gold standard), suboptimal neonatal evaluation, and inadequate length of neonatal follow-up (some anomalies may not express themselves immediately after birth).[29]

Obesity is a global health problem of increasing prevalence. The World Health organization (WHO) characterizes obesity as a pandemic issue, with a higher prevalence in females than in males.[32] Accordingly, many pregnant patients have a high body mass index (BMI), and the examination is compromised by sound attenuation (Video 8–1). This can lead to repeat sonographic examination attempts throughout gestation in order to improve visualization. One group observed that repeated ultrasound examinations for suboptimal visualization of the fetal heart at a later gestational age dramatically reduced suboptimal visualization; however, obese patients continued to have much higher rates of persistent suboptimal visualization.[33] In another study, Hendler and associates[34] found that maternal obesity increased the rate of suboptimal visualization of fetal cardiac structures by 49.8% and of the craniospinal structures by

31%. They reported that the optimal gestational age for visualization of these areas in obese patients was after 18 to 20 weeks. Increased maternal BMI may also affect the accuracy of the sonographic estimate of fetal weight. A recent study in 2009 found that the proportion of estimated fetal weights within ±10% and within ±20% of the birth weight significantly decreased with increasing BMI categories.[35] One strategy we use to optimize sonographic visualization is to perform the ultrasound examination in the early second trimester transvaginally, with a repeat sonogram several weeks later, if necessary.

Unfortunately, obesity confers a higher rate of early miscarriage and congenital anomalies, including neural tube defects.[32] In 2009, a systematic review and meta-analysis was performed examining maternal obesity and the risk of congenital anomalies.[36] Compared with women of recommended BMI, obese women were at increased odds of pregnancies affected by neural tube defects, hydrocephaly, cardiovascular anomalies, cleft lip and palate, anorectal atresia, and limb reduction anomalies. The authors noted that further studies are needed to confirm whether being overweight rather than obese confers the same risks.

The Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) trial was the first randomized clinical trial of second-trimester ultrasound in the United States conducted in the 1980s.[37] The trial recruited patients from 109 practices (81 private, 15 academic, and 13 health maintenance organizations). The content of the examinations consisted of the following: identification of the number of fetuses, presentation, placental location, amniotic fluid volume, biparietal diameter, head circumference, abdominal circumference, femur length, and an anatomic survey, including intracranial anatomy, four-chamber view of the heart, demonstration of the spine in transverse and coronal planes, stomach, kidneys, bladder, umbilical cord insertion, and all extremities. More than 15,000 pregnant women were randomly allocated to either routine scanning or an ultrasound examination only when indicated. An additional scan was performed in the study group early in the third trimester. The goal of the trial was to determine the benefits, if any, of routine ultrasound among pregnant women at low risk. Although the identification rate of anomalies in this study was three times better with routine versus indicated ultrasound (35% vs. 11%, respectively), the sensitivity of 17% for anomalies detected between 15 and 22 weeks was extremely low.

The findings of the trial underwent intense scrutiny. One potential source of bias was that practice-based patients were used, which may have created an inadvertent selection bias (vs. a community- or hospital-based population). Others criticized the simplicity of the scans performed. The investigators reported a relative detection rate of 2.7 (95% confidence interval [CI] 1.3–5.8) for tertiary compared with nontertiary ultrasound units.[37] The detection rate of anomalous fetuses was 35% versus 13% in nontertiary centers. Sonographic screening did not significantly affect the management or outcome of pregnancies complicated by congenital malformations. This was to be expected because there was no standardized response to the sonographic findings. Diagnostic ultrasound is not a therapeutic instrument.

In 1998, Van Dorsten and coworkers[38] reported that the sensitivity of ultrasound for anomaly detection at a tertiary care center (in women at risk for anomalies) was 89.7%. Although the sensitivity was decreased (47.6%) in the lower risk population (screening group), it was sufficient to ensure cost-effectiveness for the patients.[38] In 1999, the Eurofetus group[39] reported the results of a study designed to evaluate the sensitivity of routine ultrasound screening for fetal malformations. Nearly 200,000 pregnant women (the largest group among screening studies) were enrolled and evaluated in 60 hospital laboratories in 14 countries. The sensitivity rate was 64% (2363 of 3685), a rate much higher than that in the RADIUS study. However, the two trials may not be comparable. Women in the RADIUS trial were at very low risk because strict exclusion criteria were applied before patient recruitment occurred. Further, the criteria used to designate major fetal anomalies (gold standard) were very liberal. Both of these factors could have lowered sensitivity. In contrast, all women in the Eurofetus trial were studied, regardless of risk status, and only "truly" major abnormalities were considered as endpoints; this classification may have artificially raised the sensitivity of the ultrasound screening.

Women in the Helsinki trial[40] underwent one screening examination in the second trimester; 40% of major fetal anomalies were detected, including most anomalies of the central nervous system or genitourinary system and cases with multiple anomalies. In this trial, screening was less effective in detecting cardiac and gastrointestinal tract anomalies. This finding is logical because many bowel abnormalities are sonographically "silent." In addition, cardiac morphology changes in response to malformations and might not be seen when first imaged, unless flow abnormalities are sought. In the 1991 Belgian Multicentric Study,[41] 154 of 381 structurally abnormal fetuses were correctly detected by ultrasound (sensitivity 40%). The specificity and positive and negative predictive values were 99.9%, 95%, and 98.6%, respectively.

We examined the efficacy of a complete sonographic survey (as described in this chapter) for the detection of fetal abnormalities and correlated the findings with perinatal autopsy results.[42] Of 88 abnormal autopsy findings, 85 fetuses had one or more abnormal structural sonographic findings, giving a sensitivity of 97% for anomalous fetuses. The low sensitivities reported in the past may be, in great part, the result of a failure to look for specific abnormalities. On autopsy, 372 separate abnormalities were found. Antenatal sonography detected 75% and 18%, respectively, of the 299 major and 73 of the minor abnormalities. Thus, the sensitivity for minor abnormalities was poor, even when a complete sonographic survey was performed. In 65% of cases, there was either complete agreement or only minor differences between sonographic and autopsy findings.[42]

Because sensitivity for the antenatal sonographic detection of fetal anomalies is highly dependent on the clinical setting and the expertise of the sonographer, there is insufficient evidence to list a single estimate of the sensitivity of routine ultrasound as a screening tool for fetal anomalies. However, the specificity of a fetal anatomic survey exceeds 99% in many studies.[37,43–45] Specificity measures the proportion of negatives that are correctly identified (i.e., the percentage of truly normal fetuses who are identified as normal on ultrasound) and is related inversely to the rate of false-positive diagnoses. Therefore, in low risk patients,

ultrasound is helpful in excluding anomalies and detecting normal features but may not be equally reliable in detecting anomalies. The sensitivity of screening programs should continue to improve because of technological advances (e.g., three-dimensional sonography) and uniform and detailed training of practitioners.[29]

Antenatal detection of an anomalous fetus, especially one with a life-threatening defect, allows the delivery of these infants in a tertiary care center that can provide immediate and appropriate care, maximizing survival. Is this statement supported by evidence in the literature? In the 1994 RADIUS study,[37] screening did not affect the detection, management, or outcome of fetuses with anomalies. However, of the infants with life-threatening anomalies, 75% (21 of 28) survived in the routinely screened group, compared with 52% (11 of 21) in the nonscreened group.[37] The study may have been inadequately powered to address this specific question, and although many fetal medicine practitioners are convinced, additional studies are required.

Another important question is whether routine ultrasound improves overall perinatal morbidity and mortality rates. For example, routine sonography increases the accurate detection of multiple gestations, gestational age, and placental abnormalities. Table 8–4 summarizes three trials that investigated the perinatal morbidity and mortality rates of pregnancies in which routine ultrasonography was performed.[27,31,46] The perinatal mortality rates were similar in the routine sonography and control groups in both the RADIUS[27] and the Stockholm[46] trials. However, the perinatal mortality rate in the Helsinki trial[31] was significantly lower in the routine ultrasound group (4.6 of 1000 vs. 9.0 of 1000). This difference was attributable mainly to improved early detection of major malformations, leading to pregnancy termination.[31] There were no differences in perinatal morbidity rates between the study and the control groups in these three trials (see Table 8–4).[27,31,46] Although two trials had a similar distribution of birth weights between study groups,[27,31] the third trial had fewer births less than 2500 g in the routine ultrasound group.[46] The mean birth weight was also higher

in the routine ultrasound group in women who smoked, and the authors speculate that this difference may be attributable to healthier maternal behaviors after these women saw their fetuses on ultrasound.[46] Although the authors of the RADIUS trial concluded that the adoption of sonographic screening in the United States would increase health care costs without improving perinatal outcome or providing measurable benefit from early detection of fetal anomalies, another study concluded that routine screening for anomalies improves perinatal outcome by leading to termination of pregnancy for certain anomalies and delivery at tertiary care centers for life-threatening malformations.[38] The prospective trials also showed that twin gestations are diagnosed earlier with routine sonography. In the Helsinki trial,[31] 100% of twins were detected before 21 weeks in the routine ultrasound group, compared with 76% in the control group. Furthermore, the perinatal mortality rate was reduced (27.8 of 1000 vs. 65.8 of 1000).

A subgroup analysis was also performed in the RADIUS study[27] for infants who were small for gestational age and neonates born at 42 weeks or later. There was no improvement in overall outcome for these conditions when routine ultrasound was performed. The available evidence indicates that routine sonography will, at a minimum, improve perinatal outcome in low risk pregnancies by decreasing perinatal mortality rates following induced abortions after the detection of fetal abnormalities.

Sonographic screening for anomalies may also provide value to both patients and physicians that are not quantifiable in terms of psychological reassurance, antepartum management, referral, genetic counseling, or preparation of families and health care providers. The benefits discussed earlier may outweigh the "risks" of ultrasound (e.g., false-positive diagnosis). Most patients will choose anomaly screening if given a choice and counseled on the current diagnostic capability of sonography. Pregnant women usually do not perceive ultrasound as a "test," but rather as a tool to evaluate the fetus as a patient. We agree with this philosophy and argue that examination of the fetus as a

---

TABLE 8–4

Three Trials Comparing Perinatal Morbidity and Mortality Rates in Patients Undergoing Routine Ultrasonography (vs. Control Groups)

TRIAL	PERINATAL MORBIDITY	PERINATAL MORTALITY	P	MEAN BIRTH WEIGHT AND NO. OF INFANTS WITH LOW BIRTH WEIGHT (<2500 G)	P

patient should be a routine practice, as it is in all aspects of adult medicine.

The last screening issue to address is the cost-benefit analysis of routine second-trimester sonography. We performed a cost-benefit analysis based on the RADIUS trial, comparing routine second-trimester sonography in low risk pregnant women with a policy of not offering screening. Routine second-trimester sonographic screening is associated with net benefits only if the sonogram is performed at a tertiary care center.[47] Another study showed that a one-stage second-trimester screening ultrasound was both cost-effective and associated with fewer perinatal deaths.[48] Finally, Van Dorsten and coworkers[38] assessed the cost-effectiveness of anomaly screening in their patient population and concluded that routine screening was cost-effective. There seems to be little doubt that the cost-effectiveness of routine sonographic screening for fetal anomalies rests not on the tool but on the caliber of the sonographer. The costs of poor sonography cannot continue to be tolerated in an already stressed health care system. The cure is not to deny women access to valuable screening techniques; the cure is to require proof of the sonographer's skill.

Sonographic Aneuploidy Markers and Genetic Sonography

The most common autosomal trisomy in liveborn infants is Down syndrome, or trisomy 21, which was first described by John Langdon Down in 1866. Autosomal trisomies are primarily the result of meiotic nondisjunction, the risk of which increases with maternal age. The first screening method for fetal trisomy 21 was introduced in the early 1970s and was based on maternal age. Amniocentesis was offered to women 35 years or older, based on the findings of an early study that stated that the risk of a procedure-related loss approximated the likelihood that a midtrimester fetus of a 35-year-old woman would have trisomy 21 (1 in 270). There has been a fundamental shift in birth trends since the 1970s, with more births occurring to women older than 35 years.[49] In 1974, women 35 to 49 years old accounted for just 4.7% of live births compared with 12.6% in 1997.[49] As a result, the prevalence of fetal trisomy 21 during the second trimester has increased from 1 in 740 in 1974 to 1 in 504 in 1997. However, the fact remains that most infants with trisomy 21 are born to women younger than 35 years. Fetuses with aneuploidy account for 6% to 11% of stillbirths and neonatal deaths,[50] whereas chromosomal defects that are compatible with life, but associated with significant morbidity, occur in 0.65% of newborns.[51]

In January 2007, the American College of Obstetricians and Gynecologists (ACOG) in their *Practice Bulletin*[52] raised the issue of whether invasive diagnostic testing for aneuploidy should be available to *all* women. They stated that the decision to offer invasive testing should not be solely age-based, and that a maternal age of 35 years alone "should no longer be used as a cutoff to determine who is offered screening versus who is offered invasive testing." Therefore, all women (regardless of age) should have the option of invasive testing.[52]

Nevertheless, among high risk women while some will choose to have invasive testing as a first option, others will instead first undergo either first-trimester screening or second-trimester genetic sonography (± biochemistry) and use the information derived from ultrasound to obtain an adjusted risk for Down syndrome to guide their decision about genetic amniocentesis. Accordingly, the genetic sonogram evolved from a patient's perspective, with the purpose of possibly avoiding invasive testing.

A large body of literature attests to the specific use of second-trimester genetic ultrasonography for antenatal detection of trisomy 21 by seeking aneuploidy markers. We offer genetic sonography as an option to all (and only) high risk patients (i.e., advanced maternal age at the time of delivery, abnormal serum marker screen results, or both). The information derived from this sonogram is used to generate an adjusted risk of Down syndrome to guide a woman's decision about genetic amniocentesis. When the findings on genetic sonogram are normal in high risk patients, the amniocentesis rate is only 3%.[53] The amniocentesis rate increases in direct proportion to the number of abnormal sonographic markers identified, with almost 100% of women selecting invasive testing when four or more markers are seen. Since the initiation of our genetic sonography service in 1992, over a 10-year period, more than 5000 women have avoided amniocentesis based on normal findings on genetic sonogram. If the fetal loss rate related directly to amniocentesis is between 1 in 100 and 1 in 300, then more than 17 to 50 fetal lives were saved, attesting to the power of genetic sonography.

Screening based on maternal age identifies at most 47% of fetuses with trisomy 21, with a false-positive rate of 13% to 14% (a rate that has increased in recent years).[49] Based on advanced maternal age, 140 amniocentesis procedures are required to detect one fetus with trisomy 21,[54] implying that one healthy fetus will be lost for every two to three affected fetuses identified. Although the combination of maternal age and second-trimester biochemical screening results increases the detection rate to 60% to 65%,[12] 60 to 70 amniocentesis procedures are required to detect one fetus with trisomy 21.[54] Thus, one healthy fetus will be lost for every three to five fetuses in which trisomy 21 is detected. As a result, some have challenged the practice of offering invasive testing to all high risk pregnant women (based on age or second-trimester biochemical screening results).[12] Reducing the screen-positive rate is beneficial, regardless of an individual's personal opinion on testing. Genetic sonography reduces the invasive testing rate by refining the selection of candidates for invasive testing without significantly decreasing detection rates.

Ideally, genetic sonography is performed between 18 and 20 weeks. The window may be shifted higher to 20 to 22 weeks if the option of pregnancy termination is not lost by the delay because visualization might improve. It is a targeted examination for fetal aneuploidy (predominantly trisomy 21) during which the sonographer searches for abnormal fetal biometry, fetal structural anomalies, and other markers of aneuploidy.[53] Because only 25% of fetuses with trisomy 21 have a sonographically detectable major anomaly in the second trimester,[54] the examination must include other markers to increase sensitivity (Table 8–5). Markers of aneuploidy that are detectable on ultrasound include shortened long bones, increased nuchal fold thickness (Fig. 8–17), pyelectasis (Fig. 8–18), choroid plexus cysts (see Fig. 8–3), short ear length, wide iliac wing angle,

TABLE 8–5

Aneuploidy Markers of the Genetic Sonogram

Structural anomalies, including cardiac (four-chamber and outflow tracts)

Short femur (observed to expected < 10th percentile)

Short humerus (observed to expected < 10th percentile)

Pyelectasis (anteroposterior diameter of renal pelvis ≥ 4 mm)

Nuchal fold thickening (≥6 mm)

Echogenic bowel (similar to echogenicity of iliac bones)

Choroid plexus cysts (>10 mm)

Hypoplastic middle phalanx of the fifth digit

Wide space between the first and the second toes (sandal gap)

Two-vessel umbilical cord

Echogenic intracardiac focus, short tibia, short fibula, short ear (since October 1997)

Absent nasal bone (since 2003)

FIGURE 8–19

hyperechoic bowel, echogenic intracardiac focus (see Fig. 8–12), sandal gap toes (Fig. 8–19), hypoplastic midphalanx of the fifth digit, clinodactyly, and absent NB (see Fig. 8–7). The risk of fetal trisomy 21 increases with the number of markers present. Each marker alone (except thickened nuchal fold or absent NB) has low to moderate sensitivity for trisomy 21 and does not necessarily increase the risk of aneuploidy when found in isolation in low risk patients. However, the risk of fetal aneuploidy may increase when thickened nuchal fold, absent NB, or multiple sonographic abnormalities or markers are detected in low risk patients or when any isolated markers are seen in high risk patients.

A thickened nuchal fold (sensitivity 40%; false-positive rate 0.1%)[55] along with absent NB (41% sensitivity and 100% specificity for fetal trisomy 21) are among the most sensitive and specific markers for Down syndrome and involve straightforward training.[56] Importantly, when we added absent NB to the other sonographic markers of aneuploidy, the sensitivity of genetic sonography increased from 83% (24 of 29) to 90% (26 of 29).[56] Absence of the NB was noted in two fetuses with trisomy 21 with no other ultrasound markers for aneuploidy.

There is a large overlap in bone measurements between affected and normal fetuses. A short femur length (measurement-to-expected length ≤ 0.91) is found in 24%,[57] and a short humerus (measurement-to-expected length < 0.90) in 50% of affected fetuses, with a false-positive rate of 6.25%.[58] The sensitivity of pyelectasis (anteroposterior diameter of the renal pelvis ≥ 4 mm in the second trimester) for trisomy 21 is 25%.[58] Echogenic bowel has a reported sensitivity of 7% to 12.5%, whereas an echogenic intracardiac focus (see Fig. 8–12) has a reported sensitivity of 18%.[58] We examined the sensitivity of a short sonographic ear length for trisomy 21.[59] Forty-one percent (21 of 51) had an ear length at or below the 10th percentile. However, a short ear length was not as sensitive a marker for trisomy 21 as it was for trisomy 13 (100%) or trisomy 18 (96%). The association between trisomy 21 and choroid plexus cyst(s) is controversial.

In 2008, Molina and colleagues[60] examined the fronto-maxillary facial (FMF) angle in normal (n = 150) and trisomy 21 fetuses (n = 23) at 16 to 24 weeks of gestation using three-dimensional ultrasound. In the normal group, there

was no significant association between the FMF angle and gestational age. The mean FMF angle was 83.9 degrees (range 76.9–90.2 degrees), and the 95th percentile was 88.5 degrees. In 65.2% ($n = 15$) of the Down syndrome fetuses, the FMF angle was greater than 88.5 degrees. Therefore, they concluded that in the majority of second-trimester fetuses with trisomy 21, the FMF angle is increased.

Several studies have reported the accuracy of genetic sonography to detect trisomy 21 in high risk populations.[53] When "abnormal" is defined as the finding of at least one marker on ultrasound, the overall sensitivity was 77% (range 50%–93%), and the false-positive rate was 13% (range 7%–17%).[53] Thus, whereas it is clear that the use of multiple sonographic markers improves the sensitivity of sonography for detecting trisomy 21, it also results in a higher false-positive rate. In 1998, an 11-center collaborative study examined the sensitivity of sonography for the detection of trisomy 21.[61] Eighty-five percent of fetuses with trisomy 21 ($n = 241$) had at least one abnormal finding on ultrasound. In 2003, an eight-center study evaluated the utility of second-trimester genetic sonography in high risk women, including 176 fetuses with trisomy 21.[62] The sensitivity for the detection of trisomy 21 was 72% (center range 64%–80%). Approximately half (47%) of the fetuses with trisomy 21 had a thickened nuchal fold of 5 mm or more.

In 1996, our group[63] was the first to publish findings on the use of second-trimester genetic sonography to guide clinical management of pregnancies in women at high risk for trisomy 21. In 1999, we began to counsel women that the likelihood of trisomy 21, in the absence of abnormalities or markers, was reduced by at least 80% from the a priori risk (second-trimester biochemical screening results or, if unavailable, maternal age).[53] Our experience was reassuring. Over almost a 10-year period (November 1992–August 2002), we evaluated 5299 fetuses with genetic sonography. The findings were normal in 85% (no markers seen); 12% had one marker, and 3% had two or more markers. When at least one marker was present, the sensitivity, specificity, and positive and negative predictive values for trisomy 21 were 87% (52 of 60), 91% (4395 of 4831), 11% (52 of 488), and 99.8% (4395 of 4403), respectively. Approximately two thirds of fetuses with trisomy 21 had two or more abnormal sonographic markers.

Over the years, we have found that more and more high risk women prefer genetic sonography as their first option, rather than amniocentesis (Table 8–6). Since 1998, more than 70% of women chose to begin with genetic sonography. Accordingly, the number of amniocenteses performed has decreased. The total amniocentesis rate (the sum of amniocentesis procedures as the first option plus amniocentesis procedures performed after genetic sonography) decreased from 99.6% in 1993 to 32% in 2002. Several years ago, we examined the accuracy of genetic sonography for the detection of fetal trisomy 21 according to the indication for testing (advanced maternal age, abnormal second-trimester biochemical screening results, abnormal second-trimester biochemical screening results in women younger than 35 years, and abnormal second-trimester biochemical screening results in women 35 years and older). We also examined the risk of trisomy 21 after normal findings on genetic sonography.[64] We found that the magnitude of the risk adjustment after normal findings on a genetic scan was independent of

* Includes advanced maternal age (≥35 yr) with or without abnormal serum biochemistry results, abnormal serum biochemistry results in women younger than 35 years, or family history of chromosome abnormality.
† Includes women who underwent genetic amniocentesis only as their first option and women who underwent amniocentesis after genetic sonography.
‡ The genetic sonogram service was available for only 2 months in 1993 (November and December).

the testing indication and there were no significant indication-specific variations in the accuracy of genetic sonography.

Although some advocate second-trimester genetic sonography for screening of the general population, we believe that it should be reserved only for the high risk population for several reasons. First, a high degree of expertise is required to exclude sonographic fetal malformations (especially subtle cardiac defects), and this expertise is not widely available in many countries including the United States. Second, the application of genetic sonography to low risk women may be inappropriate and perhaps dangerous, in light of the high screen false-positive rate (12%–15% in the high risk population), which is likely even higher in a low risk population. In low risk women, the a priori risk of trisomy 21 may be so low that the presence of one aneuploidy marker (e.g., pyelectasis) would not elevate the risk enough to justify amniocentesis. Therefore, with this approach, the positive predictive value and perhaps even the sensitivity of genetic ultrasound for fetal trisomy 21 are likely to be decreased in low risk patients. Third, the accuracy of second-trimester aneuploidy markers has been studied mainly in high risk populations. Extrapolation of such accuracy to low risk women may not be appropriate. Some have concluded that an isolated marker (other than increased nuchal fold thickness, absent NB, or structural anomalies) should not be used as an indication for amniocentesis testing in the low risk population.[53] Others argue that if it is applied to the low risk population, any risk adjustment must reflect both the a priori risk of trisomy 21 and the sensitivity of the specific marker identified.

Clinicians should not recommend amniocentesis to low risk patients who have an isolated marker identified because the sensitivity is low, with the possible exception of increased

nuchal fold thickness[65] and/or absent/hypoplastic NB. However, the incidental finding of an organ or structural anomaly (with few exceptions), nuchal fold thickening, absent/hypoplastic NB, or two or more aneuploidy markers in a low risk patient should trigger counseling and informed consent with the patient. The patient should be informed that if the accuracy of genetic ultrasound is extrapolated from high risk to low risk women, then the risk of trisomy 21 is likely high enough to justify offering genetic amniocentesis. In these patients, the risk of trisomy 21 is higher than the risk of amniocentesis-related fetal loss, regardless of maternal age or second-trimester biochemical screening results (unless the a priori risk < 1 in 10,000). Certain isolated sonographic fetal abnormalities (e.g., gastroschisis) are not usually associated with aneuploidy and do not require further invasive testing.

The following description is the approach that we have used successfully with high risk patients. Genetic sonography is an adjunct to maternal age and serum screening (triple or quadruple, whichever is available) to adjust the risk of fetal trisomy 21 for each patient, based on our accuracy. The a priori risk is based on serum screening results. If serum screening results are not available or if testing was not performed, the risk is based on maternal age. We then multiply the a priori risk with various likelihood ratios (LRs), depending on the presence or absence of aneuploidy markers. For example, if the a priori risk of fetal trisomy 21 is 1 in 274 and the results of genetic sonography are normal, the adjusted risk of fetal trisomy 21 is (1 in 274 × 0.20 [1/5 residual risk]), or 1 in 1370, a reduction of at least 80%. The degree of risk reduction depends on several factors, such as the sensitivity of the ultrasound and the criteria and number of aneuploidy markers sought. Most recent studies utilize a negative LR that ranges somewhere between 0.2 and 0.4 after a normal genetic scan, corresponding to a 60% to 80% reduction in risk. The revised risk is then discussed with the patient. The patient should be told that the genetic scan can never reduce her risk to 0%. In our experience, the presence of only one of the following markers increases the risk of trisomy 21 minimally or not at all: short femur length, short humerus length, pyelectasis, echogenic bowel, hyperechoic focus in the left ventricle, short tibia length, short fibula length, short ear length, choroid plexus cyst greater than 10 mm, a hypoplastic middle phalanx of the fifth digit, a sandal gap toe, and a two-vessel cord. Therefore, the risk of fetal trisomy 21 remains the same (1 in 274). Once two or more markers are visualized, or a thickened nuchal fold, or absent NB, no matter what the a priori risk is, the adjusted risk for trisomy 21 is almost always higher than the risk of amniocentesis. An adjusted risk of trisomy 21, based on the genetic sonogram, is given, even for high risk patients. For example, based on age alone, a 44-year-old patient is at high risk for fetal trisomy 21. However, if second-trimester biochemical screening results are 1 in 798 (a priori risk) and the findings on genetic sonogram are normal, the adjusted risk for trisomy 21 is 1 in 3990. If the same patient has one soft marker, the adjusted risk for Down syndrome remains the same, or is slightly higher than 1 in 798 (LR 1.00).

Although it would intuitively seem that certain markers (e.g., nuchal fold thickening, absent NB, or cardiac defects) in isolation are very "strong" and would increase the risk for trisomy 21, we have found these markers most frequently in

combination with other markers. Either a triple or a quadruple screen risk is acceptable as an a priori risk, because most of our findings are based on high risk patients who underwent serum testing.

If the results of genetic sonography are normal, we still reduce the risk of fetal trisomy 21 by 80%, and the revised risk is then discussed with the patient. However, in the presence of aneuploidy marker(s), we no longer multiply the a priori risk with various LRs to give an actual adjusted risk. Instead, we counsel the patient that her risk for fetal Down syndrome is "increased," and we offer and discuss genetic amniocentesis. In other words, if only one marker is present (with the exception of structural anomaly, thickened nuchal fold, or absent NB), we recommend invasive testing *only* if the patient is high risk based on the a priori risk. Conversely, once two or more markers are visualized, or isolated thickened nuchal fold or absent NB, we offer invasive testing, regardless of a priori risk status.

Ideally, it would be optimal to establish an individual LR for each aneuploidy marker so that risk adjustments may be made when a marker(s) is sonographically present. LRs of isolated markers have been reported in several studies.[66–69] By using LRs, the post priori risk is then estimated. However, if one examines the LRs reported for a specific marker (such as short humerus), these values can vary widely. Thus, for this reason, we believe that in general the presence of isolated sonographic markers should not be used to adjust the a priori risk for fetal Down syndrome. We also do not utilize LRs of isolated markers because, in our experience, the overwhelming majority of Down syndrome fetuses have multiple markers in combination, rather than in isolation. In fact, based on our own data, approximately two thirds of fetuses with Down syndrome will have two or more abnormal sonographic markers. Therefore, we have been unable to generate stable and reliable positive LRs of isolated markers. Accordingly, until individualized LRs can be reliably established, we do not provide actual adjusted risks for fetal Down syndrome in the presence of aneuploidy marker(s).

A different method that has been utilized is to integrate the risk of sonographic markers with the a priori risk based on maternal age.[70] This is called AAURA (age-adjusted ultrasound risk adjustment) for fetal Down syndrome and is used for women of all ages. With this method, sonographic markers are "weighted" by the strength of individual findings, expressed as LRs. The authors base the individual risk assessment of fetal Down syndrome on maternal age and the presence or absence of each of the sonographic markers, in terms of LRs. Investigators using AAURA report that both the sensitivity of fetal Down syndrome detection and the false-positive rate increase with maternal age. This is felt to be appropriate because older women desire a high sensitivity, and the clinical alternative is amniocentesis for all women age 35 years or older (100% false-positive rate).[71] AAURA also minimizes the false-positive rate for younger women (4%) with a satisfactory sensitivity (61.5%).[71]

Recently, we have also altered our clinical management to reflect the emergence of first-trimester screening. First-trimester screening is discussed in detail in Chapter 7. Studies performed in the 1990s revealed a strong association between the size of the fluid collection at the back of the fetal neck in the first trimester (NT) and the risk of Down syndrome.[72]

An increased NT thickness is now widely recognized to be an early presenting feature of a wide range of fetal genetic, chromosomal, and structural anomalies. Subsequently, an important achievement in first-trimester screening for Down syndrome occurred when large studies in the United States and United Kingdom demonstrated that NT could be combined with two first-trimester maternal serum analytes (free β-hCG and pregnancy-associated plasma protein A [PAPP-A]). The mean level of free β-hCG in first-trimester Down syndrome pregnancies is elevated to 1.98 MoM,[73] and the mean level of PAPP-A is reduced to approximately 0.43 MoM.[74] When serum analytes are combined with NT (or combined first-trimester screening), the result is higher detection rates for Down syndrome. In looking at prospective first-trimester screening studies, when fetal NT (along with maternal age) is combined with free β-hCG and PAPP-A, the detection rate for Down syndrome is 87%, for a false-positive rate of 5%.[75] Another recent paper examining prospective studies of combined first-trimester screening found that for a total of more than 160,000 pregnancies screened (>600 Down syndrome fetuses), the overall sensitivity for Down syndrome was 87% (95% CI 84.0%–89.4%), for a 5% false-positive rate.[76] Therefore, it is evident that for a 5% false-positive rate, the sensitivity for Down syndrome by utilizing combined first-trimester screening is far superior to that of maternal age (30%) and second-trimester triple screen (60%–70%).

Because of the current availability of both first- and second-trimester screening tests, several approaches to Down syndrome screening have been evaluated. However, it is important to point out that not all strategies include NT measurement because this screening approach is not available in all regions and this measurement may not be successfully obtained in all patients. Nevertheless, when women have undergone first-trimester screening for aneuploidy, they should not undergo independent second-trimester serum screening in the same pregnancy[52] because the false-positive rates are additive, resulting in many more unnecessary invasive procedures (11%–17%).[77,78] Instead, women who desire a higher detection rate for Down syndrome can have either an integrated or a sequential screening test, which *combines* both first- and second-trimester screening results, or seek an ultrasound laboratory that is certified to perform comprehensive first-trimester screening (PAPP-A, hCG, NT, NB, ductus venosus, tricuspid valve). At present, patients undergo combined first-trimester screening, with a subsequent maternal serum concentration of α-fetoprotein (MSAFP) only in the second trimester. We then utilize the combined first-trimester screen risk as the a priori risk for genetic sonography. If the patient does not have first-trimester screening performed (but, rather, quadruple screening), then these results are used as the a priori risk, as has been done traditionally in the past.

Others have evaluated second-trimester genetic sonography after first-trimester Down syndrome screening. In 2005, members of the FASTER (First and Second Trimester Evaluation of Risk) trial in the United States[79] examined the role of second-trimester genetic sonography in a population that already underwent first-trimester combined screening and second-trimester quadruple screening. There were 8533 patients who underwent genetic sonography, including 62 cases of Down syndrome. Although there were 3 Down

syndrome cases undetected by either first- or second-trimester or combined screening, genetic sonography detected all these cases, so that no Down syndrome fetus was missed by the overall screening program. The sensitivity of combined first-trimester screening was 84% (false-positive rate 6.6%); however, by using the genetic sonogram to modify the risk, this resulted in higher sensitivity (92%), with a reduction in the false-positive rate to 5.6%. Similarly, the sensitivity of quadruple screening was 88% (false-positive rate 11%); however, by again using the genetic sonogram to modify the risk, this resulted in higher sensitivity (93%) with a reduction in the false-positive rate to 7.4%.[79] Thus, second-trimester genetic sonography improved the performance of both first- and second-trimester screens by significantly reducing the false-positive rates, with simultaneous increases in sensitivity.

Krantz and associates[80] used previously published data in 2007 to mathematically model the effect of second-trimester sonography after combined screening. In this model, when genetic sonography was used as the second part of a stepwise sequential screen, Down syndrome detection increased to 94.6% from 88.5% by combined screening alone, with an accompanying increase in the screen-positive rate from 4.2% to 5.4%. When genetic sonography was used as the second part of a contingent sequential test for intermediate-risk combined screen results, Down syndrome detection and screen-positive rates were 93.3% and 4.9%, respectively. The authors concluded that second-trimester genetic sonography could serve as an effective screening test after first-trimester combined screening.[80] In 2009, a retrospective cohort study was performed to evaluate Down syndrome screening performance of the first-trimester combined test followed by second-trimester genetic sonography.[81] Sonography was evaluated as the second part of (1) a stepwise sequential test applied to combined screen-negative pregnancies and (2) an integrated test applied to all combined screen patients, regardless of the latter results. The authors found that second-trimester genetic sonography after first-trimester combined screening may improve Down syndrome detection, but at the expense of increasing screen-positive rates, which they deemed unacceptably high.

Risk adjustment for trisomy 21 is institution-specific and the published experience from one center does not necessarily apply to another.[82] Each center performing genetic sonography must monitor their sensitivity for the detection of trisomy 21 to provide patients accurate, detailed, and updated counseling about their degree of risk reduction when ultrasound findings are normal. Considering the range of expertise available in many countries, it is reasonable to suggest limiting genetic sonography to specialized centers.[11] In 2007, ACOG stated in their *Practice Bulletin*[52] that risk adjustment based on second-trimester ultrasonographic markers should be limited to centers with ultrasonographic expertise and centers engaged in clinical research, to develop a standardized approach to evaluating these markers.

We analyzed the cost of universal amniocentesis and genetic sonography and concluded that genetic sonography was cost-effective when the sensitivity for the detection of trisomy 21 was greater than 74%.[64] We observed that genetic sonography saved the health care system 9% and reduced the loss rate of normal fetuses as a result of amniocentesis by 87%.[83] Genetic sonography is also cost-effective in

women younger than 35 years who are at moderate risk for Down syndrome based on their second-trimester biochemical screening results as well as in patients with advanced maternal age who decline amniocentesis after second-trimester genetic counseling.[84] Offering genetic sonography to these patients is associated with cost savings for most acceptable genetic ultrasound accuracies. Finally, another study indicated that the combination of second-trimester genetic sonography with traditional serum markers may further improve diagnostic accuracy.[85] Various integrated algorithms combining serum analytes and sonographic markers have been reported (e.g., nuchal thickness, humerus length, serum α-fetoprotein, hCG) but have not been validated prospectively.

THREE-DIMENSIONAL SONOGRAPHY

Three-dimensional ultrasound (3DUS) was first introduced in the late 1980s. 2D ultrasound (2DUS) acquires a single plane of image information with traditional transducers. 3DUS, however, acquires *volume* data utilizing one of several techniques. The resulting data can be viewed in single or multiple planes or in combination with a rendered image that conveys the information from the entire volume (the "classic" 3D appearance).[86] The initial machines were somewhat slow, but display times have decreased dramatically with the evolution of computer processors. With the current generation, 3D reconstruction is fast with high resolution, providing not only a 3D image in real time but also a display generated using standardized protocols. The image quality is directly related to the image quality of the 2D scan used to acquire volumes. In some cases, multiplanar imaging in a standard orientation allows the sonographer to be more confident of a finding compared with conventional 2D imaging.

This technology has the potential to provide both the physician and the patient with more accurate and additional information about the fetus (e.g., extent or size of anomalies) than is possible with traditional 2DUS. Other advantages of 3DUS include rapid acquisition of volume data, use of new orientations and planes (not obtainable with 2D scanning), earlier maternal-fetal bonding, and improved comprehension of the fetal anatomy by the patient and family.[86] Another important role of 3DUS relates to the ability to store volume data that can be manipulated long after the patient has left the examination room.[87] Sonographic volumes can also be transmitted electronically from a remote site for full interpretation and evaluation elsewhere, making teleradiology ultrasound image interpretation easier and less operator-dependent.[88] This capability has the potential to increase the use of sonography in remote locations, where a sonographic expert is not present.

3DUS may be more useful than conventional 2DUS for the evaluation of malformations. Merz and colleagues[89] studied 204 anomalous fetuses and concluded that 3DUS ultrasound was advantageous compared with 2DUS in 62%, equivalent in 36%, and disadvantageous in 2%. In a similar study of 63 fetuses with 103 anomalies, 3DUS was advantageous in 51%, equivalent in 45%, and disadvantageous in 4%.[90] Several anomalies, such as cleft lip and abnormal facies, were seen only with 3DUS. Most anomalies were better visualized with 3D than with 2D imaging.[89,90] Not only was patient management altered in 1 out of 20 patients,

but the improved visualization helped physician and family understand the anomalies. In 2005, Gonçalves and coworkers reviewed the published literature on 3DUS and four-dimensional ultrasound (4DUS) in obstetrics, to determine whether 3DUS adds diagnostic information to that currently provided by 2DUS.[91] They concluded that 3DUS provides additional diagnostic information for the diagnosis of facial anomalies, especially facial clefts. Moreover, they found evidence that 3DUS provides additional diagnostic information for neural tube defects and skeletal malformations. However, large studies comparing 2DUS and 3DUS for the diagnosis of congenital anomalies have not provided conclusive results.[91]

Second- and Third-Trimesters

3D imaging is useful in the second and third trimesters for anomalies of the skull, brain, face, heart, spine, limbs, urinary tract, umbilical cord, and placenta.[86] Other applications under study include evaluations of the placenta, umbilical cord, cervix, fetal weight, and uterine anomalies (e.g., bicornuate, septate). 3DUS can improve the accuracy of length, area, and volume measurements as well.[88] Various strategies have been utilized, ranging from manual outlining of structures to semiautomatic and fully automatic algorithms that segment organs and structures for analysis.[88]

One of the most valuable features of 3DUS is the ability to rotate the face so that it can be viewed directly in an upright position. Surface-rendered displays are successfully obtained in 70%.[86] The fetal face can be rotated into a standard symmetrical orientation and reviewed millimeter by millimeter by scrolling through the volumes.[92] Several studies have concluded that 3DUS was beneficial for the detection of facial anomalies, such as cleft lip or palate, midface hypoplasia, asymmetrical facies, micrognathia, facial masses, hypotelorism or hypertelorism, facial dysmorphia (sloping forehead, flat facies, flat nose), holoprosencephaly, and deformed ears.[86] 3DUS is particularly valuable when seeking a cleft lip or palate, especially the primary, or hard, palate. Some anomalies detectable on 3DUS were missed on 2DUS, including cleft lip or palate, micrognathia, flat facies, unilateral orbital hypoplasia, and cranial ossification defect.[86] In one series, 2DUS identified only 45% of fetuses with cleft palate, whereas 3DUS enabled the detection of 86%.[93] Artifacts produced from 3D volumes can imitate "clefting" of lips that are actually normal. These artifacts include shadowing by an adjacent umbilical cord, motion during image acquisition, NB shadowing, and misidentifying a nostril as a cleft.[86]

It is almost always possible to obtain a fetal profile, a crucial part of the examination. In addition, rotation of the volume allows consistent and accurate depiction of the midsagittal plane. 3D imaging of the face may be difficult early in gestation, if there is oligohydramnios, if limbs obscure the face, or when the face is close to the uterine wall or placenta.[86]

3D imaging is valuable in the examination for fetal skull defects, intracranial pathology and symmetry, and abnormal sutures or fontanelles. The "three-horn view" contains the anterior, inferior, and posterior horns of the lateral ventricles in a single slice.[94] Fluid in the inferior horn is abnormal and is an early sign of ventriculomegaly. By placing the

"marker dot" in the volume, the sonographer can "navigate" through ventricles, parenchyma, and cystic structures and along vascular structures.[86] These images may be useful for consulting pediatric neurologists and neurosurgeons. The fetal spine is often imaged more clearly with 3DUS. Image quality is improved with rendering techniques that optimize the appearance of bone for the diagnosis of scoliosis, hemivertebrae, and neural tube defects. Studies suggest that 3D evaluation allows for an accurate determination of the level of a neural tube defect because the transverse and coronal images are viewed simultaneously with the rendered image.[95]

In the past, cardiac 3DUS was compromised by the rapid motion. However, recent technological developments of motion-gated cardiac scanning allow almost real-time 3D/4D fetal heart scans. Spatiotemporal image correlation (STIC) acquisition is an indirect motion-gated offline scanning mode.[96] Consecutive volumes can then be used to reconstruct a complete heart cycle that displays in an endless loop. Accordingly, this cine-like file of a beating fetal heart can then be manipulated to display any acquired scanning plane at any stage in the cardiac cycle.[97] 3D/4D sonography has been used to estimate fetal cardiac ventricular volume, calculate ejection fraction and stroke volume,[98] and diagnose or facilitate the diagnosis of congenital cardiovascular malformations.[99,100]

Abnormalities of the fetal abdomen and pelvis (and, in some cases, their volume) can be imaged with 3DUS (e.g., gastroschisis, omphalocele, bowel obstruction, hydronephrosis, multicystic dysplastic kidney). However, it is not clear whether additional information is obtained compared with 2D. Abnormalities of the genitalia may also be assessed with 3DUS.

The fetal extremities can usually be imaged with 3DUS because of the rapid acquisition. If the limb moves during an acquisition, the volume should be discarded and another one acquired. With conventional 2D, motion often obscures limb anatomy or makes assessment difficult. However, once a 3D volume is obtained, the structure can be studied carefully without motion, and the limb can be "rotated" to various orientations for full evaluation. Rendered images can be used to evaluate surface and bony features and the number and position of digits. In evaluating the lower extremities for clubfeet, it is often difficult to determine whether this is a "transient" (false-positive) or "fixed" (true-positive) event. 3DUS may help in some cases.

3DUS offers several advantages over conventional 2D imaging in fetuses with skeletal dysplasia. Abnormal bone shapes, shortened ribs, and abnormal facies are more accurately identified with volume acquisition.[86] Garjan and associates[101] reported that 3DUS allowed for the identification of abnormalities that were not seen on 2D in three out of seven fetuses with skeletal dysplasias. Specific bones may be imaged with 3DUS to narrow the normally wide differential diagnosis of skeletal dysplasias (see Chapter 20). A recent study concluded that 3D/4D technology was a useful sonographic tool for evaluating the fetal thorax, in that it enhanced diagnostic precision and provided superior spatial visualization of the anomalies.[102]

3DUS has been used to estimate fetal weight using volume data for the abdomen and extremities because it is impossible to obtain an entire fetal volume.[86] Some studies suggest that 3DUS may be more accurate than 2DUS for weight

prediction.[103] Others, however, have found that fetal weight in prolonged pregnancies can be estimated using 2D sonography with the same accuracy as with 3D.[104] Birth weight prediction has also been investigated using 3DUS and fractional limb volume.[105] A 2009 prospective study compared inter- and intraobserver variation of fetal biometric measurements using 2D- and 3D-derived images.[106] The authors observed that the use of 3DUS significantly reduced intraobserver variation for head circumference, abdominal circumference, and femur length and reduced the interobserver variation for femur length. Fetal liver and lung volumes have also been reported.[107,108] Chang and associates[107] concluded that measurements made with 2DUS underestimated the fetal liver volume compared with 3DUS.

The cervix can be imaged with 3DUS, along with the entire cerclage, if present. Vascular structures and their distribution and extent (e.g., umbilical cord, vasa previa, placenta accreta, velamentous insertions, aneurysm of the vein of Galen) have all been evaluated with 3DUS.[86] Image acquisition can be difficult and time-consuming at times because of motion, flash artifacts, and the longer time volume acquisition with color and power Doppler techniques.

A great advantage of 3DUS is the potential for enhanced early maternal bonding with the fetus. Among patients who undergo 3DUS for reassurance, those women with a history of fetal or neonatal demise, those with a history of a fetus with congenital anomalies, those carrying fetuses with lethal anomalies, those treated for infertility, and couples who have a surrogate carrying their pregnancy seem to derive the most benefit.[86]

In summary, the world is three-dimensional and 3DUS provides anatomic images that are more easily understood by both physicians and patients. It offers women and their care team an improved understanding of the anomalies found on 2DUS, clarifies the extent of the anomaly, and provides visual confirmation of the reality of the abnormality. It also facilitates bonding with the fetus.

SCREENING FOR TRISOMY 18 AND OTHER ANEUPLOIDIES

Trisomy 18 (Edwards' syndrome) is the second most common autosomal trisomy and has a uniformly poor prognosis. Second-trimester serum triple-marker screening can identify 60% to 75% of fetuses with trisomy 18 when a separate analysis is performed seeking low levels of all three analytes, with or without consideration of maternal age.[109,110]

Sonography has high but variable sensitivity for detecting trisomy 18 (64%–100%), particularly when the search is part of a thorough anatomic survey.[26] We found that all fetuses with trisomy 18 had four or more sonographic anomalies (one fetus had 19 separate detectable anomalies).[26] Shortened ear length was present in 96%, bilateral clenched or closed hands or overlapping digits in 95%, and central nervous system abnormalities in 87%. In another study, we observed shortened ear length (≤10th percentile) in 100% of fetuses with trisomy 13, 96% of fetuses with trisomy 18, 75% of those with Turner's syndrome, and 91% of those with other various aneuploidies.[59] Many investigators have confirmed that abnormal hands are seen in most fetuses with trisomy 18.[26] Other sonographic abnormalities that are

common in trisomy 18 include growth restriction, abnormal feet, choroid plexus cysts, and structural cardiac defects. We observed intrauterine growth restriction in 63% of fetuses with trisomy 18.[26]

In a large retrospective review of 98 second-trimester fetuses with trisomy 18, the authors were able to identify abnormal fetal anatomy or abnormal biometry in 97% of these fetuses.[111] In 2008, Zheng and coworkers[112] observed in a population of 26 trisomy 18 fetuses, that 3D/4D sonography enabled the identification of additional diagnostic information in 84 and influenced the obstetric management in 4.

Choroid plexus cysts are visualized in 1% (range 0.3%–3.6%) of normal fetuses in the second trimester (see Fig. 8–3). These cysts may be associated with trisomy 18,[113] and in the past, genetic amniocentesis was considered even if they were isolated. *However, a cyst can be considered "isolated" only after a detailed fetal survey shows no other structural abnormalities or markers.* In our study, half of the fetuses with trisomy 18 had a choroid plexus cyst, but these were always associated with multiple other sonographic abnormalities (i.e., never isolated).[26] In another study, none of 98 fetuses with an isolated choroid plexus cyst had aneuploidy, whereas 100% of the 13 fetuses with a choroid plexus cyst and major anatomic abnormalities had trisomy 18.[114] In our experience, the risk of aneuploidy is very low and does not justify amniocentesis if no other anomalies are found (especially if the hands are open and the ear length is normal). Many investigators concur that if the choroid plexus cyst is isolated and the patient is at low risk for fetal aneuploidy, the presence of these cysts should not affect management. In fact, the authors of a 2004 editorial recommended that when a choroid plexus cyst is the only detected abnormality (an isolated marker on a second- or third-trimester sonogram that meets the most recently adopted AIUM performance guidelines), the sonographic report emphasizes that as an isolated finding in a patient considered low risk for fetal aneuploidy, a choroid plexus cyst is not clinically significant and does not change her from low to high risk status.[115]

Similarly to genetic sonography for fetal trisomy 21 screening, normal findings on a complete anatomic survey in experienced hands should "decrease" a patient's risk of trisomy 18 (regardless of the presence of choroid plexus cysts or abnormal second-trimester biochemical screening results) to a low level sufficient to avoid genetic amniocentesis after appropriate patient counseling.[26] A 2009 study of 8763 pregnancies at increased risk of trisomy 18 based on serum screening including 56 whose fetuses had trisomy 18 noted sonographic anomalies in 89% of trisomy 18 fetuses compared with 14% of normal.[116] They reported that if the genetic sonogram was normal (no structural anomaly or soft marker), the risk was reduced by approximately 90%.[116] Therefore, the authors concluded that if the genetic sonogram is used as a sequential test following serum biochemistry, a normal ultrasound study reduces the likelihood of trisomy 18 substantially, even if a woman has abnormal serum biochemistry.

Trisomy 13 (Patau's syndrome) has an extremely poor prognosis. Its phenotype is so characteristic that a diagnosis can often be based on clinical features alone. Because fetuses with trisomy 13 usually have severe abnormalities, it follows that the sensitivity of prenatal sonography for the detection is very high, with most studies reporting sensitivities above 90%.[117–119] Watson and colleagues[120] achieved a 95% detection rate (36 out of 38) after 17 weeks based on either the presence of an anomaly or abnormal fetal biometry. Early-onset growth restriction is common in trisomy 13 and triploidy. In particular, triploidy is associated with a characteristically small body relative to the head.

CRITICAL REVIEW OF THE EVIDENCE ON SECOND-TRIMESTER SCREENING FOR FETAL ABNORMALITY

There is no uniform population-based screening for trisomy 21 in the United States. In fact, there are even laboratory-dependent variations in the specific second-trimester serum markers used. Moreover, the emergence and availability of first-trimester screening has complicated screening strategies and choices even further for frontline clinicians. Whereas some centers now use an approach that involves both first- and second-trimester screening, others use second-trimester serum marker screening only, and some couple serum screening with an ultrasound for sonographic markers by unsupervised practitioners; only a small minority attempt to derive individual risks for fetal trisomy 21 (Table 8–7). In short, the current system in the United States is inconsistent with overall high quality and high value and should not be sustained. The addition of more screening tests (especially when additive or sequential) increases false-positive rates, patient anxiety, invasive testing rates, and procedure-related pregnancy losses. However, it may be possible to decrease the invasive testing rates while maintaining high sensitivity if sequential tests are interpreted in light of the results of earlier tests.[121] Another variable to consider is that if 80% to 95% of fetuses with trisomy 21 are detected by first-trimester screening, the predictive values of second-trimester screening (ultrasonography and biochemical screening) will be dramatically reduced.[121] In theory, second-trimester biochemistry will probably identify at best-only 6% (60% of the residual 10%) of affected pregnancies screened by NT alone plus first trimester biochemistry while doubling the overall invasive testing rate (from 5% to 10%).

There is also no uniformity in screening for fetal malformations. Table 8–7 lists several approaches that are used clinically. Examples include A and C (then J or K), B (then J or K), F (then J), H only, J only, and so on. We prefer A and C (then J or K), but believe that regardless of the first- and/or second-trimester screening tests performed, and even if the patient undergoes invasive testing, a second-trimester sonogram to evaluate the fetal anatomy is the standard.

It is clear the plethora of trisomy 21 screening options has proved a source of confusion for patients and physicians. The type of test to offer also depends on several circumstances, such as when the patient presents for prenatal care, number of fetuses, the availability of chorionic villus sampling (CVS), prior obstetric history, family history, desire for early test results, and the availability of registered providers in the region of practice. Not every provider who does ultrasound is qualified; not every laboratory will provide up-to-date options. For example, not all strategies will include NT measurement because this screening approach requires specialized training on an annual basis to have

Various Approaches Used Clinically in Screening for Fetal Malformations and/or Aneuploidy

APPROACH	DESCRIPTION	NOTES
A	First-trimester risk adjustment (age, NT, biochemistry results), with or without other markers (e.g., nasal bone, tricuspid regurgitation).	Might not be available in all regions, and NT measurement might not be obtained successfully in all patients.
B	Second-trimester serum screening (triple or quadruple).	Quadruple screening has higher sensitivity and should be utilized.
C	MSAFP.	Performed in the second trimester for those who had only first-trimester screening for aneuploidy or who have normal results from CVS.
D	Integrated (first plus second trimester).	NT, PAPP-A, quadruple screening. Results reported only after *both* first- and second-trimester screening tests are completed.
E	Serum integrated (first plus second trimester).	PAPP-A, quadruple screening. For patients without access to NT measurement or when reliable measurement cannot be obtained.
F	Stepwise sequential (first plus second trimester).	First-trimester test result: a. Positive: diagnostic test offered. b. Negative: second trimester test offered. c. Final: risk assessment incorporates first and second results.
G	Contingent sequential (first plus second trimester).	First-trimester test result: a. Positive: diagnostic test offered. b. Negative: no further testing. c. Intermediate: second-trimester test offered. d. Final: risk assessment incorporates first and second results.
H	Invasive testing (CVS, amnio) offered automatically to patients with AMA or abnormal screening results.	Discuss risks and benefits of invasive testing. Genetic sonogram not performed.
I	Invasive testing (CVS, amnio) offered to all women, regardless of age.	Discussed in ACOG Practice Bulletin: Screening for Fetal Chromosomal Abnormalities (January 2007)*
J	Sonographic fetal anatomy survey in second trimester; offer amnio, depending on results.	Not AMA or has normal screening results. No calculated adjusted risk for aneuploidy given.
K	Genetic sonogram (only high-risk patients); offer amnio if risk adjustment using negative LR is still abnormal or if marker(s) present.	A priori risk: first-trimester combined screening (if not done, then second-trimester serum screening or maternal age) Based on absence or presence of aneuploidy markers, structural anomalies, and abnormal biometry on ultrasound.
L	No testing performed.	Patient declines testing.

AMA, advanced maternal age; amnio, amniocentesis; CVS, chorionic villus sampling; LR, likelihood ratio; MASFP, maternal serum α-fetoprotein; NT, nuchal translucency; PAPP-A, pregnancy-associated plasma protein A.
* American College of Obstetricians and Gynecologists (ACOG): Screening for fetal chromosomal abnormalities. ACOG Practice Bulletin No. 77. Obstet Gynecol 2007;109:217–227.

access to the calculation algorithms, and this measurement may not be successfully obtained in a given subject. It is not practical to have the patient choose from among the large array of screening strategies that might be used.[52] It is important that providers review the evidence, identify which tests are available in the practice area, and determine which strategy or strategies will best meet the needs of these patients before deciding which strategy to offer.[52] The goal is to offer screening tests with high detection rates and low false-positive rates that also provide patients with the diagnostic options they prefer.[52] It is important but often overlooked that discussions about sensitivity and false-positive rates, disadvantages and advantages, limitations, and risks/benefits of screening tests and invasive procedures be conducted with patients.

One reasonable approach is to offer those patients seen in early pregnancy aneuploidy screening that combines first- and second-trimester testing in some fashion (*integrated, sequential,* or *contingency*).[52] The *integrated* approach to screening uses both first- and second-trimester markers (NT, PAPP-A, quadruple screen) to adjust a woman's age-related risk of having a child with Down syndrome.[122] However, the results are reported only after *both* first- and second-trimester screening tests are completed. In the FASTER trial, the detection rate was 94% to 96% (5% screen-positive rate).[77] Whereas some patients value early first-trimester screening, others are willing to wait several weeks if this will result in a higher detection rate and decreased chance of an invasive test.[123] The disadvantages of integrated screening are many and include (1) patient anxiety generated by having to wait 3 to 4 weeks between start and completion of the screening; (2) the loss of opportunity to consider CVS if the first-trimester screening indicates a high risk for aneuploidy[124]; and (3) patients may fail to complete the second-trimester portion of the screening test (after performing the first-trimester component) and, as a result, be left with no

screening results. If comprehensive first-trimester screening (biochemistry, NT, NB, ductus venosus, tricuspid valve) is available, there is little benefit to integrated screening for all women. Whether a patient chooses first-trimester screening or waits for an integrated screen will vary depending on personal preferences, the types of invasive tests available, the risks they present, the patient's plans for termination, and the patient's previous experiences. If NT cannot be performed for various reasons, an alternative is to perform *serum integrated* screening (PAPP-A, quadruple screen, no incorporation of NT measurement). In the FASTER trial, the serum integrated screen resulted in an 85% to 88% detection rate.[77] Under these circumstance, the delay is acceptable to most women.[125]

Sequential screening may be more advantageous because the patient is *informed* of the first-trimester screening result. Those patients who are at highest risk may decide to have a diagnostic test, whereas those at lower risk can still take advantage of the higher detection rate achieved with additional second-trimester screening. There are two proposed strategies: *stepwise sequential* screening, and *contingent sequential* screening. In the *stepwise sequential* strategy, women determined to be at high risk (Down syndrome risk above a predetermined cutoff) after the first-trimester screen are offered genetic counseling and the option of invasive testing, whereas women below the cutoff are offered second-trimester screening. For a 5% false-positive rate, the detection rate using the stepwise sequential strategy is 95%.[77] In the *contingent sequential* strategy, patients are classified as high, intermediate, or low on the basis of first-trimester screen results. Women at high risk are offered CVS, and those at low risk have no further screening or testing. Only those women at intermediate risk are offered second-trimester screening. Contingent sequential screening has been proposed as a model (88%–94% predicted detection rate; 5% false-positive rate),[126] but large clinical trials using this approach have not yet been published. Therefore, this approach maintains high detection rates with low false-positive rates, while reducing the number of second-trimester tests performed. For both the stepwise and the contingent strategies, patients at highest risk identified by first-trimester screening are offered an early invasive procedure. Both first- and second-trimester results are used to calculate a final risk for aneuploidy in patients at lower risk.

As previously discussed, the performance of first- and second-trimester screening tests *independently* yields a high sensitivity for Down syndrome (94%–98%), but the screen-positive rates are additive, leading to many more unnecessary invasive procedures (11%–17%).[77,78] Therefore, it has been recommended that women who have had first-trimester screening for aneuploidy not undergo *independent* second-trimester serum screening in the same pregnancy.[52] Women who desire the highest sensitivity can have either an integrated or a sequential screening test, which *combines* both first- and second-trimester screening results. Many still recommend maternal serum α-fetoprotein for neural tube defect detection; others argue that an examination by a skilled sonographer has an even higher yield.

Ultimately, the screening strategy chosen will depend on the availability of CVS and sonologists who are appropriately trained in obtaining first-trimester sonographic markers. For instance, when CVS and comprehensive first-trimester screening are not available, one can offer: (1) integrated screening to patients who present in the first trimester, in order to take advantage of the improved detection rate and low-false positive rate and (2) second-trimester screening to those patients presenting after the first trimester.[52] It is suboptimal to offer patients first-trimester screening but to have no physician available who can perform CVS if that is what the patient desires. If NT measurement is unavailable or cannot be obtained in a patient, a reasonable approach is to offer: (1) serum integrated screening to patients who present early and (2) second-trimester screening to those who present later.[52] If one practices in an area where every possible screening strategy is available, it is reasonable to choose two screening strategies for the practice. For example, one can offer: (1) either comprehensive first-trimester screening or sequential screening for patients presenting for prenatal care prior to 14 weeks and (2) second-trimester serum screening for patients presenting after 13.6 weeks of gestation.[52]

A relatively new Down syndrome screening protocol is one that combines quadruple screening with nuchal fold and long bone measurements in the second trimester.[127] It has been shown to be a feasible method (90% sensitivity; 3.1% false-positive rate) to improve Down syndrome screening performance over either sonography or second-trimester serum markers by themselves. The authors suggest that efficacy may be comparable with that reported for combined first- and second-trimester (integrated) screening.[127]

Another approach is to provide all women the option of invasive testing, regardless of age. As discussed previously, in January 2007, ACOG[52] raised the issue in their *Practice Bulletin* that *all* women (regardless of age) should have the option of *invasive* diagnostic testing for aneuploidy. However, it is important to discuss the differences between screening and diagnostic testing with all women. Certainly, it would be ideal if all women were offered aneuploidy *screening* before 20 weeks' gestation, regardless of maternal age.[52]

The significance of sonographic markers identified by a second-trimester ultrasound examination in a patient who has had a negative first-trimester screening test result is unknown.[52] We believe that if the patient is otherwise low risk, the presence of only one marker (with the exception of structural anomaly, thickened nuchal fold, or absent NB) after a thorough, targeted survey will not significantly increase the risk of Down syndrome. However, if the patient is otherwise high risk, we would consider her a candidate for genetic sonography and, in the presence of marker(s), would counsel the patient that her risk for fetal Down syndrome is increased and offer and discuss genetic amniocentesis.

We anticipate that, with growing expertise, more genetic sonograms will be offered as a first choice to high risk patients and will become the standard of care in this group, with targeted fetal scans reserved for the low risk patient. Some patients may prefer first-trimester screening, second-trimester screening, or a combination of both, just as some may prefer CVS to second-trimester amniocentesis. High sensitivity is important for high risk women, whereas low false-positive rates are most desirable among low risk women.

SUMMARY OF MANAGEMENT OPTIONS
Second Trimester Screening for Fetal Abnormalities

Management Options	Evidence Quality and Recommendation	References
General		
Discuss the screening options in the first and second trimesters and decide on an individual pregnancy management plan (e.g., serum testing, ultrasound, invasive testing)	—/GPP	—
Invasive diagnostic testing (CVS, amniocentesis) for aneuploidy offered to all women, regardless of maternal age	IV/C	52
Second-Trimester Serum Screening		
Use quadruple screen testing for greater sensitivity	IIa/B	15,16
Combine with detailed sonography to screen for aneuploidy	III/B	53
	IIa/B	64
Neural tube defect screening should be offered in the second trimester to women who elect only first-trimester screening for aneuploidy or who have had a normal result from CVS	IV/C	52
After first-trimester screening, subsequent second-trimester Down syndrome screening is not indicated, unless it is being performed as a component of the integrated test, stepwise sequential, or contingent sequential test	IV/C	52
Second-Trimester Sonography		
Perform a detailed survey to increase sensitivity, and screen all patients with this test	—/GPP	—
Genetic sonography should be offered only to high risk patients and performed by experienced laboratories	III/B	53
Use three-dimensional sonography to add more information to two-dimensional sonography, if available	IV/C	86
	III/B	89,90
Authors' Practice		
For all patients, perform combined first-trimester screening (age, nuchal translucency, biochemistry)	IIa/B	75
For all patients, perform MSAFP only in the second trimester	IV/C	52
For all patients, perform fetal anatomy survey or genetic sonogram in second trimester (both detailed examinations), depending on circumstances	III/B	53
	IIa/B	64
Invasive testing also discussed as an option, when applicable	—/GPP	—
Perform three-dimensional ultrasound, if necessary	IV/C	86
	III/B	89,90

CVS, chorionic villus sampling; GPP, good practice point; MSAFP, maternal serum α-fetoprotein.

Invasive Procedures for Antenatal Diagnosis

GEORGE ATTILAKOS and PETER W. SOOTHILL

Videos corresponding to this chapter are available online at www.expertconsult.com.

INTRODUCTION

Obstetric ultrasound fostered the development of invasive techniques to assist in antenatal diagnosis. Methods such as chorionic villus sampling (CVS), amniocentesis, fetal blood sampling (FBS), and fetal tissue biopsy allow testing of fetal materials for chromosomal, genetic, and biochemical abnormalities. The type of procedure selected depends on many factors, including the indication, the gestational age, and how soon the result is needed. Possible applications are increasing rapidly with advances in human genetics and the evolution of molecular tools, but all invasive in utero diagnostic techniques carry a risk of fetal injury or death. These risks must be properly explained to the parents during the informed consent process. Noninvasive approaches, such as measuring free fetal DNA in the mother's blood, show great promise but, are at present, used clinically only in specific areas, such as fetal blood group or sex prediction.[1] Although the use of free fetal DNA and the introduction of effective screening strategies have led to fewer invasive procedures being performed,[2,3] the latter are required for the definitive diagnosis of most fetal genetic problems.

This chapter summarizes the indications, methods, and complications of the most common invasive diagnostic methods.

ISSUES COMMON TO ALL INVASIVE DIAGNOSTIC TECHNIQUES

All of the techniques described in this chapter share certain features.

Guidelines for Training

The Royal College of Obstetricians and Gynaecologists (RCOG) published guidelines for amniocentesis and CVS, including guidance on training in antenatal invasive diagnostic methods.[4] They are praised for their efforts to seek standards. They suggest that practitioners who perform invasive procedures must have a high level of training in obstetric ultrasound and that training with clinical skills models be considered. Because training is now competency-based, they do not specify a minimum number of supervised procedures before practitioners can act independently. However, they suggest that trainers perform at least 50 ultrasound-guided invasive procedures annually. After completing training, physicians should perform at least 10 invasive procedures per year in order to retain their skills, although it is emphasized that there is no evidence on the subject. It is also recommended that amniocentesis for multiple gestation be performed in a tertiary fetal medicine unit.

Training in CVS and FBS is not part of general obstetric training and is usually limited to trainees who specialize in fetal and maternal medicine. Units that perform more complex fetal procedures should perform enough procedures each year to maintain skills. They should periodically audit the results and make these available to patients and colleagues. A reasonable minimum number of complex procedures is 12 per year.

Consent

The procedure, its goals, and likely or significant complications must be explained in language that is understandable to the patient so that written informed consent can be obtained. The specific considerations for each procedure are discussed later.

Audit of Practice

It is important that the rate of complications for individual operators is monitored through robust mechanisms. Because the incidence of complications is small, it is proposed that the 95% confidence interval (CI) be used as a monitoring tool.[4] For example, the miscarriage rate for amniocentesis should not be more than 3 out of 50 or 4 out of 100 consecutive procedures. If these values are triggered, a change may be necessary. A method of prospective performance monitoring by statistical process control charts has been described.[5] The complication studied was multiple needle insertion for amniocentesis, and the authors used the 90% CI as a "warning" line and the 95% CI as an "action" line. An individual with poor performance would have triggered the action line after 55 procedures.

Sampling Site

Ultrasound is used to determine the best site to obtain the sample, considering the target size, needle length, needle path, and potential injury to structures in the path. The skin site for needle insertion is planned, but the position chosen reflects the ultrasound-guided technique used.

Ultrasound-Guided Needling Technique

Two approaches to ultrasound-guided needling are used: needle guide and freehand.

Needle Guide

The needle guide technique uses a sector or curvilinear ultrasound transducer with a guide that has an attached needle channel. Lines on the ultrasound screen indicate the path of the needle when inserted down the guide. The transducer is moved until these lines cross the intended target. This approach allows the use of thinner needles (i.e., 22–26 gauge) than those needed for a freehand procedure (i.e., 20–22 gauge). Despite the use of a thinner needle and the fact that the entire length of the needle is not usually seen, the tip is visible as a bright dot. Some have suggested that the complication rate may be lower than with the freehand technique, perhaps because the needle is thin and its movement confined to a single plane, though data on this are limited.[6] The guide does not seem to increase the need to remove and reinsert the needle, nor is there a relationship between the number of insertions and the complication rate.

Freehand

The freehand technique uses a curvilinear or linear ultrasound transducer. The ultrasound transducer is moved until the intended sampling site is identified and appears on one side of the ultrasound screen, with the skin insertion point on the other. The intended needle path is nearly perpendicular to the ultrasound beam, allowing the length of the needle to be adequately imaged (Fig. 9–1). The freehand
technique allows the operator to adjust to changes during the procedure (such as contractions or fetal movements) and is the preferred approach of the authors.

Some operators prefer to have an assistant control the scanning transducer, but then the operator forfeits control of the intended needle path. Others prefer a single-operator technique in which one hand holds the needle and the other holds the ultrasound transducer. An assistant is required to withdraw the needle stylet, fix a syringe, aspirate at the right time, and place the sample in appropriate containers without spillage, contamination, or mislabeling.

Preparation

Regardless of technique, the atmosphere should be informal, and any additional staff required should be present for the procedure and introduced to the patient. Anything that gives the patient an image of an "operation" (e.g., surgical masks, hats, drapes) should be minimized or replaced by a scrupulous "no-touch" technique. The length of the needle required depends on abdominal wall thickness, amniotic fluid volume, and fetal and placental positions. An 8- to 12-cm needle is usually sufficient, but if in doubt, the distance should be measured on the screen before the procedure. Detailed ultrasound examination of the fetus is performed before the procedure because the discovery of structural defects, impaired growth, or other problems may alter the physician's and patient's choice. New ultrasound findings may make the procedure unnecessary, or help subsequently, when there is an unusual chromosomal finding such as mosaicism.

Needle Path Selection

If using the freehand technique, the target is visualized on screen, and the transducer is rotated through 180 degrees until a path that avoids fetal parts and maternal vessels is identified. The transducer is adjusted until the sampling site and the skin insertion point are on opposite sides of the screen. With the freehand technique, the best skin insertion point is determined by observing sonographically the effect of digital pressure on the maternal abdomen. When a needle guide is used, simply line up the needle track with the target.

Antiseptic and Anesthetic

The skin insertion site is scrupulously cleaned with antiseptic solution (e.g., chlorhexidine). Procedures that require larger than a 22-gauge needle may be helped by local anesthetic, which is injected first into the skin and then into the abdominal and uterine peritoneum. When using the freehand technique, the anesthetic injection may help confirm the needle angle required to follow the intended path and may decrease the need to change the direction of the sampling needle during the procedure. When a needle guide is used, simply line up the needle track with the target and inject the local anesthetic with a shorter needle. Patients who have undergone amniocentesis with a 22-gauge needle with and without local anesthesia reported similar pain scores and certainly lower pain scores than outpatient gynecologic procedures.[7–9]

FIGURE 9–1
Ultrasound view of an amniocentesis needle (N) entering a pool of amniotic fluid. F, fluid; P, placenta.

Viral Infections

Consideration should be given to the possibility of fetal infection by maternal-fetal transmission during the procedure. It appears the risk of fetal infection by hepatitis B is low and the hepatitis B e-antigen status can help guide counseling.[10] Similarly the risk of hepatitis C transmission appears low, but such data are limited.[10] Vertical transmission of HIV is rare, and the virus is not detectable in amniotic fluid even if it is detectable in the maternal blood.[11] However, the risk of vertical transmission may be increased by amniocentesis, particularly if the mother is not on antiretroviral therapy[12] and if a fetal "needle-stick" occurs. It is recommended that all screening options are considered in the case of mothers with HIV before invasive procedures are offered.[10] The use of antiretroviral therapy is likely to reduce the risk of infection.[12,13]

Postprocedure Considerations

The patient should be shown both the fetus and the motion of the fetal heart on the ultrasound monitor after the procedure. The sample is carefully labeled, and the details are confirmed by the woman before the sample is taken to the laboratory. The information submitted to the laboratory must be sufficient for testing to be done and diagnosis to be made. It should include information about consent, including permission to store DNA and maintain cells lines, if applicable.

Alloimmunization

An invasive procedure associated with placental bleeding has a risk of Rhesus sensitization.[14–16] After an invasive intrauterine procedure, 500 IU rather than 250 IU anti-D immunoglobulin can be given intramuscularly to an at-risk Rhesus-negative woman, and indeed, the Society of Obstetricians and Gynaecologists of Canada recommends a dose of 1500 IU (300 μg) following amniocentesis, CVS, or cordocentesis.[17]

Multiple Pregnancies

Invasive procedures should be performed in women with multiple pregnancies only in a fetal medicine unit.[4] In the first trimester, the chorionicity of each sac should be carefully determined and the placental implantation site mapped.[18] In monochorionic pregnancies, a single amniotic fluid sample may be reasonable, unless ultrasound shows discordance for fetal abnormalities when both fetuses should be sampled. In dichorionic pregnancies, both sacs should be sampled separately, either with a single needle through the intertwin septum[19–21] or with two separate maternal abdominal punctures.[22] The operator should be able and willing to perform a selective feticide if an abnormal result is discordant or refer the patient to an appropriate center. The fetal loss rate after amniocentesis in twin pregnancies appears slightly higher than in singleton pregnancies.[23] The excess risk of miscarriage in various studies has been calculated between 1.2% and 1.8%.[22,24]

Ultrasound guidance eliminates the need for any dye injection, and if used, potentially harmful dyes such as methylene blue should not be used.[25] Instead of using a dye, some operators inject 2 to 3 mL of amniotic fluid mixed with air back in the amniotic sac after the first amniocentesis. This creates intense echogenicity in the first amniotic sac for 30 to 60 seconds, which allows adequate time for the second amniocentesis to be performed. If an injection of dye seems prudent, indigo carmine is preferred. Fetal zygosity can be determined from DNA when clinically indicated or when the fetuses are at risk for inheritable syndromes.[26]

Complications

The loss rate after an invasive diagnostic procedure is a combination of the procedure-related loss rate and the background loss rate. The background loss rate is much higher if the fetus has an anomaly (e.g., chromosomal abnormality, intrauterine growth restriction, fetal hydrops).[27] The procedure-related loss rate is the product of many factors, including maternal age, operator experience, type of procedure, technique used, and the difficulties experienced during the procedure.[6,28] The gestational age at the time of the procedure is also relevant. In one study, the rate of fetal loss in older women after transabdominal and transcervical CVS was 5.8% and 6.2%, respectively, if done before 12 weeks, but 2.4% thereafter.[29] Some portion of the excess loss early in gestation reflects losses destined to occur whether the procedure was done or not. Early CVS and diagnosis of aneuploidy may result in termination, with all of the physical and psychological implications for the parents, whereas delayed CVS or amniocentesis may, by virtue of the later gestation, allow time for spontaneous loss to precede the planned procedure. Several multicenter studies failed to show consistent procedure-related differences with regard to the safety of CVS compared with other methods.[30,31]

The procedure-related loss rate for CVS, amniocentesis, and FBS is reported in many studies, including those listed in Table 9–1.[6,14,30,32–60] No standard criteria are used to determine background loss rates. Postprocedural loss rates generally include all up to 28 weeks and up to term in some studies.[14,48] Others suggest that most procedure-related losses occur within 2 weeks of the procedure (Table 9–2).[27] Procedures should be confined to centers with volumes large enough to calculate their own loss rates rather than to quote the rates of other units.

SPECIFIC PROCEDURES

Chorionic Villus Sampling

Introduction

CVS, or placental biopsy, is performed from 11 weeks onward for the diagnosis of many chromosomal and genetic conditions. Amniocentesis used to be the most common invasive diagnostic test, but over the last few years, CVS use has grown in some countries to more than 50% of the invasive diagnostic procedures,[3] and the procedure is associated with more than 50% of diagnoses of chromosomal abnormality,[61] probably because of first-trimester screening. CVS is usually performed by transabdominal needle aspiration, although some practitioners still use a transcervical

technique, with catheter aspiration or biopsy. Many consider transcervical CVS an obsolete technique because of the higher procedure pregnancy loss rates.[55]

Indications

Fetal trophoblast cells, especially from the mesenchymal core of the villi, divide rapidly. The advantage of first-trimester CVS is rapid diagnosis at an early gestation. If an abnormality is detected, surgical termination, rather than medical induction, can be offered. Early detection of chromosomal disorders is the most common indication for CVS. The introduction and growing availability of first-trimester screening for Down syndrome (e.g., nuchal translucency, β-human chorionic gonadotropin [β-HCG] and pregnancy-associated plasma protein A [PAPP-A] measurement)[62] have increased the importance of CVS. Noninvasive approaches, such as measuring maternal plasma free fetal DNA, have made invasive testing for sex-related disease unnecessary in 50% of the cases because it is required only when the fetus is the at-risk sex.[2,63] Because of the increasing number of diagnosable monogenic disorders, couples with a family history of a genetic disorder should be offered genetic counseling, either before conception or early in pregnancy. Rapid direct preparation of the fetal karyotype or fluorescent in situ hybridization (FISH) have largely been replaced with quantitative fluorescent polymerase chain reaction (QF-PCR) of chromosomes 13, 18, 21, and Y, if requested. Fetal cells are also cultured for karyotype analysis, but it is very likely that this will be replaced by molecular whole genome approaches such as array comparative genome hybridization (CGH). CVS can be used at any time in gestation, and placental biopsy is a very successful way to obtain a karyotype after delivery when the fetus has died.

PROCEDURE

CHORIONIC VILLUS SAMPLING

Consent

The procedure should be described to the patient. Counseling must include the aims of the CVS (i.e., karyotype, DNA analysis), and the risk of a serious complication (often described as 1%), including miscarriage, either procedure-related or background, should be quoted. The possible risk of limb defects is mentioned by some, but the risk is minimal after 10 weeks. The limitations of a karyotype and the risks of unrelated abnormalities that are not detected by a karyotype should be explained. Patients should also be informed of the small chance that testing will show confined placental mosaicism or sex chromosome abnormality and the small possibility of a further invasive technique such as amniocentesis or fetal blood sampling to confirm a diagnosis. Alternative diagnostic techniques may be discussed. Only after the counseling process is complete is the patient asked to provide written consent.

Sampling Site

The ideal target is a thick part of the placenta that can be sampled at an angle that allows a long needle path through the placenta and avoids a perpendicular path toward the chorionic plate. Very rarely, at approximately 11 weeks, transabdominal CVS is difficult if the uterus is retroverted, the placenta is posterior, and a lateral approach is not possible. Some operators switch to a transcervical approach, but we would ask the patient to return in a week, when sampling may be easier.

Target Puncture

Transabdominal CVS can be done either freehand or with a needle guide. With the "double-needle" technique (Fig. 9–2), after a local anesthetic has been administered, the first needle is advanced through the maternal skin, through the uterine wall, and into the placenta. The stylet is removed, and a second needle is passed into the placenta and attached to a syringe that contains normal saline. The placental villi are then aspirated.[64,65] By drawing the finer needle into the outer needle during aspiration, the sharp bevel of the first needle seems to cut the villi, reducing the need for needle movement and presumably reducing placental trauma.[66] A placental biopsy forceps may also be used through an outer guide needle. With the double-needle technique, if the tip is inserted correctly into the placenta, maternal contamination cannot occur. If a single needle is used, the aspirated tissue can be examined with a dissection microscope to exclude maternal contamination, but the risk of contamination should be considered. Whatever technique is selected, the sample is placed in a suitable CVS medium before it is transferred to the cytogenetics laboratory.

Maternal contamination of chorionic cell cultures may lead to a false-negative diagnosis, particularly when polymerase chain reaction (PCR) amplification is used and in some biochemical examinations. Operator experience reduces the risk of maternal cell contamination.

Transcervical CVS

This approach is less common now because of an apparent increased risk of fetal loss and an increased
FIGURE 9–2
An 18- to 21-g double needle for chorionic villus sampling (CVS). The stylet of the 18-g (pink) needle is removed and the thinner 21-g (green) needle is passed into the placenta for the aspiration of the villi.

likelihood of failure.[67–69] Only 2%, and now probably less, of fetal medicine consultants in the United Kingdom perform transcervical CVS.[70] Some practitioners consider this approach useful in high risk patients who require early diagnosis or when the uterus is retroverted and the placenta is posterior or when an anterior wall leiomyoma makes an abdominal approach difficult. A bendable polyethylene catheter with a metal obturator is introduced through the cervix and advanced into the placenta under ultrasound guidance. A syringe that is partially filled with saline is attached to the hub and a vacuum created to aspirate 10 to 50 mg of tissue, which is then rinsed into a Petri dish. Some units prefer curved biopsy forceps.[71]

Complications

CVS should be performed only under continuous ultrasound guidance. Canadian[57] and Danish[55] trials found no significant difference in procedure-related loss rates between the first and the second trimesters. Only the Danish study[55] allowed a randomized comparison of transabdominal CVS and second-trimester amniocentesis and the fetal loss rates were similar. A 1% excess fetal loss rate is usually quoted for amniocentesis and CVS.

Some reports suggest that first-trimester CVS (including those performed as early as 6–7 wk) may be associated with severe limb defects.[72–74] These defects were not observed in CVS performed after 11 weeks' gestation. The World Health Organization (WHO) International Registry for Limb Defects found no difference in the prevalence of limb defects after CVS compared with the background population.[75,76] Therefore, during counseling, it is standard practice to indicate that there is no increased incidence of limb defects after 10 weeks.

Placental Mosaicism

Confined placental mosaicism occurs in approximately 1% of samples,[77–80] but this rate may be lower with experienced laboratories. Analyzing several cultures makes it easier to detect in vitro changes because they are usually present in a single culture (pseudomosaicism). However, the same finding in several or all of the cultures increases the likelihood of true mosaicism, either confined to the placenta or present in both placenta and fetus. In this case, another fetal tissue, such as blood or amniotic fluid, should be tested depending in part on the particular chromosome involved. The finding of structural abnormality on ultrasound is very important and makes it much less likely that the results are caused by confined placental mosaicism.

Late Placental Biopsy

Several small series indicate that late placental biopsy is both safe and reliable for diagnosis. The loss rate is similar to that of first-trimester CVS.[81,82]

Conclusion

CVS provides a rich source of fetal cells or DNA for analysis of karyotypic and genetic disorders. It is usually performed after 11 weeks, typically by a transabdominal route. One advantage of first-trimester CVS is that an abnormal result allows surgical termination, if desired. Mosaicism is a rare complication in about 1% of samples; the rate is lower with amniocentesis.

Amniocentesis

Introduction

Amniotic fluid contains amniocytes in addition to fetal cells from the skin, genitourinary system, and gut, along with biochemical products that may be removed for analysis. Amniocentesis should be performed only under continuous ultrasound guidance.[4]

Indications

GENETIC

Amniocentesis is usually performed to determine fetal karyotype. Indications for fetal karyotyping include an abnormal screening test result for trisomy 21, advanced maternal age, a sonographically detected structural abnormality, previous aneuploidy, and known chromosomal translocation in either partner. With the advance of genetics and molecular biology, more genetic diseases can be diagnosed by amniocentesis rather than other more "direct" methods: for example, harlequin ichthyosis can now be diagnosed with DNA-based testing on amniotic fluid rather than fetal skin biopsy.[83,84]

The amniotic fluid container is labeled and examined by the patient for accuracy, and the sample is sent promptly to the cytogenetics laboratory for analysis. The amniocytes are studied during the metaphase stage of cell division. Although standard culture techniques require 2 to 3 weeks, newer methods, with the cells grown on a cover slip, allow a complete analysis in 7 to 10 days,[85] and it is likely karyotyping will be replaced by molecular approaches in the next few years. Approximately 0.5% of cultures are unsuccessful; less often, maternal contamination complicates the diagnosis.[86] Less than 0.4% of cultures show evidence of pseudomosaicism or true mosaicism.[87,88] FBS may be helpful, but a normal result does not guarantee that all is well.

Direct DNA probing of interphase chromosomes by FISH can be used to detect known deletions, such as 22q in at-risk pregnancies, in addition to rapid diagnosis of trisomy 13, 18, and 21,[89,90] but the latter has been replaced by QF-PCR. Although a positive test result is reliable, detecting 90% or more of chromosomal abnormalities, some problems detectable by karyotyping will not be found on rapid testing. Currently, rapid aneuploidy screening is usually performed with QF-PCR whose detection rate for the common aneuploidies (chromosomes 13, 18, 21, X, and Y) is 98.6%.[91] QF-PCR has some advantages over FISH, which is why it is used more widely. It has been argued that QF-RCR could be used as a "stand-alone" test (no karyotype performed), but this could result in a small proportion of abnormalities not being diagnosed.[92] PCR-based primers are now used with DNA from amniotic fluid samples to determine almost all potentially relevant fetal red blood cell and platelet genotypes.[93,94] Methods using free fetal DNA in maternal blood are likely to further reduce the need for amniocentesis. In some countries, it is already used to detect fetal D status, when indicated, as part of routine prenatal care,[63] and high throughput testing is being introduced to reduce the administration of the blood product anti-D in routine antenatal prophylaxis.[95]

BIOCHEMISTRY

Molecular DNA analysis has largely replaced amniocentesis to diagnose inborn errors of metabolism and cystic fibrosis by measuring fetal enzymes activity and their products or substrates. Likewise, amniocentesis to measure α-fetoprotein and acetylcholinesterase to diagnose a neural tube defect are rarely necessary because of the reliability of ultrasonography.[96]

FETAL INFECTION

Although cytomegalovirus is excreted in fetal urine and fetal infection is reliably detected by culture of amniotic fluid,[97,98] PCR technology is the method of choice for the antenatal diagnosis of fetal viral infection because many viruses grow poorly in clinical laboratories (also see Chapters 27–31). PCR has replaced the traditional mouse inoculation test for toxoplasmosis because it can be used earlier in pregnancy and has greater sensitivity (also see Chapter 32).[99] As with traditional methods, a false-negative result may occur if there has been insufficient time for transplacental passage to occur. Therefore, in cases of suspected toxoplasmosis, a negative amniocentesis result does not provide complete reassurance and ultrasound follow-up is recommended.[100]

CHORIOAMNIONITIS

Successful amniocentesis is possible in 49% to 98% of women with preterm premature rupture of the membranes (PPROM).[101] The likelihood of successful sampling is higher in more recent publications.[102] The specimen can be assessed by direct microscopy, Gram stain, culture, and a series of new proteomic tools. It is unclear whether management based on the information gained in women with PPROM changes the clinical outcome. No randomized trial supports the use of routine amniocentesis to diagnose chorioamnionitis in women with either preterm labor or PPROM, although a small study showed an increased hospital stay for babies in the "no amniocentesis" group.[103] A recent feasibility study concluded that a randomized study of amniocentesis versus no amniocentesis in women with PPROM would be feasible.[104] Amniocentesis may be useful when the woman is asymptomatic and fetal infection is suspected. Between 17% and 34% of asymptomatic women with PPROM have positive culture findings,[101] which may allow for earlier diagnosis and treatment.[105] However, most women with positive culture findings deliver within 48 hours, and there is inadequate information to guide antibiotic selection to ensure therapeutic concentrations at the site of infection.

FETAL LUNG MATURITY

Improved gestational dating, appropriate use of corticosteroids, and a growing understanding of the timing of iatrogenic premature delivery have nearly eliminated the need for amniotic fluid analysis to assess fetal lung maturity.[106]

Early Amniocentesis

Some had hoped that early amniocentesis (<15 wk) would be an alternative to CVS.[53,107,108] However, the risks of early amniocentesis, including spontaneous abortion, stillbirth, and neonatal death, are greater than those of CVS.[54] The

Canadian Early and Mid-trimester Amniocentesis Trial (CEMAT) group concluded that early amniocentesis should be performed only in special circumstances because of the higher fetal loss rate and incidence of talipes with early versus second-trimester amniocentesis.[59] The risk of membrane rupture is particularly high when performed before 13 completed weeks, possibly because, at this stage, the amnion is not adherent to the chorion and so is more likely to rupture and persistent amnion chorion separation may be a risk factor even later in pregnancy. Several other studies found an increased risk of oligohydramnios and associated orthopedic abnormalities, including talipes equinovarus.[52,54] Tenting of the amniotic membrane and the smaller amount of fluid in the amniotic sac before 15 weeks increase the incidence of a "dry" tap.[109] The sample volume is smaller and there are fewer cells per milliliter, although the percentage of cells dividing is higher. Djalali and colleagues[110] reported that longer culture times were required after early amniocentesis.

PROCEDURE

AMNIOCENTESIS

Amniocentesis is performed under ultrasound guidance after 15 weeks' gestation. A typical karyotypic study requires the removal of 15 to 20 mL of amniotic fluid.[4] Removal of larger volumes should be avoided unless necessary for specific tests.

Consent

The indication and risks of the procedure should be fully explained to the woman. Serious or frequently occurring risks of amniocentesis that should be quoted to patients.[111] These include miscarriage (≤1% excess risk), failure to obtain the sample, fetal injury, maternal bowel injury, amniotic fluid leakage, severe sepsis (<1/1000), and failure of cell culture. Preprocedure counseling by a midwife-practitioner has been successfully introduced in some hospitals.[112]

Antiseptic and Anesthetic

The skin is scrupulously cleaned with antiseptic solution (e.g., chlorhexidine). Local anesthetic is not normally required for diagnostic amniocentesis, because it does not decrease the pain perception.[7,8]

Target Puncture

Under ultrasound guidance, the needle is advanced into the targeted pool of amniotic fluid, with care taken to avoid the fetus, placenta, and cord (see Fig. 9–1). A 22-gauge needle is usually used.[70] If the freehand technique is used, the ultrasound beam is directed so that the length of the needle is visualized, allowing the operator to alter the course in response to fetal movements and contractions. When the tip of the needle reaches the targeted location, a very small volume of amniotic fluid is aspirated and discarded to avoid maternal contamination. Approximately 15 to 20 mL of fluid is aspirated and sent for analysis. To prevent maternal contamination, the syringe is removed from the hub before the needle is withdrawn from the patient.

Complications

Early studies, including CEMAT, reported a total loss rate of 3.2% after amniocentesis.[59,113] These losses are believed to reflect, at least in part, the large needles used (>19 gauge) as well as unsuccessful attempts. The British Working Party on Amniocentesis reported a 2.4% total fetal loss rate before 28 weeks (stillbirth rate of 1.2% vs. 0.8% in control subjects) and neonatal death (0.5% control subjects), but concluded that the loss rate attributed directly to amniocentesis was 1.5%.[14] The only randomized trial of low-risk women suggested a 1% risk of spontaneous abortion after amniocentesis.[58] Interestingly, a secondary analysis of the patients enrolled in the FASTER (First and Second Trimester Evaluation of Risk) trial[114] showed no difference in the fetal loss rates before 24 weeks between the amniocentesis and the control groups.[41] It would be premature to adopt this conclusion, because recent literature reviews suggest an excess fetal loss after amniocentesis of 0.6%.[115,116] It is possible that the control group had a higher loss rate because of undiagnosed chromosomal abnormality cases still being included while not being present in the amniocentesis group. Our study of fetal loss after amniocentesis (defined as the total loss rate minus known lethal condition minus losses beyond 2 weeks postprocedure) was 0.7%.[27] The RCOG advises that a 1% risk should be quoted to patients, and if lower risks are quoted, they should be supported by robust local data.[4] Perforating the placenta increases the relative risk of loss 2.6 times and increases the maternal serum α-fetoprotein level 8.3 times. The transplacental route should, therefore, be avoided unless no other option is available.

Although no randomized controlled trials assessed the procedure-related loss rate from amniocentesis in multiple pregnancies, case-control studies suggest that the loss rate is only slightly higher than the background rate (1.15%–1.8%).[22–24,27,117]

OLIGOHYDRAMNIOS

Up to 2% of amnioceteses are associated with chronic leakage of amniotic fluid. It is plausible that the risk is smaller with the use of smaller needles. There are variable reports of an increased prevalence of neonatal respiratory morbidity after amniocentesis; the small risk of oligohydramnios after amniocentesis may contribute to this complication.[14,118,119] Similarly, talipes equinovarus is rarely attributable to amniocentesis, and probably only secondary to oligohydramnios.

FETAL TRAUMA

Inadvertent puncture of the fetus during amniocentesis has not been not reported in a large series when the procedure was performed under continuous ultrasound guidance by experienced operators.[58] Several case reports suggest an association between amniocentesis and skin dimpling, fistulas, cord hematoma, and corneal perforation.[120–123] Because intended fetal puncture rarely leaves a mark and similar findings occur in neonates who did not undergo amniocentesis, the association is dubious. However, this is obviously to be avoided, partly because of possible risks of viral transmission such as HIV.

Conclusion

Amniocentesis after 15 weeks is the most widely performed antenatal diagnostic technique. It is relatively simple to perform, and although a fetal karyotype is the most common indication, the procedure has many uses. The application of PCR has steadily reduced the amount of amniotic fluid needed for testing and the time required for at least an initial result.

Fetal Blood Sampling

Introduction

Fetal blood was first obtained during labor from the capillary circulation of the presenting part.[124] FBS in a continuing pregnancy was first undertaken transabdominally by fetoscopy to diagnose severe inherited diseases, with termination planned if the fetus was affected. Cordocentesis was first reported in the 1980s.[125] The development of medical approaches to fetal disease has made the role of fetal phlebotomy (typically by cordocentesis) comparable with that in postnatal medicine.

Indications

Indications for FBS may be grouped into diagnostic and therapeutic areas. Here we focus on the diagnostic indications. FBS is indicated when the potential benefit of a change in management outweighs the procedure-related risks.

Diagnostic Uses
CHROMOSOMAL ABNORMALITIES

The rapid rate at which white blood cells divide allows a high-quality karyotype with good chromosome banding within 48 to 72 hours. The most common indications for a rapid karyotype are fetal malformation or severe early-onset fetal growth restriction detected by ultrasonography. However the value of the speed of the result is falling with the routine use of amniotic fluid PCR or FISH. Other problems that can be investigated by fetal blood cytogenetic analysis include possible mosaicism and culture failure after either amniocentesis or placental biopsy. For many indications, QF-PCR has replaced FBS.

SINGLE-GENE DEFECTS

FBS can diagnose hemoglobinopathies, coagulopathies, severe combined immunodeficiency, chronic granulomatous disease, and some metabolic disorders.[126] FBS is performed less often for antenatal diagnosis of single-gene disorders than previously because many can be diagnosed earlier in gestation by applying DNA techniques to amniocytes. FBS remains an option for at-risk patients who seek care late and when DNA analysis is not possible.

ANEMIA

Although various indirect methods are used to assess fetal anemia (also see Chapter 13), the definitive test before and after birth is measurement of the hemoglobin concentration. This may be required in maternal red cell alloimmunization[126] and some cases of nonimmune hydrops.[127] The reliability of the use of middle cerebral artery Doppler peak velocity to diagnose anemia has greatly reduced the role of FBS to detect anemia.[18]

THROMBOCYTOPENIA

Severe fetal thrombocytopenia as a result of alloimmune thrombocytopenia may lead to cerebral hemorrhage before, during, or after birth and might cause mental handicap or death (also see Chapter 14). The fetal platelet count can be measured to guide diagnosis and treatment, but this is used much less than previously because of the effectiveness of intravenous immunoglobulin, which is now often used without FBS.[128]

HYPOXIA AND ACIDOSIS

Fetal acidemia may be excluded by Doppler studies of the fetal vasculature (also see Chapters 10 and 11). Suspected fetal hypoxia or acidemia can be confirmed or refuted by fetal blood gas analysis.[129] Increasing evidence shows that chronic fetal acidemia is associated with impaired long-term neurodevelopment.[130] However, there is no convincing evidence that the benefits of fetal acid-base status outweigh the risks of FBS, and therefore, it is rarely indicated.

INFECTION

Appropriate fetal blood tests (e.g., infection-specific fetal immunoglobulin M or detection of specific genomic material by PCR) can determine whether maternal infection has led to fetal infection. However, the difference between being "infected" and "affected" (i.e., damaged) must not be forgotten. Fetal blood tests are almost never used because the reliability of amniotic fluid PCR has become established and the importance of ultrasound findings is clear.

MONITORING OF TRANSPLACENTAL THERAPY

Some fetal diseases are treated by drugs that are given to the mother, cross the placenta, and achieve therapeutic concentrations in the fetus. Examples include antiarrhythmic agents (e.g., flecainide or digoxin) to correct fetal tachyarrhythmias and gammaglobulin to improve low fetal platelet counts. FBS can be used to measure fetal drug levels.[131,132]

Procedure Options

The operator chooses the intended sampling site and guide technique from several options, described earlier.

SAMPLING SITE

Umbilical Cord Vessels (Cordocentesis)

FBS was first performed under fetoscopic guidance[133] and entailed a 2% to 5% risk of serious complication.[134] In addition, the maternal sedation used to facilitate the procedure affected the fetal blood gas measurements.[135] Ultrasound-guided needling is considered safer and the preferred technique.[125,136]

The placental origin of the umbilical cord is often the easiest site to puncture. Many prefer this site because of its fixed location, which prevents movement of the needle. Others accept free loop puncture, but use pancuronium to minimize subsequent fetal movement. Some use free loop puncture without fetal paralysis and suggest no obvious increase in fetal loss rate.[137] A relevant consideration is not the location, but the ease of access. The fetal origin of the umbilical cord is problematic because there is no length to buffer the effect of fetal movement after puncture and the potential for bradycardia may be increased. Although cordocentesis is usually done after 18 weeks, success is reported as early as 12 weeks, at the cost of an increased fetal loss rate.[138,139]

Fetal Intrahepatic Vessels

Blood can also be obtained from the intrahepatic portion of the umbilical vein (Fig. 9–3).[131,140] This procedure is useful when the umbilical cord insertion is not accessible. It can be made easier by administration of vecuronium or pancuronium into the vein[141] for fetal paralysis. This is especially useful when a lengthy transfusion is anticipated. The complication

Fetal blood sampling by ultrasound-guided needling of the intrahepatic vein.

FIGURE 9–4
Fetal blood sampling by ultrasound-guided needling of the heart.

FIGURE 9–6
Cordocentesis with the freehand technique.

NEEDLING TECHNIQUE

A needle guide or freehand technique may be used (Figs. 9–5 and 9–6). A combined technique, in which the needle guide is used for the approach to the cord and a freehand technique for the vessel puncture, has also been described.[146]
FIGURE 9–5
A typical needle guide used to perform cordocentesis. The small footprint allows the needle to enter the sonographic plane shortly after it penetrates the skin.

P R O C E D U R E

FETAL BLOOD SAMPLING

The following elements are shared, regardless of whether FBS is performed freehand or with a needle guide. FBS should be performed only by physicians who have extensive experience with other obstetric, ultrasound-guided needle procedures (e.g., amniocentesis, transabdominal CVS). Units that offer this service must perform enough cases to maintain expertise; 20 procedures per year is a reasonable minimum. This typically requires a center with many referrals.[147]

Preparation

An urgent delivery may be required if the pregnancy is at a potentially viable gestation, and if the indication for the procedure has not led the patient to request a conservative approach in the event of complications (e.g., a major brain malformation). Otherwise, the procedure must be performed at a site with easy and rapid access to an operative delivery room with an anesthetist immediately available in viable pregnancies. The mother should be positioned to avoid supine hypotension; hyperventilation and sedation should be avoided. An 8- to 12-cm needle is usually sufficient depending on several factors including amniotic fluid volume and maternal obesity, and the distance should be measured on the ultrasound screen before starting if there is any doubt.

Needle Path Selection

A transplacental approach usually provides the easiest route to the placental cord origin, unless the placenta is entirely posterior. However, in women with red cell alloimmunization, transplacental puncture boosts the

rates of this approach are comparable with those of cordocentesis, and this seems applicable to intravascular transfusion as well.[142] There is possibly a smaller likelihood of bleeding after this procedure, which may make it more suitable for use when severe fetal thrombocytopenia is suspected.[143]

Fetal Heart

The heart is larger than the umbilical cord, and puncture of the heart is relatively simple (Fig. 9–4). Despite fear of damage, cardiac puncture is relatively safe.[144] The heart can be used in the unusual event that the umbilical cord or hepatic vein cannot be punctured and fetal blood must be obtained. It can also be useful if an emergency blood transfusion is required (e.g., to treat procedure-related bleeding) or for feticide. Because the fetal heart contains blood from different circulatory origins, it may not be suitable for blood gas assessment.[145]

FIGURE 9–7

maternal antibody titer as a result of fetal-maternal hemorrhage.[148] Therefore, it is best to avoid the placenta, unless transfusion is anticipated in an alloimmunized woman (Fig. 9–7).

Target Puncture

Cordocentesis

Many operators prefer the placental origin of the umbilical cord, approximately 1 cm from the placenta, because the blood obtained from this site must be fetal. A closer puncture can lead to confusion. The needle is brought close to or even touching the umbilical vein, and then sharply advanced the remaining distance. A slow advance may push the tissue away, even at this relatively fixed site. After the needle tip is visualized within the lumen of the umbilical cord, the stylet is removed. If the needle is ideally sited, blood will fill the hub. A 1-mL syringe is applied tightly to the hub, and blood is withdrawn. After 20 weeks, 7 mL may be sampled, but before 20 weeks, the volume removed should be the minimum necessary for the specific tests. Often, no blood is obtained initially and the operator must assess whether the needle tip has passed through the vessel lumen or perhaps is located in Wharton's jelly. The needle is sharply advanced or gently withdrawn, and the shaft is rotated 180 degrees between the operator's finger and thumb while suction is maintained.

Occasionally, amniotic fluid is obtained when the needle tip appears intraluminal. With the freehand technique, the needle is moved side-to-side in search of cord movement. With a needle guide, an up-and-down movement of the needle produces the same result. Cord movement indicates that the needle has passed through the cord. It is withdrawn until no more amniotic fluid is aspirated, the syringe is changed (because even a small amount of amniotic fluid is a very powerful coagulant), and the procedure is continued. If the needle has passed through the side of the cord without entering a vessel lumen, it is withdrawn slightly and its path adjusted. If the tip is lateral to the umbilical cord, it is withdrawn and the needle used to touch the vein before the puncture attempt is repeated.

It is essential to identify the vessel that has been entered if blood gas results are to be interpretable. If the puncture is performed at either the placental or the fetal origin of the umbilical cord, the vessel can usually be identified by the direction of turbulence after rapid injection of up to 1 mL of normal saline.[136] If fetal paralysis is desired, intravascular administration of pancuronium (0.2–0.3 mg/kg estimated fetal weight) serves the same purpose as saline for identification.

Intrahepatic or Heart

If the intrahepatic vein or the heart is the intended sampling site, fetal paralysis with intramuscular pancuronium (0.2–0.3 mg/kg estimated fetal weight) may be used. The effect is rapid (within minutes) and lasts for 90 to 120 minutes. The techniques for needle path selection and guidance are similar to those described for the umbilical cord. However, the fetal chest or abdomen is entered first, the direction is checked, and the needle is advanced into the sampling site as a separate movement. The heart is best entered through the anterior chest, through the thick muscle of the ventricles to reduce blood leakage and avoid damage to the valves or electrical conduction system.

A double-needle technique has also been described.[149] The first needle is used to puncture the fetal body cavity and a second, finer needle is passed within the first to puncture the target. This technique offers the theoretical advantage of the stiffness of the first needle and the small caliper of the sampling needle.

Postprocedure Monitoring

The puncture site is observed ultrasonically for bleeding after the needle is removed. Bleeding is common after transamniotic cordocentesis, but is usually brief and without clinical significance. After bleeding has stopped, the fetal heart rate is measured. Bradycardia is the most common complication of cordocentesis, but it is usually transient. If the fetus is previable, the woman should wait in the hospital until she feels well and then return home. There are no special precautions or restrictions. If a local anesthetic is used, she should be warned to expect a bruised sensation in a few hours. Cramping is noted in about 10% of women. Acetaminophen (paracetamol) or another nonprescription analgesic can be used safely. If the fetus is viable, the heart rate pattern is assessed by cardiotocography for at least 30 minutes before discharge. Pancuronium causes a nonreactive tracing, with mild fetal tachycardia. The mother should be warned that perceptible movement might not return for several hours.

In the rare event that bleeding from the puncture site is prolonged and heavy, maternal blood may be collected into heparinized syringes for an emergency fetal transfusion. This is most likely with alloimmune thrombocytopenia when the fetus is profoundly thrombocytopenic.

Laboratory Testing

Several laboratory techniques are available to rapidly confirm that the blood sample is fetal and pure. However, they may be unnecessary if the technique described previously is used. Further, they may be

unusable if the fetal blood has been replaced with adult blood by transfusion. It is prudent to send a small sample of blood for a hematology profile to confirm that the mean cell volume is increased and that the hemoglobin concentration, white blood cell count, and platelet count are normal.

Complications and Risks
FETAL

The principal complications of FBS that threaten fetal well-being are, in order of frequency, fetal bradycardia (probably as a result of smooth muscle spasm after inadvertent puncture of the umbilical artery), hemorrhage or an obstructing hematoma at the puncture site,[150] and intrauterine infection.[151] Chorioamnionitis is often caused by *Staphylococcus epidermidis*. It typically causes myalgia, arthralgia, and a low fever 4 to 10 days after the procedure. There is no evidence to support prophylactic antibiotic administration, and most of the antibiotic agents used achieve poor amniotic fluid levels so prophylaxis is unnecessary. Placental abruption shortly after cordocentesis has been reported,[152] and PPROM has a frequency similar to that of amniocentesis. There is a risk of transmitting infection from the mother's blood (e.g., hepatitis, HIV) to the fetus, but this risk is probably low and possibly lower with the use of antiretroviral treatment in patients with HIV.[10–13] It has not yet been documented. Nevertheless, invasive procedures should be avoided when a mother has a life-threatening viral illness, unless the fetal indication warrants the additional risk.[153] A case of fetal hepatic necrosis in a growth-restricted fetus within 24 hours of intrahepatic vein blood sampling has been reported.[154]

POSTPROCEDURE LOSS RATES

Several well-recognized factors affect postprocedure loss rates. Loss and complication rates are clearly related to the indication for sampling and the final fetal diagnosis.[6,46,47,49,51,155] The background risk of intrauterine death is high when there is a severe structural malformation or a major chromosomal abnormality. The risk of profound bradycardia is significantly increased by fetal hypoxemia and arterial puncture. There does not appear to be an increased risk after cordocentesis in fetuses with a single umbilical artery.[156] Gestational age at sampling is also an important determinant because a viable fetus can be delivered if a complication arises. Emergency cesarean section may prevent fetal death, but by the time the problem is recognized and delivery is accomplished, the neonate may survive permanently damaged or die in the neonatal period. Performing the procedure near the delivery suite minimizes these risks, if delivery can be accomplished within 15 minutes.

The literature must be interpreted carefully because postprocedure loss rates are described after the application of qualifiers. It is essential to control for the indication or final diagnosis when comparing loss rates. It is only by doing so and by limiting the comparison to healthy fetuses that the risk of the technique is shown. Reports of procedures performed freehand show a total procedure loss rate of approximately 1% to 2%, depending on the mix of indications. In one study of 202 pregnancies, the loss rate was 1 of 76 (1.5%) fetuses sampled for antenatal diagnosis, 5 of 76 (7%) sampled for an anomaly, 4 of 29 (14%) sampled for fetal assessment, and 9 of 35 (25%) sampled for nonimmune hydrops.[47] The fetal loss rate was similarly low in more recent studies.[137,143] Transfusion carries a considerably higher procedure-related risk than FBS.

MATERNAL

The main maternal risk associated with FBS is red cell alloimmunization. The fetal blood type should be tested in at-risk women, and anti-D immunoglobulin should be given if the fetus is Rhesus-positive. Chorioamnionitis or emergency cesarean section can create secondary maternal risks. When FBS or transfusion is undertaken and the fetus is considered viable, maternal aspects of emergency delivery should be considered. Needle injury to the maternal intra-abdominal organs, such as intestines, or vessels may be more common than recognized, but significant morbidity has not been reported after FBS. Maternal intra-abdominal infection and bleeding would be expected to occur at the same rate as that for amniocentesis.

Conclusion

FBS is indicated when the potential benefits of a change outweigh the procedure-related risks. The risks and benefits to both the fetus and the mother should be considered. Most prefer FBS by ultrasound-guided needling of the umbilical cord (cordocentesis). The fetal heart and intrahepatic vein are alternative sampling sites. None of these techniques should be attempted unless the operator has considerable experience with related procedures. The most important determinant of the fetal loss rate is the indication for sampling.

Fetal Tissue Biopsy

Although progress in molecular biology allows more diseases to be diagnosed from fetal DNA, some conditions still require testing of fetal tissue, such as skin, liver, and muscle. These tests are rarely indicated because the diseases are rare. Only experienced fetal medicine specialists should perform them. Rapid advances in the field mandate close contact with a clinical geneticist to stay abreast of new developments.

Skin Biopsy
INDICATION

Histologic examination of a fetal skin biopsy specimen is useful for the diagnosis of some bullous disorders (congenital bullous epidermolysis, epidermolysis bullosa dystrophica, epidermolysis bullosa lethalis),[134,157–159] hyperkeratotic disorders (congenital ichthyosiform erythroderma, epidermolytic hyperkeratosis, Harlequin ichthyosis)[159–162] (Figs. 9–8 and 9–9), or oculocutaneous albinism.[159] A molecular understanding of these diseases has made early diagnosis by CVS possible, and therefore, the number of skin biopsies performed has decreased since the early 1990s.[159] Occasionally, fetal skin biopsy can confirm true fetal mosaicism.[163]

PROCEDURE

Fetoscopy is rarely performed diagnostically, but the development of new fiberoptic scopes has decreased the pregnancy loss rate to less than the rate of 2% to 5% associated with classic fetoscopic methods.[157]
FIGURE 9–8
Histologic features of skin from a fetus with harlequin ichthyosis.

FIGURE 9–9
An infant with harlequin ichthyosis.

These scopes are popular aids for some therapeutic fetal procedures (e.g., laser ablation). For skin sampling, this technique has been replaced by ultrasound-guided biopsy, commonly performed with a 20-gauge biopsy forceps introduced through a 16- to 18-gauge needle. Obtaining multiple small biopsy specimens of skin from the scalp over the occiput or from the buttocks is recommended.[164,165] The fetal skin heals well after biopsy.

LABORATORY TECHNIQUES

Histologic and biochemical tools like electron microscopy and immunohistochemistry[159] are used to diagnose skin conditions. Several ichthyoses and genetic conditions associated with ichthyoses are diagnosable with fetal cells obtained from CVS, amniocentesis, or FBS.[162]

Fetal Liver Biopsy

Amniotic fluid cells and placental tissue may be used to diagnose most fetal metabolic diseases.[166] However, some inheritable inborn errors of metabolism show defects in enzyme activity confined to the liver and require a fetal liver biopsy.[167,168]

P R O C E D U R E

Fetoscopic[157] and ultrasound-guided[168] procedures are used (Fig. 9–10). Either a hollow needle or a Tru-Cut biopsy needle is inserted through the skin, over the right upper quadrant of the fetal abdomen, and into the liver (Fig. 9–11). The biopsy specimen is sent to a laboratory. Normal overall activity of a number of enzymes but low activity of a specific enzyme is considered evidence of disease.

Fetal Muscle Biopsy

The most common inheritable major muscular dystrophy is Duchenne's muscular dystrophy, which is caused by a defect in the gene for dystrophin.[169] Although it is often diagnosable antenatally from fetal DNA obtained by CVS, with molecular analysis seeking either a deletion mutation or a linkage analysis, the gene is large, with many possible defect sites.[170] In some cases, no deletion is found and biopsy is the only recourse.[171,172] Other myopathies can also be diagnosed.[173]

LABORATORY TECHNIQUES

A wide range of studies is possible. For Duchenne's muscular dystrophy, the biopsy specimen is examined to confirm the presence of muscle and treated with an immunofluorescent antibody for dystrophin protein (Fig. 9–12).[174]
FIGURE 9–11

(Courtesy of Prof. S. Love, Department of Neuropathology, Bristol, UK.)

These uncommon procedures should be performed only by experienced fetal medicine specialists.[175] The maternal abdominal skin is anesthetized, and a small nick is made with a scalpel to facilitate the entry of a Tru-Cut biopsy gun[171] (Fig. 9–13). Under ultrasound guidance, the tip is advanced into the fetal buttock or thigh in a down-and-out direction. The coring guide is extended,
FIGURE 9–13
KlearKut biopsy gun.

and the trigger is pulled to cut the biopsy specimen. Risks of the procedure include fetal bleeding, nerve damage, and pregnancy loss. There are reports of maternal contamination,[176] but this can be prevented with a double-needle technique.

Other Organ Biopsy

Histologic diagnosis of fetal tumors would be helpful in many cases, and there are reports of biopsy of fetal mediastinal and renal tumors.[177] However, biopsy of any tumor can cause uncontrollable bleeding, leading to severe fetal damage or death. In many cases, the histologic features vary in different locations. As a result, biopsy of a fetal mass is rarely advised.

Conclusion

Most antenatal fetal diagnoses are based on fetal DNA obtained by CVS, amniocentesis, or FBS. However, fetal skin, liver, and muscle biopsy specimens are required for some lethal or severely disabling conditions. These are complex procedures, with significant risk to the pregnancy, and they should be performed only in tertiary fetal medicine centers by experienced clinicians.

Prenatal Fetal Surveillance

TZE KIN LAU

Videos corresponding to this chapter are available online at www.expertconsult.com.

INTRODUCTION

The purpose of obstetric care is to optimize maternal and fetal safety. The clinical decisions are always a balance between the risks to the fetus if delivered and the risks to the mother and fetus if the pregnancy continues. In an attempt to stratify risk, a variety of screening tests are performed during the prenatal and intrapartum periods to identify the high risk population. These tests include the patient history, physical examination, laboratory tests, and sonographic assessments. In this chapter, we focus on what additional tests are available to monitor those pregnancies identified by one means or another as high risk of chronic hypoxia and determine the optimal timing for intervention or delivery.

Fetal surveillance for specific conditions is addressed in detail in the relevant chapters in this book, including fetal abnormality (see Chapters 7–9, 15–20, and 24), fetal infection (see Chapters 26–32), fetal anemia (see Chapter 13), fetal endocrine problems (see Chapter 21), fetal tumors (see Chapter 22), and multiple pregnancy (see Chapter 23) and are not dealt with in this chapter. Intrapartum fetal surveillance is covered in Chapter 69. This chapter provides a more general discussion on the various tests for suspected or actual chronic fetal hypoxia that are available and their applications and limitations. Specific conditions related to chronic hypoxia are also dealt with in detail in the relevant chapters including growth restriction (see Chapter 11) and amniotic fluid abnormalities (see Chapter 12). In general, most fetal surveillance tests have a single goal—the detection of chronic fetal hypoxia. The theory is that by identifying the hypoxia-associated physiological changes before the fetus has suffered from long-term irreversible damages, preventive measures can be implemented. A corollary is that fetal compromise follows a relatively predictable pattern, allowing the surveillance tests to be repeated in defined intervals. These surveillance tests are not useful for the prediction or prevention of fetal damage due to acute events, such as major abruption or cord accidents.

NORMAL FETAL PHYSIOLOGY AND ADAPTIVE RESPONSES TO HYPOXIA AND METABOLIC ACIDOSIS

In normal pregnancies, the fetus lives in a relatively low-oxygen environment compared with that after birth. Several mechanisms ensure effective delivery of more than adequate oxygen to the growing fetus. First is the high blood flow rate, the consequence of a high cardiac output (estimated to be ~2.5 mL/min and 200 mL/min at 12 and 30 weeks, respectively, corresponding to ~170 mL/kg/min).[1] This is about double the cardiac output of about 75 mL/kg/min in a normal resting adult. In addition, placental exchange surface area continues to grow with advancing gestation. Second is the presence of a central shunting mechanism. Oxygenated fetal blood returning from the placenta through the umbilical vein bypasses the fetal liver via the ductus venosus (DV) to reach the fetal heart directly, and then through the formen ovale or the ductus arteriosus to reach the aortic outflow. These intrauterine shunts ensure that the most oxygenated blood is channeled with shortest delay to the most important organs including fetal brain and heart. Third is the well-known fact that the fetal hemoglobin has a higher affinity for oxygen, assisting the extraction of oxygen from maternal hemoglobin. The higher affinity works synergistically with the higher fetal hemoglobin level, which also increases its oxygen-carrying capacity.

Acute and chronic hypoxia induces different fetal responses.[2] Chronic hypoxia induces many adaptive responses in an effort to compensate for the reduction in oxygen concentration in the environment. However, it is unknown presently what causes cell damage during chronic hypoxia. Organ damages may occur with more severe degree of hypoxia, or perhaps when hypoxia is complicated by metabolic acidosis. Recent study also suggests chronic hypoxia induces a fetal inflammatory response syndrome in the absence of infection.[3]

One of the more important effects of chronic hypoxemia as it relates to monitoring is the redistribution of blood flow

so that there is preferential flow to the essential organs including the brain, heart, and adrenal glands,[4] a process referred to as "centralization." Blood flow to other organs tends to remain normal or decreased (the trunk), but further decreases with worsening hypoxemia.[2] Plasma hemoglobin level also increases in association with an increase in erythropoietin. Initially, fetal hypoxemia leads to an increase in fetal cardiac output. But with progression to severe hypoxia, cardiac dysfunction causes a reduction in cardiac output and failure of the normal cerebral vascular protective mechanism, leading to loss of cerebral vascular variability and increase in cerebral vascular resistance, in particular in the presence of metabolic acidosis.[5] Many of the early adaptive changes would seem to favor fetal survival. Many of these adaptations can be detected clinically by sonographic examinations and, therefore, can be useful in assessment of fetal well-being to assist the decision of timing for intervention before irreversible fetal damages occur. Their presence was thought in the past to be suggestive of fetal hypoxia, but not necessarily fetal damage. Recent study suggests that chronic hypoxia induces fetal inflammation, which might explain why randomized trials to date have failed to show improvement in long-term neurodevelopmental status after early intervention.

Conversely, chronic hypoxia alone usually will not induce significant changes in fetal movement or heart rate pattern until it is complicated by metabolic acidosis. Fetal movement and breathing movement are significantly reduced with acute hypoxia, but are usually normalized when the hypoxia is prolonged.[6] Reduction in fetal movement or breathing movement usually does not occur in chronic hypoxia until the fetus develops acidosis.[5] Similarly, fetal heart rate patterns are usually normal in case of mild chronic hypoxia, and abnormalities such as absence of acceleration or deceleration occur only with more severe hypoxia especially when acidosis is also present.[5–7] Because changes in fetal behavioral parameters are late signs of severe hypoxia with acidosis, the observation of normal fetal movement or fetal heart rate pattern does not exclude fetal hypoxia. Frank late decelerations do not usually occur in chronically hypoxemic fetuses until hypoxia-mediated cardiac dysfunction occurs.

INDICATIONS

The aims of fetal surveillance are to
- Reduce the incidence of fetal death.
- Minimize morbidity by optimizing the timing of delivery.
- Identify more clearly those fetuses genuinely at risk of chronic hypoxia and avoid unnecessary intervention in those that are not.
- Identify those fetuses at greater risk of acute hypoxia in labor.

The indications are maternal and/or fetal conditions known to be associated with chronic fetal hypoxia.

Common indications include
- Hypertensive disorders of pregnancy.
- Chronic renal disease.
- Maternal diabetes.
- Antiphospholipid syndrome and related autoimmune diseases.
- Cyanotic heart disease.
- Specific perinatal infections.

Common fetal indications are
- Intrauterine growth restriction (IUGR).
- Abnormal amniotic fluid volume.
- Reduced fetal movements.
- Vaginal bleeding.
- Abdominal pain without a clear explanation of its cause.
- Postdate pregnancy.

Tests of fetal surveillance are also initiated for less clear indications including a history of a previous stillbirth or growth-restricted fetus and raised maternal serum α-fetoprotein.[8] In many of these situations, a statistical association with poor perinatal outcome has been reported, but underlying chronic fetal hypoxia has not been proved. The dangers in instituting fetal surveillance in pregnancies without clear evidence of a risk of chronic hypoxia are unnecessary interventions.

Even for conditions with well-defined fetal risks, strong and clear scientific proof that a particular fetal surveillance test improves perinatal outcome is generally lacking owing to the difficulty in conducting good randomized trials.

For those with an indication for fetal surveillance, the gestation at which these tests should be initiated depends largely on the prognosis for neonatal survival should intervention be required owing to an abnormal test result—"practical fetal viability." If delivery is not considered to be a viable management option, for example, at a gestation of 24 weeks, there seems little ground for initiating fetal surveillance testing. Although the lower threshold for practical fetal viability obviously depends on the ability and performance of the local neonatal intensive care unit, the initiation of fetal surveillance testing cannot be justified under 24 weeks in the best circumstances, and more often not until 26 weeks' gestation.

FETAL MOVEMENT COUNTING

It has been known for decades that women with intrauterine fetal death often note a reduction in the quantity or quality of fetal movement prior to the loss being documented. This led to the introduction of fetal movement counting as a mean to monitor fetal health. However, most trainees in this specialty will quickly realize in their early years of training that many women who present with reduction in fetal movement have perfectly normal pregnancy with normal fetal outcome, and many who had incidental diagnosis of intrauterine fetal death during routine follow-up report normal fetal movement the day before or even at the time of diagnosis. There has been much controversy as to the validity and usefulness of using fetal movement counting as a fetal surveillance tool.

The perception of fetal movement is subjective. Previous studies have shown wide variation in the proportion of fetal movements documented on real-time ultrasound that were perceived by the woman, ranging from 16% to 80%.[9,10] In a recent multicenter study in Norway, 51% of the pregnant subjects reported they were concerned about perceived reduced fetal movement, of which 42% were concerned that her child was sick and 26% that her child would die.[11]

The most obvious question in using fetal movement counting as a fetal surveillance tool is when a reduction in fetal movements becomes significant. There are many

methods of fetal movement surveillance, but perhaps the most commonly used is the Cardiff method in which fewer than 10 movements in 12 hours is considered abnormal. However, the period of absent fetal movements in healthy fetuses is only 15.5 and 37 minutes at 32 and 40 weeks, respectively,[12] although this could be up to 75 minutes in term fetuses.[13] The average number of movements per hour is 31 during the last 10 weeks of pregnancy,[6] and the mean time required to appreciate 10 fetal movements is 20.9 ± 18.1 minutes.[14] Therefore, the Cardiff count-to-10 method is too conservative and will not allow early detection of fetal complications. It appears logical to shorten the time during which a reduction is considered significant. Moore and Piacquadio,[14] in their prospective study, instructed their subjects to report to the delivery suit if they had fewer than 10 fetal movement counts within a 2-hour period. When compared with historical data, such a strict protocol was shown to have reduced the perinatal mortality rate by a quarter, with a 13% increase in antepartum tests and tripling of interventions for fetal compromise. Such a strict protocol, although not impossible to accomplish, is not practical in most societies, and the findings have yet to be replicated. However, using a strict protocol of 2 hours to define abnormal fetal movement will undoubtedly increase the false-positive rate into an unacceptable range and impose significant stress to the pregnant women.

In the largest available randomized trial comparing formal fetal movement counting versus no instruction to monitor fetal movements involving 68,654 women, there was a trend to more antenatal admission, increased use of other fetal testing methods in the fetal movement counting group, but no difference in any of the measured fetal outcome variables.[15] The authors acknowledged that maternal reporting of reduced fetal movements did identify fetuses at increased risk of fetal death; however, those deaths were not prevented because of false reassurance provided by the subsequent fetal surveillance (largely nonstress test [NST]). The study could not rule out a small beneficial effect of fetal movement counting, but at best, the policy would have to be used by some 1250 women to prevent one unexplained antepartum late fetal death. In point, decreased/absent fetal movement is a late sign of chronic fetal hypoxia with acidosis. In theory, therefore, compromised fetuses presenting with this sign may be too late for any useful intervention other than to deliver a damaged baby. Furthermore, excessive fetal movement that sometimes accompanies acute events may be incorrectly interpreted by the woman as reassuring.

The Cochrane Database of Systematic Review of the use of fetal movement counting for the assessment of fetal well-being reported four studies, involving 71,370 women with 68,654 of these being in one cluster-randomized trial. There were no clinically relevant significant differences. The authors' conclusions were that "the review does not provide enough evidence to influence practice. In particular, no trials compared fetal movement counting with no fetal movement counting. Robust research is needed in this area."[16]

The use of fetal movement counting as a form of fetal surveillance was also not supported by the U.K. National Institute for Clinical Excellence (NICE) guideline on antenatal care for the National Health Service in England published in 2003. It concluded that "routine formal fetal-movement counting should not be offered" as a grade A evidence, and the same recommendation was reconfirmed in the updated version in 2008.[17]

Although formal fetal movement counting should not be offered, there will be times when pregnant women recognize and present themselves because of absent or reduced fetal movement. Abnormal fetal movement has been linked to a long list of possible causes including fetal growth restriction (FGR), oligohydramnios, and congenital malformation,[18] but the false-positive rate is very high. Therefore, the principles of management of this group of women are to exclude imminent fetal jeopardy, to identify possible underlying causes, and to avoid unnecessary intervention. High-level evidence on the appropriate management scheme for this group of women is lacking. A variety of options have been suggested ranging from using simple symphysis–fundal height measurement alone,[19] ultrasound assessment of fetal size/growth, NST or cardiotocogram (NST/CTG), NST with amniotic fluid assessment, or full biophysical profile study to Doppler study.[20] In practice, many advocate a comprehensive approach to assessment of the "at-risk fetus" using several methods in combination rather than relying on a single test alone. This is discussed in more detail later. In general, the simple detection of fetal heart activity may be sufficient in women who present with reduced fetal movement before the gestation of practical fetal viability because of the difficulty in interpreting the CTG at this gestation and the potential risks of unnecessary intervention outweigh the potential benefits.[21] For those who presented with reduced fetal movement late in the third trimester, an NST/CTG should be performed to exclude immediate fetal jeopardy. A sonogram should be performed if the CTG is abnormal unless immediate delivery is considered. If the CTG is normal, the role of routine sonogram is uncertain. The use of fetal Doppler examination in the absence of CTG or sonographic abnormalities late in the third trimester does not seem to provide useful additional information.[21]

BIOPHYSICAL PROFILE OR BIOPHYSICAL SCORE

The biophysical score (BPS) was introduced in 1980 by Manning and coworkers.[23] It assigns a maximum of 2 points to each of five variables including fetal breathing movement, fetal movements, fetal tone, qualitative amniotic fluid volume, and the NST. The first four variables were assessed by ultrasound examination, which was also useful for the detection of fetal anomalies. A normal BPS was defined as a score of 8 or 10 with normal amniotic fluid and indicative of a healthy fetus that is unlikely to die within the subsequent 7 days. A fetus with a score of 8 due to reduced amniotic fluid is considered as high risk for chronic compensated hypoxia and, therefore, either should be delivered or should repeat the BPS not less than twice a week. A BPS of 6 is considered equivocal and has to be individualized. If immediate delivery is not considered possible, the test should be repeated on same day or in the following morning. A BPS of 4 or less is abnormal and delivery should be seriously considered. This team subsequently recommended the BPS be initiated at a frequency of once per week in most high risk cases and at least twice per week at or beyond 42 weeks' gestation.[22]

In their initial study of 216 subjects, the perinatal mortality rate was found to be 0 to 600 when all five variables were normal and abnormal, respectively.[23] Based on a review of more than 54,000 BPS tests, they estimated that the false-negative rate, that is, fetal death despite a normal BPS, was only 0.6 per 1000.[22] The largest experience was subsequently reported by Manning and colleagues,[23] but the false-positive rate was little discussed. The false-positive rate for the BPS has been reported in only small case series and has been estimated to be about 75%.[22,24] Such a high figure was probably due to the incorrect interpretation of the primary data. The latest meta-analysis included five trials, involving 2974 women. Most trials were not of high quality. Although the overall incidence of adverse outcomes was low, available evidence from randomized controlled trials does not support the use of the biophysical profile (BPP) as a test of fetal well-being in high risk pregnancies. There were no significant differences between the groups in perinatal deaths or in Apgar score less than 7 at 5 minutes. Combined data from the two high-quality trials suggest an increased risk of cesarean section in the BPP group (relative risk [RR] 1.60, 95% confidence interval [CI] 1.05–2.44). However, the number of participating women was relatively small ($n = 280$). The authors concluded that additional evidence was required to be definitive regarding the efficacy of this test in high risk pregnancies.[25]

Given the labor-intensiveness of the standard BPS, and the realization that NST and amniotic fluid volume are probably the most important elements of BPS, a modified BPP using just the NST and amniotic fluid assessment was proposed as a fetal surveillance method,[26] reserving the complete BPS or other testing for those with abnormal modified BPP. Miller and colleagues[27] reported the use of modified BPP in more than 15,000 subjects and achieved a false-negative rate of 0.8/1000. It had a lower false-positive rate than the contraction stress test (CST) and was noninvasive.

Overall, the BPS test demands a higher level of technical skill, is more time-consuming, and requires more resources for equipment when compared with other tests. Furthermore, abnormalities of the biophysical parameters used in the BPS are generally late signs of hypoxia likely complicated with acidosis.[28] Intensive monitoring using BPS may be useful in identifying those with impending death, but might not be able to allow the detection of early fetal compromise. Together with the high false-positive rate and lack of supportive evidence of its superiority over other surveillance tests available, BPS does not appear to be a logical choice as a routine or first-line fetal surveillance test. At best, there is only fair evidence to justify their use as recommended in high risk pregnancies.[29]

NONSTRESS TEST

The observed association between gross fetal movements and transient fetal heart rate (FHR) accelerations in normal fetuses formed the basis of NST. It is a simple and noninvasive test that can be repeated as often as necessary. The assumption of the NST is that if FHR accelerations are absent for a prolonged period of time, there is a high likelihood of fetal hypoxemia. However, a clear understanding of the underlying physiologic basis is needed to realize the many limitations of this test.

Physiology

The baseline FHR falls gradually during the last half of gestation up to 30 weeks, and then remains stable at 142 beats/min over the last 10 weeks of pregnancy when all FHR data are analyzed.[30] In general, a baseline FHR between 110 and 160 beats/min in late pregnancy is considered normal, though it is suggested that a baseline rate above 150 beats/min is a potential sign of fetal hypoxemia and should be investigated further.[31,32] At the same time, an increase in variability and frequency of accelerations is observed with rising gestation.[30,33] FHR accelerations are strongly related to gross fetal movement: 85% of all FHR accelerations are associated with gross fetal movements, and 92% of all gross body movements are associated with FHR accelerations.[34] It is thus not surprising that accelerations are absent during fetal quiescence or the quiet phase of fetal sleep. In fetal sleep, neuromuscular blockade abolishes only one third of the FHR accelerations, indicating that the majority of accelerations in the fetus occur with movements as a result of central neuronal output affecting both the cardioaccelerator fibers and the motor neurons, rather than being a direct result of the movement.[35]

A healthy fetus exhibits an average of 34 accelerations per hour in late pregnancy.[36] In one small study, the longest time between successive FHR accelerations was 37 minutes, but it is likely the absence of an acceleration for up to 80 minutes could still be normal.[37] These accelerations require intact and mature neurologic control between the fetal central nervous system and the fetal heart. However, the occurrence of normal FHR accelerations in the presence of significant cerebral anomalies suggested that the NST is dependent only upon the fetal brainstem and NST predicts oxygenation and function at that site rather than normality of the entire central nervous system.[37]

The sympathetic and parasympathetic systems have important roles in the regulation of the FHR. Previous studies, mostly on animals, reveal that the sympathetic system develops early in fetal life, whereas the parasympathetic system develops more slowly[38] and exerts very little influence on the tone of resting fetal cardiovascular function until the third trimester.[39] It is generally believed that the FHR variability is caused in part by the opposing influence of the sympathetic and parasympathetic stimuli to the fetal heart. It is, therefore, not surprising that FHR variability is in general lower in the second and early third trimesters.

Owing to the immaturity of the fetal nervous system, a significant proportion of NSTs performed in the preterm fetuses are nonreactive, estimated to be 50% between 24 and 28 weeks[40] and 25% between 28 and 32 weeks.[41,42] However, once a tracing becomes reactive, it is not correct to attribute a nonreactive tracing to early gestational age. Beyond 32 weeks, the incidence of nonreactive NSTs is no different from that at term.

Fetal bradycardia occurs promptly with acute hypoxia, followed by fetal death if the hypoxia is severe and prolonged. Otherwise, the fetal heart rate will gradually return to normal followed by tachycardia.[6] Mild chronic hypoxia does not usually cause heart rate abnormalities. Moderate to severe chronic hypoxia, in particular those complicated by acidosis, is associated with a reduction in FHR variability and at times an absence of accelerations.

Technique

The NST is a simple test that can be performed in the outpatient setting. A transabdominal Doppler ultrasonic transducer is used to record the FHR, while a tocodynamometer is applied to detect uterine contractions. In principle, the use of tocodynamometer is unnecessary if the woman is not in labor or does not present with uterine contractions. The recording is continued for 20 minutes, although some may stop recording at 10 to 15 minutes when there are already an adequate number of FHR accelerations present. The woman is usually asked to press a button whenever she feels a fetal movement, leaving a mark on the recording to indicate the presence of fetal movement.

Interpretation

There are extensive studies and professional guidelines on the interpretation of intrapartum cardiotocogram. Antenatal NST is usually interpreted using criteria described for intrapartum cardiotocogram (see Chapter 69). The NST is generally considered normal (or reactive) when there are two or more accelerations of FHR of 15 beats/min for at least 15 seconds' duration over a 20-minute recording after 32 weeks. Although by definition each acceleration should be accompanied by fetal movement, the presence of such a marking of fetal movement on the recording at the time of acceleration is usually not considered essential because (1) the majority of FHR accelerations are known to be associated with fetal movements and (2) women are able to detect only 16% to 80% of fetal movements. When the criteria for reactivity are not met, the test is considered nonreactive. A reactive strip is reassuring that the fetus will not die within the next 7 days.

To reduce the incidence of false-positive nonreactive rates when the NST is performed in preterm fetuses, it has been suggested that an acceleration be defined as FHR increase of 10 beats/min or more above the baseline lasting 10 seconds or longer in pregnancies of fewer than 32 weeks.[43]

Implications

A reactive tracing is generally considered a strong indicator of a healthy well-oxygenated fetus; this opinion, though, is inaccurate because fetuses with acidemia typically have reactive tracings until cardiac deterioration begins. About 85% of NSTs are reactive in the initial assessment. The perinatal mortality rate during the subsequent week in this group is low, 0.3% to 0.5%, compared with 3% to 4% in those with nonreactive NST.[44,45] Therefore, if the indication of the NST is ill-defined and there was no other underlying risk factor of worry, there may not be any need for further NST or monitoring. However, if the indication persisted, for example, FGR, the NST may be repeated at weekly intervals. In very high risk pregnancies, the false-negative rate associated with a weekly NST will be higher, and many advocate increasing the frequency of NST from weekly to twice-weekly, which has been shown to be associated with a reduction in the perinatal mortality rate from 6.1 to 1.9/1000.[46] In general, one should interpret a reactive NST

to mean only that the fetus is okay at the time of assessment but not necessarily completely normal. How long after the test the fetus will remain okay depends on the rate of deterioration of the underlying pathology. If a rapid deterioration is not considered to be likely, weekly testing is adequate. If a very rapid deterioration is expected, it is appropriate to repeat testing daily or several times a day depending on the disorder.

A normal NST should not be equated to a normal baby. There is good evidence that a fetus who survived after an acute insult may have a normal NST, although the nervous system could have been severely damaged by that insult. The same may be said for chronically hypoxemic fetuses who have for the moment "adapted" to their adverse environment.

Fetal activity is strongly associated with the fetal wake-sleep cycle, with the most movement occurring during rapid eye movement sleep and the least during quiet sleep. The most common cause of a nonreactive NST is fetal inactivity (sleep cycle). Therefore, the test may be continued for an extended period if the initial part is nonreactive with the goal of differentiating a nonreactive NST due to fetal quiescence or to significant fetal hypoxia. The longer the nonreactive pattern persists, the greater the likelihood the fetus is hypoxic. There is no consensus as to how long one should continue with the NST. However, a nonreactive pattern for more than 80 minutes would be very unusual. A prolonged nonreactive pattern for up to 120 minutes is associated with high perinatal mortality and morbidity,[47,48] and such fetuses probably should be delivered if mature, recognizing that significant neurologic damages might have already occurred, and delivery prevents only a perinatal death and not necessarily a handicap. This is an important consideration during counseling of women for delivery in the presence of prolonged nonreactive NST.

The second most common cause of a nonreactive NST is prematurity. This is particularly true for those who are less than 32 weeks' gestation. In this group, the height of accelerations does not normally exceed 10 beats/min. In high risk preterm pregnancies, one should carefully consider what to do in case of a nonreactive pattern before prescribing surveillance with an NST. In this group, the use of the BPS may offer an advantage (see earlier).

Mild variable decelerations are commonly seen in antenatal NST and they are generally not associated with poor perinatal outcome. In fact, it is a normal finding in preterm pregnancies if not associated with oligohydramnios. There is no good evidence to support or refute whether the occurrence of nonuniform decelerations in an antenatal NST is predictive of poor fetal outcome.

The most recent update of the meta-analysis of CTG for antepartum fetal assessment in high risk pregnancies included only four studies involving 1627 pregnancies.[49] Antenatal CTG appeared to have no significant effect on perinatal mortality or morbidity. In fact, there was a trend to an increase in perinatal deaths in the CTG group (risk ratio [RR] 2.05, 95% CI 0.95–4.42, 2.3% versus 1.1%). However, the total number of women studied was too small for meaningful interpretation of the value of this assessment. Furthermore, all the trials were quite old and might be difficult to relate to current practice.

Variation of Techniques

There was a burst of enthusiasm for the application of vibro-acoustic stimulation to the fetus who showed a nonreactive pattern during the late 1980s and early 1990s. The technique involved a brief exposure of the fetus to a vibroacoustic signal applied through the maternal abdomen (often using the "electronic artificial larynx") to evoke a response from the fetus, typically in the form of accelerations.

The latest meta-analysis of nine trials including 4838 participants demonstrated that fetal vibroacoustic stimulation reduced the incidence of nonreactive antenatal CTG (reported in seven trials; RR 0.62, 95% CI 0.52–0.74) and reduced the overall mean CTG testing time (reported in three trials; weighted mean difference −9.94 min, 95% CI −9.37 min to −10.50 min).[50] However, it is unclear whether the use of such a strong stimulus will have long-term adverse effects on the unborn fetus, and therefore, this device should be used with caution. It is also unclear whether the fetus with significant acidemia will be more likely to have a reactive tracing, increasing the chance of a false-negative result.

Limitations

Although those pregnancies with nonreactive NST are at higher risk of perinatal mortality and morbidity, the great majority are still normal if delivered at that point, that is, a false-positive result. This high false-positive rate and low positive predictive value can lead to a very high intervention rate without significant improvement in the overall perinatal outcome. The only way to avoid this dilemma is to use this test carefully, in particular to avoid using it in a low risk population. One should resist the temptation to prescribe testing to a woman on a "just in case" basis. Limiting the use of NST to well-defined high risk cases will maximize the positive predictive value.

CONTRACTION STRESS TEST

This CST is included here for completeness, because it is now only rarely performed. The CST was probably the first specific test available for fetal surveillance and based on the understanding that hypoxic fetuses poorly tolerate regular uterine contractions, leading to progressive myocardial dysfunction with bradycardia. The setup for the CST begins with an NST. After confirming a normal fetal heart pattern without strong uterine contractions, intravenous infusion of oxytocin or maternal nipple simulation is initiated to induce uterine contractions, until three contractions in every 10 minutes are obtained for 10 to 30 minutes. The test is considered negative if there are no late or significant variable decelerations, positive if late decelerations are present in at least 50% of the contractions, suspicious or equivocal if there is intermittent late or variable decelerations, and unsatisfactory if adequate uterine contraction cannot be induced. This test is time-consuming and usually takes 1 to 2 hours to complete.

The negative test is highly predictive of a good outcome, and the risk of antenatal death is 0 to 0.4/1000.[51] A positive test is predictive of fetal hypoxia, with a corrected perinatal mortality rate of 176.5/1000. The false-positive rate is usually quoted as high, ranging from 8% to 57%,[51] which is wrong because the definition used by the original studies

was the number of unaffected infants delivered after a positive CST.[29] The denominator used was not the total number of true negative, but the total number of test positives.[52]

As with many other fetal surveillance tests, strong scientific proof of clear clinical benefit of CST is lacking. Since the 1990s, the CST has been largely replaced by other alternative methods thath are easier to administer, less invasive, and lack the possibility of precipitating fetal compromise.

DOPPLER STUDIES

The application of Doppler assessment of the unborn fetus as a method of fetal surveillance is relatively new. But research since the early 2000s has demonstrated that Doppler is probably the best available tool for fetal surveillance, providing a physiologic approach to the management of high risk pregnancies. At present, there are two major roles for antenatal Doppler testing as it relates to fetal surveillance: (1) monitoring of pregnancies complicated by uteroplacental dysfunction and FGR and (2) monitoring the fetus at risk for anemia.

Principle of Doppler Studies

All Doppler tests are based on the Doppler principle, which states that sound reflected from a moving target will shift its frequency in proportion to the velocity of the target. This Doppler shift can be measured directly by ultrasound, equipment that then calculates the corresponding velocity of the original target object. In obstetrics, Doppler is typically used for the study of vascular blood flow. A number of display modes exist, but all Doppler examinations discussed herein are limited to pulsed-wave spectral Doppler unless specified. Because the Doppler shift is dependent on the angle of insonation, being highest when they are in parallel, the estimated velocity will not be the true velocity unless this angle of insonation is zero.

To facilitate the Doppler examination, various angle-independent indices have been derived, including the pulsatility index (PI) and resistance index (RI). Under standard conditions, both PI and RI correlate with downstream vascular resistance. Thus, a high PI or RI represents high peripheral resistance, ande a low PI or RI represents a reduction in peripheral resistance and possibly increased blood flow. One must keep in mind that the value of PI or RI is also affected by other determinants such as FHR or blood viscosity.

Pathophysiology of Placental Dysfunction and Fetal Growth Restriction (See also Chapter 11)

Some studies reveal that changes in the Doppler waveforms of different uteroplacental and fetal vessels follow a relatively predictable pattern in pregnancies complicated by placental dysfunction and FGR.[7,53] The early changes may be first manifest in the uterine artery, followed by umbilical artery and middle cerebral artery (MCA). Often, the uterine artery waveform remains normal and the umbilical artery first shows increased resistance. Sequentially, fetal hypoxia leads to decreased resistance in the MCA and, with the onset of hypoxia-mediated cardiac dysfunction, abnormal flow in

the DV reflecting decreased cardiac compliance. If the fetus remains undelivered and continues to deteriorate, terminal signs will occur, including a reduction in fetal movement, decelerations in the fetal heart, and evidence of fetal cardiac failure.

Doppler flow pattern and indices of the uterine artery reflect the impedance or resistance of the maternal circulation of the uterus and placental bed. In the nonpregnant state, Doppler waveform of the uterine artery is a high resistance pattern with a notch. During normal pregnancy, trophoblastic invasion and remodeling of the spiral arteries lead to a substantial reduction in resistance and the disappearance of notching. Conversely, persistence of high uterine artery Doppler PI is a typical early feature of abnormal placentation, representing a defective or delayed trophoblastic invasion. There is increasing evidence that the measurement of uterine artery Doppler indices may be a useful screening test in the early or mid trimester for the identification of at-risk pregnancies.[54,55] However, it is not a useful test for fetal surveillance.

Doppler indices of the umbilical artery normally decrease with advancing gestation because of the physiologic reduction in placental vascular resistance. In FGR due to uteroplacental dysfunction, placental vascular resistance remains high and, as a consequence, the PI of the umbilical artery is higher than normal. The umbilical artery gives information only on placental blood flow, and not the fetal adaptation to hypoxia nor the consequences of this adaptation.[56] In other words, a normal umbilical artery waveform is inconsistent with chronic fetal hypoxia due to placental insufficiency unless there has been an acute placental abruption or the mother is herself hypoxemic. In association with fetal hypoxemia, there is a reduction in MCA PI, indicating a reduction in cerebral resistance and an increase in cerebral blood flow, a phenomenon called the "brain-sparing effect."[57] These early changes in Doppler indices of the umbilical artery or the MCA or their ratio may be useful in assisting the diagnosis or early detection of uteroplacental dysfunction.[7]

Progressive placental pathology (thrombosis, fibrosis, inflammation) further increases resistance to umbilical artery blood flow, occasionally demonstrating absence or reversal of end-diastolic flow. These are late signs, associated with a significant increase in perinatal mortality: 20% when there is absent end-diastolic flow and 68% when there is reverse end-diastolic flow.[58] Deterioration of cardiac function leads to disappearance of the brain-sparing effect and the MCA indices become "normal."

Venous Doppler provides valuable information about fetal cardiovascular and respiratory responses to hypoxia. Abnormalities of venous Doppler waveforms are in general late signs of uteroplacental dysfunction, indicating advanced stage of fetal hypoxemia and decompensation.

The DV is the most extensively studied venous vessel. With worsening fetal condition, there will be progressive increase in the PI of DV, and eventually the absence or the reversal of the a-wave.[59] Among all Doppler tools and other fetal surveillance methods, the DV Doppler study is the best single predictor of perinatal outcome.[60] It also appears that deterioration in DV precedes an abnormal CTG, and therefore, DV may be a better parameter than CTG to determine the optimal time of elective delivery of the very premature fetus with growth restriction.[61]

The Use of Doppler Studies in the Diagnosis of Uteroplacental Dysfunction and Intrauterine Growth Restriction

The diagnosis of IUGR depends on the demonstration of small–for–gestational age fetal parameters or flattening of the growth curve. However, size is less important than the mechanism. The diagnosis of IUGR secondary to chronic hypoxia can be accomplished only through Doppler studies. If all these Doppler studies are normal, the fetus is small because of some other mechanism (e.g., genetics, viral infection) and does not require intensive monitoring because intervention has no chance to alter outcome. However, if the Doppler studies demonstrate a high resistance pattern of the uterine artery and the umbilical artery with corresponding changes in the MCA, the fetus is likely to have IUGR secondary to chronic hypoxia and requires close monitoring.

Use of Doppler to Monitor Intrauterine Growth Restriction (See also Chapter 11)

Once IUGR or uteroplacental dysfunction has been diagnosed, the pregnancy should be closely monitored if delivery is not considered the most appropriate action. In general, if the arterial Doppler shows early changes only, that is, raised resistance, the fetus is still in a compensated stage and the risk of immediate intrauterine death is low. Repeating the Doppler studies periodically every 1 to 3 weeks (depending on findings) is usually adequate. If the umbilical artery Doppler shows absence or reversed diastolic flow, the MCA resistance will be reduced and the DV may be abnormal. Under these conditions, a pulsatile waveform may also be seen in the umbilical vein. The risk of perinatal mortality is substantially increased. The fetus should be either delivered or monitored more frequently. Overall, in cases of IUGR, the presence of abnormal Doppler is the best predictor of adverse perinatal outcome, and Doppler wave analysis should be included in the surveillance of these fetuses.[62,63]

The value of Doppler ultrasound in surveillance of the high risk fetus is supported by the latest meta-analysis of 16 studies involving 10,225 fetuses.[64] Compared with no Doppler ultrasound, the use of Doppler ultrasound in high risk pregnancy (especially those complicated by hypertension or presumed impaired fetal growth) was associated with a reduction in perinatal deaths (RR 0.71, 95% CI 0.52–0.98, 1.2% versus 1.7%). The use of Doppler ultrasound was also associated with fewer inductions of labor (RR 0.89, 95% CI 0.80–0.99) and fewer cesarean sections (RR 0.90, 95% CI 0.84–0.97), without reports of adverse effects. The authors' conclusions were that "the use of Doppler ultrasound in high risk pregnancies reduced the risk of perinatal deaths and resulted in less obstetric interventions."

In term pregnancies complicated by uteroplacental dysfunction and IUGR, one should seriously consider delivery if the umbilical artery already shows minimal end-diastolic flow. Although the risk of immediate perinatal mortality and morbidity due to hypoxia is low, the perinatal complications are significant higher if these pregnancies are allowed to go on.

In preterm pregnancies, less than 34 weeks, the risk of prematurity outweighs the benefit of delivery if the venous Doppler is still normal. (Refer to the management paradigm

in Chapter 11.) One must remember that, although IUGR due to placental dysfunction usually follows a predictable sequence of cardiovascular changes detectable by Doppler examination, the sequence is less predictable in IUGR associated with other causes such as preeclampsia, perhaps because of the speed with which the pathology evolves.[65] Therefore, the optimal frequency of fetal surveillance has to be considered individually.

Fetal Anemia (See also Chapter 13)

Other than placental dysfunction, Doppler ultrasound plays a central role in the management of fetal anemia. Many sonographic and Doppler measurements have been associated with the degree of fetal anemia secondary to alloimmunization, including placental thickness, umbilical vein diameter, and liver or spleen size.[66] However, most of these parameters are either difficult to measure with precision or the association is not strong enough to have clinical utility. Among them all, the peak systolic velocity (PSV) of the MCA is the most predictive of fetal anemia.[67] The increase in MCA PSV in the anemic fetus is probably the combined result of increased cardiac output and decreased blood viscosity, all of which increase the PSV.

In normal pregnancy, the MCA PSV increases with gestational age. Mari and associates[68] pioneered its application in a study of 111 fetuses at risk of anemia due to red blood cell alloimmunization. Using a cutoff of PSV of 1.5 multiple of median, they observed that MCA PSV predicted all cases of moderate to severe anemia with a 12% false-positive rate.[68] These findings have been confirmed by subsequent investigators with minor discrepancies. It is also possible to predict which fetus is likely to deteriorate and require in utero therapy later because the rate of increase in MCA PSV per week is highest among those who subsequently become moderately to severely anemic.[69]

The assessment of MCA PSV requires meticulous attention to ensure that the measurement is reproducible. It is usually measured in an axial section of the fetal head below the plane for measurement of biparietal diameter. Using color Doppler to aid identification of the MCA, the Doppler gate is placed at the proximal point close to the origin of the MCA, taking care that the angle between the ultrasound beam and the vessel is 0 degrees.[70] The use of MCA PSV assessment enables repeated, noninvasive fetal monitoring to determine the presence and degree of anemia and to determine whether and when in utero therapy is likely necessary.

After in utero transfusion, the immediate fetal MCA response to the increased hematocrit is a reduction in PSV.[71] However, adult red cells have very different characteristics from fetal red cells, and a large amount of adult red cells could affect the reliability of using the MCA PSV to time the next transfusion.[72] The MCA PSV should be used as an adjunct to clinical experience rather than the absolute yardstick upon which to determine the timing of the next procedure.

There is increasing evidence that an elevated MCA PSV reflects anemia and not necessarily a singular cause of anemia. An elevated MCA PSV has been described in cases of fetal parvovirus infection, Kell sensitization, massive fetomaternal hemorrhage, homozygous alpha-thalassemia, or placental chorioangioma.[73–77] Therefore, the assessment of MCV PSV

is an important diagnostic tool in the evaluation of pregnancies complicated by fetal hydrops or cardiac failure.

OTHER TESTS

The most recent Cochrane review reported that the use of biochemical tests of placental function led to no obvious differences in perinatal mortality.[78] The available trial data do not support the use of estriol estimation in high risk pregnancies. Unfortunately, the review included only one eligible trial of poor quality. In summary, there is no evidence to support the use of biochemical testing as part of fetal assessment. Furthermore, there is likely to be little enthusiasm for conducting such trials because biochemical testing has been superseded by biophysical testing in antepartum fetal assessment.

Placental grading enjoyed popularity in the 1980s and early 1990s but is now not used widely in clinical practice. However, there has been only one randomized controlled trial of routine placental grading as a screening tool in a low risk population.[79] It showed an improved perinatal outcome in the scanned group compared with those who were not scanned. However, there are several important points about that study. The numbers in the study were smaller than would normally be expected to show a significant difference in fetal outcome measures, the group that did not have placental grading had a higher incidence of adverse fetal outcome than would normally be expected for a low risk population, and the improvement in outcome did not exclusively occur in those with abnormal placental grading. Further research regarding placental grading in high risk pregnancies is needed.[80]

COMPREHENSIVE APPROACH TO PRENATAL FETAL ASSESSMENT AND MANAGEMENT

It is clear that no one test is sufficient for the management of fetuses at high risk of chronic hypoxia and that a comprehensive approach is more appropriate and relevant in practice.[81,82] In studies that have attempted to document the sequence of deterioration in chronic fetal asphyxia, the general conclusions are that abnormalities in the umbilical artery waveform tend to appear first followed by cerebral redistribution, early venous changes, and reduced breathing movements. Amniotic fluid volume starts to fall and FHR short-term variability to reduce next. Abnormal umbilical venous pulsation, reversed umbilical artery pulsation, abnormal fetal movements and tone, and fetal bradycardia tend to be late events. These concepts are graphically displayed in Figure 11–6 in Chapter 11.

Thus, although there is no agreed standard of practice for surveillance and management of high risk fetuses, many centers use a combination of fetal growth and umbilical artery Doppler recordings together with CTG, BPP, other Doppler studies and give the mother steroids if preterm delivery is contemplated. The optimum timing of delivery remains an unanswered question, although most would not continue the pregnancy beyond 34 weeks if there is a persistent abnormality of the umbilical artery Doppler recordings. Chapter 11 discusses these issues in more detail and an example of a management algorithm is shown in Figure 11–9.

SUMMARY OF MANAGEMENT OPTIONS
Prenatal Fetal Surveillance (in the normally formed fetus)

Management Options	Evidence Quality and Recommendation	References
Indications		
High risk patients—where there is a risk of chronic fetal hypoxia	III/B	2,3,5–7
• **Maternal:** cyanotic heart disease; diabetes; autoimmune disease; chronic renal disease; hypertensive disease; inadequate nutrition; smoking (often synergistic with other factors); alcohol and other drug abuse		
• **Placental/fetal:** IUGR; recurrent abruption; preeclampsia; abnormal amniotic fluid volume; reduced fetal movements; abdominal pain without a clear cause; postdates pregnancy; previous stillbirth/IUGR		
• **Combined:** raised serum α-fetoprotein	III/B	8
Principles		
Select test appropriate for pathology/problem if possible/known	—/GPP	—
Comprehensive assessment of mother and fetus	III/B	81,82
Multiple and repeated fetal assessment methods are more likely to be informative than any single test	III/B	81,82
Methods—Maternal		
Clinical (e.g., evaluation of hypertension, cardiac disease)	—/GPP	—
Laboratory (e.g., diabetes, Kleihauer, renal and liver function)	—/GPP	—
Biochemical testing		
No evidence to support use in high risk pregnancies	Ia/A	78
Methods—Fetal		
Ultrasound measurement of fetal growth, see Chapter 11		
Amniotic fluid volume, see Chapters 11 and 12		
Umbilical artery Doppler velocimetry	Ia/A	64
• Only test shown in randomized trials to reduce perinatal morbidity and mortality		
• No information about optimum frequency of use		
Regional recordings of fetal blood flow		
Indicate degree of fetal compromise in		
• Chronic fetal hypoxia	III/B	28,65,81,82
• Anemia	III/B	68,69,71
Uterine artery blood flow before 24 wk	III/B	54,55
Identifies those pregnancies at risk of IUGR and preeclampsia and use may improve outcome		
CTG/NST		
• Predicts short term outcome	III/B	45,46,48
• Computerized assessment is more accurate		30
• No evidence that use improves outcome	Ia/A	49
• Probably best in combination with other methods	III/B	81,82

Fetal Growth Disorders

AHMET ALEXANDER BASCHAT

INTRODUCTION

Disturbance of normal fetal growth can result in abnormal weight, body mass, or body proportion at birth. The two principal fetal growth disorders are intrauterine growth restriction (IUGR) and macrosomia, both of which are associated with increased perinatal mortality and short- and long-term morbidity. Perinatal detection of fetal growth disorders has evolved dramatically since the late 1960s. Before antenatal ultrasound assessment of fetal growth was clinically available, fetal growth was defined by birth weight. The absolute birth weight was classified as either macrosomia (>4000 g), low birth weight, very low birth weight, or extremely low birth weight (<2500 g, <1500 g, and <1000 g, respectively). The landmark observations of Lubchenco and colleagues[1] in 1963 showed that the classification of neonates by birth weight percentile had a significant prognostic advantage because it improved the detection of neonates with IUGR and who are at increased risk for adverse health events throughout life.[2–4] Neonates are now classified as very small for gestational age (<3rd percentile), small for gestational age (<10th percentile), appropriate for gestational age (10th–90th percentile), or large for gestational age (>90th percentile).[5] With the development of reference ranges for fetal measurements and the study of their growth rates with advancing gestation, it became possible to apply the concept of growth percentiles prenatally. Subsequently, it became possible to relate absolute and serial fetal measurements to their gestational age–specific percentiles in order to diagnose abnormal fetal size and growth velocity. The detection of a fetal growth disorder is further enhanced if the reference ranges for fetal biometric data and birth weight account for maternal height and race and fetal birth order and sex[6] (growth potential). A neonate may be of normal weight but still significantly lighter than its growth potential. Growth potential percentiles are superior to conventional reference ranges for the prediction of adverse perinatal outcome.[7,8]

The detection of abnormal body mass or proportions is based on anthropometric measurements and ratios that are relatively independent of sex, race, and to a certain extent, gestational age. The ponderal index [(birth weight (g)/crown-heel length^3) × 100][9] is one tool that has high accuracy for the identification of IUGR[10] and macrosomia,[11] independent of the birth weight percentile.[12] In one study, 40% of neonates with a birth weight below the 10th percentile did not have growth restriction based on the ponderal index.[10] From a clinical perspective, the ponderal index correlates more closely with perinatal morbidity and mortality than traditional birth weight percentiles, but might miss proportionally small and lean neonates with growth restriction.[13,14] Inappropriate fetal growth is also suggested by abnormal symmetry between head and abdominal measurements. Again, a different subset of neonates is identified with this descriptive approach.[15]

A gold standard for birth weight criteria that distinguishes between abnormal and physiologic growth patterns is highly desirable for any study of the relationship between neonatal size and outcome. Although the immediate effect of disturbed fetal growth is an abnormal expression of the growth potential, the effect on outcome and fetal programming is determined predominantly by the underlying condition.

REGULATION OF FETAL GROWTH

Fetal growth is regulated at multiple levels, and successful placentation is required for the coordination of key components within the maternal, placental, and fetal compartments. The key elements required for successful placentation are the normal development of maternal and fetal vascular supply, synthetic activity of the placenta, establishment of transplacental carrier proteins for substrates that require active transport, a decrease in the maternal-fetal diffusion distance to facilitate passive transport, and a matched increase in maternal-fetal perfusion and surface area with advancing gestational age. First-trimester blastocyst adherence and implantation initiate placental vascular development, which is necessary for the delivery of nutrients and oxygen to the growing trophoblast beyond simple diffusion. Successful adherence permits differentiation of placental transport mechanisms and the activation of paracrine and endocrine signaling pathways between the mother, the placenta, and the fetus by the second trimester. Trophoblast invasion into the maternal spiral arteries and fetal villous sprouting decrease the blood flow resistance in both vascular compartments of the placenta. These developments together with the marked increase in villous vascular surface area are essential for efficient and coordinated nutrient transfer and

waste and gas exchange that ensure normal fetal growth and development.

After fertilization, the cytotrophoblast migrates to form anchoring villi between the decidua and the uterus through controlled breakdown of the extracellular matrix by metalloproteinases and localized expression of adhesion molecules, including integrins and collagen IV. Simultaneously, hypoxia-stimulated angiogenesis initiates vascular connections between the maternal circulation and the intervillous space. Angiopoietins, placental growth factor, and placental protein 13 (PP-13) are three important regulatory substances expressed in increasing concentrations during this early critical phase of placental vasculogenesis.[16–18] Once the maternal blood supply to the intervillous space is established, increasing quantities of placental secretory products appear in the maternal circulation. Concurrently, extravillous cytotrophoblasts infiltrate the maternal spiral arteries, progressively remodeling the vessel walls so that the musculoelastic media is lost.[19,20] This decrease in uterine artery blood flow resistance can be documented by Doppler interrogation of the uterine artery waveform, first by the disappearance of the early diastolic notch, then by a progressive increase in diastolic blood flow toward term (see later).

In the fetal compartment, villous proliferation of the trophoblastic trabeculae is initiated by the 18th day after conception. By the 5th week of gestation, all villi contain extraembryonic mesenchyme and capillaries in the villous stroma. These mesenchymal villi form the originating pool for all subsequent villous types. The differentiation into stem villi is critical for establishing distinct arterial and venous circulation in the villous vascular tree. Further differentiation into villous subtypes and continuous villous vascular branching results in an increase in the vascular exchange area, thinning of the cytotrophoblast, and a decrease in blood flow resistance in the umbilical arterial circulation.[21,22] In addition to the angiopoietins, basic fibroblast growth factor and its low-affinity heparin sulfate reception and the vascular endothelial factor system may be involved in the regulation of villous angiogeneis and sprouting.[22]

These vascular maturation processes result in low-resistance, high-capacitance vascular beds that allow increasing and matched perfusion of the maternal and fetal placental compartments. Intervillous blood flow is regulated mainly through paracrine factors, such as nitric oxide, endothelin, adenosine, released cyclic guanosine monophosphate, and fetal atrial natriuretic peptide.[21] After successful placentation, approximately 600 mL/min maternal cardiac output[23,24] is matched to 400 mL/kg/min fetal flow distributed over a term placental exchange area of 12 m[2].[25]

Once the blood supply to the trophoblast and fetal circulation is established, placental transport capacity is the major determinant of maternal-fetal nutrient transport. All substances that traverse between the maternal and the fetal circulation must pass through the villous trophoblast, a syncytial bilayer 4-μm thick that consists of a maternal microvillus and a fetal basal layer.[26] Its capacity for transport is enhanced by a growing membrane surface area and increased density and affinity of carrier proteins for glucose, amino acids (mainly), and fatty acids.[27–30] The sodium/hydrogen (Na/H[+]) family of transport proteins maintains syncytiotrophoblast intracellular pH and cell volume homeostasis,

ensuring proper function of the transplacental substrate carrier proteins.[31] By the second trimester, these placental activities consume 40% of the O_2 and 70% of the glucose entering the uterus, leaving the rest for fetal use.[32–34] This proportion decreases progressively until term.

With the establishment of placental transport systems, endocrine signaling between maternal, placental, and fetal compartments helps to coordinate placental and fetal growth. Maternal metabolic changes include postprandial hyperglycemia, lipolysis, and increased fasting levels of free fatty acids, triglycerides, and cholesterol. All of these enhance substrate availability to the placenta and fetus and are at least partly mediated by increases in placental levels of lactogen and leptin. Similarly, maternal intravascular volume expansion and its relative refractoriness to vasoactive agents promote steady nutrient delivery to the placenta.[35]

Placental and fetal growth is regulated by a combination of factors including substrate availability, placental perfusion in the maternal compartment, endocrine or paracrine signaling, and perfusion and nutrient exchange area in the fetal compartment of the placenta. In addition, the design of the fetal circulation is unique because it allows for preferential streaming of nutrients via three principal shunts. Nutrients that enter the circulation through the umbilical vein first reach the ductus venosus. Here 70% to 80% of the umbilical venous nutrients returning continue on to the liver first and reach the heart through the hepatic veins. The remainder of umbilical venous blood is distributed directly to the heart through the ductus venosus.[36] Glucose and amino acids thus preferentially reach the liver for glycogen storage and stimulate insulin release from the fetal pancreas. The subsequent release of insulin-like growth factors I and II provides the major stimulus for fetal growth and differentiation.[37] Leptin stimulates fetal pancreatic growth and transplacental amino acid transport and affects fatty acid transport. Therefore, it may be an important modulator of fetal body fat content and body proportions.[38,39]

At the level of the right atrium, the directionality of incoming bloodstreams ensures nutrient-rich blood from the ductus venosus is distributed to the myocardium and brain, whereas venous return from the body is distributed to the descending aorta and ultimately to the placenta for reoxygenation and nutrient and waste exchange.[27,40] Blood leaving the ventricles reaches the brain through branches arising from the preductal aorta. An increase in right ventricular afterload redistributes blood toward the left ventricle and, therefore, the myocardium and brain. At the level of the ductus venosus and aortic isthmus, however, the same changes promote the distribution of blood from the descending aorta toward the cerebral circulation. Therefore, shunting at the level of the ductus venosus affects the whole body whereas changes at the level of the foramen ovale and the aortic isthmus affect the right-left balance of nutrient flux.[41] In addition to the preferential distribution of left- and right-sided cardiac output, several organs can modify local flow by autoregulation to meet oxygen and nutrient demands.[42]

Normal placental and fetal growth across pregnancy is characterized by sequential cellular hyperplasia, hyperplasia plus hypertrophy, and finally, hypertrophy alone.[43] Placental growth follows a sigmoid curve, plateauing earlier in

gestation than does the fetal growth curve. Between 16 weeks and term, human fetal weight increases 20-fold.[43] The fetal growth curve is exponential, with maximal growth occurring in the third trimester when significant body mass and particularly adipose tissue are accumulated.

FETAL GROWTH RESTRICTION

Etiology and Risk Factors

Several conditions may interfere with normal placentation and culminate in either pregnancy loss or IUGR. Broadly categorized into maternal, uterine, placental, and fetal disorders, these conditions affect either nutrient and oxygen delivery to the placenta, nutrient and oxygen transfer across the placenta, fetal uptake, or regulation of growth processes. When they are sufficiently abnormal, they produce growth restriction characterized by a reduction in fetal cell size, and when they are early and severe enough, they reduce cell number and thus growth potential postnatally (Fig. 11–1). In clinical practice, considerable overlap occurs between conditions that determine the manifestation, progression, and outcome of growth restriction.

Maternal causes of placental dysfunction such as chronic renal disease, collagen vascular disease, hypertension, and some thrombophilias typically affect placental vascular development. Uterine abnormalities can also interfere with placentation and affect nutrient delivery to the fetus. Abnormal placental vascular development (either primary or secondary to maternal conditions and fetal abnormalities, both chromosomal and anatomic) account for the vast majority of cases of IUGR in singleton pregnancies.[44–48] Usually, the earlier the onset of the disease process, the more likely the fetus is to be symmetrically small, with a reduced cell number, and the more likely the etiology is to be either a severe maternal vascular disorder, a fetal infection, or a chromosome disorder.[49]

In addition to primary factors that initiate placental dysfunction, aggravating circumstances with additional impact include smoking, malnutrition, and drug use. Many risk factors act synergistically. For example, the adverse effect of smoking is doubled in thin, white women and further potentiated by poor maternal weight gain.[50] Similarly, the possible benefits of low-dose aspirin therapy and the detrimental effects of excessive blood pressure reduction are also more apparent in this group of women.[51,52]

Pathophysiology

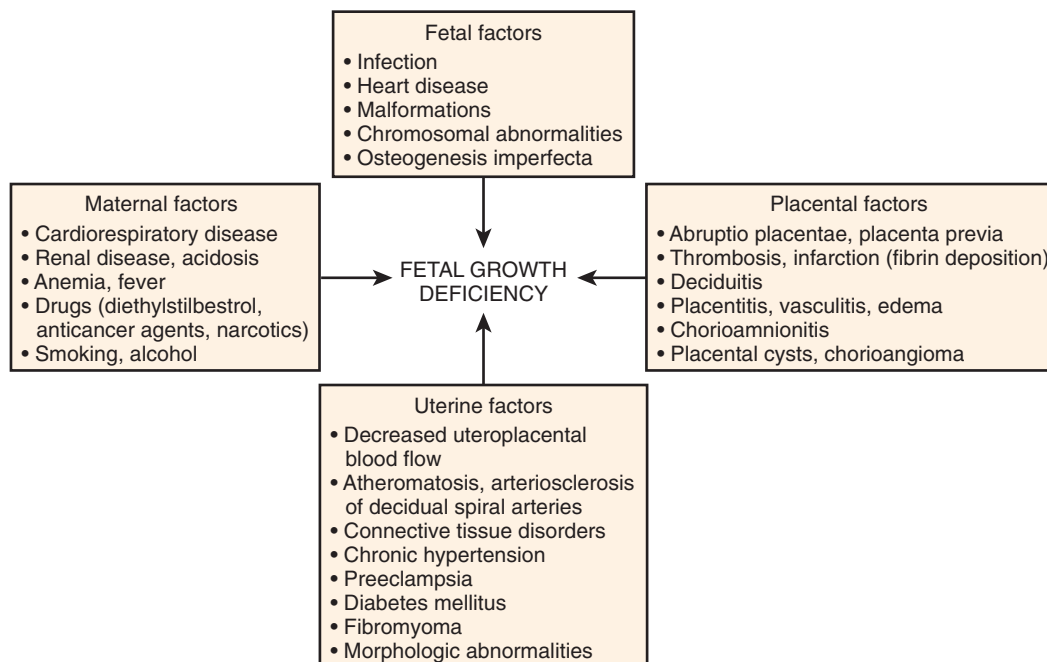
Interference with the placental nutrient supply can affect all aspects of placental function. The gestational age at onset, the magnitude of injury, and the success of adaptive mechanisms determine the ultimate severity. Mild placental disease is more likely to affect organ function and maturation at the cellular level, with little perceivable growth delay perinatally, but may affect adult health (fetal programming), often through epigenetic modifications. With more severe placental disease, fetal growth delay and adaptive organ responses become evident in utero. Exhaustion of the placental and fetal adaptive potential leads to decompensation, with variable progression and manifestations in the fetal organ systems. Adaptive responses that are intended to enhance fetal survival in a hypoxic environment may become destructive under conditions such as acute ischemia-reperfusion. Much of the long-term effect of growth restriction is unclear, as are the effects of obstetric intervention. As a result, severe disturbances of fetal growth pose a challenge to even the most experienced multidisciplinary team.


FIGURE 11–1
Causes of growth restriction by compartment.

Mechanisms of Placental Dysfunction

The efficiency of maternal-fetal exchange of nutrients, fluid, and waste can become suboptimal when there is a decrease in substrate transporters, an increase in the diffusion distance between the maternal and the fetal compartments, a decrease in the exchange area or increased impedance to blood flow in the maternal and fetal compartments in the placenta. It is important to recognize that not all of these mechanisms become clinically detectable unless they reach a certain threshold of severity. Typically, earlier-onset placental dysfunction produces a more severe clinical picture with marked manifestations, whereas late-onset growth delay first manifest in the third trimester may produce few clinically detectable findings. Diffusion may be adequate to meet embryonic nutrient needs, but compromises fetal survival and growth potential. Typically, trophoblastic invasion is confined to the decidual portion of the myometrium, and the spiral and radial arteries do not transform into low-resistance vessels.[19,53,54] Altered expression of vasoactive substances increases vascular reactivity, and if hypoxia-stimulated angiogenesis is inadequate, placental autoregulation becomes deficient. Maternal placental floor infarcts and fetal villous obliteration and fibrosis increase placental blood flow resistance, producing a maternal-fetal placental perfusion mismatch that decreases the effective exchange area.[21,41,55,56] With progressive vascular occlusion, fetoplacental flow resistance is increased throughout the vascular bed, which is the metabolically active placental mass, and nutrient exchange decreases or is outgrown.

The severity of placental vascular dysfunction is clinically assessed in the maternal and fetal compartments of the placenta with Doppler ultrasound. An early diastolic notch in the uterine arteries at 12 to 14 weeks (Fig. 11–2) suggests delayed trophoblast invasion,[57] whereas persistence of "notching" beyond 24 weeks provides confirmatory evidence.[19,56,58] A reduction of umbilical venous blood flow volume may be the earliest Doppler sign of subtle decreases in fetal villous perfusion.[59] Umbilical artery waveforms correlate with both the tertiary villous architecture and the blood flow resistance. If villous damage is minimal, elevated blood flow resistance may be seen only with sophisticated Doppler techniques.[60] At least 30% of the fetal villous vasculature is abnormal when the umbilical artery end-diastolic velocities are low and Doppler resistance indices are elevated.[61] Absence or reversal of umbilical artery end-diastolic velocity suggests that 60% to 70% of the villous vascular tree is damaged (Fig. 11–3).[61,62] Abnormal flow patterns in the uterine arteries are consistent with abnormal implantation and indicate an increased risk of preeclampsia, placental abruption, and early-onset IUGR.[63] Abnormal umbilical flow patterns indicate an increased risk of hypoxemia and acidemia proportional to the severity of Doppler abnormality.[21,64–66] It is important to note that mild placental vascular abnormalities leading to fetal growth restriction may not produce umbilical artery Doppler abnormalities but rather may be reflected in isolated abnormalities in cerebral artery Doppler waveforms.[67,68]

FIGURE 11–2
Flow velocity waveforms obtained from the uterine artery beyond 24 weeks' gestation. *A*, High-volume diastolic flow is established, indicating successful trophoblast invasion. *B*, Impaired trophoblast invasion of the spiral arteries is associated with elevated placental vascular resistance and persistence of an early diastolic notch in the uterine artery flow velocity waveform.

FIGURE 11–3
A, The normal umbilical artery flow velocity waveform has marked positive end-diastolic velocity that increases in proportion to systole toward term. *B*, Moderate abnormalities in the villous vascular structure increase blood flow resistance and are associated with a decrease in end-diastolic velocity. When a significant proportion of the villous vascular tree is abnormal, end-diastolic velocities may be absent (*C*) or even reversed (*D*).

Metabolic and Cellular Effects of Placental Dysfunction

Oxygen and glucose consumption by the placenta is unaffected when nutrient delivery to the uterus is only mildly restricted and fetal demands can be met by increased fractional extraction. Fetal hypoglycemia occurs when uterine oxygen delivery (and likely substrate delivery) is less than a critical value (0.6 mmol/min/kg fetal body weight in sheep) and fetal oxygen uptake is reduced.[32,34,69] Insulin is an important fetal growth factor. Fetal pancreatic insulin responses are blunted by mild hypoglycemia, allowing gluconeogenesis from hepatic glycogen stores.[70–73] At this stage, fetal glucose stores and lactate are preferentially diverted to the placenta to maintain placental metabolic, endocrine, and nutrient transfer function.[27,30,32]

As the nutrient supply worsens, fetal hypoglycemia intensifies and secondary energy sources are required. Proteins are catabolized to gluconeogenic amino acids. However, limitations in placental amino acid transfer eventually result in hypoaminoacidemia.[28] Decreased transfer leads to relative deficiencies of circulating long-chain polyunsaturated fatty acids, whereas metabolic limitation leads to hypertriglyceridemia and the inability to establish essential adipose stores. Even if provided adequate substrate, inadequate oxygen is available to maintain oxidative metabolism. Hypoglycemia, hyperlactic acidemia, and a growing base deficit correlate with the degree of fetal hypoxemia and protein energy malnutrition.[27,74–78] Down-regulation of several cellular transporters and the Na/H^+ pump affects placental cellular function and aggravates the condition further.[28,29,31,33] In this setting, the fetal brain and heart switch primary nutrients from glucose to lactate and ketones.[79] Cardiac metabolism may consume as much as 80% of the circulating lactate.[80,81]

Simultaneously, the principal endocrine growth axis (insulin and insulin-like growth factors I and II) as well as leptin-coordinated fat deposition is down-regulated.[82] As a result, the placenta and fetus do not reach their size potential. The combination of fetal starvation, a modified endocrine milieu, and deficient tissue stores limits fetal growth and affects cellular and functional differentiation in many target organs.

Fetal Response in Major Organ Systems

Vascular and metabolic disturbances within the placenta lead to alterations in many fetal organ systems. Cardiovascular and central nervous system functions are best studied and provide the most practicable clinical means to document the progression of disease and assess the fetal condition.

Changes in fetal blood flow are related to placental resistance, fetal oxygenation, organ autoregulation, and vascular reactivity. Because of the parallel arrangement of the fetal circulation, placental dysfunction has specific effects on the relative distribution of right and left ventricular output. An increase in the right or a decrease in the left ventricular afterload shifts cardiac output toward the left ventricle, supplying well-oxygenated umbilical venous blood to downstream organs. In the compensated hypoxemic state, fetal cardiac output is increased and organ autoregulation maintained.[83,84] The responses of the fetal trunk and cerebral circulation to hypoxemia differ from each other. The peripheral arteries constrict and truncal resistance increases, as evidenced by the elevated umbilical, thoracic, and descending aorta Doppler resistance indices ("hind limb reflex") that account for most of the increase in right ventricular afterload.[85–88] The fetal cerebral circulation dilates in response to hypoxemia. Fetal cerebral vasodilation is reflected in decreased Doppler indices (poorly described as "brain-sparing")[89,90] and reduces left ventricular afterload. This changing balance between right and left ventricular afterload decreases the cerebroplacental Doppler index ratio[91] and redistributes well-oxygenated left ventricular output to the heart and brain.[85,86,92,93]

Enhanced blood flow to individual organs is documented in the myocardium,[94] adrenal glands,[95] spleen,[96] and liver.[97] Conversely, blood flow resistance in the peripheral pulmonary arteries,[98] celiac axis,[99] mesenteric vessels,[100,101] kidneys,[102,103] and femoral and iliac arteries[104] increases. The overall effect is an improved distribution of well-oxygenated blood to vital organs, with preferential streaming of descending aorta blood flow to the placenta for reoxygenation. In contrast, blood flow to organs that are not vital for fetal survival is decreased. These Doppler-determined parameters are corroborated by direct measurements of cardiac output,[85] increases in umbilical venous volume flow,[59,105] and progressive decreases in amniotic fluid volume after long-standing redistribution.[103] Further, there are increased circulating levels of endothelin, arginine vasopressin, norepinephrine, epinephrine, vasoactive intestinal peptide, and atrial natriuretic peptide[106–108] that are related directly to the severity of the acid-base disturbance. These adaptations are likely responsible for the enhanced vascular reactivity that may aggravate the patient's clinical status and increase the complication rate during cordocentesis.

Mild placental dysfunction results in the delayed maturation of several fetal behaviors. The normal behavioral sequence of development for the fetus proceeds from the appearance of movement, to coupling and cyclicity of behavior, and finally, to integration of movement patterns into stable behavioral states. Likewise, the development of autonomic reflexes superimposed on intrinsic cardiac activity determines the characteristics of the fetal heart rate. These reflexes originate in the brainstem and are modulated by the ambient oxygen tension, signals from higher brain centers, the reticular activating system, and peripheral sensory inputs. Variations of heart rate and episodic accelerations coupled with fetal movement indicate normal functioning of these regulatory sites. Once organized, behavioral states are established (typically by 28 weeks' gestation), diurnal and responsive cyclicity (e.g., to maternal glucose) and their coupling to heart rate variables (heart rate reactivity) are usually achieved.[109]

A delay occurs in all aspects of central nervous system maturation in fetuses with IUGR and chronic hypoxemia.[110–114] There is also a progressive decline in global fetal activity.[115] The combination of delayed central integration of fetal heart rate control, decreased fetal activity, and chronic hypoxemia results in a higher baseline heart rate, with lower short- and long-term variation (on computerized analysis) and delayed development of heart rate reactivity.[113,114,116–119] Computerized heart rate analyses show that the changes in characteristics are particularly evident between 28 and 32 weeks. Progressive fetal hypoxemia is associated with a gradual decline in amniotic fluid volume,

fetal breathing, gross body movement, tone, and computerized read and traditional fetal heart rate variability. This decline is determined by the central effects of hypoxemia or acidemia, independent of cardiovascular status.[120–124]

Placental dysfunction affects many other fetal organ systems. Hypoxemia-stimulated erythropoietin release increases red blood cells through both medullary and extramedullary hematopoiesis.[65,74,125–127] More complex interactions are observed with persistent hypoxemia and progressive degrees of placental vascular damage. Nucleated red blood cell precursors enter the peripheral circulation independent of erythropoietin levels.[128,129] Placental platelet aggregation and consumption increases the risk of thrombocytopenia.[130,131] Other organ-specific alterations of note include thyroid dysfunction, increased cortisol level, vitamin deficiency, and immune deficiency. The effect of these fetal manifestations on short- and long-term outcome is unknown.

Fetal Decompensation

If placental dysfunction is progressive or sustained, the adaptive mechanisms become exhausted and decompensation begins. Multiple-organ failure as a result of placental dysfunction is caused by the metabolic milieu and the regulatory loss of cardiovascular homeostasis. Metabolic abnormalities are exaggerated, acidemia worsens, and the risks of intrauterine damage or perinatal death increase dramatically.

Forward blood flow in the venous system is determined by cardiac compliance, contractility, and afterload. The normal venous flow velocity waveform is triphasic and, therefore, more complex than the arterial waveform. It consists of systolic and diastolic peaks (S-wave and D-wave) that are generated by the descent of the artrial-ventricular ring during ventricular systole and passive diastolic ventricular filling, respectively. The sudden increase in right atrial pressure with atrial contraction in late diastole causes a variable amount of reverse flow, producing a second trough after the D-wave (A-wave) (Fig. 11–4). A decrease in forward cardiac function marks the onset of cardiovascular decompensation[83–85,132] and causes decreased forward velocity during atrial systole (A-wave). Impaired preload handling, as evidenced by increased venous Doppler indices (discussed subsequently),[133,134] is documented in the precordial veins (ductus venosus, inferior vena cava,[135] and superior vena cava[136]), hepatic veins (right, middle, and left hepatic[137,138]), and head and neck veins (jugular veins[139] and cerebral transverse sinus[140]). If the failure to accommodate preload is progressive, umbilical venous pulsations may develop as the ultimate reflection of increased central venous pressure (Fig. 11–5).[141] This finding is consistent with umbilical venous pressure measurements obtained at the time of cordocentesis in profoundly growth-restricted fetuses. Simultaneously, autoregulation may be exaggerated in the coronary circulation[84,85] or may become dysfunctional in the cerebral and placental circulation.[142–144]

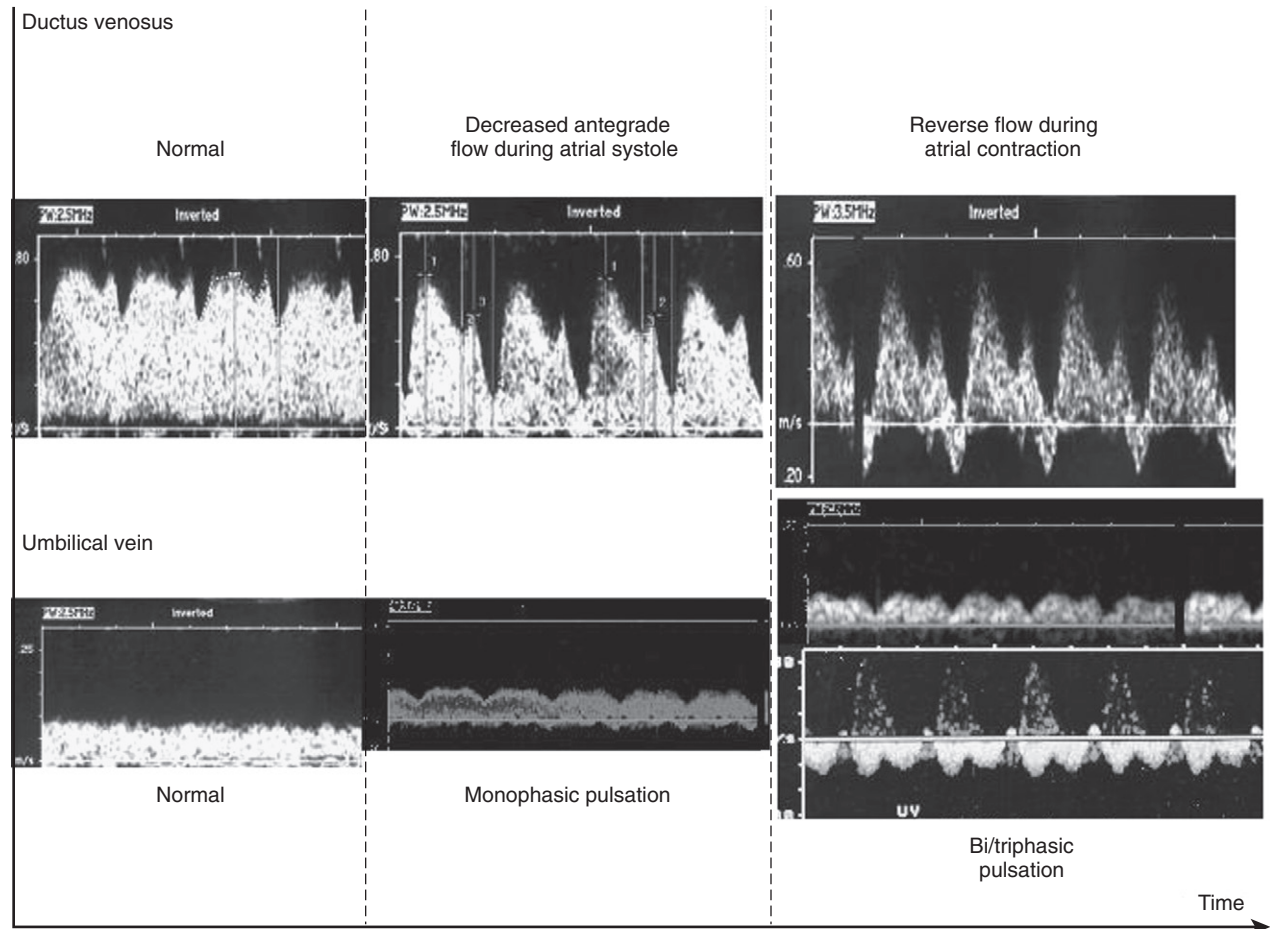
Progressive metabolic acidemia is associated with oligohydramnios and loss of fetal breathing, movement, and tone.[145,146] Abnormal fetal heart rate patterns, including overt late decelerations or a decrease in the short-term variability on computerized analysis, develop and appear to be related to metabolic status and concurrent worsening of cardiac function.[118,120,123,132,143,147] In the final stages of compromise,

cardiac dilation with holosystolic tricuspid insufficiency, complete fetal inactivity, and spontaneous late decelerations may be seen before fetal death.[148]

The sequence of deteriorating cardiovascular, biophysical, and heart rate parameters is reasonably predictable in 70% to 80% of fetuses with IUGR before 34 weeks.[121,149] Flow abnormalities confined to the umbilical or cerebral circulation are typically early changes.[150–152] The progressive decline in (computerized) heart rate variability and increasing venous Doppler indices are closely related.[140,153] Oligohydramnios, loss of fetal tone and/or movement, abnormal venous flow, and overt heart rate decelerations are typically "late" changes.[152,153] Closer to term, the relationship between cardiovascular and biophysical deterioration is weaker, largely because of less prominent Doppler abnormalities.[154–156] In contrast, the correlation (but not necessarily the slope of the regression) between the deterioration of biophysical parameters and the acid-base status is relatively independent of gestational age (Fig. 11–6).[109,118]

Increasing evidence indicates there are significant differences in the rate and severity of clinical progression in IUGR fetuses based on the gestational age at onset and the degree of umbilical artery Doppler abnormality. Two patterns of progression in venous Doppler abnormalities occur in pregnancies diagnosed prior to 34 weeks. First, there may be a rapid loss of umbilical artery end-diastolic velocity typically leading to venous Doppler abnormalities within 4 weeks of the clinical diagnosis. A slower progression of placental Doppler abnormalities may allow a latency interval of 6 weeks until delivery. In contrast, late-onset IUGR is associated with little change in umbilical artery Doppler but rather

FIGURE 11–5

Progression of abnormal venous flow patterns. *Left*, Normal flow in the ductus venosus, with antegrade flow throughout the cardiac cycle. The umbilical vein equally shows constant flow. An increase in the retrograde flow component during atrial contraction is believed to be the hallmark of decreased cardiac function and reflects increased cardiac end-diastolic pressures. *Center*, Flow in the umbilical vein may show a monophasic pulsatile pattern, with nadirs corresponding to atrial contraction. *Right*, In the most severe form of cardiac dysfunction, reverse flow occurs during atrial contraction in the ductus venosus. Pulsations in the umbilical vein may show a biphasic profile, with systolic and diastolic peaks or even retrograde flow during atrial contraction (triphasic).


a decline in the cerebroplacental Doppler ratio and/or isolated new onset of brain sparing.[62] These differences in progression between early-onset (<34 wk) and late-onset IUGR have important implications for surveillance (see later).

Screening Options for Growth Restriction

Clinical

The maternal uterine fundus is objectively measured and charted during each antenatal visit. After 20 weeks' gestation, the normal symphyseal fundal height in centimeters approximates the number of weeks' gestation after appropriate allowances for maternal height and the fetal station. The reported sensitivity of fundal height for the detection of IUGR ranges from 60% to 85%, and the positive predictive values are 20% to 80%. Although measurement of the symphyseal fundal height is a poor screening tool for the detection of IUGR, the accuracy of subsequent ultrasound prediction of IUGR is enhanced if there is clinical suspicion of IUGR based on lagging fundal height.

Biochemical

At least four hormone or protein markers measured in the maternal sera early in the second trimester are associated with subsequent IUGR. These include estriol, human placental lactogen (hPL), human chorionic gonadotropin (hCG), and α-fetoprotein (AFP) (see Chapters 7 and 8). Clinically, maternal serum AFP is the most useful as a marker of abnormal placentation. Most studies conclude that a single, unexplained elevated value increases the risk of growth restriction 5- to 10-fold, proportional to the magnitude of the elevation. As a result, some argue that AFP measurement is clinically useful, even after earlier aneuploidy screening by nuchal translucency measurement.

Uterine Artery Doppler Studies

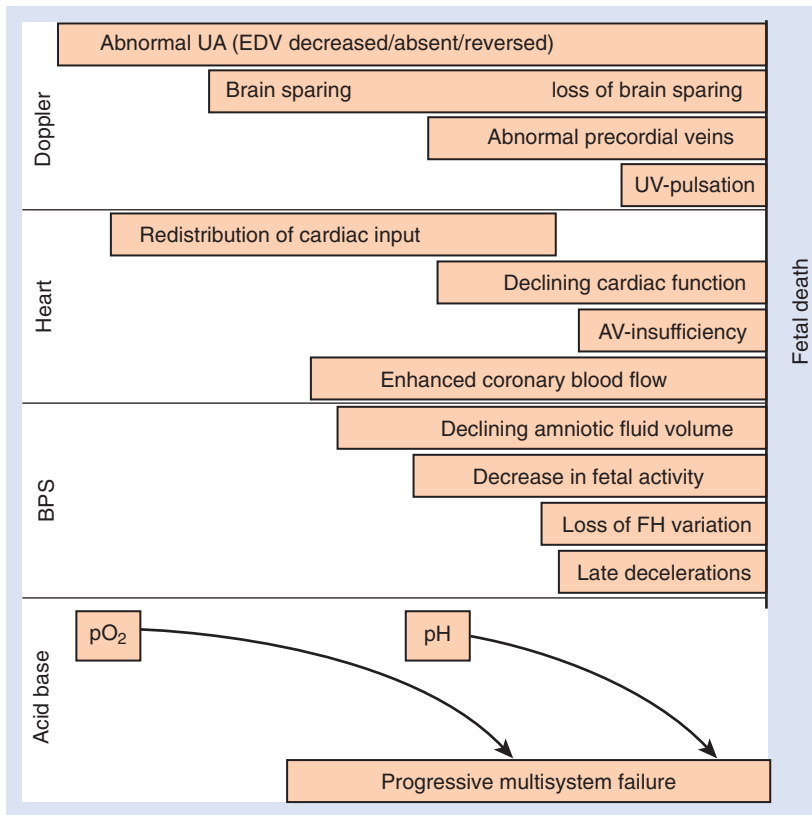
Deficient placentation is highly associated with gestational hypertensive disorders, IUGR, and fetal demise.[157,158] A uterine artery Doppler resistance profile that is high, persistently notched, or both, identifies women at high risk for preeclampsia and IUGR. The sensitivity is up to 85% when performed between 22 and 23 weeks' gestation.[159,160] Because


FIGURE 11–6
Progressive deterioration in fetal cardiovascular and behavioral variables seen with declining metabolic status. In most fetuses with intrauterine growth restriction, Doppler abnormalities progress from the arterial to the venous side of the circulation. Although cardiac adaptations and alterations in coronary blood flow dynamics may be operational for a variable period, overt abnormalities of cardiac function and evidence of markedly enhanced coronary blood flow usually are not seen until the late stages of disease. The decline in biophysical variables shows a reproducible relationship with the acid-base status. If adaptation mechanisms fail, stillbirth ensues. AV, atrioventricular; EDV, end-diastolic velocity; FH, fetal heart rate; UV, umbilical vein.

low-dose aspirin treatment initiated this late in pregnancy improves neither placental function nor long-term outcome,[161] first-trimester screening tests are under investigation. However, they cannot be recommended for clinical use at this time. The utility of first-trimester uterine artery screening appears to be profoundly affected by the target population. Although low risk patients derive little benefit, high risk patients (those with thrombophilia, hypertension, or a history of preeclampsia or a fetus with IUGR) who are given low-dose aspirin because of bilateral uterine artery notching at 12 to 14 weeks have an 80% reduction of placental disease compared with matched control subjects given placebo.[162] Although low-dose aspirin therapy initiated beyond the first trimester may have benefit in a highly select group of patients, uterine artery Doppler studies provide diagnostic and prognostic information beyond this point. The risk of complicating preeclampsia or HELLP (hemolysis, elevated liver enzymes, and low platelets) affecting fetal outcome is increased more than 10-fold when abnormal umbilical artery Doppler findings are associated with bilateral uterine artery notching.[163] The response to an abnormal uterine artery Doppler waveform after 24 weeks should be monitoring of blood pressure and not serial Doppler studies.

First-Trimester Integration of Maternal Physical Characteristics, Biochemistry, and Uterine Artery Doppler Studies

Because the most severe forms of placental dysfunction originate during the first trimester and interventional strategies appear most effective at this point, there is increasing focus of late to identify early markers of placental failure. Integration of maternal history, physical characteristics, uterine artery Doppler, and biomarkers of early placental development are considered most promising. Maternal risk factors alone yield a sensitivity of only 45% for the prediction of preeclampsia and/or fetal growth restriction.[164] The addiition of first-trimester mean arterial blood pressure (MAP) increases the detection rate to 62.5% and reduces the false-positive rate.[165] Further integration of uterine artery Doppler indices with serum markers such as placental growth factor (PLGF) and placental protein 13 (PP-13) holds promise in identifying over 90% of pregnancies that will be complicated by early-onset preeclapmsia with a 10% false-positive rate.[166,167] However, performance of these integrated screening models appears to vary among populations and further research is necessary to identify optimal predictive algorithms and determine the best management strategies for patients identified as high risk.[168]

Ultrasound Assessment
(See also Chapter 10 and Appendix)

The first step in the management of IUGR is the identification of fetuses that are truly at risk for an adverse outcome. This requires the exclusion of small, but normally grown fetuses and those normoxic fetuses with IUGR caused by a condition that cannot be altered by obstetric management (e.g., aneuploidy, nonaneuploid syndromes, viral infection). The diagnosis of placenta-based fetal growth restriction relies on the presence of small fetal measurments in association with other ultrasound signs that are consistent with placental dysfunction. Ultrasound biometry is thus the

primary diagnostic tool for the documentation of fetal growth disorders, whereas the assessment of amniotic fluid volume and placental, cerebral, and venous Doppler studies provide the supporting evidence for placenta-dependent hypoxia.

Because almost all fetal measurements change with gestation, the accurate assessment of gestational age is a necessary first step so that percentile ranks of the absolute measurements can be derived. Once gestational age is assigned, the interpretation of an ultrasound growth study is based on the fetal anatomic survey, amniotic fluid volume, percentile rank of fetal size measurements, interval growth since the last study, and functional assessment of the fetoplacental unit with Doppler ultrasound (umbilical and uterine arteries). It is not appropriate to describe growth abnormalities in terms of the difference beween the measured "week" size and the expected.

The adequacy of fetal growth cannot be determined by a single sonographic examination without a preexisting estimate of gestational age. Even after several examinations, fetal growth assessment is facilitated by knowledge of the likely gestational age because the rate of growth for many parameters also varies with gestation. The traditional assessment of gestational age is based on the first day of the last menstrual period (LMP). Yet, gestational age is uncertain in 20% to 40% of pregnant women who keep a written menstrual calendar.[169,170] This fact reflects both normal physiologic variation in the timing of ovulation and misinterpretation of implantation bleeding as menses by either the patient or the caregiver. Other potential and common variables that may explain an apparent discrepancy between sonographic and LMP-based gestational age include oral contraceptive use, increased cycle length, breast-feeding, and a limited number of coital exposures. Because all commonly used ultrasound tables are based on women with a known LMP rather than a known ovulation or conception date, they share the inaccuracy of menstrual dates (±3 wk). Because normal variation among fetuses also increases with advancing gestational age, the accuracy of the sonographic estimate of age diminishes. An estimated date of confinement (EDC) is based on the LMP when the sonographic estimate of gestational age is within the predictive error (7 days in the first semester, 10–11 days in the second trimester, and 21 days in the third trimester). Once the EDC is set by this method or a first-trimester ultrasound, it does not change, even if subsequent measurements deviate from the expected values. Repeated reassignments of the EDC are confusing to the physician and patient, and interfere with the ability to diagnose fetal growth abnormalities.

After establishment of the best obstetric estimate of gestational age, the next critical step is the selection of appropriate reference ranges. Because the goal is to identify poorly growing fetuses, the reference tables for ultrasound measurements should not be population-based, but rather based on uncomplicated pregnancies delivered at term. Individualized reference ranges of growth potential that account for maternal, ethnic, and fetal variables provide the most accurate reference.[6]

Because fetal growth restriction has many underlying etiologies that affect the timing of onset and fetal features, no single sonographic method is adequate for diagnosis. Only a complete evaluation that includes the maternal history and fetal, placental, and amniotic fluid characteristics can direct an appropriate diagnostic workup and perinatal management.

Direct Measurements

BIPARIETAL DIAMETER (See also Appendix)

Although biparietal diameter is easy to measure, it is a poor tool for the detection of IUGR. The physiologic variation inherent with advancing gestation is high, cranial growth delay as a result of insufficient nutrition is relatively late, and the shape of the cranium is readily altered by external forces (e.g., oligohydramnios, breech presentation).[171] Further, a technically adequate biparietal diameter may be hard to determine if the fetal head is oriented in a direct anterior or posterior position.

HEAD CIRCUMFERENCE (Table 11–1) (See also Appendix)

Head circumference is not subject to the same extrinsic variability as biparietal diameter. The measurement technique is important because calculated head circumference

measurements are systematically smaller than those directly measured. Thus, the table selected should be based on measurements obtained with the same method as your laboratory used.

ABDOMINAL CIRCUMFERENCE (Table 11–2) (See also Appendix)

Abdominal circumference is the single best measurement for the detection of IUGR because it is related to liver size, which is a reflection of fetal glycogen storage.[172–174] The abdominal circumference percentile has the highest sensitivity and greatest negative predictive value for the sonographic diagnosis of IUGR, whether defined postnatally by birth weight percentile or by Ponderal index.[10] Its sensitivity is further enhanced by serial measurements obtained at least 14 days apart.[175] Because of its high sensitivity, some type of abdominal measurement should be part of every sonographic growth evaluation. Because abdominal circumference reflects fetal nutrition, it should be excluded from the calculation of the composite gestational age after the early second trimester.

The most accurate abdominal circumference is the smallest value obtained at the level of the hepatic vein between fetal respirations because the smallest perimeter most closely approximates the plane perpendicular to the spine. The practice of averaging several measurements only increases the measurement error. A measured circumference is superior to either a calculated circumference or the sum of several diameters because the shape of the fetal abdomen is typically irregular.[176] As with bony measurements, the circumference of a healthy fetus grows within a fixed percentile range. An abrupt change in the percentile, especially an increase, suggests that the current measurement results from an oblique cut and should be repeated.

If a normal table based exclusively on healthy women delivering appropriately nourished neonates at term is used (see Table 11–2), an abdominal circumference above the percentile 2.5 for gestational age is inconsistent with IUGR.[10] If a table based on a cross-sectional population is used (i.e., including small for gestational age, appropriate for gestational age, preterm, and term newborns), the 10th percentile is more appropriate. The positive predictive value of a low abdominal circumference percentile for IUGR is approximately 50% in any given population. It is best not to label a fetus "growth-restricted" and trigger expensive fetal surveillance unless the circumference is far below normal or other ultrasound variables support the suspicion.

TRANSVERSE CEREBELLAR DIAMETER
(See also Appendix)

Transverse cerebellar diameter is one of the few soft tissue measurements that correlates well with gestational age[177] in

the IUGR fetus. This structure is relatively spared the effects of mild to moderate uteroplacental dysfunction. Whether its measurement offers an advantage over bony measurements in the assessment of compromised fetal growth is controversial.[178,179]

Measurement Ratios

Approximately 70% of neonates with asymmetrical growth restriction have a head circumference–to–abdominal circumference ratio 2 standard deviations (SDs) above the norm.[180] However, both the sensitivity and the positive predictive value of this ratio for growth restriction are worse than that of either abdominal circumference percentile or sonographically estimated fetal weight (discussed later).[10,181]

The cephalic index is the ratio of the biparietal diameter to the occipitofrontal diameter. Proposed as an age-independent aid to identify dolichocephaly and brachycephaly,[182] it is of limited value. Dolichocephaly is rare before the third trimester, and the ability to measure head circumference easily eliminated the need to recognize mild degrees of either dolichocephaly or brachicephaly as it relates to the prediction of gestational age. This ratio has also been proposed as an aid for the diagnosis of trisomy 21. The sonographic signs of aneuploidy are reviewed in Chapters 7 and 8.

The femur length (FL)–to–head circumference ratio was proposed as a tool to identify short-limbed dwarfism, hydrocephaly, or microcephaly.[183] However, the greatly improved resolution of modern ultrasound equipment makes this measurement unnecessary for the diagnosis of hydrocephaly (see Chapter 17); dwarfism, because the length of the fetal limbs is well below the 10th percentile for gestation (see Chapter 20); or microcephaly, which is diagnosed when head circumference is more than 3 SDs below the mean.

It would be attractive if the sonographic FL could be used to generate an index of fetal mass because it correlates with neonatal crown-heel length. Unfortunately, no clinically useful formula has been obtained. The FL–to–abdominal circumference ratio has lower sensitivity, specificity, and positive and negative predictive values for the diagnosis of IUGR than either the abdominal circumference percentile or the sonographic estimate of fetal weight.[10,184,185]

Sonographic Estimate of Fetal Weight

Many general purpose and special application formulas have been devised; several are listed in Table 11–3.[186–188] The accuracy of most (±2 SDs) is 10% or greater, and none has proved superior to the first devised by Warsof and reported by Sheppard.[186] Although an estimate of fetal weight does not routinely add to the abdominal circumference percentile for the diagnosis of IUGR, it adds a graphic image that is easy for both patient and referring physician to conceptualize. Although its sensitivity is considerably lower than that of the abdominal circumference percentile, the positive predictive value of a fetal weight estimate below the 10th percentile is greater.

Amniotic Fluid Measurement

The ultrasound estimation of amniotic fluid volume is a poor screening tool for IUGR or fetal academia.[189] However, in clinical practice, it is an important diagnostic and prognostic tool. Oligohydramnios may be a first incidental finding noticed in pregnancies with fetal growth restriction. If this is noticed, a complete ultrasound assessment of fetal growth should be performed, because up to 96% of fetuses with fluid pockets less than 1 cm may be growth-restricted.[190] In patients with suspected growth delay, amniotic fluid volume can be an important differential diagnostic pointer. In the setting of small fetal size, excess amniotic fluid volume suggests aneuploidy, or fetal infection,[191] whereas normal or decreased amniotic fluid is compatible with placental insufficiency.

Placental and Fetal Doppler Studies

The quantification of blood flow volume with Doppler studies is prone to error because of variations in insonation angle and the measurement of vessel diameter. Consequently, Doppler waveform analysis with angle-independent Doppler indices is preferred for fetal surveillance. The most widely used arterial indices are the systolic-to-diastolic ratio,[192] resistance index,[193] and pulsatility index (Table 11–4).[194] A relative decrease in end-diastolic velocities elevates each of the indices and usually reflects increased downstream resistance. When end-diastolic flow is lost, the systolic-to-diastolic ratio approaches infinity and the resistance index becomes 1. The pulsatility index offers the advantage of a smaller measurement error, narrower reference limits, and the theoretical advantage of ongoing numeric analysis, even when end-diastolic velocity is lost.[195]

In the diagnosis and management of fetal growth restriction, several vascular territories provide information about specific aspects of the disease. The Doppler findings that suggest placental dysfunction are a decrease in absolute umbilical venous volume flow[196] and elevated blood flow resistance in the umbilical arteries and uterine arteries. Findings that suggest fetal hypoxia include a decrease in blood flow resistance in the fetal cerebral circulation.[90] Beyond the early adaptive responses in the cerebral circulation (see later), examination of the venous system provides information about forward cardiac function and the impacts of advanced placental disease and progressive hypoxemia.

TABLE 11–3

Sample Formulas Validated Prospectively for Sonographic Estimates of Fetal Weight

TABLE 11–4

Doppler Indices for Arterial and Venous Flow Velocity Waveforms

DOPPLER INDICES	CALCULATION
Arterial Flow	
Pulsatility index	$\dfrac{\text{Systolic-end-diastolic peak velocity}}{\text{Time-averaged maximum velocity}}$
Resistance index	$\dfrac{\text{Systolic-end-diastolic peak velocity}}{\text{Systolic peak velocity}}$
Systolic-to-diastolic ratio	$\dfrac{\text{Systolic peak velocity}}{\text{Diastolic peak velocity}}$
Venous Flow	
Preload index	$\dfrac{\text{Peak velocity during atrial contraction}}{\text{Systolic peak velocity}}$
Pulsatility index for veins	$\dfrac{\text{Systolic-diastolic peak velocity}}{\text{Time-averaged maximum velocity}}$
Peak velocity index for veins	$\dfrac{\text{Systolic-atrial contraction peak velocity}}{\text{Diastolic peak velocity}}$
Percentage reverse flow	$\dfrac{\text{Systolic time-averaged velocity}}{\text{Diastolic time-averaged velocity}} \times 100$
Ductus venosus preload index	$\dfrac{\text{Systolic-diastolic peak velocity}}{\text{Diastolic peak velocity}}$

In the venous system, the magnitude of flow reversal during atrial contraction varies considerably in individual veins. Reverse flow may occur during atrial contraction in the inferior vena cava and hepatic veins. In contrast, normal blood flow in the ductus venosus is forward throughout the cardiac cycle. Because of the complex nature of the venous flow velocity waveform, several venous Doppler indices are described (see Table 11–4).[135,152,197–200] No venous Doppler index appears to offer a significant advantage over the others.[201] Except for the descending aorta pulsatility index, all fetal arterial and venous indices change with gestational age. Thus, interpretation of Doppler findings requires accurate knowledge of gestational age.

It is standard practice in many locales to perform ultrasound twice during pregnancy to enhance the identification of fetuses with IUGR and improve outcome,[181] though the cost-benefit ratio of this practice remains unclear.[202,203] The combination of fetal biometry and umbilical artery Doppler is the best available tool for the identification of a small fetus at risk for adverse outcome.[68,204–206] Randomized trials and meta-analyses confirm that the use of umbilical artery Doppler in this setting is associated with a significant reduction in perinatal mortality rates and less iatrogenic intervention, despite the lack of a standardized response in those trials.[207–209] Before 34 weeks, small fetal size associated with an elevated umbilical artery Doppler index is likely to reflect placental dysfunction. Near term, when umbilical artery Doppler findings may be subtler, a decrease in the middle cerebral artery Doppler index or the cerebroplacental ratio increases suspicion for fetal growth restriction, even if the umbilical artery blood flow resistance index remains within the normal range.[156,206]

Although the umbilical artery flow velocity waveform is primarily determined by the architecture of the villous vascular tree (and therefore placental blood flow resistance), study of other fetal arterial vessels is required to determine the effect on the fetus. Changes in Doppler measured flow profiles of numerous arteries are described in association with IUGR. However, it seems logical to use vessels that represent a single vascular bed, are easy to sample at a low insonation angle, and provide the most information about the fetal response to hypoxemia. For example, flow in the fetal descending aorta is affected by changes in the placenta as well as by the peripheral fetal vasculature, and these changes may be difficult to detect at a small insonation angle. In contrast, the middle cerebral artery is easily identified and examined at a favorable angle. The scanning technique and reference ranges also require standardization because measurements may vary significantly in different portions of the same vessel. Similarly, measurements of the cerebroplacental ratio are affected by the indices used in calculation, and a standardized approach with gestational reference ranges rather than single cutoff values should be used.[210]

With continued compromise, there is little further change in the middle cerebral artery Doppler waveform save the notable exception of "normalization" of Doppler indices. Therefore, the next step after identifying evidence of fetal hypoxemia is to monitor cardiac function through study of the venous system. The inferior vena cava and ductus venosus Doppler indices and umbilical venous pulsations correctly predict acid-base status in a significant proportion of neonates with IUGR. This combination, rather than single-vessel assessment, provides the best predictive accuracy. Although the choice of Doppler index is guided by operator preference, familiarity with the examination technique for all three vessels is encouraged to offer the greatest flexibility in clinical practice.[201]

Biophysical Profile Score

The biophysical profile score (BPS) applies categorical cutoffs for a composite of dynamic variables, such as fetal tone, breathing, gross body movement, and amniotic fluid volume, as well as traditional fetal heart rate analysis. The cutoffs were chosen to account for biologic variation and maturational differences; therefore, they produce a reliable relationship with fetal acid-base status, regardless of gestational age and underlying pathology.[146,211] Although a gradual decrease in all of these parameters precedes an overtly abnormal BPS, an analysis of the percent change in these variables offers no advantage for the prediction of acidemia.[115] A normal score is usually achieved within the first 10 minutes of study. One notable disadvantage of the BPS is that apart from amniotic fluid volume, it lacks variables that allow useful longitudinal prediction of compromise in pregnancies affected by IUGR.[124] This limitation must be considered if BPS is selected as the sole monitoring tool (discussed later).

Diagnosis and Evaluation of Fetal Growth Restriction

The diagnosis of fetal growth restriction is based on the measurement of objective fetal parameters and requires

TABLE 11–5

Causes of Severe Intrauterine Growth Restriction, University of Iowa, 1984–1992

knowledge of normal and abnormal growth as well as the basis for these standards. Ideally, the estimate of gestational age is not based solely on a recent sonographic estimate.

The postnatal definition of IUGR is of pragmatic concern because it affects the stated accuracy of antenatal diagnosis. For example, a thin fetus whose estimated weight is normal might be classified postnatally as growth-restricted by the Ponderal index. Practitioners must understand the diagnostic criteria used in their hospitals, and neonatal caregivers should not rely solely on birth weight percentiles.

"Asymmetrical" and "symmetrical" growth restriction are descriptive terms and not diagnoses. More relevant than symmetry is the timing of onset. Late-onset growth restriction of structurally normal fetuses after 32 weeks' gestation usually results from placental dysfunction. These fetuses are slender, with normal head circumference and body length. In contrast, early-onset growth restriction is often associated with aneuploidy, congenital infection, or more severe forms of placental dysfunction (Table 11–5). Although these fetuses may be symmetrically small when delivered weeks or months after the initial diagnosis, they are often asymmetrical when first identified. Although the significant differences in clinical progression between early- and late-onset IUGR are being increasingly recognized, effective incorporation into clinical management has not yet been accomplished. Undiagnosed IUGR continues to account for approximately 60% of unexplained stillbirths at term.[212,213]

Maternal History and Examination

In view of the many maternal disorders that affect placental development, thorough maternal medical, medication, and obstetric histories should be obtained. A family history of unexpected thromboembolic events or a history of a previous pregnancy affected by early-onset IUGR or fetal demise should be sought. Maternal studies for antiphospholipid antibodies and thrombophilia are more likely to have a diagnostic yield with such a history.[214]

Two-Dimensional Ultrasound Assessment of Fetal Size

The most accurate prediction of fetal growth delay can be achieved if fetal growth parameters are related to customized growth curves.[6] When reference ranges based on normally grown fetuses are used, a fetus is considered "at risk" for growth restriction when the abdominal circumference

percentile is less than percentile 2.5 (or the 10th percentile if a population-based table is selected) but the estimated fetal weight is above the 10th percentile. Suspicion is strengthened when both the abdominal circumference percentile and the estimated weight are abnormally low or when progressive growth delay occurs. Serial ultrasound examinations at least 14 days apart allow assessment of growth patterns and may provide additional diagnostic clues. Fetuses that are constitutionally small are more likely to show normal interval growth.[175] In contrast, fetuses with aneuploidy or placental dysfunction are more likely to show progressive growth delay and to "fall off" the growth curve.[44,175,215] Because fetuses with "suspected" and "diagnosed" IUGR are managed similarly and because the accuracy of the diagnosis based on a small abdominal circumference alone is only approximately 50%, there is no need to worry the parents unnecessarily by basing the diagnosis on a single parameter. Once the suspicion of IUGR is raised, an evaluation of fetoplacental blood flow and anatomy is required.

Two-Dimensional Ultrasound of Fetal Anatomy and Possible Invasive Testing

A thorough ultrasound examination to detect major anomalies and markers of aneuploidy is mandatory in all fetuses with IUGR. Fetal echocardiography to detect major cardiac anomalies (e.g., atrioventricular canal defect) and evaluate cardiac function should be part of that examination. Echogenic bowel or liver or increased amniotic fluid volume suggest an increased risk of either aneuploidy or viral infection,[216,217] particularly in patients with normal umbilical and uterine artery Doppler findings.[44] A chromosomal abnormality is associated with 20% of cases of severe, early-onset IUGR. Although half of these abnormalities are lethal, a fetus with trisomy 21 may pose philosophical problems for both the physician and the patient. Knowledge of a major anomaly, such as atrioventricular canal defect, can lead the parents in one direction or another in terms of pregnancy termination or cesarean delivery for fetal distress.

Doppler Velocimetry of Arterial and Venous Circulation

The fetal vascular responses to placental dysfunction were discussed earlier. There is now considerable knowledge about the relationship between Doppler findings and perinatal outcome that allows for an accurate, noninvasive assessment of the presence and severity of fetal hypoxemia. Until recently, the clinical role of Doppler ultrasound in the overall evaluation of fetal growth disturbance was unclear. Part of the problem was the diverse nature of the published studies. Investigators sought to predict a variety of neonatal outcomes with disparate etiologies using a single parameter, such as umbilical artery index. Not surprisingly, the positive and negative predictive values were, as a whole, unsatisfactory.

Based on the current level of knowledge, we have designed a clinical evaluation algorithm that uses "progressive" Doppler studies of fetal vasculature. Although Doppler findings in each of the examined vascular beds correlate with fetal acid-base status, there is a wide variation in fetal pH with abnormal results (Fig. 11–7). However, as with most

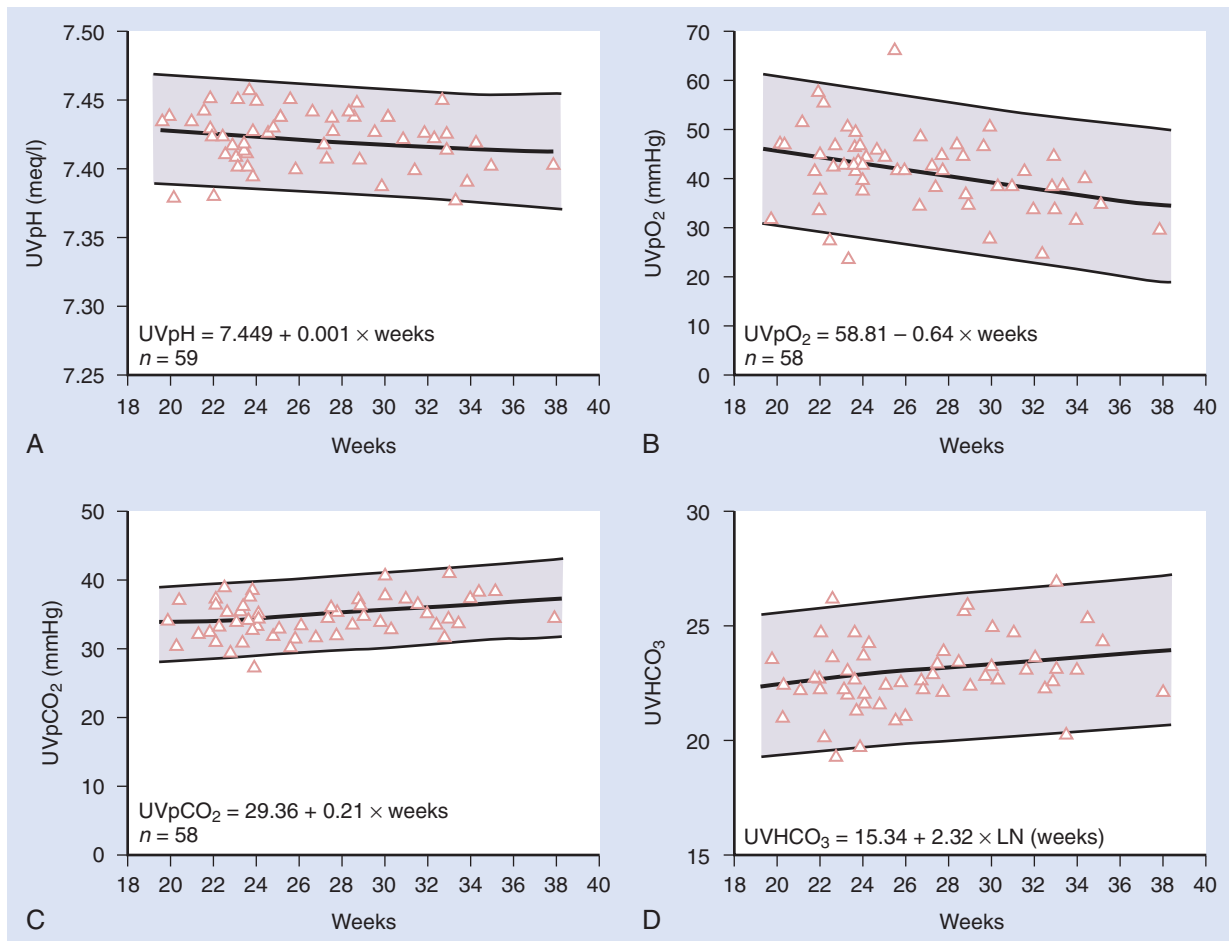
obstetric tests, the negative predictive values are superb. A normal umbilical artery Doppler index is inconsistent with fetal acidemia as a result of uteroplacental dysfunction. Absence of umbilical artery end-diastolic velocity indicates significant villous abnormality; however, the relationship between placental pathology and fetal acidemia is inconsistent both at cordocentesis and at birth.[64,66,218–220] This inconsistency may occur because the oxygen demands of the fetus vary with gestational age. A 23-week fetus can withstand a much higher degree of placental dysfunction than a 32-week fetus. Thus, further evaluation of other fetal organs is necessary to determine the fetal response to the hypoxemia present and to refine the prediction of fetal acid-base balance. Brain-sparing (cephalization, or centralization), elevation of the thoracic and abdominal aortic pulsatility index, and an abnormal cerebroplacental ratio are each associated with fetal hypoxemia and a decrease in pH of at least 2 SDs.[66,88,221] Elevation of the precordial venous Doppler indices (inferior vena cava and ductus venosus) provides the most consistent relationship to a significant decrease in umbilical venous pH (~4 SDs) in fetuses with IUGR.[135,221,222] Because not all fetuses with IUGR have abnormal venous flow, venous Doppler has a sensitivity of approximately 70% and a specificity of 60% to 70% for the identification of significant fetal acidemia typically defined by postnatal norms.[201,221,222] Umbilical venous pulsations occur at a late stage of compromise, and if they are observed concurrently with an elevated venous Doppler index, they improve sensitivity in the prediction of birth pH of less than 7.20.[201] Normal fetal arterial pH in the absence of labor should be greater than 7.32 at term and even higher preterm (Fig. 11–8).

In preterm fetuses with IUGR, Doppler findings of progressive abnormality are associated with increased perinatal mortality and morbidity rates.[94,132,133,154] Although neonatal morbidity is determined primarily by the gestational age, the risks of stillbirth and acidemia are significantly related to the extent of venous Doppler abnormality.[133,154] Therefore, multivessel Doppler studies of the arterial and venous systems are required for the best prediction of critical outcomes in preterm infants with IUGR.[223]

Although our understanding of the relationships between Doppler-derived flow measurements and short-term outcomes has greatly improved, there is relatively little information on the relationships between Doppler measurements and outcome parameters in infancy and adult life. Elevation of fetal aortic blood flow resistance and associated increases in reversal of blood flow in the aortic isthmus are associated with neurodevelopmental delay in early childhood.[224–226] In early-onset growth restriction, early gestational age at delivery, lower birth weight, and absent/reversed umbilical artery end-diastolic velocity are the stronger predictors of adverse neurodevelopment even when biophysical variables are considered.[227,228] Similarly, adverse long-term neurologic development at school age appears most closely related to reversal of umbilical artery end-diastolic velocity.[229] In late-onset fetal growth restriction, evidence of brain sparing has an independent adverse impact on neurodevelopment even in small fetuses with normal umbilical artery blood flow resistance.[230,231] Although initial studies suggested a

FIGURE 11–8

Normal umbilical venous (UV) pH (*A*), pO$_2$ (*B*), pCO$_2$ (*C*), and base excess (*D*) shown as the 95% prediction interval across gestation. (From Weiner CP, Sipes SL, Wenstrom K: The effect of fetal age upon normal fetal laboratory values and venous pressure. Obstet Gynecol 1992;79:71.)

A. UVpH = 7.449 + 0.001 × weeks, n = 59
B. UVpO$_2$ = 58.81 − 0.64 × weeks, n = 58
C. UVpCO$_2$ = 29.36 + 0.21 × weeks, n = 58
D. UVHCO$_3$ = 15.34 + 2.32 × LN (weeks)


protective effect of brain-sparing on cognitive outcome, 5-year follow-up showed no sustained benefit.[232] This time-worn phrase seems a misnomer.

Computerized Cardiotocography and Biophysical Profile Score

Like the observations made with Doppler measurements, a progressive decline in acid-base status can be identified by fetal heart rate analyses and the assessment of fetal breathing, tone, gross body movement, and amniotic fluid volume. Each component of the BPS relates to fetal oxygenation, but the five-component BPS most effectively predicts fetal acid-base status. Although a reactive cardiotocogram (CTG), even by criteria graded for gestational age, virtually excludes hypoxemia, a nonreactive CTG is associated with a wide range of pH values.[145,211] The prediction of acidemia is improved by computerized fetal heart rate analysis. All computerized variables (e.g., short-term, long-term, and mean minute variations) and episodic or periodic changes are related to a range of normal and abnormal fetal pH values.[116,118,119] In fetuses with IUGR, short-term variation

below 3.5 msec as a result of prolonged episodes of low variation appears the best predictor of an umbilical artery pH of less than 7.20.[147] Although it is clearly abnormal in a nonlaboring patient, the clinical relevance of this pH value after labor is not clear. Loss of fetal breathing movements is associated with moderate hypoxemia and a wide range of pH values at the time of either cordocentesis or birth. In contrast, the absence of fetal tone and gross body movement is almost always associated with acidemia (see Fig. 11–7). By accounting for physiologic variability, the BPS maintains its relationship with fetal pH in fetuses with IUGR, independent of gestational age. However, the BPS has limited utility in the prediction of longitudinal deterioration in these fetuses.[124,149]

The relationships between the BPS parameters and long-term outcome were studied in large cohorts of patients. A low BPS was associated with neonatal complications, cerebral palsy, cortical blindness, and attention deficit disorder.[233] Although randomized testing was not performed, the application of the BPS management algorithm was associated with a significant decrease in the frequency of cerebral palsy in the tested population. Our current understanding of

the mechanisms underlying cerebral palsy are inadequate to accept or reject the likelihood this association is real or spurious.

Integrated Fetal Testing

The combined use of multiple testing modalities to monitor fetuses with IUGR has several advantages because of the wide clinical spectrum and the variance in the relationship between testing and outcome variables.[234] The information gained by combining them may be additive because deterioration of cardiovascular and biophysical parameters is initially independent. The Doppler studies enable longitudinal assessment, and the BPS helps refine the relationship with fetal pH. This combined approach provides the most accurate fetal assessment, particularly in preterm fetuses with growth restriction even when the computerized CTG is taken into consideration.[235–240] The management details are described later.

Prenatal Management Options

Diagnostic and therapeutic interventions often go hand in hand when IUGR is suspected, and management options may need to be reevaluated as gestation advances. The goal of the initial evaluation is to make a presumptive diagnosis of IUGR and then to use the clinical presentation to direct additional diagnostic workup. Subsequently, antenatal surveillance is instituted and tailored to the severity of the fetal condition and gestational age, considering the strengths and weaknesses of the available tests. Therapeutic interventions are dictated by the maternal and fetal condition as well as by gestational age, while respecting the wishes of the parents.

Presumptive Diagnosis of Intrauterine Growth Restriction

Fetuses with a small abdominal circumference percentile are at risk for IUGR. A flattening growth curve on two consecutive examinations at least 14 days apart (in the third trimester, preferably 21 days apart) heightens diagnostic suspicion. Individualized reference ranges based on normal pregnancies and maternal characteristics are probably the most accurate.[6] Beyond 24 weeks, an elevated umbilical artery Doppler index is strong corroborating evidence for IUGR as a result of placental dysfunction. A false-positive diagnosis of IUGR is likely in a sonographically small fetus with a normal umbilical artery Doppler examination, and the risk of fetal distress in labor as a result of chronic hypoxia is low. After 34 weeks, the umbilical artery Doppler index may be within the normal range, and a decreased cerebroplacental ratio or middle cerebral artery Doppler index the only supporting evidence of placental-based IUGR.[68,156,241,242] After completion of the anatomic survey and assessment of amniotic fluid volume, the fetus is categorized as either likely or unlikely to have IUGR. Based on the combination of findings, the fetus may have evidence of one of four diagnoses: aneuploidy, viral infection, placental dysfunction, or nonaneuploid fetal syndromes.

Diagnostic Workup

It is important to determine the specific etiology of IUGR before delivery when possible. Figure 11–9 illustrates a

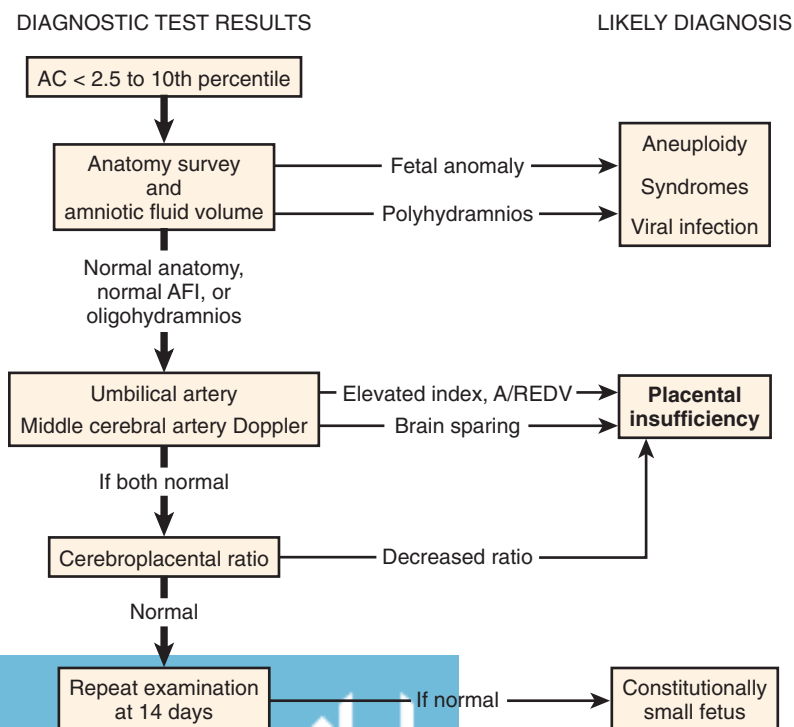
DIAGNOSTIC TEST RESULTS   **LIKELY DIAGNOSIS**


FIGURE 11–9
A decision tree following the evaluation of fetal anatomy, amniotic fluid volume, and umbilical and middle cerebral artery Doppler. The most likely clinical diagnosis is presented on the righthand side. A high index of suspicion for aneuploidy and viral and nonaneuploid syndrome needs to be maintained.

decision tree following the evaluation of fetal anatomy, amniotic fluid volume, umbilical and middle cerebral artery Doppler in cases of suspected IUGR and the most likely clinical diagnosis for a specific combination of parameters.

The wide availability of fluorescent in situ hybridization for fetal karyotyping for major chromosomal abnormalities from amniocytes offers the possibility of a result within 48 to 72 hours in many centers. Polymerase chain reaction of amniotic fluid samples can provide accurate and reproducible detection of the viral genome (see Chapter 30). Thus, amniocentesis should be offered to all patients with early-onset IUGR (<32 wk) and those with symmetrical IUGR detected later in gestation. In addition, women with known familial syndromes may be tested for single-gene mutations if appropriate gene probes are available. The relative ease of amniocentesis and the advances in antenatal surveillance that allow for an accurate assessment of the fetal acid-base status have largely obviated the need for cordocentesis.

However, cordocentesis is the technique of choice if more in-depth diagnostic information is needed. For example, fetal blood sampling provides direct measurement of fetal acid-base status (of value, especially at the threshold of viability, where the variance of Doppler methods is much greater), hepatic transaminases, a complete blood count, serology, and polymerase chain reaction for evidence of fetal viremia, all of which increase the diagnostic yield. For example, although traditional serologic and culture techniques identify an infectious etiology in 5% of fetuses with IUGR,[243] the yield roughly doubles when polymerase chain reaction is employed.[216] Although specific treatments for fetal infection are not available, antenatal diagnosis is important. First, the fetal response to infection is often transient; therefore, the opportunity for diagnosis is lost and the neonate inappropriately excluded from specific follow-up when the diagnostic efforts are delayed until delivery. Further, infected neonates typically shed virus. They should be isolated for the protection of pregnant staff and susceptible nursing mothers of other newborns. Finally, fetuses with IUGR caused by congenital infection are well oxygenated in the absence of placentitis. Extensive antenatal testing geared toward the detection of hypoxemia is unnecessary, and the need for iatrogenic intervention low in the absence of oligohydramnios.

The measurement of hematologic parameters can also shed light on the etiology while final karyotyping is pending and provide additional information about the severity of disease. Fetuses with IUGR and chronic hypoxemia are more likely to have elevated erythropoietin levels and polycythemia. Macrocytosis is more typical of trisomic and triploid fetuses.[244,245] In addition to an elevated nucleated red blood cell count, fetal thrombocytopenia and anemia are signs of chronic compromise associated with poor perinatal outcome.[74,125,128,129,246,247]

The diagnostic benefits of cordocentesis must be weighed against the risks on a case-by-case basis. Early-onset growth restriction increases the risk of reactive fetal bradycardia after cordocentesis in proportion to the severity of fetal hypoxemia.[248] There is roughly a 1 in 5 risk that a fetus with severe IUGR will have bradycardia after cordocentesis. The higher the umbilical artery Doppler resistance index, the

greater the likelihood a bradycardia will occur. The mother of a fetus of borderline viability should decide in advance whether emergency cesarean delivery is to be performed in the event of sustained bradycardia. Cordocentesis must be performed in close proximity to a delivery suite and only by individuals trained in surgical delivery.

Once the diagnostic workup is initiated, management and outcome are largely determined by the underlying condition and the decisions made by the parents. If aneuploidy is the explanation, the cause and risk of recurrence are known. This knowledge may help to reduce the inevitable parental soul-searching and guilt feelings that accompany any perinatal loss. The diagnosis of a structural anomaly that is incompatible with survival eliminates both the need for extensive (and expensive) antenatal monitoring and the high likelihood of cesarean delivery for fetal indications. Documentation of infection allows precautions to be taken to minimize the risks of infection in the nursery as a result of viral shedding. Management is difficult in fetuses with early-onset IUGR as a result of placental dysfunction. In these otherwise normal fetuses, outcome is determined by the condition at birth and the degree of prematurity.[133,154,249]

Maternal and Fetal Therapy

Intrauterine therapeutic options are limited in pregnancies complicated by IUGR. The first step is to reduce or eliminate potential external contributors, such as stress or smoking, and to encourage maternal rest daily in a lateral position. Although the efficacy of these maneuvers is unproved, these simple steps should maximize maternal uterine blood flow. In addition, bedrest in the hospital may be considered because it has theoretical advantages over rest at home. First, even the most motivated patient rests less and less as time passes. The family support structure may be poor, and the patient may not have any real opportunity to rest. Second, hospitalization facilitates daily fetal testing. The choice of inpatient versus outpatient management is based on the severity of the maternal or fetal condition and the local standard of care.

Although low-dose aspirin therapy (81 mg/day) does not help severe early-onset IUGR, it may help patients with mild placental dysfunction.[250,251] In view of its documented safety,[252,253] we typically consider low-dose aspirin therapy after the diagnosis of placental-based mild IUGR.

IUGR as a result of placental dysfunction is the most common fetal disorder that is potentially amenable to direct fetal therapy. To be a candidate for this therapy, the fetus must show a proportionate increase in fetal oxygen and substrate delivery. Techniques to achieve these goals are available. Maternal hyperoxygenation,[254,255] intravascular volume expansion,[256] and hyperalimentation[257] are reported. Many issues, such as the effect of therapy on outcome, patient selection, efficacy, and the requisite testing required to monitor the fetus during therapy, remain to be resolved. Until these issues are clarified, this therapy is experimental.

Universally available therapeutic options that may improve outcome include antenatal administration of corticosteroids to hasten fetal lung maturity in the preterm fetus and delivery at an institution with a neonatal care unit that can carry out the complex management of the neonate with

IUGR. Antenatal corticosteroids should be administered to any fetus with IUGR when delivery is anticipated before 34 weeks. The long-held belief that the "stress" of the intrauterine condition enhances maturation and protects against prematurity is not supported by large population studies of neonates with IUGR.[3,258]

Timing and Mode of Delivery

Because of the limited intrauterine treatment options and the possibility of continued fetal damage as a result of progressive metabolic deterioration, the timing of intervention is critical. Only recently have survival statistics for growth-restricted neonates that are prenatally diagnosed become known.[259] Below 26 weeks, less than 50% of IUGR neonates survive, and intact survival in a similar proportion cannot be expected until 28 weeks' gestation. The effect of birth weight and gestational age on these statistics is so strong that deterioration of venous Doppler parameters does not produce an independent impact until 28 weeks. Between 24 and 32 weeks, each day gained in utero may increase the neonatal survival rate by 1% to 2% and earlier delivery without clear indication is likely to increase to result in iatrogenic mortality.[124,249,259] Although chronic in utero acidemia rather than chronic hypoxemia alone appears to be most strongly associated with intellectual impairment postnatally, prematurity and neonatal complications have an independent impact on neurodevelopment.[227,228,260,261] In preterm IUGR pregnancies, the current emphasis lies on modifying monitoring intervals based on clinical signs of disease acceleration in order to achieve safe prolongation of pregnancy to gain gestational age. The delivery threshold can be progressively lowered with advancing gestation. In IUGR pregnancies presenting after 34 weeks' gestation, the timing of delivery is straightforward.[262] Delivery takes place either at term, when fetal lung maturity is documented, if fetal distress occurs, or if the maternal condition dictates delivery. Between the age of viability and 32 weeks, however, the risks of perinatal damage from fetal deterioration compete with the risks of iatrogenic prematurity.

Prenatal Surveillance Tests (See also Chapter 10)

In euploid fetuses with presumed uteroplacental dysfunction, the patterns of deterioration are characteristic, but variable, and place specific demands on antenatal surveillance. In addition to acute assessments of fetal well-being, the likelihood of clinical progression necessitates a plan for longitudinal surveillance. At each examination, signs of disease acceleration should be sought because they require shortening of the monitoring interval. Traditional fetal heart rate analysis, assessment of fetal activity (tone, movement, breathing), and evaluation of fetoplacental blood flow (arterial and venous Doppler) allow the most precise assessment of fetal well-being. Computerized fetal heart rate analysis, serial amniotic fluid volume measurement, and knowledge of arterial and venous Doppler status allow a reasonably accurate prediction of longitudinal progression.[140,149,152,153,242]

Management of Intrauterine Growth Restriction with Integrated Fetal Testing

At the University of Maryland, we use an approach that combines fetal heart rate analysis with Doppler and biophysical assessment initiated at 24 weeks' gestation. The management algorithm is guided by the severity of the maternal and fetal condition and by gestational age. It includes arterial and venous Doppler studies and determination of the BPS (Fig. 11–10).

Integrated fetal testing has three core elements: correct diagnosis of IUGR, assessment of fetal well-being, and prediction of fetal deterioration to time delivery. Delivery is indicated when the results of fetal testing are grossly abnormal, when fetal lung maturity is documented, or when maternal disease poses a serious risk to the mother. Before 34 weeks, a single course of betamethasone should be completed over 48 hours, when delivery is anticipated, to ameliorate neonatal respiratory disease and reduce the risk of intraventricular hemorrhage.

Although local preferences for antenatal surveillance and management vary, several guiding principles apply. First, the limits of viability and intervention dictated by the accepted standard of care must be discussed with the patient when management is initiated. Second, because cardiovascular deterioration is such a prominent feature of IUGR, Doppler assessment must be an integral part of antenatal surveillance. No other method effectively predicts deterioration prospectively. Third, the management of IUGR is too complex to rely on a single surveillance modality. If alternative surveillance methods are used, longitudinal monitoring should be tailored to the limitations of the surveillance test. For example, traditional nonstress testing analysis lacks the sensitivity and interobserver agreement needed to facilitate longitudinal monitoring. For this purpose, computerized heart rate monitoring offers superior accuracy. Similarly, if the BPS is the sole method of surveillance in severe IUGR, daily testing may be necessary to provide longitudinal assessment.[263]

Delivery Management Options

The premature neonate with IUGR requires the highest level of neonatal intensive care, and intrauterine transport to an appropriate institution is recommended in all cases of early-onset IUGR. The route of delivery is dictated by the severity of the fetal and maternal condition, along with other obstetric factors. Cesarean section without a trial of labor is indicated when the risks of vaginal delivery are unacceptable. These circumstances include prelabor evidence of fetal acidemia, spontaneous late decelerations, or late decelerations with minimal uterine activity. When fetal testing shows less serious conditions and gestational age is more advanced, the delivery route is tailored to the cervical Bishop score and preinduction oxytocin challenge testing might be required. Pharmacologic or mechanical ripening of the cervix, placement of the woman in the left lateral decubitus position, and the use of supplemental oxygen increase the likelihood of successful vaginal delivery.

FIGURE 11–10

Management algorithm for pregnancies complicated by intrauterine growth restriction (IUGR) based on the ability to perform arterial and venous Doppler as well as a full five-component biophysical profile score (BPS). AC, abdominal circumference; AFV, amniotic fluid volume; A/REDV, absent/reversed end-diastolic velocity; CPR, cerebroplacental ratio; DV, ductus venosus; HC, head circumference; MCA, middle cerebral artery; NICU, neonatal intensive care unit; tid, three times daily; UA, umbilical artery.

(From Baschat AA, Hecher K: Fetal growth restriction in placental disease. Semin Perinatol 2004;28:67–80.)

IUGR UNLIKELY		
Normal AC, AC growth rat and HC/AC ratio UA, MCA Doppler, BPS and AFV normal	Asphyxia extremely rare Low risk for intrapartum distress	Deliver for obstetric, or maternal factors only, follow growth

IUGR		
AC < 5th, low AC growth rate, high HC/AC ratio, abnormal UA and/or CPR; normal MCA and veins BPS 8/10, AFV normal	Asphyxia extremely rare Increased risk for intrapartum distress	Deliver for obstetric, or maternal factors only, fortnightly Doppler Weekly BPS
	With blood flow redistribution	
IGUR diagnosed based on above criteria, low MCA, normal veins BPS 8/10, AFV normal	Hypoxemia possible, asphyxia rare Increased risk for intrapartum distress	Deliver for obstetric, or maternal factors only, weekly Doppler BPS 2 times/week
	With significant blood flow redistribution	
UA A/REDV Normal veins BPS 6/10, oligohydramnios	Hypoxemia common, acidemia or asphyxia possible Onset of fetal compromise	> 34 weeks later: deliver < 32 weeks: antenatal steroids repeat all testing daily
	With proven fetal compromise	
Significant redistribution present Increased DV pulsatility BPS 6/10, oligohydramnios	Hypoxemia common, acidemia or asphyxia likely	> 34 weeks later: deliver < 32 weeks: admit, steroids, individualized testing daily vs. tid.
	With fetal decompensation	
Compromise by above criteria Absent or reversed DV a-wave, pulsatile UV BPS < 6/10, oligohydramnios	Cardiovascular instability, metabolic compromise, stillbirth imminent, high perinatal mortality irrespective of intervention	Deliver at tertiary care center with the highest level of NICU care

SUMMARY OF MANAGEMENT OPTIONS
Intrauterine Growth Restriction

Management Options (See also Chapter 10)	Evidence Quality and Recommendation	References
Prenatal		
First-Trimester Screening		
Uterine artery Doppler in patients with thrombophilia, previous midtrimester loss, or previous IUGR. Give low-dose aspirin (75–100 mg/day) if bilateral notching occurs.	Ib/A	162

Intrauterine Growth Restriction—cont'd

Management Options (See also Chapter 10)	Evidence Quality and Recommendation	References
Second-Trimester Screening		
If bilateral uterine artery notching persists until 24 wk, there is only a marginal benefit of low-dose aspirin in selected patients. There is no evidence of a harmful effect.	Ib/A	161,250–253
On Clinical Suspicion of IUGR		
Two abdominal circumference measurements are obtained at least 14 days apart, with umbilical and middle cerebral arteries, to distinguish between normally grown small and growth-restricted fetuses.	Ib,IIa/A,B	68,156,174,175, 207,208,241
Follow for IUGR if: • Abdominal circumference < 5th percentile or growth rate <11 mm in 2 wk. • Umbilical artery Doppler index is elevated. • Cerebroplacental ratio is decreased. • Middle cerebral Doppler index is decreased (centralization) even if uterine artery Doppler is normal (especially after 34 wk).		
With a Diagnosis of IUGR		
If the sole monitoring tool is biophysical profile scoring, up to daily testing is required. In the preterm fetus with IUGR <37 wk, multivessel Doppler, including arterial and venous Doppler, provides the best assessment of disease severity.	IIa/B III/B	251 133,152,154,223
The most accurate assessment of fetal status is obtained with combined Doppler and biophysical assessment.	III/B,C	124,236,238,239
The timing of delivery is still guided by local standards of care and expert opinion; clear indicators for delivery timing have not been tested in a randomized fashion.	Ib/A	249
Administer betamethasone when delivery is anticipated before 34 wk.	III/B	3,249,258
Labor and Delivery		
Route of delivery is determined by fetal status before the onset of labor as well as maternal and obstetric factors. Oxytocin challenge test may be useful before induction. The left lateral decubitus position is used during labor.	III/B	133,137,149,174

IUGR, intrauterine growth restriction.

FETAL MACROSOMIA

Fetal macrosomia is the result of excessive fetal growth, which is the opposite of fetal growth restriction. Two terms are used to identify such growth: *large for gestational age* (discussed earlier) and *fetal macrosomia*, implying a birth weight above 4000 or 4500 g, regardless of gestational age. Unlike in IUGR, the morbidity and mortality rates for macrosomic fetuses are more closely related to absolute birth weight than to birth weight percentile. Although an estimated fetal weight above the 90th percentile might predict macrosomia, the sharp increase in adverse perinatal outcome with birth weight greater than 4500 g makes this a more suitable diagnostic cutoff.[264–267] In the United States, 10% of neonates have a birth weight greater than 4000 g, and in 1.5%, it is

more than 4500 g.[268] Macrosomia is associated with significant fetal, neonatal, and maternal risks that emphasize the need for antepartum detection and modified intrapartum management. Maternal diabetes mellitus is the most common identifiable cause of excessive fetal growth (see Chapter 44).

Etiology and Risk Factors

Genetic factors, such as parental height and race, and the level of maternal hyperglycemia during pregnancy are important determinants of birth weight. In decreasing order of importance, recognized risk factors for macrosomia include a previous macrosomic infant, prepregnancy maternal obesity or excessive maternal weight gain, multiparity,[269] a male fetus, post-term gestation, Hispanic race,[270]

present maternal height and weight at birth, and maternal age younger than 20 years.[271]

The positive relationship between maternal height, weight, and body mass index and neonatal birth weight is likely the expression of genetically predetermined growth potential[6] as well as maternal glycemic status.[272,273] Women who previously delivered a child larger than 4000 g are 5 to 10 times more likely than negative control subjects to deliver an infant larger than 4500 g in a subsequent pregnancy.[271,274] Women who themselves had a birth weight greater than 3600 g are twice as likely to deliver a neonate larger than 4000 g.[275] Male infants are typically heavier than females at any gestational age, and more males than females have a birth weight greater than 4500 g.[267] As fetal growth continues, the proportion of infants larger than 4500 g increases from 1.5% at 40 weeks to 2.5% at 42 weeks.[268]

Environmental and genetic interactions are complex. Much birth weight variation is unexplained, and most infants with macrosomia have no identifiable risk factor.[264] Further, no risk factor predicts macrosomia accurately. Several inheritable syndromes associated with fetal macrosomia are listed in Table 11–6.

Pathophysiology

Excessive fetal growth may result from optimal placentation and excess substrate availability or overstimulation of the fetal insulin–insulin-like growth factor–leptin axis. Maternal glucose is freely transported across the placenta whereas maternal insulin is not. Increased fetal blood glucose concentration therefore stimulates endogenous fetal insulin production, which is anabolic in nature and in the presence of sufficient glucose can lead to excess growth. Maternal diabetes mellitus is the primary example of excess substrate availability and subsequent fetal hyperinsulinemia. Maternal obesity and excessive maternal weight gain are also associated with intermittent periods of hyperglycemia and thus may act by the same mechanism. Mean glucose concentration in women with impaired glucose tolerance and increased fetal blood insulin are strongly associated with birth weight and macrosomia.[276,277] Recent results from the Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study revealed a continuum between impaired glucose tolerance and increasing risk for adverse perinatal outcome.[278] Progressive immune recognition and improved placentation with successive pregnancies could explain the increasing birth weight observed in subsequent pregnancies. Overexpression of placental substrate transporters has not been evaluated systematically as a cause of otherwise unexplained macrosomia.

The fetal growth pattern and type of tissue overgrowth reflects the underlying etiology. Insulin-sensitive tissues, such as the heart, liver and spleen, thymus, adrenal gland, subcutaneous fat, and shoulder girdle, display differential glycogen and fat deposition when insulin levels are high. As a result, total body fat, shoulder and upper extremity circumference, upper extremity skinfold thickness, and liver size

TABLE 11–6

Genetic Causes of Macrosomia

SYNDROME	CLINICAL FEATURES	INHERITANCE
Perlman's syndrome	Fetal macrosomia with visceromegaly, ascites, and polyhydramnios; bilateral renal hamartomas; Wilms' tumor; cryptorchidism; facial abnormalities; micrognathia; volvulus; ileal atresia; diaphragmatic hernia; interrupted aortic arch; corpus callosum agenesis	Autosomal recessive
Lethal macrosomia with microphthalmia	Macrosomia, microphthalmia, median cleft palate; associated with respiratory infection in early life and early infant death	Autosomal recessive
Macrosomia adipose congenita	Macrosomia, voracious appetite, precocious skeletal development; death in first year common	Autosomal recessive
MOMO syndrome	Macrocephaly, retinal coloboma, nystagmus, mental retardation, delayed bone maturation	Autosomal dominant
Cleft lip or palate, characteristic facies, intestinal malrotation, congenital heart disease	Macrosomia, bilateral cleft lip or palate, flat facial profile, lethal complex congenital heart defect, bifid thumbs	Autosomal recessive
ABCD syndrome	Macrosomia, defective intestinal innervation, neonatal fatal intestinal dysfunction	Autosomal recessive
Simpson-Golabi-Behmel syndrome	Macrosomia, macrocephaly, coarse facies, hypertelorism, cleft palate, ventricular septal defect, pulmonic stenosis, transposition of great vessels, patent ductus arteriosus, lung segmentation defects, cervical ribs, pectus excavatum, 13 pairs of thoracic ribs, diaphragmatic hernia, polysplenia, duplication of renal pelvis, postaxial polydactyly, syndactyly of the 2nd–3rd fingers, clubfoot, corpus callosum agenesis, cerebellar vermis hypoplasia, hydrocephalus, embryonal tumors, Wilms' tumor	X-linked recessive
Weaver-Smith syndrome	Macrosomia with predominant developmental features	Autosomal dominant
CHIME syndrome	Early-onset migratory ichthyosiform dermatosis, seizures, mental retardation, cleft palate, tetralogy of Fallot, transposition of the great vessels	Autosomal recessive
CANTU syndrome	Generalized congenital hypertrichosis, narrow thorax, cardiomegaly	Autosomal recessive
Marfan's syndrome	Macrosomia, micrognathia, enophthalmos, predominant features postdelivery	Autosomal dominant
Beckwith-Wiedemann syndrome	Macrosomia, macroglossia, cardiomegaly, omphalocele, Wilms' tumor	Autosomal dominant

ABCD, autosomal-recessive neural crest syndrome with albinism, black lock, cell migration disorder of the neurocytes of the gut, deafness; CANTU, congenital hypertrichosis, osteochondrodysplasia, cardiomegaly; CHIME, coloboma, heart anomaly, ichthyosis, mental retardation, ear abnormality; MOMO, macrosomia, obesity, macrocephaly, ocular abnormalities.

are disproportionately greater in macrosomic fetuses of diabetic women compared with those fetuses of women without diabetes.[279,280] These differences in growth patterns are at least partially responsible for the associated fetal, neonatal, and maternal risks. The function of the liver as the primary fetal glycogen storage organ makes preferentially accelerated abdominal circumference growth an important physical characteristic of significant macrosomia.

Fetal and Neonatal Risks

Macrosomia is associated with increased perinatal mortality; intrapartum risks, including shoulder dystocia; brachial plexus injury; skeletal injuries; meconium aspiration; perinatal asphyxia; and postpartum complications, including respiratory distress syndrome and neonatal hypoglycemia.[264,265,281,282] The complication rates reflect the absolute birth weight. Perinatal morbidity rates are increased in infants larger than 4500 g, and mortality rates are increased in infants larger than 5000 g.[283] Rates of shoulder dystocia and associated clavicular fracture increase 10-fold.[284] Yet, only a small percentage of macrosomic fetuses have complicated deliveries. The risk of shoulder dystocia is significantly affected by the underlying cause of macrosomia. In women without diabetes, shoulder dystocia occurs in 9.8% to 24% of deliveries with a fetus weighing more than 4500 g. The prevalence is doubled in women with diabetes.[266,285,286] The additive impact of birth weight and maternal diabetes was recently reaffirmed for neonates with a birth weight above 4000 g. When macrosomia was associated with gestational diabetes, the risk of shoulder dystocia was increased 8 times and the associated risk for brachial plexus injury was increased 12 times.[287] Clavicular fracture and brachial plexus injuries, including Erb-Duchenne palsy, are most frequently associated with shoulder dystocia.[284,288] However, the risk of brachial plexus injury is increased independent of the mode of delivery or the clinical diagnosis of shoulder dystocia. This finding suggests an in utero origin for at least some brachial plexus injuries.[289] When birth weight exceeds 4500 g, the risk of shoulder dystocia is 18- to 21-fold higher than that in neonates with lower birth weight.[267,280,290]

Maternal Risks

Maternal complications of macrosomia are also related to neonatal birth weight. The incidences of cephalopelvic disproportion and prolonged labor increase at birth weights above 4500 g, and as a result, the cesarean delivery rate doubles.[265,290] The incidence of postpartum hemorrhage greater than 1000 mL increases with birth weights above 4000 g.[291] The rate of third- and fourth-degree laceration is especially increased when shoulder dystocia is diagnosed.[292] Thromboembolic events and anesthetic complications are increased in great part because of the increased need for operative intervention.

Diagnosis

There are no useful, general-purpose screening tools for the detection of macrosomia. A history of obstetric and maternal risk factors (discussed earlier) heightens the clinical index of suspicion. In addition, an unexplained very low serum maternal serum AFP level is associated with increased

birth weight and an increased prevalence of obstetric complications.[293]

Clinical Examination

Mothers of infants with birth weight greater than 4500 g have greater symphyseal fundal height than expected.[294] However, several variables, including amniotic fluid volume and maternal body habitus, limit the usefulness of this measurement unless it is combined with clinical palpation or Leopold's maneuvers.[295] Prospective studies of fundal height measurement combined with Leopold's maneuvers report sensitivity of 10% to 43%, specificity of 99.0% to 99.8%, and positive predictive values of 28% to 53% for the detection of macrosomia.[296,297] The mother's subjective assessment of fetal weight in comparison with an earlier pregnancy can be as accurate as the clinical assessment by Leopold's maneuvers.[298]

Ultrasound

Ultrasound prediction of fetal weight loses accuracy above 4000 g and does not exceed the diagnostic accuracy of clinical estimates.[298–300] Only 50% of fetuses larger than 4500 g weigh within 10% of the predicted weight.[301] In women without diabetes mellitus, the sensitivity of ultrasound for the detection of macrosomia (birth weight > 4500 g) is 22% to 44%, with specificity of 99% and positive predictive values of 30% to 44%.[302,303] There are several reasons for these inaccuracies. First, even at lower weights, the typical error associated with sonographic estimates is 10%, a large error in a macrosomic fetus. Second, the accuracy of these formulas, when confined to macrosomic fetuses, is even lower, up to 13%.[304] Because the birth weight of macrosomic infants is largely determined by organ size and fat deposition, formulas that include abdominal circumference and exclude bony measurements perform better than those that do not.[302] Ultrasound methods that account for skin thickness[305] or incorporate algorithms to calculate fetal volume might have a role in the future.[306] Ultrasound can provide diagnostic information on fetal anatomy, organ size, and fat deposition. Further, ultrasound allows an objective assessment of amniotic fluid volume that may prompt further evaluation for underlying syndromes (see Table 11–6) or recommendation for diabetes testing when hydramnios is suspected. In women with diabetes mellitus, macrosomia may be a biologic indicator of suboptimal maternal metabolic control. Because hyperglycemia can be a cause of hydramnios and macrosomia, the combined observation of increased amniotic fluid volume and accelerated fetal abdominal girth should prompt repeat ultrasound assessment for the confirmation of accelerated growth and the risk for macrosomia.

Management Options

Accelerated fetal growth is a sign of suboptimal glycemic control in maternal diabetes mellitus. In this setting, increased surveillance and strict glucose monitoring and glycemic control significantly reduce the risk for macrosomia.[307] In the absence of maternal diabetes mellitus, the management of suspected macrosomia focuses on the timing and type of delivery and intrapartum management. Evidence suggests that labor induction for suspected macrosomia, defined as estimated fetal weight of 4000 to 4500 g,[308] increases

the cesarean delivery rate without improving perinatal outcome.[309] Although seemingly logical, labor induction should not be undertaken in the absence of a high cervical Bishop's score.

Because perinatal and maternal risks increase with birth weight, and cesarean section reportedly decreases the risks of birth trauma and brachial plexus injury,[265,280,284] it is logical to conclude that elective cesarean delivery should be offered beyond a certain estimated fetal weight. However, there is insufficient study to support this practice. No clinical studies demonstrate a significant reduction in the birth injury rate by adopting such a practice, although arguably, a much larger sample size is needed. Cohort and case-control studies do confirm that a trial of labor is safe and cost-effective at estimated fetal weights of 5000 g or less.[310] For suspected fetal macrosomia less than 5000 g, prophylactic cesarean section does not appear to reduce birth trauma significantly in the absence of maternal diabetes mellitus. In these women and those with other risk factors, such as a history of shoulder dystocia in a macrosomic infant, estimated weight is important when planning the delivery route. In addition, although the predictive accuracy of fetal weight estimates is poor above 5000 g, most authors agree that prophylactic cesarean section should be offered.[265,290]

During labor, special attention is given to the progress of labor and the uterine contraction pattern. Cesarean delivery is indicated when the estimated fetal weight exceeds 4500 g; the second stage is greater than 2 hours with documented adequate uterine contractions (>200 Montevideo units), or there is an arrest of descent. The risk of shoulder dystocia is increased by assisted vaginal delivery. A trial of vaginal delivery after a previous cesarean delivery appears safe for both infant and mother, with success rates of 58% when birth weight is less than 4500 g and 43% when birth weight is higher.[311]

SUMMARY OF MANAGEMENT OPTIONS
Fetal Macrosomia

Management Options	Evidence Quality and Recommendation	References
Prenatal		
On Clinical Suspicion of Macrosomia		
• Abdominal circumference 95th percentile, particularly if associated with increased amniotic fluid volume.	III/B	186
• Exclude gestational diabetes.	—/GPP	—
• Family history of inheritable disorders (see Table 11–6).	—/GPP	—
With Diagnosis of Macrosomia		
• Maternal glycemic control, if indicated.	See Chapter 44	
Labor and Delivery		
Delivery indicated for maternal factors; induction vs. expectant management is associated with increased cesarean rate without improved outcome.	IIb/B	308
Delivery Route	III/B	310,311
• For estimated fetal weight < 4500 g, offer vaginal delivery and vaginal birth after cesarean section.		
• For estimated fetal weight > 4500 g in a diabetic patient, offer elective cesarean delivery.		
• For estimated fetal weight > 5000 g in nondiabetic patient, offer cesarean delivery.		
Early detection of protraction disorder is made by failure to progress over 3 hr with > 200 Montevideo units.	III/B,C	284–286,310

Abnormalities of Amniotic Fluid Volume

MARIE H. BEALL, RON BELOOSESKY, and MICHAEL G. ROSS

INTRODUCTION

Amniotic fluid (AF) surrounds the fetus after the first few weeks of gestation. AF serves to protect the fetus and umbilical cord from compression, has antibacterial properties that may protect the fetus, and serves as a reservoir of water and nutrients. Perhaps most important, it provides the necessary conditions for normal development of the fetal lungs and musculoskeletal and gastrointestinal systems.[1]

Aberrations in AF volume, both low (oligohydramnios) and high (polyhydramnios), are associated with a multitude of pregnancy-related problems. An understanding of the basic physiologic mechanisms that regulate both AF volume and composition is required to devise effective management strategies for pregnancies complicated by disorders of fluid volume.

Sources and Volume of Amniotic Fluid

AF derives from a number of fetal and nonfetal sources, with the relative contribution from each source changing across gestation. Early in gestation, AF is thought to be derived from the mother directly across the amnion and the fetal surface of the placenta and the fetal body surface.[2] In midgestation, fetal urine begins to enter the amniotic sac[3] and the fetus begins to swallow AF, although the daily volume flows are quite small. The fetal lungs also begin to secrete liquid into the AF at this time.

Abundant human and animal data are available regarding the source and composition of AF during the latter half of gestation. The developing human fetus becomes sufficiently large near term to allow noninvasive methods (e.g., ultrasound) to estimate volumes and flows; in addition, direct measurements in chronically catheterized ovine fetuses can be conducted at this time. Near term, the major sources of AF production are fetal urine and lung liquid; the major routes for resorption of fluid are fetal swallowing and the intramembranous pathway (from AF to fetal circulation). The known minor sources of AF production and clearance include secretions from the fetal oral-nasal cavities and the transmembranous pathway (from AF to maternal circulation).

Despite large variances in current estimates of human fetal urine production,[4,5] we feel the best estimates of daily amniotic volume flows in the near-term fetus are[6]

- Flow into the amniotic sac
  - Fetal urine production—800 to 1200 mL/day.
  - Fetal lung liquid secretion—170 mL/day.
  - Oral-nasal secretions—25 mL/day.
- Flow out of the amniotic sac
  - Fetal swallowing—500 to 1000 mL/day.
  - Intramembranous flow—200 to 400 mL/day.
  - Transmembranous flow—10 mL/day.

These values are experimentally derived, primarily using animal models, and likely to be refined as more studies are reported.

In human pregnancy, AF volume increases dramatically during the first two trimesters, from 20 mL at 10 weeks to an average of 770 mL at 28 weeks. After 28 weeks, the AF volume changes little until 39 weeks, after which it decreases dramatically (see Figure 65 in Appendix of Normal Values).[7] Although the average AF volume in the third trimester is 700 to 800 mL, the range of normal is very wide and a normal fetus at 32 weeks may have more than 2000 mL, or less than 500 mL of AF. This wide range of normal compounds the problem of assessing the AF volume in a pregnancy.

Evaluation of Amniotic Fluid Volume

A diagnosis of an AF volume abnormality may be suspected by physical examination (size/dates variance), but the diagnosis is generally made by examination of the fluid compartment. Although AF volume can be assessed by invasive means, such as dye dilution, these are not used in clinical practice. The amount of AF is most commonly evaluated using ultrasound, although the ultrasound estimation of AF does not correlate well with either actual AF volumes[8] or fetal outcomes.[9–11] The amniotic fluid index (AFI)[12,13] or the single deepest pocket (SDP)[14] of AF are both used as semi-quantitative measures of fluid volume. In assessing the AFI, the sonographer measures the deepest AF pocket in each of the four quadrants of the abdomen (as defined by the umbilicus and the linea nigra). Pockets are measured perpendicular to the floor with the patient supine and should not contain small parts or umbilical cord. The AFI is the sum of the four measurements. The SDP is the single largest measurement so obtained. Commonly used definitions of AF abnormalities include an AFI of 25 cm or greater or less than 5, or a SDP of 8 cm or more or less than 2. These AFI values are considerably outside of the 5th or 95th percentile (see

Figure 66 in Appendix of Normal Values),[15] leading some centers to adopt different cutoffs. Using the 5th and 95th percentiles, however, greatly increases the number of patients labeled as having an AF abnormality, though many of these fetuses will have no significant pathology[9] supporting the use of the values just discussed. In addition, evidence suggests that the SDP is more specific than the AFI, without sacrificing sensitivity, suggesting that SDP may be a preferable test for AF abnormalities.[16,17] SDP may also be a more satisfactory test for certain special circumstances, such a multiple gestation,[18] when the AFI is undefined.

OLIGOHYDRAMNIOS

Oligohydramnios is a decreased amount of AF, affecting 3% to 5% of pregnancies.[19] The expected amount of AF varies during and between pregnancies, making the absolute definition of "normal" problematic; however, an AF volume of less than 250 to 300 mL appears to be abnormal at any time during the second half of human pregnancy (see Figure 65 in Appendix of Normal Values). Assessing AF volumes is also problematic. In most protocols, a pregnancy lacking a single pocket of 2 cm, or one with an AFI less than 5 cm, is deemed to demonstrate oligohydramnios. Many centers regard AFIs of 5 to 8 cm as being "borderline normal," following the findings of Phelan and coworkers,[12,20] and "severe" oligohydramnios describes a situation in which there is no measurable AF.[21] Unfortunately, two-dimensional estimates of AF volume correlate poorly with actual volume, and in particular, the measurements discussed earlier demonstrate poor specificity for the diagnosis of oligohydramnios, as measured by tracer dilution.[22] When the two measures were compared, a recent meta-analysis suggests that the SDP method yields a similar perinatal outcome with increased specificity for the diagnosis of oligohydramnios when compared with AFI.[16,23,24] Some authors have also suggested that the subjective impression of diminished AF on ultrasound examination is at least as accurate as the various measurement scenarios.[25,26]

Etiology

Conditions associated with ologhydramnios are shown in Table 12–1. The most likely etiology of oligohydramnios varies depending on gestational age (Fig. 12–1). The etiologies and relative frequencies of midtrimester oligohydramnios were illustrated in a series of 128 fetuses first noted to have severe oligohydramnios at 13 to 24 weeks' gestation.[21] The following etiologies were observed: fetal anomaly (51%), preterm premature rupture of membranes (PPROM) (34%), placental abruption (7%), intrauterine growth restriction (IUGF) (5%), and unknown (4%). Six of the 65 anomalous fetuses were aneuploid. The pregnancy outcome was generally poor owing to fetal or neonatal death or pregnancy termination. In the third trimester, the distribution of abnormalities is different. One recent study of patients greater than 28 weeks[27] described a 28% rate of fetal growth restriction, a 9% rate of abruption, and a 4% rate of congenital anomalies. Although this study excluded patients with preexisting ruptured membranes, 14% of patients with oligohydramnios ruptured membranes after the diagnosis had been made. The perinatal mortality was higher in pregnancies complicated by oligohydramnios than in the overall population.

T A B L E 1 2 – 1

Conditions Associated with Oligohydramnios

Obstetric Complications
Premature rupture of the membranes
Fetal growth restriction
Postmaturity

Maternal Complications
Dehydration

Fetal Anomalies
Renal agenesis
Bilateral multicystic kidneys
Polycystic kidney disease
Chromosomal anomalies
Collecting system abnormalities or obstruction

Rare Complications
Maternal diabetes insipidus
Tubular dysgenesis
Meckel-Gruber syndrome
Perlman's syndrome
FIGURE 12–1
Etiology of oligohydramnios in fetuses with severe oligohydramnios, defined as no visible amniotic fluid (AF) on ultrasound, diagnosed in the second (*A*) and third (*B*) trimesters.
(*A* and *B*, Redrawn from Shipp TD, Bromley B, Pauker S, et al: Outcome of singleton pregnancies with severe oligohydramnios in the second and third trimesters. Ultrasound Obstet Gynecol 1996;7:108–113.)

Excluding membrane rupture, oligohydramnios may be a consequence of a reduction of urine flow from the fetal kidney to the amniotic cavity. Defective urine production by the fetal kidney may be due to reduced renal perfusion. Maternal dehydration may be associated with oligohydramnios[28,29]; this is thought due to reduced flow of water from the maternal to the fetal compartment decreasing fetal intravascular volume and enhancing fetal plasma hypertonicity and fetal vasopressin-induced urinary antidiuresis. The donor twin in the setting of twin-twin transfusion syndrome (TTTS) will also demonstrate oligohydramnios due to reduced intravascular volume.[30,31] A number of authors have also described alterations in fetal renal artery flow associated with oligohydramnios, both preterm and posterm,[32–34] consistent with the theory that with marginal placental function, fetal blood flow is redirected to vital organs, including the brain. The fetal kidneys are less well perfused, reducing fetal urine volume. Flow in the fetal renal artery also may be reduced by maternal use of certain drugs. Indomethacin has been reported to cause oligohydramnios by this mechanism, although this has been debated.[35] The mechanism of action of indomethacin involves its antagonism of prostaglandins.

Fetal renal function may also be impaired as a consequence of renal disease. Maternal use of angiotensin-converting enzyme (ACE) inhibitors has been associated with fetal renal damage, including renal tubular dysgenesis and renal failure (see also Chapter 35).[36,37] Infantile polycystic kidney disease is an autosomally inherited disease (usually recessive) characterized by fetal kidneys that acquire a characteristic sonographic hyperechoic appearance, and impaired function and is associated with oligohydramnios.[38,39] In addition, there are fetuses with multicystic dysplastic kidneys, a developmental abnormality that may progress during gestation.[39] The pregnancy may also be complicated by fetal renal agenesis, which is associated with profound oligohydramnios. Renal agenesis is occasionally found with many chromosomal abnormalities, and with a variety of other syndromes, as well as an isolated finding.[40]

Finally, fetal urine output may be reduced owing to an obstruction in the urinary tract downstream from the kidney, especially bladder outlet obstructions. Posterior uretheral valves, prune belly syndrome, and uretheral atresia are common diagnoses in these pregnancies.[39,41] These obstructions are generally amenable to diagnosis by antenatal ultrasound, because there is an associated dilation of the bladder and/or renal collecting system above the lesion.

Diagnostic Workup

The diagnostic workup of oligohydramnios flows from a knowledge of etiologies. In the second trimester, fetal anomalies are an important cause of oligohydramnios. Ultrasound may be of use in the diagnosis of fetal abnormalities such as renal agenesis or polycystic kidneys[42] or of an obstructive lesion, and magnetic resonance imaging (MRI) may be helpful in confirming these findings (Fig. 12–2). When visualization of the fetus is limited by the oligohydramnios, Doppler ultrasound of the renal arteries (Fig. 12–3) may be helpful in making the diagnosis of renal agenesis[43]; absence of a fetal renal artery signal is reliable evidence of either renal agenesis or a severely dysplastic, nonfunctioning kidney. In some cases, transabdominal amnioinfusion (see

FIGURE 12–2
Posterior urethral valve visualized by magnetic resonance imaging. Note enlarged bladder with "keyhole" appearance of the proximal urethra (*arrow*).
FIGURE 12–3
Normal renal arteries at ultrasound (*arrows*).

later) may be of benefit in allowing a thorough evaluation of the fetus by ultrasound.[43,44] Fetal karyotype may be advisable in order to exclude a fetus with a lethal chromosomal abnormality. With severe oligohydramnios, the karyotype may be obtained by a placental biopsy[45,46] or after amnioinfusion followed by removal of fluid for karyotype.[47] In the face of a fetal urinary obstruction, it has been common to obtain fetal urine for electrolytes or for β-microglobulin in order to predict residual fetal renal function. Such predictive tests have performed poorly, and some authors now consider oligohydramnios as a sufficient indicator of poor fetal renal function (see also Chapter 18).[41,48,49]

In the second or third trimester, ruptured membranes are diagnosed using a combination of history, physical examination, including a sterile speculum examination for pooling of fluid, and confirmatory laboratory tests. Confirmatory tests include vaginal pH, examination of dried secretions for ferning, and ultrasound estimation of AF volume.[50] Used in combination, this testing scheme is more than 90% accurate in the diagnosis of ruptured membranes. Recently developed tools include the measurement of cervical/vaginal placental α-microglobulin-1 (PAMG-1), which is at least as accurate as traditional tools, but is positive in at least a third of women in labor at term despite traditional evidence of intact membranes. Thus, its strength would appear to be its negative predictive value. Others have suggested that a negative fetal fibronectin swab also excludes rupture. If a question persists, a dye such as indigo carmine can be instilled into the amniotic sac and the patient observed for the leakage of blue-stained fluid vaginally. In addition to ruptured membranes, maternal dehydration is a consideration. Dehydration can be suspected by history and physical examination. Although the diagnosis can be confirmed by the finding of increased maternal serum osmolality, in practice, most mothers are offered oral hydration as the remainder of the workup proceeds.

When it develops near term, oligohydramnios should prompt an evaluation of the fetus for evidence of growth restriction and fetal compromise. Although oligohydramnios as diagnosed clinically is associated with fetal growth restriction,[51] it is poorly predictive of abnormal pregnancy outcomes.[51,52]

Risks and Prognosis

Maternal Risks

Oligohydramnios may be associated with an increase in maternal complications. Premature rupture of the membranes, which is one of the main causes of oligohydramnios, is associated with increase risk of chorioamnionitis and maternal morbidity. Among obstetric risks, a meta-analysis of over 10,000 oligohydramnios cases observed an increased risk for cesarean delivery.[53] Others have described an increased risk for labor induction[27] and for small–for–gestational age birth weight.[54]

Fetal Risks

Reduced AF in the first trimester is an ominous finding; the pregnancy often aborts. In one series, 15 of 16 patients (94%) with a normal fetal heart rate and small sac noted on first-trimester sonogram went on to spontaneously abort compared with only 4 of 52 control patients (8%) with normal sac size.[55]

In the second trimester, the prognosis depends on the underlying etiology and severity of the oligohydramnios: Pregnancies with isolated mild or moderate idiopathic oligohydramnios have a good prognosis.[14,56,57] Serial sonographic examinations are helpful for following the natural history of the process, which may remain stable, resolve, or progress to development of severe oligohydramnios and/or fetal growth restriction. In contrast, severe second-trimester oligohydramnios often ends in fetal or neonatal death. In a series of 128 infants,[21] survival occurred in 35/43 (81%)

fetuses with PPROM, 2/9 (22%) fetuses with abruption, 1/5 (20%) fetuses with idiopathic oligohydramnios, 1/65 (1.5%) fetuses with congenital anomalies, and 0/6 fetuses with fetal growth restriction. It should, however, be noted that many of these women chose pregnancy termination because of the poor prognosis. In particular, severe oligohydramnios due to PPROM in the second trimester has been reported to have a 90% mortality rate when the duration of the latency period was more than 14 days,[58] leading to a sense of futility regarding these pregnancies. A more recent report,[59] however, describes 23 pregnancies complicated by PPROM and severe oligohydramnios prior to 24 weeks who were delivered between 2006 and 2008. Six pregnancies (26%) were stillborn prior to 24 weeks, and 2 pregnancies were delivered of live (surviving) infants with latency periods less than 14 days. Of the 15 patients delivered after 24 weeks with at least 14 days of PPROM, 1 was not resuscitated and died at delivery, 2 died of pulmonary hypoplasia, and 1 died of necrotizing enterocolitis. The survival of all patients with PPROM prior to 24 weeks was 43%, and the survival of those remaining pregnant to 24 weeks was 76%. Sixty percent of those delivering after 24 weeks with at least 14 days of PPROM had pulmonary hypoplasia, but only 22% of these infants died in the neonatal period. It appears the key element for survival is the presence of at least some amniotic fluid between 18 and 23 weeks' gestation. Absence of amniotic fluid during this interval regardless of the mechanism is highly associated with perinatal death.

Surviving infants may have significant morbidities. Preterm delivery, either spontaneous or indicated by maternal or fetal complications, occurs in more than 50% of pregnancies with severe second-trimester oligohydramnios.[56,57,60,61] Infants may have anatomic and functional abnormalities consistent with the Potter sequence, such as skeletal deformations, contractures, and pulmonary hypoplasia. Pulmonary hypoplasia, in particular, presents a threat to the survival of the fetus with severe second-trimester oligohydramnios, although newer interventions, such as inhaled nitric oxide and high-frequency ventilation, have improved survival in this condition.[59] Various techniques have been suggested to identify fetuses at risk for this complication,[62–66] with the most successful one at present the ultrasound-determined lung volume and pulmonary blood flow.[67] Kohl and colleagues[68] have performed fetoscopic tracheal occlusion to improve pulmonary outcomes in fetuses with ultrasound findings suggestive of pulmonary hypoplasia (see later), though this remains an investigational therapy.

The prognosis of third-trimester oligohydramnios is not as dire as oligohydramnios found in the second trimester. For example, one series included 122 cases of severe oligohydramnios initially diagnosed in the third trimester and 128 initially diagnosed in the second trimester. Perinatal survival was 85% and 10%, respectively.[21] Most cases of severe oligohydramnios in the third trimester occurred at or near term; they were not associated with Potter-like effects, although they were often associated with fetal growth restriction. Some,[69,70] but not all,[71] studies have shown an inverse relationship between AF volume in the third trimester and the incidence of adverse pregnancy outcome. Small sample size likely affected the results of negative studies. Adverse outcomes are related to umbilical cord compression, uteroplacental dysfunction, and meconium aspiration. In

particular, uteroplacental dysfunction and cord compression are associated with fetal heart rate abnormalities that may lead to cesarean delivery and low Apgar scores.[21,53,72]

Management Options

Standard Management

Maternal hydration is commonly used in an attempt to increase AF volume in patients without fetal urinary tract abnormalities, and several studies report an increase in amniotic fluid volumes after maternal hydration. In one study, four groups of oligohydramnios patients were randomized to intravenous hypotonic fluid, intravenous isotonic fluid, oral water, or control. Only the intravenous hypotonic fluid and oral water groups had an increased AFI compared with the controls (2.3 and 3.3 cm, respectively), emphasizing that maternal plasma osmolality reduction rather than maternal plasma volume expansion is etiologic in increasing the AFI.[73] In a recent randomized clinical trial comparing the effect of maternal intravenous hydration with 0.5 normal saline versus placebo on the AFI in patients with oligohydramnios, no difference was demonstrated between the two groups,[74] whereas an observational study of hydration with 5% dextrose in water did find an increase in AFI,[75] confirming the importance of hypotonic replacement. In a blinded trial of oral hydration versus control, women with both decreased and normal AFIs increased their AFI in response to consumption of an additional 2 L of water daily.[76,77] Similarly, a trial of oral hydration with water in 10 women with oligohydramnios found an increase in AFI and an improvement in measures of uteroplacental perfusion.[78] These data were sufficient for the Cochrane collaboration to note that maternal hydration "may be beneficial in the management of oligohydramnios."[79] We consider that in cases of oligohydramnios in which immediate delivery is not indicated, oral hydration with water may have benefit, particularly in patients with evidence of maternal dehydration. By contrast, there is no evidence for a benefit from maternal isotonic volume expansion or the use of diuretics to increase fetal urine flow.[80] Although there appears little doubt that maternal fluid status affects the fetus, the clinical utility is weak.

Experimental Management

As a decrease in maternal osmolality appears to improve AF volumes, we examined the effect of reducing maternal osmolality by combining maternal hypotonic hydration with 1-deamino-[8-D-arginine] vasopressin (DDAVP).[81] There was indeed an increase AFI in women with oligohydramnios compared with untreated controls. However, there was no comparison with hydration alone, and this treatment regimen remains experimental.

Procedures

Amnioinfusion, or the instillation of fluid into the amniotic cavity, might be expected to prevent the pulmonary and orthopedic consequences to the fetus and to allow visualization of the fetus by ultrasound. However, multiple procedures are needed because of the natural circulation of the fluid or leakage because of membrane rupture. A few reports describe multiple amnioinfusions being performed to replace AF in pregnancies complicated by fetal renal abnormalities,[82–84] the majority in patients with early membrane rupture in which it was associated with improved perinatal survival,[85–88] an increased latency period,[87,89–91] and a reduced need for cesarean delivery.[86] However, the procedure was more successful in patients who retained the infused fluid,[92] and some authors performed a test infusion to determine those patients who would benefit from the procedure.[93] There was no reported association of amnioinfusion with chorioamnionitis.[87,91] It is difficult, however, to advocate for this procedure after 23 to 24 weeks when fetal lung development should be completed.

PROCEDURE

TRANSABDOMINAL AMNIOINFUSION

1. Some authors pretreat the patient with antibiotics, especially if the procedure is being done for ruptured membranes.[87] Others include antibiotics in the infusion. There is no evidence to objectively support this practice.
2. After informed consent and sterile preparation, a 20-g needle is advanced into the gestational sac:
   - The placenta is avoided if possible.
   - The needle is aimed for an existing fluid pocket or for an area between the limbs.
3. Correct needle placement is identified
   - If fluid is present, fluid may be aspirated.
   - If no fluid is present, a small amount of saline may be injected to confirm intra-amniotic needle placement.
4. Sterile tubing attached to a stopcock, large syringe, and saline intravenous line is attached to the needle.
   - Prime the tubing to avoid injecting air into the amniotic sac, because this greatly interferes with visualization by ultrasound.
5. Fluid is injected with continuous ultrasound guidance.
   - Saline is used in nearly all trials and appears to be effective. An argument has been made that lactated Ringer's solution more closely resembles the composition of natural amniotic fluid.[94]
   - Many authors warm the saline to 37°C,[87] though there are no published studies on the difference between room temperature and warmed saline for preterm amnioinfusion.
   - Fetal heart motion may be observed by ultrasound.
   - For therapeutic amnioinfusion, the aim is to achieve a normal AFI.
6. After the procedure, the patient is monitored for 24 hours for leakage, fever, or uterine contractions.
7. Anti-D globulin is administered to Rh-negative mothers.

Other than amnioinfusion, a variety of interventions have been proposed for the patient with oligohydramnios remote from term, especially for the patient with early gestation and PPROM. O'Brien and associates[95] used a gelatin sponge to plug the cervix, in addition to cervical cerclage and amnioinfusion, in 15 women who suffered rupture of the membranes at or before 21 weeks. Six of the 15 fetuses survived to hospital

discharge, though several of these had orthopedic sequelae of oligohydramnios. Human platelets and cryoprecipitate (Amniopatch) have been injected into the amniotic sac in cases of membrane rupture after amniocentesis. Although individual reports have suggested good outcomes with this technique,[96–99] a full comparison of risks and benefits is needed. A number of case reports have examined the injection of fibrin "glue" through the cervix.[100] Here too, a full examination of this technique is lacking.

Fetal Surgery (See also Chapters 18 and 19)

Fetal surgical approaches to the management of oligohydramnios fall into two areas: bladder drainage and tracheal occlusion. In the case of urinary collecting system obstruction, there have been a large number of reports of shunt placement into the fetal bladder. More recently, there have been reports of the ablation of posterior uretheral valves by fetoscopy. Vesicoamniotic shunts may reduce the prevalence of pulmonary hypoplasia, but they have no confirmed value in preserving renal function despite the use of fetal urinary electrolytes to select patients with functioning kidneys for treatment. Among 14 patients who underwent procedures for posterior uretheral valve (average gestational age 22.5 wk), all fetuses had urinary electrolyte values believed to be consistent with adequate renal function. Of the 8 born alive and surviving the neonatal period, 5 had chronic renal disease, including 3 who required renal transplantation.[49] Similarly, a report from Egypt describes 12 patients who had vesicoamniotic shunts placed for posterior uretheral valves. Of the 8 survivors, 4 had normal renal function, a rate similar to that achieved when treatment is postnatal.[101] Another report describes 20 male fetuses treated for a variety of lower urinary tract obstructions.[41] Ninety percent of the treated children survived for 1 year. Of the survivors, 8 had normal renal function, and 6 of 10 with impaired renal function were candidates for renal transplant.

Fetoscopic therapy has been undertaken for some anomalies, but data upon which to judge effectiveness are currently limited.[102–104] Fetoscopic tracheal occlusion has been employed to prevent or alleviate the pulmonary hypoplasia associated with second-trimester oligohydramnios.[68,105] These innovative approaches are exciting but clearly remain experimental.

SUMMARY OF MANAGEMENT OPTIONS
Oligohydramnios

Management Options	Evidence Quality and Recommendation	References
Identify Cause (If Possible)		
Detailed history to include drug exposure, maternal medical illnesses, prior prenatal screening for aneuploidy, prior ultrasound findings, symptoms of membrane rupture.	—/GPP	—
Rupture of the membranes is ruled out by physical examination.	—/GPP	—
Ultrasonography to assess: • Degree of oligohydramnios (AFI). • Presence of growth deficiency. • Presence of fetal anomalies. • Presence and appearance of the kidneys. • Presence of fetal renal arteries. • Fetal and uterine blood flow studies. • Fetal well-being.	III/B	42
Amnioinfusion may have a role in diagnosing or confirming suspected PPROM or fetal anomaly.	III/B	44
Patient Counseling		
Prognosis depends on gestational age, severity of oligohydramnios and diagnosis.	III/B	21
• Severe oligohydramnios in the second trimester is often associated with fetal death and congenital abnormalities. The patient may wish to consider pregnancy termination.	—/GPP	—
• Third-trimester oligohydramnios is more often associated with PPROM and IUGR. Delivery may be indicated.	—/GPP	—

POLYHYDRAMNIOS

Polyhydramnios is the condition of excessive AF. Clinically detectable polyhydramnios occurs in 1% to 3% of pregnancies.[19,106] The 95th percentile for the maximum AF volumes in normal pregnancy is about 2200 mL (see Figure 65 in Appendix of Normal Values); however, abnormal pregnancies can have AF volumes of many liters.[107] At Harbor-UCLA, an AFI of 25 cm or greater is used as the clinical definition of polyhydramnios.[108] Other definitions commonly used include an AFI of 24 cm or greater, or a SDP of greater than 8 cm.[108] The 95th percentile AFI at maximum fluid volumes for normal gestations is between 18 and 20 cm (see Figure 66 in Appendix of Normal Values), leading some centers to use lower cutoff figures. But as with the diagnosis of oligohydramnios, such thresholds greatly increase the number of patients labeled as having an AF abnormality without an association with adverse outcome. The higher AFI cutoff selects the majority of fetuses with an abnormal outcome, while avoiding the need to perform an extensive workup on a number of normal fetuses.[109] Polyhydramnios is often categorized as mild, moderate, or severe; although these terms are not strictly defined, they correspond roughly to AFIs of 25 to 30, 30 to 35, and greater than 35 cm,[110] or SDPs of 8 to 11, 11 to 15, and greater than 15 cm.[42]

Etiology

Conditions associated with polyhydramnios are shown in Table 12–2. As for oligohydramnios, knowledge of AF dynamics aids our understanding of the underlying etiology of polyhydramnios. In general, polyhydramnios may be caused either by excess fetal urine or lung fluid or by a defect in AF resorption. Because there are no known conditions characterized by a defect in intramembranous flow, resorptive defects reflect deficiencies in fetal swallowing or upper

gastrointestinal tract obstructions that prevent AF resorption.

Inherited disorders causing increased urine production in utero are rare. The Bartter syndromes are autosomal recessive defects in various components of the salt resorption system in the thick ascending limb of the nephron,[111] characterized by polyuria. In some instances, the polyuria may extend to fetal life, creating polyhydramnios.[112] Perlman's syndrome[40,113] and Beckwith-Weideman syndrome[114] are inherited disorders of renal development also associated with polyhydramnios. However, these are overgrowth syndromes, with large fetal kidneys and increased urine output.

More commonly, excess urine flow is due to fetal volume overload. Volume overload is likely the cause of

polyhydramnios in the amniotic sac of the recipient in a twin-twin transfusion[31,115]; atrial natriuetic peptide has been implicated in the increased urination.[116] Fetuses with tachyarrhythmias may present with polyhydramnios[42] that resolves with reversion of the cardiac rhythm. Fetuses with severe anemia from red blood cell alloimmunization[117,118] may also present with polyhydramnios. Polyhydramnios due to anemia or tachyarrhythmia may reflect increased cardiac output. Increased cardiac output is responsible for the polyhydramnios associated with placental chorioangioma and other tumors.[119] Fetal infections such parvovirus B19 may result in polyhydramnios in association with hydrops,[120,121] though parvovirus infection is rarely associated with polyhydramnios alone. Polyhydramnios and fetal hydrops may also occur with congenital syphilis infection.[122]

Fetuses of diabetic mothers may demonstrate increased AF, and the likelihood is correlated with glycemic control.[123] Here, excess AF likely reflects increased fetal urine output due to an osmotic (glucose) diuresis. One study using a two-dimensional ultrasound estimate of fetal urine output reported normal fetal urine output in diabetic pregnancies.[124] Three-dimensional methods appear more reliable and may become useful for routine estimation of bladder output in pregnancies with polyhydramnios.[125,126]

Polyhydramnios may also be a consequence of fetal anomalies leading to disruptions in fetal swallowing or resorption of fluid. Fetuses with severe central nervous system abnormalities, such as anencephaly, can have polyhydramnios caused by poor swallowing effort,[42] as may fetuses with disorders characterized by muscle weakness (e.g., myotonic dystrophy).[127,128] In addition, fetuses with obstructions of the mouth or oropharynx,[129–132] esophageal atresia,[133,134] or duodenal atresia[135] are often identified after the development of polyhydramnios. Fetuses with thoracic abnormalities such as diaphragmatic hernia[136,137] or cystic adenomatoid malformation of the lung[138] may also present with polyhydramnios due to esophageal compression,[139] alterations in hemodynamics,[140] or perhaps increased lung fluid production. In many cases, these structural anomalies are associated with chromosomal abnormalities.[141] A lack of fetal swallowing does not lead to polyhydramnios in all cases. Only 26% of anencephalic fetuses developed polyhydramnios in one study,[142] and in animals, the inability to swallow fluid may or may not result in polyhydramnios, depending on changes in intramembranous absorption.[143]

Risks and Prognosis

Some of the more common complications of polyhydramnios are listed in Table 12–3.

Maternal Complications

Mild-to-moderate polyhydramnios creates minimal maternal symptoms, generally consisting of abdominal discomfort and slight dyspnea.[144] In moderate-to-severe polyhydramnios, there may be maternal respiratory distress and often edema of the lower extremities. Severe polyhydramnios increase is associated with an increased prevalence of preeclampsia in association with the "mirror" syndrome.[145] Marked polyhydramnios may increase the incidence of preterm birth due to uterine overdistention[146,147] (see later).

TABLE 12–3

Pregnancy Complications Associated with Polyhydramnios

CONDITION	RELATIVE RISK
Pregnancy-induced hypertension	2.7
Urinary tract infection	2.8
Premature delivery	2.7
Premature rupture of the membranes	3.0
Abnormal fetal presentation	2.5
Cesarean section	4.0
Intrauterine demise	7.7
Neonatal death	7.7
Nuchal cord	3.3

Data from Golan A, Wolman I, Sagi J, et al: Persistence of polyhydramnios during pregnancy—Its significance and correlation with maternal and fetal complications. Gynecol Obstet Invest 1994;37:18–20.

The increased AF volume and overstretched myometrium place the patient with polyhydramnios at risk of labor complications. Spontaneous labor with intact membranes often produces contractions that are of poor quality.[148] There is an increased incidence of fetal malpresentation,[106,149,150] which further increases the likelihood of cesarean delivery.[106,147,151] Rapid decompression following rupture of the membranes has been linked to abruptio placentae[152,153] and amniotic fluid embolus (see also Chapters 58 and 78). Similarly, there appears an increased risk after delivery of uterine atony and postpartum hemorrhage.[42]

Fetal Complications

Most cases of mild polyhydramnios are idiopathic and carry a low risk of undiagnosed anomalies, and abnormalities present may not amenable to antenatal diagnosis.[107] Often, it is associated with fetal macrosomia.[108,147,154] It is, however, associated with an increased risk of delivery complications such as preterm labor and fetal malpresentation (see Table 12–3). In one report,[108] polyhydramnios with a normal fetus carried a 10% to 20% risk of preterm birth and a 3% to 5% risk of fetal death. Severe polyhydramnios has a higher risk of perinatal mortality (Table 12–4).[155,156] Potentially, increased intra-amniotic pressure could interfer with placental blood flow and thus compromise fetal oxygenation.[157,158] Polyhydramnios is also associated with a variety of fetal anomalies and other conditions, such as severe anemia and TTTS. In these cases, the outcome of the pregnancy depends more on the etiology than the polyhydramnios.

Diagnostic Workup

The mainstay of diagnosis in polyhydramnios is targeted ultrasound. Goals of the examination are to define fetal number and chorionicity (if multiple gestation), quantitate the fluid, and evaluate the fetus for structural abnormalities, fetal heart rate, and evidence of fetal hydrops. Fetal activity, bladder volume, and voiding can also be assessed. Amniocentesis for a karyotype (especially when significant congenital anomalies are detected) and a search for fetal infection may be indicated. In one large representative series, the prevalence of aneuploidy in anomalous fetuses with

DEGREE	SDP	AFI	FREQUENCY (%)	PERINATAL MORTALITY (PER 1000)	ANOMALIES (%)
Mild	>8	>24	68	50	≤6
Moderate	>11	>32	19	190	≤45
Severe	>15	>44	13	540	≤65

AFI, amniotic fluid index; SDP, single deep pocket.
From Harman CR: Amniotic fluid abnormalities. Semin Perinatol 2008;32:288–294.

polyhydramnios was 10%.[159] Whether a karyotype should be obtained in the absence of anomalies or growth restriction is more controversial because the likelihood of aneuploidy is much lower in the setting of a normal sonogram. In this same series, the prevalence of aneuploidy was 1%,[159] a range consistent with that reported in prior series.[109,160–163] We recommend karyotype in cases of severe polyhydramnios because of the increased risk of aneuploidy in most series, the possibility that anomalies escaped detection during the sonographic examination, and the low risk of the procedure, especially if fluid is being withdrawn for therapeutic reasons (see later).

In addition to the fetal examination, maternal testing for diabetes and isoimmunization may be useful if not previously performed. Maternal history may suggest testing for other etiologies such as infections or drug exposures.

Management Options

Standard

The most effective treatments for polyhydramnios address the specific diagnosis, such as diabetes control and fetal TTTS. These treatments are described elsewhere in this text. The goal of nonspecific treatment in polyhydramnios is to relieve intolerable maternal symptoms and to avert preterm delivery. Mild and moderate polyhydramnios are usually managed expectantly, and treatment is reserved for symptomatic patients and for those with severe polyhydramnios. Many authors will treat severe polyhydramnios regardless of maternal symptoms due to the increase in intra-amniotic pressure found in these pregnancies.[157]

One possible treatment paradigm is to reduce maternal to fetal water flow. Although maternal dehydration should reduce transplacental water flow, manipulations of the maternal plasma volume or osmolality, as with diuretics, are not used because they may reduce placental blood flow and impair fetal oxygenation.[164] Fetal urine flow in polyhydramnios has been manipulated with maternally administered prostaglandin synthase inhibitors with good results. Several series and case reports document the use of indomethacin to treat polyhydramnios,[165–171] although there are no randomized trials for this indication. Indomethacin may also act through an effect on the fetal membranes,[106] but most likely, it increases the resorption of water in the renal tubule by inhibition of prostaglandins.[42,106] The most commonly used dose of indomethacin is 25 mg every 6 hours,[106] although some report doses up to 200 mg/day.[150,168,171] In most reports, the dose is reduced or stopped if there is oligohydramnios or signs of fetal ductal constriction. Otherwise, the

indomethacin may be continued if effective in reducing the AF volume until 32 to 34 weeks when the risk of ductal constriction begins to rise. It may be possible to taper the dose and discontinue indomethacin treatment earlier if severe polyhydramnios does not recur. Indomethacin is not used in TTTS, because there are serious concerns of exacerbating the condition of the donor fetus.

Indomethacin has a variety of undesirable fetal effects, including closure or constriction of the ductus arteriosus,[170] the development of oligohydramnios,[172] and fetal renal damage,[173,174] although not all reports support these associations.[175] We obtain serial fetal echocardiographic evaluation at weekly intervals if the treatment exceeds 48 hours. Sonographic signs of ductal constriction include tricuspid regurgitation and right ventricular dysfunction. We also monitor the AF volume and reduce or discontinue indomethacin if the AFI is less than 8 cm.

Experimental

SULINDAC

Sulindac is a nonsteroidal anti-inflammatory agent that also results in reduction of the AF volume, but may have less potential than indomethacin to constrict the fetal ductus arteriosus[106,176–178] when used as a tocolytic. One study concluded that sulindac has less effect than indomethacin on fetal urine production, a negative for this indication.[106]

OTHER THERAPIES

In the ovine pregnancy, intra-amniotic DDAVP is rapidly absorbed by the fetus and causes a marked decrease in fetal urine flow.[179] Modulation of the amniotic membrane water channels (aquaporins)[180] may also represent a potential future therapeutic intervention to normalize AF volume.

Procedures

Removal of large amounts of AF by amniocentesis (therapeutic amniocentesis, or amnioreduction) is used to manage the maternal symptoms of polyhydramnios. The procedure has also been used to avert preterm delivery and claimed to improve fetal oxygenation by reducing intra-amniotic pressure,[181] though there is no good evidence of efficacy for fetal indications[182] other than in TTTS.[183–187] The role of amnioreduction in TTTS has diminished after studies showing improved outcome with fetoscopic laser therapy prior to viability.[188]

Two protocols are used for amnioreduction: standard amnioreduction, in which fluid is removed at a rate of 45 to 90 mL/min, and aggressive amnioreduction, in which fluid

is removed more rapidly.[189] Both techniques are associated with similar complications rates (4%–15%) including PPROM, infection, placental abruption, and fetal death.[183,189,190] It is uncertain whether some or all of these complications occur as a part of the natural history of polyhydramnios because none of the studies included an untreated control arm. On average, two procedures are needed to reduce AF volume chronically, although some patients, particularly those with TTTS, require many more.[189–191] One case report described 12 amnioreductions removing a total of 21,600 mL of fluid; the infant was diagnosed with West's syndrome at follow-up 16 months after delivery.[107]

PROCEDURE

THERAPEUTIC AMNIOREDUCTION

1. Prior to the procedure, a decision should be made as to the possibility of delivery in the case of fetal distress. If emergency cesarean delivery is a consideration, the procedure is best done in or near the surgical suite.
2. After informed consent and sterile preparation, an 18- to 20-g needle is advanced into the gestational sac, avoiding the placenta if possible. The needle may be angled slightly to allow for a decrease in uterine size with amnioreduction.
3. Once the cavity is entered, a stopcock and tubing are attached to the needle hub, and a large syringe is used to remove fluid one syringe at a time. Wall suction,[192] vacuum bottles,[193,194] and wound suction systems[190] are all described to allow for more rapid fluid removal. The goal is a normal AFI of 10 to 20 cm (some are even more aggressive, aiming for an AFI <10 cm[190] or relative oligohydramnios[189]).
4. There is no evidence identifying the best monitoring protocol after amnioreduction. We monitor uterine activity for 12 to 24 hours, and follow AF volume every 1 to 3 weeks as indicated by the severity of the process. Amnioreduction can be repeated if severe polyhydramnios recurs.

Fetal Surgery

No fetal surgical intervention is specifically targeted to polyhydramnios, with the exception of fetal laser ablation of vascular anastomoses in patients with TTTS. Several reports describe indirect therapy such as shunting of intrathoracic cystic lesions[195] or fetal surgery for thoracic lesions or teratomas.[196,197]

SUMMARY OF MANAGEMENT OPTIONS
Polyhydramnios

Management Options	Evidence Quality and Recommendation	References
Identify Cause (If Possible)		
Detailed history to include drug exposure, maternal diabetes, prior prenatal screening for aneuploidy, family history of myotonic dystrophy or past history of skeletal dysplasia/arthrogryposis, history of red cell alloimmunization.	—/GPP	—
Maternal blood sugar series/glucose tolerance test and blood type/antibody screen if not previously done.		
Ultrasonography to assess:		
• Degree of polyhydramnios (AFI). • Presence of fetal anomalies, especially those that would impede swallowing. • Evidence of fetal anemia. • Evidence of fetal tachyarrhythmia. • Evidence of TTTS.	III/B	161,198,199
Offer karyotope for anomalous fetus or severe polyhydramnios.	III/B	107,159
Karyotyping for isolated mild polyhydramnios controversial—only offer if increased a priori risk. Consider assessment of viral infection.	III/B	120,160
Patient Counseling		
Prognosis depends on severity and etiology. Best prognosis with mild, idiopathic.	—/GPP	—
All pregnancies with severe polyhydramnios have an increased risk for preterm delivery and perinatal mortality. Other risks depend on etiology.	III/B	107,108,147,154

Management Options	Evidence Quality and Recommendation	References
Treatment (to Relieve Maternal Symptoms; Prolong Gestation)		
If mildly asymptomatic, manage expectantly; no evidence to suggest diuretics and salt or fluid restriction are of value.	—/GPP	—
Specific treatment depends on underlying cause (see relevant chapters).	—/GPP	—
Consider amnioreduction (see text) for severe polyhydramnios or earlier if patient is symptomatic and prolongation of pregnancy indicated.	IV/C	106,189
Indomethacin may decrease AFI, but there may be significant fetal side effects.	IIb/B	165–171
Sulindac may be helpful; studies on its use with polyhydramnios are needed.	III/B	106
Alert pediatricians (e.g., need to assess upper gastrointestinal patency, risk of neonatal milk aspiration).	—/GPP	—

AFI, amniotic fluid index; GPP, good practice point; TTTS, twin-twin transfusion syndrome.

INTRODUCTION

It is now almost 80 years since neonatal hydrops, anemia, and jaundice were first recognized as a single disease characterized by perinatal hepatosplenomegaly, extramedullary hematopoiesis, and nucleated red blood cells (RBCs) on the peripheral smear.[1] What followed is a fetal success story. Levine and coworkers[2] identified a decade later that the rhesus (Rh) antibodies on the RBCs of affected but not unaffected neonates was cause of the anemia. The basic "story" was 60% completed 7 years later when Chown[3] proved transplacental fetal to maternal hemorrhage was a cause of maternal isoimmunization. In 1961, hemolytic anemia became the first treatable fetal disease after Liley[4,5] characterized its natural history and then successfully transfused affected fetuses intraperitoneally with adult RBCs. Freda and colleagues[6] completed the basic story when they demonstrated in 1964 that passive immunization of Rh-negative individuals with Rh-positive antibodies prior to purposeful exposure to Rh-positive RBCs prevented immunization.

Since then, we have learned progressively more about the intricacies of this complex disease, and incremental progress on the clinical side has rendered fetal hemolytic disease a rare cause of perinatal morbidity and mortality in the industrialized world. Rodeck and associates[7] achieved the first high survival rate for hydropic fetuses using fetoscopic intravascular transfusion in 1981. In 2000, Mari and coworkers[8] demonstrated that the majority of moderately to severely anemic fetuses were noninvasively identifiable by the measurement of the fetal middle cerebral artery peak velocity, essentially ending the need for amniocentesis and reducing that for fetal blood sampling. Lastly, the discovery of fetal free DNA in the maternal circulation by Holzgrieve and colleagues[9] in response to Lo and associates'[10] determination of fetal sex in a maternal blood led to the noninvasive genotyping of fetal Rh genes in many countries.

INCIDENCE

Though antibodies to D antigen remain most common, the development of immunoprophylaxis has diminished its relative importance and enhanced that of the other antigen groups (Table 13–1). Yet, anti-D antibody remains the prototype for maternal RBC alloimmunization and is used for illustration throughout this chapter.

The incidence of Rh-negative individuals varies by race, with a low of 1% in Chinese and Japanese to a high of 100% in the Basques, in whom the mutation likely originated.[11] In North American whites, the incidence of Rh-negative genotype is 15%, and in blacks, it is 7% to 8%. Thus, the incidence of alloimmunization varies greatly among populations. The overall incidence of alloimmunization has declined dramatically since the late 1990s owing in part to immunoprophylaxis and smaller families.[12]

PATHOPHYSIOLOGY AND RISKS

Maternal RBC alloimmunization results from exposure and response to a foreign RBC antigen. Transplacental fetal to maternal hemorrhage is the most common cause of alloimmunization. Heterologous blood transfusion is the second most common cause overall, but the most common cause of sensitization to uncommon antigens (see Table 13–1). Some 75% of women have fetal RBCs identified on a Kleihauer-stained peripheral smear during either pregnancy or delivery.[13] Both the frequency and the size of the bleed increase with advancing gestation: from 3% and 0.03 mL, respectively, in the first trimester up to 45% and 25 mL in the third trimester. Spontaneous abortion, too, is associated with fetal to maternal hemorrhage, but the incidence is less than 1% and the volume usually under 0.1 mL. In contrast, surgically induced abortion has a 20% to 25% risk of transplacental hemorrhage of a significantly greater volume.

The Rh system has long been known to be one of the most complex blood group systems; over 50 different Rh antigens have been identified.[14] The arrangement and configuration of the Rh locus result in gene conversion events that produce hybrid proteins, which represent additional Rh antigens. In most patients, three pairs of closely linked Rh antigens—Cc, Dd, and Ee—are inherited, one from each parent, as two sets of three alleles. An individual may be homozygous or heterozygous for each of the three alleles. The presence, absence, or silence of the D antigen site determines whether an individual is Rh-positive or Rh-negative. Genetic testing for Rh can now be used to detect a recessive D-negative allele or to determine the inheritance of Rh genes carrying mutations that encode altered Rh

proteins. The latter is especially relevant for sickle cell disease patients who, because of genetic disparity with white donors, are at high risk for becoming alloimmunized.

The Rh protein complex is critical to cell membrane structure. Rh-null erythrocytes, which lack Rh proteins, are stomatocytic and spherocytic, and affected individuals have hemolytic anemia.[15] Rh proteins appear to mediate key interactions with the underlying cytoskeleton through protein 4.2 and ankyrin.[16–18] Several functional studies and structural modeling reveal that the Rh blood group proteins are members of an ancient family of proteins involved in ammonia transport,[19–21] and nonerythroid Rh proteins have been found in brain, kidney, liver, and skin,[22–24] each sites of ammonia production and elimination.

Because certain combinations are more common than others, the D genotype can be predicted from the phenotype obtained using antibody specific sera for D, C, c, E, and e (Table 13–2). The d antigen has never been detected, and its existence is questionable. The genes for all other Rh alleles are sequenced, and the genotype can be determined directly using polymerase chain reaction (PCR) technology.

There are more than 16 recognized epitopes. The first (and most common) is the Du-positive variant in which the patient is actually Rh-positive, but D expression is weakened by the presence of a C allele on the complementary chromosome (e.g., Cde/cDe). These women are not at risk for D alloimmunization. The second type is sometimes termed Du-negative. Here, part of the D antigen is missing. These women are at risk for D alloimmunization and should receive immunoprophylaxis when otherwise indicated.[25]

The primary immune response to the D antigen occurs over 6 weeks to 12 months. It is usually weak, consisting predominantly of immunoglobulin M (IgM) that does not cross the placenta. As a result, the first pregnancy is not typically at great risk. Fifteen percent of Rh-negative volunteers will become sensitized after a 1-mL exposure of Rh-positive erythrocytes. The proportion increases to 30% after 40 mL and 65% after 250 mL. Three percent of women with uncomplicated pregnancies become sensitized at delivery after a small fetal to maternal hemorrhage (0.1 mL). A second antigen challenge generates an amnestic response that is both rapid and almost exclusively IgG. Bowman[26] observed that the longer the interval between challenges, the greater the increase in both the quantity of antibody and the avidity that it binds the RBC. These features increase the risk of severe fetal disease.

Fetal hematopoiesis consists of three overlapping phases corresponding to the major hematopoietic organ: mesoblastic, hepatic, and myeloid. Erythropoiesis begins in the fetal yolk sac by day 21, then moves to the liver, and finally reaches the bone marrow by 16 weeks' gestation.[27] The decreasing contribution of the liver is characterized by an exponential decrease in the number of circulating

erythroblasts. Whereas ABO antigens are weakly expressed on fetal erythrocytes, the Rh antigens are well developed by day 30 of gestation. Anti-D antibody-triggered hemolysis is not complement mediated. Rather, the anti-D–coated fetal RBCs are destroyed extravascularly by the reticuloendothelial system at an increased rate. The response of the affected fetus reflects the quantity and subclass of IgG antibody, the efficiency of placental passage, the avidity at which the antibody binds the antigen site, the maternal HLA makeup, and the maturity and efficiency of the reticuloendothelial system. For example, IgG1 and IgG3 appear to be the important subclasses for fetal hemolytic disease, and the maternal to fetal placental transport of IgG3 is significantly greater in pregnancies at risk for hemolytic disease.[28] Further, there is a strong correlation between human leukocyte antigen (HLA)-DQB1 allele *0201 and both an indirect Coombs titer greater than 512 and fetal anemia.[29]

Hemolytic anemia occurs when the erythrocyte life span declines below 70 to 90 days and the hematopoietic system can no longer meet demands. Anemia may develop slowly over several months in association with a gestationally low reticulocyte count and a gestationally normal bilirubin, or within a week in association with reticulocytosis and hyperbilirubinemia.[30,31] Significant fetal anemia is associated with increased erythropoietin, but in the absence of labor, the concentrations are lower than those observed in adults with the same hemoglobin deficit. Erythropoiesis may occur anywhere in the fetal-placental unit. Both the fetal liver and spleen are enlarged secondary to extramedullary hematopoiesis and congestion. Nucleated RBC precursors (erythroblasts) are released into the peripheral circulation, hence the term *erythroblastosis fetalis*. The greater the number of erythroblasts, the greater the likelihood an antenatal transfusion therapy will be necessary.

All direct fetal sequelae of hemolytic disease relate to the development of anemia. In general, the fetus tolerates mild to moderate anemia well. However, metabolic complications develop as the anemia worsens. Because the RBC is the principal fetal buffer, a metabolic acidemia with hyperlactatemia develops in fetuses with severe anemia.[32]

The precise mechanism leading to the development of hydrops is uncertain, but the elements are clear. First, the hemoglobin deficit for gestation must be extreme.[33] Because the normal hemoglobin concentration rises with advancing gestation, hydrops occurs at higher absolute hemoglobin levels during late compared with early pregnancy and is rare before 20 weeks. Second, though hepatomegaly could potentially hinder cardiac return or cause portal hypertension, it cannot be a major factor in light of the findings listed subsequently. Nor is hypoalbuminemia secondary to liver failure a contributor, as once thought based on postnatal studies,[34] because the albumin concentration is normal for gestation in all but premoribund, hydropic fetuses.[30,31] Finally, cardiac dysfunction, probably secondary to insufficient oxygen-carrying capacity, occurs in at least 90% of hydropic fetuses. This dysfunction is detectable immediately prior to the development of hydrops and resolves rapidly after transfusion with an increase in the fetal oxygen-carrying capacity. It is characterized by an increase in the biventricular cardiac diameter, systolic atrioventricular valve regurgitation, and an elevated umbilical pressure for gestation[35] (Fig. 13–1A). Consistent with ventricular

dysfunction, the umbilical venous pressure rises to a greater extent in the hydropic fetus after intravascular transfusion compared with the nonhydropic fetus.[36,37] Within 48 hours of the first RBC transfusion and well before the hydrops resolves, the umbilical venous pressure declines into the normal range. This reversal is too rapid for the occurrence of hydrops to be explained solely by hepatosplenomegaly. Thus, cardiac dysfunction is probably the immediate cause of immune hydrops.

Hyperbilirubinemia secondary to erythrocyte hemolysis is an important part of alloimmune hemolytic disease. Heme pigment is first converted into biliverdin by heme oxygenase and then to a water-insoluble, lipid-soluble bilirubin (the indirect fraction) by biliverdin reductase. Both the fetus and the neonate have reduced levels of glucuronyl transferase, the enzyme necessary for the production of the water-soluble diglucuronide. Indirect bilirubin unbound to albumin penetrates the lipid neuronal membrane, causing cell death. During normal pregnancy, both the fetal serum albumin and bilirubin concentrations rise linearly with advancing gestation (see Fig. 13–1*B* and *C*).[35,38] Most fetal bilirubin under normal and hemolytic conditions is indirect (unconjugated) bilirubin; there is no need routinely to fractionate it. The normal fetal total bilirubin is 5 to 10 times above normal adult levels, suggesting placental bilirubin transport is limited. Bilirubin rises progressively as the severity of hemolysis increases. The total bilirubin concentration in fetuses with hemolytic disease often exceeds 3 mg/dL before the development of anemia.[31]

The neonate with severe hyperbilirubinemia is at risk to develop an encephalopathy (kernicterus). The concentration of bilirubin necessary to cause kernicterus also rises with advancing gestational age. Thus, whereas a term neonate can tolerate a total bilirubin of 25 mg/dL, the extremely preterm neonate is at risk for kernicterus when the total bilirubin level exceeds 12 mg/dL. Affected neonates are initially lethargic and then become hypertonic, lying with their neck hyperextended, their back arched, and their knees, wrists, and elbows flexed. They suck poorly and ultimately develop apneic episodes. Fortunately, bilirubin toxicity is rarely observed with current monitoring protocols and treatment. Neural tissue in the auditory center is particularly sensitive to indirect bilirubin. Survivors often have profound neurosensory deafness and choreoathetoid spastic cerebral palsy. When severe signs of toxicity are present, the mortality rate approximates 90%

MANAGEMENT OPTIONS FOR THE DETECTION OF ALLOIMMUNIZATION

The identification and management of potential fetal hemolytic disease employs several methods for the detection of antibodies either in the maternal serum or bound to the fetal RBC. The tests used vary among countries and not all are covered.

Agglutination Tests

Saline

Rh-negative RBCs suspended in saline agglutinate when serum added to the slide contains IgM but not IgG. IgM does not cross the placenta.

Colloid

Rh-positive RBCs suspended in a colloid medium such as bovine albumin agglutinate if serum containing either IgM or IgG is added to the slide. Thus, if both saline and colloid tests are positive, the antibody may be either an IgM or an IgG. Pretreating the serum with dithiothreitol disrupts the sulfhydryl bonds of IgM and prevents its binding to the RBC. IgG is unaffected by dithiothreitol.

Antiglobulin or Coombs Tests

INDIRECT

RBCs of specific or mixed antigen type are incubated with the patient's serum. The addition of antihuman antiglobulin causes agglutination if the RBCs adsorb antibody from the patient's serum. The reciprocal of the highest dilution that causes agglutination is the titer. Indirect antiglobulin titers are one to three times more sensitive for the detection of RBC alloimmunization than colloid agglutination. In Europe and the United Kingdom, the amount of circulating anti-D is compared with an international standard and reported in International Units per milliliter with a threshold of 15 IU/mL recommended for invasive testing because only mild hemolytic disease of the fetus/newborn is usually noted with anti-D levels below this level.

DIRECT

Antihuman antiglobulin is added directly to the RBCs from the patient. Agglutination indicates antibody is bound to the RBC. It may be eluted off and identified by performing an indirect test using type-specific antigen type cells.

ENZYME PRETREATMENT

RBCs are incubated with either a proteinase (e.g., trypsin) or bromelin to reduce the negative electric potential between cells. Treated cells lie closer together in saline and more readily agglutinate by the IgG bound to them. These are the most sensitive manual methods for the detection of RBC alloimmunization. The technique can be automated, permitting detection of microgram quantities of antibody. Unfortunately, the automated techniques also produce false-positive tests, which limit their application.

Other Serum Tests

Two other tests have been suggested—the Marsh Score and the Monocyte Monolayer assay. Neither in comparative study performs significantly better than Coombs titers.[39,40] One study using monocyte-mediated chemiluminescence suggested it has advantages for antibody quantification,[41] but the technique has not been pursued further.

MANAGEMENT OPTIONS FOR THE Rh-NEGATIVE PATIENT IN PREGNANCY

All women, regardless of past medical and obstetric history, should have on record at least two blood type determinations that are in agreement. Typically, blood is drawn from nulliparous women for ABO and Rh blood type during the first prenatal visit and again after delivery. All pregnant women should have an RBC antibody screen (both indirect

and direct Coombs tests) performed at booking. This includes women previously typed as Rh-negative or found to have a negative antibody screen. Laboratory errors remain a significant contributing cause of anti-D prophylaxis failure. In addition, almost of the women who require a fetal transfusion have an RBC antibody directed against an antigen other than D.[30] Although there is controversy on how Rh-positive women can be cost-effectively managed after an initial negative screen, the most complete approach is to repeat the antibody screen at 32 weeks in search of newly developed non–anti-D antibodies.

Nonsensitized Rh-Negative Women

The indirect Coombs test is repeated monthly beginning at 18 to 20 weeks in at-risk Rh-negative women without evidence of sensitization. Many units screen for new alloimmunization far less frequently for financial and practical reasons. In some societies, it may be reasonable to test the father, and if he is Rh-negative, repeat the screen only once between 32 and 34 weeks' gestation. However, paternity is on occasion other than claimed or simply unknown. If the father is tested, the patient should be informed in private of the potential risk for management error should paternity be other than that stated. The decision how to approach paternity is best left to the physician's discretion.

Maternal-fetal ABO incompatibility reduces the risk of D alloimmunization.[14] If the father is heterozygous Rh-positive, there is a 50% chance the fetus will be Rh-negative. If the father is also ABO incompatible with the mother, there is a 60% chance that the fetus will be ABO incompatible. If the fetus is both R-positive and ABO incompatible with the mother ($0.5 \times 0.6 = 0.3\%$ probability), then the risk of maternal Rh alloimmunization is reduced from approximately 16% to 2%.

Successful passive immunization for Rh factor isoimmunization with anti-D immunoglobulin was first achieved in 1964. The U.S. Food and Drug Administration approved its use in 1968 after confirming efficacy in male prisoners. Anti-D immunoglobulin is extracted by cold alcohol fractionation from the sera of individuals with high titers. This extraction process removes viral pathogens such as HIV and hepatitis B, and an infectious risk from anti-D immunoglobulin has not been substantiated. Anti-D immunoglobulin binds D antigen sites on fetal erythrocytes present in the maternal circulation. Presumably, blockade of these sites prevents immune recognition by B lymphocytes, and the transformation of activated B lymphocytes to IgG-producing plasma cells never occurs. Anti-D immunoglobulin has a half-life of 24 days, and a standard 300-µg dose provides 12 weeks of protection against exposure to up to 30 mL of blood, or 15 mL of erythrocytes. Before the introduction of anti-D immunoglobulin, 10% of susceptible pregnancies developed hemolytic disease of the fetus and newborn. Approximately 90% of these were due to fetomaternal hemorrhage at term. Administration of anti-D immunoglobulin within 72 hours of delivery reduces this incidence by 90%. The administration of an additional dose at 28 weeks produces a further decline in incidence from 2% to 0.1%. Lower doses may be effective but have a higher failure rate. Although the 72-hour limit is based on the original study protocol evaluating the efficacy of anti-D immunoglobulin, beneficial effects may still be present with administration up to 28 days after delivery.

Current guidelines for management of Rh-negative women with uncomplicated pregnancy are focused on the prevention of isoimmunization from physiologic fetomaternal hemorrhage (Table 13–3). If a patient is Rh-negative and the antibody screen is negative on the first prenatal visit, the screen is repeated at 28 weeks and anti-D immunoglobulin administered if negative. Another antibody screen is repeated in labor. If the father is Rh-negative and there is no question on paternity, the prophylactic doses of anti-D immunoglobulin can be omitted.

Women with vaginal bleeding of unknown origin should receive anti-D immunoglobulin prophylaxis (see Table 13–3). Routine antenatal anti-D immunoglobulin therapy is

---

TABLE 13–3

Preventive Guidelines for Rh-Negative Women in Pregnancy

TIME	TEST	ANTI-D-IG DOSE
First prenatal visit	ABO and Rh blood typing, direct and indirect Coombs test	None
28–29 wk	Direct and indirect Coombs test for newly developed antibodies	300 µg*
32 wk	Direct and indirect Coombs test for newly developed antibodies	None
At birth	Neonatal cord blood for ABO and Rh type as well as direct Coombs test for red blood cell–bound antibodies	
Within 72 hr of delivery	Rosette test, Kleihauer-Betke estimate of fetoplacental hemorrhage	300 µg (individualize for Kleihauer-Betke result)
First-trimester spontaneous miscarriage		50–200 µg
First-trimester therapeutic abortion		300 µg
Following prenatal diagnosis by chorionic villous sampling of amniocentesis		300 µg
Other high risk situations—abdominal trauma, placental abruption, antepartum hemorrhage	Rosette test, Kleihauer-Betke estimate of fetoplacental hemorrhage	300 µg (individualize for Kleihauer-Betke result)

* Some protocols recommend the use of a lower dose of anti-D Ig at 28 wk followed by a further dose at 34 wk in nonimmunized Rh-negative women. Anti-D Ig, anti-D immunoglobulin.

cost-effective and should be administered to all nonsensitized Rh-negative women with an Rh-positive fetus or a fetus whose status is unknown at 28 weeks' gestation.[42,43] Anti-D immunoglobulin is also administered after amniocentesis if the fetal Rh genotype is unknown, because it carries a 2% risk of maternal sensitization even when performed under ultrasound guidance.[44] Umbilical cord blood is obtained at delivery from Rh-negative women to determine the neonatal ABO and Rh blood type and to seek RBC-bound antibodies. Anti-D immunoglobulin (300 mg) prevents maternal sensitization secondary to fetal-maternal hemorrhage when the volume is less than 30 mL of Rh-positive blood.[45,46] Maternal blood is screened by Kleihauer testing for evidence of a fetal-maternal hemorrhage in excess of 30 mL. This test exploits the relative resistance of fetal hemoglobin to acid denaturation. Acid citrate buffer is used to remove adult hemoglobin, leaving RBC ghosts. The maternal blood is examined on a counting chamber after fixation with 80% ethanol and hematoxylin-eosin staining. The amount of fetal blood in the maternal circulation can be approximated from the number of fetal RBCs per grid using this formula:

Fetal cells/Number of maternal cells = Estimated blood loss/ Estimated maternal blood volume in milliliters (85 mL/kg).

About 1 in 400 women suffer a larger bleed and require more anti-D immunoglobulin.[45] Cesarean section and manual removal of the placenta each increase the risk and magnitude of fetal-maternal hemorrhage. In situations in which the estimated bleed exceeds 30 mL, 150% to 200% of the estimated anti-D immunoglobulin requirement is given.

Postpartum, anti-D immunoglobulin may be withheld if the last administration was less than 21 days previously and passively acquired antibodies are still demonstrable on the antibody screen. The rosette test may also be performed in maternal blood to assess the need for further administration of anti-D immunoglobulin. Rosette formation indicates the presence of fetal RBCs, and dosage of anti-D immunoglobulin may have to be adjusted, guided by the Kleihauer-Betke test.

Sensitized Rh-Negative Women

Figures 13–2 and 13–3 illustrate two useful paradigms. Rh immune globulin has decreased the prevalence of RhD alloimmunization in pregnancy so that only approximately 6 cases occur in every 1000 live births. Its rarity means that most obstetricians are inexperienced and thus warrants consideration of consultation with, or referral to a maternal-fetal medicine specialist with experience in the monitoring and treating sensitized pregnancies.

Noninvasive Evaluation

Once an alloimmunized woman is identified, the medical professional caring for the mother must make some estimate of the risk of fetal disease. The prediction of fetal risk by combining the maternal obstetric history and serologic examination is an imprecise art. The magnitude of fetal and neonatal disease typically progresses from one pregnancy to another. The risk of hydrops in the undiagnosed and untested pregnancy approximates 10% in the first sensitized pregnancy.[26]

If maternal indirect Coombs antibody titers are performed in the same hospital using constant techniques, the results are typically reproducible and of clinical value in predicting the presence or absence of fetal disease. The practitioner must be familiar with the laboratory's threshold to avoid clinical error. When the maternal titer is below that threshold, it should be repeated at monthly intervals. In the absence of a relevant clinical history, the fetus may be followed noninvasively by the measurement of the peak middle cerebral artery velocities once that critical titer is exceeded. The utility of antibody titers above the threshold in predicting fetal risk is greatest during the first sensitized pregnancy. In subsequent pregnancies, titer and history are inadequate measures upon which to base management. Bowman and Pollack reported in 1965[47] that a lethal management error would occur in a third of severely sensitized fetuses if only maternal obstetric history and antibody titer were relied upon.

One of the most important advances in the management of fetal hemolytic anemia since the late 1990s is the development and application of molecular tools to determine the fetal genotype for most of the offending RBC antigens. It is possible using PCR to rapidly and accurately determine the fetal antigen status from either maternal blood, amniocytes, or a placental biopsy specimen.[48–54] It is time that Rh-negative women were routinely tested for the fetal genotype in the early second trimester using a peripheral blood sample. This practice would reduce the use of Rh immunoglobulin by over 40% with proportional decreases in serial laboratory samples and ultrasound examinations. At the very least, determination of the fetal Rh genotype should be standard after any second-trimester amniocentesis or chorionic villus sampling (CVS) in an at-risk woman.

Ultrasound evidence of fetal anemia determines the timing of invasive fetal testing. Brass and coworkers[55] were the first to observe in adults a relationship between the systolic flow velocity in the middle cerebral artery and hematocrit. Subsequently, several investigators demonstrated that the development of fetal anemia is associated with increased middle cerebral artery peak systolic velocities (Fig. 13–4).[56–58] Though at least half of anemic fetuses have normal peak velocities,[59] high peaks corrected for gestational age typically indicate moderate to severe anemia.

Other sonographic findings have been claimed to either precede the development of hydrops or predict fetal anemia, including amniotic fluid volume, liver and spleen length or thickness, placental thickness, increased bowel echogenicity, and the cardiac biventricular diameter.[32,60,61] Unfortunately, none of these sonographic markers is reliable. Further, the fetal hematocrit may change rapidly from one week to another. We have observed several fetuses with a normal hematocrit become hydropic over a 7-day period without a change in the maternal antibody titer. Each had a completely normal two-dimensional ultrasonographic examination 7 days before the detection of hydrops.

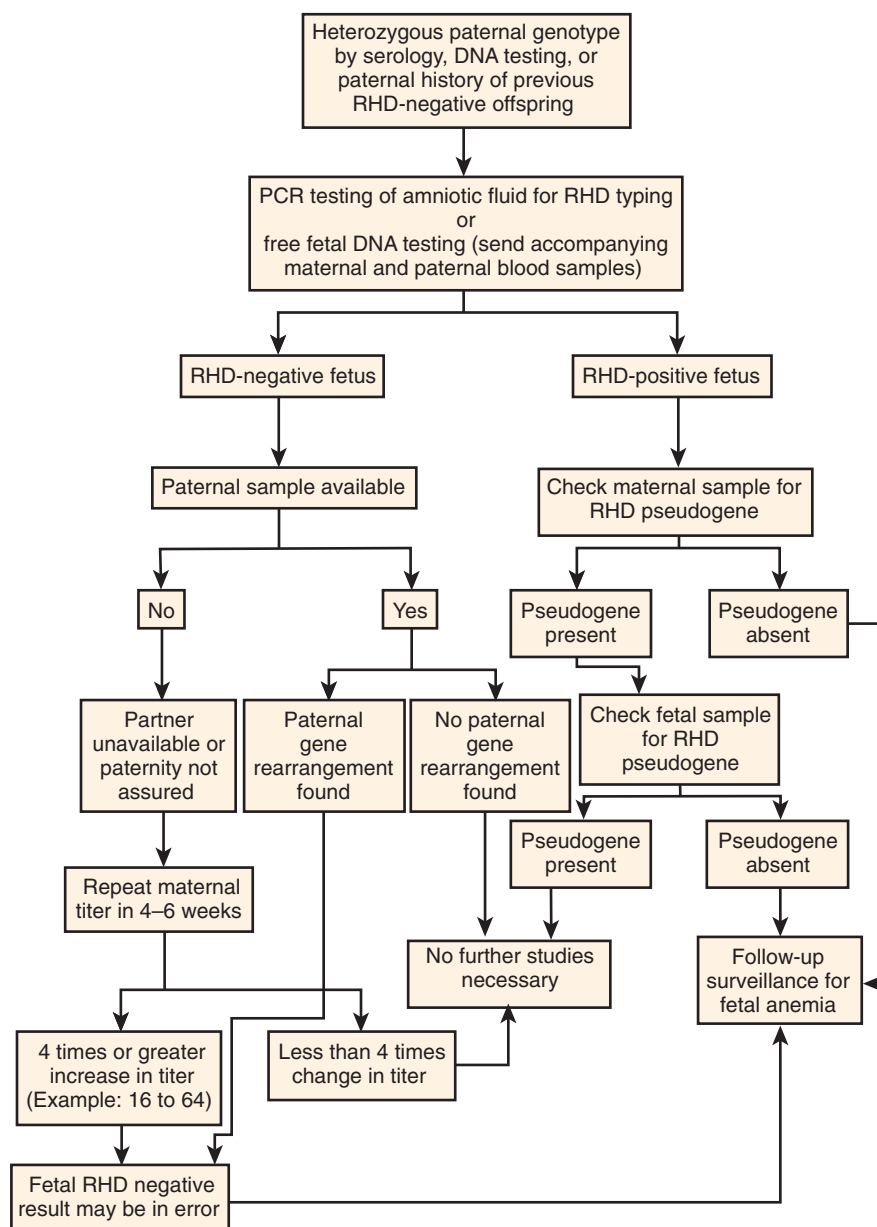
In summary, the measurement of middle cerebral artery peak velocities is an excellent noninvasive tool for the monitoring of fetal anemia. It is the standard of care for the pretherapeutic management of fetal hemolytic disease. Other than that, ultrasonography is an adjunct to, not a replacement for, invasive fetal studies.


FIGURE 13–2
Sample algorithm for determining the fetal RhD status in the case of a maternal rhesus D antibodies and a heterozygous paternal genotype. PCR, polymerase chain reaction; RHD, rhesus D. (Modified from Moise KJ: Management of rhesus alloimmunization in pregnancy. Obstet Gynecol 2008;112:164–176.)

Invasive Evaluation

Two invasive methods have historically been used to search for fetal anemia secondary to hemolytic disease:

- Indirect: spectrophotometry (the ΔOD450) using a specimen of amniotic fluid obtained by ultrasound-guided amniocentesis.
- Direct: fetal blood studies using a sample obtained by fetal blood sampling.

The argument over which technique to use ended with the development of peak middle cerebral artery flow velocity. If the patient is not already being followed in a center with expertise in the management and treatment of fetal hemolytic disease, she should be referred to one immediately upon discovery of an elevated peak middle cerebral artery flow velocity. There, a fetal blood sample should be obtained and, if fetal anemia is confirmed, treatment initiated. If the fetus is not anemic, the interval until the next sample is determined by the hematologic profile described subsequently. The following information on amniotic fluid spectrophotometry is provided for practitioners who practice in areas with no other options.

AMNIOTIC FLUID SPECTROPHOTOMETRY

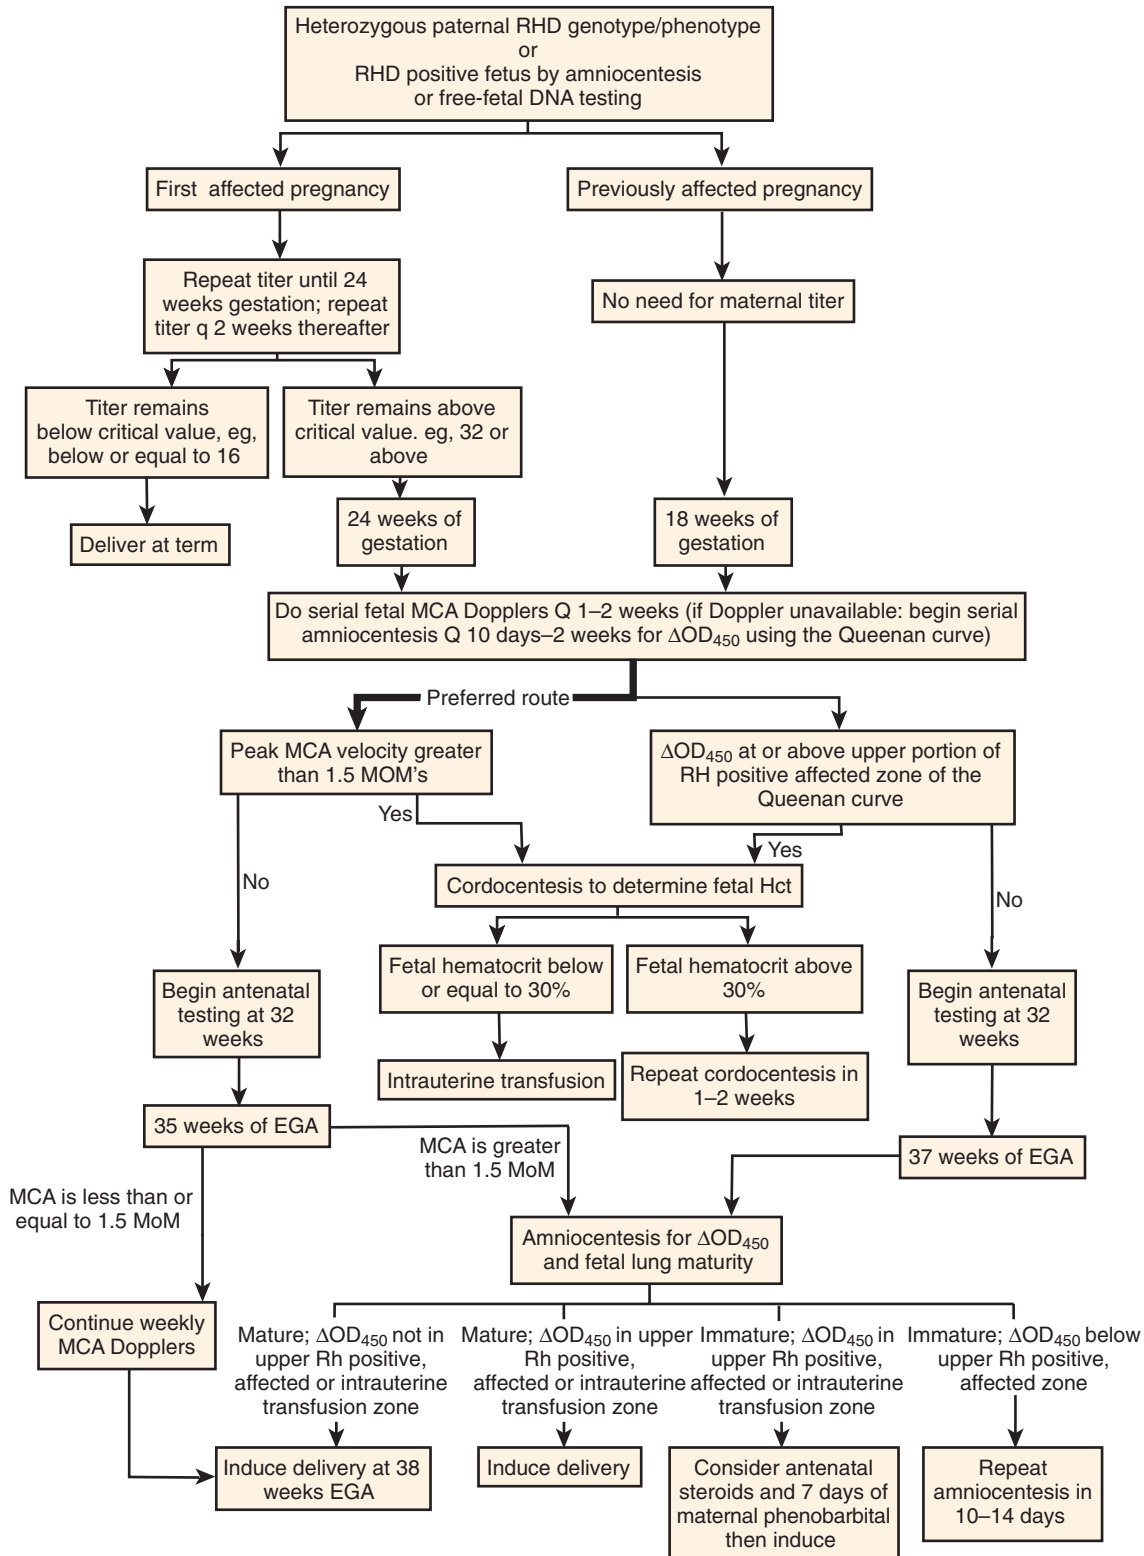
The fetus with hemolytic anemia frequently has an elevated serum bilirubin (Fig. 13–5).[31] By the middle of the second trimester, the amniotic fluid consists predominantly of fetal urine and tracheopulmonary effluent; thus, the amniotic fluid


FIGURE 13–3

FIGURE 13–4

Peak velocity of systolic blood flow in the middle cerebral artery in 111 fetuses at risk for anemia due to maternal red cell alloimmunization. *Open circles* indicate fetuses with either no anemia or mild anemia (≥0.65 MoM hemoglobin concentration). *Triangles* indicate fetuses with moderate or severe anemia (<0.65 MoM hemoglobin concentration). *Solid circles* indicate the fetuses with hydrops. The *Solid curve* indicates the median peak systolic velocity in the middle cerebral artery, and the *dotted curve* indicates 1.5 MoM.

(From Mari G, Deter RL, Carpenter RL, et al: Noninvasive diagnosis by Doppler ultrasonography of fetal anemia due to maternal red cell alloimmunization. Collaborative Group for Doppler Assessment of the Blood Velocity in Anemic Fetuses. N Engl J Med 2000;342:9–14.)
bilirubin is also elevated. Although William Liley[4] was not the first to use amniotic fluid spectrophotometry for the management of rhesus disease, he standardized an approach that has remained essentially unchanged since first reported in 1961. Although the ΔOD450 satisfactorily predicts the relative fetal hematocrit when used appropriately, it is best at predicting hydrops.

Amniotic fluid is obtained by ultrasound-guided amniocentesis (see Chapter 9), transported to the laboratory in a light-resistant container to prevent degradation of bilirubin, centrifuged, and filtered. If the fetal blood type is unknown, an aliquot of the sample should be subjected to PCR to confirm the fetal genotype is antigen positive.

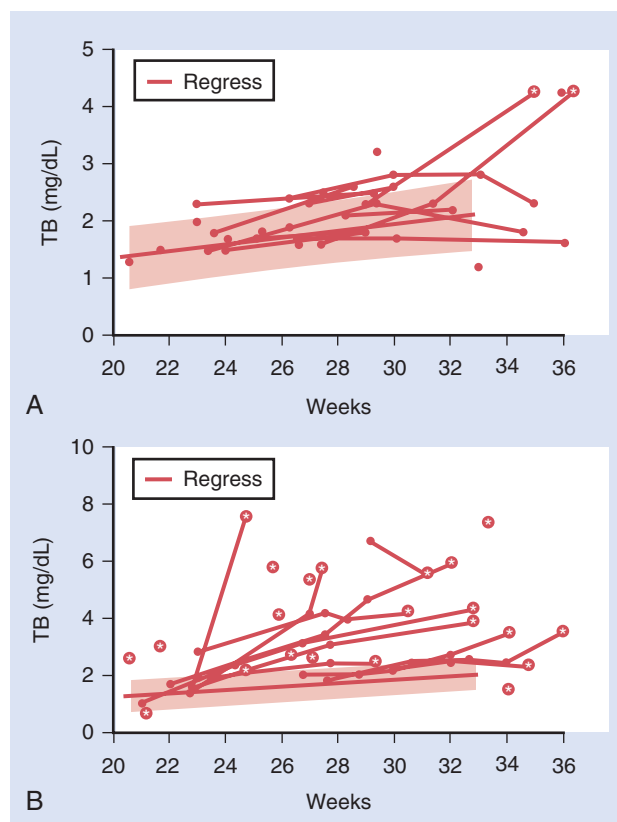
The optical density (OD) is measured between 700 and 350 nm and plotted on semilogarithmic graph paper with the wavelength on the x-axis. A line parallel to the y-axis is drawn through 450 nm, and the deviation from linearity of the absorption trace measured at that point. The result is plotted on semilogarithmic paper with gestational age on the x-axis and ΔOD450 on the y-axis (Fig. 13–6). Based on the study of 101 amniotic fluid specimens from sensitized pregnancies obtained between 28 and 35 weeks' gestation, Liley[4] observed that the ΔOD450 normally declined with advancing gestation (the opposite direction of the fetal serum bilirubin concentration) (Fig. 13–7). The graph is divided into three ascending zones. Zone 1 represents mild or no fetal disease. Zone 3 indicates severe disease with the possibility of hydrops developing within 7 days. Zone 2 is intermediate, with the disease severity increasing as zone 3 is approached. Amniocentesis is repeated at 1- to 2-week intervals, depending on the gestational age, the zone of the ΔOD450, and the change from the preceding sample. Management is dictated by the trend revealed by serial values. A fetal blood sample is performed when either the ΔOD450 is in zone 3 or serial amniotic fluid specimens reveal a progressive and rapid rise of the ΔOD450 into the upper 80% of zone 2.


FIGURE 13–5

(From Weiner CP, Williamson RA, Wenstrom KD, et al: Management of fetal hemolytic disease by cordocentesis: I. Prediction of fetal anemia. Am J Obstet Gynecol 1991;165:546–553.)

The determination of hemolytic disease severity by amniotic fluid spectrophotometry has several important disadvantages. First, its application requires serial invasive procedures over the space of several weeks. In a 20-year experience that included 1027 women, Bowman[26] performed a mean of 3.1 procedures per patient. Each procedure carries a risk of

FIGURE 13–6
Semilogarithmic plot of an amniotic fluid ΔOD450. * illustrates a spike in the absorption of light produced by contaminating blood.
(Courtesy of G. Snyder, University of Iowa.)

enhanced maternal sensitization as well as a loss from either amnionitis or premature rupture of the membranes. Though there are no large series reported of women undergoing amniocentesis after 22 weeks' gestation to document the frequency of such complications, some conclusions may be drawn from studies of second-trimester genetic amniocenteses. Amniocentesis performed under ultrasound guidance is clearly associated with sensitization, amnionitis, and rupture of membranes (~1 in 300–400). Simplicity does not mean safe.

Second, amniotic fluid spectrophotometry is an indirect test for fetal anemia. The natural history studies by Liley[4,5] revealed a wide range of disease severity for a given ΔOD450 at any gestational age between 28 and 34 weeks (see Fig. 13–7). Liley's postnatal observation is confirmed antenatally using fetal blood sampling. Though most obvious for zone 2, it is also true for zone 3 measurements. In a series of 11 fetuses with a ΔOD450 in zone 3 followed for several weeks, 30% had a clinically acceptable hematocrit at birth.[62] Gottval and Hilden[63] concluded that the maternal indirect Coombs titer was actually superior to the ΔOD450 for the prediction of fetal anemia, and yet the titers were useful only when less than 32 or more than 1000.

The third disadvantage of amniocentesis and the ΔOD450 is that the system was modeled on anti-D alloimmunization. This author and others have shown that Kell

	Hs g/100 mL

N	Unaffected

FIGURE 13–7
Relationship between the ΔOD450, hemoglobin, and gestational age. Note, for example, that of fetuses between 28 and 31 weeks and a ΔOD450 in low zone 2, 25% are unaffected, whereas 18% are either profoundly anemic or dead.
(From Liley AW: Liquor amnii analysis and management of pregnancy complicated by rhesus immunization. Am J Obstet Gynecol 1961;82:1359–1368.)

alloimmunization has salient pathophysiologic differences that account for the very poor performance of the ΔOD450 reported in the past.[64,65] Fetuses with Kell alloimmunization have lower serum bilirubin concentrations and lower reticulocyte levels for their degree of anemia compared with D-alloimmunized fetuses. Vaughan and colleagues[66,67] found that monoclonal IgG and IgM anti-Kell antibodies inhibit the growth of Kell-positive erythroid burst-forming units and colony-forming units in a dose-dependent fashion. This suggests that the fetal anemia secondary to Kell reflects erythroid suppression at the progenitor cell level.

The fourth disadvantage of amniocentesis is that the normal ΔOD450 in the second trimester is mid zone 2 of the Liley curve. Some have concluded that there is no clinically useful correlation between the ΔOD450 reading and the fetal hemoglobin before 28 weeks.[68] Yet, amniocentesis is often initiated weeks earlier.

The fifth disadvantage of the ΔOD450 measurement is that it is subject to a variety of extrinsic errors that can interfere with its laboratory measurement, for example, maternal hyperbilirubinemia and specimen contamination with blood or meconium.

In summary, the ΔOD450 is an outdated tool and should be performed only when there is no other option because it is inferior in accuracy and arguably more dangerous for mother and child.

FETAL BLOOD SAMPLING

The safety of fetal blood sampling is detailed in Chapter 9. The loss rate reflects the indication for the procedure, the presence of hypoxemia, the vessel actually punctured, and the technique used (needle guide vs. freehand).[69,70] It has been estimated that technique accounts for at least 30% of losses. Using a needle guide, the loss rate for alloimmunization is less than 0.3%, a rate similar to that of amniocentesis. Further, the size of the fetal-maternal bleed after fetal blood sampling when a needle guide is used and the placenta is not punctured is similar to that after amniocentesis.[71] It has been suggested that the magnitude of the bleed is much greater when the freehand technique is used.

The first fetal blood sample is taken when the peak middle cerebral artery velocity becomes elevated. Laboratory tests performed on the first and subsequent fetal blood samples are listed in Table 13–4. Either a strongly positive direct Coombs test or a manual reticulocyte count outside the 95% confidence interval (Fig. 13–8) is a high risk factor for the development of antenatal anemia if the fetus is not anemic when sampled.[72]

A sensitive and specific assessment of the risk for developing anemia in the 30% to 50% of nonanemic fetuses can be made using direct fetal hematologic and serologic tests (Fig. 13–9). A prospectively validated protocol for risk assessment and the timing of any repeat fetal blood sampling are shown in Table 13–5. There is a direct correlation between the reticulocyte count, the strength of the direct Coombs test, the risk of fetal anemia, and the trimester in which it occurs.[17] Untreated neonates remain at significant risk for postnatal complications (Table 13–6).[72]

Delivery of the nontransfused affected fetus is planned between 37 and 38 weeks' gestation in a medical center capable of caring for a neonate with potentially severe hyperbilirubinemia.

Treatment Options

SUPPRESSION OF MATERNAL ANTI-ERYTHROCYTE ANTIBODIES

Several methods are used in severely sensitized women to suppress or ameliorate either the maternal antibody concentration or its effect on the fetus. None are of proven efficacy.

Plasmapheresis

Although plasmapheresis reduces antibody concentration by as much as 80%,[73] the decline is transient. Plasmapheresis may delay the need for fetal transfusion by a few weeks. This costly procedure is indicated only when there is a history of hydrops prior to 20 to 22 weeks and the father is homozygous for the offending antigen. Plasmapheresis is begun at 12 weeks, removing 15 to 20 L/wk. It entails a risk of hepatitis and should not be undertaken lightly.

Immunoglobulin

The maternal intravenous infusion of immunoglobulin (400–500 mg/kg maternal weight every 4 wk) reportedly reduces

Likelihood of a fetus requiring transfusion based on its hematologic pattern.

the severity of fetal hemolytic disease.[74] There are no prospective randomized trials. Rarely indicated alone in light of the currently available therapies, intravenous immunoglobulin may be effective as an adjunct to plasmapheresis.[75] Another option is to administer the immunoglobulin directly to the infused fetus. Several abstracts suggest that such fetal therapy has the potential to reduce the frequency of transfusion therapy.[76–80] Yet, the usual interval between transfusions at those institutions was shorter than recommended here.

FETAL TRANSFUSION

Fetal transfusion therapy should not be undertaken in the absence of hydrops without first confirming that the fetus has significant anemia. The author has recommended a hematocrit below 30% because it is below the 2.5th percentile for all gestational ages older than 20 weeks.[72] These procedures should be performed only by individuals with considerable and regular experience whenever possible.

Intraperitoneal Injection

The original, but least preferred, method for fetal transfusion is the intraperitoneal injection of packed RBCs that are

TABLE 13–7
Protocol for Fetal Intraperitoneal Transfusion

Preparation

Confirm fetal hematocrit <30%
Prepare donor blood as fresh as possible and compatible with both
  mother and fetus
Buffy coat poor, washed in saline ×3, and irradiated
Final hematocrit 90% ideal
Prepare two sets of tubing with three-way valves for transfusion; filters
  are mandatory
Diazepam, 5–10 mg slow IV for maternal comfort
Lateral displacement of the uterus, support lower back
Acetone wipe to remove ultrasound contact gel from the skin
Povidone-iodine or alcohol surgical preparation of the skin
Drape as desired and prepare surgical tray
    20-g Tuohy needle 25 cm long
    20-mL syringe
    5-mL normal saline
Pancuronium, 0.3 mg/kg estimated fetal weight
Sterile prepare ultrasound transducer

Transfusion

Target fetal abdomen between umbilicus and bladder; avoid liver
Administer pancuronium intramuscularly targeting the fetal buttock
Insert Tuohy needle into selected site
Confirm intra-abdominal, extravascular location by injecting saline
Infuse donor blood in 1-mL aliquots over 10 min checking the fetal
  heart rate after each aliquot
Continue transfusion until planned volume infused calculated by
$$volume = (wk\ gestation - 20) \times 10\ mL$$

Follow-up

Continuous heart rate monitoring until fetal movement resumes
Document complete absorption of donor blood by serial
  ultrasonography
Examinations every 2–3 days
Second transfusion after complete absorption; thereafter, repeat at
  4-wk intervals

absorbed via the lymphatic vessels with fetal respiration for absorption. It is rarely indicated in modern fetal medicine, typically with severe disease prior to 18 weeks' gestation. The protocol used in our unit is shown in Table 13–7. Approximately 10% of the transfused cells are absorbed daily by the nonhydropic fetus; absorption is greatly decreased in hydrops. The volume infused is a compromise between the amount necessary to correct the estimated hemoglobin deficit and the amount that will safely fill the intra-abdominal cavity. The formula of Bowman is practical:

$$Volume = (weeks'\ gestation - 20) \times 10\ mL$$

Once absorption is complete, the residual hemoglobin concentration may be estimated by the following equation:

Residual hemoglobin concentration
$$= ((0.8x)/(125y)) \times ((120 - z\ days)/120\ days)$$

where x is the amount of donor blood in grams transfused, y is the estimated fetal weight, z is the interval in days since the last transfusion, and 120 is the estimated life (in days) of the transfused blood.

The second transfusion is performed after the first has been completely absorbed and subsequently at 3- to 4-week intervals. If the fetus is hydropic and survives the first intraperitoneal transfusion, the fetal abdomen is drained at the time of second transfusion to minimize pressure and maximize the volume of fresh cells infused. The last transfusion is performed no later than 32 weeks' gestation.

Intraperitoneal transfusion has many drawbacks. In addition to a slow correction of the hemoglobin deficit, there is a higher risk of trauma and the unique risk of obstructing cardiac return should intra-abdominal pressure rise too high. Intraperitoneal transfusion should be performed only when percutaneous access to the fetal vasculature is problematic (e.g., <18 wk). Nor is there any advantage to combining intravascular and intraperitoneal transfusions. The combined intraperitoneal/intravascular procedure does not reduce the actual number of required needle punctures. The highest reported survival rates with intraperitoneal transfusion are well below those for intravascular transfusion.[81–83] The risk of fetal death per transfusion was six times that of intravascular transfusion in a comparison of historical data from an experienced team in Winnipeg, Canada.[83]

In summary, intraperitoneal transfusion is rarely indicated in the modern practice of fetal medicine.

Intravascular Transfusion

In contrast to intraperitoneal transfusion, the goal of intravascular transfusion therapy is the delivery of a healthy, nonanemic neonate at term when it can better transition to ex utero life and withstand the associated hyperbilirubinemia. Transfusions are begun when the fetal hematocrit declines below 30%.[35] Though most fetuses tolerate a hematocrit of 25% or lower without clinically significant sequelae, this cutoff point has proved a pragmatic threshold for the following reasons:

- Hematocrit of 30% is below the 2.5th percentile after 20 weeks' gestation (Fig. 13–10).
- Women referred often travel great distances and cannot come either semiweekly or even weekly without great hardship.
- It is difficult to predict with certainty how fast the fetal hematocrit will decline.
- Treatment of anemia prevents the development of hydrops that would greatly increase the chance of an adverse outcome.

The protocol used in our unit for intravascular transfusion is shown in Table 13–8. Blood for the transfusion should be fresh when available, and compatible with both mother and fetus. Infectious agents routinely tested for include cytomegalovirus (CMV), hepatitis A through C, and HIV. Some blood banks use a lymphocyte filter in lieu of serologic testing for CMV. This procedure has the added benefit of reducing the risk of graft-versus-host disease without irradiating the blood. The blood is prepared on the day of transfusion, rendered leukocyte poor, and washed several times in saline to remove particles associated with viral transmission infection. It is then resuspended in saline to a hematocrit between 70% and 80%. Blood with a higher hematocrit mixes poorly; that with a lower hematocrit unnecessarily increases the volume required.

The patient is made comfortable with pillows under her knees to take pressure off the lower back. The uterus is

TABLE 13–8

Protocol for Fetal Intravascular Transfusion

Preparation

Confirm fetal hematocrit <30%
Preparation of donor blood as fresh as possible and compatible with both mother and fetus
Buffy coat poor, washed in saline ×3, irradiated
Final hematocrit 70%–80%
Preparation two sets of tubing for transfusion and measurement of UVP
Filters are mandatory
Diazepam, 5–10 mg slow IV for maternal comfort
Lateral displacement of the uterus, support lower back
Acetone wipe to remove ultrasound contact gel from the skin
Povidone-iodine or alcohol surgical preparation of the skin
Drape as desired and prepare surgical tray
    Eight 1-mL tuberculin syringes
    Flush three with heparin (100 U/mL); fill one with lidocaine (1%), and fill one with desired dose of pancuronium (0.3 mg/kg sonographically estimated fetal weight)
    Three 3-way valves
    One 5 inch (12 cm) 22-gauge needle
    Three 4 × 4 gauze sponges
Prepare transducer

Transfusion

Puncture vein at most accessible site
Immediately administer pancuronium—paralysis will be rapid
Aspirate 1 mL for complete blood count, Kleihauer stain, and reticulocyte count; check hematocrit immediately
Aspirate 1 mL for venous blood gases
Measure pressure and confirm puncture is of umbilical vein
Begin infusion of packed red blood cells after double-checking that there is no air in the system
Infuse half the estimated requirement (see Table 13-9)
Repeat blood sampling and pressure measurement
Halt transfusion if the rise in the UVP has exceeded 10 mm Hg; check heart rate to rule out bradycardia as an explanation
If UVP is acceptable, calculate remaining volume necessary to achieve a hematocrit of 50%; infuse that volume
Repeat blood sampling and pressure measurement; remove needle if UVP is at acceptable level
Monitor fetus until spontaneous movement resumes

UVP, umbilical venous pressure.

---

displaced laterally to avoid supine hypotension during the transfusion. Because the transfusion takes on average 25 to 30 minutes for completion, diazepam 5 to 10 mg intravenously is given to enhance maternal comfort and cooperation. The abdomen is surgically prepared and draped, and the operator's hands are gloved. Neither a surgical mask nor a cap is necessary. Nor is there evidence that prophylactic antibiotic administration is either effective or cost-efficient. The skin is the main source of bacterial contamination. The operator must never touch the shaft of the needle. A new needle is used if one must be removed after insertion into the skin. With this protocol, the incidence of amnionitis is less than 0.5%. The skin is infiltrated with 1% lidocaine in light of the duration of time the needle is in situ.

The easiest approach to the umbilical vein is selected and punctured with a 22-gauge needle. Forty percent of the author's transfusions are performed in a free loop of cord. The intrahepatic portion of the umbilical vein is preferred by some operators. A larger-gauge needle unnecessarily increases the risk of premature rupture of the membranes. Immediately following the free return of blood, the fetus is paralyzed with pancuronium (~0.3 mg/kg of the estimated fetal weight [EFW], range 0.2–0.6 mg/kg), regardless of the puncture location, because any fetal movement may lacerate the vessel or dislodge the needle. Should the latter occur during transfusion, a catastrophic Wharton jelly hematoma with concomitant decrease in umbilical blood flow can result. Pancuronium, as opposed to other agents used for neuromuscular blockade, has the advantage of increasing heart rate secondary to catecholamine release. There is no advantage to not paralyzing the fetus. Without pancuronium, intravascular transfusion decreases both the fetal heart rate and cardiac output, prolonging the time required for the fetus to clear the acid contained in the preserved banked donor blood. With pancuronium, the fetal heart rate remains at or above the pretransfusion rate. The injection of the pancuronium, followed by the measurement of the umbilical venous pressure, allows for the definitive identification of the vessel punctured. The needle is removed if the artery is inadvertently entered because the risk of fetal bradycardia is fivefold greater than that for the vein. Though furosemide is used (3 mg/kg EFW) by some, including the author, clinical and laboratory investigations have failed to show measurable benefit.[84]

The equipment for an intravascular transfusion is illustrated in Figure 13–11. The blood must be filtered immediately prior to transfusion to remove aggregates that could occlude the microvasculature. Careful attention is paid so as to purge the system of all air. Using a series of three-way valves, an assistant injects the donor blood while the operator is free to concentrate on the fetus and needle placement.

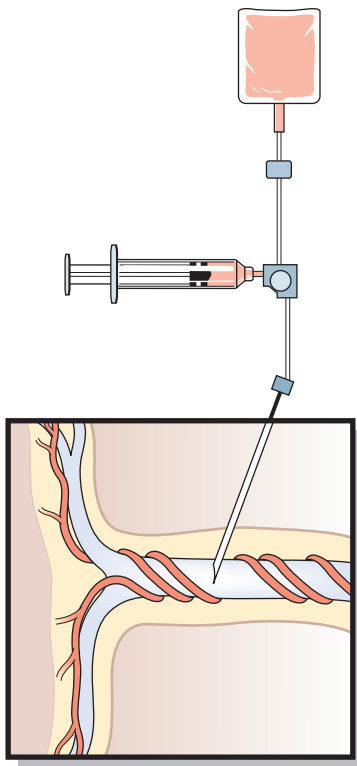
FIGURE 13–11
Setup for an intravascular transfusion.


TABLE 13–9

Approximate Volumes of 72% Hematocrit Blood Required for Intravascular Transfusion after the First Transfusion

GESTATION (WK)	VOLUME (ML)
≤22.5	25–40
22.5–27.49	45–65
27.5–32.49	75–90
≥32.5	100–120

The assistant must remain poised to halt the infusion if there is any abrupt change in flow resistance. To minimize the time the needle is in place, the blood is infused with haste (5–10 mL/min).

Except for the first transfusion of a hydropic fetus described later, the post-transfusion target for the fetal hematocrit is 48% to 55%. The volume required depends on gestational age and the initial hematocrit. Assuming similar opening and closing hematocrit measurements at each transfusion, the volume infused is dependent on the gestational age (Table 13–9).

HYDROPS

Because hydropic fetuses have myocardial dysfunction that prevents them from tolerating the required infusion volume,[37]

the target hematocrit after their first transfusion is only 25%. Twenty-four hours later, the hematocrit can be safely brought to 50% during a second transfusion. The decline in umbilical vein pH (UVpH) that normally occurs during transfusion is especially important to the severely anemic fetus. The RBC is the principal fetal buffer, and the pH of the citrated banked blood is 6.98 to 7.01. Our losses of hydropic fetuses after transfusion occurred even though the increase in their umbilical venous pressure during the procedure was acceptable and there was no acute bradycardia. All losses, however, were associated with a profound acidemia, and the deaths occurred hours after transfusion. It is suggested the acidemia aggravates myocardial failure. We now infuse bicarbonate in 1-mEq increments to maintain the UVpH above 7.30. There have been no further losses since that practice was initiated in 1988, and the overall survival rate for hydropic fetuses using this protocol now exceeds 95% in our center.

Several formulas have been proposed to calculate the volume of blood necessary to correct the hemoglobin deficit. Though reasonably accurate, none is reliable enough to remove the needle without first checking the hematocrit. Further, there is a possibility of overtransfusion when any formula is relied upon blindly. The author prefers to transfuse half the estimated total volume and then check the hematocrit. Based on the increase in hematocrit achieved following the first aliquot, the remaining volume necessary is rapidly and accurately calculated. Contrary to the adult or child, donor blood with a hematocrit below 80% equilibrates rapidly, perhaps because of the rapid fluid exchange across the placenta. On multiple occasions, the author has found that the hematocrit 24 hours after the transfusion to be within a few percentage points of the closing hematocrit. However, transfused blood with a hematocrit higher than 80% is more viscous and does not equilibrate as rapidly.

The decline in hematocrit after transfusion is more rapid and variable between the first and second transfusions compared with subsequent procedures. This variability results from the differing rates of destruction of disparate amounts of fetal antigen-positive and banked antigen-negative RBCs. Except for the hydropic fetus, the second transfusion is performed 2 weeks after the first. Subsequently, the decline in hematocrit per week is predictable for any given fetus (Fig. 13–12). The rate at which the hematocrit declines between transfusions with advancing gestation is such that by 34 to 35 weeks, delivery may be safely delayed 4 to 5 weeks until term without another transfusion. These findings have been confirmed.[85]

The fetus is monitored during transfusion. Many prefer to image the fetal heart at periodic intervals to rule out bradycardia; although important, it is of limited value. A second option is umbilical venous pressure measurement, which has several advantages. First, an occasional nonhydropic fetus (~5% in the author's experience) with a low hematocrit does not tolerate the transfusion volume necessary to correct the hemoglobin deficit. An increase in the umbilical venous pressure of more than 10 mm Hg is associated with an increased perinatal mortality rate. Either the transfusion should be halted or an appropriate volume of blood removed to reduce preload if the pressure rises more than 10 mm Hg.

$n = (22/28)$
$r = -0.34/-0.84$
$P = 0.11/<0.0001$

TABLE 13–10

Acute Nonhematologic Effects of Intravascular Transfusion

Cardiovascular
Increased intravascular volume
Decreased heart rate (without pancuronium)
Decreased cardiac output (without pancuronium)
Increased umbilical venous pressure
Increased renal blood flow
Decreased placental resistance measured by Doppler
Decreased aortic resistance measured by Doppler

Biochemical
Acidemia (blood preservative, inadequate fetal buffer capacity)
Increased oxygen-carrying capacity
Increased viscosity
Increased atrial natriuretic peptide
Increased prostacyclin
Increased prostaglandin E_2
Increased iron stores (chronic)

Second, fetal bradycardia increases the umbilical venous pressure. The third option is pulsed Doppler, which can also help differentiate the two causes of an elevated umbilical venous pressure by dropping a Doppler gate on the umbilical artery. Whichever technique is selected, it is important to keep the needle in place because any resuscitative efforts necessitated by a fetal bradycardia are facilitated by access to the fetal circulation.

Intravascular transfusion has many effects on the fetus (Table 13–10) other than raising the hematocrit.[86–88] Some, such as the increases in atrial natriuretic peptide and prostacyclin, help the fetus tolerate a volume load that postnatally would be lethal. Prostaglandin synthetase inhibitors are contraindicated for two reasons: (1) an increase in fetal prostacyclin and prostaglandin E_2 (PGE_2) is part of the normal adaptive response to the abrupt increase in intravascular volume[88] and (2) there is no evidence they are of any utility.

Adequate transfusion therapy rapidly suppresses fetal erythropoiesis. The fetal erythropoietin level declines and the average reticulocyte count is less than 1% by the third transfusion. It is advantageous to perform at least two transfusions 3 weeks apart prior to delivery because postnatal complications of hyperbilirubinemia are significantly less likely to occur after two or more antenatal transfusions.[36] In experienced hands, losses are uncommon and confined to the previable fetus. In the author's view, there is no justification for routine preterm delivery. The last transfusion can be performed at 34 to 35 weeks' gestation and labor induced at 37 to 38 weeks.

DELIVERY

The obstetric philosophy need not be altered for the non-anemic, transfused fetus. Antenatal transfusion is not a reason to deny a vaginal birth after cesarean section. If the final hematocrit at the end of the last transfusion was 50%, it will be in the mid-30s in the umbilical cord at delivery. Typically, the neonatal hematocrit increases approximately 15% within 8 hours of delivery, reflecting a massive shift of extracellular and intravascular fluid. The hematocrit then declines to or below the delivery level over the next few days to weeks.

POSTNATAL CARE

Postnatally, infants who received in utero transfusion therapy do remarkably well with an average hospitalization stay of less than 7 days (unpublished data). Because they are delivered at term, a higher peak neonatal bilirubin concentration is tolerated and is normally manageable with just phototherapy. Double-volume exchange transfusion is rarely needed when two or more antenatal transfusions are performed. Small, simple ("top-up") transfusions are frequently necessary, beginning at a few weeks of age, because fetal erythropoiesis has been suppressed by the regular transfusions (see later) and the banked blood transfused 5 weeks earlier is at the end of its life span. This anemia is typified by a low reticulocyte count. The neonatal hematocrit and reticulocyte count should be monitored weekly. If not, a severe anemia may escape detection with resulting high output cardiac failure and failure to thrive. The pediatric goal is to keep the neonate asymptomatic but with a modest anemia so as to drive erythropoiesis. Newborns may be 16 weeks old before reticulocytes reappear on the peripheral smear. Once a reticulocytosis is noted, further transfusion therapy is generally not needed. The need for neonatal transfusion can be decreased significantly by the administration of recombinant human erythropoietin.[89]

Effect of Anemia and Treatment on the Fetus

It is remarkable how well the fetus tolerates all but the most severe anemia. Fetuses who have a mild, chronic anemia are neither growth deficient nor acidemic. Though mild to moderate anemia is not associated with dramatic antenatal sequelae, severe anemia clearly is. As dramatic as hydrops fetalis may be, it is for the most part preventable and completely reversible. Hydropic fetuses not yet severely acidemic recover quickly with appropriate transfusion therapy and on long-term follow-up appear without specific sequelae.[90,91]

Transfusion therapy has a predictable and desirable effect on fetal erythropoiesis. With adequate RBC replacement, the reticulocyte count and percentage of circulating RBCs of fetal origin drops rapidly (Fig. 13–13). Part of this decline is due to consumption of newly formed fetal RBCs as they emerge from the fetal bone marrow and liver. However, after two transfusions correcting the hematocrit to 50%, smears of neonatal bone marrow reveal decreased erythrogenic precursors.[82] The greater the number of antenatal transfusions (i.e., the longer the period of fetal erythrocytic suppression) performed, the less severe the hyperbilirubinemia postnatally and the longer the suppression of erythropoiesis postnatally.[25] These findings coupled with the decrease in fetal plasma erythropoietin concentrations after several transfusions are indicative of marrow and liver suppression.

The long-term outcomes of the most severely affected fetuses have until recently been the subject of scant study. We conducted a case-control study of all 16 consecutive children born at the University of Iowa between July 1985 and August 1990 who as fetuses had intrauterine intravascular transfusion therapy for alloimmune hydrops fetalis.[87] Eight nonhydropic older siblings were control subjects. Hospital records were reviewed and parents completed behavioral questionnaires and were interviewed. Affected children and their sibling controls received comprehensive neuropsychological evaluations, hearing tests, and neurologic examinations. The hydrops children had cranial computed tomography (CT) scans for the measurement of brain and ventricular volumes. No significant differences were noted between the hydrops group and the sibling control group on neuropsychological measures (Table 13–11). Modest but statistically significant correlations were noted between the severity of anemia at the time of hydrops and composite standardized testing of nonverbal and computational skills at follow-up. The first child treated was electively delivered at 35 weeks. He suffered complications of kernicterus associated with a maximum bilirubin of 28 mg/dL. A second child who at 25 weeks' gestation experienced a prolonged fetal bradycardia (heart rate of 40 beats/min for 5 min) due to technical difficulties during an intra-arterial transfusion followed by delivery had cerebral palsy. The remaining 13 children had physical, neurologic, and neuropsychological findings within the normal range. Of the 16 CT scans, 14 were normal, and 2 revealed minor structural abnormalities. Mean total intracranial volume was 1477 mL. All intracranial volumes were within published normative values.

ABO INCOMPATIBILITY AND MINOR BLOOD GROUP ANTIGENS

ABO incompatibility rarely causes fetal disease because the antibodies are often IgM and because these antigens are not

Fetal Hemolytic Disease

Management Options	Evidence Quality and Recommendation	References
Prevention of Rh Hemolytic Disease in Nonimmunized Women		
Routine screening in Rh-negative women at booking and regularly through pregnancy	III/B	30
Antenatal prophylaxis at delivery	Ib/A	46
Antenatal prophylaxis at 28–34 wk and at delivery	IIb/B	42
Prophylaxis after potential sensitizing events	III/B	44
Prediction of Disease Severity in Immunized Women		
Refer to experienced center when critical antibody titer reached	—/GPP	—
Noninvasive determination of fetal RhD status	III/B	48–54
Measure maternal serum anti-D antibody concentration serially	III/B	40
Sonographic imaging to predict severity of disease—poor without evidence of frank hydrops	III/B	61
Middle cerebral Doppler is reliable for noninvasive screening for the presence of fetal anemia	III/B	57
Amniocentesis bilirubin/ΔOD450 from 27–41 wk—three zones helpful in managing patients (true level of anemia not known)	III/B	4
Liley curves of amniotic fluid bilirubin/ΔOD450 between 18 and 25 wk detected only 32% of fetuses with an Hb <6 g/dL (appropriate management and survival may not be directly correlated with Hb <6 g/dL)	III/B	68
Fetal blood sampling is to be performed whenever the peak middle cerebral artery velocity is elevated to confirm the presence of anemia	III/B	57
Treatment		
Fetal blood transfusion is treatment of choice; intravascular (see Table 13–8) is preferable to intraperitoneal (see Table 13–7)	IIa/B	83
Intravascular transfusion is associated with a >90% survival rate	III,IIa/B,B	36,83
Decline in donor red blood cells is ~2%/day	III/B	85
The efficacy of IVIG as a treatment for severe fetal hemolytic disease has not been established; the same is true for plasmapheresis; many reserve these for women with a history of early-onset hydrops (presenting before 22 wk)	IIb/B	74
Long-term neurodevelopmental outcome after intravascular transfusion is normal in most cases	III/B	92
Kell sensitization does not behave like Rh disease	IV/C	65
Kell sensitization is due to inhibition of erythroid progenitor cells by anti-Kell antibodies	III/B	67
Delivery Options		
In Nontransfused Fetus	—/GPP	—
At 37–38 wk		
In Transfused Fetus	—/GPP	—
Last intravascular transfusion at 34 wk (unless dangerous or difficult) and deliver at 37–38 wk		
32–34 wk (with prior maternal steroid therapy) for intraperitoneal transfusion		
Neonatal Care		
Pediatric surveillance from birth	—/GPP	—
Phototherapy		
Exchange transfusions if severe		
Top-up transfusions and long-term hematinic supplementation may be necessary		

GPP, good practice point; Hb, hemoglobin; IVIG, intravenous immunoglobulin; RhD, rhesus D.

strongly expressed on the fetal erythrocyte. Alloimmunization to minor blood group antigens is usually due to blood transfusion. Although Lewis antibodies are most common, they are almost always IgM and do not pose a risk for fetal disease. Further, the antigen is poorly expressed on the fetal erythrocyte. Therefore, the risk for hemolysis is low.

Kidd, Kell, and Duffy are the most common minor blood group antigens that cause perinatal hemolytic disease. Kell alloimmunization is of particular interest because the pathophysiology differs from the others. The clinical course is particularly unpredictable by indirect fetal assessment because the anti-Kell IgG antibodies damage or inhibit erythrocyte progenitors. Severe anemia and hydrops may develop rapidly with low antibody titers and ΔOD450 values. Management is similar to Rh isoimmunization with monitoring and intervention tailored to the individual circumstances.

OTHER CAUSES OF HEMOLYTIC DISEASE

Rare causes of fetal and neonatal hemolytic disease include hemoglobinopathies, RBC membrane defects, and RBC enzyme deficiencies. Because thallassemia can affect the α and β hemoglobin chains, it may result in disease in utero. Bart's hemoglobin (deletion of all four α chain genes) is the most severe form and causes hydrops fetalis. Hemoglobin H disease (deletion of three α chain genes) is less severe, but the affected patient requires lifelong transfusion treatment. In contrast, sickle cell disease (defective β chain) does not manifest in utero owing to the protective effect of fetal hemoglobin.

FUTURE PREGNANCIES, PREPREGNANCY CONSULTATION

Modern approaches to fetal hemolytic disease have drastically reduced the impact of this disease on the family. Though we may be cognizant that it may occur, we do not expect to lose a fetus to hemolytic disease. Several women under our care have, after presenting with a hydropic fetus in the first treated pregnancy, gone on to a second and a third treated pregnancy. Though not unreasonable to

suggest, there is no reason to badger these women toward either an undesired surgical sterilization or a pregnancy by artificial insemination with an Rh-negative donor to avoid a recurrence. It is, however, essential they understand the time demands required of them, along with the costs and risks involved. This information is best supplied prior to conception.

Fetal Thrombocytopenia

FRANK P. H. A. VANDENBUSSCHE, ANNEKE BRAND, and
HUMPHREY H. H. KANHAI

INTRODUCTION

Platelets are first seen in the embryonic circulation at 5 to 6 weeks' postconceptual age.[1] Normal fetal mean (standard deviation) values are 159 (34) $\times 10^9$/L in the first trimester,[2] 245 (65) $\times 10^9$/L in the second and third trimesters,[3] and 308 (69) $\times 10^9$/L at term birth.[4]

Fetal and neonatal thrombocytopenias are defined as a platelet count below 150 $\times 10^9$/L and can be further classified according to the severity:

- Mild thrombocytopenia (100–149 $\times 10^9$/L) does not require treatment.
- Moderate thrombocytopenia (50–99 $\times 10^9$/L) also does not require treatment, but both mild and moderate thrombocytopenias may trigger additional diagnostic tests.
- Severe thrombocytopenia (20–49 $\times 10^9$/L) requires diagnostic evaluation and treatment.
- Very severe thrombocytopenia (<20 $\times 10^9$/L) is associated with a high risk of spontaneous intracranial hemorrhage (ICH) and requires urgent diagnostic evaluation and treatment.

At birth, only 1% to 2% of term infants are thrombocytopenic, but the incidence of thrombocytopenia during the neonatal period then rises to 3% to 5%[5] and may even reach 35% to 72% in preterm infants undergoing intensive care.[5,6]

The focus of this chapter is the immune-mediated thrombocytopenias. Thrombocytopenia secondary to either platelet allo- or isoimmunization is found in 0.3% of newborns.[7] Fetal/neonatal alloimmune thrombocytopenia (FNAIT) is the most frequent cause of severe and very severe fetal thrombocytopenia, and it is amenable to prevention and treatment.

ALLOIMMUNE THROMBOCYTOPENIA

Incidence

Alloimmune thrombocytopenia results from maternal antibodies directed against an antigen on the fetal platelet membrane, localized on glycoprotein (GP) IIIa (CD61) of the GP IIb/IIIa complex. The preferred terminology for these alloantigens is at present human platelet antigen (HPA). The first discovered antigen system was named Zw (Zw^a and Zw^b) after the first two letters of the patient's family name.[8]

A few years later, the PL^A system, which appeared to be identical to Zw, was described.[9] The International Platelet Antigen Working Party suggests the name *human platelet antigen* (HPA).[10] The nomenclature is based on the chronologic numbering of alloantibodies in the order of their discovery. The letter "a" or "b" is assigned to the high- and low-frequency alleles, respectively. "W" marks an HPA system antigen of which only one allele is identified so far.

The incidence of a particular HPA varies by race.[11] In whites, 2% are negative for HPA-1a, which accounts for about 85% of FNAIT. Anti-HPA-1a antibodies are produced in approximately 11% of the HPA-1a–negative mothers.[12,13] The other antigens most commonly involved in FNAIT among whites are HPA-5b and HPA-3a.[11]

The development of anti-HPA-1a antibodies is strongly associated with the presence of the HLA class type II DRB3*0101. The absence of DRB3*0101 in an HPA-1a–negative woman virtually precludes the development of antibodies. About one third of HPA-1a–negative women who are DRB3*0101-positive develop antibodies.[12,14,15] The incidence of severe thrombocytopenia caused by anti HPA-1a antibodies approximates 1 in 1100 pregnancies.[12]

Risks

In contrast to red blood cell immunization, platelet alloimmunization affects the first pregnancy in half of the cases.[16] Most infants with FNAIT are born either without symptoms or with petechiae or bleeding from puncture sites. The most serious complication of FNAIT is internal hemorrhage, such as gastrointestinal, lung, and intracranial bleeding (ICH), occurring in either the fetus or the newborn. ICH is the most frequently occurring internal hemorrhage in FNAIT and causes serious perinatal morbidity and even death.[17] The risk of perinatal ICH as a result of HPA-1a–induced fetal thrombocytopenia approximates 11% excluding fetal deaths and 15% including fetal deaths.[18] Prospective studies with HPA-1a antibody screening programs document in aggregate an incidence of severe FNAIT of 0.04%, of intrauterine death of 0.002%, and of ICH of 0.006%.[19] Most cases of FNAIT are identified after the birth of an affected child. The degree of fetal thrombocytopenia reportedly remains similar or increases in 80% of subsequent pregnancies when the father is homozygous for the offending antigen.[20,21] HPA

antibody detection is possible using the monoclonal antibody-specific immobilization of platelet antigens assay (MAIPA) (both sensitivity and specificity >90%), but MAIPA is rather complex and time-consuming and should be used only by experienced laboratories. Simpler techniques based on the MAIPA have been developed, but unfortunately, some have lower sensitivity (70%–75%) and specificity (85%).[22] Several prospective studies have shown a correlation between anti-HPA-1a antibody level and severity of thrombocytopenia in the newborn.[12,13,23,24] A correlation was also found in two retrospective studies,[25,26] whereas one other retrospective study did not find such a relationship.[27] One study on antenatal HPA-1a antibody screening and intervention with cesarean section and neonatal platelet transfusion has been published.[19] Antenatal screening, however, is not routine practice, given the low prevalence of ICH in an unselected population, the low sensitivity of screening tests, and uncertainty about the most appropriate prophylactic interventions.

The risk for ICH in a subsequent pregnancy of HPA-1a–alloimmunized women depends on the obstetric history. In the large majority of FNAIT cases, the risk of an ICH in a subsequent pregnancy with an HPA-1a–positive fetus, after the birth of a thrombocytopenic sibling without ICH, approximates 7%.[18] In contrast, the recurrence rate of ICH in subsequent offspring of women with a history of FNAIT approximates 75%.[18] Most cases of ICH in utero occur in the third trimester, though ICH has also been documented before 20 weeks.[28] ICH in utero may cause either fetal death or, if the fetus survives, fetal hydrops or hydrocephalus.

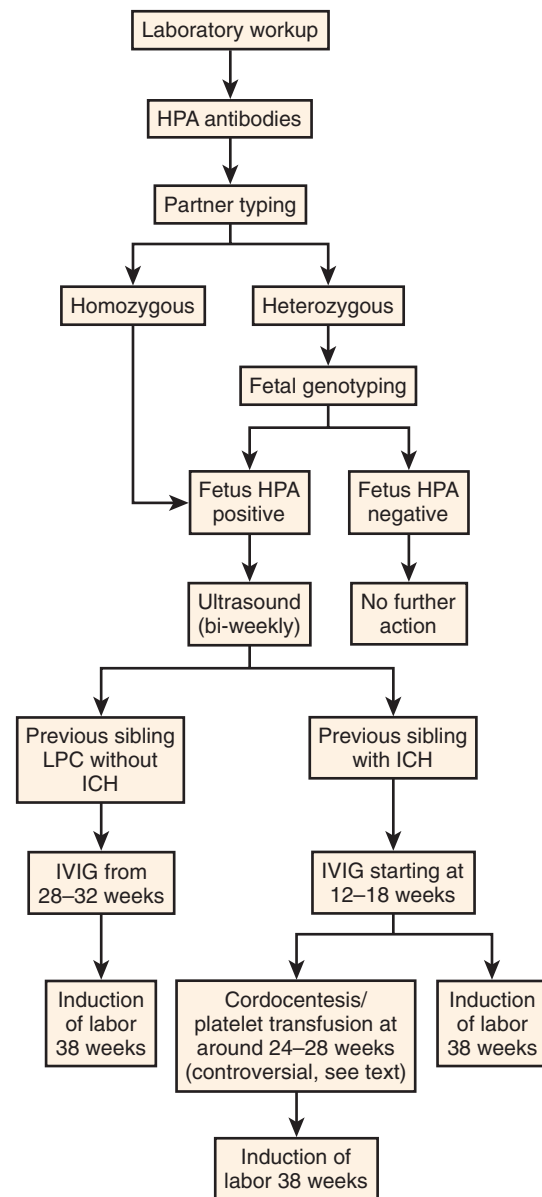
It is not known why one fetus with FNAIT may experience antenatal ICH whereas another fetus with a comparable degree of thrombocytopenia does not. In addition, fetuses and neonates with comparable degrees of thrombocytopenia caused by isoimmune thrombocytopenia (ITP) are not at risk for ICH or other life-threatening internal bleeding. The GP IIb/IIIa complex on the platelet membrane carries not only the HPA-1a or HPA-1b antigen but also most of the autoantigens involved with ITP antibodies. The IIb/IIIa complex is also expressed on vascular endothelium. Although no data are available, one may postulate that the density of antigenic molecules of HPA-1a and the autoantigens on IIb/IIIa may be different.

Management Options (Fig. 14–1)

Prepregnancy

Prepregnancy management begins with an accurate diagnosis of FNAIT in the previous pregnancy. Platelet alloimmunization should be part of the differential diagnosis in all cases of neonatal thrombocytopenia (platelet count < 100 × 10^9/L in term infants). The laboratory evaluation includes

- Confirming the presence of anti-HPA antibodies in maternal serum.
- Cross-matching of the maternal serum with paternal platelets, both untreated and chloroquine-treated (to remove HLA antigens that may cause a "false-positive" test).
- HPA pheno- or genotyping of mother and father.
- Exclusion of maternal thrombocytopenia.

FIGURE 14–1
Management of platelet immunization.


HPA: human platelet antigen; LPC: low platelet count; ICH: intracranial hemorrhage;
IVIG intravenous immunoglobulins to the mother (1g/kg/week; dose finding studies are underway, see for example www.noich.org)

When the diagnosis of FNAIT is established, and the couple is considering another pregnancy, prepregnancy counseling in a specialized center is advised. Counseling should include documentation of disease severity in the index case, the antibody specificity, and the hetero-/homozygosity of the father. In very severe instances, donor insemination or preimplantation diagnosis using a single cell of the blastomere can be considered.[29]

Prenatal

When the father is heterozygous for the offending antigen, fetal HPA-typing is advised. Genotyping for all important HPAs is possible using polymerase chain reaction (PCR). Fetal genotyping using cell-free fetal DNA in maternal plasma is now reliable from the early second trimester onward (de Haas M, personal communication). When the fetus is positive for the offending antigen, and thus at risk for severe thrombocytopenia, the pregnancy should be managed in collaboration with a specialized fetal medicine center.

Several strategies can be used for the monitoring and treatment of pregnancies at risk for FNAIT,[20,30–32] including fetal blood sampling (FBS) with platelet transfusion when indicated, and maternal treatment with intravenous immunoglobulin (IVIG) and corticosteroids. In one review of the literature, 26 different combinations of treatment were reported.[17] Unfortunately, there are no reports of controlled trials that compare intervention to nonintervention, and all recommendations are based on historical control subjects and natural history surveys. With these limitations, the current treatment of choice is a weekly maternal infusion of immunoglobulin at a dose of 1 g/kg of maternal weight. Several case series, published since the initial report of Bussel and associates in 1988,[33] confirm that weekly IVIG increases the fetal platelet count to a variable degree.[20,34,35] The result of a multicenter, prospective, randomized trial comparing IVIG with or without dexamethasone revealed a 70% response rate with IVIG alone.[36] Dexamethasone did not improve the effect when used routinely.[36] Significantly, in this study and in others, there were no instances of ICH in IVIG-treated perinates, even if they failed to respond with an increased platelet count.[35,37–39] Further trials are needed to determine the optimal dose of IVIG.[30] Recently, the NOICH study group (www.noich.org) conducted a multi-center study comparing the standard dose of 1 g/kg/wk with a lower dose of 0.5 g/kg/wk. This study was stopped after 2 years of recruitment because only 23 patients of the calculated sample size of 106 patients had been randomized. The outcome in this underpowered trial showed no difference between the standard and the lower doses. None of the neonates had an ICH.

Although FBS is the only tool available to directly monitor the severity of fetal thrombocytopenia, its routine use is not advised. FBS has caused fatal hemorrhage from the umbilical cord puncture site in fetuses with a low platelet count. Special precautions may lower the risk of complications in these patients (Table 14–1). The published literature reports a mean fetal loss rate of FBS in FNAIT pregnancies of 1.6% per procedure. In addition, there is a risk of procedure-related complications such as emergency cesarean section for fetal bleeding and bradycardia of 2.4% per procedure.[18,35,37,39] The reported complications might be method-related, because no increased risk was seen when a needle guide was used.[40] Platelet transfusion is problematic because the half-life of transfused platelets is only 4 to 5 days. Thus, FBS and platelet transfusions are required frequently throughout pregnancy once initiated, introducing a cumulative risk for complications. Transfused platelets may degranulate and release serotonin, compounding the risk of a bradycardia. The cumulative risk of fetal loss with transfusion therapy

---

TABLE 14–1

Extra Safety Precautions for Fetal Blood Sampling in Pregnancies at Risk for Severe Thrombocytopenia

The procedure should be performed by the most experienced members of a fetal medicine unit.

Sample in the umbilical vein and thus avoid puncturing the artery.

Use a hematologic cell counter in order to obtain the platelet count within 2 min.

If the fetal platelet count $<50 \times 10^9$/L, compatible platelets may be infused before withdrawal of the needle.

---

approximates 6% per pregnancy.[40,41] Given the 70% likelihood that the initial fetal platelet count between 20 and 28 weeks in FNAIT pregnancies with affected siblings is 50×10^9/L or less,[20] we suggest IVIG be started as a precaution after the fetal genotype results confirm an affected fetus.

The antenatal management protocols in FNAIT should be based on the following principles. First, the primary goal is the prevention of ICH and not just fetal thrombocytopenia per se. Second, the protocol should reflect the obstetric history. Given the fact that the large majority of patients have a sibling with a history of more or less severe thrombocytopenia, but without ICH, and that the risk of ICH approximates the procedure-related complication rate of invasive therapy, it is best to avoid FBS. Considering that the majority of in utero ICH occurs later in pregnancy and the cost of IVIG, treatment of pregnancies with no ICH history may be delayed to 28 to 32 weeks (see Fig. 14–1). We have seen no ICH or other serious morbidity applying this approach to 48 women in Leiden since the mid 2000s.[38] In fetuses whose siblings experienced an ICH, IVIG should be initiated at 12 to 18 weeks. FBS at 24 to 28 weeks to evaluate the response might be considered. When the anticipated risk of complication from FBS is higher (e.g., less experienced operators), the IVIG can be continued until delivery without periodic sampling (see Fig. 14–1). In recent years, we have treated seven pregnancies in five women with an older sibling with ICH, according to this less invasive protocol.[37] Each received 1 g IVIG/kg/wk (median 16 wk; range 16–29 wk) without initial or follow-up FBS. None of the neonates showed any signs of internal or external bleeding.

Labor and Delivery

Labor should be planned by the obstetrician in close consultation with the fetal medicine and pediatric teams and the blood bank to ensure that compatible platelets are available shortly after birth. A term delivery can be achieved in almost all pregnancies treated with IVIG. If serial fetal platelet transfusions are necessary, we suggest elective delivery after 32 weeks because of the risks of continued cordocentesis and platelet transfusions.

There is no consensus about the safety of vaginal birth in FNAIT infants. However, there is no evidence that a vaginal birth increases the risk of ICH in a treated term infant with FNAIT. The preponderance of perinatal ICH in FNAIT occurs before the start of labor.[17,18] More recently, we showed that in pregnancies with FNAIT and a thrombocytopenic sibling without ICH, vaginal delivery was not

associated with neonatal ICH.[42] Similar to ITP, we suggest that an instrumented vaginal delivery be avoided if the fetal platelet count is unknown. In Leiden, in women with FNAIT, whose prior child did not suffer ICH and who have received IVIG, we perform cesarean delivery for obstetric indications only. Lastly, cesarean delivery does not guarantee protection against ICH in a severely thrombocytopenic infant.

Postnatal

In platelet alloimmunized pregnancies, the newborn's platelets count should be tested daily for the first 5 to 7 days. Thrombocytopenia in the neonate may respond to IVIG.[43] In severe cases and in infants treated prenatally with at least four infusions of IVIG, transfusion with compatible platelets is the first-line treatment to obtain immediate correction of thrombocytopenia.[44] However, if immediate correction of the platelet count is warranted, and HPA-compatible platelets are not available, random platelet transfusions can give transient improvement without causing side effects.[45] Breast-feeding is not contraindicated in FNAIT newborns. In cases of severe fetal thrombocytopenia, brain imaging should be performed.

Summary

Severe platelet alloimmunization leading to perinatal ICH is a rare but potentially disastrous condition. Management strategies should focus on the prevention of ICH and not thrombocytopenia per se. There is a lack of adequately sized, well-designed studies regarding management.[30] The index pregnancy is the most important factor for risk estimation of ICH. The majority of ICH cases occur during fetal life. Maternally administered IVIG is the first-line therapy in pregnancies at risk of severe disease and appears to reduce the risk of ICH even when the fetal platelet count has shown no response.

SUMMARY OF MANAGEMENT OPTIONS
Alloimmune Thrombocytopenia

Management Options (see Fig. 14–1)	Evidence Quality and Recommendation	References
Prepregnancy		
Review history of index case, including severity.	—/GPP	—
Investigate:	—/GPP	—
• Confirm HPA antibodies in mother.		
• HPA genotyping of both parents.		
• Exclude maternal thrombocytopenia.		
• Cross-match maternal serum with paternal platelets.		
Provide counseling of parents about risks (principally ICH) and potential management.	—/GPP	—
Sister(s) should be typed to establish whether they are at risk during pregnancy.	—/GPP	—
Prenatal		
Management should be in a specialist center.	—/GPP	—
With a heterozygous father, perform fetal genotyping early in second trimester, preferably from ffDNA in maternal plasma.	—/GPP	—
No further action if the fetus is HPA-negative.	—/GPP	—
Maternal anti-HPA antibody titer has limited value in the prediction of severity.	III/B	12,13,22–27
Treatment regimen varies and is controversial:	IV/C	17,31,38
• Maternal IVIG weekly (0.5–2 g/kg) is the main approach; timing may be determined by severity in previous baby.	III/B	20,34,35,38
• FBS for fetal platelet count might be reserved only for those with previous ICH; advisable to defer sampling until after IVIG started.	III/B	39
• Oral corticosteroids do not improve platelet response to IVIG alone.	Ib/A	30
• Reserve corticosteroids for IVIG-resistant cases.	III/B	33
• Limit repeated FBS and intravascular transfusions of fresh platelets to cases that fail to respond to maternal therapy.	III/B	20,34,35
Regular ultrasound of the fetal brain.	—/GPP	—

Management Options (see Fig. 14–1)	Evidence Quality and Recommendation	References
Labor and Delivery		
Close liaison with pediatric staff.	—/GPP	—
Fetal platelet transfusion just before delivery may be considered even if a cesarean section is contemplated; there is no evidence that abdominal delivery reduces risk of ICH.	III/B	38
Postnatal		
Monitor neonatal platelet count daily for the first 7 days; platelet transfusion and IVIG for 4 wk if platelets $<50 \times 10^9$/L.	—/GPP	—
In cases with a low platelet count managed with IVIG during fetal life, consider platelet transfusion only.	—/GPP	—
Breastfeeding is not contraindicated.	—/GPP	—

FBS, fetal blood sampling; ffDNA, cell-free fetal DNA; GPP, good practice point; HPA, human platelet antigen; ICH, intracranial hemorrhage; IVIG, intravenous immunoglobulin.

ISOIMMUNE THROMBOCYTOPENIC PURPURA

Incidence

Adult ITP has an annual incidence of 6 per 100,000 population and most often affects young women.[46] Consequently, a past or present history of ITP complicates 1 to 5 per 10,000 pregnancies.[47] Typically, the woman has a history of ITP and presents with or without thrombocytopenia in pregnancy. However, a first presentation of ITP in pregnancy is not rare. The general issues relating to ITP are covered in Chapter 40.

Risks

Maternal

Platelet counts in pregnant women with ITP tend to decrease, reaching their nadir during the third trimester.[48] Unless the counts are very low, the patient either is asymptomatic or experiences easy bruising. However, some patients do bleed despite platelet counts above 20×10^9/L ("wet" thrombocytopenia). In these instances, it is assumed that the autoantibodies interact with functional receptors on the platelet surface.[49] Women who do not respond to treatment are at risk of bleeding during pregnancy and delivery. The lowest maternal platelet count during the prior pregnancy is fairly predictive of the extent of thrombocytopenia in successive pregnancies. One third of pregnant ITP patients need treatment to increase the platelet count. Moderate to severe bleeding occurs in only about 5% of the cases.[50]

Fetus and Newborn

The perinatal mortality rate is around 0.6% with virtually all losses secondary to related medical illnesses, rather than fetal thrombocytopenia.[51] Severe in utero bleeding is not documented in ITP. The risk of severe neonatal thrombocytopenia needing treatment ranges from 9% to 15%.[51–53] In large series, neonatal ICH is reported in 0% to 1.5%.[50,54,55] The nadir neonatal platelet count with inherent major risk for hemorrhage occurs 1 to 4 days after birth.[48,56]

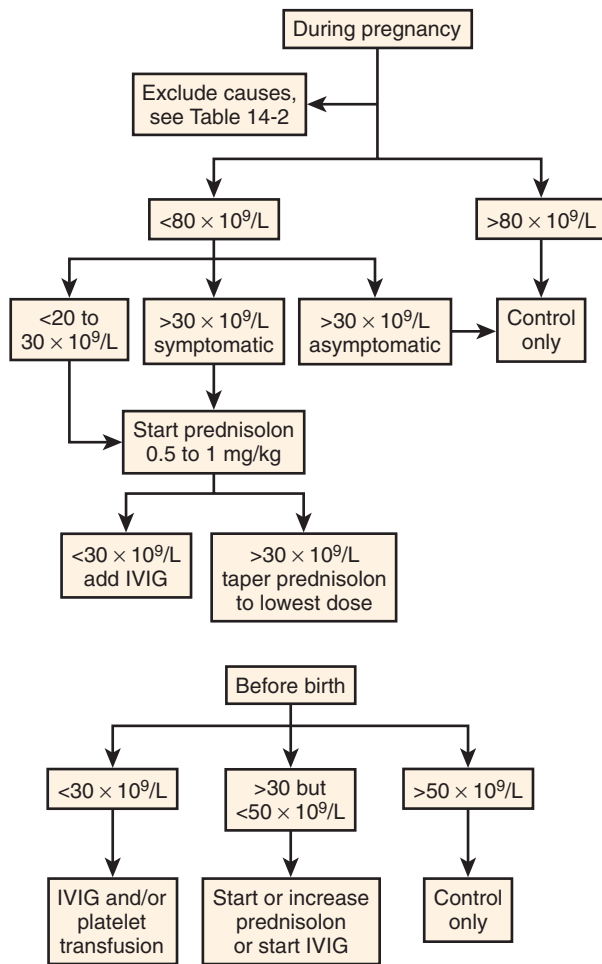
Because the majority of cases with ITP during pregnancy have a benign course, several investigators have sought to predict the risk of fetal thrombocytopenia. Such information could be of practical importance because it would dictate the center selected for delivery. In most studies, however, there was only a weak correlation between newborn platelet counts and maternal platelet counts or the presence of antibodies in the maternal serum.[46,51,55,57] Several studies have reported a better correlation between the newborn platelet count and a maternal history of splenectomy.[53,58] Perhaps the strongest predictive factor for neonatal thrombocytopenia is an older sibling with a platelet count below 50×10^9/L.[59] A report that HLA (DRB3*) type in the mother is protective against neonatal thrombocytopenia requires confirmation.[60] Even though each of these factors in isolation is a weak predictor, we think that the combination of a prior sibling with severe thrombocytopenia, together with a mother with a history of splenectomy and severe maternal thrombocytopenia during the current pregnancy, indicates a high probability of severe neonatal thrombocytopenia and indicates the need for delivery in a tertiary hospital.[61]

Management Options (Fig. 14–2)

None of the published guidelines for the management of ITP in pregnancy and during the neonatal period are based on a high level of evidence, and most are based on cohort studies.[46,55,63,64]

Prepregnancy

ITP is not a reason to advise against pregnancy, except perhaps for those women refractory to corticosteroids and splenectomy and who cannot maintain a platelet count above 30×10^9/L despite immunosuppressive drugs.[55,63] The risk of fetal morbidity and mortality are never a reason to advise against pregnancy, given the virtual absence of severe fetal bleeding and low risk of severe neonatal bleeding complications.[56] A history of a thrombocytopenic older sibling, together with maternal thrombocytopenia and need of maternal treatment to increase the platelet count, may be indications for pregnancy care in a hospital with multidisciplinary experience with these patients.[59,60]

FIGURE 14–2
Management of maternal thrombocytopenia (<100 × 10⁹/L) in pregnancy and before birth.


IVIG: intravenous immunoglobulin, suggested dose is 1g per kg body weight weekly

TABLE 14–2

Laboratory Investigations in a Pregnant Woman with Thrombocytopenia

TEST	AIM
Blood film	Exclude spurious thrombocytopenia, HELLP, TTP, other hematologic diseases
Liver function	
Proteinuria	
Coagulation tests–aPTT, lupus anticoagulant	Exclude rare causes of thrombocytopenia
SLE serology	Consider when indicated
HIV	
Thyroid function tests	
Heparin-dependent antibodies	Exclude HIT

aPTT, activated partial thromboplastin time; HELLP, hemolysis, elevated liver enzymes, liver function disturbances, low platelet count; HIT, heparin-induced thrombocytopenia; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura.

PRENATAL MANAGEMENT IN THROMBOCYTOPENIC WOMEN WITHOUT A HISTORY OF ISOIMMUNE THROMBOCYTIC PURPURA

The most common cause of a maternal platelet count of 100 to 150 × 10⁹/L, occurring in 6% to 7% of pregnancies, are incidental thrombocytopenia of pregnancy or gestational thrombocytopenia (GT). GT accounts for more than 70% of cases of maternal thrombocytopenia and has no detrimental effect on mother and child. Hypertensive disorders and some very rare causes, such as HIV, von Willebrand's disease type IIB, and underlying systemic diseases such as systemic lupus erythematosus (SLE), antiphospholipid syndrome, thyroid dysfunction, and hematologic diseases must be excluded (Table 14–2). No further analysis is indicated to distinguish GT from ITP once these conditions are excluded. Bone marrow aspiration is reserved for suspected hematologic malignancy. Thrombocytopenia below 100 × 10⁹/L occurs in 1% to 2% of pregnant women.[48] Even then, guidelines do not recommend testing for maternal platelet-associated immunoglobulin G (IgG) antibodies because the rates of false-positive and false-negative results are high.[46,53,57,63] However, the platelet count should be monitored every 2 weeks and, if it falls below 50 × 10⁹/L, the patient should be managed based on the assumption she has ITP, although rare cases of severe GT, refractory to corticosteroids and IVIG, have been described.[64]

WOMEN WITH A HISTORY OF ISOIMMUNE THROMBOCYTIC PURPURA

Treatment indications for ITP during pregnancy are similar to those for ITP in nonpregnant individuals. Platelet count should be monitored at an interval dependent on the initial platelet count and every 2 weeks if it is below 50 × 10⁹/L. The need for prenatal therapy is based exclusively on maternal indications, with the goal of maintaining the count above 20 × 10⁹/L (or higher in case of bleeding symptoms).[46,55] First-line therapy is the lowest effective dose of corticosteroids (see Fig. 14–2). In case of corticosteroid refractoriness or side effects, IVIG is the second-line treatment. The effect of IVIG lasts only 2 to 3 weeks and sometimes decreases with repetitive dosing. Therefore, IVIG is best reserved for use late in pregnancy or immediately prior to delivery. Immunosuppressive drugs (such as azathioprine, rituximab, or vincristine) are best avoided in the first trimester. Splenectomy is rarely needed during pregnancy. There has been no demonstrable effect of maternal treatment such as corticosteroids or IVIG on the fetal platelet count.[65,66]

The association of ITP with other autoimmune diseases is well known. In SLE, patients may present with immune thrombocytopenia and have clinical features and therapeutic responses similar to those with ITP. However, thrombocytopenia in SLE associated with antiphospholipid antibodies (aPLs) may overlap with syndromes associated with small vessel occlusions such as thrombotic thrombocytopenic purpura (TTP), HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome, and even catastrophic antiphospholipid syndrome.[67,68]

Labor and Delivery

A history of splenectomy, current maternal thrombocytopenia, or treatment for ITP or thrombocytopenia in a sibling at birth dictates delivery at a center with expertise in maternal-fetal medicine. A maternal platelet count above 50×10^9/L is generally considered safe for either vaginal or cesarean delivery, though the factual basis for this recommendation is weak. The majority of members of a consensus panel considered a platelet count higher than 30×10^9/L, without bleeding symptoms, safe for vaginal delivery.[55] A low platelet count may even be an argument against cesarean delivery. Should the count be below 50×10^9/L, IVIG, platelet transfusions, or both may be given to raise the count by the time of delivery. American and Dutch guidelines consider 50×10^9/L as a safe level for epidural anesthesia.[46,69]

There is convincing evidence that the route of delivery does not alter the risk of severe fetal or neonatal internal hemorrhage,[46,51,55,63] and cesarean delivery is undertaken for standard obstetric indications. However, it is prudent to avoid manipulations such as fetal scalp blood sampling, vacuum extraction, or rotational or mid-forceps delivery.[46,55,69] Several investigators have suggested either FBS or scalp blood sampling to estimate the fetal platelet count. However, this practice cannot be condoned because altering the route of delivery based on the fetal platelet count does not change the outcome. Further, scalp blood samples do not provide reproducible platelet counts,[53] and the fetal risks of FBS exceed the risk of fetal hemorrhage from ITP.[70]

Routine thrombosis prophylaxis in cases of surgical delivery, immobilization, or individual risk factors should be undertaken unless there is either bleeding or severe thrombocytopenia ($<50 \times 10^9$/L). When the platelet count is between 50 and 100×10^9/L, the risks of thrombosis and bleeding should be carefully weighed against each other.[46] One third of ITP patients have antiphospholipid syndrome and these patients have a higher risk of thrombosis.[71]

Postnatal

Maternal platelet counts often improve over the first 6 weeks. Tranexamic acid (1 g given three times daily) may reduce excessive vaginal bleeding. Breastfeeding is not contraindicated.[55,65] The newborn's platelet count, even if normal at birth, should be tested for at least the first 5 days, because one third develop a delayed thrombocytopenia.[51] Neonates with counts below 50×10^9/L may bleed and the risk for ICH is 0% to 1.5%.[50,51,54] It is estimated that 15% of neonates require treatment.[72] IVIG and corticosteroids are both recommended as first-line treatment and are combined with platelet transfusion if counts are below 20×10^9/L or if there is bleeding.[46,51,63,73] Ultrasound brain imaging is recommended in these cases.

Summary

The management of ITP during pregnancy is based on several large and well-designed clinical cohort studies demonstrating that ITP runs a benign course in pregnancy for both mother and child. Severe fetal bleeding and in utero ICH remain unreported. If confronted with such a case, other bleeding disorders and alloimmune antibodies must be sought before assuming the explanation is ITP.

SUMMARY OF MANAGEMENT OPTIONS **Isoimmune Thrombocytopenia**		
Management Options	**Evidence Quality and Recommendation**	**References**
Prepregnancy		
Risk of neonatal thrombocytopenia is increased if there was a previously affected pregnancy.	III/B	59,61
Avoidance of pregnancy may be an issue in women refractory to splenectomy, steroids, and immunosuppression.	III/B	62
Prenatal		
Laboratory investigations:		
• Exclude other causes (see Table 14–2).	II/B	48,51
• Monitor maternal platelet count every 2 wk during pregnancy in cases with a history of ITP or platelet count $<50 \times 10^9$/L.	IV/C	46,55
Maternal treatment:		
• Threshold count varies between 30 and 50×10^9/L.	III/B	46,63
• Corticosteroids are first-line therapy; taper to lowest dose.	IV/C	46,55
• IVIG is best reserved for administration between 36 and 37 weeks (predelivery).	IV/C	46,55
• Consider splenectomy with severe ITP in early pregnancy with no response to steroids or IVIG; immunosuppressives (vincristine and azathioprine) are options for refractory disease in late pregnancy.	—/GPP	—

SUMMARY OF MANAGEMENT OPTIONS
Isoimmune Thrombocytopenia—cont'd

Management Options	Evidence Quality and Recommendation	References
Labor and Delivery		
Plan delivery in a center with appropriate multidisciplinary expertise.	—/GPP	—
Aim for platelet count >50 × 10⁹/L before delivery.	III/B	46,63,66
Maternal platelet transfusion is needed to cover delivery if platelet count <50 × 10⁹/L.	—/GPP	—
Epidural anesthesia is considered safe if platelet count >50 × 10⁹/L.	III/B	69
FBS at 38–39 weeks and fetal scalp blood sampling in labor are not justified.	III/B	46,48,55,63
Cesarean section is performed for obstetric indications; no evidence shows that the risk of fetal/neonatal hemorrhage is lessened by elective cesarean section.	III/B	46,48,53,55,63
Minimize (some advocate avoidance of) fetal scalp sampling and assisted vaginal delivery, especially by vacuum extraction.	III/B	46,55,63
Episiotomy should be avoided if possible with low maternal platelet counts.	—/GPP	—
Postnatal		
Monitor neonatal platelet counts for 5 days:	III/B	46,51,63
• IVIG if <50 × 10⁹/L.	IV/C	73
• Platelet transfusion if <20 × 10⁹/L or if clinically indicated.	—/GPP	—
Breastfeeding is not contraindicated.	III/B	55,65

FBS, fetal blood sampling; GPP, good practice point; ITP, isoimmune thrombocytopenic purpura; IVIG, intravenous immunoglobulin.

OTHER CAUSES OF FETAL THROMBOCYTOPENIA

Fetal Infections

Petechiae at birth were reported in 14 % of neonates born after maternal cytomegalovirus (CMV) infection in the first trimester of pregnancy.[74] Neonates with symptomatic CMV infection have petechiae in 75% of cases,[75] and ICH has been reported with fetal CMV infection.[3,76] Other fetal infections have also been associated with thrombocytopenia: toxoplasmosis, rubella, syphilis, HIV and Epstein-Barr virus.[3,77,78] Maternal infection with parvovirus B19 may be followed in 5% to 10% of cases by inhibition of fetal erythropoiesis, severe anemia, and hydrops. Fetal thrombocytopenia in parvovirus infection is most probably caused by bone marrow suppression.[78] In a series of 30 severe cases of parvovirus infection, treated with fetal erythrocyte transfusions because of hydrops, de Haan and coworkers[79] found severe thrombocytopenia in 46%. Although in their series no fetal ICH or procedure-related bleeding occurred, Segata and colleagues[78] reported two procedure-related fetal deaths in a series of 11 fetuses in which the FBS was performed at the placental insertion or in a free loop.

Aneuploidy

Fetal triploidy is the aneuploidy most frequently associated with severe thrombocytopenia.[80] There is also an association between fetal trisomies and thrombocytopenia; 6% of newborns with Down syndrome are diagnosed with severe thrombocytopenia,[81] and more than half of newborns with trisomy 18 and 13 present with thrombocytopenia, but this is rarely severe.[82]

Genetic Syndromes

Severe thrombocytopenia is a hallmark of fetuses or newborns with a variety of rare autosomal recessive or X-linked genetic syndromes:

- Thrombocytopenia with absent radius (TAR) syndrome associated with skeletal and nonskeletal abnormalities. The pathogenesis of thrombocytopenia is unknown, but it is thought that there is a decreased response to thrombopoietin.[83] Platelet counts generally improve over the first year of life and may later approach normal adult levels.
- Congenital amegakaryocytic thrombocytopenia (CAMT) often presents with bleeding symptoms within the first week after birth with no other abnormalities but

thrombocytopenia. It is caused by mutations in the c-Mpl gene, leading to an absent or defective thrombopoietin receptor, a severe reduction or absence of megakaryocytes in bone marrow, and up to 10-fold increased serum levels of thrombopoietin. Patients with CAMT finally develop bone marrow failure.[83]

- Bernard-Soulier syndrome (BSS) is due to quantitative or qualitative abnormalities in the GP Ib/IX complex, a platelet von Willebrand factor adhesion receptor. Severe thrombocytopenia in homozygous newborns has been reported.[84] During pregnancy, females with BBS lacking GP Ib/IX, can produce antibodies to the GP Ib/IX complex on fetal platelets. The offspring may consequently develop severe thrombocytopenia and fetal ICH similar to FNAIT.[85]
- Gray platelet syndrome is associated with lifelong bleeding disorders and may present with fetal or neonatal thrombocytopenia.[86]
- Neonatal hemochromatosis is characterized by hepatocellular failure and is often associated with severe thrombocytopenia. It has been considered as a gestational alloimmune disorder that may be responsive to maternal high-dose IVIG.[87]
- Wiskott-Aldrich syndrome (WAS) has an X-linked inheritance and is due to abnormalities in platelet and lymphocyte cytoskeleton and signaling. It presents with severe thrombocytopenia, very small platelets, and associated features of eczema and recurrent infections.[88]

Thrombocytopenia may also be found in fetuses or newborns with other genetic syndromes:

- Amegakaryocytic thrombocytopenia with radioulnar synostosis (ATRUS) has been associated with mutations in HoxA11 and with high levels of thrombopoietin.[83]
- Paris-Trousseau thrombocytopenia is an autosomal dominant macrothrombocytopenia with deletion of the q23-24 region on chromosome 11, a region also deleted in Jacobsen's syndrome.[89]
- Kasabach-Merritt sequence, also called hemangioma-thrombopenia syndrome, may present with severe fetal thrombocytopenia.[90]
- X-linked thrombocytopenia (XLT), like WAS, is associated with an abnormality in the WAS protein, but these abnormalities give rise to a milder phenotype.
- MYH9-related thrombocytopenia syndromes include May-Hegglin anomaly, Fechtner's syndrome, Sebastian's syndrome, and Epstein's syndrome. These are autosomal dominant mutations, leading to a defective cytoskeletal contractile protein in hematopoietic cells. In general, affected individuals do not have life-threatening bleeding events.[91]
- Niemann-Pick is a lysosomal storage disease that is often associated with in utero thrombocytopenia.
- Osteopetrosis is a heterogeneous disorder characterized by osteoclast failure that may present with severe anemia, thrombocytopenia, infections, progressive deafness, and blindness.
- Hemophagocytic lymphohistiocytosis, an immune dysregulation of the monocyte-macrophage lineage, typically represents with pancytopenia.
- Bone marrow involvement is the cause of thrombocytopenia in metastatic neuroblastoma, glycogen storage diseases, organic acidemias, and aminoacidemias.

Severe Rhesus D Hemolytic Disease

In a large cohort of symptomatic rhesus D alloimmunized pregnancies, severe thrombocytopenia was found in 3% of cases prior to the first fetal red cell transfusion.[92] There was an association between the presence of severe hydrops and severe thrombocytopenia. Perinatal mortality in the severely thrombocytopenic group was 36%, compared with only 5% in the nonthrombocytopenic group. Furthermore, 2 of 14 survivors in the thrombocytopenic group had an ICH in the neonatal period. In contrast, fetuses with severe anemia due to Kell immunization are generally not at risk of severe thrombocytopenia.[93] Severe thrombocytopenia probably carries an increased risk of bleeding from the puncture site in the umbilical cord.[94]

Drug Exposure

Drug-induced thrombocytopenia has been described after administration of antibiotics, antiepileptics, and antidepressants, but case reports mostly concern adults. Theoretically, these effects could also occur in fetuses and neonates.

Management Options

Both in rhesus D disease and in fetal infections, a low platelet count seems to be a marker for poor outcome rather than a cause of bleeding, and evidence is lacking that platelet transfusion prevents hemorrhagic complications in fetuses with severe thrombocytopenia. Bleeding after cordocentesis, despite immediate platelet transfusion, has been reported in red cell and platelet alloimmunization.[94,95] Moreover, a platelet transfusion may be associated with complications, such as volume overload, cardiac arrest, or thromboembolic events, supposedly because of release of vasoactive substances.

Summary

Most instances of spontaneous fetal ICH due to severe thrombocytopenia are caused by FNAIT or CMV infection. However, a fetal medicine specialist may be confronted, unexpectedly, with a low platelet count while performing an intrauterine transfusion or a diagnostic FBS. The risk of procedure-related complications may then be increased. It is unclear whether platelet transfusions are beneficial in these circumstances.

Fetal Cardiac Arrhythmias: Diagnosis and Therapy

MERT O. BAHTIYAR, BEVIN WEEKS, and JOSHUA A. COPEL

Videos corresponding to this chapter are available online at www.expertconsult.com.

INTRODUCTION

Clinical Significance

Fetal cardiac arrhythmias are common in clinical practice and may be associated with significant morbidity and mortality. Most reflect transient, isolated ectopic beats with less than 2% of fetal rhythm disturbances resulting in a sustained and clinically significant arrhythmia. However, sustained episodes can occur and, if not treated appropriately, lead to congestive heart failure, nonimmune hydrops, and even fetal or neonatal demise. In this chapter, we define fetal arrhythmias and review their frequency, the methods of detection, and their basic mechanisms, as well as their management. We illustrate the importance of a team approach to fetal arrhythmia management, involving physicians from each subspecialty needed to care for mother, fetus, and newborn.

History

Cremer[1] first described fetal electrocardiography in 1906. Fetal electrocardiography proved reliable for identifying tachycardias but was limited in its ability to determine the etiology. In the 1950s, Smyth[2] described invasive electrocardiographic monitoring with an intra-amniotic electrode. Despite this technologic advance, its use remained limited because it required ruptured membranes for access.

Fetal rhythm assessment became practical with the advent of echocardiography, specifically M-mode. Robinson and Shaw-Dunn[3] detailed the use of M-mode in the evaluation of fetal arrhythmias during the early 1970s. As ultrasound technology expanded to include two-dimensional and both spectral and color Doppler modes, numerous authors described additional echocardiographic techniques for the identification and differentiation of fetal arrhythmias. More recently, fetal magenetocardiography has been shown to be able to detect fetal arrhythmias.[4]

Definition

A *fetal dysrhythmia* is best defined as an irregularity in the fetal cardiac rhythm or a regular rhythm that remains outside the normal range. The currently accepted normal range in clinical practice is between 110 and 160 beats/min, although

somewhat higher rates may be seen during labor, especially with maternal fever or dehydration. The American College of Obstetrics and Gynecology (ACOG)[5] and 2008 National Institute of Child Health and Human Development Workshop Report on Electronic Fetal Monitoring[6] established the normal range of fetal heart rate between 110 and 160 beats/min. This range does not exclude hypoxic fetuses. Davignon and coworkers[7] found the heart rate for infants younger than 1 day of age was between 88 and 168 beats/min with mean of 123 beats/min. Any of these ranges may serve as a guide, and the identification of heart rate may be based on data collected for an extended period to ensure that any deviations are not associated with uterine contractions, decelerations, maternal fever, or physiologic fetal activity such as hiccupping.

Frequency

Fetal arrhythmias are relatively common at routine obstetric visits, with a frequency ranging from 1% to 3% of all pregnancies.[8,9] In our experience, they account for approximately 10% to 20% of referrals for fetal echocardiography.[10] Few of these referrals to fetal cardiologists are for dysrhythmias determined to be of clinical significance.[11] In newborns, the most common causes of irregularities are either extrasystoles or respiratory sinus arrhythmia, the variation in the heart rate related to respiration, increasing with inspiration and decreasing with expiration, which is a normal finding and requires no further evaluation. Extrasystoles occur in upward of 14% of term, healthy newborns[12] and account for 43% to 98% of fetal arrhythmia referrals.[13,14] The vast majority of the extrasystoles are atrial in origin, with premature ventricular contractions accounting for less than 4%.[13-15]

The fetal arrhythmias diagnosed in 1384 patients evaluated at our institution over 20 years are listed in Table 15–1. The experience reflects the general findings of others: that extrasystoles are the most common cause of fetal arrhythmias and that tachycardias are more than twice as common as bradycardias.[9,14] The most common causes of fetal tachycardias are atrioventricular (AV) reentry supraventricular tachycardia (SVT), atrial flutter, and sinus tachycardia. Rare causes of SVT include chaotic atrial or atrial ectopic tachycardia, atrial fibrillation, junctional tachycardia, and ventricular tachycardia, each constituting less than 1% of fetal

TABLE 15–1

Incidence of Fetal Cardiac Arrhythmias—Department of Maternal-Fetal Medicine, Yale University School of Medicine

ARRHYTHMIA	NUMBER
Isolated extrasystoles	1213
Tachycardias	114
Supraventricular tachycardia	69
Atrial flutter	21
Sinus tachycardia	7
Ventricular tachycardia	7
Atrial fibrillation	4
Atrial ectopic tachycardia	4
Junctional tachycardia	2
Bradycardias	51
Complete AV block	39
Second-degree AV block	10
Sinus bradycardia	2

AV, atrioventricular.

arrhythmias.[13,14,16] The most common cause of fetal bradycardia is complete atrioventricular block (CAVB), which accounts for more than three quarters of cases. Other, less frequent causes of bradycardia include isolated sinus bradycardia, advanced second-degree AV block, prolonged QT interval syndrome, and fetal toxicity.[17,18]

ASSESSMENT OF A FETAL ARRHYTHMIA

A variety of methods are available for the evaluation of fetal cardiac arrhythmias. The majority of techniques are noninvasive, though invasive techniques, such as scalp electrodes, are used occasionally. We focus on commonly used noninvasive techniques, their advantages and disadvantages, and the future of fetal arrhythmia detection and differentiation.

When a fetal dysrhythmia is detected, the first step is to determine the etiology of the abnormal rhythm. Multiple factors must be considered, because fetal dysrhythmias can result from maternal connective tissue disorders, drugs, hyperthyroidism, or infection or can be a sign of fetal compromise or an intrinsic fetal rhythm disturbance. A complete maternal assessment should be made, including inquiries regarding recent illnesses, medicinal and recreational drug use, caffeine intake, and signs of hyperthyroidism. A complete family history is essential with an emphasis on the presence of inherited causes of arrhythmia, such as prolonged QT interval syndrome, congenital deafness (associated with prolonged QT interval syndrome), previous fetal demise, sudden unexplained death in family members younger than 50 years of age, and tuberous sclerosis. In addition, the fetus must be thoroughly evaluated for signs of hydrops, compromise, or structural cardiac disease.

Auscultation

The simplest method to detect a dysrhythmia is by auscultation with a stethoscope. The technique is a quick, easy, and readily reproducible tool. It was also the most common method of fetal heart rate assessment prior to electronic fetal monitoring (EFM).[19] Since the advent of EFM in the 1960s, the use of fetoscopic auscultation has dwindled. If a brady- or tachyarrhythmia is detected during auscultation, further investigation into the cause of the dysrhythmia is indicated.

Doppler

Doppler ultrasound is the most commonly used screening tool for fetal dysrhythmia. A beam of sound is directed toward fetal cardiac structures such as valves, walls, or aortic pulsations, which is reflected back to the transducer at a slightly different frequency due to tissue or blood movement. Doppler principles are employed in two readily available methods: the handheld Doppler device, which is frequently used for routine office assessment of the fetal heart rate, and as part of cardiotocography. Both devices have proved to be highly effective tools for the detection of fetal dysrhythmias. The handheld devices can be used from the 12th week of gestation, whereas cardiotocography is not usually used before 24 weeks.

Fetal Electrocardiography

Fetal electrocardiography (FECG) is another method for the detection of fetal dysrhythmia. It is similar in principle to standard electrocardiography, with the placement of electrodes on the maternal abdomen to record the differences in electrical potential arising from the fetal cardiac electrical activity. Most fetal QRS complexes are easily identified from the raw signal with FECG, and with signal averaging, the P-waves can be located occasionally. T-waves are rarely seen on these recordings. However, because it requires signal averaging over time to assess P-wave morphology, it is not useful in real-time examinations (e.g., for occasional extrasystoles or intermittent tachycardias). Despite some limitations of use later in pregnancy owing to the electrical insulating nature of vernix caseosa, serial noninvasive FECG of normal fetuses from 18 to 41 weeks' gestation has been shown to achieve good success in FECG detection.[20]

Intrapartum ST segment analysis forms the basis of the STAN ECG system.[21] However, this requires direct application of a scalp electrode, which can be done only if the amniotic membranes are ruptured. In addition, the STAN ECG waveform is achieved by signal averaging, so this technique cannot be used for fetal rhythm anomalies.

Magnetocardiography

Described by Kariniemi in 1974,[22] fetal magnetocardiography (FMCG) has potential utility in the evaluation of ventricular arrhythmias. FMCG noninvasively records the magnetic activity of the fetal heart generated by electrical excitation after maternal signals are filtered out. With specialized offline analysis of the magnetic activity, an equivalent of the surface electrocardiogram (ECG) is created. Its use and reliability are documented from 20 weeks to birth.[23] Numerous studies demonstrate the accuracy of FMCG for the diagnosis of fetal arrhythmias such as atrial and

ventricular ectopy, SVT, atrial flutter, CAVB, torsades de points, and ventricular tachycardia (VT).[24–26]

The advantages to FMCG over FECG include the following: it takes less time (seconds vs. minutes), it overcomes the assumption that mechanical activity correlates with electrical activity, and it has greater reliability. FMCG is currently the only antenatal method of measuring cardiac repolarization, which can identify long QT syndrome (LQTS). The disadvantages of FMCG include its size, high cost, and severely limited availability of the equipment, resulting in restricted use in current clinical practice.

Echocardiography

Fetal echocardiography is the current gold standard for the diagnosis and monitoring of fetal arrhythmias and relies on the extrapolation of mechanical events back to presumed antecedent electrical events and the assessment of their temporal relationship. Its status is due, in part, to its widespread availability and relative ease of use. Ongoing improvements in ultrasound technology make this diagnostic modality an increasingly effective means of defining fetal arrhythmias. A significant advantage of fetal echocardiography is its safety throughout pregnancy, starting as early as 11 weeks[27] with a transvaginal probe and 14 weeks transabdominally. Both fetal atrial and ventricular rates along with the AV activation sequence are readily seen. Knowledge of the activation sequence facilitates differentiation of the arrhythmia into ventricular or supraventricular and long or short ventriculoatrial (VA) time interval tachycardia. Limitations associated with the use of fetal echocardiography for arrhythmia assessment are primarily due to fetal lie and difficulty in accurately interrogating structures that represent atrial and ventricular electrical activity. In addition, fetal well-being, cardiac structure, and hemodynamics can be evaluated concurrently with the arrhythmia assessment.

In addition to a careful examination of the fetal heart and circulation, assessment of a fetal arrhythmia should include a detailed, full sonographic examination of the fetus, looking for syndromic features, especially those associated with chromosomal abnormalities. Fetal echocardiography is also crucial in the chronic follow-up of fetuses with clinically significant arrhythmias to assess hemodynamic consequences and overall fetal well-being.

The two most common echocardiographic methods of arrhythmia analysis are M-mode and spectral Doppler. Although either method alone is reliable in the majority of fetuses, comfort in performing and interpreting both techniques is essential in the event that fetal position or a restricted ultrasound window limits the use of one or the other method.

M-Mode

In M-mode echocardiography, the M-mode line is positioned by two-dimensional (2D) image guidance to transect one structure that represents atrial contraction (atrial wall or AV valve) and one that represents ventricular contraction (ventricular wall or aortic or pulmonary valve). Atrial systole is represented by the onset of atrial wall movement or the A-wave of the mitral or tricuspid valve inflow, and ventricular systole is represented by the onset of ventricular wall movement or the opening of either the aortic or the pulmonary valve. The fetal cardiac mechanical movements are then plotted against time. From a hard copy of the M-mode tracing, a "ladder diagram" of atrial and ventricular activity can be constructed[28] (Fig. 15–1). Cardiac time intervals are then measured from the M-mode tracing along with the sequence of atrial and ventricular events and intervals (VA and AV).

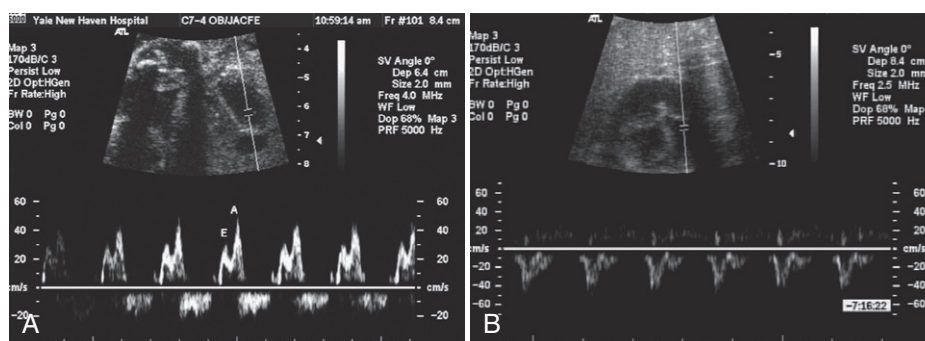
The main limitations of M-mode echocardiography are technical (obtaining properly positioned and interpretable tracings) and the assumption that mechanical cardiac events reflect electrical events. The latter can lead to an errant diagnosis with junctional ectopic tachycardia, which occurs when the electrical focus originates in the AV node. In this case, by M-mode echocardiography, the mechanical activity of the ventricle precedes the atrium, thus mimicking VT. Atrial wall motion may be minimal in atrial fibrillation or in the setting of a dilated, poorly contractile atrium. Lastly, discerning the A-waves of the mitral or tricuspid valve can be quite challenging.


FIGURE 15–1
A, Doppler flow velocity waveform of normal flow across the mitral valve. Note that early ventricular filling (E) has a lower velocity than active atrial systole, reflecting the dependence of the fetal myocardium on atrial systole to overcome the inherent stiffness of the immature muscle. *B*, Doppler flow velocity waveform of flow across the mitral valve in a fetus with reentrant tachycardia. Note the reversal of the normal E:A ratio. Time scale is twice that shown in *A*.

Spectral Doppler

Spectral Doppler is the second echocardiographic method of fetal arrhythmia assessment. Similar to M-mode, under 2D image guidance, the sample volume is placed in a location that allows for the simultaneous recording of flow representing atrial and ventricular systole. The sample volume can be placed in a number of locations, such as the left ventricular outflow tract, which will record mitral valve inflow and ventricular outflow, the pulmonary vein and pulmonary artery, the inferior vena cava and the aorta, or the superior vena cava and aorta.[29–33] We find that the simplest to obtain is left ventricular inflow and outflow from an apical four-chamber view (see Fig. 15–1). After the appropriate sample volume position has been attained, a tracing of the flow velocity is recorded, a ladder diagram is constructed, and the sequence of atrial and ventricular events and intervals is deduced similar to M-mode. The main limitation is that this requires proper fetal positioning and the need to place the Doppler sample volume from an apical four-chamber view so as to maximize both inflow and outflow velocities.

Tissue Doppler Analysis

Tissue Doppler analysis, using myocardial depolarization signals of simultaneous sampling sites in the atrium and ventricular myocardium to assess temporal events in the fetal heart, has been shown to correlate well with intervals obtained on electrocardiography.[10] This technique eliminates some of the limitations that arise in more conventional methods including those that are positional and gestational age–related. Rein and colleagues described a method of independently obtaining timing data from the wall velocities of all four cardiac chambers that was used to construct a "fetal kinetocardiogram," which permitted precise calculation of timing intervals even when atrial and ventricular activity occurred simultaneously or when early atrial activity was weak and, thus, accurate analysis of the mechanism of fetal arrhythmias.[34]

MECHANISMS OF TACHYARRHYTHMIAS

Fetal arrhythmias are generally first detected during routine prenatal visits or ultrasound examinations. Transient fetal rhythm disturbances represent up to 10% to 20% of all indications for fetal cardiac evaluations at tertiary centers.[13] The cause of these transient arrhythmias is usually extrasystoles, typically atrial in origin. The incidence of malignant fetal arrhythmias, ventricular and supraventricular, is unknown but is believed to be rare. The most common causes of fetal tachycardias are AV reentry SVTs, atrial flutter, and sinus tachycardia. Rare causes of fetal tachycardia include atrial ectopy, atrial fibrillation, and junctional and ventricular tachycardia, which constitute less than 1% of fetal arrhythmias. Knowledge of the incidence, mechanism, and associated morbidity and mortality rates of the different arrhythmias is critical in determining the appropriate treatment for the fetus.

IRREGULAR HEART RATE

Premature Atrial Contractions

Premature atrial contractions (PACs) are the result of nonsinus atrial depolarization that occurs earlier than the expected sinus beat. PACs are the most common fetal dysrhythmia, with a prevalence of 1% to 3% of all pregnancies.[35] They may originate from either the right or the left atrium and may be conducted through the AV node either in the normal fashion or aberrantly or they may block at the level of the AV node. PACs are associated with illicit drug use, trisomy 18, and hyperthyroidism[36] and occur more commonly later in gestation. It is also hypothesized that some fetal PACs are caused by an aneurysm of the flap valve of the foramen ovale.[37] Rarely, isolated PACs are reported to trigger episodes of sustained SVT. Fetal PACs are easily recognized either by their characteristic early atrial wall movement (M-mode), mitral inflow (Doppler) pattern, or inferior vena cava flow (Doppler) pattern.

Management Options

Isolated PACs require no treatment, but because of their association with SVT, recurrent auscultation of the fetal heart rate is prudent until the ectopic beats resolve. This management strategy also permits recognition of the infrequent cases of isolated extrasystoles that may go on to develop a clinically significant arrhythmia. There is no increase in the incidence of structural heart disease in affected fetuses[13]; however, fetuses with congenital heart disease as well as those with normal hearts may not tolerate even the minor hemodynamic changes that can be associated with extrasystoles. Frequent, blocked PACs (e.g., fetal bigeminy) may appear to be a fetal bradycardia. Patients are advised to avoid caffeine and medications that may increase ectopy, such as β-adrenergic drugs (e.g., terbutaline). Persistent postnatal ectopy warrants only a neonatal ECG and consideration for a 24-hour Holter monitor.

Premature Ventricular Contractions

Premature ventricular contractions (PVCs) are caused by early, nonsinus depolarization of the ventricles. A compensatory pause may be observed if the PVC is conducted in retrograde fashion through the AV node to the atrium. PVCs produce a characteristic Doppler flow pattern with absence of diastolic flow across the AV (mitral) valve prior to the initiation of ventricular systole (aortic outflow). They account for approximately 2% to 4% of all fetal ectopy.

Management Options

PVCs are usually benign and generally warrant simple maternal avoidance of cardiac stimulants such as caffeine. Under rare circumstances, PVCs may be a harbinger of cardiomyopathy, myocarditis, structural cardiac malformations, or LQTS.[38] Postnatal ventricular ectopy requires an ECG to evaluate the corrected QT interval as well as consideration of placement of a 24-hour Holter monitor in order to quantify the frequency of the ectopy. An echocardiogram may also be recommended to assess the neonatal cardiac

structure and function as well as for the presence of intra-cardiac tumors.

TACHYCARDIA

Sinus Tachycardia

Sinus tachycardia in a fetus is defined as a sustained heart rate between 160 and 210 beats/min with 1:1 AV concordance. If the rate is greater than 210 beats/min and nonvariable, SVT should be considered. Persistent fetal sinus tachycardia may be secondary to acidosis, hypoxic ischemic encephalopathy, anemia, myocarditis, infection, maternal fever, and maternal drug ingestion or use of stimulants.[39] Although maternal thyroid hormone does not cross the placenta, prenatal thyrotoxicosis secondary to transplacental passage of thyroid-stimulating immunoglobulin (TSIG) with maternal Graves' disease has also been associated with fetal sinus tachycardia.[40] Management of persistent sinus tachycardia involves recognition and treatment of the underlying cause. Sinus tachycardia should be differentiated from ventricular tachycardia (see later discussion). In sinus tachycardia, atrial systole precedes ventricular contraction, whereas in ventricular tachycardia, ventricular contraction precedes the atrial systole. This can be difficult to distinguish in utero. Sinus tachycardia may be suspected if there are gradual accelerations or decelerations in fetal heart rate rather than abrupt changes as well as preserved heart rate variability.[10]

Supraventricular Tachycardia

Fetal SVT may present at any time after 15 weeks. SVT is a general term used to describe an arrhythmia of nonsinus origin at or above the bundle of His, and thus characterized by a narrow QRS complex (Fig. 15–2) with 1:1 AV conduction. The causes of SVT are categorized by their dependence on the AV node for propagation of the arrhythmia. Those that require the AV node to maintain the tachycardia (Wolff-Parkinson-White [WPW] syndrome, atrioventricular

node reentry tachycardia [AVNRT], permanent junctional reciprocating tachycardia [PJRT], concealed accessory pathway [CAP], and Mahaim pathways) are referred to as *AV node–dependent*. In these cases, the presence of an accessory pathway in conjunction with the normal AV node allows formation of a circuit through which electrical activity can be propagated both anterograde and retrograde between the atria and the ventricles. Those forms of SVT that do not require the AV node to be maintained (atrial fibrillation, atrial flutter, atrial and junctional ectopic tachycardia) are referred to as *AV node–independent tachycardias*. Reentrant tachycardias are the most common mechanism of fetal tachycardia, accounting for 70% to 80% of fetal SVT.[41]

Based upon their mechanism of propagation, the AV node–dependent SVTs are further divided into the short and long VA tachycardias. This distinction is important in determining the correct medication to control fetal tachycardia. The VA time in tachycardia is determined by simultaneous Doppler interrogation of either the SVC (A) or the ascending aorta (V) or by measuring mitral (A) and aortic (V) flow in the left ventricular outflow. The VA time is considered long if it is greater than one half of the V-V interval. The use of fetal echocardiography and Doppler interrogation is particularly useful in distinguishing between these types of SVT because it allows easy measurement of time intervals.[10]

Atrioventricular Node–Dependent Supraventricular Tachycardia

SHORT VENTRICULOATRIAL TACHYCARDIA

The most common form of SVT is the short VA, AV node–dependent SVT. This category includes concealed accessory pathways, WPW syndrome, and typical AVNRT. Characteristics unique to these tachycardias include rates of 220 to 300 beats/min (typically close to 240 beats/min), little rate variability, and 1:1 VA concordance. In these forms of tachycardia, the VA interval is less than half the duration of the R-R interval. Atrial and ventricular ectopic beats typically trigger abrupt initiation and cessation of the tachycardia, which may be intermittent or sustained. These arrhythmias generally cannot be differentiated in utero. On rare occasions, a short VA SVT occurs in conjunction with structural cardiac disease (e.g., rhabdomyoma, ventricular inversion, or Ebstein's anomaly of the tricuspid valve). In this instance, WPW syndrome should be suspected because of its known association with these lesions.

Management Options

In general, these arrhythmias respond to transplacental digoxin or β-blocker therapy unless hydrops is already present. Occasionally, when digoxin or β-blockers fail or when there is already hydrops, second-tier antiarrhythmic agents such as flecainide, sotalol, or amiodarone become necessary and are usually effective. Preterm delivery is rarely, if ever, indicated in nonhydropic fetuses with this form of SVT. Close to term or with documented fetal lung maturity, delivery is preferable to continued unsuccessful attempts at in utero treatment. At a minimum, all patients should have a postnatal ECG to determine the etiology of the tachycardia, which will help guide further medication. If
FIGURE 15–2
Doppler flow velocity waveform of flow into pulmonary artery in a fetus with reentrant supraventricular tachycardia. Typical rate of 235 beats/min is shown.

structural cardiac disease is suspected, a transthoracic echo-cardiogram should be performed. Usually, the antiarrhythmic medication(s) are continued up to a year postnatally to avoid recurrence.

LONG VENTRICULOATRIAL TACHYCARDIA

Incessant slow fetal SVT may be due to a slowly conducting accessory pathway found in PJRT. The incidence of this fetal tachycardia is extremely rare. It is characterized by long VA times, an incessant nature, and slower rates (180–220 beats/min) and can readily be misdiagnosed as sinus tachycardia. Owing in part to its incessant nature, it is a relatively dangerous arrhythmia, capable of causing severe cardiac dysfunction and hydrops fetalis.

Management Options

PJRT rarely responds to digoxin or β-blockade, so flecainide or sotalol would be the appropriate choices.

Atrioventricular Node–Independent Supraventricular Tachycardia

ATRIAL FLUTTER

Atrial flutter accounts for approximately one third of fetal tachycardias.[36] This rapid, regular atrial rhythm is propagated by reentrant pathways contained within the atrium itself and is characterized by atrial rates of 400 to 550 beats/min typically with a slower ventricular response. Because the reentry cycle occurs within the atrium, propagation through the AV node is not necessary to maintain the tachycardia. The ventricular rates vary, depending on whether there is uniform conduction of atrial beats. The most common form of AV conduction in fetal atrial flutter is 2 : 1 AV block. The diagnosis of atrial flutter can be made by fetal echocardiogram showing a fast atrial rate with variable AV conduction, or the typical sawtooth appearance on a fetal magnetocardiogram (Fig. 15–3). Atrial flutter is often an isolated finding but may be associated with structural cardiac defects that dilate the atrium, such as Ebstein's malformation, atrial septal defects, hypoplastic left heart syndrome, and cardiomyopathy as well as with WPW
Flow in ductus venosus of a fetus with reentrant supraventricular tachycardia. Normal flow is unidirectional in contrast with bidirectional flow shown here.

syndrome[35] and associated AV node–dependent reentry tachycardia. Hydrops occurs in upward of 35% of the fetuses with incessant atrial flutter.

Management Options

The management of atrial flutter is based on either termination of the intra-atrial reentry or by ventricular rate control. Ventricular rate control can be accomplished with the maternal administration of digoxin in the absence of hydrops fetalis. Sotalol has shown to be effective for arrhythmia termination in 80%.

It is prudent to continue transplacental treatment throughout pregnancy once the fetal rate is successfully converted, with careful attention to maternal drug levels, ECG, and symptoms to avoid adverse treatment effects. The prognosis for fetal atrial flutter is excellent if delivery is at term and there is no associated structural cardiac disease. After successful conversion to sinus rhythm, the majority of pediatric patients do not experience recurrence and require no treatment. Early delivery is indicated only if the fetus fails to respond to medications or has hydrops fetalis.

ATRIAL FIBRILLATION

Atrial fibrillation is a rare fetal arrhythmia with a reported incidence of 0.2%.[36] It is characterized by an extremely rapid, chaotic atrial rate of greater than 500 beats/min with variable ventricular conduction due to blocking at the level of the AV node. In cases of fine atrial fibrillation, the atria may appear to actually stand still during fetal echocardiography. Atrial fibrillation can occur in association with Ebstein's malformation of the tricuspid valve, thyrotoxicosis, and cardiac tumors.

Management Options

No antiarrhythmic agent has to date been used to convert fetal atrial fibrillation to sinus rhythm. Ventricular rate control can usually be achieved with transplacental digoxin administration. The prognosis for atrial fibrillation is unknown, owing in part to its relative rarity and the fact that the majority of cases are associated with structural and other conduction abnormalities. Postnatally, newborns are converted to a sinus rhythm through direct current cardioversion. Atrial fibrillation is not an indication for early delivery unless hydrops fetalis develops or fetal compromise is suspected based on biophysical testing.

ATRIAL TACHYCARDIA

Ectopic or *chaotic atrial tachycardias* are rare but are occasionally seen in the later stages of pregnancy. This arrhythmia is characterized by regular or irregular atrial and ventricular Doppler flow patterns, depending on the atrial rate and AV conduction. Gradual speeding and slowing of the heart rate may be identified. Atrial tachycardia is typically well tolerated and hydrops fetalis is rare.

Management Options

Once the diagnosis is established, medical management should be initiated, but the arrhythmia is frequently resistant to basic drug therapies such as digoxin and β-blockers.[42] Flecainide is the drug of choice for fetal atrial ectopic tachycardia. Postnatal recognition and treatment might be needed if the tachycardia is persistent.

JUNCTIONAL ECTOPIC TACHYCARDIA

Congenital *junctional ectopic tachycardia (JET)* is an extremely rare, incessant form of ectopic focus SVT. The focus is located within the AV node, resulting in near-simultaneous electrical activation of the atria and ventricles and superimposition of the A-wave on the V-wave, though more pronounced dissociation of the ventricles from the atria can occur, mimicking VT. This arrhythmia is unique in its inheritance pattern; approximately 50% have a close family member affected. JET is very difficult to diagnose in utero without FMCG and is frequently resistant to conventional therapy. The mortality rate approaches 35% in infancy.[43]

Management Options

Fetuses with JET may respond to either amiodarone or sotalol.

VENTRICULAR TACHYCARDIA

VT is another relatively rare form of tachycardia with the focus originating in the ventricle(s). It may be associated with fetal myocarditis, myocardial dysfunction of any cause including hypertrophic cardiomyopathy, tuberous sclerosis, or LQTS. The most common form of VT is called *slow ventricular tachycardia* or *accelerated idioventricular rhythm*. The rate is between 160 and 200 beats/min and does not warrant any intervention. VT is diagnosed when faster heart rates, greater than 200 beats/min, are observed. In addition, AV dissociation is frequently seen, with the ventricular rate being faster than the atrial rate, although 1:1 AV rates can be seen in the setting of retrograde VA conduction.

Management Options

Sustained fast fetal VT with or without hydrops fetalis is often refractory to treatment, which requires agents such as amiodarone, lidocaine, or sotalol. β-Blockers should be considered in suspected LQTS in an effort to minimize fetal sympathetic stimulation and reduce the incidence of fetal VT.

BRADYCARDIAS

Fetal bradycardia is defined as a persistent heart rate below 100 beats/min not associated with uterine contractions or periodic decelerations. A thorough investigation into fetal well-being and cause of the dysrhythmia is warranted when fetal bradycardia is detected. First, extrinsic, noncardiac causes of fetal bradycardia such as drugs, maternal hypothermia, and mechanical compression of the umbilical cord must be excluded.[18,44] If the bradycardia persists and no obvious extrinsic causes are evident, the next step is to determine the exact rhythm (e.g., sinus bradycardia, partial or CAVB, or atrial bigeminy with blocked premature beats) to facilitate appropriate management. As previously noted, a maternal history or screening for connective tissue disorders or drug use, along with a complete family history, probing for arrhythmias, pacemakers, and structural heart disease or congenital deafness in close family members, is warranted.

Sinus Bradycardia

Sinus bradycardia can be differentiated from other causes of fetal bradycardia by Doppler or M-mode echocardiography. The hallmark of sinus bradycardia is the presence of a normal AV activation sequence with 1:1 conduction. Confirmation that any slow heart rate is due to sinus bradycardia is mandatory to rule out advanced AV block or CAVB or blocked premature atrial ectopic beats. In addition to rhythm confirmation, a thorough fetal assessment is necessary to seek signs of fetal compromise, hydrops fetalis, or structural cardiac disease. Well-known causes of fetal sinus bradycardia include fetal hypoxia, sinus node dysfunction, LQTS, and heterotaxy syndrome with left atrial isomerism, in which the fetus has two left atria and thus lacks a true sinus node, which is a right atrial structure.

Management Options

The management of a fetal sinus bradycardia depends on the cause as well as the clinical status of the fetus. Close observation generally is all that is necessary if the fetus is not compromised, and all extrinsic causes of sinus bradycardia are removed. A postnatal ECG should be performed to rule out or confirm the presence of a prolonged QT interval.[45]

Atrioventricular Block

The designation *AV block* describes an abnormality in the conduction of atrial impulses through the AV node to the ventricles. This abnormality can range from a simple delay in impulse transmission, as in first-degree AV block, to a complete interruption of signal transmission with failure of AV communication, classified as CAVB or third-degree AV block. Each form of AV block has a distinct anatomic or physiologic cause for the electrical abnormality, and some can be either transient or permanent in nature. In utero, these abnormalities are diagnosed using either fetal echocardiography or FMCG with postnatal confirmation by electrocardiography. The following sections focus on the definition, evaluation, and treatment of more advanced forms of fetal AV block.

Second-Degree Atrioventricular Block

Second-degree AV block is defined as the failure of at least one nonpremature atrial impulse to be conducted to the ventricles. A number of different forms of second-degree AV block exist. Mobitz type I, or Wenckebach, is the most common, but least significant. Wenckebach is characterized by a progressive prolongation of the PR or AV interval with an eventual dropped ventricular beat. The delay occurs in the AV node, proximal to the bundle of His.[46] This conduction abnormality is generally transient in nature and is caused by vagal influence. In rare instances, it can be caused by digitalis toxicity or inflammatory disorders that affect the cardiac muscle. No treatment is necessary in asymptomatic fetuses. Mothers should be screened for presence of anti-Ro anti-La antibodies and the fetus observed closely for progression.

The more pathologic forms of second-degree AV block include Mobitz type II and the advanced types. Type II second-degree AV block is characterized by constant P-P and PR intervals followed by a nonconducted atrial impulse, whereas nonconducted atrial bigeminy may have more

variability of atrial events resulting in nonconduction of an early atrial impulse through a refractory AV node. The anatomic site of block is at or below the bundle of His.[47] High-grade or advanced second-degree AV block occurs when two or more successive sinus atrial impulses are not propagated through the AV node. If either form of AV block is identified, the presence of prolonged QT interval syndrome or maternal connective tissue disorders must be investigated and the perinate followed closely for progression to CAVB.[48]

Complete Atrioventricular Block

Fetal CAVB or third-degree AV block is the complete failure of sinus or atrial impulse conduction to the ventricles. The atrial rate must be faster than the ventricular rate to ensure that the AV dissociation is not due to accelerated junctional or ventricular rhythm (e.g., sinus bradycardia with appropriate junctional response or an accelerated junctional or ventricular rhythm). The prevalence of CAVB in liveborn infants is 1 in 20,000.[49] The majority of affected fetuses fall into one of two distinct groups: those with structural cardiac disease and those with maternal connective tissue disorders.[50–52]

The association between fetal CAVB and maternal autoimmune disorders is well established.[53–56] It occurs typically after 18 weeks' gestation in fetuses of women with systemic lupus erythematosus (SLE), Sjögren's syndrome, rheumatoid arthritis, scleroderma, and undifferentiated connective tissue disorders[57–59] who have maternal autoantibodies designated anti-SS-A/Ro, anti-SS-B/La, or both.[59,60] Many women carrying a fetus with CAVB do not have symptoms of any connective tissue disorder at the time, with half demonstrating only serologic evidence of disease.[61] In addition, the vast majority of mothers with SLE do not have children with CAVB.[62] The risk of a woman with SS-A/Ro and SS-B/La antibodies and no prior affected infant having a fetus with heart block is 1% to 2%.[63] There are no reliable markers to detect which fetuses of affected women will go on to develop CAVB, and the onset of lower-order AV block and the progression to CAVB might be quite sudden. The risk of recurrence of CAVB in subsequent pregnancies after delivering an affected infant is 10% to 16%.[51,60]

The conduction system is damaged by maternal antibodies that cross the placenta and react with their corresponding antigens expressed on the surface of cells in the fetal cardiac conduction system, resulting in immunoglobulin deposition on the cells and fibrosis of the affected cells. The resulting local inflammatory reaction leads to permanent damage of the fetal cardiac conduction system and developing myocardium due to localized cellular apoptosis.[64–68] It has been proposed that impaired physiologic clearance of those apoptotic cells results in their accumulation and that in turn leads to inflammation and cellular injury.[69]

The second group of fetuses with CAVB have structural cardiac disorders. The etiology of nonimmune complete AV block was postulated by Lev[70] to be a developmental abnormality of the AV node. This abnormality results from either complete absence of the AV node, lack of union between the AV node and the distal conduction system, or the presence of an aberrant, non- or poorly functioning system.[70] The most common structural cardiac abnormalities associated with CAVB are AV septal defects, both with and

without associated left atrial isomerism, and AV-VA discordance (corrected transposition of the great arteries).[50,52] Additional cardiovascular malformations (tetralogy of Fallot, atrial septal defects, transposition of the great vessels, and tricuspid atresia) are described in conjunction with conduction disorders, without any clear association between the structural abnormality and the conduction defect.[50,52]

In addition to those with well-known immunologic and structural causes, a small group of patients has been identified with a genetic mutation that results in CAVB. An autosomal dominant mutation in the cardiac transcription factor Nkx2.5 can result in familial atrial septal defects and AV node conduction abnormalities including Holt-Oram syndrome. There are also fetuses with structurally normal hearts but a mutation in SCN5A, a sodium ion channel, that is responsible for long QT interval and Brugada's syndrome, who can have a range of AV conduction abnormalities including CAVB.[71]

In contrast to the oft-quoted dogma that the majority of fetuses with CAVB without structural cardiac abnormalities have few if any problems with gestation and delivery, several studies document an exceptionally high mortality rate among these fetuses and neonates. The mortality rates range from 7% to 33% in the setting of a structurally normal heart and as high as 86% for those with structural cardiac lesions.[50–52,61,72] Poor outcomes are especially associated with structural cardiac disease, left atrial isomerism, hydrops, ventricular rates below 55 beats/min, atrial rates below 120 beats/min, AV valve regurgitation, dilated cardiomyopathy, endocardial fibroelastosis, prolonged corrected QT interval, or delivery at less than 33 weeks' gestation.[50,73]

Management Options for Heart Block

Second-degree AV block (Mobitz type I/Wenckebach): No treatment is necessary in asymptomatic fetuses. Mothers should be screened for presence of anti-Ro and anti-La antibodies and the fetus observed closely. If the dysrhythmia is transient and there is no evidence of either congenital heart disease or maternal autoimmune disorders, then consideration should be given to the possibility of LQTS, particularly if there is a coexisting history of sinus bradycardia or ventricular arrhythmias or a family history of LQTS.[74,75]

SECOND-DEGREE ATRIOVENTRICULAR BLOCK (MOBITZ TYPE II AND ADVANCED TYPES)

Management of these conduction abnormalities is similar to that of complete AV block (see next item).

THIRD-DEGREE OR COMPLETE ATRIOVENTICULAR BLOCK

The goal of management of a fetus with CAVB is the birth of a healthy, viable infant. This outcome is best achieved through a two-tiered approach. First, early identification of the fetus at risk for developing CAVB is extremely important, allowing for the initiation of therapies in an attempt to prevent the onset or progression of the conduction abnormality or its sequelae. These goals may be accomplished by increasing the fetal heart rate or contractility or by blunting or removing the inflammatory stimulus through immune suppression. Second, early intervention(s) is required at the first sign of fetal compromise including consideration of premature delivery.

Maternal or direct fetal administration of sympathomimetic agents such as terbutaline, isoproterenol, and salbutamol have some efficacy in increasing both fetal heart rate and contractility.[50,76–79] Reported fetal responses to these agents range from no improvement to complete resolution of hydrops and survival.[50,76,77,79,80] The wide applicability of these results is limited by the small number of patients treated, the highly variable clinical situations, and concomitant use of additional therapies. We believe it is unlikely this therapy works in a sustentative fashion, because it does nothing to restore AV concordance. The relative stiffness of the fetal ventricular myocardium, and the consequent reliance of the fetus on atrial systole for normal ventricular filling, makes the fetus exquisitely sensitive to interruption of this relationship.

Another approach to increase the fetal heart rate is through ventricular pacing. Transvenous and epicardial ventricular pacing has been performed in fetal animal models, and transuterine-transthoracic pacing has been reported in a few human fetuses.[81–83] Despite technical successes, all reported treated fetuses have died. With the advent of new, smaller (1.4-Fr), soft-tipped temporary pacing wires, transvenous ventricular pacing mighty become more feasible and less risky to mother and fetus in the future, although placement would require open fetal surgery with the pacemaker generator itself buried under the fetal skin to avoid exposure of the fetus to entanglement with free-floating wires in the amniotic sac.

Reduction of the maternal antibody titer or the fetal inflammatory response to the antibodies is accomplished through either suppression or removal of the offending agents. Removal of the anti-SS-A/Ro and anti-SS-B/La antibodies was reported in a few cases by plasmapheresis with variable results. Intravenous gammaglobulin has also been reported to reduce the maternal anti-Ro antibody titer.[84] Despite their encouraging results, only a limited number of patients have undergone these therapies during pregnancy.

Fluorinated steroids such as dexamethasone and betamethasone have been used for prevention and treatment of CAVB.[65,66,85–87] A retrospective case-control investigation compared pregnancy outcomes of those treated with fluorinated steroids to those untreated.[88] Although steroid use for fetuses with complete AV block failed to resolve the AV conduction defect, it was associated with some improvement in hydrops and other symptoms. Steroids administered shortly after the onset of early AV block (second-degree) may have reversed the block or prevented its advancement in at least some fetuses.[88] Maternal high-dose dexamethasone initiated at the diagnosis of fetal CAVB and continued for the remainder of the pregnancy has also been suggested to improve fetal and neonatal survival.[73] These findings suggest fluorinated steroids are a therapeutic option in fetuses with early forms of AV block to prevent progression and potentially cure the abnormality. However, a recent multicenter prospective study of dexamethasone failed to alter the progression of second- to third-degree block. In rare cases, dexamethasone was successful in reverting first- or second-degree block.[89] Although steroids will not reverse CAVB, they may ameliorate myocardial inflammation and dysfunction and help optimize fetal cardiac output. Steroids can also be considered in fetuses with hydrops, although lack of response should prompt rapid taper of the steroids to avoid complications of long-term steroid use in pregnancy.

In summary, fetal CAVB is a relatively rare condition with rapidly evolving management. We recommend early fetal echocardiography in all mothers with anti-Ro and anti-La antibodies (SS-A and SS-B). Fetuses with structural cardiac disorders associated with CAVB should be closely observed for signs of an arrhythmia. In the fetus of a mother with a connective tissue disorder, early detection of advanced AV conduction abnormalities should at least prompt the consideration of fluorinated steroids with the goal of preventing the progression of the inflammatory process. The presence of hydrops or ventricular rates below 55 beats/min should trigger the reconsideration of therapy with steroids if not previously utilized. Additional studies on the benefits of plasmapheresis and intravenous immunoglobulins are needed. In addition, the patient should be referred to a center with expertise in high risk obstetrics and fetal cardiology as well as pediatric and neonatal pacemaker implantation and management.

Management of Fetal Tachyarrhythmias—General

The management of a fetus with a dysrhythmia should involve a coordinated team approach including experts in obstetric imaging, fetal medicine, electrophysiology, and pediatric cardiology and typically coordinated by the fetal medicine expert. Strasburger and coworkers[29] observed a higher rate of cesarean section (84% vs. 18%) and lower gestational age at delivery (37 wk vs. 39 wk) in infants managed at nontertiary centers without prenatal pediatric cardiology support suggesting a high level of physician discomfort. Medications are often administered to pregnant women with hopes that the beneficial effects of the drug will be transferred to the fetus. For many of these medications, the kinetics of drug transfer is poorly studied. When transplacental antiarrhythmic therapy is to be administered, the authors also work with an adult electrophysiologist to guide dosage selection and assist in monitoring the mother for adverse events and side effects.

Hydrops Fetalis (See also Chapter 24)

Hydrops fetalis is defined as skin edema plus an abnormal collection of fluid in at least two other areas such as ascites, pleural or pericardial effusions, polyhydramnios, or placental edema. Cardiac reasons for the development of hydrops include structural cardiac defects and rhythm disturbances, which are the primary causes of up to 50% of all cases of nonimmunologic hydrops.[90] Rhythm disturbances are thought to lead to fetal heart failure and hydrops secondary to reduced diastolic filling time in conjunction with the normally decreased compliance of the fetal myocardium in comparison with postnatal myocardium and resulting in increased fetal filling pressures. Risk factors for hydrops fetalis and subsequent poor outcome include prematurity, sustained SVT exceeding 12 hours resulting in impaired ventricular filling and/or cardiac dysfunction, and structural cardiac defects. The ventricular rate and the mechanism of tachycardia have not been clearly shown to be risk factors for the development of hydrops.[11] Untreated hydrops fetalis

can be associated with decreased fetal movement, fetal metabolic acidemia, myocardial dysfunction, and poor tolerance of labor. In addition, placental edema may contribute to decreased placental drug transfer requiring higher doses, more drugs (two vs. one), or more days (12.5 vs. 3) to control their arrhythmia.[91] Mortality may be as high as 13% at term for fetuses with hydrops and rises as gestational age falls.[92]

Therapeutic Options

One must balance the risks and benefits before initiating medical therapy for fetal tachyarrhythmia. We are currently unsure of the exact pharmacokinetics of many of the medicines used in transplacental treatments. All the drugs we might use have potentially dangerous side effects and might be proarrhythmic for both the mother and the fetus. They might not be effective, and there could be spontaneous resolution of the tachycardia even without treatment. Therefore, the treatment for fetal tachycardia depends on a multitude of factors including the type of arrhythmia, gestational age of the fetus, maternal and fetal health, and the presence of either structural cardiac disease or hydrops.

Therapeutic options for a fetal tachyarrhythmia include monitoring without pharmacologic intervention, transplacental or direct administration of antiarrhythmic medications to the fetus, or delivery of the fetus with postnatal arrhythmia management. Intermittent tachycardia in the near-term fetus is often well tolerated, but the management choice for most fetuses with tachycardia at or very near term (≥34–35 wk) is delivery. The nonhydropic fetus with an intermittent tachyarrhythmia can often be safely and effectively induced with oxytocin for vaginal delivery as long as there are sufficient intervals of normal rhythm present to permit electronic fetal heart rate monitoring. In pregnancies with evidence of fetal compromise or cardiac dysfunction, a complete fetal and maternal assessment must be performed and the pros and cons of all available treatment options weighed by the treatment team and family. Treatment is typically undertaken for fetuses with existing heart failure or those at high risk of developing heart failure, whereas no intervention other than intensive fetal surveillance is a reasonable therapeutic option for fetuses with intermittent tachycardia and the absence of any evidence of hemodynamic compromise.

When the treatment of a fetal arrhythmia is indicated, a number of options are available. Transplacental therapy is preferred for a stable arrhythmia when both the fetus and the mother are in excellent health. If for some reason transplacental therapy is not an option, consideration must be given to direct fetal therapy with drug infusion into the umbilical vein, into the amniotic fluid, or by direct fetal intramuscular injection. The following sections review the advantages as well as the risks of each of these therapeutic options and provide data and clinical scenarios that apply to each therapy.

Signs of fetal compromise must be sought whenever a fetal arrhythmia is detected. Delivery of a hydropic fetus prior to 34 to 35 weeks' gestation is associated with a very high mortality and is indicated only under exceptional circumstances, such as failed transplacental/direct therapy, worsening diastolic dysfunction, or a poor fetal biophysical profile.[79] When iatrogenic premature delivery is desirable

rather than mandatory, documentation of fetal lung maturity by amniocentesis may help with the decision. If the pregnancy is at or before 34 weeks, appropriate doses of betamethasone or dexamethasone should be administered to hasten fetal lung maturation.

Pregnancies close to term should be delivered rather than exposing the mother to these potent medications. The aim of transplacental therapy is to use the normal function of the placenta as a fetal drug delivery mechanism. Transplacental therapy is indicated in fetuses with a stable biophysical profile and sustained tachycardia.[93] Those fetuses with tachycardia less than 30% of the time and without hydrops can probably be left untreated and instead followed closely. This decision should be individualized and based on the ability to follow the patient closely. We believe twice-weekly echocardiographic evaluation of nonhydropic infants is warranted. In contrast, many neonates with any episode of nonsinus, AV node–dependent tachycardia will receive antiarrhythmic medications for up to 1 year of age to minimize their risk of developing congestive heart failure.

Antiarrhythmic medicines should be initiated under close supervision. With the exception of β-blockers, most antiarrhythmic drugs require close monitoring of both fetus and mother for side effects as well as successful conversion to sinus rhythm. We believe that when most antiarrhythmic drugs are initiated, the mother should be monitored as an inpatient on cardiac telemetry in consultation with an adult electrophysiologist to monitor the maternal ECG, electrolytes, and vital signs. Conversion can generally be achieved within a few days. Once control or steady state is achieved, the patients may be discharged with close follow-up. Conversion rates of fetal SVT range from 80% to 90% and are lowest when there is already hydrops present.[94] The resolution of hydrops after successful treatment of tachycardia may take several weeks. Acceleration of fetal maturity with corticosteroids should be considered if elective preterm delivery seems likely.[95]

Pharmacokinetics and Choice of Antiarrhythmic Agents

Transfer of any drug across the placental barrier is promoted by low molecular size, low ionization, and high lipid solubility.[96] The rate of diffusion is also dependent on fetal-maternal concentration gradient and the thickness of the placental membrane. Higher doses of drugs are often required to achieve therapeutic levels during pregnancy because of increased blood volume and volume of distribution, increased protein binding of drugs, increased hepatic metabolism, and greatly increased glomerular filtration rate in the mother. The placenta is able to transfer, concentrate, and metabolize drugs to inactive metabolites, although it is worth noting that some antiarrhythmic metabolites are themselves active agents. Fetal metabolism of drugs is primarily renal or placental because hepatic enzymes are immature (only 20%–50% active). The potential myocardial depressant effects of these medications must be considered, especially in the setting of existing or potential myocardial dysfunction in affected fetuses. The transplacental transfer of drugs, particularly digoxin, may be poor in the presence of hydrops fetalis, making management of fetal SVT with associated hydrops more difficult. To circumvent mitigating

factors that affect transplacental transfer, direct umbilical or fetal intramuscular administration of drugs has been used successfully to treat the fetus directly after a transplacental approach had failed.[97,98]

The proper diagnosis of the type of tachycardia is required to guide therapy. Based on a 1998 survey of 15 institutions treating fetal arrhythmias, the most commonly used drug was digoxin (78%) followed by flecainide (18%), verapamil (7%), procainamide (6%), quinidine (6%), amiodarone (6%), propranolol (2%), and sotalol (2%).[82] Verapamil and other calcium channel blockers are contraindicated in newborns owing to the risk of profound hypotension and shock and should be used rarely and with extreme caution, if at all, in fetuses. In addition, quinidine has proarrhythmic effects and also should be used rarely. Amiodarone is effective in 90% of reentrant SVTs and 60% of atrial flutter. However, the half-life of amiodarone after prolonged usage is

measured in weeks, and the potential for profound fetal hypothyroidism, and consequent goiter and even cretinism, mandates great caution. The maternal ECG and side effects including thyroid, liver, and pulmonary should be monitored along with desired fetal effect, and the dose titrated for optimal response. Standard doses and some common side effects of different drugs are listed in Table 15–2.

Prognosis

The perinatal mortality rate for fetal tachycardia with hydrops ranges from 3.5% to 30% in different studies. The differences may relate to the use of different antiarrhythmic agents, some with proarrhythmic effects, the incidence of premature delivery, and fetal interventions including cordocentesis.[99] Marked acidosis, prematurity, and prolonged tachycardia are also associated with hydrops and long-term postnatal sequelae including neurologic problems.[100]

TABLE 15–2

Pharmacologic Agents Used to Treat Fetal Arrhythmias

DRUG	ADVERSE EFFECT	DOSING RANGE	MECHANISM OF ACTION	THERAPEUTIC LEVEL
Digoxin	Nausea, bradycardia, vision disturbance, first- and second-degree AV block, rhythm disturbances	Loading dose: 1200–1500 µg/24 hr IV Maintenance: 375–875 µg/day PO divided bid	Slows ventricular rate by partially blocking the AV node	0.8–2.5 ng/dL
Propranolol	Low birth weight, hypoglycemia, bradycardia, increased uterine tone	80–320 mg/day PO in three to four divided doses	β-Blocker	25–50 ng/mL
Flecainide	Fetal demise, conduction defects, QT interval prolongation, proarrhythmia	100–400 mg/day PO divided bid-tid	Class Ic; slows conduction velocity in most cardiac pathways by effects on Na channels	0.2–10 µg/mL
Sotalol	Tiredness, dizziness, nausea, QT interval prolongation, torsades de pointes	80–160 mg PO bid-tid	β-Blocker with additional class III antiarrhythmic properties with prolongation of cardiac action potential through blockage of K channels	Not known
Amiodarone	Nausea, thrombocytopenia, visual disturbances, QT interval prolongation, hypothyroidism	Loading dose: 1200 mg PO q6h Maintenance: 600–900 mg/day	Primarily class III antiarrhythmic with prolongation of phase 3 of cardiac action potential through blockage of K channels. Also has β-blocker–like and K channel blocker–like actions as well as Na channel effects	0.7–2.8 µg/mL

AV, atrioventricular.

SUMMARY OF MANAGEMENT OPTIONS

Fetal Cardiac Arrhythmias

Management Options	Evidence Quality and Recommendation	References
Irregular Fetal Heart Rate		
Prenatal Diagnosis		
Careful history and examination to exclude	IV/C	36
• Familial long QT interval syndrome. • Maternal illicit drug use. • Maternal hyperthyroidism.		
Fetal echocardiography to confirm cardiac normality; detailed fetal sonography to exclude syndromes; consider karyotype if aneuploidy (especially trisomy 18) suspected.	III/B	13
	IV/C	36

SUMMARY OF MANAGEMENT OPTIONS
Fetal Cardiac Arrhythmias—cont'd

Management Options	Evidence Quality and Recommendation	References
Prenatal Treatment		
No treatment if isolated (as in the majority of cases).	—/GPP	—
Avoid caffeine and drugs that promote ectopy (e.g., β-sympathomimetics).	—/GPP	—
Weekly ausculation to confirm no progression to SVT.	—/GPP	—
Postnatal		
If ectopic beats persist in the neonatal period, perform ECG and consider 24-hr Holter monitor as well as echocardiography.	IV/C	38,45
Tachycardias		
Prepregnancy		
Counseling of those with history of		
• WPW syndrome.	IV/C	36
• Familial long QT interval syndrome.	IV/C	38,45
Prenatal Diagnosis		
Auscultation and fetal echocardiography for sustained fetal rate >180 beats/min.	—/GPP	—
Ultrasound evaluation of cardiac structure, function, presence of hydrops, and mechanism of arrhythmia (including M-mode and spectral Doppler).	III/B	8
Search for other abnormalities with ultrasound; consider karyotype if aneuploidy suspected.	—/GPP	—
Prenatal Treatment		
Depends on	—/GPP	—
• Underlying mechanism/diagnosis.		
• Persistence of tachyarrhythmia.		
• Presence of hydrops.		
• Gestational age.		
Nonsustained tachycardia requires monitoring but no treatment unless hydrops is present.	—/GPP	—
Medical (Transplacental) control of sustained tachycardia; five drugs are commonly used: Digoxin. β-Blockers. Flecainide. Soltalol. Amiodarone. **Sinus tachycardia**—Treat cause (e.g., maternal thyrotoxicosis). **Short VA SVT**—preceding five drugs have been used. **Long VA SVT**—use flecainide, soltalol. **Atrial flutter**—digoxin, soltalol. **Atrial fibrillation**—no intrauterine drug is effective; DC after birth. **Atrial tachycardia**—flecainide. **Junctional ectopic tachycardia**—soltalol, amiodarone. **Ventricular tachycardia**—soltalol, amiodarone.	III,IV/B,C	44,91,99
Monitor maternal ECG and drug levels with use of these drugs.		
Therapy delivered directly to the fetus has been effective, particularly in the setting of hydrops.	III/B	97,98
Delivery is an option if close to term (34+ wk); short trial of drug therapy before delivery if hydrops even if close to term is a possible option because newborns with hydrops have poor prognosis.	—/GPP	—

Management Options	Evidence Quality and Recommendation	References
Postnatal		
12-lead ECG to confirm WPW or long QT interval syndrome and precise diagnosis.	IV/C	38,45
Take local advice re prophylactic treatment for tachycardia—some will not use this routinely. Some centers will treat asymptomatic neonates for 6–12 mo and review.	—/GPP	—
Treat recurrent tachycardia in infancy (medical therapy or ablation).	III/B	91,93
Bradycardias		
Prepregnancy		
Counseling of women with the following risk factors for CAVB:		
• Previous child with CAVB.	III/B	98
• Maternal anti-SSA (Ro) or SSB (La) antibodies (1%–2% risk).	III/B	59,63
• Maternal heart block.	—/GPP	—
• Previous child with left atrial isomerism.	—/GPP	—
• Familial prolonged QT interval syndrome is a possible risk factor.	IV/C	38,45
Prenatal Diagnosis		
Detailed and serial echocardiography (every 1–2 wk) of antibody-positive mothers and those with a positive family history.	—/GPP	—
Fetal echocardiography for persistent fetal rate <100 beats/min.	—/GPP	—
Serial echocardiography (every 1–2 wk) for emerging block (second- or third-degree heart block).	—/GPP	—
Irregular rhythms	—/GPP	—
• If occasional, clinical follow-up. • If persistent, fetal echocardiography and intensify follow-up.		
Evaluation of asymptomatic mothers for anti-Ro and anti-La antibodies and autoimmune disease (rheumatoid arthritis, Sjögrens syndrome, systemic lupus erythematosus, or undifferentiated autoimmune syndrome).	III/B	59,63
Prenatal Treatment		
Early steroids (dexamethasone/betamethasone) are common first-line treatment; no evidence of benefit of prophylactic steroids.	III/B	78,84,88
More research is needed into role of plasmapheresis and IVIG.	IV/C	78,84
Inotropic/chronotropic support is of limited benefit.	III/B	72,86
Fetal pacing has been attempted but without success.	IV/C	79,85
Consider early delivery in tertiary center if hydrops is evident, but generally try to avoid preterm delivery.	—/GPP	—
Mode of delivery—intrapartum monitoring of fetal distress may be difficult in CAVB.	—/GPP	—
Postnatal		
Temporary pacing may be necessary.	III/B	51,72
Permanent pacemaker for rate <60 beats/min, symptoms, or structural disease.	III/B	51,72

CAVB, complete atrioventricular block; DC, dilation and curettage; ECG, electrocardiogram; GPP, good practice point; IVIG, intravenous immunoglobulin; SVT, supraventricular tachycardia; VA SVT, ventriculoatrial supraventricular tachycardia; WPW, Wolff-Parkinson-White.

INTRODUCTION

Examination of the fetal heart is a part of the comprehensive fetal scan, but a complete examination can be a challenge to even an experienced sonographer. Ultrasound techniques used in fetal cardiology have evolved impressively over the years; no other fetal organ is examined with so many modalities as the heart including two-dimensional imaging, M-mode examination, spectral Doppler, color Doppler, power, high-definition digital Doppler as well as tissue Doppler.[1] Very recently, three-dimensional (3D) and four-dimensional (4D) technology were introduced into fetal cardiology and first experiences reported.[1]

Structural and functional abnormalities do affect later cardiac development, and the importance of antenatal diagnosis is well recognized in modern perinatal medicine. Congenital heart disease (CHD) complicates 0.4% to 1.1% of live births[2] and accounts for 35% of infant deaths secondary to congenital disease.[3] Cardiovascular anomalies are frequently associated with other anomalies.[4,5] In this chapter, the indication and the sonographic technique for assessing fetal cardiac status are reviewed, the principal structural cardiac diseases described, and the available management options discussed.

INDICATIONS FOR FETAL ECHOCARDIOGRAPHY

"Routine" Fetal Echocardiography

Despite the high incidence of CHD, "routine" fetal echocardiography (i.e., all pregnancies) remains unavailable in many locations because it requires sophisticated equipment, a skilled operator, and meticulous scanning. It is simply not practical to screen the entire obstetric population at the present. Moreover, the pregnancies at greatest risk of CHD are those in which an abnormality of the fetal heart is suspected during the routine 18- to 23-week anatomic scan. This underscores the importance of a meticulous scanning of the fetal heart in all pregnancies at this gestational age in order to identify those who should be referred for fetal echocardiography.

Selective Fetal Echocardiography

Fetal echocardiography is performed in selected pregnancies at increased risk of carrying a fetus with a CHD. Risk factors can be divided into familial, maternal, and fetal (Table 16–1).

There is an association between increased nuchal translucency (NT) measured between 11 and 13 + 6 weeks of gestation and CHD (see Chapter 7).[6,7] The prevalence of major cardiac defects increases exponentially with NT thickness,[7] from 4.9 per 1000 when the NT thickness is below the median to 8.7 per 1000 when the NT is between the median and the 95th percentile to 18.2 per 1000 when the NT is between the 95th and the 99th percentiles.[7] Further, abnormalities of cardiac function have been demonstrated in fetuses with normal cardiac anatomy but increased NT,[8] suggesting a pivotal role for NT measurement in the screening of fetuses who should undergo fetal echocardiography.

More recently, several new ultrasonographic markers were added to first-trimester screening for fetal aneuploidies including the presence of tricuspid regurgitation (TR) and reverse flow in the ductus venosus (DV). Each is an independent predictor of CHD. In euploid fetuses with an increased NT, TR is present in half of those cases with CHD but in only 5.6% of those without CHD.[9] Likewise, the finding of an absent or reversed A-wave in the DV in euploid fetuses with an increased NT is associated with a threefold increase in the likelihood of CHD, whereas a normal DV halves the risk for such defects.[10] As a consequence, studies of both DV flow and TR at 11 + 0 to 13 + 6 weeks' gestation promise to be good markers for CHD with and without an abnormal NT.

Reports on the efficacy of screening for CHDs vary widely with sensitivities ranging between 10% and 81%.[11–13] These differences may reflect the characteristics of study population (low or high risk), type of study (prospective and retrospective), level of experience of operators, modality of examination (four-chamber view or four-chamber view + outflow tract visualization), and quality of follow-up (postnatal clinical examination or postnatal echocardiography). With the current technology and with a proper training of examiners, demonstration of the four-chamber view allows

TABLE 16–1

Indications for Fetal Echocardiography

Family History
Previous affected fetus or child
Maternal or paternal congenital heart disease
History of a single gene disorder (Di George's, Noonan's, Marfan's, William's, Holt-Oram syndromes)

Maternal History
Metabolic diseases
  Insulin-dependent diabetic mother
  Maternal phenylketonuria
  Connective tissue disease
Exposure to teratogens
  Alcohol
  Valproic acid
  Phenytoin
  Isoretinoin
  Lithium
  Hydantoin
Infections
  Rubella
  Parvovirus
  Coxsackievirus
  Cytomegalovirus

Fetal
Arrhythmias
Extracardiac anomalies
Hydrops
Hydramnios
Growth restriction
Chromosomal defects
Increased nuchal translucency thickness at $11 + 0 - 13 + 6$ weeks' gestation
Trucuspid regurgitation at $11 + 0 - 13 + 6$ weeks' gestation
Retrograde flow in the ductus venosus at $11 + 0 - 13 + 6$ weeks' gestation
Abnormal heart at 18–20 weeks routine scan (usually abnormal four-chamber view)

TABLE 16–2

Schematic Approach to Scanning the Fetal Heart

Cardiac Malformations

Make diagnosis—see later for systematic approach
Inform the patients (possibilities and limitations)
Fetal position
Fetal situs (transverse section of the upper abdomen)
Real-time view of the fetal heart
Apical four-chamber view
  Size of heart (one third of the thorax)
  Two atria of approximately equal size
  Two ventricles of equal size, normally contracting
  Morphologically right ventricle on right
  Two opening atrioventricular valve
  Pulmonary veins
Lateral four-chamber view
  Integrity of interventricular septum (muscular portion)
  Foramen ovale flap
Left ventricle outflow tract, aortic arch
  Aorta arise from left ventricle
  Integrity of interventricular septum (membranous portion)
  Opening aortic valve
  Regular size of aortic arch
Right ventricle outflow tract, ductus arch
  Pulmonary artery rise from right ventricle
  Opening of pulmonary valve
  Regular size of main pulmonary artery
  Branching of pulmonary artery and continuity with ductus arteriosus
Three-vessel view
  Pulmonary artery, aorta, and superior vena cava visualization
  Identification of trachea and thymus
Systemic venous return
  Transverse section of upper abdomen position of aorta (left and posterior) and inferior vena cava (right anterior)
  Parasagittal view of fetal trunk (inferior and superior vena cava)
Pulmonary venous return
  From apical four-chamber view, identify inlet in left atrium

Doppler Echocardiography

Color

Apical four-chamber view
  Normal ventricular filling
  Absence of regurgitation
Ventricle outflow tracts
  Normal aortic and pulmonary artery color visualization
  Absence of flow reversal
Three-vessel view
  Same color direction in pulmonary artery and aorta

Pulsed

Apical four-chamber view
  Mitral and tricuspid velocity waveforms flow only during diastole (E- and A-waves)
  Ventricle outflow tract
  Aortic and pulmonary velocity waveforms flow only during systole (peak velocity, time to peak velocity, cardiac output?)
Ductus arteriosus flow
  Flow throughout all cardiac cycle
  Highest velocities in fetal circulation
  Exclude ductal constriction (PI < 2)
Venous flow
  Inferior vena cava reflects overall cardiac function
  Poor cardiac function is associated with increased reverse flow during atrial contraction (high preload index)

for the detection of 40% to 50% CHDs in low risk pregnancies. Additional visualization of the outflow tracts increases the detection rate to 65% to 70%. Experience has a significant impact on the examination of the fetal heart and the prenatal detection rate of major CHDs. The learning curve is fairly flat because a sonographer already confident in obtaining the four-chamber view may require another 3 years to properly visualize the outflow tracts.[14]

ULTRASONOGRAPHIC EXAMINATION OF THE FETAL HEART (TABLE 16–2)

Timing of Fetal Echocardiography

Women should be seen within 48 hours of referral when an anomaly is suspected to avoid growing parental anxiety during the interval between detection and consultation. Planned fetal echocardiography is typically performed between 20 and 22 weeks.[15] The maternal abdominal wall thickness, prior abdominal surgery, and the number of fetuses each influence the ideal time for study.

Transvaginal ultrasonography or high-resolution transabdominal probe permits a detailed view of the fetal anatomy early in gestation from 11 weeks onward.[16,17] We currently limit performance of these early scans to woman with an

increased NT with or without TR or abnormal DV flow, with a prior affected child, or with insulin-dependent diabetes.[18] At this gestational age, fetal echocardiography is mainly used to confirm or refute normal cardiac anatomy rather than to establish a specific diagnosis, Because the sensitivity of early echocardiography is at a maximum 60%,[16] it should be repeated between 20 and 22 weeks even if the first is normal; an additional 20% of the CHDs will be evident.[17]

General Principles

It is imperative that the mother is informed before the examination in a clear and considerate manner about the reason for the fetal cardiac evaluation and its efficacy and limitations.[19] The findings of the scan should then be explained at the end of the examination. Fetal echocardiography consists of several steps:

1. Determine the fetal cardiac orientation and position.
2. Evaluate the cardiac anatomy.
3. Evaluate the cardiac hemodynamics and function using color and pulsed Doppler.

Fetal Cardiac Orientation and Position

The examination begins with identification of the fetal head and spine so that the fetal right and left sides are known. The fetal visceral orientation, known as *situs*, is easily identified by noting the location of the following landmarks while viewing a transverse section of the upper abdomen (Fig. 16–1).

1. The stomach and spleen are on the left.
2. The abdominal aorta is a circular, pulsating structure on the left, anterolateral to the spine without another vessel posterior.
3. The inferior vena cava (IVC) is an elliptical structure on the right of the spine in a plane anterior to the aorta.
4. The umbilical vein bends to the right, continuing in the portal sinus.

The arrangement described previously constitutes *situs solitus*. An abnormal visceral-vascular arrangement may be either *situs inversus* or *situs ambiguous*. In the former, the
visceral-vascular arrangements are the mirror image of *situs solitus*, so that the stomach and aorta are on the right and the IVC and the liver are on the left side. *Situs ambiguous* refers to a condition in which there is an abnormal arrangement of the abdominal and thoracic organs and is usually associated with cardiosplenic syndromes.

Normal Fetal Cardiac Anatomy

A sequential approach is applied to fetal echocardiography based on the pathologic and angiographic examination of the heart.[20] The main steps include identification of the cardiac position within the body, identification of the cardiac chambers, study of atrioventricular (AV) connections, study of ventriculoarterial connections, and study of venous return to the atria. This is accomplished by examining the following standardized, echocardiographic planes.

APICAL FOUR-CHAMBER VIEW

The apical four-chamber view is found in a cross-sectional scan of the fetal thorax just above the level of the diaphragm where the normal heart is almost horizontal, mainly on the left side of the chest with the apex pointing left. The apical four-chamber view is the single most important view of the heart and provides the following anatomic information (Fig. 16–2):

1. The heart is correctly situated in the thorax with the apex on the left, and it occupies about one third of the thorax. The ratio between the cardiac and the thoracic circumferences in this view during end-diastole (i.e., while the AV valves are closed) is constant across gestation with an upper limit of 0.58.[21] Larger values suggest either cardiomegaly or a small chest.
2. There are two atria of equal size. The two ventricles are approximately equal in size and thickness, and in real time, their contractility appears similar.
3. The right ventricle is on the right and near the anterior thoracic wall. It has a septomarginal trabeculum, or moderator band, located near the apex in contiguity with the interventricular septum. The left ventricular cavity is smooth.

FIGURE 16–1
Transverse section of the upper fetal abdomen shows the spleen, stomach (ST), aorta (AO), inferior vena cava (IVC), and umbilical vein (UV).
FIGURE 16–2
Apical four-chamber view of the fetal heart. Ao, aorta; Fo, foramen ovale; LV, left ventricle; MB, moderator band; PV, pulmonary vein; RA, right atrium.

4. Two AV valves open in real time, and the insertion of the tricuspid valve is located more toward the apex than the mitral valve.

5. The interatrial septum, the foramen ovale, and the interventricular septum are visualized. The atria and ventricular septa meet at the level of AV valve, generating a crux.

6. The pulmonary veins enter the left atrium.

The four-chamber view is an essential component of any study of the fetal heart, but alone is insufficient, because less than a third of congenital defects are detectable.

LATERAL FOUR-CHAMBER VIEW

This view allows visualization with higher resolution of certain structures lying perpendicular to the line of ultrasound transmission. The artifactual dropout at the level of the high portion of the interventricular septum and of the atrium septum secundum common in the apical four-chamber view is avoided, and the integrity of the interventricular and interatrial septa is optimally demonstrated. This view also allows enhanced imaging of the foramen ovale and the movement of its valve into the left atrium (Fig. 16–3).

LEFT VENTRICLE OUTFLOW TRACT

It is possible to obtain a long-axis view of the fetal heart in an oblique section of the fetal thorax. This section reveals the following landmarks (Fig. 16–4):

1. The mitral valve is seen between the left atrium and the left ventricle, and the posterior leaflet is shorter than the anterior leaflet.

2. The anterior leaflet of the mitral valve is continuous with the posterior wall of the aorta.

3. The anterior wall of the aorta is continuous with the interventricular septum.

4. The aortic valve and its movement are seen at the base of the aorta. By orienting the transducer from the left shoulder to the right hemithorax, the aortic arch and the origin of the brachiocephalic vessels are fully visualized (Fig. 16–5).

RIGHT VENTRICLE OUTFLOW TRACT

This view is a transverse cross-section of the fetal thorax. The pulmonary artery is seen arising from the right ventricle anterior to and left of the ascending aorta (circle and sausage image) (Fig. 16–6). The movement of the pulmonary valve is seen. With slight movement of the transducer, the

FIGURE 16–3
Transverse section of the fetal thorax shows the lateral four-chamber view. The *dotted line* connect the spine(s) with the sternum and allows calculation of the cardiac axis (angle between the *dotted line* and the intraventricular septum). ao, aorta; dx, right side; L, lung; bm, band moderator; pv, pulmonary vein; sx, left side; vs, left ventricle.
FIGURE 16–4
Long-axis view of the fetal heart shows the continuity between left ventricle (LV) and aorta (ao). mv, mitral valve; ra, right atrium.
FIGURE 16–5
A, Longitudinal view of the aortic arch and the brachiocephalic vessels. *B*, Same section with flow Doppler superimposed shows the arch with its three branches: innominate artery (I), left carotid artery (c), and subclavian artery (s).

longitudinal view of the ductal arch is obtained. It is also possible to visualize the bifurcation of the main pulmonary artery and the ductus arteriosus connecting to the descending aorta in this section (Fig. 16–7).

THREE-VESSEL VIEW

From the four-chamber view, the transducer is moved parallel in the direction of the upper thorax. In this view, the pulmonary trunk with the ductus arteriosus, the aortic arch with the aortic isthmus, and the superior vena cava are seen

(Fig. 16–8). The aorta and pulmonary trunk are seen in a longitudinal view and form a V-shaped area in the posterior thorax on the left side of the spine.[22] In this section, the trachea is a circular structure with an echogenic wall adjacent and to the right of the aorta. In front of the trachea, the superior vena cava can be seen. The landmarks contained in this view include

1. Three vessels seen from left to right: pulmonary artery, aorta, and superior vena cava.
2. In descending order of size: pulmonary artery > aorta > superior vena cava.
FIGURE 16–6
Short-axis view of the fetal heart shows the outflow tract of the right ventricle (RV). AO, aorta; DA, ductus arteriosus; MPA, main pulmonary artery; RPA, right pulmonary artery; RA, right atrium.
FIGURE 16–8
Three-vessel view in a fetus with a microdeletion of chromosome 22q11 with an absent pulmonary valve resulting in a dilated pulmonary artery (PA) and absent thymus (?).
FIGURE 16–7
A, Transverse section of the fetal thorax at the level of the three-vessel view. The pulmonary artery (PA) is the largest of the three vessels; the aorta (AO) is between the PA and the superior vena cava (SVC), which is the smallest and most posterior vessel. The trachea (Tr) is visualized posterior to the aorta, and the thymus (th) is situated anteriorly. *B,* Three-dimensional display of the three-vessel view.

FIGURE 16–9
Three-vessel view of the fetal heart shows the persistence of left superior vena cava (LSVC) lateral to the pulmonary artery (PA). Ao, aorta; svc, superior vena cava.
FIGURE 16–10
Parasagittal view of the fetal trunk shows the inlet in the right atrium (RA) of the superior (SVC) and inferior (IVC) venae cavae.
3. Each lies posterior to the other: pulmonary artery anterior to aorta, aorta anterior to superior vena cava.
4. Pulmonary artery arises closest to the anterior chest wall.
5. Trachea and thymus can be visualized.

The position of the trachea in relation to these vessels may be used to differentiate a normal, left-sided aortic arch from an abnormal right-sided aortic arch.[23] Furthermore, the thymus can be seen in front of these vessels (Fig. 16–9), and its absence is a possible marker of CHD associated with a microdeletion of chromosome 22q11.[24]

From this view, a fourth vessel lateral to the pulmonary artery can be seen and represents the persistent left superior vena cava (PLSVC), an anomaly present in about 0.2% of fetuses, and the use of the multiplanar approch of 4D fetal echocardiography facilitates the diagnosis.[25] Isolated PLSVC is a benign vascular anomaly and may not affect the outcome. However, when PLSVC is detected, a meticulous study of the fetal anatomy is necessary because it is frequently associated with heterotaxy syndromes, other cardiac/noncardiac malformations, and aneuploidies.[26]

VENOUS RETURN

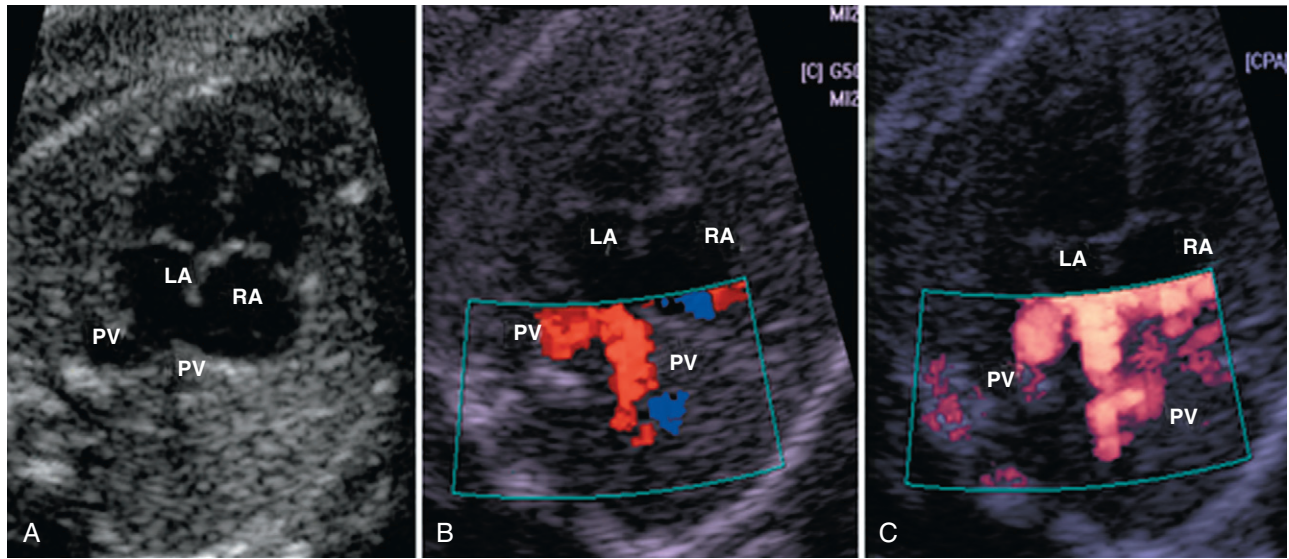
The systemic venous return is assessed using a right, parasagittal scan of the fetal thorax to demonstrate the IVC and superior vena cava entering the right atrium (Fig. 16–10). The pulmonary veins are seen entering the left atrium from either the apical or the lateral four-chamber view (Fig. 16–11).

DOPPLER EXAMINATION OF THE FETAL HEART

General Principles

Whereas real-time imaging provides information on the structural integrity of the fetal heart, Doppler ultrasonography provides information that enhances both the definition of the presence and the severity of structural and functional cardiac disease. The parameters used to describe fetal cardiac velocity waveforms differ from those used to describe the peripheral fetal vessels. In the latter, pulsatility, resistance, or systole/diastole indices are used. They are derived from the relative ratios of systolic, diastolic, and mean velocities and are independent of the absolute velocity and the angle of insonation[27] (see also Chapter 10).

In contrast, measurements at the cardiac level are absolute values and require knowledge of the angle of insonation, which might be difficult to obtain accurately. The error in the absolute velocity measurement resulting from angle uncertainty is strongly dependent on the magnitude of the angle itself. For example, the error is insignificant if the angle is less than about 20 degrees. However, when the angle is greater than 20 degrees, the cosine term in the Doppler equation converts the small uncertainty in the measurement to a large error in the velocity equations.[27] Thus, recordings should be obtained with the Doppler beam as parallel to the bloodstream as possible. All recordings with an estimated angle greater than 20 degrees should be rejected.

FIGURE 16–11
Apical four-chamber view of the fetal heart shows the inlet of the pulmonary veins (PV) in the left atrium (LA) in real time (*A*) and with the help of color (*B*) and power (*C*) Doppler.


The use of color Doppler velocimetry can help solve many of these problems by revealing in real-time the flow direction so that the beam can be properly aligned. Pulsed Doppler is generally preferred over continuous-wave Doppler because of its superior range of resolution. The sample volume is placed immediately distal to the location to be studied (e.g., distal to the aortic semilunar valves to record the left ventricle outflow). The continuous-wave Doppler may be useful when velocities are particularly high (e.g., in the ductus arteriosus) because it avoids the aliasing effect.

Parameters Measured

The parameters commonly used to describe the cardiac velocity waveforms include

1. The *peak velocity* (PV), which is expressed as the maximum velocity at a given moment (e.g., systole, diastole) on the Doppler spectrum.
2. The *time to peak velocity* (TPV) or acceleration time, which is expressed as the time interval between the onset of the waveform and its peak.
3. The *time velocity integral* (TVI), which is calculated by planimetering the area underneath the Doppler spectrum.

It is possible to calculate absolute cardiac flow from both AV valve and outflow tracts by multiplying:

$$\text{TVI} \times \text{valve area} \times \text{fetal heart rate}$$

The measurement of the valve area is also prone to inaccuracy. It is derived from the measurement of a valve diameter that is near the limit of ultrasonographic resolution. The measurement is then halved and squared in the calculation, amplifying potential errors. Despite these limitations, absolute cardiac flow can be used in longitudinal studies over a short duration during which the valve dimensions are assumed constant. It is also possible to calculate accurately the relative ratio between the right and the left cardiac output (RCO/LCO) and avoid the valve measurement completely because the relative dimensions of the aortic and pulmonary valves remain similar through gestation in the absence of cardiac structural diseases.[1]

Sites of Recordings, Velocity Waveform Characteristics, and Their Significance

Blood flow velocity waveforms can be recorded at all cardiac levels including venous return, foramen ovale, AV valves, outflow tracts, pulmonary arteries, and ductus arteriosus. Factors affecting the morphology of the velocity waveforms include preload, afterload, myocardial contractility, ventricular compliance, and fetal heart rate.[1,27] Because it is impossible to obtain simultaneous recordings of pressure and volume, these factors cannot be fully investigated in the human fetus. However, because each waveform parameter and the site of its recording are specifically affected by one of these factors, it is possible to elucidate indirectly the underlying pathophysiology by performing the measurements at various cardiac levels.

Venous Circulation

Blood flow velocity waveforms can be recorded in the superior and IVC, ductus venosus, and pulmonary, hepatic, and umbilical veins. The vessel most intensively studied to date is the DV.

IVC waveforms recorded just distal to the entrance of the DV[28,29] have a triphasic profile. There is a first forward wave concomitant with ventricular systole, a second forward wave of smaller dimension occurring in early diastole, and a third but reverse wave occurring during atrial contraction (Fig. 16–12). Several indices have been proposed for the analysis of the IVC waveforms. We found that the preload index (PLI) expressed as the ratio between the peak velocities during atrial contraction and systole (PLI = A/S) is the most

FIGURE 16–12
Velocity waveforms from the inferior vena cava. Note the typical triphasic morphology with the reverse flow (*upper channel*) during atrial contraction (A-wave).
FIGURE 16–13

reproducible and efficient index.[29] This index is related to the pressure gradient between the right atrium and the right ventricle during end-diastole, which is a function of both ventricular compliance and ventricular end-diastolic pressure.[30] Decreased cardiac function is associated with an increase in the A-wave, and as a consequence, the PLI increases.

The DV is seen in a transverse section of the upper fetal abdomen at the level of its origin from the umbilical vein. Color Doppler is superimposed and the pulsed Doppler sample volume placed just above its inlet (close to the umbilical vein) at the point of maximum flow velocity as expressed by color brightness. The DV flow velocity waveform has a biphasic pattern with a first peak concomitant with systole (S), a second peak concomitant with diastole (D), and a nadir during atrial contraction (A) (Fig. 16–13). Among the indices suggested to quantify DV velocity waveforms is the ratio of the S peak velocity to the A peak velocity (S/A). This index is angle-independent and describes DV hemodynamics efficiently.[30] The hemodynamic significance of the DV is similar to that of the IVC. In the presence of poor cardiac function, the A-wave is reduced or negative and the S/A ratio increases.

Pulmonary vein velocity waveform is recorded at its entrance into the left atrium. The waveform morphology is similar to that of the DV and characterized by positive velocities during atrial contraction (Fig. 16–14). The striking variation in the velocity waveform morphology between the IVC and the pulmonary vein reflects the different hemodynamic conditions of the fetal systemic and pulmonary venous
circulations. Indeed, an abnormal pattern has been described in corrected transposition of the great arteries, a condition in which the afterload of the left ventricle is altered.[31]

Umbilical venous blood flow is usually continuous. However, pulsations in the umbilical venous flow reflecting the heart rate occur in the presence of a relevant amount of reverse flow in the IVC during atrial contraction. In normal pregnancies, these pulsations cease after the 12th week of gestation. Before 12 weeks, they are secondary to ventricular stiffness, which causes a high percentage of reverse flow into the IVC.[1] The presence of pulsations in the umbilical vein after 12 weeks indicates severe cardiac compromise.[1] In clinical practice, the venous circulation is evaluated in sequence moving away from the heart. The further the pulsations are from the heart, the greater the stiffness/cardiac compromise.

Atrioventricular Valves

Flow velocity waveforms at the level of the mitral and tricuspid valves are recorded in the apical four-chamber view of the fetal heart. They are characterized by two diastolic peaks corresponding to early ventricular filling (the E-wave) and active ventricular filling during atrial contraction (the A-wave) (Fig. 16–15). The ratio between the E- and the A-waves (E/A) is a widely accepted index of ventricular diastolic function and an expression of both the cardiac compliance and the preload conditions.[32,33]

Outflow Tracts

Flow velocity waveforms from the aorta and pulmonary artery are recorded respectively from the five-chamber and short-axis views of the fetal heart (Figs. 16–16 and 16–17). PV and TPV are the most commonly used indices. The former is influenced by several factors including valve size, myocardial contractility, and afterload, whereas the latter is believed to reflect the mean arterial pressure.[34]

Pulmonary Vessels

Velocity waveforms may be recorded from the right and left pulmonary arteries or from peripheral vessels within the lung. The morphology of the waveforms varies according to the sample site, and their analysis has been used to study the normal development of the pulmonary circulation.[35]

Three-Vessel View

In this view, the pulmonary artery and ascending aorta have the same flow direction and thus have the same color when imaged with color-flow Doppler (Fig. 16–18). Severe outflow

FIGURE 16–15

obstruction to one of the ventricles leads to reverse flow in the pulmonary artery (right side obstruction) or in the aorta (left side obstruction) (Fig. 16–19).

Ductus Arteriosus

Ductal velocity waveforms are recorded in a short-axis view showing the ductal arch. They are characterized by continuous forward flow throughout the cardiac cycle.[26] The parameter most commonly analyzed is the PV during systole, or similarly to peripheral vessels, the pulsatility index (PI = [systolic velocity − diastolic velocity]/mean velocity).[36]

Normal Ranges of Cardiac Doppler Indices

The velocity waveforms are recordable from 11 weeks on.[1] The cardiovascular indices change dramatically at all levels up to 20 weeks. The PLI of the IVC decreases significantly,[1,24,26] the E/A ratio at both AV levels increases dramatically,[1,34] and the PV and TVI of the outflow tracts, particularly at the level of pulmonary valve, increase.[34] These changes are consistent with rapid development of ventricular compliance (explaining the decrease in the IVC PLI and

FOUR-DIMENSIONAL STUDY OF THE FETAL HEART

Detection of CHD in the general population, even when the outflow tracts are visualized routinely, depends as previously reported, on the skill of the sonographers and on their ability to interpret the findings.

Spatiotemporal image correlation (STIC) is a technique that allows examination of the fetal heart within a real-time 4D volume, displayed in a cineloop. It has been proposed that fetal echocardiography using STIC has the potential to increase the detection rates for CHD because it decreases the dependency on the sonographer's skill.[37–39] Indeed, it is possible with this technique to acquire a volume starting from the standard four-chamber view and then offline navigating inside the volume in a multiplanar way to obtain all the diagnostic planes (Fig. 16–20). We recently described a technique of analysis known as the "three-steps view" that allows us to obtain in less than 4 minutes the four-chambers-view and the outflow tract[40] (Fig. 16–21).

In order to further facilitate the identification of CHD, computer aid diagnosis software was recently developed (SonoVCAD) that allows a fully automated visualization of the diagnostic plane from volumes acquired from the chamber view.[41] Preliminary applications of this software in fetuses with transposition of the great artery suggest a clinical applicability.[42]

4D echocardiography also can be used to provide enhanced characterization of the CHD either by showing multiple diagnostic planes in a tomographic way or by allowing rendering all the heart or a portion such as a valve in a 3D way (Fig. 16–22). In this manner, it is easier to show the defect to consulting physicians from pediatric cardiology and cardiac surgery.

A further advance of 4D fetal echocardiography is that the acquisition of cardiac volumes can be performed locally at the screening center, but the subsequent analysis of suspect cases can be performed by an expert fetal echocardiographer at a remote site, reducing the number of referrals to tertiary centers of prenatal diagnosis.[43]

the increase in the E/A) and a shift in the cardiac output toward the right ventricle as placental resistance falls, decreasing right ventricular afterload.

After 20 weeks, the IVC PLI declines less dramatically whereas there is a significant decline in the S/A ratio of the DV.[30] At the level of AV valves, the E/A ratios increase progressively, reaching a value near 1 at term.[34] Similarly, the PV increases linearly at the level of both the pulmonary and the aortic valves.[34] The PV of the aortic valve is usually greater than the pulmonary artery and, under normal conditions, is always below 100 cm/sec. The change in TPV is minimal.[34] TPV measurements at the level of pulmonary valve are lower than at the level of the aortic valve, suggesting the blood pressure in the pulmonary artery is slightly higher than in the ascending aorta.[26] Quantitative measurements reveal the RCO is higher than the LCO and that the RCO/LCO ratio remains constant from 20 weeks onward with a mean value of 1.3.[1,34] This is lower than that reported in fetal sheep (RCO/LCO = 1.8) and may reflect the higher brain weight of humans requiring a higher left cardiac output.[34]

The ductus arteriosus PV increases linearly with advancing gestation, and its values represent the highest velocities in the fetal circulation under normal conditions.[36] Ductal constriction is suggested by a systolic velocity measurement greater than 140 cm/sec in conjunction with a diastolic velocity greater than 35 cm/sec or a pulsatility index value less than 2.[36]

CARDIAC STRUCTURAL ANOMALIES

Septal Defects

Septal defects are the most common CHDs with an estimated incidence of about 0.5 per 1000 live births.[2] They are either atrial, ventricular, or AV septal in location.

Isolated atrial septal defects have been diagnosed in utero, but the diagnosis remains difficult because of the foramen ovale. Echocardiographic diagnosis requires demonstration of either the absence or the reduction in the dimension of the foramen ovale valve flap (ostium secundum defect). Dropout of echoes at the level of the outlet of the atrial septum in a perpendicular view suggests the presence of an ostium primum defect or an incomplete form of AV canal.

Atrial septal defects do not impair fetal cardiac function and do so only rarely in the neonate. However, atrial septal defects are associated with other cardiac malformations (coarctation and conotruncal anomalies), an abnormal karyotype (e.g., trisomy 21), and genetic syndromes (e.g., Holt-Oram syndrome).

Ventricular septal defects are classified by their location in the septum: perimembranous, inlet, trabecular, and outlet. Perimembranous defects are most common (80%) and involve the membranous portion of the interventricular septum just below the aortic valve (Fig. 16–23). They can extend a variable degree into the muscular portion. Septal defects are not responsible for fetal compromise. Because the pressure of both ventricular cavities is similar, even large defects cause but small bidirectional shunts that do not affect intracardiac hemodynamics. The great majority of infants

with interventricular septal defects are asymptomatic in the neonatal period. It is calculated that a quarter of the ventricular septal defects close spontaneously during intrauterine life[44] and another third of the remaining ones close during the first year of life.[45]

Echocardiographic diagnosis relies on the demonstration of echo dropout in the interventricular septum (see Fig. 16–23). Care is necessary to avoid artifact due to the inherent limitations in the lateral resolution of ultrasound. The diagnosis is made only when the ultrasound beam is perpendicular to the septum (see Fig. 16–20). Color Doppler is useful for demonstrating the shunt between ventricles (Fig. 16–24). This is particularly clear when the outflow of one ventricle is obstructed (unidirectional shunt) (see Fig. 16–21). The application of new-generation equipment with high-resolution color and power energy Doppler (in which flows are independent of the angle of insonation) are

also helpful for detection of isolated ventricular septal defects.[32] Further the use of 4D ultrasonography with tomographic reconstruction seems to improve diagnosis[46] (Fig 16–25). The prognosis for an infant with an isolated interventricular septal defect is good. However, it is essential that other cardiac and extracardiac anomalies be carefully excluded and a normal fetal karyotype documented.[4,5]

Abnormal development of both the atrial and the ventricular septa is described as an AV septal defect—either the endocardial cushion or an AV canal form. The typical appearance is of a single, AV valve opening above and bridging the two ventricles (Fig. 16–26). The common AV valve may be incompetent, with systolic regurgitation leading to fetal heart failure and hydrops. AV septal defects are frequently associated with fetal aneuploidy (50% of the cases, particularly trisomy 21),[5] cardiac isomerism (cardiosplenic syndromes), and other extracardiac anomalies.[4]

Hypoplastic Left Heart

A small left ventricle secondary to mitral and/or aortic stenosis/atresia characterizes the hypoplastic left heart syndrome. Blood flow to the head and coronary artery is supplied by retrograde flow through the ductus arteriosus and the aortic arch. The incidence of hypoplastic left heart syndrome approximates 0.16 per 1000 live births and constitutes about 10% of infants with CHDs[47] and up to 20% of those detected in utero.[48]

Echocardiographic diagnosis begins with the demonstration of a small left ventricle (Fig. 16–27). The ascending aorta is severely hypoplastic, and the right atrium, right ventricle, and pulmonary artery are relatively enlarged. Color and pulsed Doppler flow examination may reveal absent flow from the left atrium to the left ventricle (mitral atresia) (see Fig. 16–25) and retrograde flow in the aortic arch.

A hypoplastic left heart is well tolerated in utero, and congestive heart failure is unusual. However, the postnatal prognosis is poor. This lesion is responsible for 25% of cardiac deaths during the first week of life.[49,50] Surgical options are limited. Norwood's three-stage operation was developed to correct this disease, and although the reported survival in selected centers reaches 60%, the long-term prognosis for these children after three procedures remains uncertain.[51,52] Cardiac transplant programs for the neonate have also been developed, but the long-term results of these too are disappointing.[53]

Pulmonary Atresia with Intact Ventricular Septum

Pulmonary atresia with intact ventricular septum makes up 3% to 4% of neonatal and prenatal series.[2,48] Two forms of pulmonary atresia are found in the fetus. In about 75%, the right ventricle is hypoplastic,[48] and in the remaining 25%, the right ventricle is enlarged (Fig. 16–28).[48] In the former instance, the tricuspid valve is atretic (see Fig. 16–26); in the latter, it is typically insufficient (Fig. 16–29). Echocardiographic diagnosis relies on the demonstration of a small pulmonary artery with an atretic pulmonary valve. The four-chamber view is abnormal and shows variable degrees of right ventricular hypoplasia.

Color and pulsed Doppler studies reveal retrograde flow in the pulmonary artery and either absent (atresia) or retrograde flow (insufficiency) across the tricuspid valve (see Figs. 16–28 and 16–29). Heart failure and hydrops often develop with tricuspid regurgitation. Anomalies of the

FIGURE 16–28

coronary arteries are common and can complicate surgical correction. Extracardiac anomalies are unusual.

Factors that affect prognosis are strictly related to ventricular size and the presence of coronary fistulas.[54] If a postnatal two-ventricular repair can be achieved, the long-term outcome can be good. Conversely, if the right ventricle is severely hypoplastic and addressed therapeutically with a Fontana procedure (placement of a circuit between the right atrium and the main pulmonary artery),[55] the action is considered palliative, associated with several short- and long-term complications.[56]

Outflow Tract Obstructions

Aortic Stenosis and Coarctation of the Aortic Arch

Aortic stenosis is found in 0.04 per 1000 live births[2] and may be supravalvular, valvular, or subvalvular.[57] The pressure in the left ventricle is increased. In severe cases, the left ventricular pressure overload decreases coronary perfusion, leading to subendocardial ischemia, secondary endocardial fibroelastosis, and in utero congestive heart failure. The echocardiographic diagnosis requires demonstration of a small and abnormal aortic valve, usually associated with an enlarged, poststenotic ascending aorta (Fig. 16–30). Doppler examination will show increased flow velocities in the ascending aorta distal to the stenotic site and, in the severe cases, regurgitation across the mitral valve (see Fig. 16–30).

Several fetal medicine specialists have attempted in utero balloon dilation of the stenotic aortic valve by transthoracic puncture of the fetus. In several instances, the procedure was a technical success with a reduction in severity[58,59]; long-term quality survival has been elusive. Although prenatal intervention might be an option, the selection of suitable cases is difficult as is the timing of the procedure.[60]

FIGURE 16–30

C, Pulsed Doppler shows high systolic velocity (>200 cm/sec). *D*, Mitral regurgitation (*blue jet*) is also evident by color Doppler. LV, left ventricle; RV, right ventricle.
FIGURE 16–31

A, Four-chamber view shows a reduction of the left ventricle due to aortic coarctation. *B*, High definition (HD) color flow demonstrated the small caliper of the aortic arch and the presence of reverse flow (*arrow*), demonstrating retrograde perfusion from the ductus arteriosus.

Coarctation is a narrowing of a portion of aortic arch, usually between the left subclavian artery and the ductus arteriosus. In some cases, the narrowing encompasses the proximal aortic arch and is defined as a hypoplastic aortic arch or, if completely interrupted, an interrupted aortic arch (Fig. 16–31). The incidence approximates 0.18 per 1000 live births and is frequently associated with other cardiac anomalies (≤90%) including ventricular septal defect, aortic stenosis, and transposition of the great arteries.[2,61] Extracardiac anomalies including diaphragmatic hernia, renal agenesis, esophageal atresia, Turner's syndrome, and the chromosome 22q11 deletion

syndrome (interruption of the aortic arch) are also frequent.

Coarctation has no significant impact on intrauterine hemodynamics because it is the right ventricle that mainly supplies the descending aorta via the ductus arteriosus. Rather, symptoms develop in the neonatal period. The only in utero echocardiographic evidence of coarctation may be a relatively enlarged right ventricle compared with the left ventricle. Additional signs of coarctation include an echogenic shelf in the aortic lumen at the level of the isthmus, a relative decrease in the diameter of the aorta compared with the pulmonary artery, and a hypoplastic arch (see Fig. 16–31).[61] Hypoplasia of the left ventricle may develop in more severe cases (hypoplastic arch or interruption).[45] The surgical mortality reported for coarctation of the aorta is lower than 10%. However, the surgical mortality may be higher because the surgical approach is similar to that for the hypolastic left heart syndrome, particularly if there is a significant left heart obstruction.[46,62]

Pulmonary Stenosis

Pulmonary stenosis occurs in about 0.9 per 1000 live births and is generally thought to result from fusion of the pulmonary valve leaflets.[2] Associated cardiac and extracardiac anomalies are less common than aortic stenosis but can include atrial septal defects and total anomalous pulmonary venous return. It is typically present in Noonan's syndrome.

The relevant hemodynamic concerns for pulmonary stenosis are the same as those for aortic stenosis. Right ventricular pressure is increased proportional to the degree of stenosis. The resulting ventricular wall hypertrophy can cause tricuspid regurgitation. The echocardiographic diagnosis relies on identification of a small, sometimes thickened, pulmonary valve with a characteristic abnormal movement (doming).[63] Poststenotic enlargement of the pulmonary artery is common. Doppler interrogation reveals increased velocities at the level of the pulmonary valve (Fig. 16–32), frequently associated with tricuspid insufficiency. The progression from stenosis to atresia in utero is well documented.[64] The prognosis is usually good, and postnatal balloon valvuloplasty is the only treatment usually required.

Conotruncal Malformations

Conotruncal malformations are a heterogeneous group of defects affecting the connection between the ventricles and the great arteries. They constitute 20% to 30% of all cardiac anomalies.[2] Conotruncal malformations include transposition of the great arteries, tetralogy of Fallot, double-outlet right ventricle, and truncus arteriosus. Unfortunately, these lesions are frequently missed during the routine obstetric sonographic examination if it is limited to the four-chamber view because the ventricles are usually similar in size. Undiagnosed conotruncal malformations can lead to neonatal emergency with considerable morbidity and mortality. However, the outcome is generally good if promptly recognized and early corrective surgery undertaken.

Transposition of Great Arteries

The prevalence of transposition approximates 0.2 per 1000 live births.[2] The complete form, characterized by AV concordance and ventricle-arterial discordance is most common. The aorta arises from the right ventricle and the pulmonary artery from the left ventricle. Either a ventricular septal defect or pulmonary stenosis is present in about half, though complete transposition is only rarely associated with extracardiac anomalies or an abnormal karyotype. Echocardiographic diagnosis requires demonstration that the left ventricle in the long-axis view connects to a great vessel with a posterior course that bifurcates (pulmonary artery) (Fig. 16–33). In the short-axis view, the vessel originating from the right ventricle has an upward course and gives rise to the brachiocephalic vessels (see Fig. 16–33).

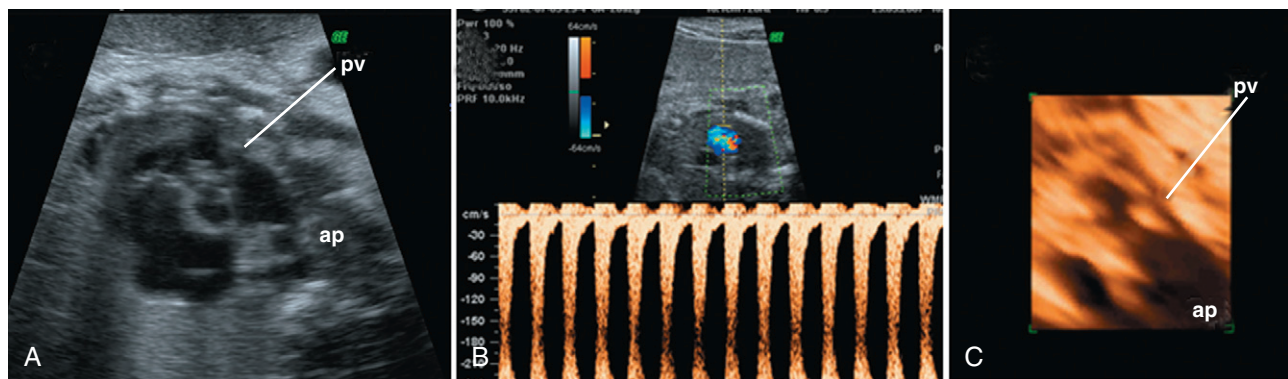
The parallel circulatory model of the fetus allows normal development, and hemodynamic compromise is unusual in utero. However, newborns may be cyanotic and deteriorate rapidly depending on the size of the shunt at the level of the foramen ovale or across any associated ventricular septal defect. Identification of a small foramen ovale prenatally might be an indication for balloon atrial septostomy (Rashkind's procedure) immediately after birth. Cardiac surgery consists of switching the great arteries and is usually performed during the neonatal period. The survival rate is 85% to 90%, particularly when the diagnosis is performed prenatally.[65]


FIGURE 16–32

A, Correct transposition of the great artery with intact septum with an apparently normal four-chamber view (A). The study of outflow tracts demonstrated the pulmonary artery (PA) (branching vessel) originating from the left ventricle (LV) (B) and the aorta (AO) originating from the anterior right ventricle (RV) (C).
FIGURE 16–34
Tetralogy of Fallot. A, Presence of a ventricular septal defect with the aorta (AO) overriding the right (RV) and left (LV) ventricles. B, Color Doppler demonstrates the presence of the ventricular septal defect with the Y sign.

Tetralogy of Fallot

Tetralogy of Fallot occurs in 0.4 in 1000 live births[2] and includes stenosis of the infundibulum of the pulmonary artery, a ventricular septal defect, an aortic valve overriding the interventricular septum, and hypertrophy of the right ventricle that usually develops after birth. The pulmonary valve is atretic in about 20%, a condition described as pulmonary atresia with ventricular septal defect. Tetralogy of Fallot is associated with other cardiac defects such as an AV canal (4%) or pulmonary valve absence (1%). Extracardiac anomalies (particularly chromosomal) are frequent.

The echocardiographic diagnosis requires demonstration of an enlarged aortic root overriding the intraventricular septum (Fig. 16–34A),[61] an intraventricular septal defect (see Fig. 16–34), and a small pulmonary valve. Color-flow mapping will reveal systolic jets from both the right and the left ventricle into the overriding aorta with a Y shape (Y sign) (see Fig. 16–34B). Cardiac failure in utero or during the first days of life is infrequent. In the absence of extracardiac defects, the survival rate after corrective surgery approximates 95%.[66] This percentage is lower when associated with pulmonary atresia[61]; in that instance, the diameter of any available pulmonary artery is crucial.

Double-Outlet Right Ventricle

The prevalence of double-outlet right ventricle approximates 0.32 per 1000 live births.[2] It is characterized by a ventricular septal defect associated with an aorta and a pulmonary artery that originates from the right ventricle anterior to the ventricular septum (Fig. 16–35). The position of the great arteries relative to each other may vary from normal to transposition (see Fig. 16–35). Associated anomalies include mitral valve atresia, AV canal, and pulmonary

Double-outlet right ventricle. Both great vessels originate from the right ventricle (RV) and a wide septal defect is present (*). However, there is an associated transposition of the great vessels and the aorta (AO) is posterior to pulmonary artery (AP).

Truncus arteriosus. A single vessel (T) overrides the two ventricles. LV, left ventricle; RV, right ventricle.
stenosis. Extracardiac and chromosomal anomalies are common. Distinguishing double-outlet right ventricle from tetralogy of Fallot can be difficult when the relationship between the great arteries is normal and pulmonary artery stenosis is present.

The hemodynamic effects of this malformation are similar to those of tetralogy of Fallot. Cardiac decompensation is unusual in utero as well as in the early neonatal period. Long-term survival after corrective surgery is good (70%–80%) in the absence of associated anomalies.[67]

Truncus Arteriosus

Truncus arteriosus complicates approximately 0.01 in 1000 live births.[2] It is characterized by a single great artery, usually larger than the aorta, arising from both ventricles and overriding the ventricular septum. The truncus supplies the systemic, coronary, and pulmonary circulations. A ventricular septal defect may be present (type A) or absent (type B). Type A has four subclasses according to the origin of the pulmonary arteries.[68] Associated intracardiac anomalies are common and include mitral atresia and aortic arch hypoplasia and interruption (type A4). Extracardiac malformations are also common.

The echocardiographic diagnosis is based on the identification of a single great vessel overriding both ventricles whose dimensions are usually larger than the aorta (Fig. 16–36). The diagnosis requires that the pulmonary arteries originate from the truncus. Distinguishing truncus arteriosus from a tetralogy of Fallot with an atretic pulmonary valve may be difficult in utero.

As with other conotruncal malformations, truncus arteriosus is not associated with cardiac decompensation in utero, but it may occur during the first days of life. Surgical correction is often complex, because the dysplastic truncal valve must be transformed into an aortic valve and a circuit created from the right ventricle to the pulmonary arteries. The survival rate at 10 years is less than 80%.[68]
Tumors of the Heart

Congenital tumors of the heart are extremely rare with an incidence estimated at 0.1 per 1000 live births. The most common is rhabdomyoma. These tend to be multiple and involve the septum. Cardiac tumors are usually isolated, but are present in 50% to 86% of fetuses with tuberous sclerosis. Frequently, they are the only detectable sign of tuberous sclerosis in utero.

The echocardiographic diagnosis is based on finding one or more hyperechogenic masses within the heart (Fig. 16–37). They can create mechanical obstruction to ventricular inflow and outflow with the subsequent development of congestive heart failure. Cardiac dysrhythmias are also seen. The postnatal prognosis depends on the presence of tuberous sclerosis. Surgical excision is necessary in selected cases. Intracardiac tumors not associated with tuberous sclerosis may also shrink postnatally and remain asymptomatic.[69]

DOPPLER EXAMINATION OF THE STRUCTURALLY ABNORMAL HEART

Real-time ultrasonography remains the primary tool for the examination of the fetal heart. However, color and pulsed Doppler flow studies are essential for a complete study. The demonstration of normal blood flow direction, a lack of turbulence, and normal velocity waveforms confirms "normal flow" in the cardiac structures and supports the impression of an anatomically and functionally normal heart. Conversely, Doppler studies may reveal abnormal flow patterns in a heart that on real-time ultrasonography appears to be structurally normal, indicating the need for additional study.

FIGURE 16–37
Apical four-chamber view shows a rhabdomyoma (*) in the right atrium (RA).
Valve Regurgitation

Valve regurgitation is characterized by bidirectional flow across the valve on Doppler interrogation. There is unidirectional flow from the atrium to the ventricle during diastole with regurgitant flow during systole. Regurgitation is uncommon across the fetal semilunar valves, where if it occurs, the regurgitation occurs during diastole.

Valve regurgitation may be either primary from valve dysplasia (e.g., tricuspid dysplasia,[70] or secondary due to increased ventricular pressure (e.g., pulmonary atresia or stenosis with intact septum) or papillary muscle dysfunction (cardiomyopathy).[71] The diagnosis of AV valve regurgitation requires demonstration of an abnormal color jet from the ventricle into the atrium during systole when imaged in the apical four-chamber view (see Figs. 16–29 and 16–30). The amount of regurgitation is proportional to the peak velocity of the regurgitant jet. High velocities can cause frequency aliasing on pulsed Doppler. As a result, continuous-wave Doppler is preferable when measuring the peak velocities. Although the amplitude of the jet is directly related to the pressure gradient across the valve by the Bernoulli equation ($P = 4V2$), it should not be used to quantify the severity of the disease because the pressure is influenced by both the severity of the obstruction and the ventricular contractility. A severe obstruction can be associated with a low-amplitude jet if ventricular contractility is too impaired to generate an adequate pressure gradient. Likewise, a low-grade stenosis associated with a normally functioning ventricle can generate a high-velocity jet in the absence of hypertension.

The duration of the regurgitant jet is of particular clinical importance.[70] Regurgitation limited to early systole is typically benign, whereas a holosystolic jet suggests severe hemodynamic compromise. Here, venous return is impaired, venous hypertension develops, and heart failure/hydrops may result.

Normal Flow Direction with High Velocities

This pattern of flow may result from hemodynamic adaptation to a hypoplastic or atretic structure in the contralateral side. For example, the flow across the tricuspid and pulmonary valves is increased in the presence of a hypoplastic left ventricle. Likewise, the flow across the mitral and aortic valves is increased in the presence of pulmonary atresia. The diagnosis is made when pulsed Doppler interrogation reveals a normal velocity waveform associated with increased PV and TVI.

Increased velocities can also occur with stenotic lesions such as pulmonary or aortic stenosis. In this setting, the flow is turbulent and the velocities high (see Figs. 16–30 and 16–32). Color Doppler allows for the identification of turbulent flow, and the velocity waveforms obtained with pulsed or continuous-wave Doppler reveal an irregular profile and a high PV. However, the PV is not used clinically to define the severity of stenosis because it also reflects ventricular contractility.

Absent Filling

No flow in a cardiac chamber suggests atresia of either the mitral (left ventricle) (see Fig. 16–27) or the tricuspid (right ventricle) valves (see Fig. 16–28). The equipment must have the correct settings and the angle of insonation must parallel the expected direction of flow (apical four-chamber view). Further, the gain, pulse repetition frequency, and filter must be correctly set to avoid artifact. Flow in the contralateral ventricle (apical four-chamber view) is proof of proper technique.

Abnormal Flow Direction

Because of the parallel nature of the fetal circulation, arterial blood can flow in a reverse direction if the flow from one ventricle is either absent or severely reduced. Examples include hypoplastic left heart or a severe coarctation in which the aortic arch is perfused in a retrograde fashion from the ductus arteriosus (see Fig. 16–31). In this way, the right ventricle can supply the cerebral and coronary circulations. Conversely, both pulmonary atresia and severe ductal stenosis are associated with reversed aortic arch flow because the pulmonary circulation depends on the left ventricle (see Fig. 16–19). Such abnormal hemodynamics are particularly important after birth.

Abnormal flow direction may be detected at the level of the foramen ovale or at the level of a ventricular septal defect, suggesting the presence of a malformation that alters the pressure equilibrium between the right and the left heart chambers. Examples include reverse direction flow (left to right) through the foramen ovale with a hypoplastic left heart or a unidirectional jet across an interventricular septal defect when there is an outflow tract lesion.

Advantages of Doppler for the Evaluation of Fetal Heart Diseases

An investigation of the cardiac flows helps to
1. Define the nature of the cardiac malformation. Copel and coworkers[72] observed retrospectively that color

Doppler was essential for establishing the correct diagnosis in 29%, helpful in 47% and neither helpful nor misleading in the remaining fetuses. We analyzed prospectively 145 fetuses with CHD and found that the combination of color and spectral Doppler was essential for the diagnosis in 34 fetuses (23%, mainly outflow tract stenosis or complex heart diseases [isomerism, double-outlet right ventricle with atresia of one semilunar valve]), useful in 62 fetuses (42%, mainly CHD complicated by valve atresia or outflow tract obstruction causing abnormal flow direction), and not helpful in the remaining 49 fetuses (34%, mainly complete AV canal and ventricular septal defects).[1]

2. Evaluate the hemodynamic consequence of CHD. The consequences of the sonographically same CHD may range in utero from no effect to cardiac failure and hydrops. This wide range of hemodynamic effects reflects the severity of the primary lesion, the presence of associated anomalies, the cardiac rhythm, and any impairment of ventricular function. The detection of regurgitation at the level of the AV valve by Doppler is a particularly useful predictor of hydrops. The presence of holosystolic, tricuspid regurgitation either isolated or associated with mitral regurgitation predicts the development of hydrops fetalis with subsequent poor prognosis. Study of the systemic venous circulation also provides a valuable index of the overall cardiac performance. Although there is no general agreement on the significance of the venous indices and on the vessel of choice, it is our experience that the velocity waveforms from IVC show a higher correlation with cardiac function than either the DV or the umbilical vein.[22] This information is helpful as the health care team formulates a plan, predicts prognosis, and counsels the parents (see also Chapter 11).

3. Monitor the evolution of CHDs. Doppler echocardiography is not only helpful in establishing the correct diagnosis but also valuable longitudinally to follow the natural history and progression of a malformation. One example is the evolution of pulmonary stenosis or atresia in fetuses with primary TR, which is presumably due to the lack of forward flow in the pulmonary artery. This has been described in fetuses with TR due to a dysplastic tricuspid valve and in fetuses with presumed cardiac overload secondary to twin- twin transfusion syndrome.[73] Similarly, a progressive increase in the severity of pulmonary stenosis of tetralogy of Fallot up to atresia is documented.[74,75] Knowledge of the pathologic evolution can be useful for the timing of delivery and/or for developing prenatal treatments such as balloon valvuloplasty in fetuses with deteriorating function.

PLANNING NEONATAL MANAGEMENT

The hemodynamic information gained from antenatal Doppler studies help predict problems after birth. For example, the neonate with a critical stenosis or atresia at the level of the outflow tract (e.g., hypoplastic left heart, pulmonary atresia with intact septum) is ductal-dependent after birth and will require continuous intravenous prostaglandin E$_1$. Closure of the ductus would have disastrous

consequences because either the systemic (left obstruction) or the pulmonary (right obstruction) blood flow depends on ductal patency. Another example is the detection of a small (restrictive) foramen ovale in a fetus with complete transposition of the great arteries and an intact septum. Here, it can be anticipated the shunt between the two circulations will be insufficient after birth, with cyanosis and rapid deterioration expected. A pediatric cardiologist should be present at delivery to promptly perform a balloon septostomy (Rashkind's procedure) if needed. Advanced knowledge of these issues permits a planned delivery at a tertiary center where the facilities exist to optimize outcome.[76]

Management Options for the Fetus with Congenital Heart Disease

Cardiac malformations are the most common birth defects, and experienced fetal diagnosis units can detect a high percentage of major malformations (i.e., lesions typically requiring surgical treatment). Once the diagnosis of a cardiac malformation is made, the following steps are recommended.

Prenatal

CORRECTLY DEFINE THE MALFORMATION

A plan of management should be formulated in concert with a multidisciplinary team that includes a fetal medicine expert and a pediatric cardiologist.

SEARCH FOR ASSOCIATED STRUCTURAL ANOMALIES

Extracardiac anomalies and a normal karyotype are common in fetuses with congenital heart defects (10% in our series). A detailed ultrasonographic evaluation in an experienced fetal medicine center is mandatory. The presence of an associated anomaly may well influence the prognosis and postnatal management.

SEARCH FOR ASSOCIATED CHROMOSOMAL ANOMALIES

A fetal karyotype is mandatory because the result will alter management. The choice of the technique is based on the gestational age of the fetus and the experience of the center (see Chapter 9). Chromosomal abnormalities are present in 10% to 40%.[5] In our prospective series of 489 fetuses with CHDs, autosomal trisomy (trisomy 18, 13, and 21) and Turner's syndrome (45XO) were the most common abnormalities and accounted for 19.4% (see Table 16–2). The incidence of aneuploidy varies with the type of malformation, being extremely high with some (e.g., AV canal) or unusual with others (e.g., transposition of a great artery). This information should be part of the patient counseling.

A detailed study of chromosome 22 is indicated in fetuses with a conotruncal malformation because a microdeletion at the critical region 22q11,2 occurs in a high frequency of fetuses with this anomaly. The 22q11,2 syndrome (also called in the past CATCH 22)[77] consists of several genetic syndromes including velocardiofacial syndrome, Di George's syndrome, Opitz G/BBB syndrome, and conotruncal anomaly face syndrome. Patients with these syndromes have some or all the following features:

Mental retardation, learning disabilities and psychiatric illness.

CHDs: mainly conotruncal defects.

Palatal anomalies: overt and submucous cleft palate, velopharyngeal insufficiency.

Facial anomalies: long face with prominent nose, malar hypoplasia, retrognathia, and minor ear anomalies.

Thymus aplasia or hypoplasia associated with hypocalcemia and immunologic deficiency.

The estimated prevalence of this deletion in the general population is 1 in 4500,[78] which makes the 22q11.2 deletion syndrome the second most common genetic condition after Down syndrome. The prevalence of this syndrome in fetuses with conotruncal anomaly approximates 20%[24] and cannot be detected by routine karyotypic analysis. It is necessary to use either quantitative hybridization or fluorescence in situ hybridization (FISH) techniques that are now standard in most genetic laboratories. It is also important to extend the genetic diagnosis of affected fetuses to the parents, because inherited microdeletions occur in 30% with the remainder being de novo. Because the transmission is autosomal dominant, a parent with the syndrome has a 50% risk of transmitting the deletion to their offspring.[78]

COUNSELING THE PARENTS

The parents are formally counseled by the care team after all useful information is acquired (correct and complete diagnosis of the malformation, presence or absence of associated structural and/or chromosomal abnormalities). It is essential that the care team include, when possible, a fetal medicine physician, a pediatric cardiologist, and a cardiac surgeon. They should describe the malformation, the possibility of surgical correction, the chance of short- and long-term survival, and the quality of life after the correction. Further information on the possible neurologic complications after the surgical procedures should be provided. Indeed, malformations requiring deep hypothermic cardiopulmonary bypass surgery may be associated with neurologic impairment in up to 10% of the cases.[79] After complete information has been provided and all questions asked and answered, the parents should be allowed freedom of choice to continue or end the pregnancy. It is particularly helpful to make an appointment a few days later to discuss their thought process or decision and, when available, to offer psychological support.

PRENATAL MONITORING

The development of the malformation should be followed serially, particularly by using Doppler ultrasonography every 2 to 4 weeks. The interval is based on the likelihood of an in utero complication developing (e.g., 4 wk for a transposition of great artery, 2 wk for a tetralogy of Fallot). Furthermore, it is important in the third trimester to monitor fetal growth, amniotic fluid volume, Doppler velocity waveforms from peripheral fetal vessels, and fetal heart rate patterns, because the prevalence of suboptimal growth and acute fetal distress is increased.

PLACE, TIMING, AND METHOD OF DELIVERY

The need to deliver in a tertiary referral center varies with the diagnosis and upon the local resources and geographic constraints. It is important to predict before birth the type of assistance that may be needed. This may range from simple observation in the nursery (e.g., small ventricular septal defect) to assistance in the neonatal intensive care unit or pediatric cardiology unit (e.g., ductal-dependent CHD, hydrops, immaturity) to immediate postnatal treatment (e.g., balloon septostomy in transposition of a great artery with small foramen ovale).

Most fetuses with CHD tolerate labor well in the absence of uteroplacental dysfunction. There is no a priori indication for cesarean delivery. Furthermore, it is rarely necessary to induce labor early for a cardiac reason, though it may facilitate postnatal management if the delivery is planned between 38 and 40 weeks.

Postnatal

Postnatal management includes further cardiac evaluation by the pediatric cardiologist to confirm the diagnosis and to assess the hemodynamic environment. The neonate is stabilized and the treatment plan activated (interventional catheterization or surgery). Continued communication with the parents during the inevitable additional postnatal diagnostic steps and on the therapeutic strategies is extremely important.

SUMMARY OF MANAGEMENT OPTIONS
Fetal Cardiac Abnormalities

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
~1% risk of congenital heart defects in pregnancy.	III/B	2,3
Counsel women at risk (see Table 16–1).	III/B	19
Prenatal		
Screening		
Increased nuchal translucency with normal karyotype indicates higher risk of cardiac anomaly and need of careful cardiac scan in second trimester.	III/B	7,8

SUMMARY OF MANAGEMENT OPTIONS
Fetal Cardiac Abnormalities—cont'd

Management Options	Evidence Quality and Recommendation	References
Routine level 2 anomaly scanning at 20 wk should include situs and orientation, apical four-chamber view, lateral four-chamber view, left outflow tract, right outflow tract, three-vessel view, and venous return.	III/B	20–22
General		
Refer all high-risk pregnancies (see Table 16–1) to specialized center for complete fetal echocardiography (see Table 16–2)	GPP	
Meticulous visualization of the fetal heart during routine ultrasound scan at 18–20 wk of gestation, especially looking for the four-chamber view.	III/B	19
After Diagnosis of a Fetal Cardiac Abnormality		
Multidisciplinary team includes specialist obstetrician, pediatric cardiologist, and where appropriate, cardiac surgeon. Establish clear plan of management.	—/GPP	—
Define the defect and the severity of hemodynamic compromise by Doppler ultrasonography.	III/B	19
Search for other cardiac and extracardiac anomalies.	IV/C	4
Offer fetal karyotyping including 22q deletion.	IV/C	4
	III/B	5
Multidisciplinary counseling and psychological support for parents: • Give full explanation of all findings. • Discuss possible treatments (medical and surgical) and their implications and complications, prognosis (short- and long-term), and impact on neurodevelopment. • Offer further meeting/discussions. • In most cases, the only options are to continue with pregnancy or termination.	—/GPP	—
In Continuing Pregnancies		
Serial monitoring of • Fetal cardiac function by real-time and Doppler echocardiography (progression of congenital heart disease). • Fetal growth (IUGR common). • Fetal well-being by NST, biophysical profile, Doppler of peripheral vessels (avoid fetal distress).	—/GPP	—
Labor/Delivery		
Delivery at tertiary center with the appropriate obstetric, pediatric, and cardiologic facilities required by the type of cardiac malformation.	III/B	65
Vaginal delivery usually possible.	—/GPP	—
Close monitoring of fetal condition (continuous fetal heart rate monitoring), though this may not be possible if arrhythmia.	—/GPP	—
Consider planned delivery after 38 weeks for cardiac malformations that may require intensive care after birth.	III/B	76
Postnatal and Neonatal		
Stabilize the neonate, confirm the diagnosis by detailed echocardiography, and plan subsequent management.	—/GPP	—
After termination of pregnancy or perinatal death: • Obtain postmortem examination whenever possible. • Arrange for bereavement counseling.	—/GPP	—
Discuss implications for future pregnancies with parents.	—/GPP	—

GPP, good practice point; IUGR, intrauterine growth restriction; NST, nonstress test.

Fetal Craniospinal and Facial Abnormalities

ROBIN B. KALISH and FRANK A. CHERVENAK

Videos corresponding to this chapter are available online at www.expertconsult.com.

INTRODUCTION

Craniospinal and facial defects are among the most commonly diagnosed congenital anomalies and have a profound impact on survival, physical appearance, and function. Because the central nervous system (CNS) is the earliest organ system to form and facial development is completed near the end of embryogenesis, teratogenic exposures such as drug ingestion, maternal illness, and infection may cause craniospinal or facial malformations at any time during embryogenesis. Genetic syndromes and chromosomal abnormalities frequently affect the development of the neuraxis and face. Further, the fetal brain continues to develop throughout gestation. Consequently, it is vulnerable to disorders of growth as well as vascular, infectious, and traumatic insults.

OPEN NEURAL TUBE DEFECTS: ANENCEPHALY, CEPHALOCELE, AND SPINA BIFIDA

General

Neural tube closure occurs in the third to fourth weeks after fertilization. Fusion begins in the region of the fourth somite and then extends both rostrally and caudally. Closure in the region of the developing head and sacrum is completed approximately 24 and 26 days after conception, respectively. Neural tube defects most likely result from either a primary overgrowth of neural tube tissue within the line of closure or a failure of induction by adjacent mesodermal tissues that interrupt closure. Depending on the timing and the extent of the interruption, defects may occur at both cranial and caudal ends of the neural tube. Large or small and continuous or noncontinuous regions of the neuroaxis can be affected. Anencephaly is a lethal disorder in which the brain and the overlying calvarium are absent. It is thought to result from failure of the entire rostral portion of the neural tube to close. Less extensive failure of closure in the rostral region results in cephalocele. Failure of neural tube closure in the more caudad regions results in spina bifida.

Open neural tube defects (ONTDs) are multifactorial in origin, arising from a combination of genetic and environmental factors that exhibit a threshold effect. Thus, the incidence of ONTD is highly variable, depending on geographic location, ethnicity, and gender. In particular, the incidence of ONTD is reportedly higher in Hispanic patients,[1,2] in female fetuses,[3] and in areas with low maternal folic acid intake.[4] Additional high risk groups include women with insulin-requiring diabetes,[5] obese women,[6,7] women with a seizure disorder taking anticonvulsants including valproic acid,[8] women consuming high doses of vitamin A,[9] and women with folate or vitamin B_{12} insufficiency.[10] Women who themselves are affected, or who have had an affected infant or sibling, have a higher incidence of ONTD than the general population. ONTDs also may be associated with aneuploidy and other rare genetic syndromes.[11]

Diagnosis

Screening for ONTD may be either biochemical or ultrasonographic. Maternal serum α-fetoprotein (MSAFP) screening does not detect all cases of ONTD, because the MSAFP concentration can be normal if the lesion is predominantly skin-covered. Amniocentesis for the measurement of amniotic fluid α-fetoprotein (AFP) and the detection of acetylcholinesterase (AChE) is usually no longer required but remains an adjunct to ultrasonography when the MSAFP is elevated but no defect is visualized. Most ONTDs can be definitively diagnosed ultrasonographically, even as early as the first trimester,[12] and do not require amniocentesis.[13] The use of three-dimensional (3D) ultrasound and fetal magnetic resonance imaging (MRI) is reputed to assist in the detection and localization of ONTDs in high risk patients.[12,14–16]

Anencephaly

The antenatal ultrasonographic diagnosis of anencephaly is based on the absence of the fetal calvaria, the domelike portion of the cranial vault. A mass of thin-walled channels, known as the *area cerebrovasculosa*, is often seen protruding from the base of the skull above the orbits (Fig. 17–1). Though easily diagnosed during the second and third trimesters, first-trimester diagnosis of anencephaly is sometimes difficult because the normal immature brain may be difficult to differentiate from the area cerebrovasculosa. However, the bony structures of the skull above the orbits should be visualized by 10 weeks' gestation. Other diagnoses

FIGURE 17–1
Coronal sonogram of the fetal head demonstrates anencephaly (note the absent cranium and small neurogenic bundle seen above the orbits).

FIGURE 17–2
Sonogram of the first-trimester fetal head demonstrates acrania.

FIGURE 17–3
Encephalocele. *A*, Sagittal sonogram of the fetal head demonstrates posterior encephalocele with herniated brain protruding through the calvarium. *B*, Transverse view of the fetal head demonstrates a small posterior skull defect consistent with cephalocele. *C*, Defect in the posterior skull with herniated brain tissue and membranes.

should be excluded; in severe microcephaly, the bones of the skull are present but might be difficult to see ultrasonographically. In the early amnion-rupture sequence, constricting bands may prevent the normal formation of the skull. In this instance, the malformation is usually asymmetrical and brain tissue is present. Amniotic bands may produce a spectrum of abnormalities from anencephaly to asymmetrical defects. Encephalocele may simulate anencephaly until a brain-filled sac is identified. Lastly, acrania, in which there is a normally formed brain with an absent skull, is often difficult to distinguish from anencephaly and, indeed, can be an early phase in the development of anencephaly (Fig. 17–2).

Cephalocele

A cephalocele resembles a saclike protrusion from the head not covered with bone. The malformation is termed an *encephalocele* when the brain has herniated into the sac. In contrast, a *cranial meningocele* does not contain brain substance. Although large amounts of brain tissue are readily seen on ultrasound, the precise diagnosis can be difficult because smaller amounts may be undetectable by

ultrasonography (Fig. 17–3).[17] The contents of the herniated sac are typically heterogeneous. The position of the defect can be determined using the bony structures of the face, spine, and when possible, the midline echo of the brain for orientation. Most cephaloceles are occipital, but they may also be parietal, frontal, or nasopharyngeal.[18] The incidence of anterior lesions is considerably higher in Asia.[19,20] Defects away from the midline or in other atypical locations are suggestive of the amnion-rupture sequence. The diagnosis

of cephalocele is certain only if the bony defect in the skull is detected. Otherwise, the diagnostic possibilities include cystic hygroma, teratoma, hemangioma, and subcutaneous cyst (Fig. 17–4).

Spina Bifida

Viewed longitudinally on ultrasound, the normal spine narrows caudally. In defective vertebrae, the posterior ossification centers are more widely spaced than those in vertebrae above and below the defect. Whereas an ONTD is detectable on a longitudinal ultrasound image by the loss of skin continuity (Fig. 17–5A), meticulous transverse examination of the entire vertebral column is usually necessary to detect smaller defects. In the transverse view, spina bifida appears as a splaying of the posterior ossification centers (see Fig. 17–5B). In the second and third trimesters, posterior
vertebral elements, including the laminae and spinous processes, are normally visible sonographically. Their absence supports the diagnosis of spina bifida. When the ultrasound examination is not definitive, 3D ultrasound and fetal MRI can be useful, allowing precise localization of the lesion and evaluation of any associated hydrocephalus.[14–16] However, two-dimensional ultrasound remains the diagnostic method of choice for evaluation of fetal anomalies including myelomeningocele.

The majority of cases of spina bifida are associated with the Arnold-Chiari malformation in which the cerebellar vermis, fourth ventricle, and medulla are displaced caudally. Nicolaides and coworkers[21] described the now-classic sonographic signs of the Arnold-Chiari malformation: the "lemon" and the "banana" signs (Fig. 17–6A).[21] A lemon-like configuration is seen in axial section during the second trimester and is caused by scalloping of the frontal bones owing to caudal displacement of the cranial contents within a pliable skull (see Fig. 17–6B). As the cerebellar hemispheres are displaced into the cisterna magna, they are flattened rostrocaudally and the cisterna magna is obliterated, causing a flattened, centrally curved, banana-like sonographic appearance (see Fig. 17–6C). These ultrasound markers are present in over 95% of second-trimester fetuses with open spina bifida.[22] Eventually, the flow of cerebrospinal fluid (CSF) becomes obstructed, causing some degree of ventriculomegaly in most cases.

Management Options

Prenatal

The management of pregnancies with ONTD depends on the severity of the lesion and parental wishes. A comprehensive survey of the entire anatomy must be undertaken in all fetuses with an ONTD by an experienced sonographer to exclude other structural anomalies. Ventriculomegaly is present in the majority of cases, and the degree of hydrocephalus and subsequent macrocephaly likely affects the prognosis.[23] ONTDs are also seen in association with a variety of genetic syndromes, features of which may be detectable by ultrasonography. A fetal karyotype is

FIGURE 17–4

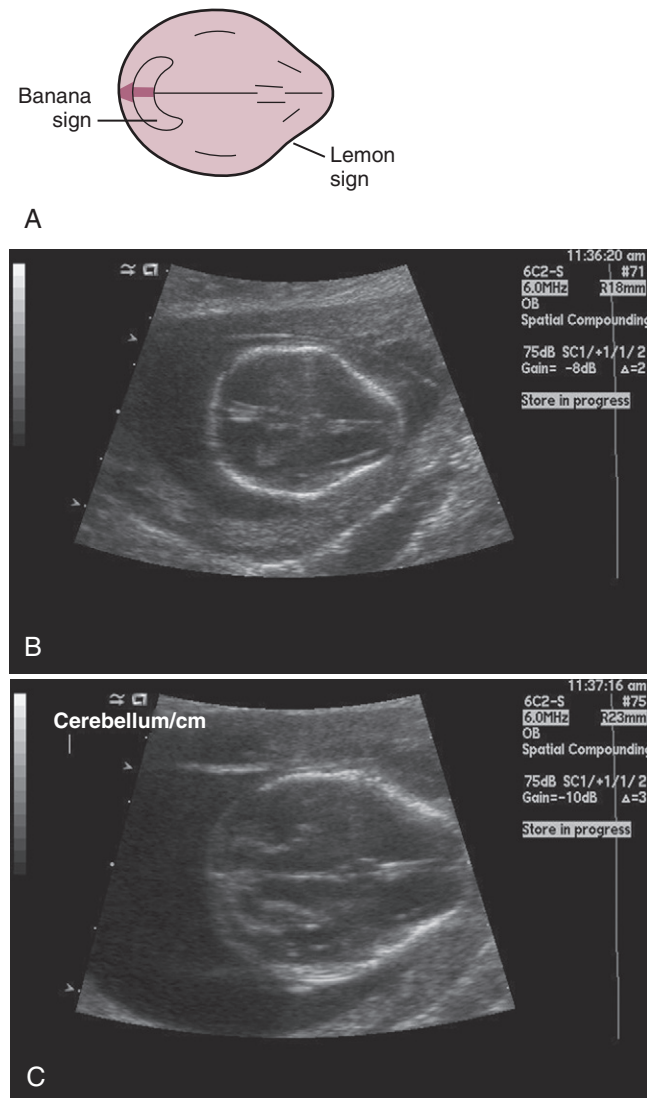
(*A*, From Nicolaides KH, Campbell S, Gabbe SG, Guidetti R: Ultrasound screening for spina bifida. Cranial and cerebellar signs. Lancet 1986;ii:72–74.).


recommended in all instances. The incidence of aneuploidy varies with the type of ONTD, but the lowest reported figure is 2%.

Most fetuses with anencephaly are stillborn or die shortly after birth.[24] Because anencephaly can be diagnosed by antenatal ultrasound with a high degree of accuracy, termination of pregnancy is an ethical option at any time in gestation.[25] If it is diagnosed in the third trimester and the parents elect termination, a number of methods are available.

The most important prognostic indicators for a poor outcome with cephalocele are the presence of brain in the protruding sac and the presence of additional abnormalities.[26–28] A comprehensive fetal ultrasound examination should be performed to exclude genetic syndromes

associated with encephalocele. In several series, 50% to 65% of affected fetuses had additional anomalies. Budorick and colleagues[29] observed that only 2 of 8 liveborns survived infancy. Brown and Sheridan-Pereira[30] reviewed 34 cases of neonatal cephalocele and noted an overall mortality rate of 29%. The most optimistic report came from Martinez-Lage and colleagues[31] who reported an overall mortality rate of 36% in 46 newborns with cephalocele, with 20 infants free of neurologic sequelae. In general, about half the infants with an isolated occipital cephalocele develop normally after surgery. The outlook is dismal for children with microcephaly secondary to brain herniation. The impact of concurrent hydrocephalus has been reduced by modern shunt therapy, and thus, hydrocephalus has less impact than the presence and amount of brain herniation. Frontal cephaloceles have a better prognosis than those in other locations because they tend to be smaller with less brain herniation.[32] Further, the loss of frontal cortex may produce fewer or less significant neurologic deficits than other areas of cortical loss.

The prognosis for spina bifida is variable. The extent and severity of the neurologic deficits depend on the presence of neural tissue in the meningeal sac and the spinal level and length of the lesion, because the spinal cord below the lesion is dysplastic.[33,34] Generally, lower extremity paralysis and incontinence of bowel and bladder are common; intelligence may be affected from either the lesion itself or the impact of treatment (e.g., shunt placement). Overall, 75% of infants born with spina bifida survive long term.[35] Twenty- to 25-year outcome was reported in one study of 118 children treated neonatally for the myelomeningocele.[35] Of the 99 patients with follow-up, 28 had died. Of the 71 survivors, 85% reached high school. One quarter suffered seizures. In another study of 117 patients born with open spina bifida, 54% had died within 38 years of closure.[36] The neurologic status of the survivors ranged from normal to severe disability. Thirty-nine of the 54 survivors had an IQ of 80 or higher; 16 could walk without assistance; 22 lived independently in the community; and only 11 were fully continent. Although improvements in the management of patients with open spina bifida have reduced the infant mortality rate, long-term disability is still significant, and late deterioration is common. Dise and Lohr[37] examined the cognitive skills of adolescents born with spina bifida up to 23 years of age. All patients, regardless of IQ, had significant impairments of mental flexibility, efficiency of processing, conceptualization, or problem-solving ability. There was a high degree of variability within profiles, all containing at least one area of dysfunction. These deficits may underlie the "motivational" and academic difficulties commonly observed in these patients.

Still, affected children can grow to be productive adults with normal intelligence. Early closure of the defect, ventriculoperitoneal shunting of any associated hydrocephalus, management of urinary and fecal incontinence by surgery, dietary management and feedback techniques are in part responsible for these improvements. It is unclear whether cesarean delivery improves the prognosis.[38] A selection bias brought about by antenatal diagnosis with termination of the most severely affected fetuses may account, at least in part, for the reportedly improved outcomes. The prognosis

for the severely affected newborn remains poor, with gross permanent multisystem defects. It is difficult to accurately predict the prognosis in the first half of pregnancy when the diagnosis is frequently made. The option for pregnancy termination should be included in counseling the patients.

Alternatively, in utero repair of myelomeningocele to stop or slow any progression in damage to the exposed spinal cord reportedly decreases the incidence of hindbrain herniation and shunt-dependent hydrocephalus.[39] The rationale for the procedure is that closure antenatally may decrease spinal cord dysplasia and preserve neurologic function by protecting it from potential insults such as amniotic fluid trauma. Although fetal surgery is promising on a theoretical basis, significant complications are associated with in utero repair, including prematurity and lethal pulmonary hypoplasia secondary to oligohydramnios. In addition, the evidence of long-term benefit, including improved lower limb motor function and bladder and bowel continence, is at this time unclear.[40,41] Danzer and colleagues[42] reviewed 54 children over the age of 3 who underwent fetal myelomeningocele closure. Although the authors observed better lower limb neuromotor function than expected, the toddlers continued to demonstrate significant deficits in motor coordination. In addition, other researchers have found no improvement in bowel or bladder function or ambulatory ability beyond the degree of impairment predicted by the level of the lesion.[43,44] In utero repair of myelomeningocele should be considered experimental until the availability of evidence shows that the benefits outweigh the risks to both mother and fetus. Currently, there is a multicentered randomized clinical trial under way in the United States in order to compare the outcomes of fetal surgery with postnatal management for spina bifida.[34]

When a meningomyelocele is diagnosed and the patient plans to continue the pregnancy, a multidisciplinary team consisting of a pediatric neurologist, neurosurgeon, obstetrician, and neonatologist should discuss the implications with the family. Support is invaluable before and after birth. Fetal surveillance is recommended for all ongoing pregnancies with the exception of anencephaly, including serial ultrasonography to assess fetal growth, head size, and severity of ventriculomegaly. Unless maternal or other obstetric indication take precedence, delivery should occur at term or with documentation of fetal lung maturity.

Labor and Delivery

Postmaturity is common in pregnancies complicated by anencephaly. Cesarean delivery is not indicated for fetal distress, but may be necessary for maternal indications. Humane care is provided to the liveborn anencephalic infant until death. The use of anencephalic newborns as organ donors remains widely debated.[45,46] Pathologic examination of the fetus is important to confirm the diagnosis and to exclude conditions in which anencephaly is part of a genetic syndrome.

The optimal mode of delivery for the fetus with cephalocele is controversial. If a large amount of brain tissue is observed in the sac, and especially if one of the more grave prognostic factors (e.g., microcephaly or associated anomalies) is also present, the parents should be counseled that the chance of a good outcome is remote and cesarean delivery

for fetal indications avoided. Decompression of a large sac or associated hydrocephalus might be necessary to allow vaginal delivery. However, cesarean delivery is an option in those rare instances in which a cephalocele is very large and sufficiently solid to cause dystocia. There is no clear objective evidence that cesarean delivery reduces birth trauma and improves neonatal outcome when a cephalocele is present. However, this does not exclude the possibility that trauma during vaginal delivery could, in theory, worsen the prognosis.

Similarly, there is no conclusive information about the optimal route of delivery for the vertex fetus with a meningomyelocele. One retrospective clinical study concluded that elective cesarean delivery prior to the onset of labor improved outcome in terms of the functional level of the spinal defect at age 2 years.[47] However, this study contained numerous sources of bias. Multiple subsequent studies, which have sought to eliminate some of the design flaws of the first study, could identify no benefit from cesarean delivery.[48–51] A randomized trial to study this question has not been done. Until it is clear whether or how the method of delivery affects the neurologic outcome in theses infants, cesarean section remains the delivery method of choice in our institution.

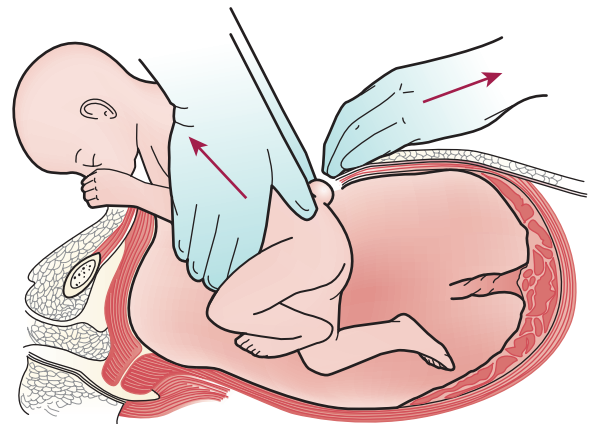
Care must be taken during delivery to minimize traction on the spine regardless of the route of delivery. If there is an indication for cesarean delivery, a low transverse incision is acceptable if the lower uterine segment is well developed. Otherwise, a vertical incision should be performed. After the head is delivered, the bisacromial diameter is positioned horizontally. Both fetal flanks are grasped and gentle traction applied in an outward direction away from the uterine wall near the meningomyelocele. The assistant retracts the edge of the uterine incision as the body of the infant is delivered (Fig. 17–7).


FIGURE 17–7
Fetus with a meningomyelocele is delivered through a low transverse uterine incision. Both fetal flanks are grasped, and gentle traction is applied in an outward direction. Assistant retracts the edge of the uterine incision as the body is delivered.

Postnatal and Prepregnancy

In the United States, the recurrence risk for any neural tube defect after one affected child may be as high as 3% to 5%[52,53] and up to 10% after having two affected offspring. The risk is greater in populations in which ONTDs are more common. The recurrence risk is 4% to 5% if one parent is affected, and 25% when the ONTD is part of the Meckel-Gruber syndrome. A cephalocele

may also occur as part of other autosomal recessive syndromes.

Randomized, placebo-controlled trials demonstrate that the likelihood of recurrence is reduced by periconceptual administration of folate (4–5 mg orally daily). This treatment should be offered to all women with a prior affected child. Antenatal ultrasonography should be performed in future pregnancies initially at 11 to 14 weeks in search of a recurrent ONTD.

SUMMARY OF MANAGEMENT OPTIONS
Open Neural Tube Defects: Anencephaly, Cephalocele, and Spina Bifida

Management Options	Evidence Quality and Recommendation	References

HYDROCEPHALUS

General

Hydrocephalus is defined as ventriculomegaly and macrocephaly associated with increased intracranial pressure. As such, hydrocephalus is a description and not a diagnosis. It results from an abnormal increase in the cerebral ventricular volume compared with brain tissue. There are many causes of hydrocephalus; it may result from abnormal formation of CNS structures, as in hydrocephalus inherited along a mendelian pattern or hydrocephalus associated with a malformation syndrome; it may result from defects acquired in utero, from infection with subsequent scarring, or inflammation and CSF obstruction, from intraventricular hemorrhage, or from intracranial tumors and mass lesions. Many cases of hydrocephalus cannot currently be assigned to any one specific etiologic category.

In general, there are four ways in which the ventricles grow to an abnormal size (Fig. 17–8):

- Obstruction to outflow (noncommunicating hydrocephalus), usually at a point of narrowing in the system (frequently the aqueduct of Sylvius or the foramina of either Lushka or Magendie).
- Impaired resorption of CSF by the arachnoid granulations (communicating hydrocephalus).
- Overproduction of CSF.
- Underdevelopment or destruction of cortical tissue with a relative increase in the size of the ventricles (hydrocephalus ex vacuo).

Obstructive causes are the most common in both fetus and newborn.[54,55] In the United States, the incidence of congenital hydrocephalus unassociated with a neural tube defect is 5.8 per 10,000 total births. This is likely an underestimate of the true incidence because both spontaneous regression and antepartum death occur in some cases.[54]

Diagnosis

A variety of techniques are advocated for the diagnosis of ventriculomegaly. Measurement of the atrium of the lateral ventricles is most common (Fig. 17–9A). This method is optimal because the width of the atrium remains constant throughout the second and third trimesters despite the fact

Impaired absorption by arachnoid granulations

Overproduction of CSF by choroid papilloma

Obstruction of the foramen of Monro

Aqueductal stenosis

Obstruction of the foramina of Luschka and Magendie

FIGURE 17–9
A, Transverse section demonstrates the distal lateral ventricle with its atrial measurements. *B*, Transverse section of the fetal head demonstrates dangling of the choroid plexus within the dilated lateral and third ventricles, consistent with hydrocephalus.

Holoprosencephaly. Transverse view of the fetal head demonstrates holoprosencephaly at 13 weeks' gestation. The falx cerebri is noted to be absent anteriorly. The anterior aspect of the fetal brain demonstrates a single ventricle.

Arachnoid cyst. A, Transverse section through the fetal head demonstrates a midline cyst. B, This cystic structure is shown to have no flow on color Doppler and to be separate from the cavum septum pellucidum, consistent with an arachnoid cyst.

that there is a decrease in the proportion of the cross-section of the brain occupied by the lateral ventricles as pregnancy advances. Cardoza and colleagues[56] presented strong evidence that a single measurement of the lateral ventricle atrium accurately differentiates a normal ventricle system from one that is pathologically enlarged.

Evaluation of the choroid plexus can also be useful when ventriculomegaly is suspected.[57] The choroid plexus usually fills the posterior portion of the lateral ventricles and appears symmetrical bilaterally, regardless of the orientation of the fetal head. In ventriculomegaly, the choroid plexus assumes a dependent position in the enlarged ventricle and appears as a dangling structure (see Fig. 17–9B). Serial ultrasound examinations are especially important for at-risk pregnancies. The absence of hydrocephalus early in gestation does not preclude its development later in gestation. Once hydrocephalus is diagnosed as an isolated abnormality, serial scans are important to identify in utero progression. The differential diagnoses for severe hydrocephalus includes alobar holoprosencephaly, hydrancephaly, porencephaly, and arachnoid cyst (Figs. 17–10 and 17–11). Another rare cause of large, intracranial fluid–like collection is an aneurysm of the vein of Galen, characterized by blood flow that can be visualized by color Doppler.

Management Options

Prenatal

Prior to the development of postnatal surgical shunting of the dilated ventricular system, the outlook for the infant with hydrocephalus was generally poor. Although some cases of unoperated obstructive hydrocephalus progressed slowly, or arrested spontaneously, massive head enlargement with blindness and mental retardation were far more common and still occur in underdeveloped parts of the world.[58]

After the development of postnatal shunting, the prognosis of isolated hydrocephalus improved greatly. Most
neonatal deaths are attributable to associated anomalies as well as obstetric trauma from cephalocentesis. Intellectual development is related to the etiology, and not necessarily to the severity of the hydrocephalus.[59,60] The association between the age at initial shunt placement and intellectual development is controversial.[61,62] Infants with associated CNS anomalies or hydrocephalus secondary to other defects, such as Dandy-Walker malformation or porencephaly, have significantly lower IQs than infants with isolated hydrocephalus.[63,64] In addition, infants with congenital hydrocephalus have somewhat lower overall survival rates than infants who develop hydrocephalus in the neonatal period.[65] A 10-year follow-up study of 129 consecutive children with non–tumor-related hydrocephalus who underwent their first shunt insertion before age 2 years[66] reported an overall mortality rate below 10%. However, motor deficits were found in 60%, visual or auditory deficits in 25%, and epilepsy in 30%. Intellectual deficits were common and 40% had an IQ below 70. Only 32% of the children had an IQ above 90. Other studies have reported a similar long-term intellectual prognosis.[67,68]

Once fetal hydrocephalus is identified, a careful sonographic search for associated fetal anomalies, including meningomyelocele, is mandatory. Because hydrocephalus

is among the extracardiac anomalies associated with congenital heart disease, fetal echocardiography should also be performed. Up to 10% have a chromosomal abnormality.[69,70] The obstetric management of fetal hydrocephalus reflects the gestational age at diagnosis, the presence of other anomalies, the results of the karyotype and infection studies, and the views of the parents. If the diagnosis is made prior to fetal viability, the patient may consider pregnancy termination. If the karyotype is normal, and the parents wish to continue the pregnancy, serial ultrasound examinations are performed to identify progressive ventricular enlargement. In some cases, ventriculomegaly may regress in utero.

Although experimental placement of ventriculoamniotic shunts in fetal rhesus monkeys yielded encouraging results, the experience in human pregnancies has been disappointing. A study of 39 fetal ventriculoamniotic shunt placements reported to the International Fetal Surgery Registry in 1993[71] listed 34 survivors: 14 had apparently normal neurodevelopment, and 18 had severe handicaps. The remaining 2 survivors had varying degrees of neurologic impairment. Children with intact intellectual development were all diagnosed with simple aqueductal stenosis. Of a total of 7 deaths, 4 were directly attributed to the procedure. Many of the fetuses were misdiagnosed, errors that would be less likely to occur using MRI. Although most fetal medicine practitioners are not placing intrauterine ventriculoamniotic shunts, others believe it is time to revisit the issue.[72]

Labor and Delivery

Serial ultrasonography may detect worsening hydrocephalus. In this situation, delivery should be considered as soon as pulmonary maturity is achieved in hopes of minimizing the potential ill effects of progressive ventricular enlargement. There is no clear indication for preterm delivery if the hydrocephalus is rapidly progressive prior to fetal lung maturity because respiratory distress syndrome, which would delay shunt placement, could actually worsen the final outcome. If delivery before fetal lung maturity is elected, maternal corticosteroids should be administered to hasten pulmonary maturity and reduce the risk and severity of respiratory distress syndrome. Fetuses with isolated disease and moderate to severe macrocephaly should be delivered by cesarean section to facilitate the atraumatic delivery of the enlarged fetal head. Attempted vaginal delivery is appropriate when the fetus is in vertex presentation and has only mild macrocephaly.

Fetal cortical mantle thickness correlates poorly with subsequent intelligence. Further, normal intelligence is possible for infants with hydrocephalus who receive optimal neonatal neurosurgical care. In cases of fetal hydrocephalus with associated anomalies that are either incompatible with life or associated with the severest forms of neurologic dysfunction (e.g., alobar holoprosencephaly, hydrancephaly, or thanatophoric dysplasia with cloverleaf skull), cephalocentesis and subsequent vaginal delivery are an acceptable alternative to cesarean delivery. Cephalocentesis is performed by passing a 14- to 18-gauge needle transabdominally or transvaginally under ultrasound guidance (Fig. 17–12). Sufficient CSF is removed to allow overlapping of the cranial sutures. This is a destructive procedure. In a small series reported by Chasen and colleagues,[73] all three fetuses were stillborn with two

delivering vaginally and one abdominally through a low transverse uterine incision.

Postnatal and Prepregnancy

Hydrocephalus has diverse etiologies and the identification of the specific cause aids greatly the subsequent genetic counseling. A postmortem examination is essential. Several heritable patterns are recognized. X-Linked recessive aqueductal stenosis carries a 1:4 risk of recurrence in future pregnancies, or 1:2 risk for male fetuses. Cerebellar agenesis with hydrocephalus is extremely rare, but also might be X-linked. Hydrocephalus is also associated with a variety of chromosomal abnormalities including triploidy, trisomies 13, 18, and 21, and certain balanced translocations. The risk of recurrence is relatively low for sporadic chromosomal abnormalities but is much higher for balanced translocations.

In addition, hydrocephalus is associated with several syndromes that manifest dominant inheritance (e.g., achondroplasia and osteogenesis imperfecta).[74] The Dandy-Walker syndrome has been reported in siblings, suggesting the possibility of autosomal recessive inheritance. Several studies suggest an increased risk of uncomplicated hydrocephalus in families with neural tube defects. Lorber and De[75] studied uncomplicated congenital hydrocephalus and found an empirical risk of 4% for a CNS malformation and 2% for spina bifida or hydrocephalus in future pregnancies. Other causes of fetal hydrocephalus include prenatal infection (e.g., toxoplasmosis), intracranial tumors or cysts, and vascular malformations. Such causes are unlikely to result in an increased risk of hydrocephalus in future pregnancies.

CRANIOFACIAL DISORDERS OF VENTRAL INDUCTION: THE HOLOPROSENCEPHALY SEQUENCE

General

The prechordal mesoderm, an embryonic connective mass between the undersurface of the neural tube and the oral cavity, is thought to be responsible for both the division of the prosencephalon or forebrain and the production of the nasofrontal process. The term *holoprosencephaly* includes several cerebral abnormalities that share incomplete cleavage of the primitive prosencephalon. Because of the underlying embryologic insult, various midline facial abnormalities are closely associated with holoprosencephaly, although the face can be normal (Fig. 17–13). The incidence of holoprosencephaly approximates 1 in 10,000 live births.[76] Holoprosencephaly is divided into alobar, semilobar, and lobar categories, based on the degree of separation of the cerebral hemispheres (Fig. 17–14). The alobar form is the most

severe, with no evidence of cerebral cortical division. The falx cerebri and the interhemispheric fissure are absent. There is a common ventricle with fused thalami. The semilobar and lobar forms represent a higher degree of brain development, with the semilobar having partial separation of the hemispheres. Although there is much variability in the types of defects in the midline cerebral structures (e.g., corpus callosum, septum pellucidum, thalamus), the olfactory tracts and bulbs are usually absent, explaining the older term "arrhinencephaly."

The holoprosencephaly sequence results in the following characteristic facial findings (Fig. 17–15):
- Cyclopia with one median orbit, proboscis from the lower forehead, and absent nose.
- Ethmocephaly with proboscis between two narrowly placed orbits and absent nose.
- Cebocephaly with hypotelorism and rudimentary nose (single nostril).
- Hypotelorism (decreased intraorbital distance), median cleft lip, and flat nose.
- Bilateral cleft lip.

Diagnosis

The dictum "the face predicts the brain" is often used to describe holoprosencephaly, because cyclopia, ethmocephaly, cebocephaly, and hypotelorism with midline cleft lip are commonly found in association with this CNS anomaly.[77] Ultrasonographic markers include hypotelorism and a single common cerebral ventricle with absent midline echo. The general appearance of the face, the position and configuration of the nose, and the integrity of the upper lip should be observed closely for clues. It may be impossible to differentiate semilobar from lobar holoprosencephaly before birth. Holoprosencephaly can be detected sonographically as early as the first or second trimester (see Fig. 17–10).

It is not sufficient to diagnose holoprosencephaly based solely on a central fluid collection in the brain, because this may also represent hydranencephaly or a midline porencephalic cyst. Other anatomic aberrations associated with holoprosencephaly detectable by ultrasound include hydrocephalus, polydactyly, and hydramnios.

Management Options

Prenatal

The prognosis for alobar holoprosencephaly is uniformly poor. Most infants die shortly after birth, and the survivors have profound mental retardation.[78] Less is known about the prognosis for lobar and semilobar varieties. A normal life span is reported, but many are severely mentally retarded. Subtle forms of lobar holoprosencephaly with little neurologic abnormality may exist. Karyotyping should be offered because of the association with aneuploidy (especially trisomy 13).

Labor and Delivery

The obstetric management of holoprosencephaly is dependent on gestational age at the time of diagnosis. Many patients opt for pregnancy termination when the diagnosis is made in the first or second trimester. Macrocephaly in the third trimester may obstruct labor and cephalocentesis should be considered to avoid cesarean delivery. The destructive nature of this procedure must be explained to the parents.

Postnatal and Prepregnancy

The diagnosis of holoprosencephaly signals the need for a careful postmortem examination and a fetal karyotype to guide the management of future pregnancies. A chromosomal anomaly may predict either a recurrence risk less than 1% (as when a trisomy is demonstrated) or a much higher risk if there is a translocation in one of the parents.

In the absence of a chromosomal abnormality, the reported empirical risk for recurrence ranges from 6% to 14%,[79,80] although some families have a 25% risk associated with autosomal recessive inheritance. Rarely, autosomal dominant inheritance is present, predicting a 50% recurrence rate. A close examination of both parents for minor signs of midline facial abnormalities (e.g., hypotelorism) is essential to rule out this possibility. Maternal diabetes should also be excluded because it significantly increases the risk of holoprosencephaly.[81]

FACIAL CLEFTS

General

Cleft lip or palate is the most common congenital facial deformity.[82] It results from failure of the nasofrontal prominence to fuse with the maxillary process. Clefts may be complete, incomplete, unilateral or bilateral, or symmetrical or asymmetrical. Although more than 100 syndromes are associated with cleft lip or palate, these syndromes probably account for fewer than 10% of cases, because the majority are isolated. A multifactorial etiology is reflected in the varied incidences depending on race, sex, and geographic location. Similar to other lesions with a multifactorial etiology, the empirical recurrence risk increases with the number of previously affected siblings.

Diagnosis

The lower portion of the face must be anterior and clearly visualized in order to demonstrate a facial cleft on antenatal ultrasound (Fig. 17–16). The coronal, sagittal, and transverse planes are used to assess the features of the lower face. Facial clefts may be suspected when either undulating tongue movements, hypertrophied tissue at the edge of the cleft, or hypertelorism is seen on ultrasound. An intact lip does not mean the palate is intact. Transverse sections may reveal a break in the maxillary ridge. Caution is necessary to avoid a false-positive diagnosis from a shadowing artifact produced by the maxillary bones. The availability of 3D ultrasound may facilitate visualization of the precise location and extent of facial clefting.[83,84]

Management Options

It is important to search carefully for other anomalies after a facial cleft is identified. Fetal karyotyping should be offered. The prognosis and management depend on the presence of associated abnormalities and the severity of the defect. If the cleft appears isolated, then the prognosis is excellent. Staged plastic surgical correction is typically offered early in infancy, though the timing of the repairs remains controversial. Prior to surgery, the newborn may experience some difficulty feeding, but this is usually remedied with a specially designed artificial palate. Antenatal diagnosis of a cleft may help the parents prepare for a visually disturbing deformity that is typically correctable and allows the birth to occur with a treatment plan in place.

DANDY-WALKER MALFORMATION

General

The Dandy-Walker malformation is characterized by the complete or partial absence of the cerebellar vermis and an enlarged posterior fossa cyst continuous with the fourth ventricle (Fig. 17–17). Hydrocephalus with ventriculomegaly is often present. Theories on pathogenesis include atresia
FIGURE 17–16

of the foramina of Lushka and Magendie and hypoplasia or gross alteration of the cerebellum. In addition to the classic Dandy-Walker malformation, a Dandy-Walker variant indicates a spectrum of anomalies classified by variable hypoplasia of the cerebellar vermis with or without enlargement of the posterior fossa. The Dandy-Walker malformation occurs in approximately 1 in 30,000 births and is diagnosed in 4% to 12% of all cases of infantile hydrocephalus.[85] There is an increased risk of chromosomal anomalies and mendelian syndromes.

Diagnosis

Dandy-Walker cyst appears on ultrasound as an echolucent area in the posterior fossa. The cerebellar vermis, a bright

FIGURE 17–17
Dandy-Walker cyst. Transverse view of fetal head demonstrates a Dandy-Walker cyst with a defect in the cerebellar vermis. In addition, the lateral and third ventricles are dilated.

echogenic midline structure caudal to the fourth ventricle, is absent or defective. As a result, the Dandy-Walker cyst is seen communicating with the fourth ventricle. Hydrocephalus usually involves all four ventricles.

Management Options

The prognosis for infants with a Dandy-Walker malformation is quite variable. A review of 50 cases of Dandy-Walker malformation and 49 cases of Dandy-Walker variant diagnosed by antenatal ultrasound[86] noted a frequent occurrence of associated anomalies and aneuploidy. Of fetuses with a classic Dandy-Walker malformation, 85% had other anomalies (32% ventriculomegaly and 38% cardiac defects) and 46% were aneuploid. Of the fetuses with Dandy-Walker variant, 85% had other anomalies (27% ventriculomegaly and 41% cardiac defects) with a 36% aneuploidy rate. Fifty of the 99 women elected pregnancy termination. Of the remaining 49 fetuses, 16 survived the neonatal period with only 8 having a normal pediatric examination at 6 weeks, including 6 with an isolated finding of Dandy-Walker variant. The overall prognosis is therefore poor and the presence of other anomalies is associated with the worst prognosis.

Hydrocephalus and associated anomalies are more common in cases diagnosed in utero and the prognosis is less favorable. The option of pregnancy termination should be discussed with the parents. There is an increased risk of chromosomal anomalies and mendelian syndromes. The Dandy-Walker malformation occurs with increased frequency in families with a history of polycystic kidney disease and after the birth of a child with Dandy-Walker malformation or another CNS abnormality. Autosomal recessive inheritance is documented in some families. In the absence of a clear genetic syndrome, the recurrence risk is between 1% and 5%.[87]

ANEURYSM OF THE VEIN OF GALEN

The cerebral veins may enlarge as a direct result of arterial fistula or adjacent arteriovenous malformation. Aneurysmal dilation of the great vein of Galen from an arteriovenous malformation is well documented. The dilated vein appears on ultrasound as a nonpulsatile, midcerebral tubular structure often seen behind the third ventricle.[88,89] MRI and 3D ultrasonography can be useful adjuncts to definitive diagnosis antenatally.[90,91] The lesion may be isolated or associated with fetal hydrocephalus or other abnormalities. The increased intracranial blood flow to a low-resistance shunt can cause cardiomegaly and hydrops, and serial studies are indicated to monitor for the development of fetal hydrops. Traditionally, the prognosis for neonates with an aneurysm of the vein of Galen was considered poor, because many die from heart failure.[92] However, therapeutic advances may be improving outcome. In one study of 18 cases of antenatally diagnosed vein of Galen aneurysm, the neonatal mortality rate was 25% despite evidence of cardiac deterioration in 94%. All survivors required digoxin therapy. Neurologic development was normal in 67% of the surviving neonates.[93]

HYDRANENCEPHALY

General

Hydranencephaly is characterized by replacement of the cerebral hemispheres with fluid covered by leptomeninges such that no cerebral cortex is present. Only the basal ganglia and remnants of the mesencephalon remain within a normally formed skull above the tentorium cerebelli. The subtentorial structures are usually intact, and the falx cerebri is frequently present. Hydranencephaly is thought to result from a severe destructive insult, most likely bilateral occlusion of the internal carotid arteries.

Diagnosis

Ultrasonographic findings include a normal cranial vault filled with fluid. The cerebral cortex is absent, but a midline echo, the tentorium cerebelli, and cerebellum may be visible. This disorder is differentiated from hydrocephalus, holoprosencephaly, and porencephaly by the absence of cerebral cortex. In severe hydrocephalus, the thin cortical mantle may be hard to detect ultrasonographically and MRI or, less frequently, intrauterine computed tomography scanning may aid diagnosis (Fig. 17–18).

Management Options

Most infants with hydranencephaly die in the first year of life. Survivors are profoundly retarded. Sporadic familial recurrences are reported, but these are the exception. In general, the recurrence risk is negligible. The option for pregnancy termination should be offered to the parents.

MICROCEPHALY

General

Strictly translated, *microcephaly* means "small head." The clinical importance of the entity is its association with mental retardation. Some authors classify postnatal microcephaly as a head perimeter smaller than 2 standard deviations (SDs) below the mean.[94] Alternatively, a definition of 3 SD below the mean for gender and age may correlate better with mental retardation.[95]

Diagnosis

The postnatal diagnosis of microcephaly is made simply by measuring the neonatal head circumference, but the antenatal diagnosis is more difficult. The head circumference is preferable to the biparietal diameter, which carries a high false-positive rate because of such normal variants as dolichocephaly. Serial ultrasound examinations are important in suspected cases because significant microcephaly may not manifest until the third trimester.

Management Options

Prenatal

Because microcephaly is a part of many different malformation syndromes, a careful search for associated anomalies is mandatory. Cortical mass may be decreased in microcephaly, leading to ventriculomegaly in the absence of an obstructive process. A careful pedigree should be taken and a search made for causes, including possible teratogen exposure, alcohol abuse, and infection. The definitive diagnosis of fetal infection requires an invasive procedure; amniocentesis and even fetal blood sampling are often necessary.

The majority of microcephalic children are mentally retarded, many severely so. As a rule, the smaller the head, the worse the prognosis. If microcephaly occurs as part of a genetic syndrome (e.g., Meckel-Gruber syndrome), the outcome is uniformly poor. However, children born with microcephaly may have normal intelligence despite their very small head size.

Exercise caution with counseling because prognosis is difficult to predict.	—/GPP	—
Labor and Delivery		
Aim for vaginal delivery; shoulder dystocia is very rare.	—/GPP	—
Postnatal and Prepregnancy		
Establish cause if not already done (teratogens, alcohol use, family history, karyotype, infection serology, necropsy).	—/GPP	—
Counsel depending on cause.	—/GPP	—

GPP, good practice point; MRI, magnetic resonance imaging.

Labor and Delivery

Vaginal delivery of a microcephalic infant is appropriate. Shoulder dystocia due to incomplete dilation of the cervix by the small fetal head is a rare occurrence.

Postnatal and Prepregnancy

The risk of recurrence for microcephaly depends on the underlying etiology. The search for an etiology should include a physical examination of the infant; a maternal history for teratogenic exposure; a careful family pedigree; chromosomal, microbiologic, and serologic studies; and an autopsy should death occur. Alcohol abuse is a common cause of mental retardation and often associated with microcephaly. Several patterns of inheritance are described within the subgroup of microcephaly without associated anomalies, which is termed "true" microcephaly. These patterns include autosomal recessive, autosomal dominant with incomplete penetrance, and sporadic patterns of inheritance.

AGENESIS OF THE CORPUS CALLOSUM
General

The corpus callosum is the great commissural plate of nerve fibers interconnecting the cortical hemispheres. It lies at the base of the interhemispheric fissure and curves in the midline, forming the roof of the third ventricle. Agenesis of the corpus callosum can occur either as an isolated anomaly or in association with other anomalies, such as hydrocephalus and holoprosencephaly. It is usually a sporadic occurrence, although it has been associated with various genetic syndromes, chromosomal abnormalities, and prenatal exposure to teratogens such as alcohol.

Diagnosis

Agenesis of the corpus callosum is diagnosed in utero on coronal and midline sagittal views of the fetal head, including the routine transverse planes. Transvaginal ultrasonography improves access to these planes by providing an acoustic window through the anterior fontanelle.

On a midsagittal ultrasound examination, the corpus callosum appears as a hypoechoic structure below the pericallosal artery, where it forms the roof of the cavum septum pellucidum and cavum vergae (Fig. 17–19). Failure to image it suggests agenesis of the corpus callosum. However, it is quite difficult antenatally to be definitive. The pathognomonic "sunburst lesion" is seen on midsagittal section and represents the radial orientation of the gyri and sulci of the cerebral cortex to the third ventricle (Fig. 17–20). Normally, the gyri and sulci parallel the corpus callosum.[96] Because the corpus callosum itself cannot be seen on transverse scan, it is necessary to search for the anatomic alterations produced by its absence. These indications include lateral displacement of the bodies of the lateral ventricles, enlargement of the atria and occipital horns producing a characteristic teardrop shape, and enlargement or upward displacement of the third ventricle (Fig. 17–21).

Note the teardrop shape of the lateral ventricle, with dilation of the posterior portion of the lateral ventricle.

Management Options

The prognosis for a fetus with agenesis of the corpus callosum is highly variable and depends on the presence of associated defects. Management is based on these underlying anomalies. Agenesis of the corpus callosum has been reported as an incidental autopsy finding in intellectually normal adults,[97] and caution should be exercised in counseling patients when isolated agenesis of the corpus callosum is suspected. 3D ultrasonography and MRI may provide additional prognostic information.

INTRACRANIAL HEMORRHAGE AND PORENCEPHALY

General

Intraventricular hemorrhage is well recognized in the newborn and often associated with prematurity. Neonatal intracranial hemorrhage is classified into grade 1 when there is isolated periventricular hemorrhage, grade 2 when there is intraventricular hemorrhage with normal ventricular size, grade 3 when intraventricular hemorrhage is associated with

acute ventricular dilation, and grade 4 when there is intraventricular hemorrhage with parenchymal involvement.[98] When severe, it can produce obstructive hydrocephalus and intraparenchymal hemorrhage. Conversely, the antenatal diagnosis of intracranial hemorrhage is uncommon. In most instances, hydrocephalus is first identified in association with echogenic areas of hemorrhage in the dilated ventricular system.

Porencephaly describes a condition in which a portion of the cerebral cortex is replaced by a cystic cavity and is thought to represent the remains of a severe intrauterine insult. The cavity may communicate with the subarachnoid space or a ventricle. Most cases result from a vascular lesion, either hemorrhagic or embolic. Areas of prior hemorrhage or tissue necrosis resorb, leaving behind porencephalic cysts. In rare cases, an infection or traumatic insult might result in porencephaly.

Diagnosis

Antenatal hemorrhage typically appears as an echogenic mass in the region of the germinal matrix or within the lateral ventricles. MRI of the fetal brain can often assist in making the diagnosis of a brain hemorrhage (Fig. 17–22). Antenatally diagnosed intracranial hemorrhage is predominantly grade 3 or 4. Consequently, these lesions are associated with a high perinatal mortality rate. These cases demonstrate that high-grade intraventricular hemorrhage can occur in the absence of birth trauma.

Porencephalic cysts appear ultrasonographically as solitary or multiple echolucent areas of variable size and location within the brain. The midline echo is present but may be displaced. Some cortical tissue may be preserved in each cerebral hemisphere. These distinctions help differentiate a large porencephalic cyst from unilateral hydrocephalus, holoprosencephaly, and hydranencephaly.

Although the prognostic validity of the grading system for neonatal intracranial hemorrhage is well established, it has not been extensively evaluated in the antenatal period. Ghi and colleagues[99] followed 109 cases of antenatally diagnosed intracranial hemorrhage and concluded that intracranial hemorrhage could be accurately identified and categorized by antenatal sonography.

Management Options

When antenatal intracranial hemorrhage is diagnosed in the absence of an identifiable cause, a search for alloimmune thrombocytopenia is warranted. Serologic studies for intrauterine infection, a fetal karyotype, and screening for maternal infections, including hepatitis and pancreatitis, might also be of value.

The prognosis for porencephaly depends on the underlying etiology, location, and volume of tissue loss. The outcome in the majority of reported cases is poor.[100] Fortunately, there is no increased risk of recurrence unless alloimmune thrombocytopenia is diagnosed. Alloimmune thrombocytopenia carries a greater than 75% recurrence risk.[101]

CHOROID PLEXUS CYST

General

Small areas of cystic dilation are seen in the choroid plexus of the lateral ventricles in 1% to 2% of all fetuses (Fig. 17–23). They typically resolve before the end of the second trimester and lack clinical significance. Choroid plexus cysts may be associated with trisomy 18. However, the great majority of fetuses with trisomy 18 have other structural abnormalities detectable by ultrasonography.

Management Options

A karyotype is recommended for all fetuses with choroid plexus cysts associated with other structural abnormalities. However, the vast majority of isolated choroid plexus cysts are clinically insignificant, and the need for karyotyping is controversial. A meta-analysis reported that the risk of trisomy 18 associated with an isolated choroid plexus cyst in all women was 1:374.[102] Another large study concluded that an isolated choroid plexus cyst increased the

mid-trimester risk of trisomy 18 enough to justify karyotyping only in women older than 35 years.[103] Other large studies have concluded that isolated choroid plexus cysts in women younger than 35 years do not increase the risk of trisomy 18 to a degree that amniocentesis is warranted.[104,105] We believe the presence of a choroid plexus cyst should be disclosed to the patient. However, counseling should take into account the presence of associated anomalies, the age of the patient, and the results of first- and second-trimester screening tests for aneuploidy.

CAUDAL REGRESSION SYNDROME

Caudal regression syndrome describes an embryologic malformation leading to structural defects in the caudal region. The severity is quite variable and may include incomplete development of the sacrum and lumbar vertebrae and disruption of the distal spinal cord, causing neurologic impairment. Caudal regression syndrome is strongly associated with maternal diabetes. Although this disorder was previously considered a severe form of sirenomelia, some evidence suggests the two defects are pathogenetically unrelated.[73] The etiology of caudal regression syndrome is unknown and most likely heterogeneous.

MAGNETIC RESONANCE IMAGING OF FETAL CENTRAL NERVOUS SYSTEM ANOMALIES

might be restricted by various factors, including reverberative artifacts from the bony calvarium, fetal position, oligohydramnios, and maternal body habitus. Although transvaginal sonography can sometimes complement or enhance the transabdominal examination,[106] ultrasound often does not have the sensitivity to detect subtle abnormalities of fetal brain development.

MRI can enhance the diagnostic accuracy of ultrasound for the assessment of fetal brain abnormalities (Figs. 17–24 and 17–25).[107,108] MRI permits acquisition of multiplanar views of the fetal brain, allowing for a detailed evaluation of the CNS anatomy that is not possible using ultrasound alone. In addition, MRI is not hindered by the same technical limitations as ultrasound, such as reduced amniotic fluid

or fetal position. The use of ultrafast MRI techniques permits good quality brain images, even when there is fetal movement.[109,110] To date, there have been no reports of adverse fetal effects from MRI. Baker and colleagues[111] evaluated children 3 years after prenatal MRI exposure and reported no deleterious effects. The information obtained from MRI may change management by enhancing the diagnostic accuracy. Sharma and colleagues[112] described a series of pregnant patients with fetal brain abnormalities in whom MRI provided valuable additional information in all cases. MRI of the fetal CNS is evolving as a useful adjunct for obtaining additional information in cases in which confirmation of a suspected abnormality or further clarification is sought.

INTRODUCTION

Genitourinary abnormalities consist of a wide spectrum of heterogeneous malformations. Urinary tract dilations and kidney abnormalities are relatively common with a prevalence ranging from 1 in 250 to 1 in 1000 deliveries.

The majority of genitourinary abnormalities are detected during routine second-trimester screening ultrasound in the absence of any significant clinical or family history. Generally, the sensitivity of antenatal screening depends on the experience of the ultrasonographer and on the timing of the onset of detectable consequences of the abnormality.[1] The diagnosis of a lethal form may become evident with severe oligohydramnios and dilation of the urinary tract. In contrast, some abnormalities, such as urinary reflux, might remain undetectable in utero. Urinary dilation above an incomplete obstruction may occur in the third trimester, when urinary volume exceeds the obstructed capacity. These will be missed unless there is a policy of routine third-trimester ultrasound. Renal abnormalities without urinary tract dilation can be detected if examination of the fetal kidneys is included in the screening ultrasound. Fetal uropathies are rarely diagnosed in the first trimester. An intra-abdominal transonic mass suggests a dilated bladder. However, it may resolve spontaneously, and follow-up is needed to confirm the diagnosis of fetal urinary tract dilation.

In contrast to uronephrologic abnormalities, isolated genital malformations are rare disorders. There is no consensus on whether the structure of the fetal genitalia should be imaged as part of a screening ultrasound examination. Minor abnormalities are virtually impossible to identify, and counseling may be extremely difficult when ambiguous genitalia are identified.

FETAL UROPATHIES

Pathophysiology

Uropathies potentially detectable in utero may be classified according to their pathophysiology:

- Obstruction of the ureteropelvic junction: This is the most common abnormality of the fetal urinary tract. The obstruction may result from compression by an ectopic vessel or may occur in the setting of duplication or ectopy
- Megaureter: True megaureter is the result of ureterovesical junction dysfunction. Megaureter associated with mild hydronephrosis often spontaneously resolves during the first years of life, whereas major hydronephrosis or a retrovesical ureteral diameter greater than 1 cm tends to resolve slowly and might require surgery.[2,3]
- Ureterocele: Cystic dilation of the distal intravesical ureter usually arises from an abnormal location of the ureteral meatus in the bladder. Ureterocele is often associated with double ureter, in which the ureterocele at the lower ureteric orifice drains the upper pole of a duplicated kidney. The lesion is associated with obstruction, accounting for the dilation of the corresponding ureter and renal pelvis. A large ureterocele can even obstruct the bladder neck with features resembling an infravesical obstruction. Antenatal diagnosis is important to plan postnatal management and to avoid future complications.[4]
- Bladder outlet obstruction: This obstruction usually occurs in the urethra, causing bladder dilation with muscle hypertrophy and hydronephrosis. The kidneys may be dysplastic, resulting in a variable degree of renal failure.[5] The most common cause of bladder outlet obstruction is posterior urethral valves. Urethral atresia is less common, causing lethal lesions with fetal anuria in the early second trimester. In spite of advances in antenatal care, posterior urethral valves may still result in postnatal renal failure.[6]
- Reflux: This common disorder is often suspected antenatally but is rarely diagnosed definitively. Occasionally, it may be diagnosed based on dynamic dilation of the upper urinary tract or dynamic imaging of reflux. In severe cases, the bladder and ureters appear dilated owing to a functional increase in urinary outflow. Antenatal diagnosis permits the initiation of prophylactic antibiotic therapy to avoid postnatal urinary infection and subsequent kidney damage. Postnatal surgery may be required for severe forms.[7]
- Prune-belly sequence: This abnormality consists of deficient abdominal wall musculature, bladder distention with renal dysplasia, absence or hypoplasia of the prostate, and cryptorchidism.[8] A patent urachus is common. The uropathy usually consists of urethral obstruction and dysfunction resulting in megacystis and bilateral megaureter. It is rare in females in whom the uropathy and the abdominal wall defect are associated with vaginal atresia, rectovaginal or rectovesical fistula, and bicornuate uterus. The prognosis depends on the amount of functional renal tissue.

FIGURE 18–1
Normal urinary tract at 12 weeks. *A*, Kidneys (frontal view). *B*, Bladder (sagittal view).
Sonographic Assessment of Normal Development of the Fetal Kidneys, Urinary Tract, and Genitalia

The fetal bladder and kidneys are identifiable by 11 to 12 weeks' gestation (Fig. 18–1) when the kidneys appear as homogeneous echoes on each side of the spine. Between 18 and 24 weeks' gestation, the medulla becomes hypoechogenic and is distinguishable from the echogenic renal cortex (Fig. 18–2). The growth of fetal kidneys parallels the fetus and can be evaluated in a quantitative manner.[9–11]

The image of the genital tubercle should be interpreted carefully during the first trimester,[12,13] although it is possible to identify fetal gender at 12 to 14 weeks in 70% to 90% of cases.[14] In boys, the urethral canal can be seen at 26 to 27 weeks, but it is easier to see in the third trimester (Fig. 18–3). Undescended testes are physiologic until 32 weeks but should be intrascrotal near term. In girls, vulval structures can be identified as early as 15 weeks and seen clearly by 22 weeks. However, a detailed analysis of a vulva anomaly is not usually feasible until 24 weeks (Fig. 18–4). In the third trimester, the external genitalia are large and easier to visualize.

It is not always possible to identify the uterus, even late in gestation. However, using three-dimensional (3D) ultrasound techniques, the uterus can be identified in 50% to 80% of cases depending on the gestational age.[15,16] The fetal sacrum is an indirect but useful marker of the harmonious development of the fetal pelvis. It curves inward progressively during the second trimester (Fig. 18–5). The anal sphincter can also be seen (Fig. 18–6).

Management Options—Overview

Once fetal urinary tract dilation is detected, the following issues should be addressed rapidly:

FIGURE 18–2
Normal kidney at 23 weeks shows corticomedullary differentiation of the parenchyma.

- The diagnosis should be confirmed.
- Associated abnormalities should be ruled out by an expert in fetal ultrasound.
- The risk of aneuploidy should be evaluated and weighed against the risks of amniocentesis.
- The risk of postnatal respiratory distress (due to severe oligohydramnios leading to pulmonary hypoplasia) should be evaluated.
- The risk of developing postnatal renal failure should be evaluated.
- A perinatal management plan should be established in collaboration with a pediatric urologist/nephrologist. The potential need for emergency neonatal surgery should be evaluated in order to plan the site of delivery.

Sonographic Diagnosis of Fetal Urinary Tract Abnormalities

Antenatal diagnosis of fetal urinary tract anomalies is relatively easy based on the identification of a dilated urinary tract. However, it is not always possible to ascertain the mechanism of the uropathy in utero, because the obstructive lesion cannot be imaged directly and urinary tract dilation resulting from vesicoureteral reflux may mimic the dilation of a true obstruction. Nevertheless, it is rarely important to recognize the exact cause of the dilation before birth. A satisfactory surgical repair can be achieved postnatally in most cases, resulting in a good pediatric outcome provided the renal function is not altered and there is no associated malformation.

Apparent Level of Urinary Dilation

Fetal uropathies can be classified by the level of dilation.[17–21] Only the renal pelves are dilated in upper dilations, whereas the ureters are also involved in midlevel dilations. Upper and midlevel dilations are also categorized as unilateral or bilateral, an important prognostic feature because postnatal renal function should be normal in unilateral cases. Dilation of the upper urinary tract may result from either ureteropelvic junction obstruction or ureteropelvic reflux. Midlevel dilation may be an ultrasonographic feature of vesicoureteral reflux as well as congenital megaureter. The bladder is involved in low-level dilations. Low urinary tract obstruction (LUTO) is mainly the result of posterior urethral valves. However, a dilated bladder may be a feature of major vesicoureteral reflux, which increases urine output through the bladder. More complex urinary defects, for example, cloacal malformations, may appear as a bladder dilation and, occasionally, as a midlevel dilation associated with minor abnormalities of the fetal pelvis. Complex pelvic floor malformations are the most common LUTO diagnosed antenatally in females, and posterior urethral valves are the most frequent cause of LUTO in males.

UPPER URINARY TRACT DILATION

There is no universally accepted definition and grading of fetal upper urinary tract dilation.

Pyelectasis

Pyelectasis is defined by moderate dilation of the renal pelvis without associated dilated calyces. The renal pelvis is measured in the anteroposterior (AP) plane on cross section. However, the upper size limit of a normal fetal renal pelvis remains controversial, partly because there is substantial overlap in renal pelvic size between normal fetuses and those who later prove to have reflux or obstruction. Low thresholds may stimulate unnecessary and potentially dangerous intervention whereas high threshold values will lead to false-negative conclusions.[22] Pyelectasis is variously defined as an AP pelvic diameter exceeding 4 to 7 mm in the second trimester and 8 to 10 mm in the third.[23–30] Depending on the definition, pyelectasis (Fig. 18–7) occurs in 1% to 3% of pregnancies. In most cases, isolated fetal pyelectasis is physiologic. However, it may be secondary to mild reflux or a ureteropelvic junction syndrome. The likelihood of pyelectasis being associated with substantial morbidity requiring postnatal surgery increases with the degree of antenatal pelvic dilation.[7,31,32] Fetuses with pyelectasis should be followed serially to determine whether dilation increases with advancing gestational age.[22,33]

Postnatal evaluation is required but should not be performed immediately after delivery because the false-negative rate is increased. At-risk neonates should have a renal ultrasound between 1 and 3 weeks of age. There is no consensus on whether and when postnatal ultrasound should be repeated and on which patients should be offered a retrograde cystogram and when. Irrespective of the postnatal strategies for the diagnosis of reflux or for the prevention of urinary tract infections, the prenatal history should be kept in mind when unexplained symptoms occur postnatally.[34–36] The sensitivity of antenatal ultrasound for
FIGURE 18–7
Mild pyelectasis at 22 weeks. *A*, Transverse view. *B*, Parasagittal view.

the detection of clinically significant reflux remains low,[20,21] and most cases of reflux are discovered after postnatal symptoms.

Hydronephrosis

Hydronephrosis is defined by an AP pelvic size of more than 1.5 cm or calyceal involvement.[37–39] In mild hydronephrosis, the calyces are slightly dilated and retain their shape. With greater upper urinary tract dilation, the calyces become rounded (Fig. 18–8). Dilated calyces are distributed regularly and connect to the renal pelvis, in contrast to the irregular pattern of a multicystic kidney in which the cysts are separate from the pelvis. In severe cases, the calyces are no longer identified separate from the pelvis, appearing instead as a large single transonic image (Fig. 18–9). The renal parenchyma is considered thinned when it is less than 3 mm thick. This finding is not always ominous because large dilations with thin parenchyma can be associated with normal renal function. The presence or absence of corticomedullary differentiation should be noted, as well as the parenchymal echogenicity and the presence of cysts. Although subjective,[40–44] evaluation of the ultrasonographic structure of the renal parenchyma may be a useful predictor of renal function, although it is less sensitive than urinalysis to predict postnatal survival with altered renal function.[45,46]

MIDLEVEL DILATIONS

Hydroureter is a dilated ureter that appears as a convoluted transonic image, located between the kidney and the bladder (Fig. 18–10); normally, the ureter is not seen ultrasonographically. Peristaltic activity suggests a megaureter. A dilated ureter may also result from vesicoureteral reflux.[47] or a ureterocele. A ureterocele appears as a round transonic image located inside the bladder and lined by a thin border (Fig. 18–11).

LOW-LEVEL DILATION

A dilated bladder that does not empty over the course of the ultrasound examination suggests an outlet obstruction. The dilated bladder is usually round, but may be larger above the umbilical arteries than below, evoking the shape of a champagne bottle cork. The image of a dilated urethra is specific for posterior urethral valves especially if seen during fetal bladder voiding, but is far from constant. At a later stage, bladder outlet obstruction can result in muscular hypertrophy imaged as a bladder wall thicker than 3 mm (Fig. 18–12). Bladder diverticula may also form. Although posterior urethral valves are the most common cause of bladder dilation in males, other etiologies are possible. Urethral atresia is an almost universally lethal condition. The atresia cannot be directly imaged, and it is usually diagnosed at pathologic postmortem examination (Fig. 18–13). Complex genitourinary anomalies should also be considered. Keep in mind that an LUTO, including posterior urethral valves, can present as a midlevel or even an upper-level obstruction with subsequent evidence of bladder enlargement.

Ascites and Urinoma

Urine may leak into the peritoneal cavity through minor and usually unidentifiable disruptions of the urinary tract wall, causing ascites. Urinary ascites is not specific for a particular uropathy and is not necessarily an ominous finding. The urinary origin of the ascites is usually apparent. Similarly, disruption of the urinary tract in the retroperitoneal space may lead to a urinoma (Fig. 18–14), which appears as a transonic image surrounding the kidney and confined within Gerota's fascia.[48] Urinomas are usually easy to differentiate from renal masses, lymphangioma, neuroblastoma, mesenteric cyst, and enteric duplications.

FIGURE 18–16   Cloacal abnormality at 23 weeks (sagittal view). Note the straightened and shortened sacrum.

Exclusion of Associated Anomalies

The first step in the management of a fetus with a urinary tract abnormality is to rule out extraurinary anomalies by a detailed ultrasonographic assessment by an experienced practitioner.[49–51] Soft markers suggestive of a chromosomal abnormality should be sought, as well as complex pelvic malformations.

Bladder exstrophy is characterized by the absence of a vesical image[52,53] and can sometimes be imaged directly (Fig. 18–15). The antenatal diagnosis of cloacal malformations is based on the association of a variety of relatively minor signs that may appear only in the third trimester.[54–58] Rectal atresia is suggested when the sacrum appears too straight (Fig. 18–16). A urodigestive fistula is suspected when the bowel is dilated with hyperechogenic material (Fig. 18–17). The image of an enlarged duplicated vagina is quite specific of a cloacal malformation[59] but might not appear until the third trimester. Visualization of the anal sphincter does not rule out the diagnosis of anal atresia (Fig. 18–18). The external

genitalia should also be carefully imaged. Fused labia may appear "floating" in the amniotic fluid. The potential for surgical repair might be difficult to establish when a complex malformation of the pelvic floor is diagnosed in utero, and the management should be discussed with an expert pediatric surgeon. Magnetic resonance imaging may be helpful in some instances. In the VACTERL association, spinal, heart, limbs or the digestive tract anomalies are associated with renal malformation.

The prune-belly sequence is another complex malformation in which the prognosis may be difficult to establish. The diagnosis is suspected antenatally when a large bladder and substantial ureteral dilation are seen with mild hydronephrosis (Fig. 18–19). Undescended testes are common. It is possible to depress the fetal abdomen with a moderate amount of pressure by the ultrasound probe.

Some less common conditions are even more difficult to diagnose than the prune-belly sequence. For example, a microcolon megacystis syndrome[60,61] is suspected when

FIGURE 18–17
Urodigestive fistula with hyperechogenic content of the small bowel at 23 weeks. *A,* Transverse view. *B,* Frontal view.
FIGURE 18–18
Absence of image of the anal margin at 23 weeks (tangential view of the perineum).

there is a large bladder and bowel dilation. However, the bowel dilation may occur only late in the third trimester. This syndrome has a poor prognosis owing to associated abnormalities in digestive function.

Karyotyping

The second step in the diagnostic workup is to consider fetal karyotyping. The incidence of chromosomal abnormalities associated with genitourinary defects was initially reported to be 12%.[62] However, in many uropathies secondary to chromosomal abnormalities, additional extrarenal defects are detectable, reducing the prevalence of aneuploidy in truly isolated uropathies such as posterior urethral valves or hydronephrosis. Thus, the risk of aneuploidy

should be evaluated and weighed against the risk of an amniocentesis.[63–66] The finding of at least one ultrasound soft marker, such as a short femur or humerus, a minor anomaly of the fingers or toes, or a facial or other structural anomaly, indicates a high risk of aneuploidy. When previous aneuploidy screening such as nuchal translucency measurement or maternal serum markers yield "borderline" risks, one should consider the finding of a fetal uropathy as raising the risk above the "action line." Unfortunately, large studies that would allow calculation of the likelihood ratio of aneuploidy associated with isolated unilateral hydronephrosis or posterior urethral valves are lacking. Regardless of the risk of aneuploidy, some parents may request karyotyping in order to maximize their opportunities of excluding associated abnormalities in a baby for whom neonatal surgery and long-term uronephrologic follow-up are likely.

Whether or not pyelectasis is an indication for karyotyping has been a matter of controversy owing to the high incidence of pyelectasis in normal children. When pyelectasis is associated with another fetal anomaly, even minor, the risk of aneuploidy is increased 10 to 20 times the maternal age–related risk[67,68] and karyotyping is indicated. Early studies suggested isolated pyelectasis to be associated with a substantial risk for Down syndrome. However, more recent studies have shown the risk of aneuploidy is increased by a likelihood ratio of only 1 to 1.5.[64,69] It is likely that in later studies, associated soft markers were diagnosed more frequently than in early reports. Careful ultrasonographic evaluation is therefore necessary to rule out associated minor abnormalities when pyelectasis is diagnosed at routine ultrasound. Pylectasis should be considered as a part of the sequential screening process for aneuploidy using multiple parameters including maternal age, nuchal translucency measurement, and maternal serum markers (see Chapters 7 and 8).[25–28,66,70–77] The integrated risk of aneuploidy should then be weighed against the risks of amniocentesis.[64]

Predicting Postnatal Pulmonary Function

Pulmonary hypoplasia (PH) is a disorder of impaired lung growth characterized by diminished size, generational branching, and vasculature. Severe oligohydramnios from 16 weeks onward appears to preclude further pulmonary development. In contrast, oligohydramnios developing after the second trimester is unlikely to result in PH because the crucial canalicular phase of lung development (occurring between 16 and 25 weeks) has largely been completed by this stage. Predicting the likelihood of PH is difficult. Most studies reporting predictive data have used cases with preterm premature membrane rupture (PPROM),[78–80] and it is not clear how applicable such data are to cases of olgo-hydramnios secondary to fetal uropathy. In the case of PPROM, additional factors such as preterm delivery and infection contribute to the outcome, and one might speculate that they will worsen the prognosis in contrast to oligohydramnios alone. However, the PPROM data suggest the following:

- If there is a mean vertical pocket of amniotic fluid on ultrasound prior to 26 weeks of greater than 10 mm, PH is very unlikely to occur.[78]
- If the mean vertical pocket of amniotic fluid on ultrasound prior to 26 weeks is less than 10 mm, there is a 90% neonatal mortality rate.[78]
- If the mean vertical pocket of amniotic fluid on ultrasound after 26 weeks is less than 10 mm, PH is very unlikely to occur.[78–80]

Thus, although absence of severe oligohydramnios before 26 weeks probably means that PH is unlikely, predicting which fetus will develop PH after birth is more difficult. New imaging methods such as magnetic resonance imaging and 3D ultrasonography have been used to evaluate fetal lung volumes and might improve the prediction of PH.[81–83]

Predicting Postnatal Renal Function

Unilateral uropathies are associated with a good functional outcome, and it is unnecessary to perform invasive fetal studies to obtain biochemical data from the abnormal kidney, regardless of renal ultrasonographic appearance. Serial examinations are required to ensure that contralateral lesions do not appear later in gestation.

The evaluation of fetal renal function with bilateral renal dilation or LUTO is based mainly on ultrasound and, in selected cases, on fetal urine analysis or fetal blood sampling. Ultrasound permits assessment of the parenchyma and the amniotic fluid volume.[18,40,84] Fetal urine analysis assesses the ability of the renal tubule to reabsorb a variety of compounds, including sodium, β_2-microglobulin, calcium, phosphorus, and glucose.[37,51,85–95] The β_2-microglobulin level in the fetal serum is thought to reflect fetal glomerular function.[96–99] Fetal sonographic features related to terminal renal failure include severe oligohydramnios and abnormal images of the renal parenchyma, such as loss of the normal corticomedullary differentiation, hyperechogenicity, and cortical cysts (see Fig. 18–12*B*). In these instances, fetal urinalysis might confirm renal failure, showing high fetal urinary concentrations of sodium and β_2-microglobulin.[100] Conversely, the functional prognosis is usually good and fetal urine

sampling unnecessary in cases of upper obstruction with normal amniotic fluid volume and normal renal parenchyma throughout pregnancy.

In select cases, the functional prognosis cannot be established ultrasonographically. These cases include fetuses with bilateral lesions and moderately decreased amniotic fluid volume and fetuses with mild alterations of the renal parenchyma. Moreover, in cases in which the antenatal diagnosis of posterior urethral valves is almost certain, the relatively high incidence of postnatal renal failure may support fetal urine sampling, even in the absence of any ominous ultrasonographic finding. For such cases, the key issue is to identify, among the children expected to survive, those who are at risk for developing postnatal renal failure from those whose renal function will remain normal after surgical repair. The establishment of prognostic values for any marker is complicated by the fact that renal failure may occur relatively late in life, underscoring the need for long-term follow-up of children in whom fetal urine analysis was performed in utero. Some studies show that fetuses with a normal urinary sodium but a urinary β_2-microglobulin above the 95th percentile are at increased risk of having a serum creatinine greater than 1 standard deviation (SD) above the mean by 1 year of age.[87] When both markers are increased, neonatal renal failure is likely. In contrast, a good postnatal outcome is anticipated when both markers are within the normal range.[87] Others report higher thresholds for fetal urinary β_2-microglobulin to predict a postnatal serum creatinine greater than 2 SD above the mean, thereby increasing specificity.[92] To increase the predictive accuracy of fetal urinalysis, sampling of the apparently less affected kidney[45] or serial vesicocentesis (as long as the values continue to improve or until they normalize) has been advocated.[92,101] In our experience, the results of fetal urinalysis should be interpreted with great care because, in the absence of ominous sonographic findings, only very high levels of urinary β_2-microglobulin (i.e., >10 mg/L) are reliable predictors of renal failure at the age of 10 to 16 years (unpublished data).

Management Options

GENERAL

Once the prognosis is determined, management options, including termination of pregnancy, occasionally fetal therapy, postnatal care, and follow-up, should be discussed with the parents. The option of pregnancy termination should be raised whenever there is terminal renal failure or multiple malformations. Fetal intervention is not indicated when there is unilateral disease or an isolated uropathy with normal renal parenchyma and normal renal function. In these instances, care is focused on postnatal management. It is important to refer the couple antenatally to a pediatric urologist/nephrologist.

IDENTIFICATION OF CONDITIONS REQUIRING EMERGENCY NEONATAL SURGERY

Some isolated uropathies in which postnatal renal function is anticipated to be reasonably good may require emergency postnatal surgery, requiring delivery in a tertiary care center with pediatric surgery facilities. These include posterior urethral valves, obstructive ureterocele, major bilateral hydronephrosis, and more generally, cases with late-onset oligohydramnios leading to the diagnosis of acute obstruction of urinary output.

Fetal Therapy

Fetal therapy for uropathies may be considered because, although obstruction of the urinary tract may be treated by relatively simple postnatal procedures, some abnormalities are associated with severe renal lesions that manifest before birth. These lesions include severe renal dysplasia, severe oligohydramnios, and pulmonary hypoplasia, leading to either perinatal death or end-stage neonatal renal failure. Although intrauterine decompression of experimental urinary tract obstruction in the fetal lamb has been shown to prevent renal dysplasia,[102–105] a positive impact of fetal urinary decompression on chronic renal disease in the human has not been demonstrated.[106–112]

Lower urinary obstruction in the human fetus has been treated by open fetal surgery, endoscopic ablation of posterior urethral valves, percutaneous vesicoamniotic shunting, serial vesicocentesis, or more recently, percutaneous fetal cystoscopy. Some of these techniques can also be applied to upper tract obstruction. Open fetal surgery was abandoned with the development of percutaneous techniques. Serial vesicocentesis has been performed as early as the first trimester,[113] but its efficacy remains unclear. Indeed, resolution of first-trimester urinary dilation following percutaneous needling may reflect the natural history of the condition rather than the intervention.[114]

Percutaneous ultrasound-guided vesicoamniotic shunting was first reported in the 1980s.[115] Briefly, a cannula is inserted through the maternal abdomen under ultrasound guidance and after local analgesia into the dilated fetal bladder or kidney. A double pigtail catheter is introduced through the cannula with the distal end placed into the dilated urinary tract and the proximal end in the amniotic cavity. Complications include chorioamnionitis, premature rupture of membranes, or preterm delivery in around 10% of cases.[116,117] Up to half of the shunts are displaced after a few days or weeks. Migration of the amniotic end into the peritoneal cavity can cause urinary ascites, which can be treated, with modest success, by placing a peritoneoamniotic shunt.[118,119] Other complications include iatrogenic gastroschisis.

Some reviews[120,121] concluded there is a lack of high-quality evidence to guide clinical practice regarding prenatal bladder drainage.[106,109,122–125] In utero drainage may improve survival in severely affected fetuses by improving lung function, but this is achieved at the expense of increasing pediatric morbidity. Long-term follow-up of shunt survivors reveals that some form of chronic renal disease is the rule. Many are ultimately transplanted. A multicenter randomized trial comparing expectant management with percutaneous shunting for lower urinary tract obstruction (PLUTO) is under way with the aim of determining whether or not fetal therapy improves survival and reduces long-term morbidity.[126] Percutaneous fetal cystoscopy has been used to directly visualize the fetal urinary tract.[127–129] This allows differentiation of posterior urethral valves from urethral atresia and fulguration of posterior urethral valves.[130]

SUMMARY OF MANAGEMENT OPTIONS

Fetal Uropathies/Dilation of the Renal Tract

Management Options	Evidence Quality and Recommendation	References
Diagnosis		
Confirm diagnosis with detailed ultrasound by expert.	III/B	42
Search for other abnormalities.	III/B	50
Consider karyotype.	III/B	62
Management		
Assess risk of pulmonary hypoplasia.	IIa/B	80–83
Assess risk of renal failure:		
• Ultrasound	III/B	40
• Urinalysis	IIa/B	87,88,91,93
Interdisciplinary management and planning includes pediatric nephrologist/urologist.	—/GPP	—
Counsel parents.	—/GPP	—
Consider termination of pregnancy in severe cases.	—/GPP	—
Plan for delivery depends on anticipated need for early pediatric surgery.	—/GPP	—
The role of fetal therapy is unclear: decompression probably reduces deaths from pulmonary hypoplasia but at the expense of long-term renal dysfunction in survivors.	Ia/A	120–125
Perform careful examination and assessment of baby after delivery or postmortem examination after perinatal death.	III/B	100

GPP, good practice point.

KIDNEY ABNORMALITIES

General

Fetal renal anomalies include those of number, location, size, and structure. These malformations are primarily renal and usually occur in the absence of a urinary tract defect. Some, such as renal agenesis or multicystic kidney disease, are common and easy to diagnose. The diagnosis and antenatal management can be more difficult when renal structural anomalies present as hyperechogenic or enlarged kidneys. The first step after a renal abnormality has been identified is to exclude associated anomalies and, if necessary, offer fetal karyotyping.

The prognosis of isolated unilateral renal abnormalities is uniformly good, whereas bilateral anomalies associated with severe oligohydramnios are lethal. In bilateral cases with normal amniotic fluid, the long-term postnatal morbidity is difficult to predict. Biochemical markers that have proved predictive of postnatal morbidity in uropathies have not been useful in fetal nephropathies. Our personal experience suggests that neither fetal urinary electrolytes nor serum β_2-microglobulin is a reliable predictor of postnatal renal function in fetuses with bilaterally enlarged and hyperechogenic kidneys and normal amniotic fluid volume (unpublished data).

Anomalies of Number

Renal agenesis can be unilateral or bilateral. It may result from early degeneration of the ureteric bud or from a failed interaction between the ureteric bud and the blastema (Figs. 18–20 and 18-21). The corresponding adrenal gland assumes a globoid shape and should not be mistaken for a hypoplastic kidney.[131] Bilateral agenesis results in the oligohydramnios sequence (pulmonary hypoplasia, dysmorphic face, and limb deformities) and is lethal.[68,132] In contrast, fetuses with unilateral renal agenesis remain symptom-free during postnatal life in the absence of associated anomalies. Minor genital anomalies such as duplicated/hypoplastic uterus, absent fallopian tube, and absent epididymis and vas efferens can be found on the ipsilateral side. They cannot be diagnosed in utero and would not alter the prognosis for survival.[118,119]

Duplication of the kidney is caused by the premature division of the ureteric bud before it connects to the nephrogenic mesoderm (Fig. 18–22). This explains its association with a double or bifid ureter. The upper ureter typically enters the bladder more caudally but might also connect ectopically to the urethra, vagina, seminal vesicle, or rectum. The upper kidney usually shows some degree of outflow obstruction and parenchymal dysplasia. Typical findings include a dilated pelvis in a dysplastic part of the kidney

FIGURE 18–20

associated with a ureterocele at the connection of the distal ureter to the bladder.[133] The accuracy of antenatal ultrasound for the diagnosis of fetal duplex kidney approximates 75%, based on two main ultrasonographic features: two separate poles in the affected kidney and a ureterocele.

Supernumerary kidney results from premature branching of the ureteric bud. The supernumerary kidney has its own ureter and blood supply and is frequently obstructed or dysplasic.

Abnormalities of Position

Ectopic kidneys are usually displaced caudally One or both kidneys may be involved and the shape is abnormal due to malrotation. Affected individuals are asymptomatic provided the renal parenchyma is well differentiated and free of dysplasia.[134] In crossed renal ectopia, both kidneys are located on the same side of the body and may be fused.

Horseshoe kidney results from the fusion of the kidneys, usually by their lower poles.[135] Fusion of both upper and lower poles produces the ring kidney. When isolated, horseshoe kidneys are usually asymptomatic. However, they are also associated with aneuploidy (trisomy 18, Turner's syndrome, and triploidy).

Isolated Abnormalities of Size and Structure

Renal hypoplasia is defined as kidney mass more than 2 SD below the mean. This condition is diagnosed postnatally except in its most severe form.

Multicystic dysplasia manifests antenatally as kidneys that have lost their normal shape (Fig. 18–23) due to macrocysts of variable diameter (≥0.5–3 cm) that are connected neither to each other nor to the rest of the urinary tract. Some clusters of tubules, rudimentary glomeruli, primitive ducts, and bars of metaplastic cartilage may be irregularly distributed within the loose mesenchyme. Multicystic dysplasia usually occurs in the absence of any obstructive uropathy. Whereas bilateral disease is lethal, unilateral forms have a good prognosis. Spontaneous involution of the multicystic kidney is usual during postnatal life and may on occasion occur in utero. The cyst size is usually constant throughout fetal life, but rarely, extremely large cysts may compress the fetal abdomen or cause dystocia and therefore require intrauterine drainage. These macrocystic lesions are easy to distinguish from polycystic kidney diseases, which present antenatally as enlarged hyperechoic kidneys. The sonographic pattern of the latter conditions is due to the microscopic cysts that fill the renal parenchyma.[136]

Autosomal recessive polycystic kidney disease (ARPKD), also referred to as *infantile polycystic kidney disease*, is an inherited disorder. It is characterized by enlarged kidneys that retain their shape. The cut surface has a spongy appearance due to elongated microcysts that have a radial orientation extending from the medulla to the cortical surface. These cysts correspond to dilated collecting ducts.[118,119] The liver is always involved with portal fibrosis and proliferation of

bile ducts.[137,138] Postnatally, the diagnosis is easy to make based on typical anatomic features. Pathologic diagnosis, however, may be more difficult in the second-trimester fetus, underscoring the need for referring abnormal kidneys to pathologists familiar with fetal renal development.

Disease expression in utero is variable.[139–143] In some affected fetuses, the kidneys remain ultrasonographically normal. In this instance, renal enlargement develops during infancy, and renal failure occurs relatively late in the second decade. At the other end of the spectrum, ARPKD manifests in the second trimester as an anuric fetus with absent amniotic fluid and dramatically enlarged, hyperechogenic kidneys with no corticomedullary differentiation (Fig. 18–24). Intermediate forms are the norm, with a variable combination of renal enlargement and late-onset oligohydramnios.[142] The responsible gene has been mapped.[144]

Autosomal dominant polycystic kidney disease is also referred to as adult polycystic kidney disease because its clinical onset usually occurs in adulthood. This term, however, is misleading because autosomal dominant polycystic disease may manifest early and occasionally quite severely, including during fetal life. Autosomal dominant polycystic kidney is a common cause of enlarged hyperechogenic kidneys in the fetus because of the relatively high frequency of the mutation in the general population.[143,145–147] Fetal autosomal dominant polycystic kidney disease often presents as moderately enlarged hyperechogenic kidneys with increased corticomedullary differentiation,[148] with normal amniotic fluid volume and bladder. It may also present as enlarged hyperechogenic kidneys with no specific feature. Fetal terminal renal failure associated with very large kidneys is a rare occurrence in autosomal dominant polycystic kidney disease. The diagnosis is easy when renal cysts are present in one of the parents. However, this hint may be lacking either because of the variability of disease expression or because the fetus has a new mutation.

In the adult, the kidneys are enlarged and their surface distorted by bulging macrocysts. During fetal life, however, the cysts are usually very small, producing a sonographic pattern of enlarged, hyperechogenic kidneys similar in appearance to that of the recessive disease.[143] In the most
FIGURE 18–23
Unilateral multicystic kidney at 20 weeks. *A*, Transverse view. *B*, Frontal view.

Enlarged hyperechogenic kidney (autosomal recessive polycystic kidney disease) at 36 weeks. *A*, Transverse view. *B*, Parasagittal view. Note the absence of corticomedullary differentiation of the renal parenchyma.
severe cases with terminal renal failure in utero, the diagnosis is made post mortem by showing both collecting tubules and nephrogenic cysts. Several mutations can result in disease. Known sites include chromosome 16 (PKD1 locus) and chromosome 4 (PKD2 locus).[149,150]

Transient nephromegaly is a poorly understood condition and can be defined as renal enlargement without any alteration of renal function. These patients may present as fetuses with moderately enlarged kidneys in which corticomedullary differentiation is usually retained. The kidneys may appear slightly hyperechogenic. The amniotic fluid volume remains normal. The ultrasonographic abnormalities tend to regress during infancy and the children remain symptom-free.[151] The uneventful postnatal course may be the only way to distinguish this condition from a true renal disease, such as polycystic kidney disease, or from less common causes of enlarged fetal kidneys.[143] Renal vein thrombosis may result in unilateral renal enlargement and hyperechogenicity.

Prenatal Management of Isolated Hyperechogenic Kidneys

The counseling of a pregnant woman after a prenatal diagnosis of isolated hyperechogenic fetal kidneys is challenging, because providing patients with overly pessimistic information leads to unnecessary pregnancy termination, whereas unrestricted reassurance may be inappropriate. Fetal ultrasonography usually fails to provide an accurate etiologic diagnosis, and fetal hyperechogenic kidneys can result from a variety of etiologies, including ARPKD, ADPKD, and transient nephromegaly.[152,153] Further, there is a wide range of outcomes within each etiologic group. Postnatal series are likely to overlook the most severe cases leading to perinatal death, as well as the mildest ones, which may remain clinically undetectable over a long period. A TCF2 gene

mutation with Mody type diabetes is occasionally associated with moderately enlarged hyperechogenic kidneys.

The outcome can be predicted accurately in the most severe cases, in which terminal renal failure is certain with the discovery of severe oligohydramnios in the second trimester. If the pregnancy is terminated, it is crucial to obtain an accurate etiologic diagnosis and to store fetal DNA, because this information may lead to first-trimester molecular prenatal diagnosis in subsequent pregnancies, should ARPKD or ADPKD be identified. A wrong histopathologic diagnosis might have dramatic consequences in terms of genetic counseling and prenatal diagnosis.

In less severe cases, antenatal counseling should be based on prospective studies with long postnatal follow-up. In our experience of a consecutive series of 45 fetuses with bilateral isolated hyperechogenic kidneys, there were 20 with ARPKD, 8 with ADPKD, 9 with other renal disorders, and 6 symptom-free survivors without an etiologic diagnosis.[143] There were 19 pregnancy terminations, 5 neonatal deaths, and 19 survivors, of whom 14 had normal renal function, 3 had mild renal failure, and 2 had end-stage renal failure. None of those with severe oligohydramnios and fetal kidneys greater than 4 SD survived ($n = 14$, 10 terminations, 4 neonatal deaths), whereas 13 of 16 with normal amniotic fluid volume and kidneys less than 4 SD survived; 9 were symptom-free with a follow-up of 34 to 132 months.

Rare Etiologies of Fetal Nephropathies

Renal tubular dysgenesis is a rare condition characterized by poorly developed or undeveloped proximal tubules, causing severe oligohydramnios.[154] It is thought to be due to an abnormality of the renin-angiotensin system because similar renal anomalies are reported after prenatal exposure to angiotensin-converting enzyme inhibitors. This lethal condition is probably inherited as an autosomal recessive

disorder and should be recognized at fetal autopsy in order to provide appropriate genetic counseling. Prolonged exposition to indomethacin may also induce renal failure, but probably by a different mechanism.[155]

Nephroblastomatosis is characterized by the presence of nephrogenic rests of metanephric blastema in both kidneys.[156] The kidneys may appear hyperechogenic with an unusually disorganized pattern of corticomedullar differentiation and this may be associated with overgrowth syndromes such as Beckwith-Wiedemann syndrome. Affected patients are also at increased risk for developing Wilms' tumor (see Chapter 22).

Renal tumors that present during fetal life are rapidly growing solid heterogeneous masses.[157] They are easy to distinguish from single transonic cysts that can also be recognized in utero but remain asymptomatic postnatally. Mesoblastic nephroma are reported to have a typical "ring" sign on color Doppler examination consisting of an anechoic ring surrounding the tumor signal.[158]

Fetal Nephropathies with Polyhydramnios

The Finnish type of congenital nephrotic syndrome may present antenatally with hydramnios, placentomegaly, and moderate growth restriction. Modest alterations in the renal parenchyma such as hyperechogenicity are inconsistent, making the antenatal diagnosis difficult in the absence of an index case.[159–161] Biochemical analysis of amniotic fluid should be considered in cases of unexplained hydramnios because this may lead to a diagnosis of fetal proteinuria (high concentration of α-fetoprotein and other proteins). Anomalies of electrolyte or aldosterone concentrations in the amniotic fluid may suggest Bartter's syndrome,[162–166] which is characterized by early-onset hydramnios and mild pyelectasis resulting from fetal polyuria.

Cystic Kidneys and Multiple Malformation Syndromes

Cystic kidneys are part of several multiple malformation syndromes.[167] The autosomal recessive Meckel-Gruber syndrome is one of the most common and lethal. It is characterized by severe oligohydramnios during the second trimester with markedly enlarged kidneys containing multiple cysts.[168,169] Encephalocele and postaxial polydactyly are characteristic of the syndrome but can be difficult to see with severe oligohydramnios.[160] Severe oligohydramnios and enlarged dysplastic kidneys can also be sonographic features of chromosomal abnormalities such as trisomy 13. Horseshoe kidney is associated with trisomy 18, Turner's syndrome, or triploidy.

The Laurence-Moon-Bardet-Biedl syndrome presents antenatally as hyperechogenic kidneys with polydactyly. Growth is usually normal during fetal life. In the Beckwith-Wiedemann syndrome, the enlarged kidneys are part of a more generalized visceromegaly, occasionally associated with an omphalocele. DiGeorge's syndrome may manifest as a heart defect associated with renal abnormalities. Zellweger's syndrome appears as renal cortical cysts with cerebral periventricular pseudocysts. Smith-Lemli-Opitz syndrome is suggested by the findings of dysplastic kidneys, fetal growth restriction, abnormal fingers, and ambiguous genitalia.

Dysplastic kidneys are also found in a variety of other syndromes, but usually as a secondary finding (e.g., short rib polydactyly associations). This underscores the need for careful ultrasonographic evaluation when abnormal kidneys are found. Fetal karyotyping should be considered when the structure of the kidneys is abnormal (hyperechogenicity/suspected dysplasia). However, isolated multicystic kidneys, renal agenesis, and ectopic kidneys are not associated with an increased risk of aneuploidy.

ABNORMAL GENITALIA

General

Although fetal ultrasound is widely used to determine fetal gender, there is no consensus as to whether the structure of external genitalia should be part of routine ultrasound screening. Genital abnormalities can have a devastating impact on postnatal life and may be the hallmark of a multiple malformation syndrome. Ambiguous genitalia can be a medical emergency in neonates with salt-wasting forms of congenital adrenal hyperplasia. An examination of the fetal genitalia is mandatory whenever a uronephrologic abnormality is found to rule out a complex malformation of the fetal pelvis (Fig. 18–25).

Sonographic Diagnosis

Abnormal fetal genitalia may be identified under different circumstances:

- A specific genetic risk based on family history. This includes 5α-reductase deficiency, androgen insensitivity, and congenital adrenal hyperplasia. However, in an increasing number of cases, the molecular defect responsible for the disease is known, allowing first-trimester genetic diagnosis using chorionic villi.
- A discrepancy between the fetal gender established on routine ultrasound and fetal karyotyping.
- Abnormal or ambiguous genitalia found during routine ultrasound, either isolated or as part of a complex anomaly of the fetal pelvis or of a multiple malformation syndrome.

Undescended testis (Fig. 18–26) can be physiologic in the second trimester. Associated abnormalities, including uropathies and the prune-belly syndrome, should be ruled out. The diagnosis of hypospadias is usually made during the third trimester. Even in experienced hands, antenatal diagnosis of hypospadias may be impossible because of fetal position or technical limitations, including oligohydramnios. Anterior or middle hypospadias is rarely identified antenatally, although it is usually self-evident on examination of the neonate. Occasionally, the fetal penis is suspected to be shorter than usual or to have an abnormal curvature (Fig. 18–27). The tip of the penis may seem blunt. Ventral deflection of urinary stream can occasionally be seen using color Doppler.[170] Posterior hypospadias may be diagnosed antenatally based on the finding of a bifid scrotum, a short, curved penis, and no urethral canal (Fig. 18–28). The angulated penis located between the two scrotal folds is said to resemble a tulip flower.[171] When associated with undescended testis, posterior hypospadias may be difficult to differentiate from masculinized female genitalia with fused labia and an enlarged clitoris.[172] Rare conditions identifiable antenatally by ultrasound include distal obstruction of the fetal urethra (Fig. 18–29), perineal tumors, congenital hernia, and penoscrotal transposition.[173]

Gender discrepancies may be explained by a variety of mechanisms.[174] A discrepancy between the phenotypic fetal gender and the fetal karyotype may result from a labeling error of the amniotic fluid sample, a typing error

in ultrasonographic or genetic records, or maternal contamination of amniotic fluid cultures. The ultrasound examination should seek to establish whether the external genitalia seem structurally normal or ambiguous. Enlarged adrenal glands in the third trimester are suggestive of adrenal hyperplasia and result more often in ambiguous virilized female genitalia than in a male phenotype with an abnormal scrotum (Fig. 18–30). The presence of a fetal uterus can occasionally be documented sonographically, but its absence can never be ascertained confidently. Conversely, when abnormal genitalia are first identified by ultrasound, fetal genetic sex is the first step toward an antenatal diagnosis. This can be achieved by fetal karyotyping[172] or by analyzing the presence of the *SRY* gene in maternal plasma.[175–177]

Management Options

In addition to establishing the anatomy of the fetal genitalia, associated abnormalities should be sought. A number of multiple malformation syndromes including Smith-Lemli-Opitz, CHARGE (coloboma, heart disease, atresia choanae, retarded growth and retarded development and/or central nervous system anomalies, genital hypoplasia, and ear anomalies and/or deafness), Prader-Willi, and camptomelic dwarfism can be associated with genital abnormalities. Cloacal malformations may be part of a more complex entity, such as the VATER (vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia) association or a caudal regression syndrome. Fetuses with bladder exstrophy have abnormal genitalia. A bifid genital tubercle with epispadias may be found in males. The diagnosis is based on the absence of a fetal bladder associated with a low-lying fetal umbilical cord insertion and an abnormal bony pelvis. Cloacal exstrophy can produce bowel abnormalities suggestive of gastroschisis associated with vesical exstrophy.

The results of the fetal karyotype should be interpreted with great care, for the "genetic" gender may not be the "true" gender of the infant. For example, XX males bearing the *SRY* gene are unambiguously boys and XY fetuses with complete androgen insensitivity present as females. Adrenal hyperplasia may be suspected by ultrasound and confirmed by measuring the amniotic fluid 17-OH progesterone concentration.

In families with a history of congenital adrenal hyperplasia, management options include first-trimester gender determination by fetal DNA analysis in maternal serum (see Chapter 21). Both male and female fetuses are at risk for adrenal insufficiency. Only female fetuses are at risk for genital anomalies, and therefore, they may benefit from dexamethasone administration via the mother as early as possible during gestation in order to limit virilization.[178,179]

In general, counseling after the antenatal diagnosis of an apparently isolated abnormality of external genitalia is challenging and might be devastating for the family. Identifying the mechanism of the anomaly is helpful. Determining the anatomy of the fetal genitalia is crucial to establish the prognosis in terms of the potential for surgical repair. Counseling by a pediatric surgeon and a pediatric endocrinologist with experience of intersex states is warranted to provide the parents with information on postnatal management and gender assignment.

Fetal Gastrointestinal Abnormalities

PETER STONE

Videos corresponding to this chapter are available online at www.expertconsult.com.

INTRODUCTION

Fetal gastrointestinal and abdominal wall malformations are easily visualized by ultrasound and may be detected either during a routine second trimester scan or during an examination for a raised maternal serum α-fetoprotein, poor fetal growth, or hydramnios. The most common gastrointestinal abnormalities detected antenatally are omphalocele, gastroschisis, and diaphragmatic hernia. The accuracy of ultrasound in such conditions is high with a very low false-positive rate.[1] Gastrointestinal anomalies should be managed by a fetal medicine specialist in collaboration with a neonatal pediatrician, pediatric surgeon, clinical geneticist, and anesthesiologist. The patient should meet this multidisciplinary team before delivery either on an individual basis or as a group. Parental informational needs vary with the stage in the diagnostic and treatment pathway.[2]

OMPHALOCELE (EXOMPHALOS)

General

This is an extraembryonic hernia due to the arrest of ventral medial migration of the dermatomyotomes. Omphalocele occurs in between 1 in 2500 and 1 in 5000 pregnancies, though this may vary with location and ethnicity.[3] "Physiologic" herniation of abdominal contents into the base of the umbilical cord is normal up until approximately 11 weeks' gestation (Fig. 19–1) and must be distinguished from an omphalocele. Importantly, omphalocele is associated with other malformations 60% to 80% of the time,[4] especially when the omphalocele is superior to the umbilicus. Pentalogy of Cantrell is a particularly severe defect consisting of a supraumbilical omphalocele, a defect in the lower sternum, deficiency of the anterior part of the diaphragm, defects of the diaphragmatic part of the pericardium, and a range of cardiac abnormalities.[5] Survival is poor, particularly with major cardiac abnormalities and aneuploidy.[6] The genomic imprinting disorder Beckwith-Wiedemann syndrome (macroglossia, organomegaly, and hypoglycaemia) is also associated with omphalocele.

Diagnosis

An omphalocele is an extra-abdominal mass enclosed in a membrane. The diagnosis is made after 11 weeks' gestation when an anterior, extra-abdominal mass is detected upon which the umbilical cord inserts rather than into the anterior abdominal wall (Fig. 19–2). Hydramnios may be present. Defect size and type have some prognostic significance. Although the omphalocele contents are usually contained in a membrane, this may rupture spontaneously. A rare variant is the "giant" omphalocele (Fig. 19–3) in which the abdominal defect is massive with a base greater than 6 cm in diameter and most of the liver is extracorporeal. Giant defects and those in which the membrane has ruptured are often associated with a small or defective thoracic cage, pulmonary hypoplasia, and postnatal respiratory complications.[7] There may be difficulty distinguishing gastroschisis from ruptured omphalocele, but the latter is commonly associated with other abnormalities (Table 19–1). Fetal growth restriction is common, and approximately one in six fetuses will be chromosomally abnormal. A small omphalocele may be missed on ultrasonography, especially if the fluid volume is reduced. However, the sensitivity of ultrasound detection exceeds 95% with a specificity of 100%.[6] The presence of a thickened cord insertion without definite signs of an omphalocele should raise the possibility of an occult omphalocele or umbilical hernia. Care should be taken to clamp the umbilical cord at delivery at least 5 cm from the neonate's abdominal wall to avoid inadvertent bowel occlusion.[8] Similarly, the presence of umbilical cord cysts requires careful follow-up.[9]

Both omphalocele and gastroschisis produce a very high maternal serum α-fetoprotein concentration during the second trimester. Amniotic fluid, if sampled, will show a faint acetylcholinesterase band and a dense pseudocholinesterase band. This pattern is opposite that of a neural tube defect.[10]

Risks

There are few obstetric risks to the mother apart from the rare complication of hydramnios. Perinatal risks include those of invasive diagnostic testing, the implications of

associated abnormalities, and postnatal surgery that may be complicated when the liver is extracorporeal.

Management Options

Prenatal

The first step is to exclude other abnormalities. This mandates a detailed ultrasonographic examination, including a fetal echocardiogram and a fetal karyotype. Abnormal cardiac findings occur in 45% of fetuses with omphalocele.[11] The ultrasonographic differentiation between omphalocele and gastroschisis is important and generally not difficult. The presence of a sac or membrane around the contents with the umbilical cord inserting upon it is pathognomonic. Difficulties arise when the sac has ruptured spontaneously or when the relationship of the herniated tissue to the umbilical cord insertion is unclear. On occasion, thickened loops of bowel in the fetus with gastroschisis may appear as a covering membrane. The peritoneal membrane can also be

difficult to visualize when there is oligohydramnios. In contrast to gastroschisis, extracorporeal liver is common (40%). Fetuses with intracorporeal liver are more likely to have chromosomal abnormalities, as are fetuses with other malformations and those with mothers of advanced age. There is probably little prognostic significance of the omphalocele contents if the karyotype is normal, except for a worse prognosis with large defects.

Parental counseling should stress the importance of a fetal karyotype. Studies based on prenatal as opposed to postnatal diagnosis show a generally poor prognosis owing to the large number of associated abnormalities and aneuploidy, especially trisomy 18.[7] Fetuses with isolated omphalocele generally have a good prognosis (although not all abnormalities may be detected before birth). Even with postnatal diagnosis, the survival rate of otherwise normal infants exceeds 75%.[12] Large abdominal wall defects can pose particular problems for both neonatal respiratory management and surgical closure, and these issues should be covered during counseling with the neonatologist and pediatric surgeon. Death of the otherwise normal infant results from prematurity sepsis or problems with short gut syndrome, which is more common with gastroschisis than with omphalocele. Long-term follow-up suggests that the quality of life for adults is similar to that of the general population, although disorders of the abdominal wall scar are reported in 37% of cases and functional gastrointestinal disorders in 51%.[13] Various orthotic interventions are available to assist in the management of giant omphalocele.[14] Parents may benefit from illustrations showing typical defects before (Fig. 19–4) and after surgery. The option of termination of pregnancy should be discussed with parents, especially when other abnormalities are present. Prolonged hospitalization, repeat surgery, and quality of life are all issues that influence parental decision-making.

FIGURE 19–4
Omphalocele at delivery. The lesion is epigastric and at the site of the umbilical cord insertion. The contents of the omphalocele may be seen through the membrane.

Labor and Delivery

Delivery should occur in a center with a neonatal medical and surgical team in attendance to optimize the transition to ex utero life and the preoperative care. There is no evidence that elective cesarean delivery a priori confers any benefit to the fetus or neonate with omphalocele with or without a ruptured sac and irrespective of the contents of the sac.[15] Theoretical concerns for vaginal delivery, including visceral trauma, dystocia, and infection, are unsupported. In one series in which the diagnosis was known in only a minority of cases, cesarean delivery made no difference to neonatal outcome.[16] There are untested scenarios in which cesarean delivery might be considered, such as extracorporeal liver when torsion with obstructed cardiac return is a theoretical concern. Neonatal morbidity in all recent series relates to associated anomalies and prematurity. Isolated cases with late morbidity and death relate mostly to complications of bowel obstruction or short bowel syndrome in association with intestinal atresia.[17]

Postnatal

Prevention of heat and fluid loss and infection are the initial goals after delivery while the neonatal evaluation is completed and the surgery planned. These infants are at increased risk of hypothermia owing to the large surface area of exposed viscera. The neonate is immediately lowered into a sterile plastic bag containing warm electrolyte (no warmer than 37.5°C), plasma solution, and antibiotics (e.g., Vi-Drape isolation bag). In emergencies, any sterile bag with warmed normal saline or lactated Ringer's solution and antibiotics will suffice. A suitable solution consists of 1 L lactated Ringer's solution, 0.5 L stable plasma protein or similar solution, and 1 million units of penicillin. The bag is tied at the level of the axillae and care is taken to avoid torsion of viscera. Alternatively, a sterile plastic bag without the fluid may be used. A nasogastric tube is passed to keep the bowel decompressed, and ventilatory support is provided when necessary.

Neonates with associated lethal structural malformations or trisomy 13 or 18 are typically managed nonsurgically. Untreated neonates generally die of dehydration or sepsis. There are two main options for comfort care: either keep the neonate comfortable, providing supportive care only, or paint the unruptured omphalocele sac with 1% mercurochrome solution, although this has been associated with renal failure. Silver sulfadiazine is now the preferred compound when surgical closure is not planned or possible in the short term.

All other infants are managed surgically with operative repair as soon as the general condition is stable. It is difficult to predict antenatally whether a primary surgical closure is possible. Small defects less than 4 cm in diameter and without extracorporeal liver are almost always closed primarily. Large defects, or those containing liver, may not be closable at the first operation. When primary closure is not feasible, the defect and contents are covered with a Silastic silo sutured to the edge of the defect. Over the following days, the contents of the silo gradually enter the abdominal cavity under the influence of gravity coupled with the silo being compressed daily. Care must be taken to avoid respiratory or circulatory compromise during these maneuvers.

Postoperative problems common to all abdominal wall defect repairs include respiratory embarrassment, pulmonary hypertension, small bowel perforation, bowel obstruction, and malrotation. The average neonatal hospital stay after a silo ranges from 3 to 4 weeks. Parenteral nutrition is often necessary for days or weeks postoperatively. In some cases, it may be 3 months before satisfactory bowel function is achieved. Weakness of the anterior abdominal wall or a poor cosmetic result after the initial surgery may be corrected in a subsequent plastic surgical revision. Adhesive small bowel obstruction is not uncommon after surgical correction of congenital abdominal wall defects, particularly in the first year of life, but this together with pain and constipation may be long-term complications.[18]

The long-term prognosis for surviving infants is generally very good, and in the absence of associated structural or chromosomal abnormalities, the risk of recurrence in a subsequent pregnancy is extremely low. The main recurrence risk is that for the associated abnormalities, although case reports of a familial recurrence have been recorded.[19] Evidence from studies of the prevalence of fetal abnormalities after grain fortification with folic acid suggests that folate supplementation reduces the risk of omphalocele but not gastroschisis.[20]

GASTROSCHISIS

General

Gastroschisis is a paraumbilical defect, usually on the right side of the anterior abdominal wall lateral to the umbilical vessels. Left-sided defects are rare but may be associated with increased risks of other abnormalities.[21] The annual prevalence of gastroschisis approximates 1 in 2500 to 1 in 3000 live births with an equal sex ratio. Many studies appear to confirm an increasing incidence of gastroschisis, particularly in young, low-parity women.[22,23] The reason for the increase is not entirely explained by increased recognition of the problem. Gastroschisis has been considered a developmental accident (disruption), but the available genetic and epidemiologic evidence, as well as that from animal models, is more consistent with it being an abnormality during embryogenesis (malformation).[24,25] However, the precise etiology remains controversial.

Recent studies have suggested associations with recreational drug use, vasoactive substances, and aspirin,[26] although not all authors have implicated aspirin.[27] Iatrogenic abdominal wall defects have also resulted from placement of a vesicoamniotic shunt for obstructive uropathy. Large birth

Gastroschisis. *A,* Transverse section of a 14-week fetus shows the cord insertion adjacent to the abdominal wall defect on two-dimensional scanning and color-flow Doppler. *B,* Sagittal section of a fetus with gastroschisis. Note the absence of a membrane surrounding the bowel. *C,* Gastroschisis at 14 weeks' gestation shown on three-dimensional ultrasound.
defect registers suggest an incidence of associated defects of around 10%,[28] with cardiac defects being seen in 10% of cases.[29]

Diagnosis

The ultrasonographic image is one of free-floating loops of bowel with no covering membrane, typically appearing like a clump of grapes (Fig. 19–5).

Risks

Maternal risks are similar to those for omphalocele, reflecting complications of the anomaly. Fetal risks are associated with complications of bowel torsion that compromise the vascular supply or obstruction associated with atretic segments of intestine. The mechanism of damage to the extruded bowel serosa in contact with amniotic fluid remains unclear, and there are a number of theories for the formation of the so-called peel or perivisceritis. Matting of the bowel, detected on ultrasound, has been associated with the presence of meconium in the amniotic fluid and peel formation.[30] However, there is little evidence that the presence of peel affects the outcomes after surgical repair. Fetal growth

restriction frequently complicates gastroschisis but is not necessarily secondary to uteroplacental vascular dysfunction.

Neonatal complications include not only reduction and closure of the gastroschisis but also atretic segments and critical shortening of the bowel. Other short-term complications relate to the use of total parental nutrition, and some children suffer longer-term bowel dysfunction and neurodevelopmental delay, especially when there has been fetal growth restriction.[31]

Management Options

Prenatal

Although the risk of associated structural abnormalities is lower than that for omphalocele, a detailed ultrasonographic search remains important. The risk of an abnormal karyotype is 1% to 3%,[28] with trisomy 18 being the most common aneuploidy. Many physicians do not consider a karyotype necessary if the gastroschisis is isolated. The most common associated abnormalities are cardiac. Other abnormalities such as bowel stenosis and/or atresia are complications of the gastroschisis itself. Cleft palate and diaphragmatic hernia

have also been reported. On rare occasions, other viscera may be present within the gastroschisis including liver, uterus, and testes.

Serial ultrasonographic examination is recommended to assess fetal growth, amniotic fluid volume, and bowel appearance. However, any appraisal of fetal nutrition based on the abdominal circumference measurement is limited because any defect will artifactually reduce the circumference. Oligohydramnios may be associated with fetal growth restriction secondary to uteroplacental dysfunction. Hydramnios is the only antenatal ultrasonographic finding correlated with severe neonatal bowel complications.[32] The appearance of the bowel and the diameter of the bowel loops are not of prognostic significance.[33,34] Increased echogenicity and apparent thickening of the bowel wall after 28 weeks may represent a fibrinous coating or peel covering binding together loops of bowel. The etiology of the peel and interventions to prevent it are debated. There is conflicting evidence for the hypothesis that amniotic fluid components cause a chemical peritonitis. Although there is evidence of intra-amniotic inflammation in human gastroschisis,[35] prolonged intestinal exposure to amniotic fluid does not invariably lead to peel formation.[36] Amnioinfusion or amnioexchange procedures are reported,[37] but there is little evidence of benefit.

An alternative explanation for peel formation is venous and lymphatic obstruction, a hypothesis supported by the observation that the intra-abdominal peritoneum does not always show a peel, although it too is exposed to amniotic fluid. Although the presence of peel can make the surgical closure more difficult, it has little correlation with outcome and resolves quickly after surgical closure. Although increasing dilation of bowel loops might appear worrisome, it is not an indication for delivery (Fig. 19–6).[38] There is no evidence to suggest that early delivery to decrease exposure to amniotic fluid improves outcome. Term delivery at 37 weeks' gestation allows for an earlier, definitive closure of the defect and shorter times to full oral feedings.[39]
Parental counseling should emphasize the high chance of a good outcome with over 90% survival and a primary closure rate over 60%, reaching almost 100% in some units (Vipul Upadhyay, personal communication). Median hospitalization time is 27 days, although prolonged hospitalization up to 444 days has been recorded.[40,41] Repeated admission is often necessary with short bowel syndromes. Long-term follow-up studies suggest some morbidity related to bowel dysfunction and an increased risk of neurodevelopmental delays in fetuses with growth restriction.[31] Uncontrolled psychological studies have suggested that children followed to 10 years of age after surgery for abdominal wall defects may have more behavioral and learning problems than expected.[42]

Epidemiologic studies have shown a relationship between intrauterine death and abnormalities of amniotic fluid volume, especially oligohydramnios, and growth restriction.[22,43] The median gestational age of fetal death in one study was 34 weeks.[22] Close monitoring during the last trimester and especially toward term is therefore recommended. In the absence of abnormalities of growth, amniotic fluid volume, umbilical artery Doppler, or cardiotocography, the pregnancy may continue to term. There is little evidence that delivery before 37 weeks improves outcome.

Labor and Delivery

Fetuses with a gastroschisis should be delivered at a referral center equipped with the appropriate facilities and staff. Cesarean delivery does not improve outcome,[44] and there is some evidence that survival rate is higher in fetuses subjected to labor. Thus, in the absence of other complications, vaginal delivery should be anticipated.

Postnatal

The immediate postnatal management is similar to that for omphalocele, but the preoperative workup and stabilization of the newborn should be expedited, because there is no protecting membrane over the bowel (Fig. 19–7). The neonate is immediately placed into a Lehey bag (or even a sterile plastic oven bag) containing the warmed electrolyte and antibiotic solution, as described under "Omphalocele." The bag is carefully tied at the axillae so not to kink or rotate the bowel, and a nasogastric tube is passed to keep the bowel decompressed.

FIGURE 19–6
Gastroschisis. Dilated loops of bowel. This fetus was delivered vaginally at term and primary abdominal wall closure was achieved.

Loops of bowel

FIGURE 19–7
Gastroschisis at delivery, unusually containing the liver. The baby was delivered by cesarean section, the indications being a footling breech presentation.

Primary closure is achieved in over 80% of cases.[45] Postoperative ventilation is generally required for about 72 hours, and total parenteral nutrition is generally required until oral feeding can commence. The surgical approach is generally a transverse incision at the level of the defect if required. A careful examination of the bowel is made for atretic segments. Any bowel incision made is closed transversely to minimize the risk of a subsequent stricture, and the abdominal wall defect is closed vertically with the umbilical cord left in place to produce a "normal" umbilicus (Fig. 19–8). When primary closure is not possible, a Silastic silo is created as with omphalocele (Fig. 19–9). Failure to pass stool by 28 days mandates a new search for atresia,, which occurs in up to 5%.[46]

The mortality rate is between 3% and 10% and is associated with prematurity, intestinal ischemia or necrosis, late sepsis, or the effects of other abnormalities. Prolonged bowel dysfunction, especially motility disorders or malabsorption, occurs in a small number of cases. Postoperative hospitalization, duration of ventilation, total parenteral nutrition, and establishment of oral feeding are generally longer after repair of gastroschisis than omphalocele.[47] One of the only long-term studies of patients with gastroschisis found that development beyond 5 years of age was normal in fetuses with isolated lesions.[48] Those with bowel atresia or complications requiring bowel resection had a higher frequency of long-term bowel problems or nonspecific abdominal complaints. Rarely, in centers where available, intestinal transplantation may be a therapy for short bowel syndrome.[49]

The risk of recurrence in subsequent pregnancies is very low, though isolated case reports indicate that familial recurrence is possible.[50] Fear of recurrence of an abdominal wall defect may affect the reproductive choices of couples.[51]

FIGURE 19–8
Abdominal wall closure in gastroschisis. Similar results are usually obtained with or without previous use of a silo.

FIGURE 19–9

CONGENITAL DIAPHRAGMATIC HERNIA

General

Diaphragmatic hernia is a protrusion or herniation of the abdominal contents into the thoracic cavity. Herniation may occur through a posterolateral defect in the pleuroperitoneal canal (the most common is the hernia of the foramen of Bochdalek), a defect in the sternocostal hiatus, the retrosternal or Morgagni hernia, a hiatus hernia, a defect in the central tendon of the diaphragm, and through complete eventration of the diaphragm. The reported annual prevalence is 1 in 3500 live births,[52] but this does not include terminations and stillbirths. Left-sided hernias are more common. Up to 50% of antenatally diagnosed cases have associated abnormalities,[53] and diaphragmatic hernia is associated with a number of syndromes, including Beckwith-Wiedemann, Pierre Robin, Fryns, and chromosomal defects such as trisomy 13, trisomy 18, and deletion 9p. Lung hypoplasia, central to the poor prognosis of diaphragmatic hernia, may originate during embryogenesis and before the visceral herniation into the thoracic cavity.[54] However, a recent study of fetal lung growth in 84 fetuses with congenital diaphragmatic hernia has challenged this view; differences in both alveolar and pulmonary vascular development were evident only in the third trimester compared with gestation-matched controls.[55] Postnatally, both pulmonary hypoplasia and pulmonary hypertension may be lethal.

Diagnosis

The most common postnatal presentation is cyanosis shortly after clamping the umbilical cord. Other signs include a scaphoid abdomen (Fig. 19–10), a barrel-shaped chest, and dextrocardia. Diaphragmatic hernia is the most common cause of dextrocardia diagnosed in the delivery suite.

FIGURE 19–10
Neonate with congenital diaphragmatic hernia shows scaphoid abdomen.

The antenatal ultrasonographic diagnosis can be difficult. A multinational study achieved an overall detection rate of 59%. Diaphragmatic hernia was detected in 51% of isolated cases and 72% of cases with additional malformations.[56] Small hernias may be missed by even the most experienced ultrasonographers. A right-sided diaphragmatic hernia is extremely difficult to identify because the liver and lung are of similar echogenicity in early pregnancy. As pregnancy advances, the lungs become more echogenic. The hypoechoic line seen on ultrasonography separating the thoracic from the abdominal cavities is an unreliable sign for the exclusion

of diaphragmatic hernia. The most sensitive sign is an abnormal thoracic location of the heart[57] (Fig. 19–11). Other signs, which are not necessarily prognostic, include hydramnios, visualization of the bowel or stomach at the level of the heart, and absence of the stomach in the abdomen. Hydramnios may result from either impaired swallowing (due to mediastinal compression) or obstruction of the upper gastrointestinal tract.

Several techniques can be used to aid diagnosis if there is uncertainty. Color and pulsed Doppler ultrasonography can help delineate the vascular anatomy when there is an echogenic mass in the fetal thorax. Magnetic resonance imaging (MRI) is especially helpful to confirm the presence of the liver in the thorax.

Management Options

Prenatal

The differential diagnosis of an intrathoracic ultrasonographic abnormality includes
- Diaphragmatic hernia.
- Cystic adenomatoid malformation of the lung.
- Extralobar sequestration (may be intra-abdominal).

1. Stomach
2. Heart
3. Lung
4. Rib
FIGURE 19–11
Ultrasound image of fetal thorax shows the appearances of a diaphragmatic hernia. Note that the heart and stomach are visualized in the same imaging plane.

- Bronchial atresia.
- Other cystic and solid mediastinal masses.

It is important to exclude other structural abnormalities notably in the cardiovascular (e.g., ventricular septal defect, tetralogy of Fallot), gastrointestinal, skeletal, and genitourinary systems because they may profoundly affect the prognosis. A karyotype is indicated. A summary of seven series revealed an overall incidence of aneuploidy of 18%; only 2% when the diaphragmatic hernia was isolated but up to 34% when other abnormalities were present.[58]

One of the challenges of antenatal assessment of congenital diaphragmatic hernia is the prediction of postnatal outcome. The option of pregnancy termination should be discussed with the parents, especially when other abnormalities are present, because the combination is generally fatal. Population-based studies indicate an overall survival rate for isolated diaphragmatic hernia of approximately 65%.[59] Although some units with extracorporeal membrane oxygenation (ECMO) facilities[60] quote survival rates over 90%, others do not.[61] Survival rates depend on a number of prenatal factors. Thus, definitive statements on the optimal management providing the highest survival rates are difficult to make at present.

There is considerable debate on the accuracy of antenatal prediction of postnatal prognosis. Early diagnosis (<25 wk) appears to be associated with poor prognosis (mortality rate ≤58%).[59,62] Hydramnios and the location of the fetal stomach do not appear to be prognostic factors,[62] nor do fetal echocardiographic variables in structurally normal hearts.[63] The presence of liver in the chest is a poor prognostic sign[62] and is associated with the triad of hydramnios, mediastinal shift, and intrathoracic stomach. This is consistent with the finding of right-sided diaphragmatic hernia being an independent risk factor for decreased survival.[59,62] The ratio of the fetal lung diameters to the head circumference (lung–to–head circumference ratio [LHR]) (Fig. 19–12) has been used as a guide to prognosis, but results have been inconsistent, possibly due to differing methods of determining the ratio, correcting for the presence of intrathoracic liver, or the effect of gestation.[64] Most series have reported measurement of LHR between 22 and 28 weeks' gestation; a ratio less than 0.8 has been associated with a 100% mortality whereas values greater than 1.4 have been associated with virtually no mortality.[65] Liver herniation and the LHR

Lung to head circumference ratio

$$\frac{a \times b}{HC}$$

have been found to be independent predictors of survival; in a review of 184 cases of left-sided congenital diaphragmatic hernia with intrathoracic liver, the overall survival was 50% and an LHR less than 1.0 was associated with a very poor prognosis.[66] When there was no liver herniation, the survival was 76.5% after 32 weeks and the LHR did not provide independent prognostic information. It is likely that changes in case selection rather than new postnatal therapies have resulted in the improved survival data. A low lung-to-heart ratio has also been reported to be a poor prognostic sign, but this is not consistent in the literature.[66]

Determination of the fetal lung volumes can be achieved by both three-dimensional (3D) ultrasound and MRI,[67] and there is a high correlation between the two modalities.[68] MRI may provide superior imaging of the ipsilateral lung compared with ultrasound. Total lung volumes, measured by MRI, were compared with LHR in one study of 148 infants born after 30 weeks' gestation. Prediction of postnatal survival was comparable between the two methods.[69] It remains to be shown whether volumetric approaches will improve the prediction of survival or guide management.

A summary of the factors considered influential on outcome is shown in Table 19–2. None are accepted as completely reliable because this condition has a spectrum of fatality or morbidity owing to varied factors, including pulmonary hypoplasia, pulmonary hypertension, morphologic and biochemical abnormalities of the lungs, and the longer-term sequelae of treatment. Consequently, some parents may opt for termination of the pregnancy rather than the uncertainty of continuing with antenatal or postnatal treatments.

Recent experience has clarified the role of fetal surgery. There is no benefit from open fetal surgery for isolated congenital diaphragmatic hernia because the results have been shown to be worse than conventional management after birth.[70] The procedure that appears to be most effective in the prevention of the egress of lung fluid from the trachea, thereby stimulating lung growth and development, is tracheal occlusion with a balloon. The indications for percutaneous fetoscopic endoluminal tracheal occlusion (FETO) have been reported as intrathoracic liver and LHR less than 1.0 at a gestation of 26 to 28 weeks.[71]

Initially, removal of the tracheal occluding balloon was done at delivery and access to facilities to perform ex utero intrapartum treatment (EXIT) were necessary. However, it now appears that endoscopic deflation or removal of the

tracheal balloon is associated with high survival. In this poor prognosis group of fetuses, survival rates of 55% are reported.[71] The timing and duration of tracheal occlusion are under investigation.

Obstetrically, the pregnancy is monitored closely for the development of hydramnios. There is limited evidence that the antenatal administration of corticosteroids reduces the severity of lung disease, and pulmonary surfactant deficiency and human trials remain incomplete. When the parents elect to continue with the pregnancy, they should meet with a member of the surgical team before delivery who will explain that a period of preoperative stabilization after birth yields better results than immediate surgical repair. Poor ventilatory parameters that fail to improve with preoperative stabilization generally do not improve postoperatively, and the prognosis is poor.

Labor and Delivery

There is no a priori indication for cesarean delivery. In the absence of massive hydramnios, labor and delivery are generally normal. However, these deliveries should be planned and occur at a referral center equipped for all likely complications.

Postnatal

Immediate intubation, ventilation, and paralysis of the newborn facilitate care, because the maintenance of good oxygenation is a good prognostic sign. Typically, the chest radiograph shows mediastinal shift with abdominal contents in the thorax (Fig. 19–13). A small study reported that maintenance of the mediastinum in a central position by preventing overdistention of the larger lung is associated with improved postoperative survival.[72] This suggests that special care should be taken during the resuscitation to avoid

causing excessive mediastinal shift or lung overdistention. There is presently insufficient evidence to support either a policy of early (<24 hr) or late (>24 hr) repair after delivery.[73]

ECMO is available in some centers for those neonates who cannot be adequately oxygenated using conventional ventilatory techniques. The criteria for ECMO vary between centers, as may the criteria for what constitutes good response. The role of ECMO remains controversial,[74] but its main place is probably in the stabilization of the neonate at the time when the fine pulmonary vasculature is very reactive, because the usual run times on ECMO are too short to permit postnatal lung growth. Use of ECMO to treat respiratory failure in congenital diaphragmatic hernia appears to be associated with a consistent 50% mortality.[74] The place of other postnatal treatments, including surfactant, partial liquid ventilation, pulmonary vasodilators,

and lung transplantation, remains to be determined. A diaphragmatic hernia and its repair are illustrated in Figure 19–14.

Survivors of postnatal repairs may suffer long-term morbidity secondary to bronchopulmonary dysplasia or other lung degenerative disorders, such as emphysema. As the numbers of survivors increases so to do the neurologic, nutritional, and musculoskeletal morbidities.[75] However, overall these problems occur in the minority of affected children, and in general, the long-term prognosis is good if the neonate survives beyond surgery.

The recurrence risk is low, except where the defect occurs as part of a genetic syndrome such as Fryns syndrome, which is an autosomal recessive trait including diaphragmatic hernia, dysmorphic facies, and distal digital hypoplasia. A number of reports have expanded the phenotype of Fryns syndrome.[76]

BODY STALK ANOMALY/LIMB BODY WALL COMPLEX

General

These rare abdominal wall defects have an annual prevalence ranging from 1 in 7500 to 1 in 42,000 pregnancies. The defect is now considered to result from early embryonic maldevelopment as a result of abnormal folding of the trilaminar disc, such that the amnion appears to form a continuous sheet between the anterior abdominal wall and the placenta.

Diagnosis

It is essential to differentiate a body stalk anomaly from other abdominal wall defects, because the former is incompatible with extrauterine life. Multiple organ system anomalies are present in most cases. Characteristically, there are neural tube and lower limb defects with scoliosis. The viscera of the fetus may appear either attached to the placenta (Fig. 19–15) or entangled with the fetal membranes. Sometimes, it may be difficult to distinguish from amniotic band sequence, but in that situation, scoliosis is not a major finding. During the first trimester, fetal parts are seen outside the amniotic cavity. The umbilical cord appears absent or abnormal.[77] The karyotype is usually normal, and amniocentesis is not required.

GPP, good practice point.

Management Options

Prenatal

The option of pregnancy termination should be offered. Vaginal delivery is the goal. When a body stalk abnormality may affect one fetus in a twin pregnancy, as has been reported after use of artificial reproductive technologies, selective fetal reduction may be offered.[78]

Postnatal

This defect is lethal. It is thought to be sporadic, and thus, the recurrence risk is extremely low.

BLADDER AND CLOACAL EXSTROPHIES, OMPHALOCELE, BLADDER EXTROPHY, IMPERFORATE ANUS

General

Both exstrophies are rare, constituting less than 2% of anorectal malformations.[79] Bladder exstrophy is around four times more frequent than cloacal exstrophy; 1 in 35,500 compared with 1 in 200,000.[80] Bladder exstrophy is distinct from cloacal exstrophy. The group of anomalies termed OEIS[81] (omphalocele, exstrophy of the bladder, imperforate anus, and spina bifida) always includes cloacal exstrophy with imperforate anus. The estimated incidence of OEIS is 1 in 200,000 births. It is unclear whether the two disorders are distinct entities or part of a continuum because some authors have considered OEIS and cloacal exstrophy to be synonymous, though the full OEIS complex includes spinal abnormalities. The primary defect is believed to be a failure of development of the caudal fold of the anterior abdominal wall leading to a defect in forming the urogenital septum. The result of this is a common cloaca with a wide range of urogenital and spinal anomalies. Suspicion of cloacal exstrophy may occur in the presence of an omphalocele associated with an infraumbilical anterior abdominal wall defect and absence of the bladder.[82]

Whatever the cause, the defects produced are severe and lead to lifelong impairments of urinary, gastrointestinal, reproductive, and likely, psychological function.

Diagnosis

Bladder Exstrophy

On ultrasound scanning, typically the fetal bladder is not seen within the abdomen. There is a soft tissue mass on the lower anterior abdominal wall with an abnormally low insertion of the umbilical cord. In severe cases, the pelvic bones will be abnormal with a wide symphysis pubis and genital anomalies. For prognostic reasons, it is important to distinguish this from cloacal exstrophy.

Cloacal Exstrophy

Cloacal exstrophy is a complicated abnormality that should be suspected in the presence of a low anterior abdominal defect and absent fetal bladder on ultrasound scanning. The defect contains an omphalocele, the bladder exstrophy, and the ileum, which herniates between the two halves of the bladder. The exposed ileum has described as looking like an "elephant's trunk." Other findings on ultrasound include multiple abnormalities.

Management Options

Bladder Exstrophy
PRENATAL

When the diagnosis of bladder exstrophy is suspected antenatally, other causes of failure to visualize the bladder should be sought. In bladder exstrophy, the amniotic fluid volume is usually normal. The maternal serum α-fetoprotein may be raised, but chromosomal anomaly is infrequent.

When the diagnosis is made, parental counseling should include the long-term prognosis in terms of urinary continence, renal function, and sexual and reproductive function in both males and females; that is, physiologic function, cosmetic appearance and body image, and psychological

well-being. Recent approaches to repair rather than urinary diversion procedures appear to be leading to much improved outcomes,[83] but surgical and functional morbidities remain significant ongoing issues for many children and adults. There appears to be an increase in urinary bladder or colorectal cancer in patients with exstrophies, and therefore, long-term follow-up would seem prudent.[84] Despite advances in surgical management, termination of pregnancy is an option for parents, given the long-term problems associated with bladder exstrophy.

LABOR AND DELIVERY

Labor and delivery are not influenced by the malformation, which would not be expected to increase complications or perinatal mortality. Delivery in a unit equipped with neonatal intensive care and surgical facilities would facilitate planning for surgery, which is now frequently performed early in the neonatal period.

Cloacal Exstrophy
PRENATAL

The antenatal diagnosis of cloacal exstrophy has been reported infrequently. It is typically associated with severe oligohydramnios, probably due to the associated genitourinary abnormalities. The maternal serum α-fetoprotein may be high when associated with either a neural tube defect or an omphalocele. Amniocentesis may be offered to establish the genetic sex of the fetus. The anomalies create difficult management issues, including neonatal gender assignment. As with OEIS, the prognosis in terms of survival depends on the severity of the defects and the associated malformations.

Termination of pregnancy is an option in view of the associated genital abnormalities, the difficult surgical repair, and the long-term problems of achieving continence and sexual and reproductive function. The clinical management of the pregnancy is otherwise unaltered. Should the patient consider continuing the pregnancy, detailed pediatric surgical consultation prior to delivery is recommended to maximize understanding of future medical care.

LABOR AND DELIVERY

There is no a priori reason for cesarean delivery. Standard obstetric management is appropriate with delivery in a unit equipped with neonatal intensive care and surgical facilities.

Omphalocele, Exstrophy of the Bladder, Imperforate Anus, and Spina Bifida Sequence
PRENATAL

Diagnosis by ultrasound is highly accurate (Fig. 19–16). Counseling for parents should include discussion of long-term morbidities and multiple hospitalizations even when neurodevelopmental progress is likely to be normal.[85,86] Some parents may wish karyotyping to determine the genetic sex of the fetus. Because reconstructive surgery would be required, the parents may wish to discuss the prognosis with a multidisciplinary team to maximize the understanding of future medical requirements. Termination of pregnancy may be offered.

LABOR AND DELIVERY

If the parents opt to continue the pregnancy, delivery should be in a tertiary center. Vaginal birth is anticipated.

POSTNATAL

Management will involve reconstructive surgery with multiple hospitalizations. Recurrence risks are difficult to determine, but there are rare cases of familial recurrence.

FIGURE 19–16
Omphalocele, exstrophy of the bladder, imperforate anus, and spina bifida (OEIS). Ultrasound image shows abnormal spine and the omphalocele with the bladder in the lower part of the abdominal wall defect.

ESOPHAGEAL ATRESIA

General

The total annual prevalence of esophageal atresia (EA) and tracheoesophageal fistula (TEF) is about 1 in 3500.[87] Half of these anomalies are isolated, with a low recurrence risk, and 50% are associated with syndromes especially the VATER (vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia) or VACTERL (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or esophageal atresia, renal agenesis and dysplasia, and limb defects; see later) groups of abnormalities. Cardiac abnormalities are the most common single anomaly seen with EA or TEF. TEF and EA typically occur together because the esophagus and trachea develop from a common diverticulum of the primitive pharynx. The upper respiratory and gastrointestinal tracts separate at between 3 and 5 weeks' gestation. The most common anomaly is esophageal atresia with a distal TEF (87% of cases). The variants of TEF are illustrated in Figure 19–17. Isolated EA and isolated TEF account for 8% and 4% of the cases, respectively.

Diagnosis

The most common antenatal presentation is hydramnios associated with preterm labor. Fetal swallowing begins around 16 weeks' gestation, and failure to visualize the stomach after this time is unusual. Failure to visualize the fetal stomach on serial scans from 20 weeks should alert the sonographer to the possibility of EA.[88] Other clues to the diagnosis are hydramnios and fetal growth restriction in the late second and third trimesters. However, the prenatal diagnosis of EA or TEF remains limited, ultrasound series reporting no more than a 56% positive predictive value for absent stomach and hydramnios.[89] In addition, nonvisualization of the thoracic esophagus on MRI is not uncommon and cannot be used as an independent reliable marker for esophageal abnormality. The differential diagnosis for the ultrasonographic absence of the stomach includes three possibilities:

- Esophageal atresia.
- Congenital diaphragmatic hernia.
- Impaired fetal swallowing from "neurologic" causes or cleft lip and palate.
FIGURE 19–17
The main types of tracheoesophageal fistula.

The stomach may simply be empty at the time of the scan, but after 20 weeks, typically it will fill over the course of the examination. In the absence of other abnormalities, a repeat scan within a few days is warranted. The diagnosis should be suspected in all cases of hydramnios (Fig. 19–18), and a targeted ultrasound examination should be part of the management of women with preterm labor. EA with TEF allows for the passage of amniotic fluid into the stomach and is not

Esophageal atresia. Scan shows hydramnios and absent stomach in the imaging plane for the abdominal circumference measurement.

CNS, central nervous system.

usually associated with either hydramnios or an absent stomach. In many cases, therefore, the diagnosis may not be possible antenatally. A very small stomach in the presence of hydramnios suggests the diagnosis. A high proportion of fetuses have aneuploidy or other malformations. The prognosis for the fetus with EA is worse than for the neonate with EA first suspected postnatally.

Occasionally, the proximal esophageal pouch can be imaged in the fetus with EA when the stomach is absent. This has been referred to as the "pouch" or "upper pouch" sign and can be seen as early as 23 weeks.[90] A blind pouch in the neck appears to have a worse outcome than a mediastinal pouch.[91] MRI has been successfully used to confirm ultrasonically suspected EA.[92] Currently, it is not possible to accurately determine the predictive value of the pouch sign nor its relationship to outcomes.[89] Failure to demonstrate the stomach necessitates a careful search for other abnormalities including the VATER or VACTERL group of abnormalities. Originally, a cluster of abnormalities including *v*ertebral, *a*nal atresia, *t*racheoesophageal atresia, and *r*adial dysplasia was termed VATER.[93] The group was subsequently expanded to *v*ertebral, *a*norectal, *c*ardiac (especially atrial and ventricular septal defects), *t*racheoesophageal atresia, *r*enal and *l*imb defects, or VACTERL.[94] Otocephaly, a major malformation of the mandible and temporal bones associated with abnormally placed ears, may also be present. These anomalies need to be considered in the assessment of the fetus and subsequent counseling.

Management Options

Prenatal

A karyotype should be obtained to rule out aneuploidy (particularly triploidy or trisomy 18), which is present in

over 10% of cases.[95] EA may be present in association with a number of complex fetal abnormalities including the DiGeorge sequence identifiable by a characteristic deletion in chromosome 22.[96] More than half of the fetuses with EA in one series had multiple malformations,[96] the VATER complex in either its complete or its incomplete forms being the most common abnormality in another series.[97] The other cluster of abnormalities sufficiently different from the VATER complex to warrant distinction is the CHARGE (coloboma, heart disease, atresia choanae, retarded growth and retarded development and/or central nervous system anomalies, genital hypoplasia, and ear anomalies and/or deafness) association (Table 19–3). These infants usually have some degree of mental retardation. In contrast, the majority of neonates with VATER-VACTERL have normal intelligence (except those associated with either trisomy 18 or 13q deletion syndromes).

When the diagnosis is made before viability, parental counseling should include the influence of any associated abnormalities on neonatal outcome, the possible related problems during pregnancy (e.g., hydramnios), and the short- and long-term prognosis after surgical repair. The latter has improved dramatically since the first recorded survival in 1939,[98] owing to improvements in both surgical technique and neonatal intensive care. Although long-term evaluation after repair suggests that respiratory and gastrointestinal morbidities improve as the individual grows into adulthood, approximately 25% will have significant pulmonary dysfunction, gastroesophageal reflux, or chest wall and spinal deformity.[99,100] The option of pregnancy termination should be offered, especially if there are multiple anomalies.

The most common anomaly is EA with a distal TEF. This is usually managed by thoracotomy with division of the

fistula and then end-to-end esophageal anastomosis. In the absence of other abnormalities, survival rates of up to 100% are reported.[98] However, birth weight and the presence of other anomalies, especially cardiac, remain the key prognostic factors; birth weight greater than 1500 g and the absence of major cardiac defects have been associated with greater than 95% survival when lethal anomalies such as trisomy 18 and complex CHARGE syndrome were excluded.[101] Another review of 176 repairs between 1985 and 1997 reported a perinatal and infant mortality rate of 22%, with a further 21% of infants having significant morbidity after 2 years of age.[102] The length of the atresia (gap length) has been also associated with prognosis,[103] but this is virtually impossible to determine on prenatal ultrasound.

Continuing pregnancies are managed along standard obstetric lines. Hydramnios complicating EA may prove difficult to manage and is associated with preterm labor. Medical management of hydramnios using indomethacin may be of value in certain fetal abnormalities, but in the one report with EA, its use was unsuccessful.[104] Other adverse fetal effects of indomethacin or cyclooxygenase inhibitors class II generally preclude their use in the third trimester of pregnancy. Therapeutic amniocentesis is an option after antenatal corticosteroids have been given to enhance pulmonary maturity.

Labor and Delivery

Labor and delivery management are not influenced by the malformation.

Postnatal

Awareness of the possibility of EA in all cases of hydramnios and in any newborn with excessive oral secretions, particularly if there are breathing difficulties or cyanosis, should lead to the same management as planned for the neonate diagnosed or suspected antenatally. Oral feeds are avoided until the diagnosis is clear to reduce the risk of aspiration pneumonia. Definitive surgery is offered once the infant's condition is stable.

The most important single determinant of outcome is the severity of the associated anomalies followed by ventilator dependence.[101] Outcome is usually good if the birth weight is over 1500 g.[104] Immediate surgical complications include anastomotic leaks, tracheal perforation, and chest infection. Late complications are related either to the development of an esophageal stricture, with obstruction to solids at the anastomotic site, or to respiratory complications including pneumonia, tracheomalacia, and tracheal compression by the upper pouch. Only 10% have respiratory complications beyond the first year and 8% an esophageal stricture. Gastroesophageal reflux and its complications remains the biggest single long-term morbidity, affecting 18% to 40% of survivors.[105,106] The less common types of EA with or without fistula (producing an airless abdomen because of either blind upper and lower pouches or an atretic fistula) might require more complex surgery, and the prognosis, especially in terms of morbidity, is worse albeit improving. In this group, gastrostomy feeding, with delay of the repair until the child grows, is more frequently required. Long-term morbidity, both respiratory and gastrointestinal, tends to improve.[105]

Although EA is said to be a sporadic abnormality, a familial form is described and recurrence risk, including that of associated abnormalities, needs to be considered.[87]

ATRESIAS OF THE BOWEL

A wide variety of congenital anomalies can occur in perinates with either gut atresias or stenoses. The specific pattern of anomalies depends on the location of the atresia. For example, cardiac and renal anomalies are associated with EA or duodenal atresia.[107] Other associations are discussed in the sections on the respective abnormality. Overall, although hospitalization may be prolonged, mortality associated with bowel atresias is low and relates primarily to birth weight and the presence of other abnormalities.[108] Pyloric atresia is a rare lesion associated with junctional epidermolysis bullosa.

Duodenal Atresia
General

Atresia of the duodenum occurs around 11 weeks' gestation after an insult to the duodenum, most commonly either just proximal or just distal to the ampulla of Vater, causes failure of canalization. Occasionally, vascular accidents or midgut strangulation associated with omphalocele are implicated. The annual prevalence of duodenal atresia approximates 1 in 6000 live births. Approximately 30% of cases of isolated duodenal atresia are associated with trisomy 21 or other aneuploidies.

Diagnosis

Hydramnios is common with upper intestinal atresias and implies total obstruction. Half the pregnancies complicated by duodenal atresia are associated with hydramnios. The sonographic diagnosis is typically made by the appearance of a "double bubble" (Fig. 19–19A) late in the second trimester, but it has been suspected as early as 12 weeks[109] and positively detected at 19 weeks.[110] Like all forms of gastrointestinal obstruction, duodenal atresia may not be diagnosable by ultrasound until the third trimester. It is important that a true transverse section of the abdomen be obtained and that a connection between the two bubbles is seen (see Fig. 19–19B). This avoids the potential confusion of an oblique scan of the stomach artificially producing a double bubble or confusing the stomach and a choledochal cyst with a duodenal atresia. Increased peristaltic waves may be seen during real-time imaging.

Management Options
PRENATAL

Associated anomalies are present in over 50%. In addition to trisomy 21 (in 30%), duodenal atresia is associated with abnormalities of chromosome 9. Other gastrointestinal malformations occur in 25% and include malrotation (28%), annular pancreas (33%; especially with duodenal stenosis), EA, imperforate anus, jejunal atresia, duplication of the duodenum, and Meckel's diverticulum.[111] Cardiac, tracheal and esophageal, renal, hepatobiliary, and pancreatic ductal abnormalities have been reported in up to 48%.
Duodenal atresia may be associated with multiple atresias of the bowel. About half the infants have early-onset growth restriction.

This range of associated anomalies mandates a detailed ultrasonographic examination and the offer of karyotyping. Fetuses with trisomy 21 have a high risk of cardiac abnormalities. They may also have heart rate abnormalities in labor not necessarily indicative of hypoxia. Indomethacin (or similar cyclooxygenase inhibitors) has been given in an attempt to treat the hydramnios.[112] Few clinically adverse effects on the fetus are documented when given for a short time before 32 weeks.

LABOR AND DELIVERY

There is no a priori indication for cesarean delivery because of duodenal atresia. As in any situation with gross hydramnios, delivery in a tertiary center is advised, both to manage the potential complications of the hydramnios and for access to neonatal surgical services. Because a double bubble is not absolutely diagnostic of duodenal atresia, other possibilities must be excluded after delivery. Passage of an orogastric or nasogastric tube after delivery followed by radiographs of the neonate will help confirm the diagnosis. The differential diagnosis includes annular pancreas, peritoneal bands, duodenal stenosis, more distal atresias, and other cystic structures such as choledochal, ovarian, and duplication cysts.

POSTNATAL

After delivery, a tube is passed into the stomach and abdominal radiographs are taken. The diagnosis can be confirmed at this stage by examination of the gas pattern. The atretic area is excised (Fig. 19–20) when the infant is stable. The prognosis for this condition, if recognized and isolated, is good and the recurrence risk is low. Operative mortality rate is up to 4%, with long-term survival rate quoted as 86%. A series of 169 patients with over 30 years follow-up showed a late complication rate of 12% with a 6% mortality.[113] Cardiac lesions or associated abnormalities such as trisomy 21 are the main contributors to long-term morbidity and death.[113]
Jejunal and Ileal Atresia

General

Jejunal and ileal atresia have an annual prevalence approximating 1 in 5000 live births. They are the second most common forms of neonatal bowel obstruction.[114] These atresias are thought to result from vascular compromise of a bowel segment after organogenesis is complete. Intestinal atresias are categorized according to the degree of occlusion or separation of the bowel on either side of the atretic segment.

Associated anomalies are less common than with duodenal atresia. Five cases of trisomy 21 were reported in one

FIGURE 19–21
Jejunal atresia. *A*, Bowel dilation at 29 weeks' gestation. *B*, Appearance of bowel at 33 weeks' gestation.
series of 589 perinates with jejunoileal atresia,[115] and none in a more recent series.[108] A special form, the "apple peel" deformity, is an autosomal recessive trait and may have a worse prognosis than the other forms of atresia.[116] Another review noted gastroschisis in 16% of cases, intrauterine volvulus in 27%, and meconium ileus in 11%.[111]

Diagnosis

The ultrasonographic appearance of jejunal atresia is that of multiple distended bowel loops (Fig. 19–21). Hydramnios is more common with upper gastrointestinal obstruction (duodenal and jejunal) than with lower obstructions. The development of ascites or an echogenic mass is a sign of bowel perforation. Detailed examination of the wall of cystic or echogenic intra-abdominal structures for peristalsis is important, because it can be associated with bowel perforation and development of a meconium pseudocyst. Other features useful antenatally for diagnosing bowel obstruction are increased peristalsis, failure to detect a normal colon late in gestation, and a disproportionately large abdominal circumference for dates.

Management Options
PRENATAL

Jejunal and ileal atresias are usually isolated from other gastrointestinal lesions. It is important to exclude other causes of echolucent structures within the abdomen, such as a urinary tract obstruction. It is suggested that serial measurements of the bowel loop diameter are of value, but these measurements correlate with neither the diagnosis of bowel obstruction nor the prognosis. The appearance of the bowel is quite variable, particularly in the third trimester, and in our experience, mild bowel dilation is typically associated with a normal outcome. However, a bowel obstruction should be suspected whenever the internal diameter of the small bowel is greater than 7 mm.[117] There is little evidence to support early delivery based on bowel loop diameter.

LABOR AND DELIVERY

Fetuses with a presumptive bowel obstruction should be delivered in a center with neonatal surgical facilities. Otherwise, obstetric management is unaltered by the presence of the abnormality. Hydramnios is not an indication for a cesarean delivery.

POSTNATAL

After delivery, the neonate is evaluated to determine the site of obstruction and the presence of any associated congenital anomalies or meconium peritonitis. The radiologic features of jejunal atresia are shown in Figure 19–22. The prognosis is very good following repair, with survival in excess of 95%.[108] Even in the group with apple peel deformity, early diagnosis and prolonged parenteral nutrition have resulted in a dramatic improvement in survival.

The risk of recurrence for jejunal and ileal atresia is small except in the group with apple peel syndrome, which would appear to follow autosomal recessive inheritance.[118]

Large Bowel Obstruction, Anal Atresia, and Imperforate Anus

General

Colon atresia is rare and largely confined to the right colon. Anorectal malformation including imperforate anus has an annual prevalence of around 1 in 2500 to 1 in 5000 live births. In the embryo, lumen development begins in the region of the descending colon. Anorectal malformations are complex, and there are several classifications aimed at producing a consistent description of the anomaly to permit comparison and assessment of outcomes with differing surgical treatments. The Krickenbeck simplification of the Wingspread classification is widely used.[119] Constipation, soiling, and complications associated with other abnormalities are all long-term morbidities, which occur in more than 50% cases. Such problems have a major impact on the survivors' lives.[120] Anal anomalies may be part of multiple

malformation syndromes, including the VATER-VACTERL and CHARGE complexes and cloacal exstrophy. They are also associated with spinal and genitourinary defects.[121]

Management Options

Large bowel abnormalities are rarely diagnosed antenatally except when part of other multiple malformation syndromes. Apart from mechanical abnormalities such as malrotation or volvulus, other reasons for dilated large bowel or increased echogenicity are meconium ileus, aganglionosis (Hirschsprung's disease), and congenital syphilis. Generally, the ultrasound findings are nonspecific, and the diagnosis is made postnatally. The fetal karyotype is generally normal.

The prenatal diagnosis of imperforate anus is made in less than 20% of cases. Overall, approximately 85% of cases are associated with additional anomalies, including 53% with urogenital abnormalities, and 13% have an abnormal karyotype.[122] Prenatal diagnosis may be made when bowel dilation is seen on ultrasound scanning, but this may be a transient finding.[123] The findings of an abdominopelvic mass or intraluminal calcification might be signs of lower bowel abnormality with communication between the urinary and the gastrointestinal tracts. Because the postnatal consequences of complex anorectal and cloacal anomalies include fecal and urinary continence problems as well as sexual and fertility difficulties, careful investigation and counseling need to be offered to parents.

MECONIUM ILEUS AND MECONIUM PERITONITIS, HYPERECHOGENIC BOWEL

General

Hyperechogenic bowel, defined sonographically as echogenicity at least equal to the surrounding bone, occurs in 0.1% to 1.8% of pregnancies in the second or third trimesters.[124] It may be transient. Meconium ileus is an obstruction of the lower ileum by thick meconium. Perforation can occur after bowel obstruction secondary to any cause, including meconium ileus, producing meconium peritonitis, intestinal atresia, volvulus, and malrotation. These conditions are rare. Meconium ileus is most commonly associated with cystic fibrosis. In contrast, most cases of meconium peritonitis are not (though cystic fibrosis should be considered). Bayesian analysis of the risk of prevalence of cystic fibrosis in a fetus with echogenic bowel yields a range of 3.3% to 13% in a mixed North American population.[125] In addition to cystic fibrosis, hyperechogenic bowel is associated with bowel obstruction, viral infection, aneuploidy, and fetal growth restriction. Intraluminal calcification may result from the mixing of meconium and fetal urine, and such findings should suggest the possibility of communication between the urogenital tract and the bowel as may occur in anorectal and cloacal anomalies. An echogenic mass in the stomach may be swallowed blood, for example, after an abruption or invasive procedure.

Diagnosis

Both meconium ileus and peritonitis have been diagnosed in the second trimester. Meconium ileus presents as either a cluster of bright echoes or the bowel appearing dilated and echogenic. Hyperechogenic bowel is present when the echogenicity is at least as bright as adjacent bone (Fig. 19–23). This definition overcomes variation in description owing to ultrasound machine settings. Distinguishing it from normal, especially late in the third trimester, may be difficult. Fetal ascites and hydramnios are signs of perforation. A hyperechoic mass or diffuse hyperechoic deposits in the fetal abdomen suggest meconium peritonitis (Fig. 19–24). The thorax may be compressed if there is a volvulus or massive bowel distention.

Management Options

Prenatal

Screening for cystic fibrosis should be offered when meconium ileus is suspected. The parents should be tested, and if at least one is a carrier (not all mutations are known), testing the fetus by either chorionic villus sampling or amniocentesis should be offered. Meconium ileus affects 15% of neonates with cystic fibrosis,[126] although a recent review of 77 cases of meconium plug syndrome showed 13% with Hirschsprung's disease but none with cystic fibrosis.[127] Meconium peritonitis is a serious condition, and the guidelines for management may be determined by the ultrasonographic appearance. For example, a discrete lesion within the fetal abdomen that appears unchanging and free of ascites or hydramnios does not warrant intervention. However, the presence of ascites, increasing abdominal distention, and hydramnios may warrant preterm delivery if the estimated risks of prematurity do not exceed the potential benefit of early intervention. There are no data to allow clear

FIGURE 19–23

FIGURE 19–24
Longitudinal section of fetal abdomen shows massive bowel dilation. The bowel is surrounded by meconium (*arrow*), indicating the development of peritonitis in a fetus with cystic fibrosis. There is gross hydramnios.

FIGURE 19–25
Longitudinal scan of a fetus shows hyperechoic liver (*crosses*). This fetus had a normal outcome.

guidance. In this situation, antepartum corticosteroid administration should be considered to hasten pulmonary maturation. Drainage of the ascites, especially if there is lung compression, has been associated with a good outcome, possibly by facilitating the transition to ex utero life. Therapeutic amniocentesis is also an option for pronounced hydramnios. Unexplained death is reported in up to 5% of fetuses with echogenic bowel presenting in the second trimester in the absence of cystic fibrosis, aneuploidy, or infection.[128] Death was associated with fetal growth restriction and oligohydramnios.[128]

Labor and Delivery

Expectant management is standard in the absence of perforation, though the neonatal intensive care team should be informed of the possible diagnosis. The management of meconium peritonitis in labor is determined by obstetric factors (e.g., the gestation and the ease with which labor can be induced). There is no information to suggest that cesarean delivery benefits the fetus with meconium peritonitis.

Postnatal

Infants with meconium ileus typically become symptomatic within the first 24 to 48 hours of life. Abdominal distention and delayed passage of the meconium plug are characteristic. Vomiting is a relatively late sign. The overall prognosis is determined in part by the success of either a Gastrografin enema or surgery in relieving the obstruction, but mainly by the severity of underlying conditions such as cystic fibrosis. The prognosis for meconium peritonitis is not good, in part due to prematurity. The recurrence rate is low except when the condition is secondary to cystic fibrosis.

ECHOGENIC ("BRIGHT") LIVER AND HEPATIC CALCIFICATIONS

General

Echogenic ("bright") liver (Fig. 19–25) is an uncommon finding with a number of causes or associations, including liver tumors, congenital viral infection, and vascular congestion. Hepatomegaly may occur in hemolytic disease or as part of a visceromegaly syndrome (e.g., Beckwith-Wiedemann syndrome). Splenomegaly in association with hepatomegaly may suggest the occurrence of fetal anemia, extramedullary hematopoiesis, or infection.

SUMMARY OF MANAGEMENT OPTIONS
Meconium Ileus/Peritonitis/Echogenic Bowel

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Diagnosis is made by ultrasound (strict criteria for echogenic bowel/liver [bone-white]).	III/B	124,126
For all, consider diagnosis of cystic fibrosis.	III/B	125,126
For echogenic bowel, consider diagnosis of cytomegalovirus or parvovirus, aneuploidy, intestinal obstruction, intra-amniotic/placental bleed, fetal growth restriction, risk of late fetal death.	III/B	126,128
Maintain vigilance for hydramnios and/or ascites.	—/GPP	128
No data support drainage or delivery if ascites or hydramnios develops.	—/GPP	—
Provide multidisciplinary counseling.	—/GPP	—
Labor and Delivery		
Timing depends on obstetric factors and/or presence of ascites/hydramnios.	—/GPP	—
Delivery in a tertiary center with full pediatric resources but otherwise normal management.	—/GPP	—
Postnatal		
For meconium ileus and peritonitis, outcome depends upon surgical feasibility of repair, associated abnormalities, perforation, and gestation.	III/B	127,128
Consider possibility of Hirschsprung's disease where cystic fibrosis excluded.	GPP	
For echogenic bowel/liver, implement pediatric assessment and management.	—/GPP	—
Recurrence risks are associated with diagnosis.	GPP	

GPP, good practice point.

Hepatic echogenic areas ("calcifications") may be on the surface or within the parenchyma (Fig. 19–26) or be associated with the vasculature.[129] The cause is not always known, and postnatal scanning does not invariably confirm their presence. Subcapsular calcifications may be seen with meconium peritonitis. Intrahepatic calcification may be associated with fetal infection or thromboses.

Management Options

Prenatal

Management is directed toward making a diagnosis. The etiology depends on the pathology. Malformations and abnormal karyotypes are seen in association with hepatic calcifications. Single or isolated liver calcification is usually of little consequence.[129] The association of hepatic calcification with congenital toxoplasmosis or viral infection is well documented. Serologic screening is commonly employed but assumes one knows which infectious agent to screen for and that a maternal response has occurred. The risks of infection and effects of toxoplasmosis on the fetus relate to
FIGURE 19–26
Hepatic calcifications in the fetal liver (*arrows*). Note the shadowing.

gestation. Toxoplasmosis immunoglobulin G (IgG) avidity testing provides guidance as to the duration of infection in the mother; a low-avidity result would be consistent with maternal infection of less than 12 weeks' duration.

Herpesvirus, echovirus, varicella, coxsackievirus, and adenovirus all have similar hepatic manifestations of infection. Hepatitis leading to ascites is not rare. The ultrasonographic appearances are nonspecific, and invasive tests are usually necessary for a definitive diagnosis.

In addition to infection, hepatomegaly may be associated with Beckwith-Wiedeman syndrome, inborn errors of metabolism, such as glycogen storage diseases, hydrops, and neoplasms. Hepatic tumors are rare. A review of fetal and neonatal liver tumors has shown that hemangiomas account for 60%.[130] A well-defined right upper quadrant mass is suggestive. Hydramnios and hydrops might be present. Management involves observation until delivery, though the fetus may develop congestive heart failure. A search for markers of aneuploidy is indicated when hepatic calcifications are seen because there is an increased risk, but typically aneuploidy is associated with other findings.[131]

Labor and Delivery

Standard obstetric management is generally appropriate, though there is an undefined risk of hepatic bleeding in labor with very large tumors.

Postnatal

Care is determined by the likely diagnosis. Delivery in a center with pediatric surgical facilities as well as neonatal intensive care is advisable.

MEGACYSTIS MICROCOLON INTESTINAL HYPOPERISTALSIS SYNDROME

General

This is a rare autosomal recessive condition manifest in utero by the findings of a dilated urinary bladder with bilateral hydronephrosis, normal amniotic fluid, and abnormal appearance of the bowel. Bowel dilation might not be apparent unless vesicocentesis has been performed.[131] The condition is more common in females. Although the etiology is unknown, histology of the bowel wall shows vacuolated smooth muscle,[132] suggesting abnormality of development and function. The prognosis is grave, but as in other fetal-neonatal dysfunctional bowel lesions resulting in short bowel syndromes and malnutrition, bowel or liver/bowel transplantation has been reported.[133]

Management Options

Prenatal

When the diagnosis has been made, termination of pregnancy may be offered. Counseling may include discussion with neonatologists, pediatric surgeons, and clinical geneticists.

Labor and Delivery

Standard obstetric management is appropriate for those opting to continue the pregnancy. Should dystocia due to fetal bladder dilation be considered likely, vesicocentesis may be offered.

SUMMARY OF MANAGEMENT OPTIONS
Echogenic Liver, Hepatic Calcifications, Hepatomegaly

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Diagnosis is made by ultrasound.	III/B	129,130
Consider infection, fetal thrombosis; where there is hepatomegaly consider infection, Beckwith-Wiedemann syndrome, inborn errors of metabolism, and neoplasms.	III/B	129,130
Consider karyotyping.	III/B	130
Monitor for ascites, hydrops, and hydramnios.	III/B	129
Labor and Delivery		
Timing depends on obstetric factors and/or presence of ascites/hydramnios.	—/GPP	—
Delivery in a tertiary center with full pediatric resources but otherwise normal management.	—/GPP	—
Postnatal		
Implement neonatal pediatric assessment and management directed toward diagnosis.	—/GPP	—
Recurrence risks are rare.	GPP

Intra-abdominal Echolucent (Cystic) Structures

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Determine the organ of origin and diagnosis.	—/GPP	
Assess for other abnormalities.	III/B	137
Continue surveillance by ultrasound during pregnancy.	III/B	134–136
Labor and Delivery		
Normal management but in a center with pediatric assessment available.	GPP	
Postnatal		
Implement pediatric assessment and management, including early neonatal ultrasonography.	—/GPP	—
Maintain neonate nil per mouth where bowel duplication or other cysts likely to require early surgical management are present.	GPP	

GPP, good practice point.

Postnatal

Delivery in a center with pediatric surgical and neonatal intensive care facilities is advisable.

ECHOLUCENT STRUCTURES WITHIN THE FETAL ABDOMEN

General

Echolucent or "cystic" structures separate from normal bowel or the urinary tract may be identified on ultrasonography, even as early as the first trimester. The differential diagnosis includes omental cysts, mesenteric cysts, ovarian cysts, urachal cysts, hepatic cysts, choledochal cysts, duplication cysts of the bowel, and retroperitoneal cysts.

Management Options

Prenatal

Intra-abdominal cysts are usually a chance finding on ultrasound. The sonographer should attempt to determine the origin of the structure and exclude other fetal abnormalities. Massive intra-abdominal cysts, especially those detected early in pregnancy, seem to have a poor prognosis, but in many cases, they remain unchanged or resolve.[134] In a recent small series of five cases of fetal abdominal cysts detected in the first trimester, three resolved but one had neonatal bowel abnormalities. In the two that did not resolve, one fetus required prenatal aspiration and the other was found to have a choledochal cyst necessitating postnatal surgery. These cases suggest the need for follow-up even if the cyst appears to resolve on ultrasound.[135]

Hepatic cysts may be isolated or associated with adult type polycystic renal disease. Isolated liver cysts are rare, but usually remain stable during pregnancy and regress postnatally without treatment.[136] Choledochal cysts (single or multiple) occur in the right upper quadrant, below the liver, and are intraperitoneal. Similar to most cystic lesions, their significance relates to postnatal management. Untreated, choledochal cysts can lead to biliary cirrhosis and portal hypertension.

Labor and Delivery

Obstetric care is unaltered by these abnormalities.

Postnatal

Knowledge of the differential diagnosis is important. The neonate should undergo an ultrasound examination as soon after delivery as feasible. Duplications of the small and large bowel may rarely communicate with normal bowel lumen. In this instance, the neonate will present with signs of bowel obstruction. Intestinal duplications in association with spinal cord and vertebral body anomalies are reported.[137]

INTRODUCTION

The sonographic detection of a fetus with a skeletal disorder presents the clinician with challenging diagnostic dilemmas and management options. In some instances, the lethality of the disorder is apparent and a discussion of pregnancy termination is appropriate. The estimated prevalence of skeletal dysplasias varies from 2 to 7 in 10,000,[1] and diagnosis might require biochemical, cytogenetic, molecular genetic, or hematologic investigation. Clinical genetic input is often required because the family history or parental examination may yield valuable clues to the diagnosis. Furthermore, a geneticist may be best placed to offer advice with regard to further investigations because the genetics of these conditions is a rapidly changing field. Consultation with a geneticist specializing in dysmorphology may be invaluable. Table 20–1 lists some of the commoner terminology used in describing skeletal anomalies.

Women typically present for the prenatal diagnosis of a skeletal abnormality in one of three ways: with a relevant family history, with an abnormality found during routine ultrasound, or because of a maternal condition. Inheritable skeletal disorders may be autosomal dominant, autosomal recessive, or sex-linked. The gene locations for an increasing number of conditions are now known, making antenatal diagnosis possible early in gestation in families at increased risk, often before any skeletal manifestation is evident ultrasonographically. In many disorders and in new presentations, ultrasound is the prime method for diagnosis. Carriers of dominant disorders have a 50% offspring risk and are expressed in the heterozygous form. Some show variable expression which may be barely noticeable in a mildly affected individual (e.g., ectrodactyly, Holt-Oram syndrome). Many dominant conditions are new mutations and thus appear sporadically. In these cases, the risk of recurrence to unaffected parents is low (~1%). If recurrence does occur, it is generally attributed to gonadal mosaicism in which some of the germ-line cells (but not the somatic cells) of one parent carry the mutation. Recessive disorders are manifest in the homozygous form and occur in the offspring of unaffected heterozygous carriers. There are also a few X-linked disorders in this group (e.g., X-linked chondrodysplasia punctata).

Several ultrasonographic abnormalities may lead to the detection of conditions with limb defects, most commonly the identification of a short femur. Sometimes, close questioning or maternal examination may reveal maternal factors relevant to the etiology, for example, insulin-dependent diabetes mellitus or drugs (Table 20–2).

ULTRASOUND SCANNING FOR FETAL LIMB ABNORMALITIES

A full examination of a fetus at risk for a skeletal abnormality requires a detailed study of the general fetal anatomy, which can provide important clues to the diagnosis. Indeed, detailed examination can help classify the underlying pathology by considering the pattern of anomalies and may indicate other aids to diagnosis (Table 20–3). In early human pregnancy, the upper limbs develop a few days in advance of the lower limbs, with the arm buds appearing at about $5\frac{1}{2}$ postmenstrual weeks followed by the leg buds a few days later. Fetal ossification begins in the clavicle at around 8 weeks' gestation, followed by the mandible, vertebral bodies, and neural arches around 9 weeks, the frontal bones at 10 to 11 weeks and the long bones at approximately 11 weeks.[2] Most skeletal structures can be identified ultrasonographically by 14 to 15 weeks,[3] but the earliest clue to musculoskeletal problems is often an increased nuchal translucency.[4] Later in pregnancy, this is reflected by an increased nuchal fold and generalized skin thickening. In some conditions, frank hydrops can also occur.

If limb shortening appears to be isolated, then fetal growth retardation (FGR) must be considered as a possible etiology.[5] In these circumstances, review of maternal serum screening results for levels of pregnancy-associated plasma protein-A (PAPP-A), β-human chorionic gonadotropin (β-hCG), and maternal serum α-fetoprotein (MSAFP) and assessment of fetal and maternal Doppler results can be useful diagnostic aids (see Table 20–3). Of 130 fetuses referred to the author's unit with abnormal femora (short, bowed, hypoplastic), 42 were thought to have short straight femurs with no other abnormalities. Only 2 of these had a skeletal dysplasia. Many were normal and had had either an incorrect assignment of gestational age or familial short stature, but 31% had FGR.[6]

TABLE 20–1

Terminology Used in Describing Skeletal Abnormalities

Achiria	Absent hand(s)	Lordosis	Dorsal convex curvature of the lumbar spine
Achiropodia	Absent hand(s) and foot (feet)	Mesomelia	Shortening of middle segment of limb (radius/ulna and tibia/fibula)
Acromelia	Shortening of distal segments of limbs, hands, and feet	Micrognathia	Small jaw or mandible
Adactyly	Absent fingers and/or toes	Micromelia	Shortening of all long bones
Amelia	Complete absence of one or more limbs from shoulder or pelvic girdle	Oligodactyly	Absent or partially absent finger(s) and toe(s)
Apodia	Absent foot (feet)	Phocomelia	Absence or hypoplasia of long bones, may have hands or feet attached
Arthrogryposis	Congenital restriction of joint movement	Platyspondyly	Flattening of the vertebral bodies
Brachydactyly	Short fingers	Preaxial polydactyly	Extra fingers or toes on radial or tibial side
Camptomelia	Bent limb or bent fingers	Postaxial polydactyly	Extra fingers or toes on ulna or fibular side
Clinodactyly	Incurved fifth finger		
Diaphysis	Central shaft of long bone	Rhizomelia	Shortening of proximal long bones (femur and humerus)
Ectrodactyly	Split hand(s) or foot (feet; lobster claw deformity)	Syndactyly	Fused fingers ± toes (skin or bone)
Epiphysis	End growing plate of bones	Scoliosis	Lateral curvature of spine
Hemimelia	Absence of distal arm or leg below elbow or knee	Talipes equinovalgus	Clubfoot—foot twisted outward
Kyphosis	Dorsal convex curvature of the spine	Talipes equinovarus	Clubfoot—foot twisted inward
Kyphoscoliosis	Combination of lateral and anteroposterior curvature of spine		

TABLE 20–2

Skeletal Anomalies Associated with Maternal Disease or Maternal Drug Ingestion

UNDERLYING ETIOLOGY	SONOGRAPHIC FINDINGS	OTHER DIAGNOSTIC AIDS
Warfarin	Rhizomelic shortening of limbs. Stippled epiphyses, kyphoscoliosis, flat face, depressed nasal bridge, renal, cardiac, and CNS anomalies.	Maternal drug history
Sodium valproate	Reduction deformity of arms, polydactyly, oligodactyly, talipes, cardiac and CNS anomalies.	Maternal drug and medical history
Methotrexate	Mesomelic shortening of long bones, hypomineralized skull, syndactyly, oligodactyly, talipes, CNS anomalies including neural tube defects, micrognathia.	Maternal drug history
Vitamin A	Hypoplasia or aplasia of arm bones, CNS and cardiac anomalies, spina bifida, cleft lip and palate, diaphragmatic hernia, exomphalos.	Maternal drug history
Phenytoin	Stippled epiphyses, micrognathia, cleft lip, cardiac anomalies.	Maternal drug and medical history
Alcohol	Short long bones, reduction deformity of arm bones, preaxial polydactyly of hands, oligodactyly, stippled epiphyses, FGR, cardiac anomalies.	Maternal history
Cocaine	Reduction deformities of arms ± legs, ectrodactyly, hemivertebrae, absent ribs, CNS, cardiac, renal anomalies, anterior abdominal wall defects, bowel atresias.	Maternal history
Diabetes	Caudal regression, femoral hypoplasia.	Maternal medical history, glucose tolerance test
Myasthenia gravis	Multiple joint contractures, arthrogryposis.	Measurement of maternal anticholinesterase antibodies
Myotonic dystrophy	Talipes and polyhydramnios.	Examination of mother for signs of myotonia, facial appearance; genetic referral
Systemic lupus erythematosus	Short limbs, Stippled epiphyses, depressed nasal bridge.	Maternal medical and obstetric history, autoimmune screen

CNS, central nervous system; FGR, fetal growth retardation.

Long Bones

The long bones are measured in a plane as near to the horizontal as possible to avoid shadowing artifact (Fig. 20–1). As a result, the longest measurement is the true measurement. Each bone should be measured independently. The pattern of shortening is a useful diagnostic aid and the length of all long bones should be checked against appropriate charts to compare both limb length and measurements of head and abdominal circumference.[7–10] Long bone shortening may be generalized (micromelia), more marked in the proximal long bones (rhizomelia) or the forearms and lower

TABLE 20–3

Sonographic Features to Be Examined When Suspecting a Skeletal Abnormality with the Major Associations and Other Diagnostic Aids

SONOGRAPHIC FINDING	CONDITION	OTHER INVESTIGATIONS TO BE CONSIDERED
Skull—Shape, Mineralization (Acoustic Shadow)		
Hypomineralized	Osteogenesis imperfecta IIA and IIC Achondrogenesis type I Hypophosphatasia (severe neonatal form)	(Phosphoethanolamine in parental urine) Parental serum alkaline phosphatase levels
Mild hypomineralization	Achondrogenesis type 2 Cleidocranial dysostosis Osteogenesis imperfecta IIB	Examine parents
Cloverleaf	Thanatophoric dysplasia type II Occasionally in short-ribbed polydactyly syndromes Antley-Bixler Craniosynostosis syndromes (Pfeiffer/Crouzon/ Saethre-Chotzen)	Screen for mutations in FGFR3 and 2 genes
Spine—Length, Mineralization, Alignment (Hemivertebrae), Organization (Stippling)		
Hypomineralized	Achondrogenesis type I	
Disorganized	Jarcho-Levin Spondylocostal dysplasia Dyssegmental dysplasia Some chondrodysplasia punctatas VATER/VACTERL	
Face—Profile (Frontal Bossing, Depressed Nasal Bridge, Micrognathia), Cleft Lip and/or Palate, Orbital Diameters for Hypo- or Hypertelorism		
Frontal bossing	Thanatophoric dysplasia Achondroplasia Acromesomelic dysplasia	Screen for mutations in FGFR3 gene

Depressed nasal bridge	Chondrodysplasia punctatas
	Warfarin embryopathy
		Drug history, mutations in ARSE gene, metabolic investigations—
		    very long chain fatty acids and sterol profile, maternal history
		    of autoimmune disease

Micrognathia	SEDC Stickler's syndrome Campomelic dysplasia	Examine parents
Cleft lip	Majewski's syndrome	
Long Bones—Length, Pattern of Shortening, Which Bones Are Affected, Symmetrical or Asymmetrical, Bowing/Evidence of Fractures, Ossification, Epiphyses for Stippling		
Isolated, straight short long bones	Fetal growth retardation Constitutional short stature	Fetal and maternal Dopplers Family history Parental stature
Femoral bowing	Campomelic dysplasia Osteogenesis imperfecta Hypophosphatasia	
Talipes	Campomelic dysplasia Diastrophic dysplasia	

Stippled epiphyses	Rhizomelic chondrodysplasia punctata
	Conradi Hunerman
	X-linked recessive chondrodysplasia punctata
	Warfarin embryopathy
		Drug history, mutations in ARSE gene, metabolic investigations—
		    very long chain fatty acids and sterol profile, maternal history
		    of autoimmune disease

Limb Girdles—Appearance of Clavicles and Scapulae		
Short clavicles	Campomelic dysplasia Cleidocranial dysostosis	Examine parents
Small scapula	Campomelic dysplasia	
Hands and Feet—Short Fingers (Trident Hand), Short Feet, Camptodactyly, Ectrodactyly, Polydactyly, Oligodactyly		
Polydactyly	Jeune's asphyxiating thoracic dystrophy Ellis–van Creveld syndrome Short-ribbed polydactyly syndromes	
Short fingers/trident hand	Achondroplasia Acromesomelic dysplasia Thanatophoric dysplasia	Screen for mutations in FGFR3 gene
Oligodactyly	Brachmann de Lange Idiopathic limb reduction defects	
Short feet	Brachmann de Lange	

Sonographic Features to Be Examined When Suspecting a Skeletal Abnormality with the Major Associations and Other Diagnostic Aids—cont'd

SONOGRAPHIC FINDING	CONDITION	OTHER INVESTIGATIONS TO BE CONSIDERED
Joints—Contractures, Pterygia, Talipes, Radial Club Hand		
Contractures		
Pterygia		
Talipes	Diastrophic dysplasia Campomelic dysplasia	
Radial club hand	VATER/VACTERL	
Thorax—Size, Length, Rib Length, Shape, Beading (Fractures)		
Narrow with short ribs	Short-ribbed polydactyly syndromes Jeune's asphyxiating thoracic dystrophy Thanatophoric dysplasia Osteogenesis imperfecta types IIA, C and B Campomelic dysplasia Achondrogenesis Hypochondrogenesis Paternal UPD14	
Beaded ribs	Osteogenesis imperfecta type IIA and C	
Associated Abnormalities—Cardiac, Renal, Intracranial, Genital		
Cardiac	Campomelic dysplasia Ellis–van Creveld Short-ribbed polydactyly syndromes VATER/VACTERL	
Renal	Jeune's asphyxiating thoracic dystrophy Short-ribbed polydactyly syndromes	
Intracranial	Majewski, Beemer Langer Thanatophoric dysplasia type II.	
Genital	Campomelic dysplasia Short-ribbed polydactyly syndromes	Karyotyping to confirm genetic sex
Liquor Volume—Polyhydramnios, Oligohydramnios		
Polyhydramnios	Achondroplasia Thanatophoric dysplasia Paternal UPD14 VATER/VACTERL	
Oligohydramios	Short-ribbed polydactyly syndromes with severe renal anomalies	
Maternal and Fetal Dopplers		
Abnormal Dopplers	Fetal growth retardation	Past obstetric history, maternal autoantibodies, maternal serum PAPP-A, β-HCG, and AFP levels

AFP, α-fetoprotein; ARSE, arylsulphatase E; β-hCG, β-human chorionic gonadotropin; FGFR3, fibroblast growth factor receptor 3; PAPP-A, pregnancy-associated plasma protein-A; SEDC, spondyloepiphyseal dysplasia congenita; UPD14, uniparental disomy 14; VATER/VACTERL, vertebral defects, anal atresia or stenosis, tracheoesophageal fistula, radial defects and renal anomalies.

legs (mesomelia) (Fig. 20–2). In some conditions, the changes may be confined to the legs (e.g., campomelic dysplasia) or arms (e.g., Holt-Oram). Hypomineralized long bones reflect less ultrasound at the proximal interface. Thus, they appear less echo-dense across the diaphysis and have a reduced acoustic shadow. Minor degrees of hypomineralization are likely to go undetected. Hypomineralization may result in fracturing, and the position and degree of bowing or fracturing should be noted. Bones may appear short, thick, and crumpled, indicating severe degrees of fracturing and undermodeling as found in osteogenesis imperfecta (OI) types IIa and IIc. It is important to note which bones are affected and where because this can help with the diagnosis. The ends of the bones should be carefully examined to exclude ephyphyseal stippling which might indicate a chondrodysplasia punctata as in rhizomelic chondrodysplasia punctata. If stippling is identified, various metabolic and

cytogenetic investigations can be done in order to try and define the underlying etiology (see Table 20–3). Examination of the joints may be useful because talipes can be a feature of several dysplasias (see Table 20–3).

Skull

Skull hypomineralization reduces both the echogenicity of the skull and the acoustic shadowing beyond it. The cranial contents are seen more clearly than normal. In severe cases of hypomineralization, such as OI types IIA and IIC and achondrogenesis type 1, the cerebral hemispheres are almost anechoic, giving the appearance of ventriculomegaly. This is excluded by showing that the choroid plexus and the walls of the lateral ventricle antrum are normally situated within the hemisphere. The skull bones are soft and can deform when subjected to pressure from the transducer.

FIGURE 20–1

A–E, Normal long bones. The bones are measured as near as possible to horizontal in the scanning plane. The limb segment soft tissue extremity is clearly visible beyond the end of the metaphyses. *A,* T, tibia; F, fibula; K, knee. *B,* F, femur; H, hip. *C,* H, humerus; E, elbow; S, scapula. *D,* R, radius; E, elbow; H, hand. *E,* U, ulna; E, elbow; H, hand.
Hypomineralization may be less obvious in disorders such as hypophosphatasia or OI types IIB and III. Variation in skull shape can also be seen in some craniosynostosis syndromes. The cloverleaf skull is seen in thanatophoric dysplasia type II.

Spine

The spine should be examined carefully in all three planes. Absent or decreased mineralization is a feature of some dysplasias (see Table 20–3). Ossification of the cervical and sacral vertebral bodies is a late event; the sacral vertebral bodies are not ossified until 27 weeks' gestation. Diagnosis of pathologic hypomineralization must be made with care. Vertebral anomalies (e.g., hemivertebrae) can occur with or without associated rib anomalies. The appearance of general disorganization may indicate ectopic calcification seen in some chondrodysplasia punctatas or bony abnormalities as in Jarcho-Levin syndrome.[11]

Face

Cleft lip or palate is a feature of many skeletal dysplasias (see Table 20–3) and may on occasions be very subtle, for example, the small midline cleft seen in Majewski's short-ribbed polydactyly syndrome (SRPS) type 2. Measurement

Femur length measurements in skeletal dysplasias.
(Modified from Griffin DR: Detection of congenital abnormalities of the limbs and face by ultrasound. In Chamberlain G [ed]: Modern Antenatal Care of the Fetus. Oxford, UK, Blackwell Scientific, 1990, pp 389–427; and Griffin DR: Skeletal dysplasias. In Brock DJH, Rodeck CH, Ferguson-Smith MA [eds]: Prenatal Diagnosis and Screening. Edinburgh: Churchill Livingstone, 1992, pp 257–313.)
of the intraorbital diameter may reveal hyper- or hypotelorism in some syndromes. Micrognathia is also associated with a number of conditions (see Table 20–3) and the mandible can be measured in the axial plane from the temporomandibular joint to the mental eminence.[12] Measurement of the mandible and orbital diameters might be more difficult in later pregnancy with increasing acoustic shadowing from surrounding bony structures.[12] A facial profile in the sagittal plane may show frontal bossing (achondroplasia, thanatophoric dysplasia), a depressed nasal bridge (chondrodysplasia punctata), or micrognathia (campomelic dysplasia) (see Table 20–3).

Thorax

Examination of the fetal thorax should include an estimation of thoracic size and examination of the ribs and length of the thoracic cavity. Many dysplasias are lethal because of associated pulmonary hypoplasia. Nomograms of thoracic circumference are available,[13] but a small chest can often be inferred by observation alone. In normal circumstances, the thorax and abdomen should be approximately the same size when viewed in the axial plane. The thorax may be normal, constricted, short, or long. Normal liver size and abdominal circumference cause the abdominal wall to protrude, giving a "champagne cork" appearance when viewed in the sagittal plane. When constricted, the ratio of heart circumference to thoracic circumference (normally ~1 : 3)[14] is increased and the heart may appear to lie outside the chest in extreme cases. The chest can also be small secondary to a short spine, as in some of the spondylodysplasias. In these situations, the chest may appear small in a sagittal plane, but when viewed in the axial plane, the ribs appear of normal length and the heart occupies the appropriate proportion of the thoracic cavity. The ribs may be short, thick, thin, beaded (i.e., fractured), flared, or irregular in shape, arrangement, or number. Examination in the axial plane may reveal short ribs, but the longitudinal plane is more likely to reveal the beading indicative of fracturing seen in OI IIA and IIC. Disorganiszation of the ribs (and spine) may be features of conditions such as Jarcho-Levin syndrome. The heart should be carefully examined because several skeletal dysplasias are associated with cardiac anomalies, for example, Ellis–van Creveld (EVC) syndrome (50%) and campomelic dysplasia (see Table 20–3).

Other Anomalies

A detailed fetal anomaly scan is recommended because there are a number of other anomalies that may give a clue to the underlying diagnosis and help target investigations. In most cases, referral to a clinical geneticist is advisable to identify further investigations and to examine the parents (see Tables 20–2 and 20–3).

CLASSIFICATION OF SKELETAL DYSPLASIAS

The genetic and pathologic etiology of skeletal anomalies is wide. Classifications can be on clinical and/or radiologic grounds,[15] by molecular/genetic etiology, or by structure and function of responsible genes and proteins (e.g., defects in structural proteins, metabolic pathways, transcription factors),[16] or a hybrid.[17] For the prenatal diagnostician, a classification based on sonographic findings is the most useful (see Table 20–3), but there can be considerable overlap in conditions and so a table listing the common diagnoses with gene location, where known, inheritance, and main sonographic findings can also be very helpful.[18] In this chapter, the gene, if known, is placed in parentheses at the heading for the appropriate syndrome.

EARLY-ONSET SEVERE SYMMETRICAL SHORT STRAIGHT LONG BONES

Achondrogenesis

Diagnosis

TYPE 1 (PARENTI-FRACCARO SYNDROME) (5q31-5q34) DTDST

The long bones show extreme micromelia with very poor modeling (e.g., femur length of 10 mm at 19 wk).[19] The calvarium and vertebral column are severely hypomineralized (see Fig. 20–2).

TYPE 2 (LANGER-SALDINO SYNDROME) (12q13-12q14; *COL2AI*)

The long bones are better modeled than in type 1 but are still extremely short, thick, and straight (Fig. 20–3A; see also

FIGURE 20–3

Achondrogenesis. *A*, Short (13-mm) humerus of a fetus with achondrogenesis type II at 18 weeks. *B*, Ultrasound scan of the trunk and head (H) of the same fetus shown in *A*. The spinal column is shown (*arrow*) as an anechoic cartilaginous column. The skull shows some mineralization. *C*, Radiograph of the fetus in *A* shows total absence of ossification in all elements of the spinal column. The ribs are short and the thorax small. There is little mineralization of the skull. *D*, Postnatal radiograph of a different fetus with achondrogenesis type 2 at a similar gestation to that in *C*. In this case, only the vertebral bodies show lack of calcification. Other features are similar to those in *C* with short, straight, reasonably modeled long bones showing flared, cupped metaphyses. The ischial bones are unossified and the ilia small and halberd shaped.

(*A* and *B*, From Griffin DR: Skeletal dysplasias. In Brock DJH, Rodeck CH, Ferguson-Smith MA [eds]: Prenatal Diagnosis and Screening. Edinburgh: Churchill Livingstone, 1992, pp 257–313.)
Fig. 20–2). The calvarium is normally ossified, and although hypomineralization of the spine is variable, it can be striking (see Fig. 20–3*B–D*).

Risks and Management Options

Achondrogenesis types 1 and 2 are lethal conditions at or before birth. Termination of pregnancy should be included as an option during counseling. The diagnosis is supported by postnatal radiography and expert pathology. Where possible, it should be confirmed by DNA analysis. The recurrence risk is 1 : 4 for achondrogenesis type 1. Achondrogenesis is usually a new dominant mutation.

Thanatophoric Dysplasia (4p16; *FGFR3*)

Diagnosis

Thanatophoric dysplasia is the most common lethal skeletal dysplasia. A definitive diagnosis is possible by 12 to 14 weeks,[20] but is more commonly made at 18 to 20 weeks.[21,22] The femur and other limb-length measurements are well below the 3rd percentile (see Fig. 20–2) and display a characteristic thickening of the metaphyses. Measurements from 14 to 21 mm at 18 to 20 weeks to 26 mm at 32 weeks are reported.[23–26] The femurs may appear bowed in some cases and straight in others (Fig. 20–4*B*). The feet and hands are

short. The short, splayed fingers are described as a "trident hand." Short stubby ribs produce a markedly small thorax (see Fig. 20–4C). The cardiothoracic ratio is high (see Fig. 20–4C) and the characteristic truncal champagne cork appearance is seen in the sagittal plane (see Fig. 20–4D). Some cases show flattening of the vertebral bodies (platyspondyly) and a short spine. The skull is normally ossified and may be macrocephalic or brachycephalic. Some variants with straight, long bones show the cloverleaf deformity (see Fig. 20–4A) produced by prominence of the parietal bones.[20,21,23,26] This sign can be recognized in the first trimester[20] but is usually more evident later in pregnancy. Cerebral ventriculomegaly may occur. The facial profile shows a depressed nasal bridge and frontal bossing. Late in pregnancy, soft tissue folds can often be seen on the arms (the "Michelin man" appearance). Hydramnios is also a later feature.

Because the majority of cases result from a mutation in fibroblast growth factor receptor (*FGFR*) 3 gene at 4p16,[27] it can be useful to test the index case. The recurrence risk is small (<1%), but confirmation by DNA analysis will allow early prenatal diagnosis and reassurance in subsequent pregnancies, although a careful scan at 12 to 14 weeks could also exclude a recurrence.

Risks and Management Options
Thanatophoric dysplasia is lethal and pregnancy termination should be included as an option during counseling. Prenatal

diagnosis using free fetal DNA extracted from maternal plasma can be used to confirm the diagnosis before delivery.[28] Postnatal confirmation of the diagnosis by radiography or DNA analysis is essential in the absence of a definitive prenatal diagnosis. Parents should be advised that recurrence risks are low because this is a new dominant sporadic condition.

CONDITIONS ASSOCIATED WITH BOWED OR SEVERELY FRACTURED LIMBS

Campomelic Dysplasia (17q24-17q25; SOX9)

Diagnosis
Early diagnosis is possible.[29–33] The characteristic midshaft bowing of the femur should be recognized during a routine ultrasound (Fig. 20–5), although there is considerable variation in presentation.[34,35] The tibia is short and bowed and the fibula hypoplastic. Marked talipes may cause the whole lower limb to be grossly bowed inward (campomelia). The ribs may be short and the thorax constricted. Brachycephaly, micrognathia, and short clavicles may be detected. Associated anomalies are found in a third of cases and include atrial/ventricular septal defect, hydronephrosis, and ventriculomegaly. Hydramnios may occur late in pregnancy. Phenotypic sex reversal in males is common; karyotyping to

FIGURE 20–5

Campomelic dysplasia. *A,* Showing bowing of the femur with short lower leg and talipes. *B,* Profile of this fetus demonstrating micrognathia.

(From Griffin DR: Detection of congenital abnormalities of the limbs and face by ultrasound. In Chamberlain G [ed]: Modern Antenatal Care of the Fetus. Oxford, UK, Blackwell Scientific, 1990, pp 389–427.)
confirm genetic sex in fetuses with bowed lower limbs should therefore be offered. This is now possible by analyzing cell free fetal DNA in the maternal blood, thereby avoiding the risks of invasive testing.[36]

Risks and Management Options

Three quarters of infants die during the neonatal period from pulmonary hypoplasia and 90% die by the age of 2 years. The prognosis depends on the severity of associated malformations. Survivors fail to thrive and can show neurologic impairment. The recurrence risk is around 5%; many cases are thought to be the result of a new dominant mutation.[34] The option of pregnancy termination should be offered. Support for the diagnosis by pathologic examination and radiography is essential before counseling the parents about the recurrence risk. Antenatal ultrasonographic diagnosis should be offered in subsequent pregnancies.

Osteogenesis Imperfecta (*COL1A1, COL1A2*)

OI is characterized by poor bone mineralization. Based on the clinical and radiologic findings, it was originally divided into four types,[37] although further subgroups have since been added[38]; all are due to mutations in the *COL1A1* and *COL1A2* genes[38] (Table 20–4). The overall incidence approximates to 1 in 10,000. Types I and IV are probably not amenable to early ultrasound diagnosis, although diagnosis has been reported in the second trimester for type IV[39] and the third trimester for type I. Types IIA, B, C, and type 3 have all been diagnosed before 22 weeks' gestation.[40–48] Some evidence suggests that recurrences are due to gonadal mosaicism and the recurrence risks should be quoted at 5% to 7%.[49,50] Type I is inherited in an autosomal dominant fashion. In type III, there is genetic heterogeneity and recurrence is reported. There is the possibility of autosomal recessive inheritance and, again, gonadal mosaicism. Recurrence risks after an isolated case are approximately 7%.[51]

Diagnosis

OI type IIA is the most common form. It is recognizable early in pregnancy by hypomineralization of the skull and

TABLE 20–4

Sonographic Features and Prognosis in Different Types of Osteogenesis Imperfecta

TYPE OF OI	GESTATION AT PRESENTATION	PRENATAL FEATURES	PROGNOSIS
Type I	Usually postnatal, occasionally third trimester	Occasional fractures late in third trimester	Variable fracturing
Type IIA	>12 wk	Hypomineralized easily deformable skull; beaded ribs; small chest; very short, crumpled long bones	Lethal
Type IIB	>16 wk	Mild hypomineralized skull, short and bowed long bones, short flared ribs with occasional beading	Usually perinatally lethal
Type IIC	>12 wk	As with IIA, but a greater degree of hypomineralization	Lethal
Type III	~20 wk	Bowed leg bones, occasional bowed radius and ulna; normal skull mineralization, normal chest with very occasional beading; long bones progressively fall below 5th percentile	Early lethality common; fractures, and progressive deformity in survivors
Type IV	≥20 wk	Long bones often within normal range; normal skull and chest; mild bowing of femur and tibia	Variable prognosis; may have rib fractures at birth

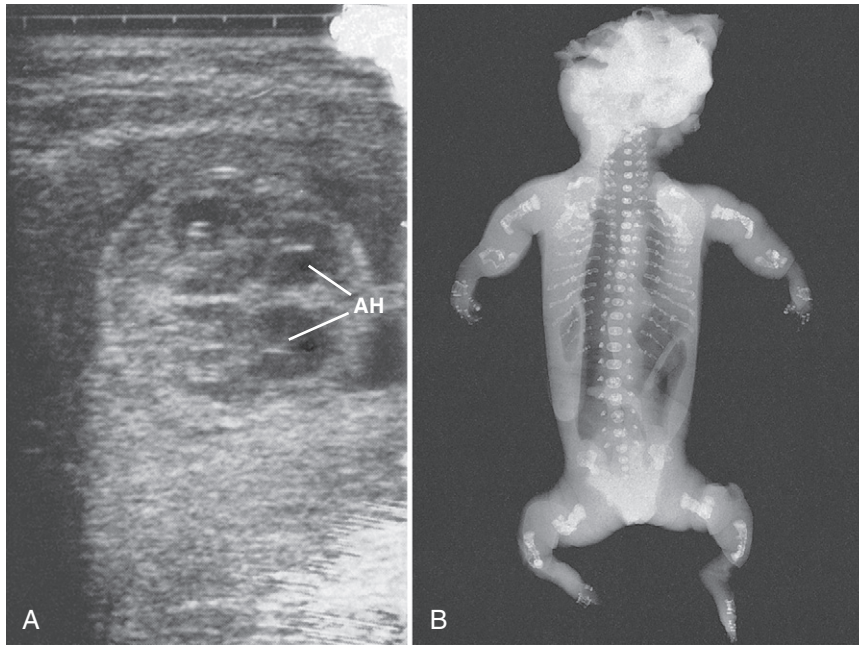
OI, osteogenesis imperfecta.


FIGURE 20–6
Osteogenesis imperfecta type IIA. *A*, Skull of a 20-week fetus shows the features of severe hypomineralization. The skull bones are poorly echogenic and cast no acoustic shadow. The cerebral hemispheres are anechoic, giving the appearance of cerebral ventriculomegaly (pseudohydrocephaly). However, the echoes from the anterior horns (AH) are normally placed. *B*, Postnatal radiograph of a fetus shows the short, bowed long bones, crumpled by multiple intrauterine fractures. The lower limbs are held in a camptomelic (bent) posture. The ribs are "beaded" from fractures, and hairline fractures are also evident in the vertebral bodies (the skull was lost in delivery).
(*A* and *B*, From Griffin DR: Detection of congenital abnormalities of the limbs and face by ultrasound. In Chamberlain G [ed]: Modern Antenatal Care of the Fetus. Oxford, UK, Blackwell Scientific, 1990, pp 389–427.)

long bones with severe micromelia.[40–47] The usual bright echo of the skull bones is lost and there is no acoustic shadow (Fig. 20–6*A*). The orbits may be unusually prominent. The cerebral hemispheres take on a transsonic character. There may appear to be ventriculomegaly, though it can be excluded by identifying the choroid plexus within normal ventricular walls and a normal posterior horn measurement. The head is brachycephalic and easily deformed by pressure from the ultrasound transducer even late in pregnancy. The long bones are hypoechoic, irregularly bowed, and crumpled as a result of multiple fractures and callus formation (see Fig. 20–6*B*). The limbs show marked, fixed campomelia and talipes. Other features, such as beading of the ribs and a small thorax, may be recognized. Amniotic fluid abnormalities can occur later in pregnancy. Type IIC has skeletal features similar to those of type IIA.

Fetuses with type IIB or III rarely have a poorly calcified skull. The femurs may show bowing (Fig. 20–7) or fracture with mild to moderate shortening, but are generally well modeled. Lower legs may be bowed and measure below the 5th percentile.[39,48] Other long bones tend to be at or just below the 5th percentile at 20 weeks, with measurements decreasing with gestation. Type I cannot reliably be excluded before viability. The clinical presentation and prognosis of types I and IV are quite variable and can show considerable overlap. Expert advice is recommended before counseling. The antenatal diagnosis of type IV has also been reported. The features are usually mild, with minimal bowing of the femurs and preservation of long bone growth.[39]

Risks and Management Options

Types IIA and C are lethal. Although type IIB is often lethal, a child may survive to infancy.[49–51] Children with type III can survive but with significant physical handicap owing to multiple deforming fractures.[52] Early postnatal treatment with bisphosphanates may improve prognosis in cases that survive.[53] Pregnancy termination is an option that should be discussed following the diagnosis of OI types II or III in view of the
FIGURE 20–7
Osteogenesis imperfecta type III. Femur (F) with midshaft bowing and poor mineralization. The cartilagenous epiphyses are evident at the knee (K).

severity of the condition. Abdominal delivery might reduce the risk of either trauma or intracranial hemorrhage.

Hypophosphatasia (1p34-1p36)

Bone hypomineralization results from a deficiency of alkaline phosphatase. This heterogeneous group of disorders varies from a lethal condition to milder forms, which become apparent only in childhood. The appearance of the lethal form is similar to that of OI type II. Although the bones are generally less crumpled, they may show marked angulation.

Diagnosis

The diagnosis may be based on biochemical, ultrasonographic, or molecular methods, or a combination. There are

very few reports of the antenatal diagnosis of hypophosphatasia.[54,55] If cranial hypomineralization is marked, the skull appears similar to that in OI type II with anechoic calvarium, prominent intracranial structures, and an easily deformed skull. The femurs and humeri are short and may be so bowed at the midshaft with osseous spurs that measurement is difficult.[56] The ribs are thin and may show fractures. The spine may be markedly demineralized, particularly in the area of the neural arch. In a case report of the milder form, the femoral bowing appeared to resolve during pregnancy.[57] Measurement of alkaline phosphatase (ALP) in amniotic fluid[58] or in cultured amniocytes is unreliable until after 20 weeks. Successful confirmation of diagnosis is possible by measuring cellular ALP in a chorionic villus sample.[59,60]

Risks and Management Options

The severe recessive form is lethal, and the option of pregnancy termination should be included in the counseling session. The osseous maldevelopment in the milder, autosomal dominant forms tends to improve with advancing age. The diagnosis must be confirmed by expert radiography and also by biochemical or genetic investigation of the parents. It is unclear whether milder forms should be delivered abdominally to avoid trauma.

SHORT LONG BONES: MILD TO MODERATE SYMMETRICAL

Fetal Growth Restriction

One of the first conditions to be considered when finding isolated mild to moderate shortening of long bones is FGR.[5,6] In this condition long bones will be normally modeled and there will be no associated visceral anomalies.

Diagnosis

The following investigations should be considered to define the etiology, which includes constitutional short stature, aneuploidy, placental insufficiency, or early signs of a late-onset skeletal dysplasia such as achondroplasia (Table 20–5):

- Detailed anomaly scan.
- Fetal and maternal Doppler scans.

- Family history.
- Amniotic fluid index.
- Down syndrome screening results.
- Karyotyping.
- Maternal blood for *FGFR3* mutation analysis.

Jeune's Thoracic Dystrophy (Asphyxiating Thoracic Dystrophy) (15q13)

Diagnosis

The severity of this condition and the degree of limb shortening are variable. The reports of prenatal diagnosis of Jeune's syndrome are based on the finding of a small thorax in high risk families.[61] The chest is reduced in the anteroposterior diameter with consequent protrusion of the anterior abdominal wall. Limb shortening is variable and can be present from early gestation (~15 wk) but, in some cases, might not be apparent until later in pregnancy (Fig. 20–8). Hydramnios may occur in late pregnancy. Associated features include renal, hepatic, pancreatic, and pulmonary dysplasia, and occasionally, postaxial polydactyly.

Risks and Management Options

Approximately 70% of liveborn children die from respiratory failure during the neonatal period. Survivors are small in stature and often succumb to respiratory, renal, hepatic, or pancreatic complications in childhood. Intelligence is normal. The option of pregnancy termination should be included in counseling if the diagnosis is made in a timely fashion, because the mortality and morbidity rates are high. This autosomal recessive disorder has a 25% recurrence risk.

Short-Ribbed Polydactyly Syndromes

There is some overlap between the main subdivisions of SRPSs[62]:

- I (Saldino-Noonan type) is associated with micromelia characterized by distinct, pointed ends to long bones and associated urogenital and anorectal anomalies.
- II (Majewski type)[63] is characterized by median cleft lip/palate and disproportionately short, ovoid tibiae. The differential diagnosis prenatally includes the orofacial digital (OFD) syndrome type 4.

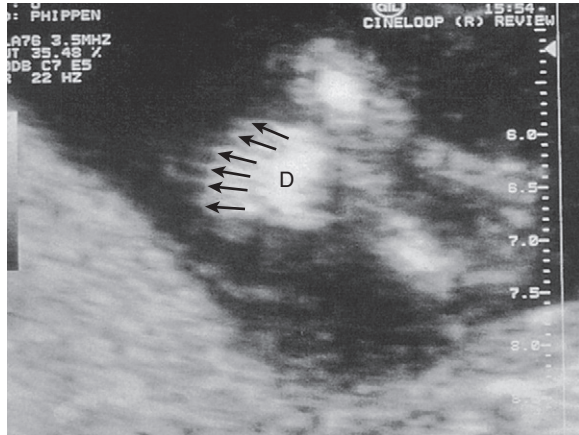
TABLE 20–5

Etiology and Aids to the Differential Diagnosis of Isolated Long Bone Shortening

CONSTITUTIONAL SHORT STATURE	PLACENTAL INSUFFICIENCY	LATE-ONSET SKELETAL DYSPLASIA
Parental short stature	Past history of FGR	Long bones may show bowing
Normally modeled long bones	Maternal autoimmune disease	Decline in long bone growth
Normal growth velocity of long bones	Generalized slowing of long bone growth	
Normal HC and AC	Decrease in AC	Normal AC; may have relative macrocephaly
Normal amniotic fluid volume	Reduced amniotic fluid volume	±Increased amniotic fluid
Normal fetal Dopplers	±Abnormal fetal Dopplers	Normal fetal Dopplers
Normal uterine artery Doppler	Abnormal uterine artery Doppler	Normal maternal Doppler
Normal anomaly scan	Normal anomaly scan	Other anomalies may be present (see Table 20–3)
Normal karyotype	±Normal karyotype	Normal karyotype

AC, abdominal circumference; FGR, fetal growth retardation; HC, head circumference.

FIGURE 20–8
Short-rib polydactyly syndrome. Scan of the foot shows six digits (*arrow*, D). (With thanks to Mr. P. Smith.)

FIGURE 20–9
Diastrophic dysplasia. Scan of the hand (H) shows proximal displacement and abduction of the thumb (T) (the "hitchhiker" thumb). Femur length measurement from this fetus at 22 weeks is shown in Figure 20–2. F, forearm.


- III (Verma-Naumoff type) is associated with short, straight long bones, a midline cleft lip, and other visceral anomalies.
- IV (Beemer-Langer type) is characterized by median cleft lip/palate, bowed forearms, and talipes and may also have a cloverleaf skull and exomphalos.

All types have a small chest secondary to short ribs and can be associated with multiple abnormalities of other organ systems. Fetal hydrops is common. Ambiguous genitalia is a common finding and requires a karyotype for confirmation of genetic sex.

Diagnosis

Prenatal diagnosis is based on the identification of a small, narrow thorax with short ribs, short limbs, and polydactyly (see Fig. 20–8). Other distinguishing features may occasionally help. A number of other uncommon SRPSs have been described.

Risks and Management Options

SRPSs are lethal owing to pulmonary hypoplasia. The option of termination of pregnancy should be included in counseling. These are autosomal recessive disorders with a 25% recurrence risk.

Ellis–van Creveld Syndrome (Chondroectodermal Dysplasia) (4p16)

Diagnosis

Limb shortening is more pronounced in the forearm and lower leg (mesomelic). Polydactyly (hands more commonly than feet) is common.[64] The diagnosis should be considered when these findings are present in association with a small thorax. A fetal echocardiogram is indicated, as more than half of these fetuses have congenital heart disease, typically an atrial septal defect.

Risks and Management Options

One third of affected children die during infancy. Survivors have normal intelligence but a final height of 105 to 150 cm.
The inheritance is autosomal recessive with a 25% chance of recurrence. The gene is known,[65] and DNA should be stored so that early antenatal diagnosis can be offered in subsequent pregnancies. The option of pregnancy termination should be discussed. Obstetric management of a continuing pregnancy is unaltered. Neonatal echocardiography is advisable.

Diastrophic Dysplasia (5q21-5q34) DTDST

Diagnosis

This condition has a variable presentation. Antenatal diagnosis is possible in severe cases based on the combination of rhizomelic limb shortening and bowing in association with the hitchhiker thumb and talipes. Diagnosis is possible in early pregnancy using transvaginal ultrasound (Fig. 20–9).[66,67] Other features may include micrognathia and cleft palate. It may be difficult to exclude the diagnosis before viability in milder cases of high risk families because the degree of limb shortening can be minimal. Identification of normal thumbs is helpful in excluding the diagnosis.

Risks and Management Options

Diastrophic dysplasia is an autosomal recessive disorder with a 25% risk of recurrence. DNA should be stored so that early antenatal diagnosis can be offered in subsequent pregnancies. A significant number of newborns die from respiratory failure and pneumonia. No specific measures are needed before birth in continuing pregnancies. Survivors have normal intellect but suffer significant and progressive physical handicap coupled with limited mobility secondary to the kyphoscoliosis and arthropathy. They require considerable mobility and physiotherapy support. Surgical release of contractures is possible but of limited value. In light of the disease severity, the option of pregnancy termination should be discussed when the diagnosis is made.

Chondrodysplasia Punctatas

For this heterogeneous group of conditions, definitive diagnosis can be difficult before birth and indeed frequently after birth as well.[68] Among the many forms, the three most common are X-linked dominant (Conradi-Hunermann disease), X-linked recessive, and rhizomelic.

Diagnosis

X-LINKED DOMINANT CHONDRODYSPLASIA PUNCTATA (XP11) EBP

This mildest form is seen only in females because the heterozygous male form is lethal. The condition is associated with asymmetrical shortening of bones; icthyosis and other patchy skin changes; areas of alopecia and sparse, coarse hair; and occasional cataracts. Intelligence is usually normal. Prenatal ultrasonographic detection has been reported in high risk cases[69] based on epiphyseal stippling and mild limb shortening.

X-LINKED RECESSIVE FORM (Xp22.22) ARYLSULPHATASE

Affected males have generalized but moderate shortening of the long bones with epiphyseal echogenicities, particularly in the femurs. There may be extensive, paravertebral epiphyseal stippling, giving the impression of a disorganized spine, and a flat face with nasal depression. Echogeniciy may be seen in the larynx. This disorder also may be seen in association with visible cytogenetic deletions of the X chromosome when it may also be associated with intellectual impairment.[70] Heterozygous female carriers are clinically normal but tend to be slightly shorter than noncarrier relatives.

RHIZOMELIC CHONDRODYSPLASIA PUNCTATA (RCDP)

RCDP1 (6q22-q24) PEX7 gene encoding the peroxisomal type 2 targeting signal (PTS2) receptor

RCDP2 (1q42) acyl-CoA:dihydroxyacetone phosphate acyltransferase (DHAPAT) gene

RCDP3 (2q31) alkyldihydroxyacetonephosphate synthase (alkyl-DHAP synthase) gene

Individuals with RCDP have rhizomelic shortening that is more pronounced in the humerus than in other long bones. The characteristic feature on an ultrasound examination is stippled epiphyses.[71–73] There may also be stippling around the pelvic bones, trachea, and larynx. Fixed flexion deformities of the limbs can be seen, more pronounced in the arm than the leg (Fig. 20–10). Cataracts may be detected later in pregnancy.[72] Cultured amniocytes and fibroblasts have low DHAPAT activity.[74]

Risks and Management Options

Many newborns with RCDP die from respiratory failure. Survivors fail to thrive and develop microcephaly associated with severely retarded neurologic development. Survival beyond the first year is unusual; the longest reported survival is 5 years. Measurements of DHAPAT activity in amniocytes or chromosome/molecular analysis are helpful adjuncts to the ultrasonographic diagnosis.[74] The option of pregnancy termination should be discussed.

FIGURE 20–10

Rhizomelic chondrodysplasia punctata. Scan of the arm and shoulder of a 21-week fetus; the humerus (H) is short (25 mm) and bowed. At both the upper (UHE) and lower (LHE) humeral epiphyses, there are echogenic accumulations representing disorganized calcification. Movement of the upper limb was limited during examination.
Kniest's Dysplasia (12q13-12q14; COL2AI)

Diagnosis

Kniest's dysplasia is characterized by moderately short, dumbbell-shaped long bones with metaphyseal flaring, restricted joint mobility, platyspondyly with vertebral clefts, and a flat face with depressed nasal bridge. Although the limbs are noticeably short at birth, antenatal diagnosis has been reported only once.[75] In this instance, the features were not evident at 16 weeks but were apparent at 31 weeks. In the author's experience of three cases, limb length was around the 5th percentile for most of pregnancy. Other features that were detected included mild micrognathia, talipes, and a short thorax.

Risks and Management Options

Affected children may survive with normal intelligence but are short (106–145 cm) and have limited mobility and severe orthopedic disabilities. Ophthalmic complications and deafness may occur in childhood.

Spondyloepiphyseal Dysplasia Congenita (12q13-12q14; COL2AI)

Diagnosis

This condition is associated with short limbs and a short spine, with final stature being approximately 120 cm. The

antenatal sonographic findings have been reported.[76,77] In one case, there was moderate shortening of the femur at 16 weeks followed by more marked rhizomelic shortening at 27 weeks.[76] No other distinguishing features were evident and a definitive diagnosis was not made. In the author's experience of one case, the chest did appear small in the parasagittal plane, but when viewed in transverse section, the ribs were of normal length and the heart occupied one third of the chest. In this condition, the chest appears small secondary to the short spine.[77] The disorder is characterized by deficient ossification of the spine, pubis, talus, and calcaneum and delayed appearance of the lower femoral and upper tibial epiphyses. Vertebrae show marked platyspondyly with ovoid vertebral bodies. The thorax is narrow and bell-shaped and the long bones are moderately short. Cleft palate might also occur.

Risks and Management Options

The disorder is compatible with prolonged survival. Myopia and retinal detachment occur in about half the survivors. Hypotonic muscle weakness and restricted joint mobility reduce overall mobility, and the spinal deformities cause progressive kyphoscoliosis.

ACHONDROPLASIA (4p16; *FGFR3*)

Achondroplasia is the most common nonlethal skeletal dysplasia with an incidence of around 5 to 15 in 100,000 births. It results from a mutation in the *FGFR3* gene located on 4p16.3.[78,79] The majority of cases are sporadic and result from a de novo paternal mutation.[80] The diagnosis is not usually evident ultrasonographically until after 24 weeks' gestation when the long bone shortening manifests (see Fig. 20–2). Achondroplasia is characterized by predominantly acromesomelic limb shortening with short fingers (trident hand). Typical facial features include a wide, prominent forehead (frontal bossing) and a depressed nasal bridge. Thoracic dimensions may be reduced and can occasionally cause transitory respiratory at birth. Relative macrocephaly is usual and ventriculomegaly can occur. The diagnosis can be confirmed prenatally by analysis of cell free fetal DNA in the maternal blood to look for one of the common mutations in the *FGFR3* gene.[81,82]

Risks and Management Options

Life expectancy and intellectual performance are good. Hydrocephaly secondary to partial obstruction of the restricted foramen magnum is usually mild and nonprogressive. Progressive neurologic problems can result from spinal cord compression secondary to progressive narrowing of the interpedicular distance, particularly in the lumbar spine as the degree of lordosis increases.[83] Corrective orthopedic surgery may be required to correct the spinal deformities and bowed legs.

Affected women often require cesarean section because of a contracted pelvis. Cephalopelvic disproportion may also occur during the delivery of an affected fetus to a normal woman if the macrocephaly is marked. The recurrence risk for two unaffected parents is low, because in these circumstances, achondroplasia usually results from a new mutation.

SHORT LONG BONES: ASYMMETRICAL

Isolated Limb Reductions

Risks and Management Options

The majority of isolated limb reductions are nongenetic, but some may occur as part of a genetic syndrome or chromosomal abnormality when there are usually other anomalies.[84] A detailed ultrasonographic examination is therefore essential. Karyotyping is recommended if associated with other nonskeletal anomalies, particularly when involving the forearms or if there are other risk factors. The prognosis for unilateral, isolated arm or leg reduction is generally good, depending on the degree of reduction, in the absence of other visceral or chromosomal abnormalities. Advances in prosthetics and orthopedics are such that much can be done to restore function and appearance of the reduced limbs. Parents should be encouraged to discuss these possibilities with appropriate professionals. There are, however, some specific syndromes associated with asymmetrical limb reduction deformities (Table 20–6).

Robert's Syndrome (Pseudothalidomide Syndrome) (8p21.1; *ESCO2*)

Diagnosis

Typically all four limbs (tetraphocomelia) are affected, similar to the teratogenic effects of thalidomide. Median facial clefting, microcephaly, joint flexion deformities, talipes, syndactyly, and extremely short or missing fingers and toes are accompanying features. Other associated anomalies include hydrocephaly, encephalocele, and renal abnormalities such as cystic or horseshoe kidneys.[85] First-trimester diagnosis has been reported using cytogenetic studies to demonstrate the premature separation of the centromeres, which produces a characteristic phenomenon of chromosome "puffing."[86]

Risks and Management Options

Affected individuals have a high perinatal mortality rate (70%–80%) and severe FGR. Survivors are often profoundly developmentally delayed. The option of pregnancy termination should be discussed. Survivors with hypoglossia-hypodactyly syndrome generally have satisfactory intellectual development, and the level of handicap depends on the severity of limb anomalies.

Femoral Hypoplasia: Unusual Faces Syndrome

This condition appears more common in the progeny of diabetic women. Cleft palate and micrognathia are associated with varying degrees of hypoplasia/aplasia of the femur. The tibia and fibula may be hypoplastic. Humeral reduction with a flexion deformity at the elbow can also be seen. Other associated abnormalities include vertebral anomalies of the lower spine, pelvic anomalies, and urogenital anomalies. The main differential diagnosis is caudal regression syndrome,

TABLE 20–6

Selected Genetic Syndromes and Chromosomal Anomalies Associated with Limb Reduction Defects

	FOREARMS	LOWER LIMBS	CARDIAC ANOMALY	GROWTH	OTHER USS FINDINGS	FH	OTHER DIAGNOSTIC AIDS
BDLS	Asymmetrical and variable forearm reduction, oligodactyly, syndactyly	Small feet	±	FGR, microcephaly	Diaphragmatic hernia		Low PAPP-A
TAR	Bilateral radial aplasia, thumbs always present and normal; ulna hypoplasia.	Absent/abnormal tibia, fibula, femur, talipes	±	Usually normal	Absent/abnormal humeri, flexion deformities	AR	Platelet count DNA analysis
Trisomy 18 Trisomy 13	Radial club hand, flexed fingers, polydactyly, absent thumbs	Talipes, rocker-bottom feet, polydactyly	+	FGR	Multiple		Karyotype
Holt-Oram	Bilateral radial abnormalities of variable severity, absent digits (especially thumb)	Normal	+	Normal		AD	Examine parents X-ray parents echocardiography
Fanconi	Hypoplastic thumbs, radial anomalies, polydactyly	Normal	±	FGR	Cryptorchidism, renal anomalies	AR	Chromosome breakage studies

Robert's	Bilateral radial and ulna hypo/aplasia	Hypoplastic or absent lower limb bones	±	Normal	Cleft lip, cystic kidneys	AR	Karyotype: chromosome puffing
VATER/VACTERL	Asymmetrical radial defects	Normal	±	Normal	Hemivertebrae, renal anomalies	–	±Hydramnios, genetics
FFU	Variable hypoplasia of forearms	Asymmetrical bowing/hypoplasia of lower limbs	–	Normal	Ectrodactyly	–	

AD, autosomal dominant; AR, autosomal recessive; BDLS, Brachmann de Lange syndrome; FFU, femur-fibula-ulna complex; FGR, fetal growth restriction; FH, family history; PAPP-A, pregnancy-associated plasma protein-A; TAR, thrombocytopenia with absent radius syndrome; VATER/VACTERL, vertebral defects, anal atresia or stenosis, tracheoesophageal fistula, radial defects and renal anomalies.

but this syndrome is not associated with the facial dysmorphisms or humeral reduction. Most individuals have normal intelligence and are ambulatory.[87]

Femur-Fibula-Ulna Syndrome

This syndrome is characterized by femoral and fibula hypoplasia/aplasia and varying degrees of ulna hemimelia.[88] It has been diagnosed antenatally.[89]

Holt-Oram Syndrome (12q21) *TXB5*

Diagnosis

The cardinal features of Holt-Oram syndrome are congenital heart disease (usually atrial or ventricular septal defect) associated with anomalies of the upper limb shoulder girdle. Abnormalities in the hand and forearm include aplastic, hypoplastic, or triphalangeal (finger-like) thumb and syndactyly and hypoplasia of the radius, ulna, humerus, clavicles, scapula, or sternum.[90,91] Ultrasonographic diagnosis has been reported.[92] This is a dominant condition, and affected individuals have a 50% offspring risk. There is no consistent pattern, and expression is very variable.[90]

Risks and Management Options

Management options depend on the severity of the cardiac malformation and the skeletal deformities. Parents should be examined because the condition is extremely variable and gene carriers may have minimal manifestations.

Thrombocytopenia with Absent Radius Syndrome (1q2.1)

The skeletal manifestations of thrombocytopenia with absent radius (TAR) syndrome are variable; bilateral radial aplasia/hypoplasia is sometimes associated with humeral or ulnar reduction or bowing. The pathognomic feature is that the thumbs are always present regardless of the degree of radial hypoplasia. The femurs can be affected, and cardiac anomalies are relatively common.[93] Thrombocytopenia is a marker of an underlying hematologic abnormality. Antenatal diagnosis is based on both the ultrasonographic findings and the documentation of fetal thrombocytopenia.[94] TAR is associated with a microdeletion at 1q21.1. In a large clinical study, the deletion occurred de novo in 25% of cases and was inherited equally from the mother or the father in the other cases.[95] The inheritance pattern resembles an autoso-

mal recessive pattern, and it is hypothesized that an additional modifier is required.

Cleidocranial Dysostosis (6p21; *CBFA1, RUNX2*)

Diagnosis

The characteristic findings are mild femoral shortening with hypoplastic clavicles (Fig. 20–11). Although the clavicle is not generally included in routine ultrasound examinations of the fetus, nomograms of clavicular length are published.[96] Examination of the clavicle may be helpful in defining the underlying pathology in the presence of short limbs. A hypomineralized cranium with wide fontanelles might also be evident.[97]
FIGURE 20–11
Cleidocranial dysostosis. *A,* Transverse scan of the clavicles of the fetus of a mother with cleidocranial dysostosis. The clavicles are short, thick, and straight. *B,* Similar posteroanterior scan of the clavicles of a normal 22-week fetus. Note the sigmoid form of the clavicle. Sp, spine.

Risks and Management Options

Individuals with cleidocranial dysostosis are generally short. They may have respiratory difficulties in infancy if the thorax is restricted. Dental and hearing problems can present in later childhood. However, the absent or hypoplastic clavicles do not cause significant handicap, and intelligence is unimpaired. Poor skull ossification tends to improve with age. Affected mothers may require cesarean section because of a small pelvis. The condition is very variable, and parents should be examined for minor manifestions.[97]

Polydactyly/Syndactyly

These conditions frequently coexist. The polydactyly can be either preaxial (on the radial side of the hand or medial side of the foot, including bifid thumb or great toe) or postaxial (on the ulnar side of the hand or lateral side of the foot). Polydactyly is associated with numerous genetic and chromosomal syndromes (see Tables 20–3 and 20–6). Isolated polydactyly can be inherited as an autosomal dominant trait with variable penetrance, particularly in some ethnic groups (e.g., Afro-Caribbean).

Ectrodactyly

Ectrodactyly (split hand) is a variant of syndactyly in which the hands resemble a "lobster claw" (Fig. 20–12). It may occur either as an isolated phenomenon or as part of several syndromes,[80] the most common of which is the ectrodactyly ectodermal dysplasia clefting (EEC) syndrome. Isolated ectrodactyly and EEC syndrome are both inherited as autosomal dominant traits with a 50% risk of recurrence.
FIGURE 20–12
Ectrodactyly. Scan of a fetal foot showing ectrodactyly. H, heel; D, digits.
(From Griffin DR: Skeletal dysplasias. In Brock DJH, Rodeck CH, Ferguson-Smith MA [eds]: Prenatal Diagnosis and Screening. Edinburgh: Churchill Livingstone, 1992, pp 257–313.)

Diagnosis

Isolated ectrodactyly may affect one or more limbs and has extremely variable penetrance. At the worse end of spectrum, it can be associated with limb reduction defects. Parents of an affected child may show only minimal changes.[98] Antenatal diagnosis is possible in more severe cases. In the EEC syndrome, ectrodactyly is associated with cleft lip or palate and skin, hair, and teeth dysplasia. Renal defects may also be present.

Risks and Management Options

Prognosis depends on the underlying etiology, and when detected antenatally, parents should be referred to a clinical geneticist for careful examination and discussion of possible underlying conditions.

JOINT DEFORMITIES

Detailed discussion of joint deformities is beyond the scope of this review. They can occur as part of a skeletal dysplasia (see Table 20–3), in chromosomal disorders or other genetic conditions (see Table 20–6), as part of a generalized contractural or neurologic syndrome, or from a deformity as a result of intrauterine pressure secondary to oligohydramnios or uterine anomalies.

Talipes

The most common positional deformity is talipes equinovarus, in which the foot is adducted and plantar inverted so that the sole points medially. In the equinovalgus (calcaneovalgus) deformity, the heel is elevated and the foot is

plantar everted. Talipes occurs as an isolated phenomenon in approximately 1 in 1200 births with varying degrees of severity, as a marker for chromosomal abnormalities, or as part of many genetic syndromes.[80,99]

Diagnosis

Positional deformities of the feet are best sought in the sagittal and coronal scanning planes (Fig. 20–13). When severe talipes equinovarus is present, the plantar view of the foot is seen in continuity with the leg in sagittal section (Fig. 20–14). Because of the many associated syndromes, a careful search for other abnormalities is mandatory before counseling. The combination of talipes and hydramnios raises the suspicion of congenital myotonic dystrophy[100] or distal dominant arthrogryposis.[101] Thus, parental examination may be helpful, particularly to look for evidence of early signs of myotonic dystrophy in the mother.[100]

Risks and Management Options

Isolated talipes is usually amenable to orthopedic correction. Karyotyping is recommended if other markers of aneuploidy or risk factors are present. Management depends on the severity of any associated structural defects and the karyotype. In the presence of a normal karyotype and other ultrasonographic anomalies, including hydramnios, genetic referral should be considered.

Rocker-Bottom Feet

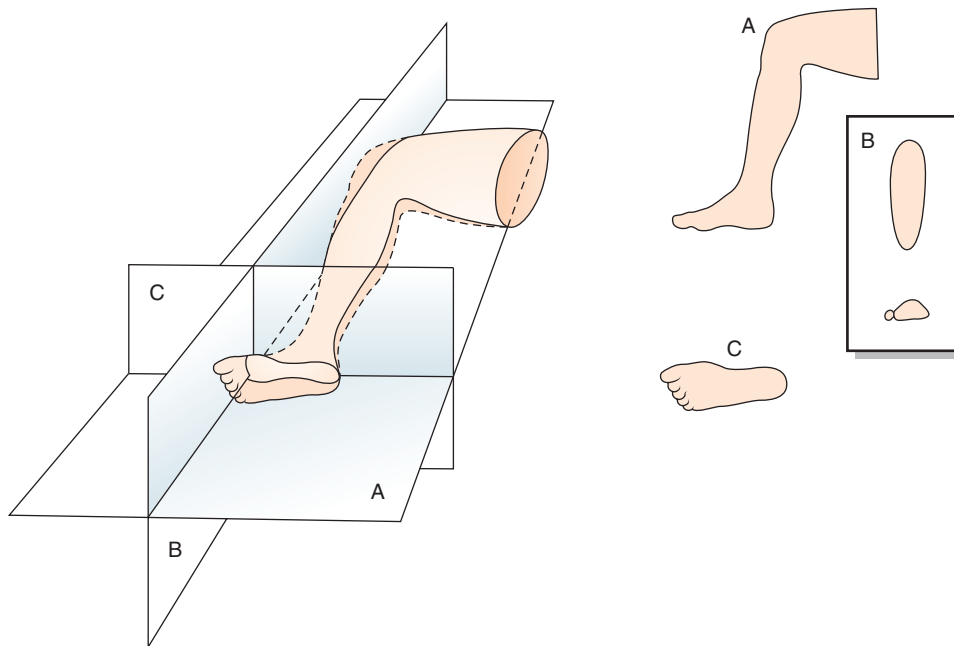
The typical appearance of rocker-bottom feet, usually caused by a vertical talus, is a posteriorly prominent heel and convexity of the normally concave contour of the plantar arch (Fig. 20–15). Rocker-bottom feet are associated with trisomy


FIGURE 20–13
Diagram represents the scanning planes employed to visualize the foot. Plane A will show rocker-bottom feet; planes A and B will show talipes; planes B and C reveal polysyndactyly.
(From Griffin DR: Skeletal dysplasias. In Brock DJH, Rodeck CH, Ferguson-Smith MA [eds]: Prenatal Diagnosis and Screening. Edinburgh: Churchill Livingstone, 1992, pp 257–313.)

FIGURE 20–14
Positional deformities. Longitudinal view of the leg shows the lower end of the femur, knee (K), tibia/fibula, and foot with talipes. The plantar view of the foot would not normally be seen in this plane.
FIGURE 20–15
Rocker-bottom foot. Sagittal scan of the foot of a fetus with confirmed trisomy 18 shows prominent heel (H) and loss of the plantar arch. T, toe.

18, 18q syndrome, trisomy 13, Pena-Shokeir sequence, and other syndromes. The finding requires a diligent search for other abnormalities. Karyotyping is indicated if other abnormalities are present.

MULTIPLE JOINT CONTRACTURES

This heterogeneous group of disorders is characterized by multiple flexion deformities of the limbs, hands, and feet, resulting in fixed immobile limbs, sometimes with cutaneous webbing (pterygia) at joint flexures. The causes include[102]

- Central nervous system disease (55%).
- Peripheral neuromuscular disorder (8%).
- Connective tissue disease (11%).
- Miscellaneous skeletal or other abnormality (19%).

Oligohydramnios is present in 7%.[66] Increased first-trimester nuchal translucency and fetal hydrops in the

second trimester are reported.[103] Deficient swallowing and fetal breathing may result in hydramnios and pulmonary hypoplasia. The etiology is broad and includes specific central nervous system abnormalities, primary myopathy, congenital muscular dystrophy, lethal multiple pterygium syndrome, and the Pena-Shokeir spectrum.[104]

Risks and Management Options

Definitive diagnosis is rarely made antenatally. At the severe end of the spectrum, these conditions are perinatally lethal. Detailed postmortem examination is advised with subsequent referral to a clinical geneticist for further investigations (see Tables 20–2 and 20–3) and counseling with regard to recurrence risks, which can be high.

SPINAL DEFORMITIES

These deformities can occur as a consequence of neural tube defects, hemivertebrae, dysplasia or agenesis of the vertebrae, or asymmetrical muscle action (severe abdominal wall defects). Neural tube defects and abdominal wall defects are reviewed in Chapters 17 and 19.

Hemivertebrae

Hemivertebrae occur when one of the pair of chondrification centers that normally combine to form the vertebral body fails to appear. Only half of the vertebral body develops and the result is lateral angulation of the spine (scoliosis). Hemivertebrae may be isolated or associated with cardiac, renal, radial, or digital anomalies, tracheoesophageal fistula, and anal atresia in the VACTERL (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or esophageal atresia, renal agenesis and dysplasia, and limb defects) association, or as a part of numerous other genetic syndromes.

Diagnosis

Hemivertebrae are recognized ultrasonographically by spinal scoliosis and asymmetry in the vertebral echoes (Fig. 20–16). A careful search for associated abnormalities is essential. Hydramnios may be the only clue to tracheoesophageal atresia. A karyotype is indicated if other anomalies are seen, because similar abnormalities may be found in trisomy 18 and 13q syndromes.

Risks and Management Options

These options depend on the presence and severity of associated anomalies. The parents should meet with an orthopedic specialist to discuss the postnatal management including surgical correction of the spinal deformity. Individuals with VACTERL association generally have normal intellectual potential.

Jarcho-Levin Syndrome (Spondylothoracic Dysplasia)

Diagnosis

The Jarcho-Levin syndrome is an autosomal recessive disorder characterized by a grossly disorganized axial

skeleton and thorax (Fig. 20–17). Vertebral bodies may be missing or fused and the hemivertebrae and ribs are frequently reduced in number with posterior fusion and anterior flaring (the "crab chest" deformity). Visceral and urogenital anomalies along with diaphragmatic hernia are also reported.[11,80]

Risks and Management Options

The majority of individuals with this condition die in the neonatal period or during early infancy as a result of respiratory insufficiency. The option of pregnancy termination should be discussed.
FIGURE 20–16
Hemivertebra. Longitudinal scan of the vertebral bodies of one of twin fetuses shows a midlumbar hemivertebra (HV). The spinal canal showed no evidence of narrowing on scan. Spinal deformity was minimal at birth. Th, thorax.
FIGURE 20–17
Jarcho-Levin syndrome. Longitudinal coronal scan of the trunk. The ribs are thick and irregular and the spinal components (Sp) grossly disorganized.

FETAL THYROID DISEASE

Introduction

Thyroxine (T_4) is synthesised and secreted by the thyroid gland. The active hormone triiodothyronine (T_3) is predominantly produced by deiodination of T_4 in peripheral tissues by the action of deiodinases. Thyroid hormone receptors (TR-α and TR-β) bind T_3 with high affinity and function as ligand-inducible transcription factors that regulate expression of T_3-responsive target genes.

The embryonic thyroid is derived from the endoderm of the buccal cavity. The gland enlarges and migrates to the lower neck by the seventh week of development. Thyroid hormone synthesis begins at 10 to 12 weeks, but appreciable amounts are released only from 14 to 16 weeks onward.[1,2] Thus, the availability of free T_4 (FT_4) to early fetal tissues is dependent on maternal T_4 levels. Whereas levels of total T_4 are very low in the fetus, FT_4 levels are actually comparable with maternal levels because of differences in T_4-binding proteins. Once fetal thyroid hormone production begins, total and FT_4 concentrations increase, reaching adult levels by the third trimester (total T_4 100–150 nmol/L, FT_4 15–25 pmol/L), while levels of total and free T_3 (FT_3) remain very low.[2] Maternal thyroid hormones continue to contribute to fetal T_4 levels until birth, as demonstrated in neonates with complete thyroid agenesis. Thyroid-stimulating hormone (TSH) remains low until 15 to 18 weeks, then increases to around 8 mU/L at term.[2] The fetal pituitary is capable of responding to thyrotropin-releasing hormone (TRH) from 20 weeks but is relatively insensitive to negative feedback from thyroid hormones until late in the second trimester.

The placenta is freely permeable to iodide substrates, TRH, thionanides. and thyroid-stimulating hormone receptor antibodies (TRAbs) but is impermeable to TSH. Transfer of T_3 and T_4 is controlled through the action of placental deiodinase enzymes. During pregnancy, differential expression of deiodinases maintains a suitable maternal-fetal gradient.[2,3] The placenta produces several peptides, including human chorionic gonadotropin (hCG), capable of stimulating the maternal thyroid. As a result, maternal FT_4 concentrations increase in early pregnancy.

Thyroid hormones are essential for optimal growth and development of the central nervous system (CNS), lung, gut, and liver and the regulation of carbohydrate, lipid, and protein metabolism. Three stages of thyroid hormone–dependent neurologic development are recognized.[3] The first occurs before the onset of fetal thyroid hormone synthesis and influences neurogenesis and neuronal migration in the cerebral cortex, hippocampus, and medial ganglionic eminence. The second occurs during the remainder of pregnancy when additional thyroid hormone–dependent processes include axon and dendrite migration, synapse formation, glial cell proliferation, and myelination. During the third (postnatal) stage, specific cell types in the cerebellum, hippocampus, and cortex (Purkinje cells) are sensitive to thyroid hormones and thyroid hormone–dependent gliogenesis and myelination continue.[3] Thus, the specific types of deficit appear to reflect the timing and duration of thyroid hormone insufficiency.[3]

Fetal Hyperthyroidism

Fetal or neonatal hyperthyroidism is a rare condition affecting fewer than 1 in 5000 pregnancies.[4] The disorder is almost invariably secondary to maternal autoimmune thyroid disorders, principally Graves' disease (GD) (Table 21–1). GD is responsible for 85% to 90% of cases of maternal hyperthyroidism, which complicates 1 in 500 to 1000 pregnancies.[5,6] The disease is caused by TRAbs that usually stimulate the receptor but occasionally block the normal effect of TSH. Fetal hyperthyroidism is caused by transplacental passage of stimulating TRAbs. This can occur in euthyroid-treated mothers, although the risk is dependent on the method and time of treatment; both medical therapy and surgery are followed by a decline in TRAbs with disappearance of TRAbs in 70% to 80% after 18 months.[7] Remission of TRAb autoimmunity is less common after radioiodine therapy.[7] Hyperthyroidism occurs in 1% to 5% of infants born to women with a history of GD,[4,8] although only half require antithyroid therapy because of symptomatic disease.[4,8] Thyroid hormone concentrations are also increased in fetuses with anemia secondary to red cell alloimmunization.[9]

Diagnosis

Fetal hyperthyroidism should be suspected in any woman with a history of active or treated GD or clinical features suggestive of hyperthyroidism.

MATERNAL THYROID FUNCTION AND ANTIBODY TESTS

Decreased TSH and increased FT_4 concentrations are diagnostic of maternal hyperthyroidism. However, maternal thyroid function does not predict fetal thyroid function. The value of measuring TRAbs is controversial and a variety of assays exist. All antibodies that can compete with TSH for binding to the TSH receptor (TSH-R) are identified as thyroid-stimulating hormone–binding inhibitory immunoglobulins (TBII). A range of commercial kits are available that record the percentage of inhibition of TSH binding to a membrane preparation of TSH-Rs (elevated levels >15%).[10] TBII is often used as a surrogate for an assay of thyroid-stimulating hormone receptor–stimulating antibodies (TSAbs), because binding and stimulation frequently go in parallel.[11] Assays are also available for both TSAbs and thyroid-stimulating hormone-receptor–blocking antibodies (TBAbs). TSAbs can be measured by immunoassay or more commonly by biologic assay involving release of cyclic adenosine monophosphate (cAMP) from thyroid cell cultures by purified immunoglobulin G (IgG; elevated values >130% or >1.3 index units [IU]).[12] Approximatey 20% of women with GD have TRAbs. Improvement of Graves' hyperthyroidism is often associated with a reduction in TSAb levels and a shift from stimulatory to blocking antibodies; Kung and Jones[12] reported that median levels of TSAb fell from 280% in the first trimester to 130% at term whereas TBAb increased from 16% to 43%.

The risk of fetal hyperthyroidism correlates with maternal TBII and TSAb.[5,8,13] The incidence of neonatal thyroid dysfunction (including overt and chemical thyrotoxicosis) was 67% if TRAbs were greater than 130% and 83% if greater than 150% compared with 11% with less than 130% antibody response.[8] Peleg and coworkers[13] reported that a TSAb of 5 IU or greater predicted neonatal hyperthyroidism with a sensitivity of 100%, specificity of 76%, positive predictive value of 40%, and negative predictive value of 100%. The risk of fetal/neonatal hyperthyroidism is very small if TRAbs are negative; of 72 women with GD and at least one prior positive test for TRAb (measured by radioreceptor TRAK assay) prospectively followed throughout pregnancy, 31 women had persistently negative TRAbs and all infants were euthyroid at birth.[14] In contrast, fetal hyperthyroidism was detected in 4 of 33 cases in which the woman had at least one positive TRAb test during pregnancy.[14] Guidelines for the measurement of TRAb in pregnancy have been produced by the European Thyroid Association[15] (Table 21–2).

FETAL IMAGING

Fetal hyperthyroidism can be associated with fetal goiter, tachycardia, fetal growth restriction (FGR), hydrops, and fetal death.[13,14,16,17] The fetal thyroid is visible in a transverse section of the neck, lying between and immediately in front of the carotid arteries, which are easily visualized with color Doppler, and in front of the trachea, which appears as a central echo-free disk[14] (Fig. 21–1). Fetal goiter is defined as a thyroid circumference greater than the 95th percentile for gestational age[18] (Fig. 21–2). Luton and colleagues[14] reported fetal goiters in 2.6% of pregnancies in women with a history of thyroid disease and in 19% of mothers with GD. In

three of five fetuses who had color Doppler assessment of the goiter had central vascularization, and none had increased fetal movements. In all five hyperthyroid cases in which all four parameters were recorded, the overall score (see Table 21–3) was 2 or greater.[16] One case also had tracheal compression and another had cardiomegaly. Peleg and coworkers[13] reported that five of six cases with neonatal thyrotoxicosis manifested fetal tachycardia, one had FGR, and another had hydrops.

Serial fetal ultrasonography is generally recommended in women with hyperthyroidism.[18] Assessment of fetal heart rate, growth, and thyroid size every 4 to 6 weeks from 22 weeks' gestation is reasonable, although more frequent scans may be prudent in women with high TRAbs.[14,22]

FETAL THYROID FUNCTION TESTS

Amniotic fluid thyroid hormone concentrations do not reliably predict fetal thyroid status.[23] Fetal blood sampling (FBS) is therefore the only method of directly assessing thyroid function. Normograms for fetal thyroid hormone and TSH levels are available.[2] In fetal hyperthyroidism, TSH concentrations are low.[19] However, FBS is associated with a small risk of pregnancy loss. This risk is justified in cases of maternal GD in which there is ultrasound evidence of a fetal goiter in order to distinguish hyper- from hypothyroidism. FBS should also be offered to women with GD with isolated sustained fetal tachycardia.[13] There is controversy regarding the role of FBS in women with GD and no ultrasound evidence of fetal involvement. Accumulating evidence suggests that invasive testing is not justified in women with negative or low TRAbs,[14] whereas there is a case for offering FBS in those with high TRAbs[24]; of 14 cases undergoing FBS because of high TRAbs (defined as TSAb levels >160% on bioassay or >10 U/L on immunoassay) or ultrasound evidence of fetal involvement, one of the two cases of fetal hyperthyroidism (with TSAb of 259%) had neither fetal goiter nor tachycardia.[5] Further studies are needed to determine whether the ultrasound score recently reported by

Huel and colleagues[16] can replace invasive assessment of fetal thyroid status.

Risks

Perinatal risks of fetal hyperthyroidism include FGR, hydrops, and hydramnios with the associated risks of preterm delivery and malpresentation. Early studies reported a perinatal mortality from fetal hyperthyroidism of up to 50%,[23] but more recent studies, incorporating maternal and fetal surveillance, indicate the risks are much lower than this.[25]

Overt neonatal thyrotoxicosis is associated with tachycardia, tachypnea, flushing, difficulty in feeding, hyperirritability, and poor weight gain. There may be associated jaundice, hepatosplenomegaly, and a bleeding tendency due to thrombocytopenia and low prothrombin levels.[25] In severely affected babies, mortality may be as high as 25% owing to cardiac arrhythmias or high output failure.[25] Long-term sequelae include craniosynostosis and neurodevelopmental impairment.[26] The half-life of antithyroid drugs in the neonate is shorter than the maternal TRAbs, and therefore, symptoms of neonatal thyrotoxicosis might not present until 5 to 10 days of age.[26] Further, TRAbs are excreted in breast milk, and there is some evidence that neonatal thyroid disease may be worse and more prolonged in TRAb-positive women who breast-feed.[27]

FETAL RISKS OF MATERNAL HYPERTHYROIDISM

In women who become pregnant while their thyrotoxicosis is under control and in those in whom the condition is diagnosed and treated early, the prognosis for mother and fetus is excellent. However, untreated or poorly controlled maternal hyperthyroidism is associated with early pregnancy loss, stillbirth, FGR, and preterm birth.[28,29] These adverse fetal effects are due to direct toxic effects of high levels of thyroid hormone because they occur in fetuses of euthyroid mothers with resistance to thyroid hormone secondary to mutations in the TR-β gene.[30] In one large retrospective

review of 249 cases of GD published in 1992, the fetal death/ stillbirth rate was 5.6%.[31] Millar and coworkers[32] reported preterm delivery in 33% of hyperthyroid mothers (odds ratio [OR] 16.5, 95% confidence interval [CI] 2.1–130), and 12% gave birth to a small–for–gestational age (SGA) infant (OR 2.2, CI 0.4–11.5). Thyrotoxicosis for 30 weeks or more during pregnancy, GD for 10 years or longer, onset of GD before 20 years of age, and high TBII at delivery (>30%) are each associated with an increased risk of delivering an SGA infant.[8] Pregnancy outcome is closely associated with maternal thyroid status, with poorer outcomes in uncontrolled women at delivery.[29,32]

Management Options

THERAPY FOR MATERNAL HYPERTHYROIDISM
(See Also Chapter 45)

Effective treatment of maternal hyperthyroidism is associated with improved maternal and fetal outcome.[8,29,32] Ideally, this should be undertaken prior to pregnancy. Mothers who remain euthyroid throughout pregnancy do not appear to be at increased risk of preeclampsia, preterm delivery, or delivery of an SGA infant.[28]

Antithyroid Drugs

Thionamides inhibit the synthesis of thyroid hormone by preventing iodination of the tyrosine molecule. Early evidence suggested that propylthiouracil (PTU) crossed the placenta more slowly than methimazole and carbimazole (which is metabolized to methimazole),[33] but this has not been confirmed in subsequent studies.[34] Case reports have linked methimazole with fetal scalp defects (aplasia cutis) and choanal or esophageal atresia.[35] However, the overall incidence of major malformations is comparable in women taking PTU and methimazole (2%–3%),[34,36] and in a prospective cohort study comparing methimazole exposed infants with controls, there was no difference in the incidence of major malformations.[37] Further, there is no evidence that the use of PTU is associated with a reduced incidence of neonatal thyroid dysfunction.[34,38] PTU, however, remains the initial preferred drug for maternal hyperthyroidism according to an expert consensus recommendation of the Endocrine Society.[35] In utero exposure to antithyroid drugs has not been associated with long-term differences in IQ scores or psychomotor development compared with unexposed siblings.[39,40]

Methimazole and, to a lesser extent, PTU are excreted in breast milk. However, studies have reported no alteration in thyroid function in infants breast-fed by mothers treated with daily doses of PTU (50–300 mg), methimazole (5–20 mg), or carbimazole (5–15 mg) for up to 8 months.[35] Mothers should be advised to take their antithyroid medication just after a feed and wait 3 to 4 hours before feeding again.

In newly diagnosed cases of maternal hyperthyroidism, the initial dose of PTU is usually 150 mg every 8 hours. The equivalent dose of carbimazole is 20 mg twice daily. Clinical and biochemical improvement is usually evident after 2 to 4 weeks, although the fetal response may take longer. Once maternal symptoms have improved and thyroid function is within the normal range, the dose should be halved. Further reductions may be possible owing to the tendency for GD

to ameliorate during the last trimester, and it is usually possible to reach a maintenance dose of 150 mg/day or less of PTU (or ≤15 mg/day of carbimazole). Side effects include nausea, arthralgia, skin rash, metallic taste, and fever. Leucopenia, agranulocytosis, and hepatitis can also occur.

The aim of therapy is to keep the mother euthyroid using the minimum amount of thionamide. Maternal thyroid function should be monitored every 4 to 6 weeks, aiming to keep the FT_4 at the upper third of the normal nonpregnant range.[6,35] With this management, serum FT_4 levels are normal in more than 90% of neonates.[37] In contrast, FT_4 levels are low in 36% of neonates when the maternal FT_4 is in the lower two thirds of the nonpregnant range.[37] If the mother remains euthyroid with a small dose of PTU (50–100 mg) or methimazole (5–10 mg), therapy should be discontinued. This may be possible in up to 30% of patients after 32 weeks.[28]

Reliable differentiation of thionamide-induced hypothyroidism (see later) from TRAb-induced hyperthyroidism in GD requires measurement of fetal FT_4 and TSH. Although fetal heart rate alone is unreliable in detecting thyroid dysfunction,[5] serial measurement of fetal thyroid size may allow early noninvasive detection of thyroid dysfunction.[14,22] Cohen and colleagues[22] measured thyroid size in 20 consecutive women with GD on PTU (1050–1150 mg/wk); thyroid width and circumference were above the 95% percentiles in 5 fetuses; in 3, thyroid size decreased concurrently with a decrease in maternal PTU dosage and all were born euthyroid. In 2 fetuses, thyroid size was unaffected by a decrement in maternal PTU dose and both were hyperthyroid at birth. Luton and colleagues[14] measured fetal thyroid size monthly from 22 weeks' gestation in 72 mothers with past or present GD; fetal thyroid circumference was normal in all 31 fetuses whose mothers were TRAb-negative and took no antithyroid drugs during late pregnancy. Thirty of the 41 other fetuses (of which 16 were exposed to maternal PTU) had normal fetal thyroid circumference; 29 were euthyroid and one hypothyroid at birth. Eleven fetuses developed a goiter; based on associated ultrasound features (see Table 21–3) and/or FBS (performed in 6 cases), 7 fetuses were diagnosed as hypothyroid and 4 as hyperthyroid. Overall, the sensitivity and specificity of fetal thyroid circumference at 32 weeks' gestation for clinically relevant thyroid dysfunction were 92% and 100%, respectively.[14] Thus, accumulating evidence suggests that serial measurement of fetal thyroid size is extremely valuable in monitoring thionamide dosage, although it remains to be determined whether, with the addition of other ultrasound parameters (see Table 21–3), ultrasound can replace FBS in the initial assessment of fetal goiter.

Surgery

Subtotal thyroidectomy can be performed successfully during pregnancy but is usually considered only for those women who develop a serious adverse reaction to thionamides or who require persistently high doses to control hyperthyroidism.[35] Maternal thyrotoxicosis must be adequately controlled preoperatively. This is most rapidly achieved with β-blocking agents and iodide. Surgical thyroidectomy of women with GD does not lead to immediate remission of the autoimmune abnormality and there is a risk, with withdrawal of antithyroid therapy and T_4

replacement of the mother, of fetal hyperthyroidism.[41] Surgical complications include hemorrhage, recurrent laryngeal nerve palsy, hypoparathyroidism, and hypothyroidism. The optimal time for surgery is during the second trimester.

Radioactive Iodine

Radioiodine is contraindicated in pregnancy, particularly after the 12th week of gestation when the fetal thyroid is able to concentrate iodine. Inadvertent administration of ^{131}I during the first trimester is associated with hypothyroidism in 3% of cases.[42]

THERAPY FOR FETAL HYPERTHYROIDISM

Treatment for confirmed fetal hyperthyroidism has included thionamide therapy in a euthyroid mother (typically following ablative therapy for GD)[42] and increasing thionamide dose in mothers on antithyroid therapy.[35] Of the four fetuses with a hyperthyroid goiter reported by Luton and colleagues[14] (two of which were confirmed by FBS), increasing the maternal thionamide dose resulted in a decrease in goiter size within 2 weeks with a return to normal thyroid circumference in one case. One fetus, referred late in pregnancy with heart failure and cardiomyopathy, died in utero at 35 weeks after FBS confirmed persistent severe hyperthyroidism. Of the remaining three cases, two were euthyroid at birth and one fetus had a low FT_4 but a normal TSH at birth. Other case reports have documented persistent hyperthyroidism despite maternal thionamide therapy.[43,44] Thus, monitoring the fetal response to alterations in maternal thionamide dose by FBS is recommended.

SUMMARY OF MANAGEMENT OPTIONS
Fetal Hyperthyroidism

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Check maternal TSH and FT_4.	III/B	6,35
Optimize antithyroid medication (consider changing to propythiouracil in preference to methimizole/carbimazole) (see Chapter 45).	III/B	33–36
Prenatal		
Monitor maternal FT_4 every 4–6 wk (aim to keep FT_4 at upper end of normal range on minimal dose of antithyroid drug) (see Chapter 45).	III/B	6,35
Measure TRAbs in women with Graves' disease who have previously received radioiodine therapy or thyroid surgery or who are taking antithyroid drugs.	III/B	15
Serial ultrasound surveillance every 4–6 wk from 22 wk' gestation in women with high TRAbs (measure thyroid circumference and fetal heart rate).	III/B	14–16
Assessment of thyroid vascularization (by color Doppler) and bone maturation may be of value in fetuses with goiter.		
Measure fetal TSH and FT_4 in fetuses with goiter or sustained tachycardia.	III/B	5,16
If fetal hyperthyroidism confirmed, adjust maternal antithyroid dose and monitor fetal response with ultrasound and/or measurement fetal TSH and FT_4.	—/GPP	—
Postnatal		
Measure TSH and FT_4 in cord blood and at 7 days of age and manage accordingly,	IIa/B	35
Consider propylthiouracil if breast-feeding. Ensure antithyroid medication is taken immediately after breast-feeding.	—/GPP	—

FT_4, free thyroxine; GPP, good practice point; TRAbs, thyroid-stimulating hormone antibodies; TSH, thyroid-stimulating hormone.

Fetal Hypothyroidism

Congenital hypothyroidism occurs 1 in 3000 to 4000 live births in nonendemic areas.[45,46] The condition can be permanent or transient. The most common cause of permanent hypothyroidism is thyroid dysgenesis, accounting for 80% of cases (see Table 21–1). This term includes thyroid aplasia (40%), thyroid hypoplasia (20%), and an ectopic thyroid (40%). Most cases are sporadic, nonfamilial embryologic defects, although familial instances have been reported.[47] Autosomal recessive inborn errors of thyroid hormone synthesis and secretion (dyshormonogenesis) occur in 1 in 40,000 births and account for 10% to 15% of congenital hypothyroidism.[47] The two most common defects result from mutations in the thyroperoxidase and thyroglobulin genes. Hypothalamic-pituitary disorders (including holoprosencephaly, septo-optic dysplasia, and Pit-1 deficiency) account for the remainder of cases.

TSAbs are responsible for about 2% of congenital hypothyroidism.[48] Reduced T_4 levels are transient and typically occur in infants of women with high levels of TBAbs.[49,50] Inadequate treatment of maternal GD has also been associated with central congenital hypothyroidism (estimated incidence 1;35,000).[51] Neonates have low FT_4 but variable TSH levels, and TRH tests indicate pituitary dysfunction. It is hypothesized that a hyperthyroid fetal environment impairs maturation of the fetal hypothalamic-pituitary-thyroid system.[51] The common thyroid autoantibodies (thyroperoxidase and antithyroglobulin), present in women with chronic autoimmune (Hashimoto's) thyroiditis, have little or no effect on fetal thyroid function.

Transient hypothyroidism may follow administration of antithyroid drugs. The effects of thionamides on fetal thyroid function are unpredictable and there is a poor correlation between fetal thyroid status and dose.[25,37] Elevated cord TSH levels occur in up to 23% of infants born to PTU-treated mothers.[37] In one series,[5] 4 of 18 cases (22%) of maternal GD treated with PTU developed fetal hypothyroidism. This can occur even with doses as low as 50 to 100 mg/day.[5] Hypothyroidism has also been reported after maternal ingestion of amiodarone and lithium and after excessive maternal iodide intake. Inadvertent administration of radioiodine after 12 weeks' gestation invariably results in permanent fetal hypothyroidism.

All preterm infants have a fall in FT_4 during the first 2 weeks of life with a return to normal values by the third or fourth week.[52] Levels of FT_4 are around 50% of those in utero, with approximately one third of preterm neonates having T_4 levels greater than 3 standard deviations (SDs) below the mean of newborns.[52] However, acutely ill infants may also have lower levels of FT_4 and FT_3 due to reduced peripheral conversion. Hypoxic FGR fetuses also have low FT_4 and FT_3 levels associated with a slight elevation in TSH.[53] The contribution of early thyroid hormone deficiency to neurodevelopmental delay in these children is unclear.

Worldwide iodine deficiency, defined as a urinary iodine excretion less than 100 µg/L,[54] is the most common cause of combined maternal-fetal hypothyroidism. The distribution of neonatal TSH concentrations has been used as an index of iodine intake; populations in which the proportion of TSH values greater than 5.0 mIU/L exceeds 3% are regarded as iodine deficient.[55] Iodine deficiency leads to deficient thyroid hormone production, TSH hypersecretion, and raised $T_3 : T_4$ ratio. Compensatory mechanisms can result in euthyroidism with goiter or varying degrees of goitrous hypothyroidism. In Zaire, where iodine intake is below 25 µg/day (recommended intake 200 µg/day), the frequency of fetal hypothyroidism, as evidenced by an elevated TSH at birth, is as high as 25%.[54] However, iodine deficiency is not present only in developing countries; the problem is still common in some areas of Europe, Scandinavia and the Middle East.[54,56] In some areas of severe iodine deficiency, infants are born with endemic or neurologic cretinism characterized by severe mental retardation, deafness, squint, and pyramidal and extrapyramidal signs. These infants are euthyroid but frequently have a goiter. In other areas, notably Africa, the infants have hypothyroid cretinism with grossly impaired thyroid function, dwarfism, and delayed sexual maturation but rarely a goiter. Variations in dietary ingestion of selenium, zinc, iron, retinoic acid, and other goitrogens are thought to account for the different phenotypes.[49] In some tissues, notably the brain and endocrine and reproductive organs, the selenium-dependent type 2 iodothyronine deiodinase plays a critical role in conversion of T_4 into T_3. Thus, in selenium deficiency, these organs are spared from the effects of iodine deficiency.[57]

Diagnosis

Fetal hypothyroidism is usually unrecognized. The condition may be suspected because of a maternal history of thyroid disease or antithyroid medication. Features include FGR, goiter, and reduced fetal movements. An abnormal fetal heart rate may occur, with both bradycardia and tachycardia reported.[4] In severe cases, there may be delayed skeletal development, congenital heart block, and cardiomegaly.[16,58] Malformations are reported in 8% of infants with hypothyroidism; of these, 28% are cardiac abnormalities.[59]

The classic neonatal features of congenital hypothyroidism are constipation, lethargy, poor feeding, and respiratory problems. Physical signs include macroglossia, dry mottled skin, "cretinoid" facies, abnormal cry, prolonged jaundice, enlarged fontanelle, umbilical hernia, and mental retardation. Depending on the cause and severity of congenital hypothyroidism, clinical features may not become apparent for several weeks or months.

MATERNAL THYROID FUNCTION AND ANTIBODY TESTS

Most women with known hypothyroidism have a history of thyroid disease and will be on T_4 replacement. Women presenting with features of hypothyroidism in pregnancy (malaise, cold intolerance, dry skin, myalgia, excessive weight gain) will often have discontinued or reduced their T_4. However, the symptoms may be subtle and a goiter not palpable. The diagnosis of maternal hypothyroidism is confirmed by an elevated TSH and a reduced FT_4. Women with GD previously treated with radioiodine or surgery should have their TRAb measured early in pregnancy[7] (see Table 21–2).

FETAL IMAGING

Hypothyroidism may be suspected if there is goiter, increased fetal movements, and delayed bone maturation

(see Table 21–3).[14,16] Hydramnios, fetal tachycardia, and FGR may also be present.[5,16] In the presence of a goiter, a color flow Doppler signal confined to the periphery of the gland is considered suggestive of fetal hypothyroidism (see Fig. 21–4); of the 32 fetuses with a hypothyroid goiter reported by Huel and colleagues,[16] 22 (69%) had peripheral vascularization of the thyroid and none had central vascularization. Fifteen (47%) also showed delayed bone maturation, 14 (44%) had increased fetal movements, and 2 (6%) had tachycardia. Using their ultrasound score (see Table 21–3), all the fetuses with a hypothyroid goiter had a score lower than 2.[16]

The majority of cases of fetal hypothyroidism occur as a consequence of sporadic, embryologic malformations and are not detected on routine ultrasound screening at 18 to 20 weeks' gestation. Occasionally, a goiter may be detected later in pregnancy at an ultrasound examination performed for other reasons.[60] When there is family history of congenital hypothyroidism due to defects in thyroid hormone synthesis or metabolism, serial ultrasound screening may detect a large goiter.

FETAL THYROID FUNCTION TESTS

The development of a goiter and/or polyhydramnios does not correlate closely with the degree of fetal hypothyroidism.[5,61] Definitive antenatal diagnosis, therefore, requires FBS and confirmation of an elevated TSH and low FT_4. Reported values of TSH in fetuses with goiter have ranged from 25 to 1640 mU/L.[60–62] If the ultrasound score reported by Huel and colleagues[16] is confirmed to reliably differentiate hypo- from hyperthyroidism goiter in prospective series, it may be possible to avoid FBS in the future. Although elevated amniotic fluid TSH levels have been reported in fetal hypothyroidism, the sensitivity of this method is unclear.[63] In many countries, all newborns are screened for congenital hypothyroidism by the measurement of TSH on a blood spot.

Risks
CONGENITAL HYPOTHYROIDISM

In congenital hypothyroidism (in which maternal thyroid function is normal), the fetal thyroidal supply is deficient to varying degrees in utero and during early infancy. Transplacental passage of maternal thyroid hormones, along with compensatory deiodinase activity, ensures thyroid hormone sufficiency during the first half of pregnancy. However, the fetal contribution is reduced or totally lacking in the second half of gestation and hypothyroxinemia persists until the diagnosis is made and treatment takes effect. As a result, children with congenital hypothyroidism manifest motor and cognitive defects, with a mean IQ significantly lower than controls. Infants with severe congenital hypothyroidism, particularly those with absent thyroid glands or who show ultrasonographic and/or serum evidence of hypothyroidism in utero, have lower IQ scores than those with less severe hypothyroidism.[64,65] Perinatal hypothyroidism appears to contribute particularly to visuospatial and fine motor deficits.[1] Although neonatal screening programs enable early T_4 supplementation, subtle deficits in cognitive and motor skills are reported even into adolescence.[66,67]

MATERNAL HYPOTHYROIDISM

In iodine-sufficient areas, overt maternal hypothyroidism occurs in 0.3% to 0.5% of pregnancies, whereas subclinical hypothyroidism (normal FT_4 but elevated TSH) has been reported in 2% to 3% of pregnancies.[68,69] In areas of endemic iodine deficiency, the incidence is even higher. Autoimmune thyroiditis is present in 15% to 55% of women with subclinical hypothyroidism and in more than 80% of women with overt hypothyroidism.[69,70]

The rate of miscarriage is increased approximately twofold in women with overt hypothyroidism. This risk appears to be related more to the presence of circulating thyroid antibodies than thyroid function.[71] Pregnancy-induced hypertension, preeclampsia, and placental abruption are purported to be more common, leading to an increased rate of preterm delivery and stillbirth.[70,72,73] Severe maternal hypothyroidism in early pregnancy has also been associated with a 56% rate of intrapartum cesarean section for fetal distress.[74] Complications are more common with overt than subclinical hypothyroidism. However, one recent study found no adverse outcomes in women with subclinical hypothyroidism (TSH levels > 97.5th percentile and FT_4 between the 2.5th and the 97.5th percentiles).[69] In contrast, women with first-trimester hypothyroxinemia (TSH levels between the 2.5th and the 97.5th percentiles and FT_4 < 2.5th percentile) had an increased risk of preterm labor (adjusted OR 1.62, 95% CI 1.00–2.62) and macrosomia (adjusted OR 1.97, 95% CI 1.37–2.83). Adequate T_4 treatment greatly reduces the risk[75,76]; in a recent randomized trial in thyroid antibody–positive women, the rate of miscarriage was reduced by 75% and preterm delivery by 69% in those given T_4 (started at 5–10 wk) throughout gestation compared with antibody-positive women who did not receive T_4 and in whom TSH levels gradually rose during gestation.[77]

Infants born to hypothyroid women are at increased risk of impairment in neuropsychological development, IQ scores, and school learning abilities. The degree of impairment is dependent on the severity, duration, and timing of the maternal thyroid insufficiency.[35] Man and Serunian[78] initially reported that mean IQ at 7 years of age was 13 points lower in children born to women who were hypothyroid during pregnancy than in those born to women who were euthyroid on T_4 replacement. Klein and associates[79] measured maternal TSH levels in 25,216 pregnant women at 15 to 18 weeks' gestation (from frozen samples obtained for Down syndrome screening) and found 2.5% had elevated TSH levels ($\geq$6 mU/L), of which 12% (6/49) also had low FT_4 levels. Children of mothers with high TSH levels scored lower than controls on all 15 of the neuropsychological tests and attained an average IQ that was 4 points below controls.[80] Of the 62 women with thyroid deficiency, 48 were not treated during pregnancy and the IQ of their children averaged 7 points lower than children born to euthyroid and T_4-treated women.[80] Further, there were three times as many children with IQs more than 2 SDs below the mean IQ of controls (i.e., <85) in the children born to untreated hypothyroid women. Further, preschool children born to hypothyroid women with suboptimal replacement (mean TSH 5–7 mU/L) have also been shown to have a mild decrease in IQ, although no deficits in language, visuospatial ability,

or fine-motor performance.[81] Even isolated first-trimester hypothyroxinemia ($FT_4 < 10.4$ pmol/L at 12 weeks' gestation, i.e., in the lowest 10th decile and a normal TSH) that persists until 24 weeks or later has been shown to be associated with delayed mental and motor function (mean deficit of 8–10 points on Bayley Scales of Infant Development) at 2 years of age compared with controls (FT_4 between the 50th and the 90th percentiles).[82] However, when FT_4 recovered spontaneously to normal later in pregnancy, outcome was normal.

IODINE DEFICIENCY

In iodine deficiency, both maternal and fetal thyroid glands are affected early in pregnancy. In a meta-analysis of 19 studies, infants were found to have an overall reduction in cognitive function of 13.5 IQ points.[83] Even when limited to mild to moderate iodine deficiency, there is clear evidence of retarded psychomotor development with low motor and attentive functions.[35]

As more information becomes available concerning the detrimental and long-term effects of maternal hypothyroidism on the fetus, many authorities have advocated screening all women as early as possible in pregnancy.[84] However, it is not certain whether FT_4 or TSH should be used, what cutoff to adopt, or what treatment should be instituted for screen-positive women. Ultimately, the value of screening and treating mildly hypothyroid women in nonendemic areas can be addressed only in large trials with adequate follow-up.

Management Options
FETAL THERAPY

Fetal therapy is indicated in cases with confirmed fetal hypothyroidism because of the risk of neurologic damage. Relatively little T_4 crosses the placenta and the amount of T_4 that would be needed to treat the fetus adequately would result in the development of maternal hyperthyroidism. Direct fetal therapy is therefore necessary. Weiner and colleagues[85] reported the first use of intra-amniotic T_4 in the treatment of fetal goiter. Subsequent reports have confirmed that effectiveness of this mode of administration with reduction in goiter size, resolution of hydramnios, and improvement in fetal thyroid function.[5,60,62] A weekly dose of 250 μg appears to be effective. This is consistent with the neonatal T_4 requirement of 10 μg/day and animal data that suggest that 90% of T_4 administered intra-amniotically is absorbed within 24 hours.[86] Whether this is the optimum dose and frequency is unclear, and larger doses (500–600 μg) given every 14 days may be as effective.[5,61] Fetal therapy should be started as early as possible once the diagnosis of fetal hypothyroidism has been made. Intra-amniotic injections of T_3 (60–120 μg) have also been used.[87] Although uptake of T_3 may be faster (with effects evident within 4–8 hr), it has a shorter half-life than T_4 (1–2 days vs. 6–7 days), and therefore, more frequent intra-amniotic injections are required.

A possible noninvasive alternative to treat fetal hypothyroidism is maternal administration of 3′-tryiodothyroacetic acid (Triac), a T_3-derived analogue that binds to thyroid hormone receptors with higher affinity than T_3. Triac crosses the placenta[88] and has been used successfully to reduce TSH concentrations and goiter size in fetal hypothyroidism secondary to PTU therapy[61,88] and to reduce TSH concentrations in a fetus affected by a mutation in the TR-β gene leading to resistance to thyroid hormones.[89] In both case reports, Triac was increased from a starting dose of 2.1 mg/day to 2.8 mg/day[61] and 3.5 mg/day,[89] respectively, in an attempt to normalize fetal TSH levels. Further experience is needed with this therapy before it can be recommended as a safe alternative to invasive therapy.

Repeat FBS 1 to 2 weeks after starting therapy appears justified to confirm that TSH and FT_4 have returned to normal. Repeat sampling is particularly important if there is a worsening in the fetal condition, failure of the goiter to resolve, or the development of polyhydramnios.[90] Worsening fetal hypothyroidism, despite repeated intra-amniotic injections of T_4, may be an indication for injection of levothyroxine into the umbilical vein.[91] In women with GD with fetal hypothyroidism, assessing the fetal response to reduction in maternal antithyroid therapy may be appropriate before considering direct fetal therapy.[5]

MATERNAL THERAPY (See Also Chapter 45)

Most women with hypothyroidism are already taking T_4 prior to pregnancy. The dose of T_4 should be adjusted preconception to ensure serum TSH is not higher than 2.5 mU/L.[35] Adequate T_4 replacement eliminates or reduces the risks of adverse pregnancy outcome. The serum FT_4 levels should be kept in the upper normal range, necessitating increased T_4 in up to 75% of patients during the first trimester.[92,93] A further 35% of women who maintain a normal serum TSH until the second trimester without increasing their T_4 replacement will require an increment during late pregnancy to maintain a euthyroid state.[92,93] Average T_4 requirements are increased by 25 to 100 μg/day during pregnancy, although this depends on the etiology of the hypothyroidism; women without residual thyroid tissue require a greater increment than women with autoimmune thyroiditis.[93] The increase in T_4 dose can be based on the initial serum TSH: 25 to 50 μg if TSH is 5 to 10 mU/L, 50 to 75 μg if TSH is 10 to 20 mU/L, and 100 μg if TSH is greater than 20 mU/L.[68] However, the maternal dose should not be increased without objective proof of the need.

Maternal TSH and FT_4 should be measured at booking, at 16 to 20 weeks, and at 28 to 32 weeks, although it has been suggested that repeat testing is not necessary unless clinically indicated.[94] Ferrous sulfate reduces the absorption of T_4, and ingestion of these drugs should be separated by at least 2 hours. After pregnancy, T_4 is reduced to the prepregnancy dose over a period of 2 to 4 weeks.[68] It is safe for women taking T_4 to breast-feed.

In severe iodine deficiency, iodine supplementation during pregnancy prevents the occurrence of hypothyroid cretinism and neonatal hypothyroidism, increases birth weight, reduces neonatal mortality, and improves developmental quotients.[95] The recommended nutrient intake for iodine during pregnancy was reevaluated in 2005 with a recommendation of between 200 to 300 μg/day, with an average of 250 μg/day.[35] Iodine can be given in the form of iodized salt, potassium iodide drips, or iodized oil.

NEONATAL THERAPY

Infants confirmed to be hypothyroid after screening should be started on replacement T_4 (15 µg/kg orally once daily) immediately. The dose is adjusted according to the TSH and FT_4.[1] Recent data confirm that it is better to suppress TSH levels as quickly as possible rather than simply normalize FT_4 levels.[96] Marginal overreplacement can usually be compensated for by endogenous deiodination.[96] After infancy, the required dose is approximately 100 µg/m²/day and FT_4 should be rechecked at 3 months, 6 months, and annually thereafter. Response to treatment appears to vary with the etiology of hypothyroidism; athyrotic infants take longer to normalize their thyroid function and probably justify more frequent monitoring in early life.[97]

FETAL ADRENAL DISEASE

Introduction

The adrenal cortex arises from the mesoderm of the mesonephros during the fifth week of embryonic development. The cells that form the medulla are derived from adjacent neural crest cells and come to be encapsulated by the fetal cortex, which rapidly increases in size from the end of the second trimester to occupy 80% of the adrenal cortex by term. The adult (or definitive) cortex, also derived from mesenchymal cells, forms a thin outer layer.

All adrenal steroids are formed from cholesterol (Fig. 21–5). In the zona fasciculata of the definitive cortex, steroid precursors are used to synthesize cortisol under the influence

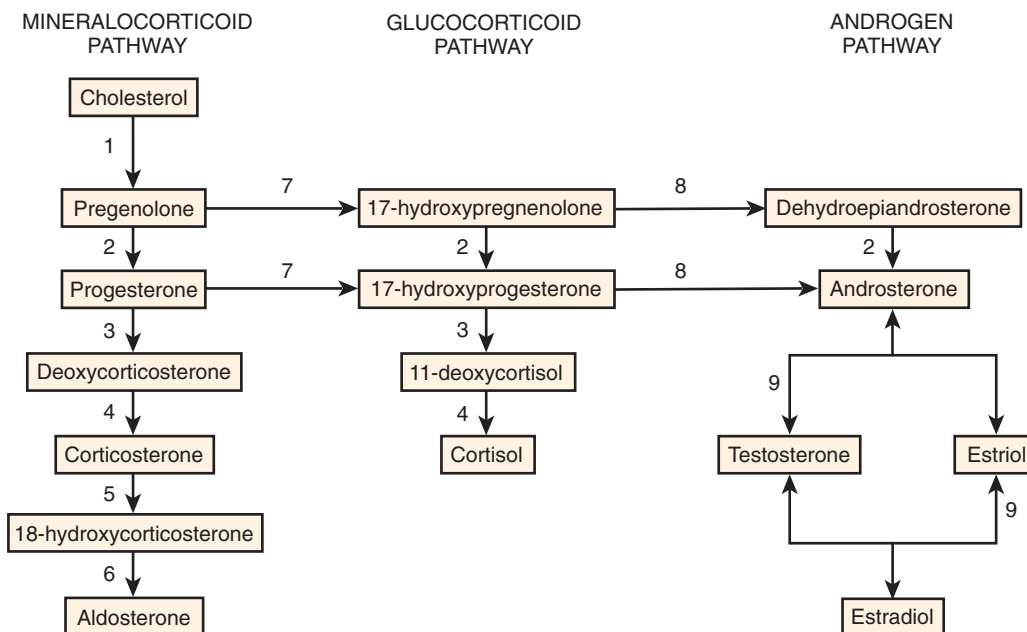
SUMMARY OF MANAGEMENT OPTIONS
Fetal Hypothyroidism

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Offer genetic counseling if previous inherited defect of thyroid hormone synthesis.	III/B	45
Iodine supplementation (250 µg/day) in areas of iodine deficiency.	Ia/A	83,95
Check maternal TSH and FT_4 and adjust thyroxine dose (aim for TSH ≤ 2.5 mU/L) (see Chapter 45).	III/B	35
Prenatal		
In fetus at risk, sonographic surveillance for reduced fetal movements, cardiomegaly, bradycardia/heart block, FGR, goiter.	III/B	5,14,16
Measure maternal TSH and FT_4 at first antenatal visit and adjust thyroxine dose accordingly (see Chapter 45).	III/B	35,68
Measure TSH and FT_4 at 16–20 and 28–32 wk and adjust thyroxine dose accordingly.	III/B	35,68
When goiter detected during a routine or indicated ultrasound examination (e.g., women with Graves' disease on antithyroid therapy) assess thyroid vascularization (by color Doppler) and bone maturation.	III/B	14–16
Measure fetal TSH and FT_4 in fetuses with goiter or delayed bone maturation.	III/B	5,16
If fetal hypothyroidism confirmed, administer intra-amniotic thyroxine and monitor response with repeat fetal blood sampling. In women with Graves' disease on antithyroid therapy, reduce dose initially and monitor response.	IIb/B	5,60–62
Postnatal		
Measure TSH and FT_4 in cord blood in at-risk fetuses.	—/GPP	—
Replace thyroxine in infants confirmed to be hypothyroid on screening/testing.	III/B	35,78,80,82
When necessary, reduce maternal thyroxine dose to prepregnancy levels.	—/GPP	—

FT_4, free thyroxine; GPP, good practice point; TSH, thyroid-stimulating hormone.

Pathways of adrenal hormone synthesis. Major pathways are indicated by *thick arrows*, minor ones by *thin arrows*. Extra-adrenal conversion of sex steroids is denoted by *double arrows*. Numbers indicate enzymatic steps as follows: 1, cholestrol side chain cleaving system; 2, 3β-hydroxysteroid dehydrogenase; 3, 21-hydroxylase; 4, 11β hydroxylase; 5, 18-hydroxylase; 6, 18-dehydrogenase; 7, 17α-hydroxylase; 8, 17,20-lyase; 9, 17β-hydroxy-steroid dehydrogenase.


of 17α-hydroxylase. Fetal cortisol concentrations rise, particularly toward term, stimulating the maturation of several enzyme systems in the lungs and gastrointestinal tract. Glucocorticoid synthesis is under the control of pituitary adrenocorticotropic hormone (ACTH). Both hypothalamic corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP) stimulate the release of ACTH, which is cleaved from a large prohormone pro-opiomelanocortin (POMC) containing the sequences of several other peptide hormones. 17α-Hydroxylase is inactive in the zona glomerulosa and precursors are used to synthesize aldosterone under the control of the renin-angiotensin system. Adrenal androgen production is insignificant during fetal life.

The fetal adrenal gland provides precursors for maternal estrogen production. The cortex contains inactivated 3β-hydroxysteroid dehydrogenase. Therefore, pregnenolone is converted primarily into dehydroepiandrosterone sulfate (DHAS), which appears in the fetal circulation from 8 weeks. DHAS is hydroxylated in other fetal tissues, particularly the liver, to 16-hydroxy DHAS, which then passes to the placenta, where it is converted into androstenedione and subsequently to estrogens.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) refers to a group of autosomal recessive disorders of adrenal steroidogenesis. The disorder may result from a defect in any of the five enzymes required to synthesize cortisol from cholesterol.

21-HYDROXYLASE (P450$_c$21) DEFICIENCY

In 90% to 95% of cases, CAH is due to 21-hydroxylase deficiency (21-OHD) resulting in a blockade of the conversion of 17-hydroxyprogesterone into 11-deoxycortisol (see Fig. 21–5). Reduced synthesis of cortisol leads to increased ACTH and shunting of precursors into the pathways of androgen synthesis. Steroid 21-OHD occurs in two forms: a severe ("classic") form and a mild ("nonclassic") form. Among severe 21-OHD patients, three quarters have the salt-wasting (SW) type, with a concurrent defect in aldosterone synthesis, and the remainder have the simple virilizing (SV) form with preserved ability to retain salt. The incidence of severe CAH is approximately 1 in 13,000 live births, but there are marked ethnic differences.[98,99]

21-OHD results from mutations in the *CYP21A2* gene, located with its pseudogene (CYP21A1P) in the polymorphic human leukocyte antigen (HLA) histocompatability complex on chromosome 6p21.3. The nucleotide sequences of these two genes are 98% identical in exons and 96% identical in introns, permitting two types of recombination events: (1) unequal crossing-over during meiosis, which results in complete deletions/duplications of CYP21A2 and (2) gene conversion events that transfer deleterious mutations present in the pseudogene to CYP21A2. More than 100 mutations have been described in 21-OHD, the two most common being a 30-kb deletion or genomic rearrangement/conversion fusing CYP21A2 with CYP21A1P (30%) and IVS2-13 A/C → G (28%).[98,100] More than 90% of these deletions are derived from 10 mutations within the CYP21A pseudogene with the remainder caused by rare sporadic mutations.[100] Correlations exist between the genotype and the phenotype; 21-OHD mutations that totally ablate enzyme activity are associated with the SW form whereas those that produce enzymes with 1% to 2% normal activity, permitting adequate aldosterone synthesis, lead to SV

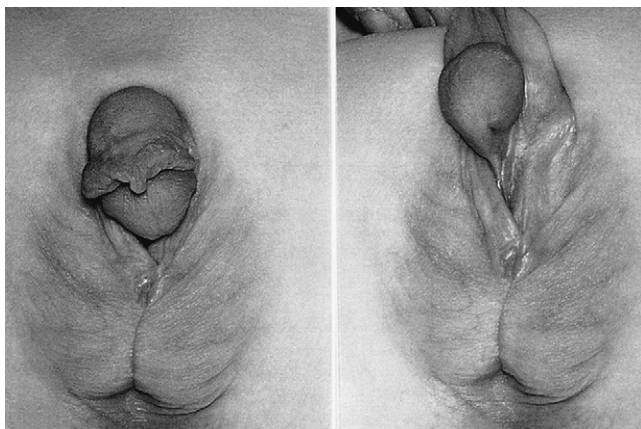
disease. A third group of mutations produce enzymes retaining 20% to 60% normal activity and are responsible for the nonclassic form.[99]

OTHER FORMS

11β-Hydroxylase (P450$_c$11) deficiency accounts for approximately 5% of CAH. 11-Deoxycortisol is not converted into cortisol, leading to a shunting of precursors into the pathway for androgen synthesis. The enzymatic defect also leads to an accumulation of deoxycorticosterone, which has significant salt-retaining properties. Two copies of the 11β-hydroxylase gene are present on chromosome 11q, and several mutations have been identified. Deficiencies of 3β-hydroxysteroid dehydrogenase, 17α-hydroxylase, and cholesterol side chain cleavage enzyme account for fewer than 1% of CAH cases. Mild or partial defects may occur more frequently.

Diagnosis

Patients with the classic SW form may present with hyponatremic dehydration, vomiting, and shock in the early neonatal period.[96,99] Female fetuses with classic 21-OHD are exposed to excess androgens from the seventh week of gestation. This leads to virilization of the external genitalia, which can vary from clitoral hypertrophy to complete formation of a phallus and fusion of the labia (Fig. 21–6), causing erroneous assignment of gender. Affected males have normal external genitalia. In the nonclassic form, virilizing symptoms appear postnatally. Females affected with 11β-hydroxylase deficiency also have ambiguous genitalia at birth. The excess deoxycorticosterone generally leads to hypertension and hypokalemia. Virilization of female fetuses is much less marked in 3β-hydroxysteroid dehydrogenase deficiency, and in the other two forms, the male is incompletely masculinized.[96,99]

The diagnosis of 21-OHD is confirmed by measurement of neonatal plasma 17α-hydroxyprogesterone (17-OHP), which typically exceeds 300 nmol/L. Classic 21-OHD deficiency is more common than phenylketonuria, and neonatal screening of blood spots to measure 17-OHP has been introduced in many countries in view of the risks from SW and late diagnosis.[96] In the United Kingdom, however, screening as part of the "Guthrie test" is not supported by the National Screening Committee.[101] This decision, made in 2006, is to be reviewed in 2010/2011. Whereas advocates of screening feel that there is insufficient acknowledgment of the considerable morbidity of CAH, there are little published data on improvements in morbidity resulting from early detection and treatment.[96] In 11β-hydroxylase deficiency, plasma deoxycorticosterone is elevated. The profile of urinary steroids by gas chromatography and mass spectrometry provides a definitive diagnosis.


Risks

Emergency treatment with sodium replacement and intravenous normal or even hypertonic saline is necessary to prevent death. Once sodium balance is restored, mineralocorticoid replacement is started with 9α-fluorcortisol (fludrocortisone) 0.1 to 0.15 mg/m²/day. Appropriate glucocorticoid replacement therapy will suppress androgen levels and allow normal growth, skeletal maturation, and puberty.[96] Hydrocortisone 12 to 15 mg/m²/day is usually given in two or three divided doses.

Postnatally untreated androgen excess may manifest as progressive virilizing changes and accelerated growth and development. The majority of female infants born with virilized genitalia require corrective surgery. More than one operation is required in 50%. Clitoral reduction is best undertaken before 6 months of age, but the timing of vaginal reconstructive surgery is controversial; previously, this was delayed until after puberty, but more recently, single-stage surgery at 2 to 6 months has been advocated.[102] In addition to progressive virilization, the high androgens affect the hypothalamic-pituitary-gonadal axis in both sexes, leading to subfertility. Follow-up studies of adult females with CAH diagnosed in infancy or early childhood suggest that one third are hirsute and their ovulation rate is less than 50%.[103] After reconstructive surgery, about 75% have an adequate vaginal introitus; in this group, pregnancy rates are approximately 60%.[103] Early treatment with glucocorticoids improves fertility. It has also been suggested that prenatal exposure to excess androgens affects subsequent sexual behavior in adolescent and adult females.[104]

Management Options

PRENATAL DIAGNOSIS

All affected families should be offered genetic counseling. Ideally, this should be performed prior to conception. Subsequent offspring have a 1 in 4 chance of being affected, with a 1 in 8 chance of a virilized female. Prenatal diagnosis was initially accomplished by measuring 17-OHP in amniotic fluid, but direct DNA analysis of the *CYP21A2* gene on chorionic villus samples obtained at 10 to 11 weeks' gestation is now standard. Between 95% and 98% of causative mutations can be identified using a combination of molecular genetic techniques (e.g., locus-specific polymerase chain reaction [PCR] and minisequencing-based arrays).[98,100] In some families, prenatal diagnosis is not possible because of either undetectable mutations, drop-out alleles, or maternal DNA contamination. Determination of satellite markers may increase the accuracy of molecular genetic analysis.[98] Molecular diagnosis is possible in some families with other

FIGURE 21–6
Severe virilization in two untreated female infants with 21-hydroxylase deficiency. There is almost complete formation of a phallus and scrotum.

forms of CAH. Otherwise, antenatal diagnosis is dependent on the measurement of steroids in the amniotic fluid.

MATERNAL DEXAMETHASONE THERAPY

The fetal adrenal gland can be pharmacologically suppressed by maternal administration of dexamethasone. Synthetic fluorinated steroids bind minimally to cortisol-binding globulin and are poor substrates for placental 11β-hydroxysteroid dehydrogenase. Thus, dexamthasone readily crosses the placenta and suppresses fetal ACTH. Because differentiation of the external genitalia begins at approximately 7 weeks of pregnancy, dexamethasone (20 μg/kg prepregnancy weight/day given in two or three divided doses) should begin before this time. Compared with previously affected sisters, treated females have reduced virilization; 25% to 50% require no genital surgery, and the extent of genital surgery is reduced in those who do require it.[105–107] However, therapeutic failures occur[108] (Fig. 21–7), and although some cases have been attributed to late initiation or early cessation of therapy, non-compliance, or suboptimal dosing, there is no obvious explanation in others. The extent of virilization can vary among affected females in the same family even without treatment.[109]

Dexamethasone can be discontinued if the fetus is male or an unaffected female (i.e., in seven of eight pregnancies initially treated). Therapy can be monitored by measurement of maternal urine estriol after 15 to 20 weeks of pregnancy. Excessive weight gain, cutaneous striae, edema, hirsutism, and mood fluctuations are the most common problems in women treated throughout pregnancy.[105,106] Hypertension and gestational diabetes do not seem to be increased.[110] Overall side effects necessitate reducing the dexamethasone dose in up to a quarter of women.[107] Reduction of the dose of dexamethasone later in pregnancy

(≤5 μg/kg/day) has been reported to maintain fetal and maternal adrenal suppression, as evidenced by urinary estriol and cortisol metabolites, but the efficacy of this regime in preventing virilization remains to be determined.[111]

No teratogenic effects have been reported in fetuses treated to term with dexamethasone; specifically, the incidence of facial clefting does not appear to be increased.[105,112] The long-term safety of prenatal treatment remains uncertain. Administration of low doses of glucocorticoids to children has been reported to produce retarded growth, diabetes, and hypertension.[113] Follow-up studies of prenatally treated CAH children suggest that birth weight, length, and head circumference are normal, as are subsequent growth and development.[105,113] However, numbers and duration of follow-up remain limited. Concerns remain about the long-term implications of antenatal therapy with respect to metabolic and cardiovascular disease as well as psychosexual/behavioral development. No negative effects on developmental milestones or cognitive development have been found in small studies,[105,114] although Trautman and colleagues[114] did find increased internalizing behavioral traits in prenatally treated children at 2 to 3 years of age. Another group reported adverse effects of prenatal dexamethasone on verbal working memory, but again the numbers studied were small.[115] Although antenatal dexamethasone appears justified, it is important to inform parents that the long-term safety and outcome of this therapy are not established.

DETERMINATION OF FETAL SEX

Fetal sex can be determined by ultrasound from 11 weeks of pregnancy, but reliable assignment is not possible until 12 to 13 weeks' gestation,[116] and a phenotypic male fetus can be a virilized female. Thus, ultrasound is of limited value in the management of an at-risk fetus, other than possibly monitoring the success of prenatal therapy.[117]

Of far greater value is the determination of fetal sex from cell-free DNA in maternal blood. Using real-time PCR, Y chromosome–specific sequences can be amplified from the plasma of women carrying a male fetus.[118] Targetting the multicopy sequence DYS14 appears more sensitive than the single copy SRY sequence (98.8% vs. 65.8% at 11–12 weeks' gestation).[119] Both SRY[120] and DYS14[121] have been detected in maternal plasma as early as 5 weeks' gestation, and recently, Martinhago and associates[121] reported accurate prediction of fetal sex in 25 of 27 cases (92.6%) at 5 weeks using DYS14. Using a protocol of duplicate DNA isolation from 2 mL of maternal plasma, Rijnders and coworkers[118] reported a negative PCR result in all 29 female fetuses. In 35 of 36 male fetuses, SRY was amplified in both DNA isolations (positive predictive value 100%), and in 1 case, only one SRY amplification was positive (negative predictive value 96.7%). Early fetal sexing allows avoidance of unnecessary dexamethasone treatment and invasive prenatal diagnosis in male fetuses.[122] When possible, dexamethasone and weekly plasma DYS14 testing should be started from 5 weeks' gestation. Dexamethasone can be stopped if DYS14 PCR is positive in two separate samples. Male sex should be subsequently confirmed as early as possible with ultrasound. When the DYS14 PCR is negative, testing should be repeated weekly until 10 weeks with a diagnostic chorionic villus sampling at 11 weeks. Dexamethasone can then be discontinued in unaffected females.

FIGURE 21–7
Partial virilization in a female infant with 21-hydroxylase deficiency treated prenatally with dexamethasone from 8 weeks' gestation. There is clitoromegaly with posterior labial fusion.

SUMMARY OF MANAGEMENT OPTIONS
Congenital Adrenal Hyperplasia

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Identify genetic mutation and feasibility of prenatal diagnosis by direct mutation detection.	III/B	98,99
Counsel families regarding risks and options for prenatal diagnosis and treatment.	—/GPP	—
Prenatal		
Start dexamethasone (20 µg/kg/dy) once pregnancy is confirmed.	III/B	105–107
Weekly maternal blood sampling for fetal sexing by PCR amplification of Y-specific DYS14 sequences.	IIa/B	120,121
If male fetus is confirmed, stop dexamethasone and confirm sex as early as possible with ultrasound.	IIb/B	105,107,121,122
If female fetus is confirmed, perform CVS at 10–11 wk' gestation—if affected, continue dexamethasone.	IIb/B	105,107,121,122
In women who continue dexamathasone:		
• Measure maternal serum estriol every 6–8 wk to confirm compliance and adrenal suppression.	III/C	105
• Ultrasound assessment of external genitalia; if there is evidence of virilization, measure amniotic fluid 17-OHP and androstenedione and, if elevated, increase dose of dexamethasone.	III/C	105,122
• Monitor for maternal side effects and if necessary reduce dose of dexamethasone.	III/C	105,107,111
Postnatal		
Examine child carefully for evidence of virilization and salt wasting.	III/C	96,99
Corticosteroid ± mineralocorticoid replacement in affected infants.	III/C	96,99
Long-term developmental follow-up of affected infants.	—/GPP	—

INTRODUCTION AND GENERAL APPROACH

Fetal tumors are rare, but can be associated with serious fetal morbidity and mortality. Recent technologic advances in ultrasound imaging have made antenatal detection possible. Early detection has significant implications for maternal and fetal well-being.[1] Once a fetal neoplasm is identified or suspected, a management strategy should be formulated based on the presumptive diagnosis and the prognosis for the specific lesion. An understanding of the ultrasonographic appearance of specific lesions, the differential diagnosis, available treatment modalities, and overall prognosis is critical in providing families with accurate information. A multidisciplinary team, with representatives from maternal-fetal medicine, neonatology, pediatric hematology-oncology, and pediatric surgery, provides an excellent source of information for the parents and allows for an integrated approach.

The prevalence of fetal tumors is difficult to estimate because of variations in the definition of congenital tumors prior to the near-universal application of ultrasonography. Historically, studies included only those tumors apparent at birth or diagnosed within the first 2 to 3 months of life.[2–4] Furthermore, tumors found in stillbirths and nonmalignant tumors may not have been reported to cancer registries. A 30-year population study in the United Kingdom from 1960 to 1989 reported an incidence of 7.2 congenital tumors, both benign and malignant, per 100,000 live births. The incidence of malignancy in neonates is estimated at 36.5 per million live births.[5] In a more recent U.S. survey of infant cancer, the average annual incidence rate for all histologies combined was 223 per million infants in the first year of life. Extracranial neuroblastoma accounted for the largest percentage of neoplasms (26%), followed by leukemias (17%), central nervous system (CNS) tumors (15%), and retinoblastoma (12%).[6]

Although the histology of congenital tumors is similar to that in older children, the incidence, presentation, degree of differentiation, and biologic behavior frequently differ.[7] Teratomas and neuroblastomas are the most common solid tumors reported, but the behavior of these lesions in fetuses and neonates is markedly different from that observed in older children.[2,7,8] The prevalences of these and other neoplasms are listed in Table 22–1.

Prior to antenatal ultrasound, the first sign of a fetal tumor was often hydramnios, which resulted from either neurologic or mechanical interference with fetal swallowing. Frequently, the diagnosis was made in the perinatal period after dystocia, fetal hemorrhage, tumor rupture, or fetal hydrops was diagnosed. Ultrasonography and magnetic resonance imaging (MRI) now allow for a thorough antenatal investigation of suspected fetal masses. Harrison and Adzick[9] observed the natural history of several tumor types and found that some fetuses were able to tolerate the mass, whereas others developed hydrops. Imaging does not provide a histologic diagnosis, but even if a biopsy were taken antenatally, the prognosis might still be obscure because the histologic appearance of malignancy in the fetus or neonate often reflects the immaturity of the patient and not tumor biology.[8] Moreover, even histologically benign lesions can cause fetal or neonatal death if the tumor mass disrupts other vital structures.[10] The location of the mass and the ability to predict the potential for impingement on vital structures are critical in assessing prognosis.

INTRACRANIAL TUMORS

Congenital brain tumors develop rarely during fetal life, with an estimated prevalence of 14 per million live births.[5] Approximately 10% of all tumors diagnosed in the perinatal period arise in the brain.[11,12] Although congenital tumors account for only 0.5% to 1% of all brain tumors diagnosed during childhood, they cause 5% to 20% of perinatal deaths due to neoplasms.[2,5,8,11–13] Fetal intracranial tumors are usually first identified during the third trimester and generally carry a poor prognosis with a global postnatal survival of only 28%. The definite diagnosis usually requires postnatal histology; however, a tentative prenatal diagnosis made via ultrasonography or MRI affords an opportunity to provide the parents with management options and prognosis.[14]

There are several differences between perinatal brain tumors and those occurring in older children. First, primary intracranial tumors in older children are mainly infratentorial (located in the cerebellum and brainstem), whereas the majority of those in the fetus and neonate are supratentorial.[8,11,12,15–17] Second, the initial presenting sign is macrocephaly due to the tumor mass, hydrocephaly, or hemorrhage, with resulting dystocia and stillbirth. The lack of fusion of the calvaria and the patent fontanelles permit expansion of the skull without increased intracranial pressure.[12,15] In contrast, older children develop signs of increased intracranial pressure, such as vomiting and focal neurologic deficits. Third, intracranial teratomas are the most frequent

intracranial neoplasms, but they are unusual in older children. Finally, some tumor types behave differently. For example, medulloblastoma is more aggressive in the perinatal period, and choroid plexus papilloma is more benign.[12] Discovery of a brain tumor in the perinatal period requires a careful search for additional defects, because 12% of congenital brain tumors result from a familial cancer syndrome.[12,18]

Teratomas

Teratomas account for 26% to 50% of intracranial masses.[12,15] They are thought to arise from midline locations within the CNS, including the pineal gland, the hypothalamus, the suprasellar area, and the cerebral hemispheres. Intracranial teratomas occur supratentorially in at least two thirds of cases.[19] However, teratomas often become so large as to preclude determination of the exact site of origin.[12] Rapidly growing tumors have been reported to erode through the orbit, oral cavity, and skull, resulting in spontaneous rupture of the scalp and skull during delivery.[20,21]

Prenatal diagnosis with ultrasonography is possible when intracranial complex masses disrupt the underlying brain architecture. Teratomas tend to appear as large cystic areas

with solid components. Histologically, mature elements from all three germ layers are usually identified along with immature neuroglial components.[12]

Diagnosis

Intracranial teratomas may present in the second trimester with elevated maternal serum α-fetoprotein (AFP)[22] or an abnormal scan. However, these investigations have been reported to be normal in a fetus later found to have a massive teratoma.[23] The most common presentation is rapid uterine growth. Macrocephaly, hydrocephaly, and an intracranial mass of mixed echogenicity with solid and cystic components are identifiable ultrasonographically.[12,21,23] There may be areas of calcification. The tumor mass can cause distortion or destruction of the normal intracranial architecture. Hydramnios occurs in 15% to 20% of cases.[12]

The differential diagnosis includes other intracranial neoplasms, intraparenchymal hemorrhage, arachnoid or porencephalic cysts, hydrocephaly, hydranencephaly, holoprosencephaly, and encephalocele. Ultrasonographic detection of a complex intracranial mass with the loss of normal intracranial architecture is highly suggestive of teratoma. In cases in which the diagnosis is uncertain, MRI can be helpful (Fig. 22–1).

Risks

Uterine enlargement and hydramnios increase the risk of preterm labor. In rare cases, the fetus may develop hydrops due to high-output cardiac failure secondary to arteriovenous shunting within the tumor,[24] which increases the risk of preeclampsia (the "mirror syndrome"). Perhaps the most significant maternal risk is dystocia due to macrocrania, and in most cases, cesarean section is required (often with a vertical incision) or cephalocentesis is necessary for vaginal delivery.[21,23,25] The massive uterine distention increases the risk of postpartum hemorrhage.

Management Options

The prognosis for a fetus with an intracranial teratoma is dismal. Most infants diagnosed antenatally are stillborn or

FIGURE 22–1
Intracranial teratoma. *A*, A large intracranial mass with solid and cystic components, as well as calcification, was noted in this fetus at 28 weeks' gestation. The mass measured approximately 5 × 3 × 7 cm and caused compression of the ventricular system and development of ventriculomegaly. *B*, A fetal magnetic resonance imaging (MRI) scan was obtained to better define the extent of the lesion. The mass appeared to be arising from the base of the brain and was associated with disruption of normal architecture.

D1 5.20 cm
D2 3.76 cm
die in the immediate perinatal period.[12] Although one case report described prolonged survival following tumor resection on the first day of life, that infant had severe motor and mental retardation.[23] In spite of the advances in neonatal surgery, intracranial teratomas are still considered a fatal condition. Given the bleak prognosis and the maternal risks, termination of pregnancy should be offered. In ongoing pregnancies, the primary goal is to minimize maternal morbidity. Women who present in preterm labor should not be treated with tocolytic agents. Every effort should be made to avoid cesarean delivery. Cephalocentesis may be required to facilitate decompression of an enlarged fetal head and allow vaginal delivery.[21]

Other Intracranial Tumors

This group predominantly comprises neuroepithelial tumors of which the common types are astrocytomas, medulloblastomas, choroid plexus papillomas, and gliomas. Mesenchymal tumors such as meningioma and craniopharyngioma are also reported in the perinatal period.

Primitive neuroectodermal tumors (PNETs) are highly malignant, small, blue-cell tumors, which are characterized by early recurrence, metastasis, and high mortality rate. They account for 13% of all fetal and neonatal brain tumors. In the three reported cases of prenatal diagnosis, PNETs were associated with progressive hydrocephalus and enlarged biparietal diameter.[26]

Some intracranial masses are associated with genetic syndromes such as tuberous sclerosis or neurofibromatosis.[27–29] Tuberous sclerosis is associated with multiple discrete echodense nodules in the cerebral cortex or ventricles. This finding or a family history of the disorder requires a careful search for other lesions, especially in the heart. Although typically not associated with antenatal cortical findings, rare patients with severe neurofibromatosis have diffuse tumor nodules throughout the entire CNS.[30]

Both neurofibromatosis and tuberous sclerosis can also be the result of a new mutation, especially in cases of advanced paternal age. Hypothalamic hamartomas are rare solid, echogenic tumors associated with Pallister-Hall syndrome.
FIGURE 22–2
Vein of Galen aneurysm. A cystic, anechoic mass in the area of the brainstem was identified at 22 weeks in this fetus. Using Doppler interrogation, the lesion was identified as a vein of Galen aneurysm.

Other anomalies associated with this syndrome include holoprosencephaly, hydrocephaly, polydactyly, palatal abnormalities, renal and cardiac malformations, and imperforate anus. Identification of a tumor in the hypothalamic area mandates a search for these other defects.[31,32]

Hyperechoic areas with marked vascularity on Doppler interrogation suggest an arteriovenous malformation. Although the leptomeningeal angiomatosis associated with Sturge-Weber syndrome may appear hyperechoic, other vascular malformations,[33] such as a vein of Galen aneurysm, may appear as a hypoechoic, cystic structures until Doppler mapping is performed[34] (Fig. 22–2).

Diagnosis

Several of the more frequent intracranial neoplasms have a characteristic appearance that aids identification. The differential diagnosis for an intracranial mass includes neoplastic lesions, vascular malformations, parenchymal or intraventricular bleeding, and infarction.[35] Astrocytomas

typically present as an intracranial mass associated with macrocrania. These tumors display a wide spectrum of cellular differentiation. The most poorly differentiated tumors (glioblastoma multiforme) generally appear as unilateral, echogenic, rapidly growing solid masses that cause either a shift or destruction of the normal intracranial architecture and contralateral hydrocephalus.[12,13,36] Enlargement of the tumor over a short interval suggests hemorrhage, which occurs more frequently in the perinatal period than in childhood.[15] Medulloblastomas originate from the cerebellar vermis and grow into the fourth ventricle and cerebellar hemispheres, giving rise to the typical ultrasound findings of an echogenic cerebellar mass, hydrocephaly, and macrocrania.[12,26] Metastasis via the cerebrospinal fluid or vascular route occurs in up to 18%.

Choroid plexus papillomas are histologically benign tumors composed of mature epithelial cells. They account for 5% of perinatal brain tumors[11] and typically appear ultrasonographically as a nodular space-occupying lesion arising from the lateral ventricle, although third and fourth ventricle lesions are reported.[11,37,38] Tumor growth results in massive production of cerebrospinal fluid and severe dilation of the ventricular system.[11] These tumors have a more favorable prognosis than other intracranial neoplasms.

Although craniopharyngiomas are a relatively common tumor of childhood, they are rarely discovered perinatally. The most frequent ultrasound findings are hydramnios, a large, cystic, calcified mass in the suprasellar region, and macrocephaly. Craniopharyngiomas may grow quite large, replacing much of the normal brain tissue. The prognosis is poor.[11]

Neoplasms involving nearly all other intracranial tissues (e.g., meningiomas and ependymomas) are reported in the perinatal period, but their occurrence is less frequent.[11]

Risks

The maternal risks are similar to those of a fetal intracranial teratoma. The propensity for the development of hydrocephaly and macrocrania predisposes to dystocia. The identification of an intracranial mass associated with a familial tumor syndrome (e.g., medulloblastoma and Gorlin's syndrome or cerebellar hemangioblastoma and von Hippel–Lindau syndrome) suggests an increased risk of malignancy in family members.

Management Options

Because teratomas tend to destroy normal intracranial architecture, the prognosis is universally poor. The prediction of prognosis is more difficult with other intracranial neoplasms. Choroid plexus papillomas have a more favorable prognosis, with a survival rate of 73%.[11] The prognosis for astrocytomas is dependent on the degree of cellular differentiation, but overall is poor, with only 37% survival rate. Neonates with glioblastomas or anaplastic astrocytomas have a survival rate of only 14%.[11] Medulloblastomas have a propensity to spread throughout the CNS and bloodstream and, therefore, have an extremely poor prognosis, with a less than 10% survival rate.[11] Intracranial lesions characteristic of phakomatoses, neurofibromatosis, or tuberous sclerosis are in general not predictive of the severity of disease.

Parents should be counseled on the differential diagnosis of the intracranial mass and the likely prognosis. Because ultrasound may not completely define the extent of the lesion, MRI can provide additional information.[39] In general, large or rapidly growing tumors that result in distortion of normal anatomy or massive hydrocephalus with macrocrania are likely to be lethal. In these cases, the option of pregnancy termination should be offered and cesarean section avoided wherever feasible.

FACIAL TUMORS

Facial tumors most commonly involve the orbits, the paranasal sinuses, the tongue, the nasopharynx, and the oropharynx. Teratomas are the most frequent tumor type, but mesenchymal tumors are also encountered.

Orbital Tumors

The antenatal diagnosis of an orbital tumor is infrequent. The differential diagnosis includes a number of nonneoplastic entities such as encephalocele, vascular malformation, orbital cyst, and lesions of the conjunctiva, eyelid, and lacrimal apparatus. In addition, conditions that cause structurally shallow orbits, such as craniosynostosis, can cause proptosis and give the ultrasound appearance of an orbital mass.

Diagnosis

An orbital teratoma presents as a unilateral mass arising within the orbit that both displaces the globe and enlarges the bony orbit. The globe may have degenerative changes and appear small because of compression. As with other teratomas, both solid and cystic components are present, but there is no evidence of communication between the cystic areas and the intracranial cavity.[40] These tumors occur twice as often in females and are more common on the left side.[41]

Retinoblastomas are the most frequent intraorbital tumors of childhood. Only rarely are these tumors large enough to visualize on antenatal ultrasound. However, giant congenital retinoblastomas protruding from the orbit are reported and can present as an exophytic, solid mass that may compress and destroy the normal ocular structures.[42]

Tumors may also arise within the ocular apparatus. Medulloepithelioma, a malignant tumor arising from the ciliary body, has an exophytic appearance and mixed cystic-solid composition that may mimic the appearance of a teratoma.[43] Massive retrobulbar orbital cysts have also been diagnosed antenatally.[44] Epibulbar tumors can also present as orbital masses. Epibulbar dermoids are cystic lesions that contain pilosebaceous epithelial elements. They are associated with Goldenhar's syndrome.[45] Dacryocystocele, secondary to obstruction of the lacrimal duct, has a characteristic cystic appearance and is located along the inferomedial border of the fetal orbit[46] (Fig. 22–3).
FIGURE 22–3
Dacrocystocele. A cystic area between the nasal bone and the right orbit was identified on ultrasound in the mid trimester. The differential diagnosis included encephalocele, epibulbar dermoid, and dacryocystocele. At birth, the overlying skin had a bluish tinge characteristic of a dacryocystocele.

Risks

Orbital tumors are unlikely to result in pregnancy complications. The degree of fetal risk depends on the nature of the lesion, because even some benign lesions can compromise future vision. Retinoblastomas diagnosed during the perinatal period are commonly due to a hereditary germ-line mutation in the retinoblastoma gene or a deletion of chromosome 13q; these mutations predispose to the development of other malignancies.[47]

Management Options

The tumor type and degree of impingement on surrounding structures determine the prognosis. In general, orbital teratomas have a favorable prognosis; even large lesions that require enucleation of the ipsilateral eye tend to have mature elements and an exceedingly low recurrence rate.[41,42] The prognosis for malignant orbital tumors such as retinoblastoma depends on the degree of spread outside the globe and the presence of any associated anomalies. A karyotype is indicated once the diagnosis of retinoblastoma is suspected. Parents should be counseled regarding the potential for postnatal treatment. Epibulbar tumors and abnormalities of the lacrimal apparatus have a favorable prognosis for survival and normal vision.[45,46] Cesarean delivery is occasionally necessary for large, exophytic tumors when there is a risk of dystocia or hemorrhage.

Nasal and Oral Tumors

Congenital vascular lesions, neoplasms, hamartomas, dental anomalies, and salivary gland lesions can occur in the oral cavity. Tumors of these cavities are rare and are most often teratomas, but granular cell tumors also occur.[48]

Diagnosis

Teratomas of the nasopharynx and oropharynx originate from the sphenoid bone, the hard or soft palate, the jaw, or the tongue. Ultrasonographically, they appear as complex heterogeneous masses that protrude from the mouth.[49–54] A subset of oropharyngeal teratomas are highly organized with recognizable organs suggestive of a parasitic twin; these tumors carry the special appellation of "epignathus."[50,55] Their location can prevent fusion of the palatal shelves, resulting in a cleft palate. Up to 9% of cases are associated with other organ system anomalies.[49] These tumors may cause hydramnios by occluding the pharynx or impeding fetal swallowing.[49,50,52,53] The maternal serum AFP was elevated in several cases.[49–52,54] Three-dimensional ultrasonography has been used to provide detailed visualization of the mass.[56]

Other rare facial tumors are reported including nasal hemangiopericytoma,[57] nasal glioma,[58] mesenchymal tumors of the paranasal sinuses, granular cell tumors of the gingiva,[59,60] and leiomyoma of the tongue.[61]

Risks

The majority of nasopharyngeal and oropharyngeal teratomas interfere with fetal swallowing and cause hydramnios.[49,50,52] For fetuses with large teratomas, there is a significant risk of malposition of the fetal head and dystocia leading to cesarean section.[52]

Although these tumors may be massive in size at birth, most are benign and have a low risk of recurrence after appropriate surgical resection.[49,52] The greatest risk to the fetus is respiratory distress resulting from an inability to establish a patent airway. Arteriovenous shunting has been reported with pharyngeal teratomas leading to placentomegaly, high-output cardiac failure, and fetal hydrops with a maternal risk of mirror syndrome.[52]

Management Options

A large tumor mass within the nasopharynx or oropharynx can impede normal gas exchange. In some cases, tumor may extend into the trachea so that even if an oral airway is attainable, respiration is still impaired. With large pharyngeal masses, delivery coordination with a team including an anesthesiologist, neonatologist, and pediatric surgeon may prove lifes-aving. The ex utero intrapartum treatment (EXIT) procedure allows either endotracheal intubation or tracheostomy to be performed while the placental circulation is maintained.[50,55,62–66] General anesthesia is used to maximize uterine relaxation and fetal anesthesia, a hysterotomy is performed, and the fetus is partially delivered to the level of the shoulders. Endotracheal intubation can then be attempted, with either a laryngoscope or a fiberoptic endoscope; if unsuccessful, tracheostomy can be performed. Some advocate having extracorporeal membrane oxygenation equipment in the operating suite.[67] Fetoplacental circulation has been maintained for more than 50 minutes, during which time fetal oxygen saturation can be easily monitored with reflectance pulse oximetry.[62,63,68]

A substantial number of women will present in preterm labor associated with hydramnios. The presence of these tumors is not a contraindication to either therapeutic amniocentesis or tocolysis, because most of these infants have a favorable long-term prognosis if they survive the perinatal period and initial surgical resection. Prematurity is not a contraindication to the EXIT procedure.[62,63]

NECK TUMORS

Masses in the fetal neck can be divided into those occurring anteriorly or posteriorly. The differential diagnosis depends on the location of the mass. Anteriorly, the most common diagnoses are goiter, thyroid/thyroglossal duct cyst, teratoma, nonseptated cystic hygroma, and branchial cleft cyst.[69] Posteriorly, the differential diagnosis includes nuchal edema, cystic hygroma, meningomyelocele, and rarely, teratoma.[70] The fetal neck is usually in a neutral position; any deviation, such as hyperextension, should prompt an investigation of possible etiologies because of the propensity for airway obstruction.[69]

Teratoma

Although cervical teratomas are the most common fetal neck tumor, only about 5% of all teratomas are located in the neck.[71,72] Extragonadal teratomas are believed to develop during early gestation when all three germ layers are in close approximation.[73] Historically, a distinction has been made between cervical and thyroid teratomas.[74] These tumors can

achieve a massive size prior to birth and distort the anatomy in the neck, face, and even thorax, but only rarely have malignant components or metastatic foci been reported.[75–78]

Diagnosis

On antenatal ultrasound, the lesion has a characteristic appearance with large solid and cystic areas extending from the anterior surface of the neck (Fig. 22–4). Calcification within the mass occurs in 40% to 50%.[69,76,78] Although maternal serum AFP is not routinely helpful in diagnosis, those with endodermal sinus derivatives may produce AFP. Hydramnios complicates 25% to 55% of cases, especially those with large tumors causing esophageal and tracheal occlusion, and may provide a clue to the extent of the lesion.[69,75,78] Fetal MRI is a useful adjunct to antenatal ultrasound, often providing clearer details of the extent of the lesion to aid in postnatal surgical planning.[78–80]

Risks

Hydramnios increases the maternal risk of preterm labor, respiratory compromise, and postpartum hemorrhage. The most substantial neonatal risk is respiratory distress due to airway obstruction leading to hypoxia and resultant neurologic injury.[77] The overall survival rate with modern surgical care is 85% to 95%, even with large tumors. The most important prognostic factor is the ability to achieve complete surgical resection of the tumor.[77,78]

Management Options

The size of the tumor and the resulting hyperextension of the fetal neck frequently cause dystocia and necessitate cesarean delivery. Because of the potential for airway complications, an EXIT procedure should be anticipated. Surgical resection is usually performed as soon after birth as possible to avoid loss of a previously secure airway. Although an operative mortality rate of 15% was reported in the past, more recent series report exceedingly low mortality rates.[78,79] The risk of morbidity due to operative injury to the thyroid and parathyroid glands, the neck vessels, and the recurrent laryngeal nerve remains significant, but an excellent functional and cosmetic result can be expected in 70% of cases.[79]

Cystic Hygroma

Cystic hygromas are malformations of the lymphatic system that appear as fluid-filled, membranous cysts, lined by true epithelium in the anterolateral or occipitocervical area. The hygroma may be small, simple, and transient or large, multiseptated, and persistent. These lesions result from the jugular lymphatic obstruction sequence, in which either the normal communication between the jugular lymphatic sacs and the jugular veins fails to form by 40 days' gestation or there is an overall lymphatic hypoplasia (Fig. 22–5).[81,82] If the lymph sacs eventually connect with the venous system or an alternative route of lymphatic drainage develops, the cystic hygroma can spontaneously resolve. However, stigmata, such as low posterior hairline and neck-webbing, may persist.[81]

Diagnosis

Ultrasound allows ready diagnosis of cystic hygroma. Their location in the posterolateral portion of the neck and their cystic multiseptated appearance are characteristic (Fig. 22–6). Large hygromas are frequently divided by incomplete septa and often have a dense midline septum extending across the full width of the hygroma. The differential diagnosis includes encephalocele, meningomyelocele, nuchal edema, and the rare posterior teratoma.[70,81,83] Differentiating features include an intact skull and spinal column, lack of a solid component, a constant position of the mass relative to the fetal head, and the separation of cysts by septa. Nuchal translucency or edema may represent the most mildly affected end of the spectrum of the lymphatic obstruction sequence. In contract to cystic hygroma, the subcutaneous fluid is more subtle (usually < 10 mm in thickness) and continuous.[70] Cystic hygroma is associated with either an

elevated maternal serum AFP or human chorionic gonadotropin (hCG).[84,85] Other anomalies may be detected in part because of the association with fetal aneuploidy. Hydrops is often associated with cystic hygroma, because both result from a defect in lymphatic formation. Associated cardiac anomalies, particularly aortic coarctation and hypoplastic left ventricle, may occur as the enlarged thoracic duct impinges on the developing heart.[86] The development of hydramnios or hydrops may reflect fetal cardiac decompensation, which reduces the chances of resolution or survival.[81]

Risks

Between 50% and 75% of fetuses with cystic hygromas are aneuploid; Turner's syndrome (45,X and variants) accounts for 75% of the aneuploidies,[81,87] with the remainder being autosomal trisomies, especially chromosomes 13, 18, and 21.[88] There is controversy as to whether anterloateral hygromas are associated with other anomalies and aneuploidy.[69] One report, however, documents an increased risk of aneuploidy and cardiovascular anomalies with both anterior and posterior hygromas.[89] Noonan's syndrome, multiple pterygium syndrome, and the Klippel-Feil sequence are each associated with cystic hygroma, as are abnormalities related to environmental exposures such as fetal alcohol syndrome.[81,88] Associated congenital heart defects are relatively common.[88,90] Hydrops occurs in 50% to 90% of fetuses with cystic hygroma because both result from a defect in lymphatic formation. Hydrops is associated with an exceedingly low survival rate.[88,91,92] Dilated lymph sacs cause elevation, protrusion, and angulation of the ear, redundant skin in the nuchal region, and altered patterns of hair growth. Dilated lymphatic channels near the heart increase the resistance to blood flow through the ascending aorta, leading to left-sided hypoplastic cardiac lesions.[86,88,90]

Management Options

Once a cystic hygroma is identified, a careful search for skin edema, ascites, pleural and pericardial effusions, and cardiac and renal anomalies is indicated. Karyotyping should be offered. When there is little fluid and the hygromas are large, the cyst can be aspirated and the karyotype obtained from the contained lymphocytes. Counseling and pregnancy management are guided by the presence of other malformations and the fetal karyotype. Because the prognosis for a fetus with a large, persistent cystic hygroma and hydrops is dismal, pregnancy termination should be offered. If the hygroma decreases in size or resolves, the overall prognosis is more favorable. Nonseptated cystic hygromas are more likely to resolve than septated lesions (98% vs. 44%) and have a higher survival rate (94% vs. 12%).[92] Fetuses with persistent cystic hygromas should be scanned periodically for hydrops.

There is no evidence that cesarean delivery improves outcome and should be avoided once a fetus with a cystic hygroma develops hydrops because of the poor prognosis. Ogita and coworkers[93] reported their experience with in utero sclerotherapy and noted the most favorable response in those fetuses without hydrops fetalis, chromosomal abnormalities, or structural abnormalities. This treatment, however, remains investigational. Isolated cystic hygromas may be surgically corrected postnatally and the prognosis for survival is then good.

When the parents opt for termination of pregnancy or when fetal death occurs, a postmortem examination should be recommended. Karyotyping should also be recommended if this has not been performed antenatally. In live births, tissue samples may be taken from fetal membranes or from the newborn itself. Because these fetuses may have chromosomal mosaicism, several tissues should be studied before concluding they are euploid. The content of postpartum counseling depends on the underlying cause.

THORACIC TUMORS

Primary tumors of the fetal lung (blastoma, fibrosarcoma, myofibromatosis, and hemangiomas) are rare, and most diagnoses are made during the neonatal period.[94] Metastatic lesions, especially from hepatoblastoma, neuroblastoma, or Wilms' tumor, are more frequent. Other mass lesions detected within the lung include vascular malformations, congenital lobar emphysema, and bronchogenic cysts.

Mediastinal and thoracic wall masses are also reported. The differential diagnosis of a mediastinal mass includes bronchogenic cyst, neurenteric cyst, esophageal duplication cyst, diaphragmatic hernia, pericardial cyst, lymphangioma, teratoma, and neuroblastoma.[95] Chest wall masses include hemangiomas, lymphangiomas, and mesenchymal tumors.

Diagnosis

Bronchogenic cysts result from abnormal budding of the bronchial tree between 4 and 8 weeks' gestation and usually lack a normal connection to the tracheobronchial tree.[96] They typically appear ultrasonographically as fluid-filled cystic areas located within either the lung or the mediastinum, most commonly in the subcarinal area. The antenatal detection of a chest wall mesenchymal hamartoma is reported.[97] With metastatic lesions, the primary tumor is often identifiable in another organ system. Approximately 15% of neuroblastomas are located in either the thoracic cavity or the mediastinum. On ultrasound, the lesions can appear either solid with calcification or cystic, which is more common.[98–100] Thoracic neuroblastomas tend to be diagnosed earlier than their intra-abdominal counterparts, and therefore, have a better prognosis. Chylothorax attributed to compression of pulmonary lymphatics by a mediastinal tumor has also been reported.[98] Lymphangiomas can occur in either the anterior or the posterior mediastinum. Vascular malformations in the pulmonary tree may be part of a genetic syndrome that is associated with multiple hemangiomas such as Osler-Weber-Rendu syndrome.

Risks

Any lesion that creates a mass effect within the fetal thorax has the potential to alter pulmonary development and cause hydrops by obstructing cardiac return. A large intrathoracic mass may compress the contralateral lung.[101] Compression of the trachea and esophagus can cause hydramnios independent of cardiac function.[102] The ultimate prognosis depends on the nature of the tumor, its resectability, the degree of lung involvement, and the extent to which pulmonary development is impeded by the mass effect. Hydramnios and mediastinal shift are poor prognostic indicators.[103]

SUMMARY OF MANAGEMENT OPTIONS **Neck Tumors**		
Management Options	**Evidence Quality and Recommendation**	**References**
Teratomas		
Assess for hydramnios and its complications.	—/GPP	—
Cesarean section may be necessary in cases of extreme dorsiflexion of fetal head or dystocia caused by large tumor.	—/GPP	—
EXIT procedure may provide up to 1 hr of uteroplacental support to allow time to secure an airway.	III/B	50,55,62,63
Plans for intrapartum intubation, ex utero tracheoplasty or ECMO should be coordinated with pediatric and surgical specialists. Surgical resection is usually performed as soon as possible after stabilization to avoid loss of secure airway.	III/B	50,55,62,63
Prompt surgery for appropriate cases after delivery has reduced the mortality rate to 15%.	III/B	76,77
Cystic Hygroma		
Search for hydrops and associated abnormalities. Offer karyotyping.	GPP	
Prognosis and management depend on cause, other anomalies, and whether the hygroma resolves.	GPP	
Offer termination of pregnancy when appropriate	GPP	
If pregnancy continues and cyst is massive, transabdominal aspiration may allow vaginal delivery; cesarean delivery is rarely justified.	GPP	
Establish cause including postmortem for abortus/stillbirth/neonatal death.	GPP	
"Cosmetic surgery" may be necessary if baby survives with a "web neck."	GPP	
Counseling depends on cause	GPP	

ECMO, extracorporeal membrane oxygenation; EXIT, ex utero intrapartum treatment; GPP, good practice point.

Management Options

The progressive growth of a bronchogenic cyst can lead to hydrops as well as bronchial abnormalities.[96] Percutaneous drainage via repeated thoracentesis or thoracoamniotic shunt placement has been reported.[104,105] The shunt will relieve hydrops only if secondary to mediastinal shift. It is unclear whether a shunt improves outcome in the absence of hydrops. MRI may assist the evaluation of large or atypical chest masses.[106] Because of the potential for respiratory compromise, fetuses with thoracic lesions should be delivered at a center prepared for appropriate fetal resuscitation and support.

TUMOR-LIKE CONDITIONS OF THE LUNG

Congenital Cystic Adenomatoid Malformation

Congenital cystic adenomatoid malformation (CCAM) is a developmental anomaly of the lung consisting of abnormal tertiary bronchioles. Most lesions are unilateral, but up to 15% have bilateral components.[107] Bronchioles display either hamartomatous changes or an arrest in embryologic development with the formation of cystic lesions of various sizes.[102,107] They usually communicate with the bronchial tree. The blood supply derives from the pulmonary circulation.

Diagnosis

CCAM lesions are classified by their histologic appearance: type I lesions account for more than 50% and are composed of large cysts; type 2 lesions make up 40% and are composed of multiple small cysts; type 3 lesions are microcystic, homogeneous, solid-appearing masses[108,109] (Fig. 22–7). Adzick and colleagues[101,110] proposed a simplified approach based on the antenatal sonographic findings; macrocystic lesions contain single or multiple cysts at least 5 mm in diameter, whereas microcystic lesions have cysts less than 5 mm in diameter and appear more echodense. For cystic lesions, the differential diagnosis includes diaphragmatic hernia, bronchogenic or enteric cysts, bronchial atresia, neuroblastoma, anterior meningomyelocele, and teratoma. For solid lesions, the main differential diagnosis is bronchopulmonary sequestration. Demonstration that the blood supply comes from

FIGURE 22–7

A type 2 congenital cystic adenomatoid malformation (CCAM) was identified in this fetus. Although there was evidence of mediastinal shift and mild cardiac deviation, the CCAM decreased in size during gestation, and the fetus was asymptomatic at birth.
the aorta excludes a diagnosis of CCAM.[88,101] Fetal MRI can provide additional anatomic detail and is helpful in distinguishing CCAM from diaphragmatic hernia.[111,112]

Risks

The antenatal natural history of CCAM is variable, and the prognosis is guided by the size and type of the mass, the progression or regression of the mass, and the presence of cardiac axis deviation, hydrops, and associated anomalies. Although initial reports suggested that solid lesions had a worse prognosis, more recent evidence suggests the overall size of the mass is more important.[88] Large lesions that cause cardiac deviation and compression of the great vessels, esophagus, or trachea, leading to hydrops and hydramnios, have a worse prognosis. Without antenatal intervention, the development of hydrops is a harbinger of fetal demise.[101,113,114] In addition, large lesions may cause compression of normal lung tissue leading to pulmonary hypoplasia. Between 10% and 20% of fetuses develop hydrops, and up to 70% develop hydramnios. Crombleholme and colleagues[113] described a technique for measuring the size of the CCAM that generates a volume ratio and then applied the ratio to predict the likelihood of hydrops developing. Approximately 15% of CCAM lesions shrink in utero with resolution of any mediastinal shift. Although many of these lesions appear ultrasonographically to involute or "disappear," this may be due in part to changes in tissue echo texture, because postnatal radiographic or antenatal MRI studies confirm the persistence of at least some lesions.[101,106,112] In the absence of hydrops, more than 90% survive with most lesions resectable postnatally.[101,107]

Although 26% of fetuses had associated anomalies in Stocker and colleagues' original report,[108] a more recent series observed that only 2% of fetuses with CCAM had associated anomalies.[101,115] Development of hydrops or hydramnios is associated with increased risks.

Management Options

A complete anatomic survey is required to rule out associated malformations, determine the size and type of lesion, and detect any cardiac deviation or evidence of hydrops. Karyotype determination should be offered if there are associated malformations. If multiple anomalies or hydrops are identified, the parents should be counseled regarding the poor prognosis and pregnancy termination offered. In ongoing pregnancies, serial ultrasound scans are indicated to identify hydramnios or hydrops. Corticosteroids for pulmonary maturation followed by delivery are options after consultation with neonatal and pediatric surgical specialists should hydrops develop at a gestation when survival is possible. The delivery of any viable fetus with a persistent thoracic mass should occur at a center prepared for potential neonatal respiratory compromise.

The management of fetuses that develop hydrops prior to viability is more problematic. In such cases, the mortality rate is 100% with expectant management. In a number of reports, decompression of a large dominant cyst by thoracentesis or thoracoamniotic shunt placement successfully reversed the mediastinal shift, pulmonary compression, and hydrops, and survival rates of up to 80% to 90% have been reported.[101,104,113] The initial procedure should be thoracentesis with cyst drainage, because in some cases this can result in complete resolution of the cyst.[113] If the fluid rapidly reaccumulates, shunt placement can be considered. The utility of shunts is limited by occlusion or dislodgment, which occurs in up to 29% of cases.[116]

Thoracoamniotic shunting is ineffective for the treatment of multicystic and solid lesions. When these lesions are large and associated with hydrops, antenatal fetal surgery is an option. Adzick and colleagues[101] described the outcomes of 13 hydropic fetuses with CCAM who underwent antenatal resection of an abnormal pulmonary lobe at 21 to 29 weeks' gestation. Eight (62%) survived. Crombleholme and colleagues[113] reported only 2 of 7 (29%) similar fetuses surviving antenatal surgery. Fetal surgery is limited to a few centers worldwide and is associated with considerable risks including chorioamnionitis, preterm premature rupture of the membranes, preterm labor, postoperative infection, pulmonary edema, and anesthetic complications, as well as an upper segment uterine scar. Percutaneous fetal sclerotherapy has also been used to successfully treat a type 3 CCAM.[117]

Bronchopulmonary Sequestration

Bronchopulmonary sequestration is an isolated mass of lung tissue that does not communicate with the tracheobronchial tree and derives its blood supply from the systemic circulation, usually from the aorta or a major branch. The lesion is thought to result from a supernumerary lung bud that arose caudal to the normal lung bud and migrated with the esophagus.[102,118] Intralobar sequestrations develop early in embryogenesis, are surrounded by lung tissue, and are covered by the same pleura. Extralobar sequestrations develop later, grow separately from the lung, and become covered by their own pleura. The lesions are typically unilateral; left-sided lesions being twice as common. Although intralobar lesions typically involve the lower lobe of the lung, extralobar regions may be found between the lower lobe and the diaphragm, within the diaphragm, in the mediastinum, or below the diaphragm. Extralobar lesions predominate in the fetus and neonate.[119,120]

Diagnosis

Bronchopulmonary sequestration appears ultrasonographically as a solid, highly echogenic, homogeneous mass. Confirmation of a systemic vascular supply using color-flow Doppler is diagnostic.[121,122] It can be very difficult to distinguish a sequestration from a microcystic CCAM if the vascular supply cannot be identified. It is usually not possible to determine ultrasonographically whether an intrathoracic sequestration is intralobar or extralobar. The differential diagnosis includes microcystic CCAM, diaphragmatic hernia, teratoma, and neuroblastoma. For extralobar lesions, the differential diagnosis includes neuroblastoma and renal tumors. Although it is usually possible to demonstrate the well-demarcated boundaries of sequestrations by ultrasound, an MRI scan can help to identify other conditions that can present with a solid echogenic mass in the lower thorax, such as diaphragmatic hernia with liver herniation.[106]

Risks

The prognosis is variable, although large sequestrations can cause pulmonary compression, mediastinal shift, and hydrops. The presence of hydrops is the most important prognostic sign. In one early series, only 36% of fetuses survived, and all fetuses with hydrops (35% of all cases) died.[126] The incidence of hydramnios was 80% and isolated pleural effusion 70%. A more recent experience of 39 continuing pregnancies reported 100% survival of nonhydropic fetuses.[101] Only 4 fetuses developed hydrops, and the only death occurred in the 1 fetus not treated antenatally.[101] Significantly, 72% of sequestrations regressed or resolved spontaneously and were asymptomatic at birth.[101] Postnatal imaging revealed residual evidence of the lesions. Regression appears more common with extralobar sequestration, possibly because the separate pleural investment allows torsion on its vascular pedicle.[123,124] Intra-abdominal extralobar bronchopulmonary sequestration is rarely associated with hydrops and has a better prognosis than intrathoracic lesions.

Even in the absence of a significant mediastinal shift, fetuses with bronchopulmonary sequestration may develop hydrothorax. This phenomenon is more common with extralobar lesions, possibly as the result of lymphatic and venous obstruction due to torsion.[119] The pressure gradient between the systemic artery and the pulmonary vein and the resultant left-to-left shunting has been postulated as an explanation with intralobar lesions.[125]

Associated foregut anomalies include tracheoesophageal fistula, esophageal duplication, diaphragmatic hernia, funnel chest, and cardiac defects. Additional malformations occur more commonly with extralobar lesions (58%) than with intralobar lesions (14%).[126,127]

Management Options

Once the diagnosis of bronchopulmonary sequestration is suspected, a complete anatomic survey is required. Although the majority of intrathoracic lesions will regress to some degree, the possibility of hydrops justifies serial ultrasound examinations. If the lesion is large and associated with either hydrothorax or hydrops, antenatal therapy may be considered, given the dismal prognosis. Weekly thoracentesis and thoracoamniotic shunt placement are reported to effectively treat hydrops and pleural effusion when there is a mediastinal shift, but do not address the underlying lesion. Any fetus that fails to respond to these therapies or has hydrops due to a large lesion without a significant pleural effusion can be considered a candidate for in utero resection of the lesion. The maternal risks of such intervention should be carefully weighed against the potential fetal benefit.[101,102,118,128–130] Isolated intra-abdominal bronchopulmonary sequestrations have a better prognosis than intrathoracic masses because these lesions do not cause pulmonary compression and hypoplasia. Like those above the diaphragm, regression occurs. Hydramnios may occur secondary to esophageal or gastric compression preventing fetal swallowing. All fetuses with bronchopulmonary sequestration should be delivered at a tertiary center equipped for appropriate resuscitative and treatment measures.

CARDIAC TUMORS

Primary cardiac tumors are rare with a reported frequency of 2.7 per 10,000 infants and young children; the prevalence in utero is unknown.[131,132] Cardiac rhabdomyoma is the most common cardiac tumor detected in infancy, accounting for 62% of cases, followed by teratoma in 21%, fibroma in 13%, and only rarely, hemangioma, myxoma, or sarcoma.[133–135]

Diagnosis

Rhabdomyoma is thought to be a hamartoma and not a true neoplasm. It can be solitary or multiple and located within any of the cardiac chambers (Fig. 22–8). The ultrasonographic appearance of rhabdomyoma is of a discrete echogenic mass, but whether the mass is mobile or fixed depends on the location.[136] Rhabdomyomas can be isolated, but they are more frequently found in association with tuberous sclerosis. Between 51% and 86% of neonates born with cardiac rhabdomyomas will subsequently be diagnosed with tuberous sclerosis. Conversely, these lesions may be found in 50% to 60% of patients with tuberous sclerosis.[136–138] The tumors associated with tuberous sclerosis are typically multiple and range in size from 3 to 25 mm. The differential diagnosis

includes fibroma, myxoma, and sarcoma, although these lesions are less common in the fetus.

Pericardial teratomas appear ultrasonographically similar to teratomas in other locations—a complex echogenic mass with cystic and solid components and occasional calcifications.[139] These tumors are located outside the heart, attach to the base of the heart and great vessels via a broad stalk, and are usually on the right. In nearly all cases, a pericardial effusion is present that assists in narrowing a differential diagnosis that includes mediastinal teratoma, extralobar bronchopulmonary sequestration, and CCAM in which pericardial involvement is rare.

Risks

All cardiac tumors have the potential to cause hemodynamic compromise and hydrops due to obstruction of normal blood flow through either the cardiac chambers or the great vessels. This risk depends on the number, size, and location of the tumors.[134] The prognosis for fetuses with a cardiac tumor and hydrops is dismal. Pediatric patients with intramural tumors are at increased risk for cardiac arrhythmias such as ventricular tachycardia and Wolff-Parkinson-White syndrome. The tumor (especially rhabdomyomas, which have conductive capability) is believed to act as an accessory conduction pathway.[136,140,141] Whether fetuses have a similar risk is unknown. Cardiac tumors are also associated with several genetic syndromes including Beckwith-Wiedemann syndrome, tuberous sclerosis, Gorlin's (basal cell nevus) syndrome, and neurofibromatosis. A detailed ultrasonographic anatomic survey should be performed to search for these stigmata.

Tuberous sclerosis is an autosomal dominant disorder, though approximately two thirds result from new mutations. Most mutations are in the *tuberin* or *hamartin* genes on chromosomes 16 or 9, respectively. Consultation with a geneticist is recommended because a mutation can be identified in some families. Although the disorder has 95% penetrance, there is markedly variable expressivity, and evaluation of the parents and the fetus' siblings by a geneticist can help confirm or refute the diagnosis. Children diagnosed with tuberous sclerosis are at risk for mental retardation and seizures, but it is not possible to predict mental function based on either the antenatal findings or the family history. It is suggested that children with cortical tubers or subependymal nodules are more likely to have unremitting seizures and severe mental retardation. Fetal MRI has been used to

identify these cortical abnormalities, which may not be visible on ultrasound.[142,143]

Management Options

The fetus with a cardiac mass should undergo serial ultrasonographic examinations to search for hydrops or an arrhythmia. If hydrops develops at a gestational age when survival is expected, the administration of antenatal corticosteroids followed by delivery should be considered. Should hydrops develop prior to viability, pregnancy termination may be offered. In the absence of hydrops, the prognosis for the fetus with a cardiac mass is favorable. Delivery should be planned at a tertiary center capable of providing pediatric cardiac surgical intervention. Intrauterine pericardiocentesis is reported to relieve cardiac tamponade with a successful outcome of pregnancy in a fetus with pericardial teratoma and a pericardial effusion.[144,145] The majority of cardiac rhabdomyomas spontaneously regress after birth.[136,141] For this reason, intervention is considered only in the presence of hemodynamic compromise. All true cardiac tumors should be evaluated postnatally and surgical resection planned. Although malignant components have only rarely been identified in pericardial teratomas, all become symptomatic eventually, thus justifying surgical therapy.[139,146]

ADRENAL TUMORS: NEUROBLASTOMA

Neuroblastoma is the most common malignant congenital tumor, with a prevalence of 0.6 to 2.0 per 100,000 live births. It originates from the neural crest cells that migrate along each side of the spine and give rise to the adrenal medulla and the sympathetic ganglia. Although tumor can arise anywhere along this path, the most common location is intra-abdominal, involving the adrenal gland. Other locations include the neck, thorax, and pelvis.[147] More than 90% of antenatally diagnosed neuroblastomas are adrenal in origin.[148]

Normal fetal adrenal development can be difficult to distinguish from neuroblastoma. Neuroblasts normally mature to form ganglion cells referred to as "neuroblastoma in situ," with a prevalence of 1 in 250 at term. The development of a clinical neuroblastoma represents a defect in the cellular maturation and differentiation. This defect may be temporary in some cases, accounting for the 15% to 20% rate of spontaneous regression.[149]

Diagnosis

The ultrasonographic appearance of adrenal neuroblastoma is variable, ranging from cystic with a thick-walled complex to solid with hyperechogenicity and foci of calcification.[99,148,149] Approximately 40% to 50% of antenatally diagnosed neuroblastomas have a cystic appearance, which may represent a stage of involution.[148] Doppler flow mapping may aid the diagnosis, because the nest of tumor cells is highly vascular, and the pulsatile flow observed in such tumors is suggestive of neovascularization.[150] The differential diagnosis includes adrenal hemorrhage, renal mass, and intra-abdominal extralobar pulmonary sequestration. Neo-

Cardiac Tumors

Management Options	Evidence Quality and Recommendation	References
Determine the tumor type and likely diagnosis; search for ultrasound markers of syndromes.	—/GPP	—
Rhabdomyoma is the most common tumor; consider the diagnosis of tuberous sclerosis. Linkage studies may confirm a familial case, but no genetic test is available to diagnose new mutations. Counseling is difficult. Fetal MRI may detect brain abnormalities that are not visible by ultrasound. Referral to a geneticist for counseling is suggested.	III/B	142,143
Assessment for hydrops and arrhythmias is needed; in the absence of hydrops, prognosis is favorable, often with spontaneous regression.	III/B	134
If hydrops develops, timing affects response:		
• Previability—offer termination.	—/GPP	—
• If pericardial effusion with tamponade develops, pericardiocentesis is necessary.	III/B	144,145
• Preterm delivery after maternal steroids is indicated if there are early signs of hydrops and gestational age is acceptable.	—/GPP	—
Tumors can resolve after birth; surgery is indicated for those that persist with hemodynamic compromise.	III/B	136

GPP, good practice point; MRI, magnetic resonance imaging.

natal diagnosis is frequently prompted by hemorrhage into nests of tumor cells.[99,149] Antenatal adrenal hemorrhage is rare but reported with Beckwith-Wiedemann syndrome.

Metastases occur frequently in utero and can be visualized with ultrasound. Hepatic metastases are seen in up to 25% of fetuses with near-total replacement of the hepatic parenchyma reported.[148,149] Other sites of metastasis include the retroperitoneal lymph nodes, bone marrow, umbilical cord, and skin. Although nearly 90% of children with neuroblastoma have elevated urinary levels of vanillylmandelic acid (VMA) or homovanillic acid (HVA), only 30% to 35% of prenatally diagnosed cases have elevated levels postnatally. Although the measurement of maternal urinary VMA or HVA has prompted diagnosis, the yield is relatively low.[148]

Hydramnios or hydrops is reported in association with neuroblastoma, and may prompt the initial ultrasound examination. The mechanism is unknown, but possibilities include fetal anemia due to bone marrow infiltration, fetal arrhythmia due to catecholamine excess, placental vascular obstruction due to tumor metastases, and vena caval obstruction due to tumor compression.[147–149] In rare cases, the presenting complaints are maternal signs of catecholamine excess such as hypertension, coagulopathy, or renal abnormality.[151] Several genetic disorders associated with abnormalities of neural crest derivatives (Beckwith-Wiedemann syndrome, DiGeorge's syndrome, and CHARGE [coloboma, heart disease, atresia choanae, retarded growth and retarded development and/or central nervous system anomalies, genital hypoplasia, and ear anomalies and/or deafness] association) are associated with neuroblastoma. In addition, a familial form of neuroblastoma is described. Thus, a prior affected child should prompt antenatal screening of subsequent pregnancies.[152]

Risks

The prognosis for the fetus depends on tumor stage and the clinical manifestations of the disease. Although the survival rate in children older than 1 year at diagnosis is only 10% to 20%, the survival rate in neonates is greater than 90%.[99,147–149] Fetal hydrops is strongly correlated with advanced disease and increases the risk of the mother developing preeclampsia. In a review of 21 fetuses with an antenatal diagnosis of neuroblastoma, 3 fetuses developed hydrops. All had advanced stage disease, and all 3 mothers had preeclampsia.[149] Two of the 3 fetuses died antenatally.

The prognosis for a fetus with either stage I or stage IV tumors (metastases involving liver, skin, or bone marrow) is excellent, with survival rates of 90% or better after resection of the primary lesion. The high survival rate reflects the tendency for these tumors to undergo spontaneous regression.[99,148] The prognosis for stages II and III disease is poor, but fortunately, they are rare. Tumor hemorrhage and rupture during labor are reported, but their occurrence is rare.

Management Options

Most women whose fetus has neuroblastoma are asymptomatic. Serial ultrasound examinations are indicated to assess tumor size, amniotic fluid volume, and fetal growth and to detect hydrops. Because dystocia can develop when the fetus has massive hepatomegaly, the abdominal circumference should be regularly monitored in fetuses with metastatic disease; cesarean section is an option should the abdominal circumference be markedly enlarged.[147,153–155] Surveillance for maternal hypertension is critical. In the setting of hydrops, the decision to deliver is based on the gestation and the potential for survival. In fetuses less than 32 weeks' gestation, antenatal corticosteroids may be administered to enhance pulmonary maturity prior to delivery. If maternal symptoms of preeclampsia develop, delivery should be considered regardless of gestation. Any fetus suspected of having a neuroblastoma should be delivered at a tertiary center where the appropriate support staff are available.

RENAL TUMORS

Although renal tumors account for only 5% of all perinatal tumors, renal masses account for 70% of all abdominal masses in the perinatal period. The majority of these masses are hydronephrotic or multicystic dysplastic kidneys.[8,156] Despite their low frequency, renal tumors are often identified antenatally because of the relative ease with which the kidneys are visualized ultrasonographically.

Diagnosis

Congenital mesoblastic nephroma is a benign renal tumor composed of spindle cell mesenchymal elements that grow between intact nephrons and replace normal renal parenchyma.[157] It is the most common renal tumor in neonates and is distinguished from Wilms' tumor by its benign clinical behavior.[8,158] Ultrasonographically, these lesions usually appear as an isolated solid mass without a distinct capsule. However, occasional cystic changes, nodular densities, or diffuse enlargement of one kidney are reported.[147] The majority of the antenatal cases reported have been associated with hydramnios.[7,8,157] The mechanism of the hydramnios is unclear, but increased renal blood flow, impaired renal concentrating ability, and impaired gastrointestinal motility due to a mass effect are all implicated.[147] The differential diagnosis includes hydronephrosis and multicystic dysplastic kidney (which can usually be excluded because of their predominantly cystic nature), Wilms' tumor, and metastasis from hepatic and adrenal gland malignancies.

Wilms' tumor appears ultrasonographically very similar to congenital mesoblastic nephroma, except a distinct capsule may be identifiable.[8,147,159] This tumor is believed to be derived from the metanephric blastema, which is the embryonic precursor of nephrons and the renal interstitium.[8] It is typically unilateral (95%) and does not cross the midline. Associated congenital anomalies are common, and Wilms' tumor is described as a component of several genetic syndromes or associations, including WAGR (Wilms' tumor, aniridia, genitourinary malformations, and mental retardation) syndrome due to an 11p13 deletion and VATER (vertebral malformations, imperforate anus, tracheoesophageal fistula, limb abnormalities, and renal abnormalities) association.[160] It is also associated with several overgrowth syndromes including Beckwith-Wiedemann syndrome, Sotos' syndrome (cerebral gigantism), Perlman's syndrome (nephromegaly, hydramnios, macrosomia, cardiac defects, and diaphragmatic hernia), and Simpson-Golabi-Behmel syndrome (coarse facies, cardiac defects, islet cell hyperplasia, vertebral abnormalities, and vestigial tail).[161] Suspicion of nephromegaly or a family history of these disorders requires a detailed ultrasound examination and careful postnatal surveillance for the development of a tumor mass. Fewer than 1% of Wilms' tumor cases are familial with autosomal dominant inheritance. However, 20% of familial cases are bilateral, compared with only 3% of sporadic cases, thus warranting a thorough postnatal evaluation of both kidneys.[162]

Risks

Congenital mesoblastic nephroma is commonly associated with hydramnios. High renin levels are reported, and hyperreninism may precipitate fetal hypertension and rarely hydrops. Other potential causes of hydrops include obstruction of the portacaval circulation, arteriovenous shunting through the tumor, and hemorrhage into the tumor.[7,147,157] The prognosis for an affected fetus depends on the identity of the mass and the presence of hydrops or associated anomalies. Simple nephrectomy is usually curative. The prognosis for Wilms' tumor depends on the stage of disease at diagnosis. Survival after surgery and adjuvant therapy is greater than 90% when disease is confined to the area of the kidney, as is usual for prenatally diagnosed tumors. The prognosis for the hydropic fetus is more guarded. Fetuses with associated anomalies should be carefully evaluated to determine whether the constellation of findings represents a defined genetic syndrome.

Management Options

Because the majority of solid renal tumors are congenital mesoblastic nephromas with a benign clinical course, pregnancy should be allowed to go to term. Periodic ultrasound examinations are indicated to monitor fetal growth and amniotic fluid volume and to exclude hydrops. Delivery should be contemplated if hydrops develops at a gestation when survival is expected. Before 32 weeks, antenatal corticosteroids should be considered prior to delivery.[147] Dystocia is reported in cases with large renal masses. Cesarean section may be considered if the abdominal circumference is markedly enlarged.

HEPATIC TUMORS

Hepatic tumors account for 5% of the total neoplasms in the fetus and neonate.[163] Embryologically, the liver is derived from endoderm and mesoderm and is the potential site for

a wide spectrum of neoplasms.[164] The most frequently identified lesions in the perinatal period are hemangio-endothelioma, hemangioma, mesenchymal hamartoma, and hepatoblastoma.

Diagnosis

Hemangioendothelioma and hemangioma are vascular tumors derived from endothelial cells forming vascular channels. A hemangioendothelioma has focal or diffuse hypercellular areas, whereas a hemangioma contains flat, inconspicuous endothelium with dilated vascular spaces.[164] Hemangioendothelioma is the most common hepatic vascular lesion in the perinate, but hemangioma is the most common vascular lesion in all age groups. Ultrasonographically, these lesions may appear hypoechogenic, hyperechogenic, or mixed, depending on the degree of fibrosis, hypercellularity, and extent of involution.[147] Hepatomegaly and multifocal lesions are seen. Doppler interrogation of the lesion confirms its vascular nature. Large vascular spaces within the mass are frequently seen with hemangioendotheliomas, and dominant feeding or draining vessels may also be identifiable.[165] Hydramnios is reported and may be due to either arteriovenous shunting or gastrointestinal tract compression. Mid-trimester maternal serum AFP levels are frequently elevated.[165]

Mesenchymal hamartomas are composed of connective tissue stroma, serous cysts, bile ducts, hepatocytes, and angiomatous components.[8,166] These lesions typically have a complex sonographic appearance with irregular solid and cystic components that can become enlarged and calcified.[167] Hepatoblastoma is the most common hepatic malignancy in the first year of life when 50% to 60% of all hepatoblastomas present. Although hepatoblastoma is believed to develop in utero, fewer than 10% of tumors are detectable antenatally.[8] Ultrasonographically, these lesions appear solid with occasional calcifications. Two thirds involve only one liver lobe, although occasionally, only diffuse hepatic enlargement causing abdominal distention may be seen.[168] Although 80% to 90% of childhood or adult patients with hepatoblastoma have an elevated AFP level, the maternal serum AFP levels are not useful for a fetal diagnosis.[8,168]

Risks

Although hemangioendothelioma and hemangioma are benign tumors, they are associated with life-threatening perinatal complications: hydrops secondary to high-output congestive heart failure and arteriovenous shunting, consumptive coagulopathy due to platelet sequestration (Kasabach-Merritt syndrome), and hemoperitoneum from intrapartum hepatic rupture. Cutaneous hemangiomas and hemangiomas in other sites, such as the eye, are reported in 40% to 45% of children with hemangioendothelioma.[164,165] There also appears to be an association between hemangioendothelioma and placental chorioangioma.[169] Although the majority of lesions regress and involute during early infancy, the size of the lesion and the degree of arteriovenous shunting will determine the antenatal risk of complications such as hydramnios, hydrops, and preterm delivery. The prognosis for the fetus that remains free of hemodynamic

compromise is excellent; the prognosis is poor if hydrops develops.[170]

Rapid growth of mesenchymal hamartomas characterized by enlargement of the cystic components is common and increases the risk of hydrops. Of 13 antenatally diagnosed cases, 5 were complicated by hydrops or maternal pre-eclampsia, necessitating delivery; the perinatal mortality rate was 25%. Intrauterine drainage of the cystic lesions has not proved beneficial; drainage does not decrease fluid production and may precipitate hemodynamic compromise. Further, most cysts are multiloculated and not amenable to a single drainage procedure. In the asymptomatic fetus delivered near term, the prognosis is favorable after surgical resection. Owing to a propensity for spontaneous regression, some pediatric surgeons recommend a conservative strategy.[167]

Hepatoblastoma is a locally invasive tumor that can, on occasion, metastasize to the lung, brain, adrenal gland, and placenta. Large tumors are associated with hydramnios and hydrops due to a combination of factors including gastrointestinal obstruction, anemia from tumor hemorrhage, vascular compression, and possibly decreased colloid oncotic pressure secondary to altered hepatic synthesis.[168] Hepatoblastoma, as well as adrenocortical and Wilms' tumors, can occur in association with Beckwith-Wiedemann syndrome; 1% of patients with this syndrome develop hepatoblastoma. Other anomalies associated with hepatoblastoma include hemihypertrophy in 2% to 3%,[164] trisomy 18, Schinzel-Giedion syndrome (congenital heart defects, midface retraction, hypertrichosis, and embryonal malignancies), trisomy 21, and genitourinary abnormalities.[147] There are few reports of antenatally diagnosed hepatoblastoma. The prognosis for these lesions is uncertain but appears dismal in the setting of hydrops.[168,171] Complete surgical resection is possible in 40% to 75% of patients, and the survival rate in this group is 60%. The prognosis is poor if complete resection is not possible owing to infiltrative or metastatic disease.[8,172]

Management Options

Once a hepatic mass is identified, serial ultrasonographic studies are indicated to monitor fetal status, tumor size, and amniotic fluid volume. The ideal mode of delivery is unclear; intrapartum rupture of large hepatic masses with fetal death is reported.[147] Therefore, cesarean delivery should be considered in cases with marked hepatic enlargement. However, the risks of operative delivery need to be carefully considered in the context of the fetal prognosis. If the fetus has no signs of decompensation, delivery occurs at term. The role of intratumor injection of corticosteroids is uncertain.[173]

INTRA-ABDOMINAL CYSTS

Although not strictly tumors, a wide variety of cystic masses are detectable in the fetal abdomen including ovarian, mesenteric, urachal, choledochal, renal, hepatic, and splenic cysts. Enteric duplication, bowel obstruction, and meconium pseudocyst may also present as cystic lesions.[174] The location, size, and appearance of the cyst usually suggest the diagnosis.[175]

Ovarian cysts are common. Approximately 95% are unilateral and the majority are benign, functional cysts that occur in response to maternal hormones and resolve spon-

FIGURE 22–9
A choledochal cyst was identified in this fetus at 20 weeks' gestation. The cyst was located in the common bile duct.

taneously after delivery. Ultrasonographically, an ovarian cyst appears as a regular, hypoechoic structure in the lower abdomen. Septations or solid components may be seen if torsion or hemorrhage has occurred. Rarely, a cyst may become so large as to impinge on other organs, cause ovarian torsion and subsequent infarction, or result in dystocia. Ultrasound-guided in utero aspiration of large cysts is reported and may reduce these risks.[176]

Choledochal cysts represent a dilation of the common bile duct arising from either a weakness in the wall of the bile duct or a developmental anomaly and distal obstruction elsewhere in the biliary tree. These cysts have a prevalence of 1 in 2 million live births and occur more frequently in females and Asians.[177,178] Ultrasonographically, they appear as simple, anechoic cysts in the upper abdomen, usually medial to the gallbladder. Occasionally, a tubular structure is seen at the junction of the right and left hepatic ducts or the cystic and common bile ducts (Fig. 22–9). Choledochal cysts are not associated with an increased rate of fetal or maternal complications.[179] However, the patency of the biliary tree must be evaluated in the neonate because it is impossible to distinguish biliary atresia from a choledochal cyst on ultrasound.[177,180,181] All infants with these lesions require surgical treatment and reconstructive surgery of the biliary connections. However, the long-term prognosis with appropriate surgical treatment is excellent.

Solitary cysts are occasionally identified in the hepatic parenchyma. These lesions are usually small and unilocular.

Embryologically, they are thought to reflect interruptions in the development of the intrahepatic biliary tree and frequently resolve spontaneously.[174]

Bowel atresia or stenosis may produce cystic dilation of bowel segments proximal to the obstruction. Megacystis–microcolon–intestinal hypoperistalsis syndrome, an autosomal recessive disorder associated with vacuolation and degeneration of the smooth muscle in the bowel and bladder walls, may present as multiple cystic structures in the abdomen that represent dilated segments of proximal small intestine and bladder. No specific antenatal intervention is required. A pediatric surgical evaluation should be obtained after birth prior to the initiation of enteral feeding should bowel atresia be suspected.

Mesenteric and omental cysts represent the benign proliferation of ectopic lymphatic ducts that lack communication with normal lymphatic channels. They occur most commonly in the small bowel mesentery. Most are asymptomatic antenatally and do not require intervention, although there is one report of an enteric cyst associated with hydrops (cause and effect unlikely).[182] Postnatally enlarging lesions may cause partial bowel obstruction, but the prognosis following surgical resection is excellent.[183] Enteric duplication cysts have a similar sonographic appearance and can be distinguished only postnatally.

SACROCOCCYGEAL TERATOMA

Sacrococcygeal teratoma (SCT) is one of the most common tumors of the perinatal period, with a prevalence of 1 in 35,000 to 40,000 live births. It is four to nine times more common in females than in males.[72,147,184–186] Like other teratomas, these tumors contain elements derived from all three germ cell layers. Sacrococcygeal tumors are believed to arise from either Hansen's node or ectopic primordial germ cells.[185,186] The majority of SCTs diagnosed perinatally are benign, but malignant degeneration complicates up to 10%, especially when there is a delay in resection or when the tumor is not entirely resected.[185,186] Lesions with foci of immature cells are described in 10% to 15% of cases.[187,188] The American Academy of Pediatrics (AAP) has adopted a staging system for SCTs that grades the involvement of intrapelvic structures and, hence, the complications associated with surgical resection. Type I tumors, the most common type, are predominantly external and protrude from the perineal region with minimal, if any, presacral component. Type

Sacrococcygeal teratomas. *A*, Type 1 lesion—the tumor is entirely extrapelvic and predominantly cystic. *B*, Type 1 lesion—although the tumor is entirely extrapelvic, it is more solid appearing. *C*, Type 2 lesion—the predominant portion of the tumor is extrapelvic, but intrapelvic portions are visible. *D*, Type 4 lesion—the tumor appears to be located entirely within the fetal pelvis with no external component evident.

II lesions are primarily external but have a significant intrapelvic portion. Type III lesions are primarily intrapelvic with a small external component. Type IV tumors are completely presacral with no external component.

Diagnosis

Teratomas are generally well circumscribed without direct invasion of adjacent tissues. The most common appearance is that of a complex mass, although predominantly solid or cystic masses are also described. The most common location is caudal and dorsal in close proximity to the coccyx[186] (Fig. 22–10). Teratomas with a significant intrapelvic component can compress the urinary and gastrointestinal tracts. Fluid-filled anechoic areas may be visualized proximal to the obstruction. Immature teratomas tend to have a more solid than cystic appearance.[72] Doppler interrogation of the tumor confirms the highly vascular nature. The feeding vessels have blood flow velocities similar to the descending aorta and may have a diameter similar to the external iliac arter-

ies.[189,190] The middle sacral artery and branches of the internal iliac artery are usually the main sources of blood.[191,192] The differential diagnosis includes meningomyelocele, hemangioma, lipoma, and other rare soft tissue tumors. A lumbosacral meningomyelocele is differentiated from teratoma based on the presence of spinal dysraphism and intracranial changes. Hydramnios, placentomegaly, and fetal hydrops are associated with SCTs containing arteriovenous malformations.[185,190]

The incidence of associated anomalies ranges from 0% to 35%.[7,184,189,193] A detailed anatomic survey focusing on skeletal/vertebral anomalies is obligatory. Defects in the area of the tumor, such as distal sacral agenesis, rectovaginal fistula, and imperforate anus, are reported and likely related to tumor growth during gestation. Aneuploidy has not been reported with SCT.[147] Maternal serum AFP levels may be elevated, especially in those tumors with foci of endodermal sinus tumor. The amniotic fluid AFP and acetylcholinesterase levels may also be elevated.[194,195] MRI can aid in ascertaining intrapelvic involvement. This information is useful in both counseling the parents and planning surgical resection.[196–198]

Risks

The prognosis for antenatally diagnosed SCT differs from that of postnatally diagnosed lesions, with estimates of mortality rate ranging from 12% to 68%.[184,190,199,200] The main causes of perinatal death are hydrops, intrapartum trauma, and postnatally either difficulties with resection or hemorrhage secondary to tumor vascularity.[185] An arterial steal syndrome often develops if the tumor contains arteriovenous malformations. The fetus may develop high-output failure due to limited cardiac pumping ability and anemia secondary to sequestration of blood in the tumor.[187–190] Because larger tumors require greater blood flow, fetuses with large, vascular, and especially solid tumors are more likely to develop hydrops.[186–188,190] The mortality rate is greater than 90% if hydrops develops.[184,185,190,200,201]

Other predictors of poor outcome include a second-trimester diagnosis and delivery before 34 weeks' gestation.[185] The risk of preterm delivery correlates with the size of the tumor and the presence of hydramnios.[187] Survival has been reported to increase from 25% for fetuses delivered before 34 weeks' gestation to 88% for those born after 34 weeks' gestation.[185] Survival was halved when the diagnosis was made prior to 30 weeks' gestation (41% vs. 84%).[185] In cases of large teratomas, defined as diameters greater than 10 cm, there was no relationship between survival and gestational age, suggesting that the risks of prematurity must be weighed against complications from further enlargement of the SCT.[202] Not only are large tumors associated with an increased risk of hydramnios, hydrops, and prematurity, they are also associated with an increased risk of dystocia, intrapartum injury, hemorrhage, or rupture, regardless of the mode of delivery.[184–186,188]

The most important variable affecting long-term outcome is the adequacy of tumor removal.[72] The presence of a substantial presacral component is associated with a worse prognosis because of the complexity involved with resection. Optimal treatment consists of an en bloc removal of the tumor and coccyx. However, with extensive presacral involvement, this cannot always be accomplished. Although both mature and immature teratomas are equally resectable, there is a greater risk of intraoperative hemorrhage with an immature teratoma, reflecting its increased vascularity. The identification of frankly malignant elements, especially endodermal sinus or embryonal cell tissue, markedly worsens the prognosis. If the primary tumor is not completely resected, there is an increased risk for recurrence, often with malignant components.[72]

Management Options

Counseling should be provided when the evaluation, including MRI, is complete. If the tumor is identified at an early gestational age or is associated with hydrops, termination of pregnancy should be offered. Serial antenatal ultrasound examinations are indicated to assess fetal well-being and to evaluate tumor growth. If hydramnios develops, amnioreduction may improve maternal symptoms and delay the onset of preterm delivery. If preterm labor develops, tocolysis can be attempted. In the fetus without evidence of cardiac decompensation, delivery is planned at or near term in a tertiary center. If signs of fetal cardiac decompensation develop after 30 weeks, corticosteroids should be administered to improve postnatal pulmonary function and delivery expedited. The optimal management for the fetus with hydrops at earlier gestational ages is unclear, but the prognosis for these fetuses is dismal.

Operative intervention to interrupt the vascular shunt in preterminal fetuses with hydrops has been attempted. Open fetal surgery with in utero debulking or complete resection of the tumor was reported in eight cases, with three long-term survivors.[203,204] Radiofrequency ablation via a percutaneous electrode has been reported in four fetuses; two died after the procedure owing to intratumor hemorrhage. The hydrops reversed in the two surviving fetuses, but both were found at birth to have large areas of soft tissue necrosis requiring reconstructive surgery.[191] Further refinement is needed.

Because of the risk of intrapartum traumatic injury, rupture, and hemorrhage, cesarean delivery prior to the onset of active labor is recommended for fetuses with an SCT greater than 5 to 10 cm in diameter.[184–188] A large vertical uterine incision is required to minimize delivery trauma, which may trigger massive hemorrhage. Type O-negative blood should be available for the neonate. Vaginal delivery may be considered if the tumor is smaller than 5 cm, with an emergency cesarean delivery should any evidence of fetal hemodynamic compromise develop.[186,192] Percutaneous aspiration of a large, predominantly cystic teratoma to facilitate vaginal delivery has been reported.[205] Regardless of the mode of delivery, successful management requires the multidisciplinary efforts of maternal-fetal medicine specialists, neonatologists, anesthesiologists, and pediatric surgeons.

Neonates who are stable and have no complications of prematurity will typically undergo surgical resection within the first few days of life. Although, in some, surgical trauma to the sacral and pelvic nerves results in urologic or bowel dysfunction, most neonates have excellent functional and cosmetic outcomes.[187,188] The long-term prognosis is determined by the extent of intrapelvic involvement and the ability to completely resect the tumor mass.

LIMB TUMORS

Limb masses are usually either soft tissue tumors (such as fibrous connective tissue tumors, lipomas), skeletal muscle tumors, or tumor-like conditions such as vascular or lymphatic anomalies or hamartomas.

Diagnosis

Soft tissue tumors are usually identified at birth or during neonatal life. In the neonate, most soft tissue limb tumors present as a palpable mass in fascia, muscle, or subcutaneous tissue or a smooth, solid, asymmetrical enlargement of a digit or extremity.[8] Hemangiomas are the most common tumors diagnosed in the neonate, but they are rarely identified before birth.[206]

Infantile fibromatosis is a benign neoplasm of fibrous tissue that occurs in fascia, muscle, or periosteum. This lesion is a type of proliferative fibroblastic disorder difficult to distinguish from low-grade fibrosarcoma and, although locally aggressive and subject to recurrence, is not associated with metastases.[8] Digital fibromas are among the most common of these lesions.[206]

Fibrosarcoma and rhabdomyosarcoma are the two most common malignant soft tissue tumors. Fibrosarcoma is usually cured by local resection, but rhabdomyosarcoma has a propensity for early metastasis and has, therefore, a less favorable prognosis.[207,208]

Congenital lymphangiomas appear ultrasonographically as multicystic masses with anechoic cyst cavities and often result in hypertrophy of the affected extremity. Because of an association with fetal aneuploidy, especially Turner's syndrome, fetal karyotyping should be offered.

Klippel-Trenaunay syndrome is a rare congenital syndrome with generalized mesodermal abnormalities including macular vascular nevus, skeletal and soft tissue hypertrophy, and venous varicosities due to abnormal small vessels.[209,210] Unilateral leg hypertrophy is the most frequent finding on ultrasound, but any extremity may be involved, as may an entire half of the body including the head and brain.[210] The finding of a complex mass in the subcutaneous tissue in the presence of hypertrophy of a limb or other body part is highly suggestive.[210] Proteus syndrome shares several features with Klippel-Trenaunay syndrome, including asymmetrical focal overgrowth, hemihypertrophy, and subcutaneous vascular abnormalities but is distinguished by the presence of warty pigmented nevi and lipoid visceral tumors.[211] This distinction may not be possible antenatally. Both syndromes have a variable prognosis.[211,212]

Risks

Vascular tumors are associated with an increased risk of fetal cardiac decompensation. Kasabach-Merritt syndrome, a consumptive coagulopathy due to intralesional clotting and platelet sequestration, occurs in superficial vascular malformations and can be life-threatening. It is reported in the neonatal period.[209]

Management Options

Close antenatal ultrasonographic monitoring is warranted once a lesion is suspected, not only to identify early signs of fetal compromise but also to monitor the size of the affected area. A markedly enlarged extremity or body wall can lead to dystocia; cesarean delivery may be necessary.
FIGURE 22–11
A large chorioangioma was diagnosed at 22 weeks' gestation. The tumor continued to grow over the subsequent weeks and the fetus developed severe hydramnios. Intractable preterm labor occurred at 29 weeks.
FIGURE 22–12
An isolated umbilical cord cyst was identified near the fetal end of the umbilical cord in this fetus. Doppler studies confirmed normal blood flow in the umbilical vessels.

PLACENTAL AND UMBILICAL CORD TUMORS

Tumors of the umbilical cord and placenta are rare. Most masses identified in these structures are vascular malformations or hematomas.

Diagnosis

Chorioangioma is the most common benign tumor of the placenta and is thought to be either an angioma or a hamartoma derived from primitive chorionic mesenchyme.[213] Small lesions are found in up to 1% of placentas. Tumors ranging in size from a few millimeters to more than 10 cm have been reported.[214]

The ultrasonographic appearance of a chorioangioma is that of a solid or complex mass on the fetal surface of the placenta (Fig. 22–11). Doppler interrogation will confirm the highly vascular nature of the mass and is required to distinguish these lesions from a placental or subchorionic hematoma.[214–216] The maternal serum AFP levels may also be elevated.[214]

Although exceedingly rare, placental teratomas are reported.[217,218] As with other teratomas, these tumors appear ultrasonographically as a complex mass.

Other solid masses identified in placental tissue include metastases from fetal and maternal primary tumors, especially melanoma.[219] Although antenatal identification of such lesions has yet to be described, they should be considered in the differential diagnosis of solid placental masses when the clinical scenario warrants.

The most commonly identified umbilical cord masses are hematomas, true cysts, and pseudocysts. An umbilical cord hematoma appears ultrasonographically as a cylindrical solid mass occluding the umbilical vein. Doppler studies may reveal turbulent flow in the area of the hematoma. True cysts in the umbilical cord are remnants of the omphalomesenteric duct or allantois and are usually located near the fetal end (Fig. 22–12). Pseudocysts are more common and represent localized degeneration and edema of Wharton's jelly, usually near the fetal end of the cord.[220,221] The differentiation between pseudocysts and true cysts cannot be made on ultrasound. Hemangiomas of the umbilical cord and varicosities of the umbilical vein are also seen antenatally, as are teratomas. Masses located at the fetal cord insertion site must be distinguished from omphalocele.[222–224]

Risks

If a chorioangioma is 4 cm or larger, the risk of hydramnios, and its attendant risks of preterm delivery and maternal morbidity, is at least 30%.[214] Large chorioangiomas contain significant arteriovenous shunts and are associated with an increased risk of high-output fetal cardiac failure due to sequestration of blood within the tumor. The prognosis is

SUMMARY OF MANAGEMENT OPTIONS
Placental and Umbilical Cord Tumors

Management Options	Evidence Quality and Recommendation	References
Carefully search for other abnormalities with umbilical cord cysts.	IIb/B	219
Assess for hydramnios and hydrops.	IV/C	212
Role of transfusion or sclerosing/occlusive therapies when hydrops develops is uncertain.	IV/C	224,227

poor if the fetus develops hydrops.[214,215] The development of fetal hydrops increases the risk of the mother developing mirror syndrome.[204] Chorioangioma of the placenta is often associated with cutaneous and visceral hemangiomas in the fetus.

Any umbilical cord mass that obstructs blood flow to the fetus can lead to heart failure and hydrops. Large umbilical cord hemangiomas may be associated with sequestration or shunting leading to hydrops. True cysts of the umbilical cord are associated with other anomalies including omphalocele, patent urachus, hydronephrosis, and mesenteric duct cysts.[221] Pseudocysts of the umbilical cord are also associated with omphalocele, hemangioma, and chromosome abnormalities, especially trisomy 18 (identified in two of seven fetuses with umbilical cord cysts in one study).[221] These conditions are thought to impair local fluid transport in the umbilical cord leading to edema and myxoid degeneration of Wharton's jelly.[221]

Management Options

Once a placental lesion is identified, close antenatal surveillance is essential to follow fetal well-being and observe for cardiac decompensation. Delivery should be considered if fetal hydrops occurs after 32 weeks. At earlier gestational ages, antenatal corticosteroids should be administered and further management individualized. Fetal intrauterine transfusion has been performed in cases of fetal cardiac decompensation as a temporizing measure.[225–227] Large chorioangiomas are associated with a perinatal mortality rate of 40%. Interventions to try to decrease the arteriovenous shunting include fetoscopic coagulation, alcohol injection, and microcoil embolization of feeding vessels.[227–229] Only alcohol injection met with reported success.[228,229]

If an umbilical vein hematoma is identified, antenatal surveillance is required to demonstrate regression of the lesion. If the hematoma appears to be growing, delivery may be required to prevent complete occlusion of venous flow. The identification of a cystic structure in the umbilical cord should prompt a detailed anatomic survey. Although the true incidence of chromosome abnormalities in the presence of a cystic cord lesion is unknown, karyotype analysis should be offered, especially if other anomalies are present.

INTRODUCTION

The incidence of multiple births in the developed world has increased dramatically over the past few decades from 1 in 100 to about 1 in 60 to 1 in 70 deliveries, with a 40% increase in twinning rates and a three- to fourfold rise in higher-order multiple births. This rise in multiple births is largely attributable to the increased application of assisted reproductive techniques (ARTs), although advanced maternal age accounts for a slight increase in spontaneous conceived multiplets.[1] At present, a policy of single-embryo transfer is encouraged in an attempt to contain this multiple birth pandemic.[2,3]

In twins, about 30% are monozygotic and 70% are dizygotic (Fig. 23–1). Although mechanisms of twinning are incompletely understood, it is commonly assumed that monozygotic twins result from the fertilization of a single egg followed by early cleavage into two halves, which develop further separately. Monozygotic twins may be dichorionic, monochorionic diamniotic, monochorionic monoamniotic, and even conjoined, depending on the time between fertilization and cleavage. The longer the time span, the more structures the fetuses will share. In terms of the presence of separate placentas for each twin, the time period around the 3rd day may be important, though this theory is not based on any firm knowledge. Further, embryo cleavage has never been observed in ART laboratories before blastocyst hatching. Nevertheless, in about 30% of monochorionic twins, cleavage is thought to occur shortly after fertilization, leading to a separate placenta for each twin (dichorionic); twins that have their own placentas are always in separate amniotic sacs and, by definition, diamniotic. However, in 70% of monozygotic twins, cleavage occurs later on, resulting in a single placenta for two fetuses (monochorionic). Rarely, cleavage takes place after the 9th day, resulting in monoamniotic monochorionic twins. Finally, cleavage after the 12th day is thought to result in conjoined twins.

It is generally accepted that dizygotic twins result from the fertilization of two different eggs, and therefore, each twin has its own placenta and amniotic sac (dichorionic diamniotic). However, some experts recently questioned this assumption of double ovulation and suggest that naturally conceived dizygotic twins also result from a single ovulation and fertilization by two sperms.[4,5] The increasing number of reports on dizygotic monochorionic twins also supports the concept that dizygotic twins may arise from within the same zona pellucida.[6,7] Nevertheless, the incidence of dizygotic twins has a hereditary component and also varies with ethnic group (up to five times higher in certain parts of Africa and half as high in some parts of Asia), advanced maternal age (2% at 35 yr), increasing parity (2% after four pregnancies), and method of conception. In contrast, the incidence of monozygotic twins is fairly constant throughout the world at 4 per 1000 births.[8] After ART, the overall majority of twins are dizygotic (95%), yet 5% are monozygotic.[9] Actually, ART may increase the risk of monozygotic twinning 5- to 10-fold, with about 1 in 20 to 1 in 50 of all iatrogenic conceptions being monozygotic compared with 1 in 250 of natural conceptions.[9] Ovulation induction rather than in vitro fertilization (IVF) seems to carry the highest risk of monozygotic cleavage: 1 in 20 versus 1 in 50.[9] Several mechanisms have been put forward to explain why ART would predispose to embryo cleavage, such as hardening of the zona pellucida with ovulation induction, extended culture, and blastocyst transfer with IVF, micromanipulations of the zona pellucida with intracytoplasmic sperm injection as well as assisted hatching.[10] As for triplets and higher-order multiplets, the overall majority now result from ART and are usually polyzygotic and therefore polychorionic/polyamniotic. Nevertheless, 5% to 10% of multiple pregnancies after ART[11] and up to 50% of naturally conceived higher-order multiplets contain a monochorionic pair.[12]

CHORIONICITY

Multiplets have a more complicated in utero stay than that of singletons, with higher incidences of growth restriction, congenital anomalies, and intrauterine demise. Monozygotic twins are at higher risk for complications than their dizygotic counterparts.[13] However, at closer look, it is chorionicity rather than zygosity that determines outcome.[14] The increased morbidity and mortality rates in monochorionic twins are primarily related to the angioarchitecture of the monochorionic placenta with its almost ever-present (96%) vascular anastomoses (Fig. 23–2),[15,16] which are virtually absent in dichorionic twin pregnancies. These vascular
FIGURE 23–2

(In collaboration with M. Cannie, UZ Leuven, Belgium.)

anastomoses are randomly distributed and can cause significant blood volume shifts between the fetuses, leading to unique complications such as twin-twin transfusion syndrome (TTTS), twin reversed arterial perfusion (TRAP), and acute fetofetal transfusion after single intrauterine fetal demise (sIUFD).[17]

Important to some selected situations, the shared circulation precludes the injection of potassium chloride for selective feticide into the target fetus' circulation. Furthermore, this single placenta, originally designed to support one fetus, has to care for two or more fetuses and is often not equally divided, explaining the increased incidence of poor growth in monochorionic compared with dichorionic multiplets.[16,18] Consequently, perinatal mortality of monochorionic twins is nearly twice as high as dichorionic twins (2.8% vs. 1.6%) and four times as high as singletons (2.8% vs. 0.7%). However, perinatal statistics underestimate the problem, because the highest fetal loss rate occurs prior to viability. As such, monochorionic twins have a sixfold higher fetal loss rate (12%) between 10 and 24 weeks than that of dichorionic twins and singletons (2%), which is largely attributable to complications of the TTTS.[19] Also, there is a direct relationship between the timing of embryo cleavage and the risk of adverse outcome, with monoamniotic and conjoined twins having the highest complication rate. For these reasons and until a proper regimen has been established, we currently perform an ultrasound scan every 2 weeks in all monochorionic twins, whereas dichorionic twins are seen on a monthly basis.

Management issues are also complicated by the fact that two or more fetuses have to be taken into account. This especially applies to monochorionic multiplets, in whom the well-being of one fetus critically depends on that of the other, because their fates are invariably linked by the vascular anastomoses in the shared placenta.

Correct determination of chorionicity is, therefore, of utmost importance to identify this high risk group, for which increased monitoring may improve outcome. Moreover, it is essential for genetic counseling and for the management of

Chorionicity determination on the first-trimester ultrasound scan. *A,* Monochorionic diamniotic twins: only two thin amniotic membranes (*arrows*) separate the two fetuses. *B,* Both yolk sacs are in a common coelomic cavity. *C,* The insertion of intertwin membrane on the chorionic surface is T-shaped; dichorionic diamniotic twins. *D,* The fetuses are separated by three layers (amnion, chorion-chorion, amnion), and the yolk sacs are in separate coelomic cavities. *E,* Where the placentas fuse, a wedge-shaped junction (Y sign) is seen.
discordant anomalies, discordant growth, and in utero demise of one twin.

Determination of chorionicity is highly accurate when performed prior to 14 weeks' gestation (100% sensitivity and 99% specificity).[20,21] At these early stages in pregnancy, the amniotic membrane is still separated from the chorion. Chorionicity determination is, therefore, simply a matter of counting the layers that separate the twins (Fig. 23–3). If there are two thin layers (two amniotic sacs) and two thick separate chorionic plates or one fused chorion (beyond 9 wk) that forms a lambda at insertion on the placenta, then they are dichorionic diamniotic. However, if there are only two thin layers (two amniotic sacs) separating the two twins, then they are monochorionic diamniotic twins. Later on in pregnancy, because of close apposition of the amnion and chorion and regression of the chorion laeve, it becomes far more difficult and often not possible at all to determine whether same-sex twins do or do not share a common placenta. Only examination of the placenta after birth will give a definite answer. Therefore, failure to determine chorionicity in multiple pregnancies undergoing first-trimester scanning is now considered substandard care. In contrast to chorionicity, it is not possible to determine zygosity of dichorionic same-sex twins on ultrasound scan: approximately 8 out of 10 will be dizygotic, but still 2 out of 10 will be monozygotic. Only genetic examination (DNA fingerprinting) can then determine zygosity, which prenatally would require an amniocentesis of both sacs. After birth, zygosity of same-sex dichorionic twins is best determined on buccal smears from both twins.[22]

Fetal Risks

Poor Growth

Multiplets are particularly prone to poor intrauterine growth, because the human uterus appears less capable of adequately nurturing more than one fetus to term.[23] Consequently, the percentage of small–for–gestational age (SGA) babies (birth weight < the 10th percentile of singleton nomograms) is about 27% in twins[24] and 46% in triplets.[25] Growth curves for twins and triplets are similar to those of singletons up to 28 weeks' gestation, when the growth velocity of multiplets begins to fall. In twins and triplets, the average birth weight crosses the 10th percentile for singletons after 38 and 35 weeks' gestation, respectively,[23] when the majority of twins and triplets actually have already been born.[26] Some authors consider this growth restriction physiologic and therefore advocate for the use of twin-[24] or triplet-[25] specific nomograms. However, twins who are SGA according to singleton standards are at equal risk of perinatal mortality compared with SGA singletons.[27] Thus, the concept that being small is "normal" for twins creates a false sense of security, with possible deleterious consequences in this high risk population. Because the similar impact of size on outcome for singletons and multiplets, singleton growth charts should be used for the clinical management of twin pregnancies.

Accurate pregnancy dating and knowledge of the chorionicity are essential, and both are most reliably determined in the first trimester.[20,21] Two methods are used to describe growth in multiplets: the growth of each individual fetus and the difference (Δ) in sonographic estimated fetal weight (EFW) between the individual fetuses (discordant growth).

A fetus is considered SGA when both the abdominal circumference and the EFW are below the 10th percentile. The EFW prediction in twins is reliable and as accurate as it is in singletons.[28] The chance of both fetuses being SGA is twice as high in monochorionic (17%) as in dichorionic (8%) twins,[19] revealing that a single placenta is less efficient for two fetuses.

The degree of discordant growth, expressed in percentages, is determined as $(A - B) \times 100/A$, where A is the weight of the heavier fetus and B is the weight of the lighter fetus. Severe growth discordancy is usually defined as a weight difference of 25% or more. It occurs in about 12% of twins[19] and 34% of triplets[29] and more commonly affects primiparous women.[30] The most accurate parameter to detect growth discordance is to compare the abdominal circumferences: a difference of more than 20 mm after 24 weeks has a positive predictive value of 83% for a birth weight difference of greater than 20% (Fig. 23–4).[31] Nevertheless, even ΔEFW may accurately predict the actual discordance at the time of birth.[32] In each pair of discordant twins, the heavier twin is usually appropriate for gestational age (AGA), whereas the lighter twin eventually becomes growth-restricted.[33]

Although severe growth discordancy complicates monochorionic (11%) as often as dichorionic (12%) twins,[19] the growth pattern and underlying pathophysiology are probably different. The onset of discordant growth in monochorionic twins is unpredictable and might present early as well as late in pregnancy,[34] whereas in dichorionic twins, the discordancy usually becomes apparent only later

FIGURE 23–4
Ultrasound image illustrates the difference in abdominal circumference in a monochorionic twin pair with discordant growth at mid gestation.

in pregnancy.[33] Monochorionic twins are, by definition, monozygotic and thus have the same genetic growth potential. Occasionally, unequal allocation of blastomeres may alter the growth potential of some monochorionic twins and account for very early discordant growth.[35]

Three factors seem to influence growth in monochorionic twins: the division of the single placenta between the fetuses,[17,18] the vascular anastomoses,[17,36] and the effectiveness of invasion of each placental portion into the spiral arteries.[37] These factors determine the magnitude of venous return upon which the fetus depends for its oxygen and nutritional supply. Unequal placental sharing is probably the most important determinant for discordant growth in monochorionic twin pregnancies.[16,18] Although it remains impossible to adequately assess the venous return and functional placental territory for each individual twin antenatally, the umbilical cord insertion site provides a good estimate.[18,38] Placental studies reveal that the combination of a velamentous and eccentric cord insertion is three times more common in monochorionic than in dichorionic twins (18% and 6%, respectively). In addition, nearly half of these monochorionic twins have a birth weight discordancy of 20% or more.[39] The site of the umbilical cord insertion can be accurately determined sonographically between 18 and 20 weeks' gestation (Fig. 23–5)[40] and identifies a group of monochorionic twins at high risk for discordant growth. Vascular anastomoses also influence fetal growth in monochorionic twins. Unequally shared placentas usually have larger anastomoses and thus a more elaborate intertwin transfusion, which may decrease the birth weight discordancy by increasing the oxygen and nutrient supply to the twin on the smaller placental share.[17] In scenarios with an unbalanced intertwin transfusion as in TTTS, the net flow will reduce and increase the birth weight of the donor and recipient, respectively. When the unbalanced flow is toward the twin with the smaller placental share, this may be advantageous. This so-called rescue transfusion could explain concordant growth in some monochorionic pairs with gross unequal placental sharing.[15] Conversely, an unbalanced flow may also lead to severe discordant growth in pairs with an equally shared placenta, especially if the flow is toward the twin with the larger placenta part.[41] Finally, growth in monochorionic twins may be determined by suboptimal implantation of the placental portion of the smaller twin, as suggested by the increased resistance of the blood flow in the spiral arteries of the smaller twin's portion of the placenta.[37]

DIFFERENCE BETWEEN TTTS AND DISCORDANT GROWTH

TTTS	Discordant growth
• Hydramnios (DVP > 8 cm) in sac recipient	• Normal amniotic fluid (DVP < 8 cm) in appropriately grown fetus
• "Stuck twin" = donor	• "Stuck twin" = growth restricted fetus

FIGURE 23–6
Differential diagnosis of twin-twin transfusion syndrome and discordant growth. DVP, deepest vertical pocket.

Dichorionic twins are dizygotic in about 90% of cases, and therefore, a different genetic growth potential might account for discordant growth; one twin may be "normal" SGA whereas the other may be "normal" AGA. In addition, each twin has its own placenta without vascular anastomoses connecting the separate fetoplacental circulations. Suboptimal trophoblastic invasion of placenta of the smaller twin may also account for growth restriction via similar mechanisms as in singletons.[42] Furthermore, growth discordance in dichorionic twins has been found to be greater in fused placentas than in separate placentas.[43]

Several investigators have addressed the use of uterine artery Doppler velocimetry at 18 to 24 weeks' gestation to predict growth restriction in twin pregnancies,[44,45] demonstrating a disappointing sensitivity of 10%. Mean uterine artery resistance is lower in twin than in singleton pregnancies, probably because of a larger placental implantation area. In addition, the normally implanted portion of the placenta supplying the AGA twin may attenuate the hemodynamic effects of suboptimal implantation of the portion of the placenta supplying the SGA twin.[46]

Other Fetal Risks

Fetal risks associated with growth restriction for multiplets are similar to singletons (see Chapter 11) and include intrauterine fetal demise and neurologic morbidity due to chronic oxygen and nutrient deprivation. Erythropoietin levels are elevated in SGA compared with AGA twins, and in twins with discordant growth, in the lighter of twins compared with the heavier.[47] Likewise, nucleated red blood cells tend to be higher in the lighter twin than in the larger; the difference increasing with greater discordancy.[48] These findings further support the concept that poor growth in twins is not "physiologic" but rather indicative of chronic hypoxia. SGA dichorionic twins have similar risks of perinatal mortality compared with singletons, whereas the perinatal mortality for SGA monochorionic twins is twice as high.[27]

Growth discordancy (birth weight difference ≥ 25%) as well as being SGA confers an increased risk for adverse perinatal outcome. Although most discordant pairs contain one or two SGA infants,[49] discordant pairs in which both are AGA still face elevated risks compared with nondiscordant pairs[50]; twins who are both SGA and discordant have the highest risks.[51] The same applies for triplets with higher degrees of discordancy associated with increasing rates of in utero demise in the smaller and middle-sized fetuses.[52]

As mentioned previously, growth-discordant monochorionic twins are at higher risk of adverse outcome than discordant dichorionic twins.[53] Unfortunately, most of the earlier data was a mixture of pregnancies with TTTS and discordant growth. Although TTTS is frequently associated with discordant growth, its distinction from isolated discordant growth is essential and based on the sonographic absence of hydramnios (deepest vertical pocket ≥ 8 cm prior to 20 wk, ≥10 cm after 20 wk) in the AGA twin in cases with discordant growth (Fig. 23–6).

Recently, several studies have addressed the pregnancy outcome of isolated discordant growth in monochorionic pairs. It complicates about 10% to 15% of all monochorionic twin pregnancies and carries an overall mortality rate of about 10%.[54,55] In about half of these, the discordancy presents at or prior to 20 weeks (early-onset), whereas in the other half, it appears only later on (late-onset). Pairs with early-onset discordant growth usually have an unequally shared placenta with large intertwin anastomoses. Also, most have abnormal umbilical artery Doppler measurements from 16 weeks onward, and consequently, the mortality is highest in this group with early-onset discordant growth (17%). Conversely, pairs with late-onset discordant growth usually have equally shared placentas with smaller anastomoses. Also, umbilical artery Doppler measurements are usually normal throughout pregnancy and their mortality rate is much lower (4%) than those with early-onset discordant growth. In a third of the pairs with late-onset discordant growth, severe hemoglobin differences are present at the time of birth. This complication is referred to as TAPS (twin anemia polycythemia sequence). This late intertwin transfusion imbalance may account for the growth discordancy and measurement of the peak systolic velocity (PSV) of the middle cerebral artery (MCA) plays an important role in the follow-up of these cases.[34]

Classification of growth restriction or discordance can also be based on the Doppler characteristics of the umbilical artery in addition to the gestational age at first presentation.[56] If a large arterioarterial (AA) anastomosis is present, such as is typically seen in cases with early-onset discordant growth, this may result in a cyclic variation in the diastolic flow component of the umbilical artery Doppler image and, thus, an intermittent absent or reversed end-diastolic flow pattern in the umbilical artery of the smaller twin that shows cyclic variations. Growth-discordant monochorionic pairs may thus have either a normal umbilical artery flow pattern (type I), a persistent absent or reversed end-diastolic flow (type II) or an intermittent absent or reversed end-diastolic flow (type III). Each of these types has distinct placental features and a different clinical outcome. Large AA anastomoses (>2 mm) are present in 70%, 18%, and 98% of type I, type II, and type III, respectively. Pregnancies with normal umbilical artery Doppler measurements (type I) have the most favorable outcome with a low risk of deterioration or unexpected demise, whereas a persistent absent end-diastolic flow (type II) carries the worst prognosis because 90% eventually show signs of deterioration and imminent demise. In fact, type II cases behave quite similar to severely growth-restricted singletons with an abnormal umbilical artery Doppler pattern. Finally, pregnancies with an

intermittent absent end-diastolic flow pattern (type III) have an intermediate prognosis, but are the most unpredictable. Because of the presence of large AA anastomoses, unexpected demise without any signs of deterioration occurs in about 15% of fetuses and half of these are double demises.[57] As mentioned previously, abnormal umbilical artery Doppler patterns are largely restricted to the group with early-onset discordant growth and most have an intermittent absent end-diastolic flow pattern (type III).[34] Better criteria are urgently needed to distinguish the discordant-growth pairs with favorable outcome from those with high risk of an adverse pregnancy and long-term neurodevelopmental outcome. A subclassification based on uterine artery Doppler may help refine the prognosis. However, a large prospective series of monochorionic pairs is first necessary to document the prognosis according to the different Doppler patterns and to refine the current classification system.

In dichorionic twins with discordant growth, the pattern of deterioration of the growth-restricted twin follows that of a growth-restricted singleton. In a series of growth-discordant dichorionic twins managed expectantly until 32 weeks, the mortality was 24% with the larger twins surviving in all cases.[58]

Twins with growth restriction and discordant growth also face increased risks of neonatal morbidity and mortality.[59,60] In discordant pairs, the lighter twin more frequently has a low 5-minute Apgar score and is at higher risk of neonatal demise, whereas the heavier twin has more respiratory difficulties when delivered between 33 and 36 weeks.[50] The fear of an intrauterine demise may prompt obstetric intervention, adding complications of iatrogenic preterm birth to the inherent complications of multiple gestations.[61] Clearly, any decision for iatrogenic preterm delivery to prevent intrauterine demise must be weighed against the risks of demise and handicap for each twin as determined by gestational age and EFW.

Finally, growth restriction is associated with increased risks of neurodevelopmental delay[62] and cerebral palsy.[63] Likewise, twins with discordant growth are at increased risk of neurodevelopmental morbidity and cerebral palsy compared with nondiscordant twins, and monochorionic pairs probably have the highest risk. Nevertheless, the magnitude of this risk for monochorionic twins is unclear and the reports conflicting. In one series of preterm twin pregnancies born between 24 and 34 weeks, the rate of impairment and cerebral palsy in growth discordant monochorionic twins was 42% and 19%, respectively, compared with 13% and 1% in growth-discordant dichorionic twins.[64] Other reports also suggest a high risk of parenchymal brain damage (12%–20%), particularly in the larger twin of a monochorionic twin pair with intermittent absent end-diastolic flow in the umbilical artery (type III).[57,65,66] Yet, all of these studies include referral cases, which likely creates a bias toward worse outcome. Other studies failed to find that either discordant growth or a birth weight less than the 10th percentile are significant risk factors for impairment.[67,68] As such, only large prospective follow-up studies of pairs with follow-up from the first trimester until infancy will establish the true morbidity of discordant growth in monochorionic twin pregnancies and can identify risk factors for adverse outcome.

Management Options

Similar to singletons, the goals of management are to prevent intrauterine demise and long-term neurologic damage due to poor oxygenation and nutritional supply. Though this discussion is restricted to twins, because twins are far more common than triplets, growth problems are more frequent and occur earlier in higher-order multiplets, and the management issues are comparable. Because of the different pathophysiology and prognosis, the managements of monochorionic and dichorionic twin gestations are discussed separately.

Dichorionic Twins

Dichorionic twins are conceptually singletons who happen to occupy the same womb at the same time. Thus, the diagnostic workup and follow-up are comparable with those of a growth-restricted singleton (see Chapter 11).

Prenatal Diagnosis

In instances of severe early-onset growth restriction, it is important to look for signs of aneuploidy and rule out structural anomalies and congenital infection because these fetuses will not, for the most part, benefit from intense antenatal surveillance and iatrogenic early birth. Study of Doppler flow profiles in multiple vessels can help to differentiate the hypoxic, growth-restricted fetus from the constitutionally or abnormal SGA but normoxic fetus.

Fetal Surveillance

Methods of fetal surveillance for growth restriction in dichorionic twins include a combination of fetal growth and amniotic fluid assessment, nonstress test, biophysical profile score, and Doppler velocimetry. Similar to singletons, uteroplacental dysfunction is associated with a sequence of Doppler and fetal biophysical profile changes, suggesting progressive deterioration and hypoxia.

Treatment

The risk of intrauterine demise with expectant management must be balanced against the risks of iatrogenic preterm birth. When both twins are growth-restricted to a similar degree (which is rare), the risks are similar for both. However, the most common scenario is discordant growth with one growth-restricted twin. The Doppler changes that allow the reliable identification of fetal hypoxemia are discussed in Chapter 11. Early delivery to rescue the hypoxemic twin may expose the AGA twin to the risks of prematurity. Therefore, it may be preferable in dichorionic twins with severe early-onset discordant growth to delay delivery until the risk of demise and handicap due to prematurity are minimal for the AGA twin, irrespective of the condition of the SGA twin. In one series, such an expectant management until 32 weeks or when EFW of the AGA twin was more than 1500 g resulted in intrauterine demise of the SGA twin in 35% of pregnancies, but no death or handicap in the AGA co-twins.[58] The initiation of intensive fetal surveillance must be planned accordingly. The timing of any intervention depends on the clarity of the diagnosis in the SGA twin and the chances of survival with and without handicap for each fetus. Though the efficacy of antenatal corticosteroid therapy to enhance maturation has not been sufficiently studied in twins, the available information suggests it is reasonable to use with discordant twins whenever an early delivery is contemplated. One can also test for fetal lung maturity if there is an option to delay delivery; it is generally recommended to sample both sacs, especially before 32 weeks.[69]

Monochorionic Twins

Monochorionic twins have an identical genetic constitution (though they will differ epigenetically) and share a single placenta with their circulations connected through vascular communications in the placenta. As such, the management of growth restriction in monochorionic twin pregnancies poses some unique challenges.

Prenatal Diagnosis

The need to search for signs of aneuploidy and exclude discordant structural anomalies and congenital infection also applies to monochorionic twins. Monochorionic twins can be discordant for most common human aneuploidies.[35,70–72] Both amniotic sacs must be sampled in order to diagnose these rare heterokaryotypic monochorionic twins. In addition, structural anomalies are more common in monochorionic twins[73] and usually affect only one fetus.[55,74] Conversely, congenital infection typically affects both twins, although the severity may vary. It is equally important to distinguish discordant growth from TTTS by the absence of hydramnios in the sac of the AGA twin.

Fetal Surveillance

It is unclear what the best method is to monitor fetal well-being in growth-restricted monochorionic twins. Doppler velocimetry of the umbilical artery may not have the same prognostic value that it has in singletons and dichorionic twin gestations. Umbilical artery waveforms reflect downstream vascular resistance, which in monochorionic twins is determined not only by the adequacy of spiral artery invasion but also by the direction and shunting across the vascular anastomoses. Large AA anastomoses can, therefore, influence umbilical artery waveforms, leading to intermittent absent end-diastolic or even reversed flow.[75] This phenomenon occurs typically in the SGA twin of a monochorionic pair with severe early-onset growth discordance (Fig. 23–7).[56,76,77] Intrauterine demise may occur unexpectedly in these fetuses, without additional signs of deterioration of either the Doppler flow profile or the biophysical profile score, because these large AA anastomoses may facilitate acute exsanguination or other hemodynamic aberrations. Conversely, the SGA twin in some cases of discordant growth may have absent end-diastolic flow from early on in pregnancy for up to 15 weeks, without any adverse effect on

FIGURE 23–7
Doppler pattern of intermittent absent end-diastolic flow as typically seen in the smaller twin of a monochorionic pair with discordant growth.

fetal survival.[78] Prior to 28 weeks, we usually review growth-discordant monochorionic pairs with abnormal umbilical artery Doppler patterns and/or discordant amniotic fluid on a weekly basis for Doppler studies and assessment of amniotic fluid volumes. From 28 weeks onward, we admit those with abnormal umbilical artery Doppler patterns for twice-daily cardiotocography (CTG) and twice-weekly Doppler and biophysical profile scores and administer corticosteroid agents. Those with normal umbilical artery Doppler patterns are further followed on a weekly basis. In cases in which the discordant growth presents for the first time in the latter half of pregnancy, measurement of the PSV of the MCA may play an important role to detect the occurrence of TAPS as a cause of the late-onset discordant growth.[34]

Treatment

In monochorionic twins, the management is complicated by the almost obligatory presence of a shared circulation. In dichorionic twins, sIUFD is associated with demise or handicap of the surviving twin in 4% and 1% and is largely attributable to extreme preterm birth. In contrast, sIUFD in monochorionic twins leads to double intrauterine fetal demise (dIUFD) in about 12% and neurologic impairment in 18% of surviving co-twins.[79] This extra morbidity and mortality is due to a combination of pressure instability as the first twin dies and acute exsanguination in the fetoplacental unit of the demised twin, all in addition to the effects of extreme preterm birth. Expectant management irrespective of the condition of the SGA until 32 weeks is, therefore, not appropriate in monochorionic twins. Possible management options for severe early-onset discordant growth in monochorionic twins are expectant management with timely birth, selective feticide by umbilical cord occlusion, or selective coagulation of the vascular communications. The problems with expectant management are that intrauterine demise may occur before viability, is difficult to predict, and might have major consequences. Demise is especially dramatic once a viable stage of gestation has been reached. As a result, some advocate elective preterm birth of all monochorionic twins with a growth discordance of more than 25% at 32 weeks after the administration of maternal corticosteroids or, at the latest, after confirmation of fetal lung maturity.

Umbilical cord occlusion may be considered prior to viability when there are signs of imminent fetal demise. The rationale for cord occlusion is that it may better protect the surviving twin against the adverse effects of spontaneous demise. However, a major drawback is that the maximum survival rate is 50%. Further, it is not always clear which signs predict impending demise in monochorionic twins. We usually offer cord coagulation when the smaller twin develops anhydramnios, persistent absent or reversed flow in the ductus venosus, or an arrest of growth over a 3-week observation period prior to viability.

Selective photocoagulation of the vascular anastomoses as it is currently performed in the treatment for TTTS also seeks to protect the AGA twin against the adverse effect of sIUFD of the SGA twin by "unlinking" the two fetal circulations. However, a small case series comparing treated and expectantly managed cases series did not show any significant difference in survival or short-term neurologic morbidity.[80,81] Several explanations for this apparent lack of benefit are possible. First, selective coagulation is technically more
challenging for discordant growth than for TTTS owing to the absence of hydramnios. Second, unequal sharing is frequently the reason for discordant growth, and coagulation of the vascular anastomoses might further diminish the already critical placental reserve of the SGA twin. Third, the elaborate intertwin transfusion in these unequally shared placentas may benefit the SGA twin by increasing its oxygen and nutrient supply. And finally, the survival rate of early-onset discordant growth is about 85%,[34,57] in contrast to a nearly 100% mortality of untreated mid-trimester TTTS. Also, long-term neurologic outcome of discordant growth appears to be much better than that of TTTS.[68] As such, a recent series on laser coagulation of the vascular anastomoses as a treatment for discordant growth with intermittent absent or reversed end-diastolic flow (type III) showed a survival of only 64% in contrast to the 85% survival rate in conservatively managed cases.[57] An overactive management might risk the loss of pregnancies that would have reached viability without demise of the SGA fetus. The potential role of laser coagulation of the vascular anastomoses in the management of discordant growth is currently the subject of a randomized controlled trial.[82]

Twins of Unknown Chorionicity

Determining chorionicity in same-sex twins with discordant growth in the second trimester can be challenging. Oligohydramnios with the intertwin membrane plastered around the

Characteristic bidirectional Doppler pattern in an arterioarterial anastomosis, which confirms monochorionicity.
SGA twin makes assessment of membrane thickness or the presence or absence of a lambda sign especially unreliable. It is estimated that just 3 out of 10 same-sex twins have monochorionic placentation. In these instances, the detection of an AA anastomosis with its characteristic bidirectional waveform (Fig. 23–8) confirms monochorionicity with 100% reliability.[83] Also, DNA determination of zygosity by amniocentesis generally rules out monochorionicity if dizygosity is confirmed.[84] In cases of persistent doubt, it is prudent to manage the pregnancy as a monochorionic twin gestation.

SUMMARY OF MANAGEMENT OPTIONS

Poor Fetal Growth in Twin Pregnancies

Management Options	Evidence Quality and Recommendation	References
Dichorionic Twins		
Exclude aneuploidy, structural anomalies, and congenital infection.	—/GPP	—
Determine when to intervene upon signs of fetal distress of the SGA twin and plan fetal surveillance accordingly.	See Chapters 10, 11 and 12	
In severe early discordant growth, it may be preferable not to intervene to maximize the chances of the AGA twin at the expense of spontaneous demise of the SGA twin.	III/B	58
Fetal surveillance is usually done by a combination of fetal growth assessment, biophysical profile scoring, and Doppler velocimetry.	See Chapter 10	
Consider administration of corticosteroids and fetal lung maturity testing whenever early delivery is contemplated.	Ia/A	299
Monochorionic Twins		
Exclude aneuploidy, structural anomalies, congenital infection, and TTTS.	IIa/B	70,71,73
Consider referral to a tertiary care center.	—/GPP	—
If spontaneous demise is presumed imminent and in the previable period, selective feticide by cord occlusion may protect the AGA twin better against the side effects of spontaneous demise.	IV/C	81
Consider elective preterm delivery at 32 wk for cases with a growth difference of ≥ 25% and abnormal umbilical artery Doppler pattern after administration of corticosteriods or at the latest when lung maturity has been established.	—/GPP	—
Fetal surveillance is usually done by a combination of fetal growth assessment, biophysical profile scoring, and Doppler velocimetry.	See Chapter 10	

Management Options	Evidence Quality and Recommendation	References
Nonstress testing and biophysical profile score are currently the best methods to ascertain acute fetal well-being, although IUFD can occur unexpectedly, despite normal biophysical profile scoring.	III/B	75–77

MONOAMNIOTIC TWINS

General

Cleavage of the inner cell mass day 9 to day 12 after fertilization is thought to result in monochorionic monoamniotic twins. These twins share not only their placenta but also their amniotic sac. Monoamniotic twins are rare, occurring in about 1 in 10,000 pregnancies and, as such, constitute 5% of monochorionic twins.[85] The umbilical cords insert usually close to each other mid placenta with multiple deep and superficial large-caliber (8–12 mm) anastomoses connecting the placental stem vessels of the twins (Fig. 23–9).[86,87]

The diagnosis of monoamniotic twin gestation is reliably made in the early first trimester by the presence one amniotic cavity containing two fetal poles and a single placenta. In contrast to what was previously suggested,[88] the presence of a single yolk does not necessarily prove monoamnionicity, as is the case in up to 15% of diamniotic twins.[89] Cord entanglement is diagnostic of monoamniotic twins and often already demonstrable in the first trimester by imaging two heart rates on pulsed Doppler in an entangled mass of umbilical cord vessels (Fig. 23–10).[90,91] Current ultrasound technology with sharper resolution usually permits the distinction between diamniotic and monoamniotic monochorionic twins. On occasion, transvaginal scanning at high frequencies will help confirm or refute any dividing membrane. The "stuck twin phenomenon" is regularly mistaken for a monoamniotic twin pregnancy because of the difficulty of seeing the dividing membrane. However, the fixed position of the stuck twin rules it out because in a monoamniotic gestation both fetuses move freely about.

Fetal Risks

Monoamniotic twins are at increased risk of congenital malformation and IUFD. Although rare, conjoined twins must be excluded. Conjoined twins are thought to arise when the embryonic disk incompletely divides beyond the 12th day of fertilization and has an estimated incidence of 1 in 50,000 pregnancies. The diagnosis is possible as early as the first trimester by the close and fixed apposition of the fetal bodies with fusion of the skin lines at some point (Fig. 23–11).[92] Intrauterine demise occurs in 60% of conjoined twins, and of those that are liveborn; the majority die owing to severe anomalies or as a consequence of surgery.[93] Except for conjoined twinning, congenital malformations occur in 38% to 50% of monoamniotic twins, usually affecting only one twin.[66,94] Up to a third of the perinatal mortality in monoamniotic twins is caused by congenital malformations.[95] Late embryonic cleavage and hemodynamic imbalances due to the large and multiple anastomoses may account for the extremely high prevalence.
FIGURE 23–9

In structurally normal monoamniotic twins, IUFD is the most important cause of mortality. More recent series report mortality rates of 0%[96,97] to 17%[95,98] with careful fetal surveillance and elective preterm birth compared with previously quoted risks of 30% to 70%.[99,100] However, most pregnancies included in these series were diagnosed in the second trimester, and the mortality would likely be higher should first-trimester diagnoses be included.[85] Umbilical cord entanglement was long considered the only reason for the high mortality rate, but almost all monoamniotic twins have entangled cords at birth (Fig. 23–12) and usually from early in gestation. "Acute" TTTS may be an important contributing factor, perhaps triggered by cord compression. Acute hemodynamic imbalances across the large-caliber anastomoses may also explain the 70% rate of dIUFD in monoamniotic twins compared with 25% in diamniotic twins.[86] Indeed, chronic TTTS is only rarely reported in monoamniotic twins,[98] probably because volume shifts through the large-caliber anastomoses are not tolerated for long periods and are more likely to lead to sudden death typically of both twins within a short time of each other. However, cord entanglement may still cause in utero demise[101] or asphyxia later in gestation if the co-twin survives.[102]

Management Options

The cornerstone of management is a targeted anomaly scan at 18 to 22 weeks to rule out associated anomalies, followed by scans every 2 weeks for growth and amniotic fluid volume, intense antenatal surveillance from 26 to 28 weeks onward, and timely delivery. It is the author's opinion that birth should be planned around 32 weeks, or at the latest when

lung maturity is established, because unexpected intrauterine demise may occur even after 32 weeks.[95,98] However, others have suggested the loss rates are extremely low after 32 weeks, possibly because there is less room for fetal movement.[103] Selective feticide for discordant anomalies in monoamniotic twins can be accomplished by fetoscopic/ultrasound-guided coagulation and laser transsection of the umbilical cord (Fig. 23–13).[104,105] The procedure is technically more challenging than in diamniotic twins owing to cord entanglement. An accessory port for fetoscopy may facilitate cord transsection and, to a lesser degree, help identify the correct cord, albeit with an unknown additional risk of preterm premature rupture of the membranes (PPROM) when compared with single-port procedures.

Although intrauterine demise in monoamniotic twins may be sudden and unpredictable, as mentioned previously, the best way to manage these cases is simply not known. Careful antenatal surveillance and elective preterm birth appear to improve perinatal survival to about 90%. Generally, it is
FIGURE 23–13

agreed that intense fetal surveillance should be started from 26 to 28 weeks onward, with regular nonstress testing to identify symptomatic cord compression and ultrasound scans for a biophysical profile score, Doppler, and growth checks. The recommended frequency is disputed, and in the literature, nonstress testing varies from twice weekly to several times a day. The high frequency of nonstress testing is justified by the suddenness of the events, but fetal demise in between remains possible. Some advocate weekly ultrasound examinations with a biophysical profile score, yet these fetuses are lost because of acute events and not because of chronic hypoxemia. Abnormal umbilical artery Doppler flow waveforms such as diastolic notch[106] or absent/reversed end-diastolic flow may indicate cord compression. But similar to monochorionic twins in general, the predictive value of an abnormal umbilical artery Doppler waveform may be different than in singletons and, like biophysical profile scoring, requires additional validation.[107] The need for hospitalization is likewise controversial and should be individualized based on the results of the ultrasound scan and antenatal testing,[108,109] although surveillance as an inpatient may improve survival rates.[110] The administration of sulindac was suggested as a means of medical amniodrainage to reduce fetal mobility in monoamniotic twins and thereby cord entanglement.[97,111] Yet, because acute transfusion seems to be an important cofactor, intrauterine demise can still occur after 32 weeks[95,98] despite sulindac.[85] For all of these reasons, we advocate birth at 32 weeks when feasible. Even though cases of successful vaginal birth are reported, cesarean delivery is preferred to avoid cord entanglement and inadvertent clamping of the cord of the second twin, which may be tightly around the neck of the first.[112]

IN UTERO DEMISE OF ONE FETUS

General

Fetuses of multifetal pregnancies are more likely to die in utero than singletons.[113] Not unexpectedly, the risk grows with an increasing number of fetuses.[114] The rate of sIUFD in twins or higher-order multiplets is difficult to ascertain during the first trimester, because the loss might occur before the diagnosis of either a multifetal pregnancy or an sIUFD. Also, the "vanishing embryo syndrome" might go unrecognized or be wrongly diagnosed as a retromembranous blood collection (Fig. 23–14). The diagnosis of sIUFD should be made when fetal remnants are clearly identified or when a later ultrasound scan demonstrates the demise or disappearance of a previously known fetus. The risk of sIUFD in twin pregnancies resulting from IVF, which are regularly followed throughout the first trimester, is maternal age–dependent and ranges from 10% to 20%, with most cases occurring prior to 12 weeks.[115] These figures are currently the best estimates available for first-trimester sIUFD in dichorionic twins, because about 90% of IVF pregnancies are dichorionic.[116] In one general population scanned between 10 and 14 weeks' gestation, the prevalence of sIUFD was 4% in dichorionic and less than 1% in monochorionic twin pregnancies (compared with 2% in singletons), with dIUFD in 1.6% of dichorionic and 2% of monochorionic twin pregnancies.[117] Thus, dIUFD appears more common than sIUFD in monochorionic twins. Gross unequal placental sharing or hemodynamic imbalances in monochorionic twins may cause sIUFD, with the connected fetal circulations leading to dIUFD. Also, chromosomal abnormalities or an adverse maternal factor (infection, teratogens) will affect both fetuses similarly. In contrast, sIUFD in dichorionic twins is twice as common as dIUFD and may be explained by either a discordant chromosomal or structural anomaly or suboptimal placentation. Because each fetus has a separate fetoplacental circulation, sIUFD will not cause co-twin demise per se, though whatever killed one may harm or ultimately kill the other. About 10% of dichorionic twins are monozygotic and, therefore, concordant for chromosomal anomalies.

From 10 to 14 weeks onward, sIUFD occurs in about 2% of dichorionic but 4% of monochorionic twin pregnancies, and dIUFD occurs in 0.2% of dichorionic and in at least 6% of monochorionic twins. This extra fetal loss of monochorionic twins occurs before 24 weeks and is largely attributable to complications of the connected fetoplacental circulations.[19,55]

Toward the end of gestation, the risk of in utero demise in twins increases from 1 in 3333 at 33 weeks to 1 in 313 at 36 weeks and 1 in 69 beyond 39 weeks. The intrauterine mortality of twins at 37 to 38 weeks is equal that of postterm singleton pregnancies, and elective birth at 37 to 38 completed weeks may be justified when uncomplicated twin pregnancies reach that milestone.[118]

Recently, several studies have addressed the risk of unexpected late intrauterine demise in monochorionic twin pregnancies. Barigye and associates reported that after 32 weeks unexpected stillbirth occurred in 4% of otherwise uncomplicated pairs, supporting a policy of elective preterm birth of all monochorionic twins at 32 weeks.[119] This figure was contradicted by other retrospective analyses[120–122] and one prospective series[55] that all report lower rates (1.2% and 2.1%) in complicated and uncomplicated monochorionic pairs. After 37 weeks, up to 2% of monochorionic twin pregnancies may be complicated by unexpected intrauterine demise.[123] Based on these figures, we now see all monochorionic twin pregnancies on a weekly basis for Doppler velocimetry, biophysical profile score, and nonstress testing from 32 weeks onward; for uncomplicated cases, we plan an elective birth around 37 weeks.

Fetal Risks

The prognosis of sIUFD for the surviving fetus depends first and foremost on chorionicity. To a lesser degree, outcome is determined by the gestational age of sIUFD. There is little evidence regarding the implications of sIUFD in the first trimester. Nonetheless, it seems most likely that sIUFD in a monochorionic twin pregnancy leads to either dIUFD or miscarriage. Rarely, the surviving co-twin may prevent the "vanishing" of the dead twin by reversed perfusion along the vascular anastomoses—a TRAP sequence.[124] Color Doppler should be used to exclude TRAP whenever sIUFD occurs in a monochorionic twin pregnancy, and if there is any doubt, follow-up scans should be arranged. It is also hypothesized that unrecognized early sIUFD in a monochorionic twin pregnancy may explain some cases of cerebral palsy and certain congenital anomalies such as renal agenesis and intestinal atresia in birth singletons, attributable to the
FIGURE 23–14
Ultrasound image of a retromembranous blood collection (*arrow*) in a singleton pregnancy (*A*), which must be differentiated from "vanishing twin syndrome" (*B*) in which felt remnants (*arrow*) can be clearly identified.

agonal hemodynamic events.[125] The outcome of sIUFD in the first trimester in dichorionic twins is usually favorable, although the rate of preterm birth and subsequent miscarriage may be increased especially if the sIUFD occurs toward the end of the first trimester. In the case series of sIUFD diagnosed between 10 to 14 weeks, 18% (3/16) of dichorionic twins subsequently miscarried.[91] This contrasts with the low rate of loss following selective embryo reduction.

A recent meta-analysis showed that sIUFD in dichorionic twins during the second and third trimester leads to co-twin demise or neurologic abnormality in 4% and 1%, respectively,[79] presumably in great part secondary to the conditions that lead to extreme preterm birth. Conversely, the same meta-analysis showed that in monochorionic twins, sIUFD results in dIUFD in 12%, and cerebral damage in 18% owing in part to acute intertwin transfusion plus the risks of extreme preterm birth.[79] Yet, this meta-analysis most likely underestimates co-twin mortality rate, because it covers survival only after sIUFD whereas a significant proportion of monochorionic twins present as dIUFD at first diagnosis. Also, immediate delivery after the diagnosis of sIUFD will reduce the rate of co-twin intrauterine demise, while increasing the neonatal death rate.[126] In a prospective series from Sebire and associates[19] that was not included in the meta-analysis, 10 monochorionic twin pregnancies were complicated by intrauterine demise, 6 were dIUFD from the start and only 4 presented as a sIUFD.

In dichorionic twins, survival seems inversely related to the gestational age at which the sIUFD occurred, with infant survival rates improving from 71% when the sIUFD occurs between 20 and 24 weeks to 98% for sIUFD occurring beyond 37 weeks.[114] In monochorionic twins, the influence of gestational age of sIUFD on outcome is less clear. It seems that early sIUFD is more often associated with death of the co-twin. However, if the co-twin survives, severe morbidity is less common. In contrast, a late sIUFD more frequently results in the birth of a liveborn infant who is neurologically damaged.[127,128]

The reported rate of cerebral palsy after sIUFD in dichorionic twins is 30 per 1000 infant survivors, with preterm birth the greatest association with this excess risk, compared with 1 per 1000 in singletons.[129,130] Specific cerebral palsy rates are not available for sIUFD in monochorionic twins. However, the cerebral palsy rate in same-sex twins (30% monochorionic and 70% dichorionic) after sIUFD is 106 per 1000 survivors, which is about three times higher than that of different-sex twins (100% dichorionic).[129] In addition, most of the twins in the same-sex group with cerebral palsy had monochorionic placentation.[130] Cerebral damage is often detectable sonographically but does not usually become apparent until weeks after the insult. Prenatal magnetic resonance imaging (MRI) may detect brain lesions earlier and with better definition.[131,132] Sonographic evidence of brain injury includes porencephaly, multicystic periventricular leukoencephalomalacia, ventriculomegaly, cerebral atrophy, and cerebellar or cerebral infarcts. Less frequently reported complications include renal cortical necrosis, small bowel atresia, aplasia cutis, and limb infarction. Originally, thromboembolic phenomena with passage of thromboplastin from the dead to the living twin were thought to be responsible for these lesions.[133] There is no evidence to support this line of reasoning, though

circulatory instability and acute exsanguination are well documented.[134] Reversed perfusion of the dead twin has been demonstrated by Doppler interrogation of the chorionic plate vessels,[135] and fetal blood sampling within 24 hours of sIUFD has consistently revealed a decreased hematocrit in the survivors with normal coagulation profiles.[136] Further, fetoscopy within 3 hours of the donor twin dying has documented reversal of transfusion with a plethoric donor and anemic recipient.[137] The outcome of the survivor may depend not only on the gestational age at sIUFD but also on the type and direction of vascular anastomoses and the fetoplacental mass of the dead twin. The presence of superficial AA anastomoses is associated with higher rates of death and neurologic damage.[126] However, significant anemia and co-twin demise may occur, even in the absence of AA anastomoses.[127] The outcome of sIUFD associated with TTTS treated by amniodrainage does not differ from sIUFD in untreated cases, and the risk of sIUFD is similar for donors and recipients. It has been suggested that the risk of co-twin death and neurologic damage is lower with sIUFD of the donor compared with sIUFD of the recipient, because transfusion is more likely to be directed toward the recipient.[126] However, small series show similar prevalences of anemia and adverse outcome in surviving recipients and donors.[127,138] Even though treatment by laser coagulation of the vascular anastomoses more frequently results in sIUFD than amniodrainage, it consistently leads less often to a dIUFD.[139,140] Significantly, anemia in the survivor is rare in the event of sIUFD after laser,[141] and the neurologic morbidity is lower than after amniodrainage.[142,143] These findings provide further support for the concept that the vascular anastomoses are responsible for most of the adverse outcomes associated with sIUFD in monochorionic twins.

Management Options

Knowledge of chorionicity is fundamental to the management of sIUFD in multiple pregnancies because the pathophysiology and prognosis varies, though not to complicate matters unnecessarily, our discussion is restricted to twins. Although sIUFD is more common in higher-order multiplets and management issues are more complex, they are based largely on the same principles as in twins. A small paragraph is dedicated to issues that are relevant to both groups of twins.

Dichorionic Twins

The main risks of sIUFD in dichorionic twins are miscarriage and severe preterm birth. Conservative management is advocated with regular ultrasound scans to check the growth and well-being of the survivor. Admittedly, parental anxiety may be an important factor in persuading the obstetrician to intervene, and these complex emotional responses should be adequately addressed by education rather than a precocious response.[144]

Monochorionic Twins

The main risks of sIUFD in monochorionic twins are co-twin demise and ischemic brain lesions secondary to acute exsanguination. Depending upon gestational age, there are additional risks of either miscarriage or severe preterm birth. It is presumed that death and especially ischemic brain damage

FIGURE 23–15

Doppler examination of the middle cerebral artery of the surviving twin of a monochorionic pair at 20 weeks' gestation, within 4 days after single intrauterine fetal demise (sIUFD) of the growth-retarded co-twin.
in the survivor occurs during or soon after the death of the co-twin. Therefore, a preemptive preterm birth is inappropriate once an sIUFD has been diagnosed, because this would only worsen the outcome of the surviving twin by adding the complications of preterm birth. Moreover, a long demise-to-birth interval is associated with a better outcome than a short demise-to-birth interval, supporting the premise of conservative management.[128] Monochorionic twin pregnancies with an sIUFD should be managed in a tertiary referral center with sufficient neonatal support. Also, regular detailed (transvaginal if vertex) ultrasound examinations of the fetal brain are indicated to detect brain injury. Unlike hemorrhage, ischemic brain injury is difficult to visualize in the early phase, and MRI scan may aid early detection.[131,132] MRI is also more sensitive than ultrasound scan to detect more subtle brain lesions.[145] It is recommended that an MRI be performed at least 2 weeks after sIUFD to optimize the detection of any injury. Fetal blood sampling shortly after sIUFD may have prognostic value because all nonanemic fetuses in one study had a good outcome and did not develop any brain injury.[127] MCA Doppler velocimetry effectively predicts fetal anemia after sIUFD in cases associated with TTTS and obviates the need of cordocentesis (Fig. 23–15). There is currently insufficient evidence that a rescue intrauterine transfusion improves outcome, though it may prevent co-twin demise probably too late to prevent brain injury.[127,138,146] Intrauterine transfusion may thus increase survival of severely handicapped infants. Additional multicenter studies are necessary to determine the benefit of rescue transfusion. In the meantime, it is best performed only in settings in which a late termination is an option if cerebral lesions are detected later in pregnancy.[146]

After birth, a thorough neonatal evaluation should be performed to detect any neurologic, renal, circulatory, and cutaneous defects. All survivors should undergo an early neonatal brain scan and ideally be enrolled for long-term neurodevelopmental follow-up.

Issues Applicable to Dichorionic and Monochorionic Twins

It seems justified to administer rhesus (Rh) prophylaxis whenever an sIUFD is diagnosed in a Rh-negative woman. Maternal disseminated intravascular coagulation does occur in singletons after intrauterine demise and retention of the fetus for more than 5 weeks. However, in twins, its incidence with conservative management appears extremely low, and it can be treated with heparin should it occur.[147,148] Vaginal birth is not contraindicated after sIUFD, but labor may be obstructed, especially if the sIUFD occurs late and the dead twin is presenting. A postmortem examination of the dead twin is advisable, especially if the cause is unknown, and the placenta should be sent for histologic examination to confirm chorionicity.

The family will require psychological support and counseling prior to, during, and after birth. The grief experienced after an sIUFD equals that for a singleton loss, and yet the parents rarely receive equal sympathy.[149] The death is invisible for the parents and their immediate associates, which hampers the grieving process. Many parents worry the dead twin will have an adverse effect on the remaining fetus and need reassurance that no additional harm is expected except for the possibility of an earlier birth. The delay between diagnosis and birth permits some grieving, but sorrow resurfaces at birth.[150] It is important not to ignore the deceased twin; the parents may wish to see it during ultrasound examination and after birth. Death after 12 to 15 weeks should end with an identifiable fetus at birth, though compressed and mummified, and parents should be prepared and told what to expect.[151]

TWIN REVERSED ARTERIAL PERFUSION

General

The TRAP sequence, also known as "acardiac twinning," is an anomaly unique to monochorionic multiple pregnancies that affects approximately 1 of 35,000 pregnancies and 1% of monochorionic twins.[152] In TRAP, blood flows from an umbilical artery of the pump twin in a reverse direction into the umbilical artery of the perfused twin via an AA anastomosis. The perfused (or acardiac) twin is a true parasite. Its blood is poorly oxygenated, and the hypoxemia contributes to variable degrees of deficient development of the head, heart, and upper limb structures. The lower half of the body is usually better developed, which may be explained by the mechanism of perfusion. Blood enters the acardiac twin via the umbilical artery and flows through the common iliac artery and aorta. What little oxygen is present is extracted in the lower part of the body, allowing at least partial development of the lower limbs and abdomen. By the time the blood reaches the upper body, most of the oxygen will already have been extracted, leading to poor development of upper body structures (Fig. 23–16).[148]

Two criteria must be fulfilled for the development of a TRAP sequence. The first is an AA anastomosis and the second discordant development[153] or in utero demise[101] of one of monochorionic twins, allowing for the blood flow reversal. Not infrequently, chromosomal abnormalities are identified in the acardiac twin, whereas the pump twin has a normal karyotype.[154,155] Embryos/fetuses with chromosomal abnormalities have a high risk for spontaneous intrauterine demise, which in dichorionic twins would lead to a "vanishing" twin. However, in monochorionic twins, the "vanishing" can be prevented by the occurrence of persistent, yet reversed, flow to the chromosomally abnormal twin via the vascular anastomoses. Therefore, whenever sIUFD is suspected in monochorionic twins on a first-trimester scan, the differential diagnosis or development of TRAP should be kept in mind and follow-up scans arranged.[124]

The diagnosis can be reliably made on ultrasound scan in the first trimester.[156] TRAP sequence is characterized by a grossly abnormal fetus that grows, may even show movements, but has no functional cardiac activity of its own. Rarely, a rudimentary heart may show pulsatility (Fig. 23–17). Marked hydrops and cystic hygroma are frequently

FIGURE 23–16
Macroscopic image of an acardiac twin with absent head and partial development of lower limbs and abdomen. This acardiac mass weighed about 4 kg and was not diagnosed until the third trimester. The patient delivered at 37 weeks, and the pump twin survived.
FIGURE 23–17
Doppler examination demonstrates cardiac activity in the rudimentary heart (70 beats/min) of the acardiac twin, with flow in the opposite direction in the aorta (140 beats/min).

A, Ultrasound image of an acardiac twin at the level of the rudimentary head with typical, severe subcutaneous edema. *B*, Doppler examination at 15 weeks' gestation demonstrates the typical retrograde flow from the pump twin toward the acardiac twin over an arterioarterial anastomosis (*arrow*).
present, especially toward the end of pregnancy. Doppler studies reveal pathognomonic features of reversed arterial perfusion through an AA anastomosis (Fig. 23–18). TRAP can easily be distinguished from sIUFD by the presence of fetal movements and the typical retrograde perfusion.

Fetal Risks

The pump twin is at risk for high-output cardiac failure secondary to the strain of perfusing the acardiac twin and extreme preterm birth associated with hydramnios.[154,157] The pump twin may be chronically hypoxemic if the deoxygenated blood from the acardiac returns by a vein-to-vein anastomosis.

The natural history of TRAP is poorly documented owing to the rarity of the disorder. Reported perinatal mortality rates for the pump twin vary between 35% to 50%[154,157] of cases diagnosed at birth, whereas some series of antenatally diagnosed cases report better,[158] similar,[159,160] and worse[161] outcomes. One explanation for a better outcome in antenatally diagnosed cases may be spontaneous resolution of the TRAP sequence following complete cessation of flow to the acardiac twin.[158,160,162] Conversely, outcome may be worse due to spontaneous demise of the pump twin leading to an early second-trimester loss not otherwise identified as a TRAP.[158] Long-term outcome data are not available for pump twins, although it is reasonable to speculate the risk of long-term cardiac and neurodevelopmental sequelae is high[163,164] owing to vascular imbalances in utero.

The prediction of outcome for antenatally diagnosed TRAP is challenging. An acardiac–to–pump weight ratio above 70% at birth was associated with increased rates of high-output cardiac failure, hydramnios, and preterm birth, suggesting that a relatively small acardiac mass is a good sign. Certainly, a larger acardiac mass will put a greater hemodynamic strain on the pump twin. However, antenatal weight estimation of the acardiac mass is hampered by the absence of normal biometric structures, and the errors are likely large. Others suggest a rapid increase in the acardiac mass to be indicative of poor prognosis.[159] Doppler velocimetry is probably the best tool to predict outcome. Large differences in the umbilical artery Doppler values suggest

relatively little flow to the acardiac twin, thereby predicting a more favorable outcome.[159–161,165] In contrast, small differences in the umbilical artery Doppler values would signify similar flows, the presence of large anastomoses placing a greater hemodynamic strain on the pump twin. Additional factors thought predictive of poor outcome are high-output cardiac failure with hydrops, hydramnios,[154] and certain morphologic characteristics of the acardiac twin such as the presence of a head and upper limbs.[157] It is unknown to what degree these parameters apply in the early second trimester, and spontaneous resolution as well as sudden demise of the pump twin remains largely unpredictable.

Management Options

As the natural history of antenatally diagnosed TRAP remains poorly documented, its treatment is equally controversial, ranging from conservative to palliative to causative. Conservative management consists of close antenatal surveillance and timed birth for signs of cardiac failure, whereas palliative treatment involves prolongation of pregnancy by serial amniodrainage and maternal administration of indomethacin for preterm labor and digoxin for cardiac failure. Reported perinatal mortality rates from conservative and palliative treatment vary widely between 10%[158] and 50%.[154] This is not surprising considering how poor the placental transport of digoxin is normally, much less when the fetus is hydropic. Also, little or no data are available on the long-term outcome of surviving pump twins, but as stated previously, there is concern about long-term neurologic and cardiac sequelae.

Causative treatment seeks to arrest the flow of blood to the acardiac twin. Several methods are proposed, ranging from hysterotomy and birth of the acardiac twin[166] to embolization of the acardiac twin's circulation[167] to fetoscopic cord ligation[168] to ultrasound-guided or fetoscopic coagulation of the umbilical cord[169,170] or intrafetal vessels.[171] Clearly, hysterotomy with selective birth of the acardiac twin is unacceptable because of the high maternal morbidity. Also, embolization by the injection of thrombogenic substances into the acardiac twin's circulation (e.g., absolute alcohol, coils, and enbucrilate gel) is also unacceptable as a first-line treatment, because dIUFD due to incomplete vascular

occlusion or embolization of the product to pump twin is not uncommon.[172,173]

A number of minimally invasive techniques are now available to produce complete circulatory confinement of the acardiac twin. Fetoscopic cord ligation causes immediate and complete interruption of both arterial and venous flow, irrespective of umbilical cord size, but is cumbersome and has a high risk of PPROM. At present, ultrasound- or fetoscopic-guided cord coagulation together with needle-based intrafetal coagulation appear to yield the most consistent results. The method of cord coagulation by laser is derived from that used for the coagulation of vascular anastomoses in TTTS.[170] It can be performed as early as 16 weeks using a double needle loaded with a 1.0-mm fetoscope and a 400-µm laser fiber (Fig. 23–19).[174] Fetoscopic laser coagulation is performed percutaneously under local or regional anesthesia using a single 1.3-mm operating sheath or 10-Fr (3.3-mm) trocar depending on the gestation. Fetoscopically guided laser offers good visual control of the coagulation site, but may fail if the umbilical cord diameter is large or, more rarely, if the amniotic fluid is stained. In these instances, bipolar cord coagulation with purpose-designed 2.4- to 3-mm bipolar forceps under ultrasound guidance is a secondary technique (Fig. 23–20). A recent series reported on the outcome of 60 pregnancies complicated by TRAP and treated with laser coagulation of the anastomoses or the umbilical cord.[175] The survival rate was 80%, and 67% gave birth after 36 weeks. In 15%, additional bipolar coagulation was necessary to achieve arrest of flow.

Needle-based coagulation techniques using laser,[176] monopolar technique,[171] or radiofrequency[177] each involve the insertion of a 14- to 18-gauge needle into the fetal abdomen under ultrasound aiming for the intra-abdominal rather than the umbilical vessels. This technique is attractive for its simplicity, the smaller membrane defect produced, and the seemingly lower risks of PPROM. It may be the preferred technique when the acardiac twin has a short umbilical cord and/or oligohydramnios. Two small recent series reporting on 13[178] and 29 cases[179] with TRAP treated with intrafetal radiofrequency ablation report survival rates for the pump twin of more than 90%. However, in monoamniotic pregnancies, the umbilical cord cannot be transected and thus late dIUFD remains a risk owing to cord entanglement.

Currently, it is not possible to conclude what the best management is for TRAP. Most cases of TRAP are diagnosed early in the second trimester when it is impossible to predict outcome. The outcome may be good without treatment if spontaneous arrest of flow occurs. Conversely, the pump twin may die unexpectedly or sustain sequelae from very preterm birth, cardiac failure, and chronic hypoxia. Early intervention may preclude the difficulties of arresting blood flow in larger, often hydropic acardiac masses, and it seems preferable not to await signs of decompensation. We believe it is justifiable to offer prophylactic, minimally invasive intervention if no spontaneous arrest of flow has occurred by 16 weeks, recognizing the pump twin may survive without any intervention in at least half of cases. The choice of technique will reflect gestational age and access to and the size of the acardiac twin. These procedures should be performed in specialized units by fetal medicine specialists familiar with different techniques in order to tailor therapy to the needs of each individual case.

SUMMARY OF MANAGEMENT OPTIONS
Twin Reversed Arterial Perfusion Sequence

Management Options	Evidence Quality and Recommendation	References
Conservative with no hydramnios or hydrops—maintain surveillance in "pump twin" for the development of hydramnios and/or hydrops and timely delivery.	III/B	154
Palliative with hydramnios or cardiac failure (variable prognosis)—serial amniodrainage and tocolysis for hydramnios and digoxin for the cardiac failure. This is a backup option if intervention is not possible.	III/B	154,158
Intervention with hydramnios or cardiac failure (hydrops)—arrest of flow toward the cardiac twin by a number of possible methods:		
• Coagulation of cord to acardiac twin.	III/B	169,170
• Ligation of cord to acardiac twin.	III/B	168
• Intrafetal (in acardiac twin) coagulation of fetal vessels.	III/B	171
For invasive treatment before 21 wk, intrafetal coagulation and cord coagulation (laser and bipolar) are effective methods to arrest flow.	III/B	169,170,172
Beyond 21 wk and in cases with hydropic cord, bipolar cord coagulation may be more effective.	III/B	169
It is justifiable to offer invasive treatment if no spontaneous arrest has occurred by 16 wk.	—/GPP	—
Mode of delivery depends on factors such as presentation and fetal health,	III/B	154

GPP, good practice point.

TWIN-TO-TWIN TRANSFUSION SYNDROME

General

TTTS is another complication unique to monochorionic multiple pregnancies. In most monochorionic twin gestations, interfetal transfusion across the anastomoses is a constant, but balanced, phenomenon. However, in 10% of monochorionic twins, a chronic imbalance in net flow develops, resulting in TTTS.[54,55] Hypovolemia, oliguria, and oligohydramnios develop in the donor twin, producing the stuck twin phenomenon. Hypervolemia, polyuria, and hydramnios evolve in the recipient twin, who can develop circulatory overload and hydrops (Fig. 23–21). TTTS usually occurs between 15 and 26 weeks and is a sonographic diagnosis based on the following criteria: hydramnios in the sac of the recipient twin (defined as deepest vertical pocket of ≥ 8 cm prior to 20 wk and ≥ 10 cm after 20 wk) secondary to polyuria, combined with oligohydramnios in the donor's sac (deepest vertical pocket ≤2 cm) secondary to oliguria. Quintero and coworkers[180] suggested a cancer-like staging system, which despite its several limitations, is still widely used. Stage I cases include those with hydramnios in the recipient sac but the bladder of the donor twin still visible. In stage II, the bladder of the donor twin remains empty (stuck twin). Stage III is characterized by severely abnormal Doppler studies: absent or reversed end-diastolic flow in the umbilical artery of the donor or abnormal venous Doppler pattern in the recipient, such as reverse flow in the ductus venosus or pulsatile umbilical venous flow. Fetal hydrops means stage IV, and the end-stage V corresponds to fetal demise of one or both twins. The purpose of any classification system in medicine is to assess disease severity, to
FIGURE 23–21
Ultrasound image of twin-twin transfusion syndrome. *A*, The donor is stuck to the uterine wall without bladder filling.
B, There is hydramnios in the sac of the recipient, who has a distended bladder.

stratify therapy, and to predict the response to a given therapy. The Quintero staging system only weakly correlates with outcome[181] and the treatment is the same for stage I to stage IV. Further, the Quintero staging system does not reflect a timescale of progressive deterioration. As such, TTTS can present as stage III from the start. Also, stage I disease can progress to stage V directly, without passing through stages II, III, and IV. At best, the Quintero staging system reflects the different possible clinical manifestations that may result from a variable contribution of intertwin transfusion imbalance, hormonal factors, and the degree of placental sharing.

As discussed previously, the differential diagnosis includes discordant growth in which the growth-restricted twin can appear "stuck" owing to oligohydramnios, but in which hydramnios is absent in the larger twin. Likewise, the isolated presence of hydramnios in one sac with normal amniotic fluid in the other precludes the diagnosis of TTTS, and in that case, other causes for hydramnios must be sought.

Many questions remain concerning the exact pathophysiology of TTTS. Nevertheless, TTTS remains best explained by the angioarchitecture. Placental anastomoses can be AA, arteriovenous (AV or VA), and venovenous (VV).[182] AA and VV anastomoses are typically superficial, bidirectional anastomoses on the surface of the chorionic plate, forming direct communications between the arteries and the veins of the two fetal circulations. The direction of flow depends on the relative interfetal vascular pressure gradients. AV anastomoses are usually referred to as "deep" anastomoses. They occur at the capillary level deep within the depth of the placenta, receiving arterial supply from one twin and providing venous (well-oxygenated) drainage to the other. The supplying artery and draining vein of the AV anastomosis can be visualized on the placental surface as an unpaired artery and vein that pierce the chorionic plate at close proximity to each other (Fig. 23–22). The AV anastomoses allow flow in one direction only and, hence, may create an imbalance in the interfetal transfusion leading to TTTS, unless balanced by an oppositely directed transfusion through other superficial or deep anastomoses.
FIGURE 23–22

(Drawing by Luc Brullemans.)

Both postnatal injection studies[15] and in vivo fetoscopic observations[183,184] indicate the presence of at least one unidirectional AV anastomosis as an anatomic prerequisite for the development of TTTS. Although a TTTS case was reported with only superficial anastomoses (one AA and one VV),[184] this seems the exception confirming the rule. The presence of bidirectional AA anastomoses is believed to protect against the development of TTTS because most non-TTTS monochorionic placentas have AA anastomoses (84%) in contrast to TTTS placentas (20%–30%).[15,184]

Although vascular anastomoses are an anatomic prerequisite for the development of TTTS, other pathophysiologic mechanisms are likely involved. Because 75% of sonographically defined TTTS has an intertwin hemoglobin difference of less than 15%,[185] this syndrome cannot be explained by the simple transfer of blood from one twin to the other. Further, there is no increased erythropoietin production in the donor[186] and no evidence of iron depletion/overload in the donor/recipient.[187] It is suggested that discordant placental function may offset TTTS, because placental dysfunction is associated with an increased fetoplacental resistance, which may promote transfusion from the growth-restricted donor twin to the recipient twin. Reduced insulin growth factor-II[188] and decreased leptin levels[189] in donors compared with recipients may indicate discordant placental development rather than transfusion as a cause of the growth restriction. Other hormonal changes occur in donors and recipients. Raised endothelin-1 levels were observed in recipients, potentially causing increased peripheral vasoconstriction and hypertension. Recipients have increased levels of atrial natriuretic peptide,[190] and those with severe cardiac dysfunction have higher levels of brain natriuretic peptide, suggestive of cardiac remodeling. Increased renin gene and protein expression are found in donor kidneys, but the expression is virtually absent in the recipient kidneys,[191,192] implicating a role of the renin-angiotensin system in TTTS. Thus, the pathophysiology of sonographically defined TTTS is most likely multifactorial with vascular anastomoses providing the anatomic basis, whereas hemodynamic and hormonal factors contribute in varying degrees to its clinical development.

Early identification of the monochorionic twin pregnancies at increased risk of TTTS would assist patient counseling and planning of follow-up. As such, pregnancies at increased risk may be followed in a fetal medicine center, which is especially relevant in geographic settings in which access is problematic. Further, for dichorionic triplets, an increased risk in the first trimester might be an argument in favor of reduction of the monochorionic pair. Finally, timely treatment of TTTS might improve outcome by preventing PPROM and/or cervical shortening, which is an important risk factor for preterm birth.[193,194]

An increased nuchal translucency (NT) (>95th percentile) in at least one fetus during the 11 to 14 weeks' examination occurs in 13% of monochorionic twins and is a marker for chromosomal anomalies, cardiac defects, and a wide range of genetic syndromes. In monochorionic twins, an increased NT may reflect early cardiac dysfunction due to hypervolemic congestion in the recipient and, thus, herald the subsequent development of TTTS. Indeed, fetuses of monochorionic twin pregnancies with increased NT have a higher likelihood for the subsequent development of TTTS (likelihood ratio 3.5; 95% confidence interval [CI]

Ultrasound image of membrane folding in a monochorionic twin pregnancy, which reflects discordant amniotic fluid in a monochorionic twin pregnancy.
1.9–6.2).[195] However, the sensitivity of the NT measurement for TTTS is only 28%, with a positive predictive value of 33%. These figures were somewhat improved in a more recent study by the same group, in which an NT discordance of 20% or more detected 52% of cases with TTTS with a positive predictive value of 24%.[196] In the same series, the difference in crown-rump length (CRL) had a similar predictive value as NT discordance. However, two other studies did not confirm NT discordance to be a significant risk factor for the subsequent development of TTTS,[197,198] although both demonstrated the difference in CRL to be predictive. As such, difference in CRL of 6 mm or more detected 52% of cases TTTS with a positive predictive value of 19%. It seems unlikely that all TTTS cases will be predictable in the first trimester. The intertwin transfusion equilibrium is probably fragile and might become unbalanced at any stage in pregnancy without any warning. Further, TTTS may result from a random and asymmetrical reduction in vascular anastomoses with placental expansion later on in pregnancy.[199]

Folding of the intertwin membrane (Fig. 23–23) at 15 to 17 weeks may be a more promising sign for the prediction of TTTS. It is present in 32% of monochorionic twin pregnancies and believed to reflect oliguria and a reduced amniotic fluid in the sac of the donor. It is associated with an increased likelihood for the development of TTTS (likelihood ratio 4.2; 95% CI 3.0–6.0). Early mid-trimester membrane folding identifies 91% of TTTS with a positive predictive value of 43%.[195]

Another proposed marker for the prediction of TTTS is the absence of AA anastomoses. These anastomoses can be detected by color-flow mapping and pulsed Doppler[83] as early as 12 weeks, though the majority become detectable after 18 weeks.[200] The difficulty with using the absence of AA anastomoses as a prognostic sign is that it is impossible in early pregnancy to ascertain whether they are truly absent or just undetected. However, when an AA anastomosis is identified, 15% of monochorionic twin pregnancies develop TTTS compared with 61% when no AA anastomosis can be detected.

Finally, a velamentous cord insertion was suggested to increase the risk for TTTS, and cord insertions can be reliably determined at 16 weeks. Fries and colleagues[201] demonstrated a higher prevalence of velamentous cord insertion in TTTS placentas than in non-TTTS placentas, 32% and 9%, respectively. In another series, the combination of an eccentric cord insertion in one twin and a marginal or velamentous cord insertion in the other was more frequently seen in TTTS,[18] though several other studies failed to identify an association.[202,203] Discordant cord insertions reflect unequal placental sharing and, therefore, seem to increase the risk of discordant growth, but not the risk of TTTS.

Within the Eurofoetus consortium,[204] we developed a two-step sonographic scoring system in the first trimester and at 16 weeks to predict a complicated outcome, defined as the occurrence of TTTS, discordant growth, or intrauterine demise.[197] If the CRL difference is 12 mm or more or if there is discordant amniotic fluid in the first trimester, then the probability of a complicated fetal outcome is about 80% and the survival rate only 50%, as compared with an 80% uncomplicated outcome and a survival rate of 93% in the screen-negative group. At 16 weeks, significant predictors for a complicated fetal outcome were difference in abdominal circumference, discordant amniotic fluid, and discordant cord insertions. This two-step risk assessment in the first trimester and at 16 weeks identified a high risk group with a more than 70% risk of complicated outcome, in contrast to an 86% uncomplicated outcome in the group predicted to be at low risk. This information is useful for patient counseling and to identify patients who may benefit from follow-up in a dedicated fetal medicine center, especially in areas where access is limited.

Fetal Risks

Untreated, TTTS has been quoted to have a mortality of nearly 100%, although advances in neonatal care mortality rates may have decreased that rate to 63%.[205] Spontaneous abortion and extreme preterm birth are associated with hydramnios, and fetal demise may result from cardiac failure in the recipient or poor perfusion in the donor. Substantial cerebral and cardiac sequelae may occur in survivors owing to the chronic hemodynamic imbalances. Both the donor and the recipient are at risk of antenatally acquired cerebral lesions with, depending on the therapy used, reported incidences of 10%[206] to 50%.[207] In donor twins, hypovolemia, hypotension, and anemia may induce cerebral hypoxia and brain damage, whereas in the recipient, hyperviscosity and cardiac failure may impair cerebral perfusion. Again depending on the therapy used, the reported incidences of cerebral palsy and major neurologic deficiencies range from 6%[208] to 26%.[143]

The risks of neurologic damage are dramatically increased after an sIUFD when the vascular anastomoses remain patent, presumably due to acute exsanguination of the survivor into the fetoplacental unit of the deceased co-twin. MCA PSV measurement seems a reliable noninvasive method to detect anemia after sIUFD in TTTS.[138] Though it is tempting to intervene based on this finding, it remains to be demonstrated whether a rescue transfusion decreases risks of neurologic sequelae.[146]

Monochorionic twins with TTTS have a reported 8% prevalence of pulmonary valve stenosis in recipients, regardless of whether these pregnancies were treated primarily by

amniodrainage or laser.[209,210] Further, up to 48% of survivors have signs of transient oliguric renal failure affecting the donor as well as the recipient, although long-term renal impairment does not appear to be a problem.[211] Also, limb,[212] gastrointestinal,[213] and cerebral infarctions[214] that preferentially affect the recipient are described and may originate from hyperviscosity or hypoperfusion.

Management Options

Laser Coagulation versus Amniodrainage

In view of the poor survival rates with conservative management, there is no disagreement that therapy should be offered. The two most commonly used therapies for midtrimester TTTS are amniodrainage and fetoscopic laser coagulation of the vascular anastomoses. However, since the Eurofetus randomized, controlled trial comparing laser treatment with amniodrainage, there is general consensus that the best treatment option for all stages of TTTS is currently laser coagulation of the vascular anastomoses.[140,215] Women with suspected TTS should be informed that amniodrainage should be reserved only for regions in which laser coagulation is not available and otherwise referred to a fetal medicine center that performs laser coagulation.

Before the advent of fetoscopic surgery, amniodrainage was the most commonly used treatment for TTTS. It controls the amniotic fluid volume, is relatively simple to perform, and is widely available. It was suggested the fetal condition might be improved by reducing the amniotic fluid pressure and perhaps enhancing uteroplacental perfusion.[216,217] The evidence for such benefit is scant. Decompression does appear to prolong pregnancy. However, amniodrainage does not address the vascular basis of TTTS and usually needs to be repeated several times to control the amniotic fluid volume. In addition, because it does not cure the disease, amniodrainage often leads to the preterm birth of two sick neonates, which increases their risk of neonatal mortality and morbidity.[218] Also, in the event of an sIUFD, the surviving twin is at high risk for anemia and neurologic sequelae.[138,214] Available data suggest that amniodrainage is "effective" only in mild cases of TTTS (stages I–II) and outright fails in a third. Such a high failure rate may indicate that its purported efficacy is a reflection of the disease's natural history. The overall perinatal survival rate with amniodrainage in uncontrolled series with cases diagnosed prior to 26 weeks was 57%.[205] This rate was confirmed in a literature review by Skupsi and associates[219] (double survival 50%; single survival rate 20%; total survival rate 61%). Worse yet, amniodrainage is associated with a 16% to 26% risk of severe sequelae in survivors.[143,205]

Whereas amniodrainage is a palliative and repetitive measure, fetoscopic laser coagulation of the vascular anastomoses seeks to address the underlying cause of the disease through a single intervention. Complete coagulation of all visible anastomotic occlusion results in the resolution of TTTS.[220] Most fetoscopic laser centers agree that coagulation of nonanastomosing vessels should be avoided whenever possible, because this increases the area of nonfunctional placental territory and, therefore, the risk of intrauterine demise.[221,222] Most centers have abandoned the nonselective technique of simply coagulating all vessels crossing the intertwin septum.[223] The vascular equator does usually not
coincide with the membranous equator, and coagulation along the intertwin septum will, therefore, lead to unnecessary placental loss. In some monochorionic pregnancies with unequal placental sharing or a large shared part of the placenta, coagulation of all anastomoses may leave too little unshared placenta for one or both fetuses, leading to sIUFD or even dIUFD. As a result, most centers now are selective, coagulating all visibly communicating vessels between the two fetuses as well as the ones from which it could not be excluded that they are anastomosing (Fig. 23–24). A "hyperselective" approach, as discussed by Feldstein and coworkers,[224] coagulating only the causative AV anastomosis is interesting from a theoretical point of view because it is simply not possible to identify this anastomosis in the presence of others. Also, leaving certain anastomoses open places the remaining fetus at risk for hypovolemic events in case of sIUFD and might lead even to a reversal of transfusion.

Two adaptations of the currently practiced technique have been suggested to improve survival rates. One is to draw a complete line of coagulation between the two vascular territories to avoid small and potentially invisible anastomoses (unpublished). Another is a sequential technique in which all AV anastomoses from the donor to the recipient are coagulated first in an attempt to minimize blood loss from the already hypovolemic donor and increase its survival rate.[225]

Laser coagulation is performed percutaneously (Fig. 23–25) under local or locoregional anesthesia. A cannula or fetoscopic sheath is inserted into the hydramniotic sac and the placenta inspected. For coagulation, the laser tip is directed toward the target vessels at as close to a 90-degree angle as possible, and with a nontouch technique, a 1- to 2-cm section of the selected vessel is photocoagulated (Fig. 23–26). At the conclusion, amniodrainage is performed until the amniotic fluid pockets on ultrasound are normal. With an anterior placenta, the amniotic sac as well as the vessels on the placenta might be more difficult to access. Some instruments have been purposely developed, but it is yet unclear whether they improve performance.[226] Placental localization does not appear to influence outcome.[227]

Few laser procedures have been reported before 16 weeks and after 26 weeks. Similar to amniocentesis, the minimum requirement for intervention should be chorioamniotic membrane fusion. Therefore, the lower limit for safe laser coagulation seems to be 15 weeks, when the use of a 1.2-mm scope is recommended to reduce membrane trauma. After 26 weeks, the procedure is more challenging because the amniotic fluid is often turbid and the anastomotic vessel much larger. Nevertheless, laser separation seems preferable to serial amniodrainage or elective preterm birth. Curing the disease prior to birth may indeed reduce the incidence of cerebral lesions.[228]

In uncontrolled series, the overall fetal survival has consistently been between 62% and 77%,[140,221] with a risk for long-term neurologic morbidity in survivors of 13% to 18%.[208,229] The Eurofetus research consortium granted by the European Commission was the first to conduct a randomized trial comparing serial amniodrainage with laser coagulation as a primary therapy for TTTS prior to 26 weeks. The primary outcome measure was survival of at least one twin at 6 months of age, and the secondary outcome measure was intact neurologic survival (Table 23–1).[140] Compared with the amniodrainage group, the laser group had a higher likelihood of survival of at least one twin to 28 days of age (76.4% vs. 51.4%). Infants in the laser group also had a lower incidence of cystic periventricular leukomalacia (laser 6% vs. drainage 14%) and were more likely to be free of neurologic complications at 6 months of age (52% vs. 31%). A recent long-term follow-up study conducted in three European centers showed an incidence of neurodevelopmental impairment of 18% at the age of 2 years.[229] Cerebral palsy was diagnosed in 6%. Donors were similarly affected as recipients. Only a low gestational age at birth was independently associated with the risk of neurodevelopmental impairment.

Another randomized controlled trial comparing laser with amniodrainage sponsored by the National Institutes of Health was stopped at 40 patients because of poor recruitment and was inconclusive.[230] Surprisingly, they reported a 70% intrauterine demise rate for the recipient and an overall survival rate of only 45% after laser treatment. A major difference with the European trial was that all patients underwent a test amniodrainage, and only patients who failed to respond were randomized. It is well established that an amniodrainage may hamper later laser treatment because of septostomy, intra-amniotic bleeding, or membrane detachment. The high mortality of the recipient might be due to the detrimental effect of the failed amniodrainage on recipient cardiac function. A recent meta-analysis that covered the Eurofetus trial as well as nine other observational cohorts concluded that laser as compared with amniodrainage was associated with an odds ratio of 2.0 for perinatal survival and 0.24 for short-term neurologic morbidity.[231] Recipients appear more likely to survive than donors. At present, laser coagulation is therefore the best available treatment and amniodrainage should be performed as an obstetric emergency in places in which there is no access to fetoscopic laser surgery or when

elective preterm birth after lung maturation is an option.[232] Future randomized trial(s) probably will address the need to perform laser in stage I disease. Because of the low number of stage I cases in the Eurofetus randomized trial, expectant management might result in better survival rates by obviating the fetal loss associated with laser coagulation.[233] Nevertheless, these trial(s) will need to address the long-term neurodevelopmental outcome, because expectant management of stage I TTTS may result in better survival rates, but not necessarily in a better long-term neurodevelopmental outcome.

Potential Complications and Follow-up after Laser Treatment

PPROM remains the most important complication of any invasive antenatal procedure. After fetoscopic laser coagulation, the incidence of PPROM prior to 34 weeks is estimated

to be 28%.[234] In 12%, PPROM occurred within 3 weeks after the procedure. At present, there is no validated method to prevent PPROM. First, there is the iatrogenic membrane defect that does not seem to close spontaneously. Perhaps because of its avascular nature and detachment from the decidua on the uterine wall, the amnion shows no sign of wound healing.[235] Second, there is probably an inflammatory response in the fetal membranes due to hydramnios (stretching) and the iatrogenic membrane defect. This may activate an enzymatic cascade that degrades the membranes and eventually leads to PPROM.[236] Although prophylactic patching of the membrane defect with collagen plugs seems promising in vitro[237] and in animal models,[238] its true role in clinical practice still needs to be established. The intra-amniotic injection of platelets may occasionally be successful to stop postoperative leakage, but it carries a risk of intrauterine demise or antenatal brain damage, probably due to the platelet release of vasoactive substances or to the formation of fibrinous bands that may constrict the umbilical cord.[239]

Preterm birth is, next to PPROM, a common cause for adverse outcome. In the Eurofetus randomized trial, one in five patients gave birth between 24 and 32 weeks' gestation. A short cervical length at the time of laser increases the likelihood of severe preterm birth.[194] An emergency cerclage immediately after laser in those patients with a cervical length of less than 15 mm may prolong the pregnancy and allow for a better outcome.[240]

In contrast to amniodrainage in which the demise of one or both fetuses often occurs remotely from the procedure, 60% of intrauterine deaths with laser are diagnosed within 48 hours and 75% within 1 week.[241] However, the surviving twin is far less likely to be anemic after laser[138] or to sustain neurologic sequelae[142] compared with survivors after amniodrainage[143] in which the anastomoses remain patent.

About 1 in 10 pregnancies of which both fetuses survive are complicated by persistent TTTS or develop TAPS.[242] These complications are most likely related to missed anastomoses,[220] which may occur in up to one third of placentas after laser treatment[243] and are usually situated near the edge of the placenta.[220,244] Missed large anastomoses may result in dIUFD or persistent TTTS, whereas missed small anastomoses may lead to iatrogenic TAPS.[220] The technique of drawing a complete coagulation line that separates the two vascular territories may reduce the number of missed anastomoses and will be tested in a randomized controlled trial.

Other fetal complications are uncommon but include limb reduction deformities,[212,245] cerebral anomalies,[214] intestinal atresia,[213] and congenital skin loss.[246,247] Each of these anomalies has been described in TTTS not treated by laser[212,248,249] and are probably related more to the disease process than the treatment.

Maternal safety should remain a priority, and serious maternal complications should be registered carefully in a registry, such as the one set up by Eurofetus.[250] Transient maternal mirror or Ballantyne's syndrome with pulmonary edema, placental abruption, chorioamnionitis, and bleeding requiring transfusion are reported, but none yet leading to maternal demise. Hecher and colleagues[251] demonstrated a learning curve and argue against scattering the experience over too many centers.

Intensive surveillance remains indicated for treated pregnancies because of the frequent occurrence of postoperative complications. We recommend weekly sonographic evaluation for the first month and then every 2 weeks thereafter. It is important that the PSV of the MCA be measured at each visit to detect postoperative TAPS, which typically occurs within the first 5 postoperative weeks. The demonstration of bladder filling and increasing amniotic fluid of the donor is a sign of TTTS resolution. Fluid usually takes a week to normalize in the donor twin, so equal fluid levels shortly after the procedure indicates that an accidental septostomy occurred during the procedure. It is important to look for possible cord entanglement thereafter and to check the limbs for any evidence of reduction deformities due to amniotic bands or to vascular insults, especially in the recipient. We also recommend detailed surveillance of the fetal brain. MRI appears more sensitive in detecting more subtle brain lesions, especially in the third trimester, and we therefore recommend a routine MRI to assess the fetal brain around 30 weeks' gestation. In cases in which severe antenatal brain damage is diagnosed, parents can be offered a late (selective) termination where jurisdiction permits. Cardiac assessment is important as well, because laser coagulation does not seem to prevent the occurrence of right ventricular outflow tract obstruction. In terms of monitoring fetal growth, there is usually a decrease in discordancy in successful procedures and more than half of the donors with growth restriction at the time of laser show catch-up growth, ultimately resulting in a normal birth weight.[252]

Alternative Management Options

Termination of the entire pregnancy may be justified based on the risk for adverse outcome and, although it is rarely pursued by parents, this option should be part of counseling. Selective feticide was suggested in 1993 as a way to try to salvage at least one twin in complicated cases of TTTS.[253] Selective feticide by bipolar cord occlusion has also been suggested for the treatment of stage III/IV TTTS.[254] This approach is certainly open for debate and the associated decisions difficult. It is not necessarily easy to determine which fetus will have the worst outcome, a major drawback because the maximum survival rate of selective feticide is 50%. At present, selective feticide should be reserved for instances of severe discordant anomalies, when imminent demise of one twin is anticipated, or in cases in which full visualization of the vascular equator is likely to be technically impossible. If in the future we are able to predict postoperative demise more accurately, then selective feticide might be a valid alternative to laser treatment in those cases with a high likelihood of recipient or donor demise.

Finally, it was suggested that intentional puncturing of the intertwin septum ("septostomy") with or without amniodrainage was beneficial by equilibrating the amniotic fluid volume. The technique is based on the observation that TTTS is rare in monoamniotic twins. It definitely increases the amniotic fluid volume in the donor's sac, but also creates an iatrogenic monoamniotic state with possibility of cord entanglement and might hamper subsequent laser therapy. Not surprisingly, a randomized controlled trial comparing amniodrainage to septostomy ($N = 14$) failed to identify any survival benefit with septostomy.[255] Therefore, septostomy is no longer recommended as treatment for TTTS.

SUMMARY OF MANAGEMENT OPTIONS
Twin-Twin Transfusion Syndrome (TTTS)

Management Options	Evidence Quality and Recommendation	References
Serial amniodrainage does prolong pregnancy and improves fetal condition by reduced intrauterine pressure, although it does not protect the surviving twin in the event of sIUFD and is only effective in mild cases of TTTS.	IIb/B	141
Laser coagulation, as compared with amniodrainage, has been shown to have better survival rates and neurologic outcome, and is therefore considered to be the best first-line treatment for TTTS in centers experienced in this technique.	Ib/A	140
Septostomy does not seem to have a survival benefit as compared with amniodrainage.	IIb/B	253
Selective feticide by cord occlusion does arrest the transfusion process and is indicated for TTTS with associated discordant anomalies or in rare cases of imminent fetal death, or when laser coagulation with full inspection of the vascular equator is technically not feasible.	III/B	254

sIUFD, single intrauterine fetal demise.

TWIN ANEMIA POLYCYTHEMIA SEQUENCE

General

TAPS refers to the occurrence of a chronic and severe hemoglobin discordancy in a monochorionic pair (hemoglobin ≤ 11 g/dL with reticulocytosis in the donor and hemoglobin ≥ 20 g/dL in the recipient), in the absence of the severe amniotic fluid discordance that fulfills the criteria for TTTS. It also results from an intertwin transfusion imbalance, but rather than discordant amniotic fluid, TAPS presents as chronic and severe intertwin hemoglobin discordance. Indeed, TAPS represents the "TTTS of the neonatologist," because it usually presents late in pregnancy and results in the birth of a large plethoric twin and usually small anemic twin that does not show signs of hypovolemic shock. Signs of chronic anemia in the donor and the absence of hypovolemic shock differentiate TAPS from acute intrapartum transfusion.[256] TTTS as it is known to the fetal medicine specialist with the predefined amniotic fluid discordances usually occurs in mid trimester and either is treated or leads to miscarriage and is therefore unknown to the neonatologist. TAPS can occur spontaneously in previously uncomplicated monochorionic twin pregnancies[41] or, as mentioned previously, after incomplete laser surgery as a treatment for TTTS[242] with small missed AV anastomoses.[220]

Iatrogenic TAPS is diagnosed antenatally by an elevated PSV of the MCA above 1.5 multiple of the median (MoM) in one twin (usually in the previous recipient) suggesting anemia and below 0.8 MoM in the other (usually in the previous donor) suggesting polycythemia.[242] Spontaneous TAPS occurs in about 5% of monochorionic twin pregnancies, usually after 30 weeks,[55] especially in pairs with progressive discordant growth after 26 weeks.[34] Also, TAPS may account for some late and previously unexplained intrauterine deaths.[55] It remains to be demonstrated whether measurement of the MCA PSV also identifies TAPS in these previously uncomplicated pregnancies. Nevertheless, MCA PSV measurements are an integral part of our routine follow-up of monochorionic twins.

The placentas of spontaneous TAPS pregnancies show a striking similarity to those of iatrogenic TAPS after incomplete laser surgery. Most spontaneous TAPS placentas have a few small (≤1 mm) unidirectional AV anastomoses without a compensating AA anastomosis,[41,220] suggesting that TAPS results from a slow net transfusion of blood across the tiny anastomoses that are typically present in these cases. Similar to TTTS, the donor may be relatively small compared with its placental territory, whereas the recipient twin may be relatively large, suggesting the intertwin transfusion imbalance in TAPS also reduces and increases the birth weight of the donor and recipient, respectively.[41]

Fetal Risks

TAPS may be involved in the etiology of previously unexplained late intrauterine demise.[55,119] Severe anemia may result in hydrops and intrauterine death of the donor, whereas at least theoretically, severe polycythemia may cause cardiac failure or vascular accidents and death in the recipient. In contrast to TTTS, fetal loss due to miscarriage prior to 20 weeks is less common because TAPS usually occurs in the third trimester and severe hydramnios is unusual.

Management Options

The optimal management of iatrogenic as well as spontaneous TAPS is unknown. Depending on the characteristics of each individual case, such as gestational age, recurrence after intrauterine transfusion, fetal hemodynamic condition, and placental localization, definitive management may consist of elective birth, cord occlusion, or fetoscopic laser coagulation.[242] For fetoscopic laser, the surgeon should be aware that visibility may be impaired by the lack of severe hydramnios and the advanced gestational age at which TAPS usually

presents. Conversely, usually only few and tiny anastomoses will need to be coagulated.

CONGENITAL ANOMALIES IN TWINS

General

Structural Anomalies

Structural anomalies are 1.2 to 2 times more common in twins than in singletons. Unfortunately, most studies do not subgroup incidence by either zygosity or placentation. Nevertheless, probably the rate per fetus in dizygotic twins is the same as that in singletons, whereas it is two to three times higher in monozygotic twins.[73] Abnormalities associated with twins include neural tube defects, brain lesions, facial clefts, gastrointestinal defects, anterior abdominal wall defects, and cardiac anomalies.[257] Even in monozygotic twins, concordance (both fetuses similarly affected) for a structural anomaly is rare (<20%).[74] Further, discordance for genetic diseases is frequently reported in monozygotic twins and may reflect variations in gene expression secondary to postzygotic mutation, parental imprinting effects, asymmetrical X inactivation,[35] and differential DNA methylation.[258] The exact mechanism of the increased prevalence of structural anomalies in monozygotic twins remains largely unknown, although several mechanisms are proposed. It is possible the twinning process itself is teratogenic owing to an unequal distribution of the inner cell mass or to cleavage after laterality gradients have already been determined, resulting in such abnormalities as midline defects.[35] Vascular events in early embryogenesis and later fetal life might account for part of the observed discordant brain and heart anomalies. In our prospective series of 202 monochorionic twin pairs, major discordant congenital anomalies occurred in 6% and always affected only one twin.[55] The prevalence of cardiac anomalies in monochorionic twins is reported to be 2.3% in those without TTTS, and 7% in those with TTTS, compared with 0.6% in the general population. Pulmonary valve stenosis in recipients accounts for all the additional congenital heart defects found in TTTS cases, suggesting a causative role for the hemodynamic imbalance. The global prevalence of congenital heart defects in monochorionic twins (3.9%) is thus comparable with that in a family with a history of congenital heart disease (2.5%). Therefore, detailed echocardiography is indicated in both the second and the third trimesters, because pulmonary artery stenosis is a dynamic process that may evolve until birth.[209] Anomalies unique to monochorionic twins are the TAPS sequence and conjoined twinning as discussed previously.

Chromosomal Anomalies

RISKS OF CHROMOSOMAL ABNORMALITIES

In dizygotic twins, the age-related risk of Down syndrome for one twin is independent of the risk for the other and should be the same as in singletons. Therefore, the risk of at least one fetus having Down syndrome should theoretically be double that in singletons. Whereas chorionicity can be accurately determined during the first trimester, there are no noninvasive means to establish zygosity antenatally. Nonetheless, dichorionic twins are dizygotic in about 90%

of cases, and all dichorionic twins are, for risk assessment, considered to be dizygotic. In a dichorionic twin pregnancy, the age-related risk of at least one twin having Down syndrome can then be calculated by adding the age-related risks together (e.g., for a 40-year-old woman: 1/100 + 1/100 = 1/50), whereas the risk of both fetuses being affected is obtained by multiplying the age-related risks (1/100 × 1/100 = 1/10,000).

In a monochorionic (and, by definition, monozygotic) twin pregnancy, the age-related risk is the same for both twins and similar to that in singletons with usually both twins affected, although discordances in the phenotypic expression of the aneuploidy are frequently observed.[259,260] It is important to note that, though rare, even monochorionic twins may be discordant for chromosomal anomalies and discordancy for nearly all common human aneuploidies (trisomy 13,[70] trisomy 21,[71] monosomy 45, X[261]) is reported. Most involve one twin with Turner's syndrome and the other twin with either a female or a male phenotype but a mosaic karyotype. This rare phenomenon is called "heterokaryotypic monozygotism," and it reflects either a postzygotic mitotic event (nondisjunction or anaphase lag) or prezygotic meiotic errors. Several mechanisms may be involved. The zygote may initially have been karyotypically normal (46), but a trisomic (47) and monosomic cell line (45) develop due to a mitotic nondisjunction or anaphase lag. Conversely, the zygote may initially have been trisomic (47), but a diploid cell line (46) may be established due to a mitotic disjunction or anaphase lag, a phenomenon known as "trisomic rescue." At the blastocyst stage, the embryo proper originates from only three to five progenitor cells, and cleavage at this stage will give rise to monochorionic twinning. If a mitotic error takes place in any of these cells, it may actually trigger the twinning process with the proliferative advantaged diploid cell line separating out the aneuploid progenitors (Fig. 23–27). If the aneuploidy is nonviable, then this aneuploid "twin" will vanish without leaving any detectable remnants.[262] However, if the aneuploidy is viable, it may give rise to hetorokaryotypic monozygotic twins.

SCREENING FOR ANEUPLOIDIES IN TWINS

Screening for aneuploidy is more complex in multiple pregnancies than in singletons because, although selective

(Courtesy of T. Van den Bosch.)

feticide is an option if only one fetus is affected, the procedures can cause the loss of the unaffected co-twin. It is essential the parents are adequately counseled on the pros and cons of screening in multiple pregnancy. The screening tests should have good detection rates and an acceptably low false-positive rate, because invasive testing carries a higher risk and is technically more challenging in multiple pregnancy.

Second-trimester serum screening for aneuploidy has disappointingly low detection rates in twins (45% for a 5% screen-positive rate), presumably because the altered biochemical markers of the aneuploid fetoplacental unit are masked by the presence of an euploid co-twin. Also, serum screening provides only the risk of at least one affected fetus being affected (pregnancy-specific risk) and cannot identify which fetus is at increased risk (fetus-specific risk). In contrast, first-trimester nuchal translucency measurement has higher detection rates, identifies the fetus at increased risk, and allows for a selective feticide in the first trimester. It is, therefore, the preferred screening method in twins. The combination of NT with first-trimester serum biochemistry further increases the detection rate. In a 3-year review of combined NT and serum screening in the first trimester on 230 twin pregnancies, detection rates of Down syndrome were 75%, with 7% of fetuses and 9% of pregnancies (with at least one fetus) having a risk above 1 in 300.[263]

Although combined NT and biochemistry screening allows a fetus-specific risk, it seems logical to quote only one risk for monochorionic fetuses (pregnancy-specific risk), because both will be affected or both will be unaffected in nearly all cases. Quoting the risk of the fetus with the largest NT may overestimate the true risk, especially because an increased NT in one twin of a monochorionic pair may be an early sign of unbalanced intertwin transfusion.[195] Screening for Down syndrome in a monochorionic pair is best achieved by quoting the average of the two NT measurements.[264] Conversely, for dichorionic twins, it makes sense to quote the fetus-specific risk, although it is probably more relevant to the parents to hear what the risk is that at least one fetus will be affected (pregnancy-specific), which is obtained by adding the two fetus-specific risks. The risk that both are affected is extremely rare and, as mentioned previously, is obtained by multiplying the two fetus-specific risks.

INVASIVE PRENATAL TESTING IN TWINS

Fetal karyotyping requires invasive testing by either amniocentesis or chorionic villus sampling (CVS). Because these procedures are technically more demanding in multiple pregnancies, they should be performed in tertiary referral centers. The choice of technique depends on the procedure-related risk, the accuracy of obtaining a result from both fetuses, and technical circumstances. Although genetic amniocentesis is a well-accepted procedure, it remains unclear whether the postprocedural loss is higher in twins than in singletons, and whether the risk increases with increasing number of fetuses. Historically, amniocentesis in twin pregnancies was considered to have higher procedure-related loss rates (2.7%–8.1%).[265] However, this may be largely attributable to the higher background risk of fetal loss in twins (6%)[266] rather than to the procedure. As such, Ghidini and associates[267] observed that amniocentesis in experienced hands did not increase loss rates significantly.

Conversely, Yukobowitz and coworkers[268] reported loss rates within 4 weeks after the procedure using a double uterine puncture that were five times higher in twins (2.6%) than in singletons (0.6%) and unexposed twins (0.6%).

Several methods can be used to ensure that all fetuses are correctly sampled. No method is demonstrably superior, and the choice reflects operator preference. In any event, great care must be taken to note distinguishing features, such as gender, placental localization, umbilical cord insertion, and fetal positions. A diagram should be made to prevent the potentially disastrous consequence of incorrect sampling. Samples should also be meticulously labeled. Amniocentesis in twins can be done through a single or double uterine entry. With the double-needling technique, each sac is sampled separately and consecutively. The injection of dyes after sampling of the first sac to ensure it is sampled only once is no longer recommended. Methylene blue is contraindicated because of its well-documented fetal risks, such as intestinal atresia, hemolytic anemia, and fetal demise.[269] Methylene is a classic, nonselective pharmacologic inhibitor of soluable guanylate cyclase, and the resulting vasospasm may explain the adverse events. Although no similar fetal risks are reported with indigo carmine, it has serotonergic properties[270] that in theory may lead to hypertension and bradycardia and is thus best avoided. A less commonly used technique is the double-needle simultaneous visualization technique.[271] An amniocentesis needle is advanced into the first cavity while a second needle is introduced into the other amniotic cavity without altering the position of the transducer. This technique permits visualization of both needles simultaneously on either site of the septum, but necessitates the presence of two operators. Finally, a single uterine entry technique is described in which the needle is first advanced into the proximal sac and fluid aspirated.[272] The stylet is replaced, and under direct visualization, the needle is advanced through the septum into the second sac. After discarding the first 1 mL of fluid to avoid contamination, a sample is aspirated from the second sac. This technique has the advantage of creating only one membrane defect and, to date, no cytogenetic errors have been reported, although there is the theoretical concern of contamination and the creation of an iatrogenic monoamniotic pregnancy.

CVS in multiple pregnancy can be performed using either the transabdominal approach, the transcervical approach, or a combination of the two. In the hands of an experienced operator, the loss rate attributable to CVS in twins may be comparable with that after amniocentesis. However, cytogenetic results are incorrect in 1.5% to 2% of cases because of contamination of one sample with villi from the other, placental mosaicism, culture failure, or sampling the same fetus twice. As a result, the resampling rate approximates 2%. To reduce the rate of incorrect sampling, it is imperative that placental localizations are accurately mapped and the extreme ends of each placenta preferentially sampled. For example, in those cases with a lower and an upper placenta, a combined technique with a transcervical approach for the lower placenta and a transabdominal approach of the upper placenta may be used.

Which technique (amniocentesis or CVS) should be used and should both be sampled? The answer largely depends on chorionicity and the risk of one or both being affected. For dichorionic twins, both CVS and amniocentesis are

valuable options. Because CVS can be performed in the first trimester, selective feticide in the event of discordant chromosomal anomaly can be done at an earlier stage with the potential for a reduced risk for the healthy co-twin. Conversely, it may be preferable to restrict CVS to fetuses at especially high risk because the higher rates of contamination (e.g., first-trimester screening risk > 1/50), and defer invasive testing to 15 weeks for amniocentesis in lower risk cases. It is generally recommended both fetuses be sampled. Even though only one has an increased NT or anomaly, 10% of dichorionic twins are monozygotic. Amniocentesis is preferred to CVS in monochorionic twins, because rare heterokaryotypic monozygotic twins can be diagnosed only by sampling both sacs. Only if monochorionicity is accurately documented in the first trimester and none of the twins shows any discordant features is it possibly justifiable to sample only one fetus (by CVS or amniocentesis). In heterokaryotypic monozygotic twins, CVS of the common placenta may show mosaicism, a normal or abnormal karyotype, depending on the type and timing of postzygotic event.[70,72] If trisomic rescue is the mechanism involved, then the diploid fetus will have a one in three risk of uniparental disomy (UPD) for the specific chromosomal pair that is trisomic in its co-twin. UPD, om which both chromosomes in a pair are inherited from the same parent, will produce an abnormal phenotype if the involved chromosomal pair carries an imprinted region/gene or homozygous recessive mutation.[273] The presence of UPD should be excluded in heterokaryotic monozygotic twins. Counseling may be very difficult in heterokaryotypic twins because it is not possible to exclude the presence of hidden, but phenotypically important, mosaicism in the twin with normal karyotype on amniotic fluid cells. Cordocentesis is of little help in monochorionic twins because blood chimerism is invariably present, making genotyping of lymphocytes unreliable.

Fetal Risks

In dichorionic twins, the presence of a discordant anomaly usually does not affect the well-being of the other twin unless associated with hydramnios (such as anencephaly, duodenal atresia) or spontaneous demise, which increases the risk of preterm birth for the healthy co-twin. An ethical dilemma arises when elective preterm birth for ex utero treatment or antenatal invasive procedures with risk of iatrogenic PPROM (such as shunt placement) to ameliorate the outcome for the affected twin places the normal co-twin at risk of iatrogenic preterm birth. In contrast to dichorionic twins, the spontaneous demise of the anomalous twin may have disastrous consequences in a monochorionic twin pregnancy, because in addition to the consequences of severe preterm birth, it may lead to acute exsanguination of the healthy co-twin with dIUFD in about 12% and cerebral damage in 18%.[79]

Management Options

There are essentially three management options for discordant structural and chromosomal anomalies:

- Conservative management.
- Selective feticide.
- Termination of the whole pregnancy..

Paramount to safe management is an accurate determination of chorionicity in the first trimester because the methods for selective feticide differ between mono- and dichorionic twins.

Management in Dichorionic Twins

In cases in which the abnormality is nonlethal but might well result in serious handicap, parents must decide whether the burden of a handicapped child is enough to risk the loss of the healthy twin from feticide-related complications. In cases in which the abnormality is lethal, it may be best to avoid such risk and conservative management is preferable, unless the condition threatens the well-being of the healthy twin. Such a dilemma is illustrated by dichorionic twins discordant for anencephaly, which is always lethal but the associated hydramnios places the healthy co-twin at risk of severe preterm birth. However, expectant management in such cases is shown to have a favorable outcome for the unaffected fetus in dichorionic twins, with about half developing hydramnios and none delivering before 28 weeks (mean 36 wk).[274,275] Nevertheless, selective feticide appears associated with a higher gestational age at birth for similar perinatal survival rates.[276]

Selective feticide in dichorionic twins is performed by intracardiac or intrafunicular injection of potassium chloride/lidocaine under continuous ultrasound guidance. It is of utmost importance to ascertain that the correct fetus is terminated by identification of gender differences, obvious structural anomalies, placental localizations, and umbilical cord insertions. The risks of selective termination are loss of the entire pregnancy and preterm birth. The overall loss rate reported by the International Selective Feticide Registry of 402 multiple pregnancies including some higher-order multiple pregnancies is 7.5%. A breakdown by gestation (5.4% at 9–12 wk; 8.7% at 13–18 wk; and 6.8% at 19–24 wk) reveals no significant differences, but a suggestion of an increase after 13 weeks. Preterm birth before 33 weeks occurred in 22%, with 6% delivering between 25 and 28 weeks.[277] One center with 200 selective feticides reported an overall loss rate of only 4%, with significantly higher loss rates in triplets or higher-order multiplets (11%) than those in twins (2.4%), with 16% of patients delivering before 32 weeks.[278] This underlines the importance of referring to experienced centers. Some have suggested deferring selective feticide to 28 to 32 weeks in order to reduce loss rates, but this is an option only in countries in which late termination is legal and this is emotionally more difficult for both parents and doctors to accept. In one series of 23 dichorionic twins with a discordant nonlethal anomaly, there were no fetal losses and all patients delivered beyond 35 weeks.[279]

Selective Feticide in Monochorionic Twins

For selective feticide in monochorionic twins, the conventional techniques of potassium chloride/lidocaine injection used in multichorionic pregnancies cannot be used because the agent can reach the other fetus by the obligatory anastomoses.[280] In addition, patent intertwin vessels may lead to acute fetofetal hemorrhage into the terminated twin's fetoplacental unit, placing the surviving twin at risk for central nervous system damage or co-twin demise.[128] Therefore, the appropriate techniques arrest and isolate the target twin's circulation completely and permanently,[281] although all have

considerably higher risks for fetal loss and very early PPROM compared with systemic injection of an agent. Further, while expectant management may be preferable in dichorionic twins with an expected spontaneous demise of the anomalous twin, monochorionic gestations specifically warrant a preventive selective feticide. This is particularly relevant for discordant chromosomal anomalies in which aneuploidy has a high spontaneous intrauterine demise rate.[282,283]

As discussed in the section on the management of TRAP, the preferred method for selective feticide is cord occlusion by either laser or bipolar coagulation. The initially reported method of umbilical cord embolization using a variety of agents, including absolute alcohol, coils, and enbucrilate gel, is no longer recommended in light of failure rates exceeding 60%.[173,284] Anecdotal successes are reported, but dIFD is unfortunately common, probably owing to incomplete vascular obliteration or migration of the sclerosants or thrombogenic products to the co-twin.

Fetoscopic cord ligation is already a historical technique, although it does cause immediate, complete, and permanent interruption of both arterial and venous flow in the umbilical cord. Though co-twin survival rates are over 70% when done fetoscopically,[285] these procedures are quite cumbersome with a high risk for PPROM. In comparison, laser cord coagulation (Fig. 23–28) is a relatively simple and straightforward procedure and uses similar instruments and setup as for coagulation of the vascular anastomoses in TTTS. It is the preferred method, especially before 21 weeks. It can be performed as early as 16 weeks, using a double needle loaded with a 1.0-mm fetoscope and a 400-μm laser fiber.[286] However, it may be difficult to coagulate the umbilical cord at later gestational ages.

For this reason, bipolar energy was explored. Initially, a large-diameter forceps was used, but now purpose-designed devices of 3.0 mm or less are on the market as well as adapted cannulas and trocars. Most procedures can be done with a single port under ultrasound guidance (Fig. 23–29), but rarely an ancillary port is used for the fetoscope to identify the correct umbilical cord (e.g., monoamniotic twins). Under ultrasound guidance, a portion of the umbilical cord is grasped at the abdominal wall, at its placental insertion, or at any other appropriate place in order to ensure correct

identification and enhance stability. We try to work completely within the sac of the target fetus and use amnioinfusion only where needed. Direct contact with the placenta, fetus, or membranes is avoided. Coagulation starts at power settings of 15 W applied for approximately 15 seconds with progressive increments of 5 W until the appearance of turbulence and steam bubbles indicative of local heat production and, hence, eventual tissue coagulation between the forceps' blades (usually between 30 and 45 W). Higher initial energy settings are avoided to prevent tissue carbonization, which may lead to the cord becoming stuck to the forceps' blades and eventual cord perforation. Confirmation of arrest of flow distal to the occlusion is performed by color Doppler after the forceps is freed from the umbilical cord by gentle manipulation. Even if there is no longer any visible

FIGURE 23–28
Fetoscopic image of laser cord coagulation.
FIGURE 23–29
A, Ultrasound image of a bipolar cord coagulation in a monochorionic twin pregnancy. B, Ascending steam bubbles (*arrows*) confirm adequate coagulation impact.

flow, two additional cord segments (preferentially at a site more proximal toward the target fetus) are coagulated. This is an additional safety precaution, because absence of Doppler flow may be caused by temporary vasospasm or asystole rather than by true vascular obliteration. We now fetoscopically inspect all coagulation sites for completeness. In monoamniotic twins or after septostomy, the cord is first coagulated and then transected with laser in contact mode to avoid later cord entanglement. After completion of the procedure, amniodrainage of excessive fluid is carried out before removal of the cannula. PSV of the MCA is measured postoperatively to detect any fetal anemia.

In our initial series of 10 affected pregnancies, 2 patients had PPROM and underwent termination. The other 8 patients delivered at a mean gestational age of 35 weeks (>15 wk after the procedure).[169] Nicolini and colleagues[287] reported their experience with 17 cases. The survival rate was 81% (13/16 survivors; 1 patient had a termination of pregnancy because of an abnormality diagnosed later in gestation). There was 1 fetal hemorrhage caused by cord perforation, which is a complication of too much energy. We reported the outcome of 80 consecutive cord coagulations in complicated monochorionic multiplets (including 7 triplets) by laser and/or bipolar coagulation performed between 16 and 28 weeks (mean 21 wk).[288] Indications were TRAP (27.5%), discordant anomaly (35%), severe TTTS (30%), and selective growth restriction (7.5%). In 70%, the laser was used as the primary technique; additional bipolar was necessary in about half of cases. Overall survival was 83% with normal neurodevelopmental outcome in 92% of infants. Persistent PPROM occurred in 38%, and if prior to 25 weeks, this was associated with a mortality of 80%. There were no serious maternal complications, except for one mild transient mirror or Ballantyne's syndrome. Five cases involved heterokaryotypic monochorionic twins (46, XY/47,XY,+21; 46, XX/47,XX,+13; 46,XY/45,X; 2 46,XX/45,X), and umbilical cord occlusion resulted in a successful outcome in all 5 cases. All 5 surviving children were phenotypically normal at birth (range 34–40 wk) and are developing normally.[72] Robyr and associates[289] reported their experience with umbilical cord coagulation in 46 consecutive cases. They reported a 72% survival rate. In their series, there was a higher incidence of intrauterine demise in procedures performed prior to 18 weeks.

Putting all the previously mentioned series together, the overall survival of umbilical cord coagulation is about 80%. About half of the losses are attributable to intrauterine demise of the healthy co-twin and about half to postnatal losses due to very preterm birth, mostly related to PPROM. Again, about half of the intrauterine deaths occur within 24 hours of surgery, and may reflect either intraoperative vessel perforation, incomplete cord coagulation by laser coagulation, or exsanguination of the surviving twin into the placenta of the dead twin, which may be especially relevant prior to 18 weeks when the placental mass is still relatively large compared with the fetal mass. Late intrauterine death has been diagnosed up to 10 weeks after the procedure and was commonly related to cord entanglement after septostomy. This finding supports the use of cord transection after septostomy or in monoamniotic gestations. Postoperative anemia diagnosed by MCA PSV measurements within 24 hours and requiring an intrauterine transfusion occurred in 2% to 3% of cases and resulted in a normal outcome in all instances.

Similar to the treatment for TTTS, PPROM is an important complication of umbilical cord coagulation, accounting for miscarriage, severe preterm birth, neonatal death, and developmental delay. We demonstrated a significant decrease from 42% to 6% in PPROM prior to 31 weeks with increasing experience, which again underscores the need to restrict this procedure to a limited number of hands.[290] To avoid the risks of early PPROM for the healthy co-twin, it may be preferable to defer selective feticide until after 24 weeks in highly selected cases of discordant anomaly in which the risk of spontaneous intrauterine demise is small (such as in severe discordant central nervous system, genitourinary, skeletal anomaly). Bipolar coagulation can then be performed using the 3.0-mm forceps by overstretching the blades, whereupon the forceps opens more widely to accommodate for the larger cord diameter. We reported on a consecutive series of five cases in which selective feticide was performed between 26 to 30 weeks' gestation. All deliveries occurred beyond 31 weeks (range 31–37 wk). All infants survived, except for one unrelated neonatal demise of a child born at 36 weeks due to a complication of failed therapy for pulmonary stenosis.[290]

It remains to be demonstrated whether needle-based intrafetal coagulation techniques[291,292] are as effective to achieve selective feticide for discordant monochorionic twins as for TRAP. As such, radiofrequency ablation for non-TRAP indications resulted in an overall survival rate of only 60% (9/15 fetuses intended to continue).[293–295] Similar survival rates were reported after intrafetal laser coagulation.[296] Although these techniques perform well in the low-flow conditions of acardiac twins in TRAP, they may fail in the normal flow conditions of a monochorionic twin with a discordant anomaly. Accordingly, larger series with long-term neurodevelopmental follow-up are necessary to establish the efficacy of intrafetal coagulation for non-TRAP monochorionic pathologies.

Currently, it is not possible to state the single best method for selective feticide in monochorionic pregnancies. The surgeon should be familiar with several techniques in order to tailor therapy to the individual requirements of each case. Generally, we recommend laser fetoscopic cord coagulation as a primary technique before 21 weeks, whereas beyond 21 weeks, laser or bipolar coagulation can be used depending on cord diameter.[297] Cord ligation should be available as back up should all other methods fail. These procedures should be performed in experienced tertiary referral centers to ensure a large enough caseload. Also, the surviving twin should be followed carefully throughout pregnancy and after birth with the minimum of an early neonatal brain scan and developmental assessment at 1 year of age.

Issues Applicable to Monochorionic and Dichorionic Twins

As for singletons, Rh prophylaxis should be given in all instances of invasive antenatal procedures in Rh-negative women in which the fetal genotype is unknown. As with the intrauterine death of one twin, the incidence of maternal disseminated intravascular coagulation appears rare and routine checks of coagulation parameters may therefore be

unnecessary. From 20 weeks onward, the use of fetal analgesia or anesthesia by administration of fentanyl or other opioid alternative should be considered prior to feticide to reduce fetal awareness and pain sensation.[298] To many people, any deliberate termination of a fetus is controversial and the decision to proceed to selective feticide may be difficult. Therefore, psychological support and counseling for the family is strongly recommended before and after the selective feticide.

Acknowledgment

SUMMARY OF MANAGEMENT OPTIONS
Congenital Abnomalies in Twins

Management Options	Evidence Quality and Recommendation	References
Issues Applicable to All Twins		
Options	—/GPP	—
Conservative management.		
Selective feticide of the abnormal fetus.		
Termination of the pregnancy.		
Offer counseling and psychological support.	—/GPP	—
Accurate chorionicity determination is essential.	IIb/B	20,21
Anti-D prophylaxis for procedures.	—/GPP	—
Dichorionic Twins		
Conservative management is usually preferred if the condition is lethal to avoid intervention loss rates.	III/B	279
Selective feticide is performed by intracardiac or intrafunicular injection of KCl.	III/B	279
Loss of the healthy fetus occurs in about 7.5% with delivery before 33 wk in 22%.	III/B	277,279
Monochorionic Twins		
Conditions with a high risk of IUFD may indicate selective feticide.	—/GPP	—
Selective feticide is performed by cord occlusion (to avoid the loss of normal co-twin if KCl used).	III/B	281,290
After cord occlusion, the healthy fetus survives in about 80%, with 80% delivering after 32 wk.	III/B	290
Careful follow-up of surviving normal twin.	—/GPP	—

GPP, good practice point; IUFD, intrauterine fetal demise.

Fetal Hydrops

JOHN S. SMOLENIEC

INTRODUCTION

Fetal hydrops is associated with high perinatal morbidity and mortality rates at all gestational ages. However, outcome statistics are greatly influenced by such factors as the etiology (immune vs. nonimmune), gestation at diagnosis, timely referral, prenatal compared with neonatal study groups, and the available health resources in the particular population and their use in the implementation of preconception and antenatal screening programs[1-3] (see Chapters 4 and 7–9). These factors are reflected in the range of reported incidences from $1:424$[2] to approximately $1:1700$[4] to $1:2000$[3] neonatal admissions for hydropic fetuses born alive in developed countries. Traditionally, fetal hydrops is categorized into immune (IH) and nonimmune (NIH) disease. Although rhesus (RhD) hemolytic disease was the most common cause of hydrops in the past (see Chapter 13), the widespread implementation of anti-D immunoglobulin prophylaxis and the improved antenatal management of at-risk fetuses have led to a significant decrease in its incidence and associated morbidity and mortality (e.g., perinatal mortality decreased from 50% to 2% in Canada[5]; see Chapter 13). In contrast, the survival rates for NIH remain less than 10%[4] and as low as 1.5% (2/138).[1] At present, NIH is more prevalent than IH $(4:1)$[3] in most countries with adequate anti-D immunoglobulin prophylaxis supplies and fetomaternal expertise.

Human fetal hydrops is the endpoint of a multitude of pathophysiologic pathways, a number of which have not been elucidated. Advances in ultrasound make fetal hydrops easy to diagnose. The "causes" or rather associations with NIH are many[1-4,6] (Table 24–1). Research using animal models[7-9] provides some understanding of the complexity of fluid dynamics within the uterus (fetal, fetoplacental, fetoamniotic fluid, and between the uterine decidua and the placenta and membranes).

INCIDENCE

The incidence is regionally dependent[1,3,4] (e.g., alpha-thalassemia) and subject to seasonal variation (e.g., parvovirus B19 epidemics.[10,11] Alpha-thalassemia is the most common cause of fetal hydrops in Southeast Asia,[2,12] where the carrier frequency ranges from 4.14%[2] for alpha-thalassemia caused by the Southeast Asian deletion in southern China to 14% in northern Thailand,[13] accounting for between 28%[13] and 55%[2] of cases in these regions. Considering the population density in this region, alpha-thalassemia is probably the leading cause of NIH in the world. Population screening can reduce the incidence of thalassemia,[1,12,13] as it has in Cyprus, providing the resources are available. Similarly, the incidence of NIH associated with aneuploidy and congenital heart disease[14,15] is likely to decrease with the implementation of first-trimester screening (see Chapter 7).

DEFINITION

Hydrops is defined as the excessive extravascular accumulation of fluid in the interstitial compartment secondary to the disruption of the normal intravascular interstitial fluid homeostatic mechanisms. The excessive accumulation of interstitial fluid, particularly in serous cavities (peritoneal, pleural, pericardial), placenta, and amniotic fluid, facilitates the sonographic diagnosis of fetal hydrops (Figs. 24–1 to 24–3). Classically, the sonographic diagnosis of hydrops requires the presence of generalized edema plus the accumulation of fluid within two or more serous cavities. However, many of the pathophysiologic pathways leading to such a diagnosis go through progressive phases in which initially fluid may be recognized sonographically in only one site.

PATHOPHYSIOLOGY

Hydrops occurs when the microvascular fluid exchange regulatory system is disturbed. Microvascular fluid exchange mechanisms in the human fetus are complex, gestational age–dependent, and poorly understood. The number of fluid exchange pathways in the fetus is greater than in either the infant or the adult. They include transplacental, transmembrane, and transcutaneous pathways. Transplacental fluid exchange has a large influence on blood volume, because the placental blood volume accounts for approximately 40% of the total fetal circulation.[16] Fetal development is associated with a continual change in the different fluid exchange pathways and forces. These routes of fetal fluid exchange may be important compensatory mechanisms when fluid homeostasis is disturbed, as shown by the common clinical

Abnormalities Associated with Hydrops*

Immune (see Chapter 13)
  Anti-D and other Rh antibodies
  Antibodies to K in Kell system
  Antibodies to Fya in Duffy system
Nonimmune
Idiopathic/unknown
Anemia (other than alloimmunization)
  Alpha-thalassemia major 1 (see Chapter 38)
  Parvovirus B19 congenital infection (see Chapter 29)
  Fetomaternal transfusion
  TTTS and variants (see Chapter 23)
  Erythroleukemia
  Congenital erythropoietic porphyria[35] (Gunther's disease)
Cardiovascular (see Chapters 15 and 16)
  Severe congenital heart disease[43] (atrial septal defect, ventriculoseptal
    defect, hypoplastic left heart, pulmonary valve insufficiency,
    Ebstein's anomaly, subaortic stenosis, atrioventricular canal defect,
    tetralogy of Fallot, heterotaxy; premature closure of foramen ovale)
  High-output cardiac failure: associated with large arteriovenous
    malformation within the fetal vasculature or tumors
  Premature closure of ductus (? indomethacin therapy)
  Myocarditis (coxsackievirus, cytomegalovirus, parvovirus B19,
    adenovirus infections)
  Tachyarrhythmias (supraventricular tachycardia, atrial flutter)[88]
  Bradyarrhythmias (heart block)
  Wolff-Parkinson-White syndrome
  Intracardiac tumors (teratoma, rhabdomyoma[84]) (see Chapter 22)
  Cardiomyopathy (e.g., fibroelastosis)
  Myocardial infarction
  Arterial calcification (e.g., idiopathic infantile arterial calcification[85])
Chromosomal (see Chapter 4)
  Trisomies
  Turner's syndrome (45 XO)
  Triploidy
Pulmonary
  Congenital hydro-/chylothorax
  Pulmonary lymphangiectasia
  Congenital pulmonary tumors/anomalies[46,47,48]
    CCAM (see Chapter 23)
    Pulmonary sequestration
    Bronchogenic cysts and other tumors (see Chapter 23)
  Diaphragmatic hernia (see Chapter 19)
  Chondrodysplasia
  Pulmonary hypoplasia
Renal (see Chapter 18)
  Congenital nephrosis (Finnish type)
  Renal vein thrombosis
  Urethral obstruction (atresia, posterior valves)
  Spontaneous bladder perforation
  Cloacal malformation
  Prune-belly syndrome
Infection (intrauterine) (see Chapters 29–32)

FIGURE 24–3
Polyhydramnios and massive ascites associated with Niemann-Pick type C inborn errors of metabolism.

association of hydramnios and placental edema with fetal hydrops regardless of the underlying cause. The fetal extracellular fluid volume (ECF) exceeds the intracellular fluid volume (ICF), though the ECF : ICF ratio declines progressively with gestation, becoming less than 1 after birth.[17] The interstitial–to–plasma volume ratio is therefore greatest in the fetus and then declines into adulthood. Control of this relatively large interstitial fluid compartment is fundamental to the understanding of fetal hydrops. Unfortunately, interstitial fluid control mechanisms are poorly understood because of the difficulty of measuring plasma and interstitial volumes.[18] The many influences on fetal fluid homeostasis make it unlikely there is a single or simple pathophysiologic explanation for all cases of fetal hydrops. The "Starling equation" does not provide pathophysiologic explanations in the fetus.[19] The fluid-dominated milieu of the fetus and the specific physiologic characteristics of the fetal heart and the lymphatic system make it particularly susceptible to hydrops. Animal research[7,8,20,21] coupled with clinical studies[19,22,23] suggest that raised central venous pressure (CVP) is a critical step in the pathophysiology of hydrops, at least with a cause associated with poor heart function (e.g., myocardopathy, obstructed cardiac return or outflow, profound anemia). The clinical use of umbilical venous pressure (UVP) in the investigation and management of some cases of fetal hydrops is a vindication of the physiologic research findings on the importance of the CVP and the lymphatic system.[22,23] At the same time, some of the traditional pathophysiologic forces such as colloid oncotic pressure are being relegated to a lower tier of importance.

RISKS

Fetal Risks

The fetal risks from hydrops are mainly fetal death with infant morbidity, an important risk in the few survivors. The commonly reported conditions associated with fetal hydrops are

- Alpha-thalassemia; aneuploidy; congenital malformations, infection, and the idiopathic (unknown) group.
- *Fetal death* is mostly influenced by the associated condition, gestation at diagnosis, gestation at delivery, and management. The reported mortality rate ranges between 45%[2] and greater than 90%.[1,3] Management options include elective abortion, various invasive diagnostic and fewer therapeutic procedures, which are in themselves associated with a risk of pregnancy loss, preterm delivery, intrauterine fetal death, and fetal trauma (see Chapters 9 and 25).
- *Infant mortality* is influenced by the etiology, severity, and duration of the hydrops, prenatal procedures performed, gestational age at delivery, and neonatal management. Congenital anomalies are consistently reported with a 57% mortality.[2] In contrast, mortality associated with primary chylothorax, an uncommon association with NIH, may be as low as 6%[2] after admission to a neonatal unit in a developed country.
- *Infant morbidity*. The short- and long-term prognosis depends on many of the factors associated with mortality. The range of more severe morbidity includes terminal cardiac failure and heart transplantation,[24] fetal cerebellar

hemorrhage associated with parvovirus B19 infection,[25] cardiac anomaly needing surgical correction, chromosomal abnormality, persistent generalized edema as a result of protein-losing enteropathy associated with congenital intestinal lymphatic hypoplasia,[26] and cerebral palsy.

Maternal Risks

- Antenatal consequences of fetal hydrops may be classified as direct or indirect:
  - *Direct consequences* include associated hyperplacentosis and hydramnios. Hyperplacentosis is a large placental mass with associated dysfunction such as villus edema, impaired oxygen exchange–hypoxia–increased angiogenic factors (i.e., soluble fms-like tyrosine kinase 1 [sFlt-1]).[27,28] This pathophysiologic process is associated with maternal dilutional anemia, edema, proteinuria, and gestational hypertension (i.e., preeclampsia or "mirror syndrome").[27,28] Hydramnios is associated with malpresentation, preterm labor, and preterm rupture of membranes (PROM) with the associated risk of placental abruption and chorioamnionitis.
  - *Indirect consequences* include the complications of intrauterine investigations and therapy, namely, PROM, chorioamnionitis, abruption (associated with amniodrainage), anemia, and maternal red blood cell alloimmunization. In the event of fetal surgery, the maternal risks include anesthetic risks, fluid overload and electrolyte imbalance, uterine hemorrhage (during entry for fetal shunting and intrauterine laser procedures[29,30]), psychological stress and associated mental illness, and even maternal death.[30] In patients undergoing open fetal surgery, the risks include adverse reproductive outcomes in 35% of future pregnancies, including uterine rupture or dehiscence, antepartum hemorrhage, and cesarean hysterectomy.[31]
- *During labor and delivery*: Hydrops may be associated with preterm labor, the side effects of tocolysis, dystocia (e.g., large tumors), cesarean delivery (e.g., associated with malpresentation, cord prolapse), abruption associated with membrane rupture in cases with hydramnios, postpartum hemorrhage (primary and secondary), and retained placenta.

MANAGEMENT OPTIONS

Prepregnancy

Prevention initiatives are based on the prevalence of conditions associated with fetal hydrops ideally identified by an audit in the region.

Prevention initiatives may include
- Prenatal screening for preventable conditions such as
  - Alpha-thalassaemia.[1,12,13]
  - Inborn errors of metabolism.
- Assessing immunity:
  - Of at-risk women of exposure to parvovirus B19 infection in densely populated areas[10] during an outbreak.
  - Possibly cytomegalovirus (CMV).
  - Syphilis.[1]

Prenatally

Once fetal hydrops is identified, the mother should be counseled regarding the following:
- Diagnosis: based on maternal and fetal investigations (Tables 24–2 and 24–3) and associated fetal risks from invasive procedures.
- Prognosis: fetal risks, both short and long term, which are influenced by the diagnosis and may remain unknown.
- Treatment: if available and feasible in the circumstances.

DIAGNOSIS

Presentation

Fetal hydrops clinically presents in one of several ways (Table 24–4). The fetal sites of fluid collection and the amount of fluid (severity) may be helpful in the management of the hydrops once the cause is ascertained. In general, oligohydramnios is a poor prognostic sign.

Investigations

A comprehensive search in the mother and fetus for the "cause" usually involves antenatal invasive procedures (see

---

TABLE 24–2

Maternal Investigations for Fetal Hydrops

Maternal History

Parvovirus B19 epidemic and close proximity to children, immunity[10]
Previous fetal hydrops or diagnosis associated with hydrops[74,75]
Previous baby with jaundice
Ethnic origin[1,12,13]
Hemoglobinopathy trait (e.g., alpha-thalassemia[1,12,13,38])
Consanguinity[75]
Congenital heart disease
Family history of hydrops (inborn errors of metabolism)[74,75]
Endocrine disorder
Symptoms of "mirror syndrome"[27,28] (i.e., preeclampsia; see Chapter 35)

Maternal Blood

Complete blood count (e.g., microcytosis–alpha-thalassemia trait)
Electrophoresis (depending upon blood count result and ethnic background)
Blood group and antibody screen (titer if antibodies present)[37]
Glucose-6-phosphate dehydrogenase and pyruvate kinase carrier status
α-Fetoprotein
Serologic tests (of limited value; see Chapters 29–32)
Syphilis[1]
Parvovirus B19[36,69]
Toxoplasmosis
Cytomegalovirus (primary and also secondary)[34]
Herpes simplex virus
Adenovirus
Coxsackievirus
Uric acid, urea, and electrolytes
Liver function including albumin
Kleihauer (-Betke) test[42]
Test of glucose tolerance
SLE, especially anti-Ro/SSA or anti-La/SSB antigens, if bradycardia/heart block
Thyroid function tests including antibodies: TSH and TSH-binding inhibitor IgG (see Chapter 21)

IgG, immunoglobulin G; SLE, systemic lupus erythematosus; TSH, thyroid-stimulating hormone.

TABLE 24–3
Fetal Prenatal Investigations for Fetal Hydrops

Ultrasound

Sites and severity of hydrops (see Figs. 24–1 to 24–5)
Detailed real-time ultrasound for congenital abnormality[14] and
    abnormality of placenta (chorioangioma[63,67]) and cord (cysts[86])
Fetal echocardiography,[44] pulsed[43] and color Doppler studies and
    M-mode
Amniotic fluid volume
Biophysical assessment (nonstress testing or biophysical profile score).

Invasive (Mainly Fetal Blood)

Hematologic tests: full blood count, hemoglobin electrophoresis
    (depending on ethnic background); group and Coombs'
Infection: polymerase chain reaction, serologic tests for acute
    phase-specific IgM antibodies for infection; culture
Blood gas analysis and pH estimation to provide an indication of the
    immediate well-being of the fetus
Karyotype (blood, placenta, amniotic fluid, ascitic or pleural fluids are
    suitable sources)
Intrathoracic pressure[58]/UVP[23]
Liver function tests (albumin)
Cultured amniotic fluid cells enzyme testing for lysosomal storage
    diseases (e.g., Gaucher's mucopolysaccharidoses[75])

IgM, immunoglobulin M; UVP, umbilical venous pressure.

TABLE 24–4
Presentation of Fetal Hydrops

By chance:
    Ultrasound examination
    Fetal heart rate recording
Ultrasound surveillance of pregnancies at risk of fetal hydrops (i.e., TTTS
    in monochorionic twin pregnancy; alpha-thalassemia trait parents[1];
    large fetomaternal hemorrhage following trauma; fetal arrhythmia;
    fetal anomaly [e.g., congenital heart defect[44]]; fetal tumor,[63] cystic
    hygroma, large nuchal translucency)
Large-for-dates/hydramnios
Reduced fetal movements
Placental abruption (e.g., associated with "mirror syndrome"[28] or
    chorioangioma[67])
Maternal diabetes
Maternal SLE/anti-Ro antibodies
Maternal preeclampsia/mirror syndrome[27,28]
Maternal parvovirus B19 primary infection or contact/at risk for
    infection[10,28,31,69]

SLE, systemic lupus erythematosus; TTTS, twin-twin transfusion syndrome.

FIGURE 24–4
Twin-twin transfusion syndrome. Recipient hydropic at 20 weeks' gestational age.
FIGURE 24–5
First-trimester large nuchal translucency and hydrops associated with aneuploidy.

Tables 24–2 and 24–3). The hydrops severity, gestational age, ultrasound identified anomalies, ultrasound Doppler assessment, and the parents' consent will influence the decision to perform these procedures. The ultrasound scan (Figs. 24–4 and 24–5; see also Fig. 24–1) may in the majority of cases assist in the diagnosis. The diagnosis may escape antenatal detection in 10%[1] to 33%.[32] Real-time gray scale and pulsed Doppler ultrasound assessment of the hydropic fetus are assuming an ever-increasing important role in the noninvasive assessment of associated causes such as structural cardiac anomalies or cardiac dysfunction secondary to hyperdynamic flow (i.e., anemia or associated with tumors or twin-twin transfusion syndrome [TTTS]). On completion of both the noninvasive fetal assessment and, ideally, the

maternal investigations, the most common invasive procedures will be fetal blood sampling (FBS) and/or amniocentesis. FBS is preferred (Table 24–5), but the associated mortality rates higher than for nonhydropic indications,[33] especially if the fetus is thrombocytopenic (e.g., parvovirus B19 infection) and when it is technically more difficult (e.g., maternal obesity, <20 wk' gestational age).

It is important to optimize the information available when planning intrauterine procedures (amniocentesis or FBS). For example, in the case of severe lung compression with heart axis deviation associated with large pleural effusions, a pleural tap may be combined with either procedure to determine the effect of decompression on the lungs and the restoration of the heart to its normal midline position. Pleural fluid can be used for investigations (karyotype, infection screen, cell type and count). Intrathoracic pressure and UVP measurements before and after the drainage may be used prognostically. The UVP is used as a surrogate for fetal CVP, and an elevated UVP for gestational age suggests cardiac dysfunction is involved. Limited human study notes a good correlation between the fetal UVP and CVP, but this relationship did not hold true in the anemic fetal sheep.[9]

Comparative Diagnostic Value of Amniocentesis and Fetal Blood Sampling

Amniocentesis

Karyotyping (FISH for chromosomes 13, 18, 21, sex chromosomes, and culture may take up to 2 wk for a result)

Infection screen–PCR

CEP—amniotic fluid is dark brown, which fluoresces red under Wood's light; increase in type 1 uro- and coproporphyrin isomers[35]

Inborn errors of metabolism screen[74] (i.e., lysosomal storage diseases[75])

Fetal Blood Sampling

Karyotyping (48–72 hr for a result in many centers)

Hematologic causes (anemia; hemoglobinopathies)

Infection screen

UVP

CEP, congenital erythropoietic porphyria; FISH, fluorescence in situ hybridization; PCR, polymerase chain reaction; UVP, umbilical vein pressure.

Role of Umbilical Vein Pressure Measurement in the Treatment of Nonimmune Hydrops

The measurement of UVP is a helpful guide in the management of fetal hydrops. There are no reports of reproducibly effective therapy or NIH associated with a normal UVP.[19] This suggests that such fetuses should not be subjected to additional invasive procedures in hopes of therapy. Normalization of an elevated UVP after treatment suggests that the therapy will be successful and the hydrops will resolve. Hydrops characterized by an elevated UVP not remedied by either surgical or medical therapy is usually progressive, and the fetus either dies in utero or requires preterm delivery for postnatal therapy.[23] It seems, therefore, that measurement of the fetal UVP should be viewed as a guide to therapy when FBS is planned but is not, in and of itself, an indication for the sampling.

Amniotic fluid may be used to karyotype and to screen for infections associated with hydrops, such as parvovirus B19, CMV primary and secondary maternal infection,[34] syphilis,[1] toxoplasmosis, and herpes simplex virus (HSV), inherited disorders of metabolism (e.g., lysosomal storage diseases; see Chapters 29–32). It is also useful in the diagnosis of the rare condition of congenital erythropoietic porphyria.[35] However, FBS provides more information (e.g., anemia, Coombs' test, UVP) along with quicker karyotyping of all 23 pairs of chromosomes than amniocentesis. Furthermore, treatment can be administered at the time of the procedure in cases of anemia, especially when suspected on the basis of an elevated middle cerebral artery peak systolic velocity (MCAPV).[36] It is important to screen for rare antibodies (Coombs' test), which can be comprehensively done only in regional blood transfusion laboratories, before making the diagnosis of NIH.[37]

Polymerase chain reaction investigation has revolutionized the diagnosis of fetal infection. A maternal infection screen should be performed before the fetal screen in order to optimize the use of the relatively small fetal sample. An extra 2-mL aliquot should be stored at –20°C in case the need for additional tests becomes apparent after the preliminary laboratory results have been completed (e.g., to screen for secondary CMV infection).[34]

The optimal time for prognostic counseling is after the results of the maternal and fetal investigations are available. After multidisciplinary counseling, the patient may elect to undergo a termination of pregnancy, should this be an acceptable option.

The study of fetal nucleic acids in maternal plasma is opening up the possibility of the diagnosis of fetal chromosomal aberrations without the risk of intrauterine invasive procedures.[38] This methodology is already in clinical use in RhD typing of the fetus (see Chapter 13).

Postmortem Examination (See Chapter 25)

When antenatal treatment has not been either possible or successful (e.g., stillbirth or termination of pregnancy), a postmortem examination of the fetus and placenta is potentially important to reduce the percentage assigned to the idiopathic category and to facilitate risk recurrence counseling.

TREATMENT

General

The overall number of NIH cases amenable to antenatal therapy is small, the exception being during parvovirus B19 outbreaks. To date, fetal hydrops has proved amenable to fetal therapy only when associated with the following:

- Anemia.
- Arrhythmia.
- Hydrothoraces.
- TTTS.
- Some tumors (case reports).

Infection, arrhythmia, and TTTS are conditions in which spontaneously reversible hydrops has been reported. The management of TTTS is detailed in Chapter 23.

Anemia

Fetal blood transfusion is the treatment of choice for hydrops secondary to anemia. The prognosis, however, may be poor in some cases of anemia (i.e., when associated with homozygous alpha-thalassemia, CMV infection, trisomy 21, or Gunther's disease).[24,25] It is important, therefore, to determine the cause of the anemia before offering intrauterine transfusion. This may mean not transfusing the fetus (with the patient's agreement) before all investigations (especially on the parents for alpha-thalassemia trait) and fetal karyotype are available. This point should be discussed during the initial counseling session; otherwise, ill-advised transfusions of the fetus with homozygous alpha-thalassemia may result in lifelong transfusions or bone marrow transplantation, iron chelation, and the associated serious neonatal complications.[38]

In Southeast Asia, alpha-thalassemia is the predominant cause of fetal hydrops.[1,12,13,39] Alpha-thalassemia major (no functional α genes) is incompatible with life. Most fetuses develop hydrops by the early third trimester (see Fig. 24–1) and, if born alive, die within hours. This is in contrast with

other common causes of fetal anemia for which the prognosis is generally good. Antenatal diagnosis using noninvasive means (ultrasound diagnosis of placental thickness and cardiothoracic ratio before 20 wk or MCAPV thereafter) or invasive methods to obtain fetal tissue samples (amniocentesis, CVS or FBS) is an option for those pregnancies at risk. Preconceptual education, screening, and counseling are to be encouraged (see Chapter 38). The prognosis may improve with advances in intrauterine therapy.[40,41]

Fetomaternal hemorrhage associated with hydrops is rare and is diagnosed based on a strongly positive Kleihauer-Betke test in the mother, an ultrasound showing hydrops, and an elevated MCAPV. It is treated by a fetal intravascular transfusion(s). Presenting symptoms are nonspecific, with the most common being decreased fetal movements. Fetomaternal hemorrhage has been associated with a number of placental disorders (e.g., chorioangioma, abruption) and external forces acting on the mother or uterus (e.g., trauma, external cephalic version, invasive procedures). Regular surveillance of the fetus using ultrasound measurement of the MCAPV for anemia for further episodes[42] is recommended, because they may be fatal. Under these conditions, delivery should be considered once the pregnancy has reached an appropriate gestation.

Glucose-6-phosphate dehydrogenase (G-6-PD) deficiency is, although a common enzyme deficiency, an extremely rare cause with NIH with anemia being more common after birth. There are no effective antenatal treatments at present. However, gene therapy may prove possible in the future, and interdisciplinary counseling including pediatric colleagues and clinical geneticists is advisable.

Monochorionic Multiple Pregnancy Conditions Associated with Hydrops (See Chapter 23)

TTTS is the most common cause of NIH in monochorionic multiple pregnancy (see Fig. 24–4). It may also occur as a complication of laser treatment (i.e., reverse TTTS; see Chapter 23). The optimal management of hydrops associated with TTTS is intrauterine laser ablation of placental anastomoses.[29,30] Other proposed treatments such as amniodrainage, umbilical cord occlusion, delivery, intrauterine fetal transfusion (following failed laser), and termination are clearly less desirable. Another complication of monochorionic multiple pregnancy associated with NIH is twin reversed arterial perfusion, the management of which is based on the same principle as that for TTTS (i.e., interrupt the blood flow between the twins; see Chapter 23).

Cardiovascular Defects (See also Chapters 15 and 16)

Cardiac anomalies are the most common anatomic anomaly associated with fetal hydrops.[1,2] However, many of these anomalies do not affect function to the extent that they can explain the hydrops. There is a strong association with aneuploidy (10%–40%). The implementation of first-trimester screening should reduce the prevalence of hydrops (see Chapter 7).

Cardiac dysfunction leading to hydrops may be caused by structural anomalies, arrhythmias, or both (e.g., heterotaxy). In general, hydrops associated with a structurally abnormal heart carries a poor prognosis, with a survival rate of 0%[43] to 17%.[44] In contrast, the prognosis is good for the majority of hydrops cases associated with a tachyarrhythmia and a structurally normal heart. The response for supraventricular tachycardia is good in the majority of cases whether the approach is transplacental or direct. In a minority of cases, the arrhythmia may be secondary to thyroid-stimulating antibodies, viral infections (myocarditis, e.g., parvovirus/coxsackie/adenovirus) or maternal autoantibodies (e.g., SSA/Ro and SSB/La antibodies), which would influence management. One mechanism by which congenital infection might cause fetal hydrops is a fetal myocarditis that in turn generates either ventricular dysfunction or tachyarrhythmia resulting in hydrops. Fetal myocarditis has even required perinatal heart transplantation.[24] Pediatric follow-up is recommended because there may be neurologic morbidity associated with a long duration of hydrops.[45]

Involvement of a pediatric cardiologist in the antenatal management (especially diagnosis and prognostic counseling[44]) is advisable. The management options for these conditions are discussed in Chapter 16.

Pulmonary Defects

The prognosis for thoracic conditions associated with hydrops is generally poor.[46,47] These conditions include congenital cystic adenomatoid malformation (CCAM), bronchopulmonary sequestration (BPS), tracheal laryngeal atresia or congenital high-airway obstruction (CHAOS), teratomas (see Chapter 22), and primary hydrothorax. The prognosis is better for conditions predominantly associated with collections of fluid such as CCAM Stoker types I and II, with the greatest therapeutic success achieved treating primary hydrothorax.[48,49] In contrast, fetal hydrops associated with solid lung masses has been more difficult to treat (e.g., CCAM type III, some type II; pulmonary sequestration; see Chapter 22). The survival of newborns with solid CCAM masses and hydrops ranges from 0% to 34%.[46,47]

The low survival has led some to offer open fetal surgery to a few highly selected cases. It is associated with an estimated 60% survival but with significant fetal morbidity and maternal morbidity that affects future pregnancies.[48] Moreover, there are an increasing number of successful therapeutic options for solid lung lesions using ultrasound-guided percutaneous injection of a sclerosant or laser vaporization.[50–52] There are also reports of spontaneous resolution of the hydrops[53] associated with regression of the lesion. Even maternal betamethasone has been reported to slow or decrease large CCAM growth.[54] In cases of hydrops associated with large pulmonary masses in which delivery is the chosen treatment option (usually when a late diagnosis is made ~ 35 wk), an EXIT (ex utero intrapartum treatment) procedure is indicated for delivery (see Chapter 22).

Fetal hydrops associated with isolated primary or congenital hydrothorax has a much improved prognosis in contrast to the poor prognosis with solid thoracic lesions. The survival rate of untreated hydrops and pleural effusions approximates 35%, but increases to 62%[49] to 67%[55]

after placement of a pleuroamniotic shunt (unscreened by UVP).

The diagnosis of congenital hydrothorax is a diagnosis of exclusion—excess pleural fluid in the absence of another detectable cause. The hydrothorax typically presents after 24 weeks when human lung development has entered the canalicular phase. The pathogenesis is unknown but is often attributed to abnormalities of the lymphatic system of the lung and/or thoracic duct.[56] The lymphocyte content of the fluid is irrelevant to either the prognosis or the diagnosis.[57] Although it has been known since the mid-1980s that placement of a thoracoamniotic shunt could reverse the hydrops, reported success rates are quite variable.[49,55] This suggests that more than one mechanism underlies the hydrops, and

shunting is targeted.[49,56] Although shunting is the most common treatment, other, less frequently reported treatment options question whether it is the best treatment.[55] The therapeutic mechanism of pleuroamniotic shunting is thought by some to be related to the decrease in intrathoracic pressure allowing improved cardiovascular function.[49,58] Others suggest the improved cardiac function reflects the correction of a mechanical obstruction to cardiac return. An initially elevated UVP associated with elevated intrathoracic pressure, both of which normalize after the effusion(s) has been, drained is consistent with the latter.[58] If the effusion recurs, placement of a thoracoamniotic shunt should be curative (Fig. 24–6). Conversely, if the UVP is normal prior to decompression of the chest, or remains elevated after the chest has been drained and the heart has returned to its normal midline position, the placement of a thoracoamniotic shunt is unlikely to be beneficial. It is also believed, based on animal models, that relief of lung compression decreases the risk of pulmonary hypoplasia.

FIGURE 24–6
Infant at birth with pleuroamniotic shunt in situ immediately before removal; no need for respiratory support.

PROCEDURE: INSERTION OF FETAL THORACOAMNIOTIC SHUNT (FIG. 24–7)

Intrauterine shunts available include the larger Rocket Medical (2.1-mm diameter shunt) and Karl Storz introducers (3-mm cannula size) and the smaller Harrison shunt (Fetal Bladder Stent Set, Cook Medical, Inc.) (1.67-mm shunt diameter) introduced via a smaller 13-gauge needle (used in early gestations[59]).
FIGURE 24–7
Procedure for the insertion of a pleuroamniotic shunt. *A,* The introducer (trocar and cannula) are sited under ultrasound guidance in the left side of the fetal chest. *B,* The trocar has been removed, the pigtail catheter sited into the cannula, and the "first-stage push rod" (*shorter rod*) used to push the distal end of the pigtail catheter in the fetal chest. *C,* The tip of the cannula is withdrawn from the chest into the amniotic space and the "second-stage punch rod" (*longer rod*) is inserted into the cannula and displaces the proximal/maternal end of the pigtail out of the end of the cannula into the amniotic space, resulting in a pleural amniotic pigtail shunt.

METHOD (USING A ROCKET SHUNT SET) (SEE VIDEO)

Hydramnios and iatrogenic oligohydramnios complicate the procedure. The usual preparations for a major invasive procedure (such as fetal blood transfusion) should be followed (see Chapter 13). The majority of procedures are performed under local anesthesia with the option of premedication. The practice of using fetal paralysis varies. Fetal analgesia may also be considered.[60]

In preparation, the ultrasound transducer is positioned to provide a transverse view of the fetal chest at the level of the maximal fluid collection. The optimal line of approach is chosen to avoid (if possible) the placenta and the broad ligament vessels (identified with color Doppler interrogation). The goal is puncture of the anterolateral aspect of the fetal thorax (as the space between ribs laterally is wider, though the arms may need to be displaced and can become entangled if lateral). Once the line of approach is determined, the maternal abdomen is cleaned, draped, and a local anesthetic instilled down to the uterine visceral peritoneum.

In order to overcome the problems with insertion of the pigtail catheter into the cannula, a guidewire and pusher are now available from the supplier. The double-pigtailed catheter with its forming wire in place is gently straightened just before inserting the introducer into the fetal chest to avoid delay. A stab incision (5 mm) is made with a blade into the maternal abdomen to minimize the resistance of insertion. The introducer (trocar and cannula) is inserted along the optimal line of approach into the amniotic cavity, taking care to minimize amnion separation and to avoid contact with the fetus. The line of entry into the fetal chest is then reviewed and adjusted as necessary. Once this secondary adjustment is made, the introducer is inserted into the pleural cavity with a sharp, stabbing motion, taking care not to traumatize intrathoracic organs and vessels. The trocar is removed, and the elongated double-pigtailed catheter with introducing guidewire carefully slid down into the cannula by an assistant, taking care not to remove the guidewire before the proximal end of the pigtail is sited within the shaft of the cannula using the guidewire pusher (to prevent jamming). Once the guidewire is removed, pleural fluid will escape the cannula. After checking that the end of the cannula is still within the fetal chest, the shorter of the two push rods (i.e., the "first-stage" pusher rod) is used to advance the distal part of the catheter (fetal component) into the fetal chest, where it should be seen to adopt its natural coiled shape. The introducing cannula is withdrawn from the fetal chest, into the amniotic cavity, taking care (while observing under ultrasound) not to withdraw the cannula too far away from the fetal chest wall lest the distant end of the catheter be pulled out of the chest. The maternal component of the double-pigtailed catheter is now pushed out of the cannula into the amniotic cavity using the longer "second-stage" push rod. The correct position of the pigtail catheter is confirmed ultrasonically. The cannula can now be removed

from the uterus and the wound sutured and dressed. If there are bilateral large effusions, a second shunt will be required because decompressing only one side actually worsens cardiac displacement.

A sonographic examination is performed 8 to 24 hours postoperatively to assess shunt function. Resolution of the majority of the effusion is expected if the shunt is working well. The hydrops itself (and the hydramnios if initially present) may take an additional 10 to 14 days to resolve. The shunt will continue to function for a variable time interval.[49] If the pleural fluid reaccumulates, it is due to either blockage or displacement. At this juncture, the decision is made whether to replace the shunt or to deliver the fetus after thoracocentesis to facilitate resuscitation at delivery. The decision will reflect the severity of any residual hydrops, the duration of the functional shunt, and the current gestational age. At delivery, the pigtail drain must be immediately occluded and removed to prevent a pneumothorax (see Fig. 24–6).

COMPLICATIONS

Insertion of a pleuroamniotic shunt is not without complications, and the patient must be carefully counseled. Maternal complications include those associated with maternal analgesia, anesthesia (with or without epidural), hemorrhage, broad ligament hematoma, abortion, PROM, preterm labor and delivery, maternal trauma, and red blood cell alloimmunization. Fetal complications include death, prematurity, fetal injury to thoracic organs and vessels, severe hypoproteinemia, shunt obstruction or actual migration into the fetal chest, and even limb entanglement with the development of circulatory compromise.[61]

Other Treatments

Single or serial thoracocentesis has been successful (54%),[55] though the success rate is as low as 10%.[49]

Percutaneous ultrasound-guided pleurodesis using OK-432 is an option. OK-432 is a preparation of *Streptococcus pyogenes,* which induces a strong inflammatory response and causes pleurodesis. The technique involves percutaneous aspiration followed by injection of OK-432. It has been used with varying success in only a few cases of fetal hydrops associated with hydrothorax. It may be more successful if used in primary hydrothorax before the development of hydrops.[62] The number of cases with fetal hydrops is small and long-term follow-up lacking. The potential systemic long-term effects of this inflammatory agent are unknown. Termination of pregnancy is also an option if there is no improvement in the hydrops after treatment especially at previable gestations.[62]

Diaphragmatic hernia is discussed in Chapter 19.

Tumors (See Chapter 22)

The prognosis for hydrops associated with tumor is poor (19%).[63] Cardiac tumors are most common in cases of

hydrops. In selected cases with a poor prognosis, open fetal surgery[48] has been used for a small number of surgically correctable conditions, in particular, solid pulmonary and sacrococcygeal tumors. Only a few centers in the world are willing to attempt such therapy. Other, less invasive (percutaneous) therapeutic options for the treatment of tumors are being tried to circumvent many of the problems of open fetal surgery with varying success. These include percutaneous laser,[52] sclerotherapy alcohol,[50,51,64] radiofrequency ablation,[65] thermocoagulation,[66] and percutaneous ultrasound-guided injection of alcohol for the treatment of sacrococcygeal teratoma; even coils have been tried (Dr. Suresh, Chennai, India, personal communication) in placental chorioangioma, the most common placental tumor.[67]

Chromosomal Abnormalities

The most common aneuploidies associated with fetal hydrops are 45XO and trisomy 21. The proportion of cases of fetal hydrops associated with chromosomal anomalies (4.3%[2]–44.8%[4]) is influenced by the availability of prenatal screening programs, especially those in the first trimester (see Fig. 24–5). It is important to exclude aneuploidy by karyotyping in all cases of fetal hydrops (see Table 24–3) before offering therapy. Aneuploidy with hydrops has a dismal prognosis, and the option of pregnancy termination is often exercised by parents (see also Chapter 4).

Infection (See also Chapters 29–32)

Fetal infection may be the primary etiology in a number of fetuses with NIH, with the reported prevalence (6.9%[4]–15%[1]) being influenced by the types of testing employed and the availability and implementation of prenatal screening (e.g., syphilis[2] was found to be the most common cause in a region where it was not routinely screened for). The application of polymerase chain reaction technologies has revealed a number of previously unsuspected fetal infections. Viral hepatitis is the most common cause of noncardiac hydrops in some populations (see Table 24–1). Hydrops of noncardiac origin does not generally progress, and preterm delivery is not usually required.

The common infectious causes of hydrops include parvovirus B19 (see Fig. 24–2), CMV, syphilis,[1] and toxoplasmosis. Less common viruses associated with hydrops include coxsackievirus and adenovirus. Apart from parvovirus-induced fetal anemia, very little can currently be done antenatally to treat these conditions once they produce hydrops.

Parvovirus B19 infection is a common cause of human fetal hydrops, and during epidemics, it may be the leading cause of hydrops fetalis in the region.[10,11] Hydrops is mainly due to profound hypoplastic anemia, but can also be associated with myocarditis[24] and hepatitis.[36] Susceptibility to infection varies up to 50%.[68] The risk of fetal hydrops is greatest during the first half of pregnancy (i.e., ~3% <20 wk compared with ~1% > 20 wk).[69] The risk of fetal hydrops may be higher in mothers with asymptomatic infection.[10] The management reflects the mechanism. Cordocentesis is the first step. A profoundly anemic fetus with no circulating reticulocytes will continue to deteriorate and should be transfused immediately. Like with rhesus disease, parvovirus

TABLE 24–6

Approximate Survival Rates for Major Treatable Causes of Fetal Hydrops

CAUSE	SURVIVAL RATES (%)
Anemia—parvovirus B19 infection	62.5[36] to 77[71]
Cardiovascular—supraventricular tachyarrhythmia	60[87] to >95[88]
Pulmonary—primary hydrothorax	62[49] to 67[55]

B19 hydrops secondary to anemia is associated with an elevated UVP. Anemic fetuses with reticulocytes present are likely on their way to recovery and may or may not benefit from a "top-off" transfusion. Serial ultrasound examinations have been used to assess severity, but are of little practical use in isolation.[11,36,70] The risk of FBS and therapy may be increased specifically in parvovirus infection because of the associated risk of thrombocytopenia.[71] However, a successful outcome may be expected in the majority of cases (77%[71]) but is influenced by fetal vascular access (i.e., method of puncture), maternal obesity, and fetal gestational age younger than 20 weeks (Table 24–6). Myocarditis secondary to parvovirus is characterized by hydrops, a normal or near-normal hemoglobin, but an elevated UVP. Hydrops secondary to B19 myocarditis has been treated with fetal digitalization. Lastly, hydrops secondary to hepatitis/peritonitis is characterized by ascites, little truncal edema, normal UVP and hemogrobin by grossly elevated hepatic transaminases. Infant follow-up is mandatory in view of the rare complications (e.g., risk of congenital red blood cell aplasia)[72] or even the need for perinatal heart transplantation.[24]

Other Causes

Generalized lymphatic dysfunction (e.g., primary hydrothorax is believed to be a variant) can be associated with abnormal vascular development. The prognosis is guarded and may include significant infant morbidity[25] and recurrence with autosomal recessive inheritance.[73]

Forms of recurrent NIH associated with inborn errors of metabolism (see Fig. 24–3) and autosomal recessive inheritance are being increasingly recognized (1%–2% of NIH cases[74,75]). Once recognized, there is the potential for prenatal diagnosis in subsequent pregnancies.

Fetal akinesia (arthrogryphosis) is another collection of conditions with numerous causes (cerebro-oculofacial-skeletal syndrome, Pena-Shokeir, multiple pterygium syndrome, Neu-Laxova syndrome) associated with fetal hydrops each of which carries a poor prognosis. The risk of recurrence is generally low, but certainly influenced by the cause (e.g., Neu-Laxova syndrome has autosomal recessive inheritance[76]).

Renal associations with hydrops are discussed in detail in Chapter 18.

Fetal Albumin "Therapy"

Pathophysiologic research suggests that fetal hypoproteinemia or hypoalbuminemia may occur as a secondary effect[9,19]

in approximately a third of nonimmune hydrops fetuses, but is distributed with equal frequency in groups with a high and low UVP (the exception being TTTS, which is discussed in Chapter 23). Clearly, the practice of giving the fetus albumin[77] in the absence of a clear understanding of the pathophysiology cannot be recommended (e.g., albumin would aggravate hydrops associated with increased capillary permeability). A more productive approach would be to conduct a comprehensive investigation to reduce this "idiopathic" group.

Outcomes

Long-term follow-up data are sadly lacking, being sporadic and by nature condition-specific.[45,78–81] The challenge aside, such follow-up is particularly important with the emergence and rapid increase in research into the developmental origins of health and disease.[82] One may speculate that fetal hydrops puts survivors at increased risk for a wide range of adult diseases via environmental and/or epigenetic mechanisms.[82] Such knowledge would be indispensable for families attempting to make an informed decision.

SUMMARY OF MANAGEMENT OPTIONS
Fetal Hydrops (See also Chapter 13)

Management Options	Evidence Quality and Recommendation	References
Prevention		
Preconceptual and prenatal screening for		
• Alpha-thalassemia.	III/B	38
• Fetal aneuploidy.	IIb/B	15
• Fetal anomalies, especially severe cardiac disease.	III/B	14
• Monochorionicity screening for TTTS.	III/B	89
Diagnosis—Investigations		
Maternal (see Table 24–2).	III/B	1,3,4,6
Fetal (see Table 24–3).	III/B	
Diagnosis will be made in 75%–90% of cases.	III/B	1,3,4,6,32
Risks of fetal invasive procedures are increased in presence of hydrops.	III/B	33
Counseling and Prognosis		
Counseling is given before and after investigations.	—/GPP	—
Prognosis is determined by the underlying etiology.	III/B	1,3,4,6,32
The earlier it is detected, the worse the prognosis.	III/B	15,69
Earlier detection is more likely to be associated with chromosomal abnormality.	III/B	1,3,4,6,15
Presence of a congenital anomaly worsens the prognosis.	III/B	43,44
Prognosis for isolated hydrothorax with hydrops is fairly good.	III/B	49,55
Generally, prognosis is good for psychomotor development in survivors.	III/B	79–81
Management—Treatment		
In utero, therapy can be effective in selected cases:		
• Intrauterine transfusions for fetal anemia (hemolytic disease [see Chapter 13], fetomaternal bleed, parvovirus)	III/B	36,70,77,79
• Antiarrhythmic medication	III/B	88
• Laser for TTTS stages 2–4 (see Chapter 23)	Ib/A	29,30
• Pleuroamniotic shunts for primary hydrothorax, cystic adenomatous malformation.	III/B	49,55
• Open surgery for chest lesions should be regarded as exceptional.	IV/C	48

Fetal Death

CARL P. WEINER

INTRODUCTION

Though 80% of pregnancies are unplanned, a fetal death is virtually always viewed as a tragedy. The known threat of an embryonic loss has passed, and both patient and caregiver are optimistic about the future. Whether the death occurs in a single or multiple gestations, it spurs the search for an explanation and changes both pregnancy management and the patient's psychosocial needs. The resulting grief may begin prior to fetal death when associated with the antenatal diagnosis of a lethal abnormality. The successful identification of the etiology may be crucial for the management of any subsequent pregnancy and have a profound impact on the woman's long-term health.

MANAGEMENT OPTIONS

Giving Bad News

Providing a patient bad news is one of the most difficult tasks a physician faces on a regular basis. The problem now is not whether it is necessary to tell the patient, but how to deliver it. There is no room for physician paternalism. Unfortunately, the act of teaching techniques for the breaking of bad news may seem as awkward as the teaching of contraception must have been in the Victorian era. Yet, these techniques can be learned and used in a busy clinical practice.

There are a number of plausible explanations as to why is it difficult to give bad news including the fear of causing emotional pain, sympathetic pain, fear of being blamed for the poor outcome, fear of a therapeutic failure and all that it entails, fear of the medical-legal consequences, fear of eliciting a loud or threatening reaction, fear of saying "I don't know," and fear of expressing emotion to a patient.

Why are patients unhappy with the way they are told bad news? The most common complaints are that the physician is not listening, is using jargon, or is "talking down" to them. The process of informing a patient about bad news should follow the basic steps of the traditional medical interview:

- Prepare for listening.
- Question.
- Listen actively.
- Show verbally that you have heard.
- Respond.

The necessary modifications and additions to the basic interview as they relate to fetal medicine include first finding out how much the patient knows or understands of the events and identifying the misinformation that must be corrected and how much the patient wants to know before beginning to share the information in an unambiguous, plain-spoken fashion that minimizes the chance of denial; responding to the patient's feelings; and then presenting an appropriate action plan.

Perhaps the most difficult component of the interview arises when the patient starts reacting to the news. People perceive bad news in a myriad of ways, some of which may not be clear to the health care provider. A mentally competent and informed patient has the right to accept or reject any treatment offered and to react to the news or express their feelings in any (legal) way they choose. Unexpected reactions often reflect a misunderstanding of the information presented. It is important to reinforce those parts of what the patient has said that are correct and then continue on from there. Avoid jargon, use diagrams and written messages, and then look for evidence of understanding. Listen for and try to address the patient's concerns; do not dismiss them as irrelevant. Common reactions run the gamut and include disbelief, anger, blame, shock, guilt, denial, hope, despair, depression, displacement, fear and anxiety, crying, bargaining, awkward questions, relief, threats, and humor. There is no question that giving parents bad news tests the entire range of one's professional skills and abilities. But if it is done poorly, the family will never forgive and their anger will grow. But if the interview is done well, they will never forget their physician's kindness.

Evaluation

The investigation of a fetal death involves both fetus and mother. It is essential that the cause of death be determined whenever possible. Only then can the likelihood of a recurrence and the possibility of prevention be ascertained. An understanding of the actual cause aids the grieving process by eliminating the natural tendency for self-recrimination. A thorough maternal past and current medical history should again be obtained and the physical examination repeated in search of an unsuspected preexisting or acquired systemic illness. If the fetus is still in utero, a targeted ultrasound examination of the uterus and contents is performed in search of fetal or placental malformations and evidence of fetal growth restriction.

The more common, known causes of fetal death are listed in Table 25–1. The fetal death rate has declined since the late 1960s and the "causes" changed.[1] For example, fetal death due to intrapartum asphyxia and Rh disease has

TABLE 25–1
Causes of Fetal Death

Maternal Systemic Illness

Diabetes mellitus
Hypertension—includes prepregnancy and pregnancy-associated connective tissue disorders
Any disorder causing septicemia with associated hypoperfusion—fetal malformations, structural and chromosomal

Fetal

Infection—bacterial, viral
Fetal immune hemolytic disease
Cord accident—includes prolapse, thrombosis, strangulation
Bands or knots and torsion (likely to be greatly overdiagnosed)
Metabolic disorders
Placental dysfunction includes those associated with fetal growth restriction, postmaturity, and abruption causing hypoxemia, placenta previa, or infarction, twin-twin transfusion, fetal-maternal hemorrhage
Inherited disorders: thombophilias

TABLE 25–2
Routine Laboratory Evaluation and Follow-up of Fetal Death

Maternal (On Detection)

Fasting blood glucose
Platelet count, fibrinogen
Indirect Coombs' test
Stain of a peripheral smear for fetal red blood cells (Kleihauer-Betke test)
Anticardiolipins, antinuclear antibodies, lupus anticoagulant
Fetal karyotype
Thrombophilia workup
Polymerase chain reaction studies of fetal products for evidence of viral infection
Amniotic fluid culture for cytomegalovirus, anaerobic and aerobic bacteria
Subsequent maternal weekly fibrinogen measurements and platelet counts if fetal death is of 4 wk' duration or more

Fetal (At Delivery)

Repeat infection workup (see Chapter 26)
Karyotype (if not done antenatally)
Postmortem examination
Fetogram (total body radiograph) if dysmorphic stigmata at postmortem examination

declined dramatically in the industrialized world, as has the death rate from unexplained growth restriction also declined. Adolescents too are at increased risk of having a fetal demise.[2] Unless the history and physical examination pinpoint the cause, a basic group of laboratory tests (Table 25–2) should be performed. A chromosome abnormality underlies about 15% of second-trimester stillbirths. An amniocentesis to both search for fetal infection (see Chapter 9) and obtain a karyotype is recommended in all cases of fetal death,[3] even in the apparent absence of extrinsic structural malformations, because the usual dysmorphic features of aneuploidy may be obscured by postmortem changes. Amniocytes can be cultured successfully weeks after the death in contrast to fetal fascia, muscle, or subcutaneous tissue, which commonly fail to provide viable cells for

culture. Another advantage of amniotic fluid is that it can be used to conduct viral polymerase chain reaction (PCR) studies. Placental tissue is also a viable source for karyotyping.

After delivery, photographs of the child are made for both the medical record and the parents. If the parents decline the photographs (a common grief/fear response), the pictures are stored with the medical record in case the parents change their minds subsequently. A checklist describing the gross presentation is a useful document, a fetogram made (xerography is an excellent modality), and permission for an autopsy sought. The performance of an autopsy significantly increases the likelihood of discovering a presumed cause.[4] Ideally, an individual with both an interest and experience in perinatal pathology should perform the autopsy. The placenta is an important component of that examination. The fetal organ cavities are cultured for both bacteria and viruses, even if an infection workup was initiated antenatally. If amniotic fluid was obtained prior to delivery, an aliquot is sent for viral PCR. There is a growing body of evidence that viral infection can have a role in poor fetal outcome. Maternal serology is, however, rarely useful.[5]

Many stillborn fetuses are small for gestational age. Customized fetal growth charts may required to demonstrate this because the use of preterm neonatal birth weight charts, derived from preterm newborns who are commonly growth-restricted, might obscure this finding.[6,7] In the absence of another explanation, growth restriction increases the likelihood that severe placental dysfunction of some etiology is the explanation.[3]

Pregnancy Management

The approach to the pregnancy after a fetal loss depends on whether it is a single or a multiple gestation, the gestational age at death, and the parents' wishes.

Singleton Gestation

At least 90% of women with an intrauterine demise labor spontaneously within 3 weeks of its detection.[8,9] About a quarter of women who retain their dead fetus for 4 or more weeks after 20 weeks' gestation develop a chronic, consumptive coagulopathy. It is a true disseminated intravascular coagulopathy (DIC) characterized by degrees of decreased fibrinogen, plasminogen, antithrombin III, and platelets and increased fibrin degradation products.[10–14] The etiology of the coagulopathy has never been conclusively determined. Using sensitive coagulation tests, pathologic activation of the clotting cascade is demonstrable within 48 hours of the demise. The incidence of the coagulopathy increases with the duration of the delay, but fewer than 2% of these women experience a hemorrhagic complication. Traditionally, labor was induced after treatment of the coagulopathy even if the cervix was unfavorable and the coagulopathy resolved within 48 hours of the delivery. Fortunately, this coagulopathy can be reversed by the administration of low-dose heparin.[15–17] However, delay decreases any hope of an informative autopsy.

A dilation and evacuation can be performed prior to 15 weeks' gestation. It remains an option until 24 weeks if the practitioner is so skilled, but the risk of maternal hemorrhage may be increased after fetal death.[18] Caution is advised. The

second and more common alternative after 15 weeks' gestation is an induction of labor. This has the advantage of leaving the fetus intact for autopsy. The method of termination has no significant impact on the rate of grief resolution.[19]

Oxytocin is not the agent of choice because it is frequently ineffective early in gestation. And although instillation of intra-amniotic hypertonic saline or glucose may shorten the time interval, it has been associated with several maternal deaths.

The development of the stable prostaglandin E and F analogues for the induction of labor has simplified induction because the efficacy of these agents exceeds 90%.[20–23] Delivery shortly after detection of the demise has several advantages. First, it brings an end to an emotionally painful event and allows the psychological healing process to begin. Second, any postmortem examination is more likely to yield useful information if done before the development of severe autolysis.

The various prostaglandin preparations may be administered via oral, vaginal, intracervical, extraovular, or intramuscular routes, depending on regional availability. Misoprostol (either per vaginam or by mouth) has a favorable cost profile and is at least as effective as other forms of prostaglandin. When used specifically for pregnancy termination in the second trimester, misoprostol administered orally is less effective (i.e., more failures) than the vaginal route (relative risk [RR] 3.00, 95% confidence interval [CI] 1.44–6.24) and side effects are more common.[24] Misoprostol regimens used for the induction of labor with fetal death during the second and third trimester range from 50 to 400 µg every 3 to 12 hours; all are clinically effective.[25] The current scientific evidence supports vaginal misoprostol dosages that are adjusted to gestational age: between 13 and 17 weeks, 200 µg q6h; between 18 and 26 weeks, 100 µg q6h; and after 27 weeks, 25 to 50 µg q4h. Caution is advised in women with a previous cesarean and lower doses should be used. In all instances, the patient should be monitored after delivery because of the risk of postpartum atony and/or placenta retention. Common complications of misoprostol include nausea and vomiting, fever, and tachycardia. Their prevalence is generally dependent on route of administration and dose and is greatly reduced by premedication.[17] Their use is discussed further in Chapter 66.

Multiple Gestation (See also Chapters 23 and 59)

The optimal management of the multiple gestation with a singleton demise reflects chorionicity. The incidence of this complication is low (<1% of all twin gestations), but the risk of prematurity, morbidity (especially neurologic), and neonatal death is high among antenatal survivors, especially in monochorionic diamniotic twins (see Chapters 23 and 59).[26,27] There are several potential explanations. First is the cause of death. Could the same stimulus, such as congenital infection or a maternal systemic illness, have caused a sublethal insult yielding a damaged survivor? If so, will continuation of the pregnancy worsen the outcome by prolonging the exposure? An informed decision requires knowledge of the cause and is a matter for individualization.

The second item to consider is whether the dead twin's continued presence poses a risk to the surviving twin. In monochorionic twin gestations, approximately half of the co-twins in an affected pregnancy will either die or experience serious morbidity[28] (see Chapters 23 and 59). Sequelae in survivors of monochorionic gestations with a single demise include bilateral renal cortical necrosis, multicystic encephalomalacia, gastrointestinal structural malformations, and even a DIC.[29–34] It was previously thought the sequelae result from the fetus-to-fetus transfer of necrotic, thromboplastic emboli through placental anastomoses. If this were true, delivery of the surviving twin as soon as possible would be prudent. However, this long-stated explanation has never been supported by a shred of evidence and can now be definitively categorized as a myth. The explanation is one or more hypotensive events occurring either during the co-twin's death associated with extensive vascular anastomosis or after the death as the surviving twin acutely hemorrhages into the dead twin's placenta.[35] As a result, preterm delivery is too late to prevent the sequelae and can only add complications of prematurity. Thus, it is prudent to observe the surviving co-twin very closely, if not continuously for the first 7 days, should the gestation appear monochorionic. It is unclear whether "prophylactic" laser photocoagulation of anastomotic placental vessels will prevent damage once the death has occurred. Survivors should be watched serially for evidence of multicystic leukoencephalomalacia.

If the pregnancy is dizygotic, the risk of death for the surviving co-twin is less than 5%.[26] There is no reason for an iatrogenic delivery prior to 36 weeks solely for the indication of a dead co-twin.

The third and final concern after the death of a co-twin is that the mother will develop coagulopathy should the pregnancy continue. This is an uncommon but treatable event. Laboratory testing for hypofibrinogenemia and thrombocytopenia should be done biweekly after the first 4 weeks. Low-dose heparin, between 10,000 and 30,000 units given subcutaneously in divided doses, is usually adequate to reverse the hypofibrinogenemia.[36,37] There is no need to prolong the partial thromboplastin time. The amount of heparin necessary may seem quite high, and is likely explained by the DIC-mediated decrease in antithrombin. Heparin can usually be discontinued 6 to 8 weeks later without recurrence of the hypofibrinogenemia.

Parental Psychosocial Care

Grief is a normal part of the process. Many hospitals have a counselor or psychologist on the perinatal team to facilitate the grieving process. There may also be local support groups consisting of women who have experienced an intrauterine demise. When appropriate, pastoral care may also be helpful. The woman's partner is encouraged to remain and provide support during labor and after delivery when the couple should be encouraged to view and hold the newborn. Too often, patients incorrectly assume they have conceived a monster. They should also be informed that any bruising and facial marks are normal. Neonatal footprints and handprints are made, and the parents should be encouraged to name the child. Photographs are taken, and if the patient does not want to keep any of these remembrance items, they should

be stored. Many women change their mind and later write to request them.

The grieving process may begin prior to the fetus' actual death when associated with the antenatal diagnosis of a lethal congenital or acquired abnormality. Whereas termination shortens the pregnancy, it does not necessarily hasten the resolution of grief.[38] Many couples electively or are required by misguided local laws to continue a pregnancy that has no hope of a living offspring. In this instance, a palliative perinatal care program might prove beneficial.[39,40]

Upon discharge from the hospital, the patient is given an appointment to return after an interval, which should be individualized to her needs. The results of all studies performed are reviewed and the parents given an opportunity to voice any questions they may have about their care.

Evaluation prior to Next Pregnancy

If the cause of death was ascertained, its implications (if any) to subsequent pregnancies should be discussed at their initial postpartum meeting, and again prior to conception if desired. The actions needed should be cause-specific. For example, the discovery of a maternal thrombophilia or connective tissue disorder coupled with the history of a prior stillbirth warrants either medical therapy, prophylactic anticoagulation, or both (see Chapters 42 and 43). The practice of ordering a barrage of antenatal surveillance tests when the cause of death was not hypoxemia due to placental dysfunction is a waste of resources if the subsequent pregnancy is characterized by normal placentation. When the cause of death has escaped detection, it is important to again reinforce to both parents that these events are usually not under their control and that they bear no guilt for its occurrence.

SUMMARY OF MANAGEMENT OPTIONS
Fetal Death

Management Options—For Singleton Pregnancy Unless Stated Otherwise	Evidence Quality and Recommendation	References
Singleton Fetal Death		
Psychosocial Support	III/B	38,40,41
Investigate for a Cause (see Tables 25–1 and 25–2):	III,IV/B,C	41–46
Maternal.		
Fetal.		
Screen for Maternal Coagulopathy		
If death of 4 wk' duration or more.	III/B	10–13
Empty Uterus (See also Chapter 66)		
Many options:		
• **<13–15 Wk**		
Vacuum evacuation/curettage.	III/B	51
Oral mifepristone followed by oral or vaginal prostaglandin 48 h later.	Ia,Ib/A	24,49,50
• **13/15–22 Wk**		
Ripen cervix with laminaria and:	—/GPP	—
Dilation and evacuation (has not been formally compared with contemporary medical methods but safer in comparison to older methods).	III/B	52
Or		
High-dose oxytocin induction.	III/B	47,53
Prostaglandin E$_2$ vaginal pessaries.	III/B	21,23,47
Misoprostol is very effective (usually oral mifepristone followed by oral or vaginal prostaglandin 48 h later).	Ib/A	22
• **22–28 Wk**		
Ripen cervix with laminaria and oxytocin induction.	—/GPP	—
	III/B	47
Prostaglandin E$_2$ vaginal pessaries with oxytocin augmentation.	III/B	21,23,48

Management Options—For Singleton Pregnancy Unless Stated Otherwise	Evidence Quality and Recommendation	References
Oral mifepristone followed by oral or vaginal prostaglandin 48 h later. This regimen may need to be supplemented by oxytocin infusion.	III/B	49,50,53
Misoprostol is very effective.	Ib/A	21
• >28 Wk		
Cervix favorable:		
Oxytocin induction.	IV/C	47,52
Misoprostol.	Ib/A	53
Cervix unfavorable:		
Ripen cervix with low-dose prostaglandin E_2 vaginal suppositories or misoprostol *without* concurrent oxytocin.		
Overall, vaginal prostaglandin E_2 is superior to oxytocin at inducing labor.	Ia/A	21,23,47, 53
Single Fetal Death in Twin Pregnancy	See Chapters 23 and 59	
Prior to next pregnancy: Review causation and plan appropriate management for pregnancy.	GPP

Intrauterine Infection, Preterm Parturition, and the Fetal Inflammatory Response Syndrome

FRANCESCA GOTSCH, ROBERTO ROMERO, and JUAN PEDRO KUSANOVIC

INTRODUCTION

Infection is a frequent and important cause of preterm parturition.[1–8] Indeed, it is the only pathologic process for which both a firm causal link with spontaneous preterm birth has been established and a precise molecular pathophysiology defined.[9,10] Fetal infection/inflammation has been implicated in the genesis of fetal and neonatal injury[11,12] leading to cerebral palsy (CP)[13] and chronic lung disease.[14]

PATHWAYS OF INTRAUTERINE INFECTION

Microorganisms may gain access to the amniotic cavity and the fetus through the following pathways: (1) ascending from the vagina and the cervix; (2) hematogenous dissemination through the placenta; (3) retrograde seeding from the peritoneal cavity through the fallopian tubes; and (4) accidental introduction at the time of invasive procedures.[15–18] The most common pathway for intrauterine infection is the ascending route.[9,15–17] Evidence in support of this includes (1) histologic chorioamnionitis is more common and severe at the site of membrane rupture[5]; (2) in virtually all cases of congenital pneumonia (stillbirths or neonatal), inflammation of the chorioamniotic membranes is present[15,17,19]; (3) bacteria identified in cases of congenital infections are similar to those found in the lower genital tract[16]; and (4) in twin gestations, histologic chorioamnionitis is more common in the first-born twin and has not been demonstrated only in the second twin. This suggests ascending infection, because the membranes of the first twin are apposed to the cervix.[16] This observation is consistent with microbiologic studies of the amniotic fluid (AF) in twin gestations. When AF infection is present, the presenting sac is always involved.[20]

STAGES OF ASCENDING INTRAUTERINE INFECTION

Ascending intrauterine infection has four stages (Fig. 26–1).[3] Stage I consists of a change in the vaginal/cervical microbial flora or the presence of pathologic organisms in the cervix. Some forms of aerobic vaginitis may be an early manifestation of this stage. Once microorganisms traverse the endocervical canal, they reside in the lower pole of the amniotic cavity (stage II). A localized inflammatory reaction causes local chorioamnionitis. The microorganisms may then traverse intact membranes and invade the amniotic cavity (stage III).[21] The last stage of ascending intrauterine infection is fetal infection (stage IV). Once in the amniotic cavity, the bacteria may gain access to the fetus by several ports of entry. Aspiration of the infected fluid by the fetus may cause congenital pneumonia. Otitis, conjunctivitis, and omphalitis are localized infections that occur by direct seeding of the microorganisms from infected AF. Seeding from any of these sites to the fetal circulation results in bacteremia and sepsis.

The fetus is exposed to microorganisms and their products (i.e., bacterial endotoxin)[22] in the amniotic cavity and responds by mounting a cellular and humoral immunoresponse.[23] The overall mortality rate of neonates with congenital neonatal sepsis ranges from 25% to 90%. This wide range may reflect the effect of gestational age on survival; the mortality of infants born before 33 weeks' gestation has been reported to be 33% for infected and 17% for noninfected fetuses.[24] Carroll and coworkers[25] reported fetal bacteremia in 33% of fetuses with positive AF culture and in 4% of those with negative AF culture. Goldenberg and colleagues[26] reported that 23% of neonates born at 23 to 32 weeks' gestation have positive umbilical blood cultures for *Ureaplasma urealyticum* and *Mycoplasma hominis*. Newborns with positive blood cultures had a higher frequency of a neonatal

The stages of ascending infection. *Stage I*: Consists of an overgrowth of facultative organisms or the presence of the pathologic organisms in the vagina, cervix, or both. *Stage II*: Once microorganisms traverse the endocervical canal, they reside in the lower pole of the amniotic cavity. A localized inflammatory reaction causes local chorioamnionitis. *Stage III*: The microorganisms may then traverse intact membranes, leading to microbial invasion of the amniotic cavity. *Stage IV*: Once in the amniotic cavity, the bacteria may gain access to the fetus by different ports of entry.

(Modified from Romero R, Mazor M: Infection and preterm labor. Clin Obstet Gynecol 1988;31:553–584.)
systemic inflammatory response syndrome, higher umbilical cord serum concentrations of interleukin (IL)-6, and more frequent histologic evidence of placental inflammation than those with negative cultures.

MICROBIOLOGY OF INTRAUTERINE INFECTION

The most common microbial isolates from the amniotic cavity of women with preterm labor (PTL) with intact membranes are *U. urealyticum, Fusobacterium* spp., and *M. hominis*.[3,8,27] In patients with preterm premature rupture of membranes (PPROM), microbial invasion of the amniotic cavity (MIAC) by *U. urealyticum* is associated with a robust inflammatory response in the fetal, amniotic, and maternal compartments.[28] *U. urealyticum* is implicated in the genesis of clinical chorioamnionitis, puerperal endometritis, postoperative wound infections, neonatal sepsis, meningitis, and bronchopulmonary dysplasia. Other microorganisms found in the AF include *Streptococcus agalactiae, Peptostreptococcus* spp., *Staphylococcus aureus, Gardnerella vaginalis, Streptococcus viridans*, and *Bacteroides* spp. Occasionally, *Lactobacillus* spp., *Escherichia coli, Enterococcus faecalis, Neisseria gonorrhoeae*, and *Peptostreptococcus* spp. are encountered. *Haemophilus influenzae, Capnocytophaga* spp., *Stomatococcus* spp., and *Clostridium* spp. are rarely identified.[29,30] Among patients with PTL, 50% of those with MIAC have more than one microorganism isolated from the amniotic cavity. The inoculum size varies considerably, and in 71% of the cases, more than 10^5 colony-forming units per milliliter (CFU/mL) are found.[5]

FREQUENCY OF INTRA-AMNIOTIC INFECTION IN PRETERM GESTATION

One third of all patients with preterm delivery present with PTL and intact membranes and one third with PPROM. The remaining third are the result of delivery for maternal or fetal indications (e.g., preeclampsia, fetal growth restriction [IUGR]). Microbiologic investigations suggest that intrauterine infection is present in 25% to 40% of spontaneous preterm births.[7] However, this is probably an underestimate because some pathogens are difficult to identify by conventional cultivation techniques. Indeed, using molecular microbiologic techniques, additional bacterial rDNAs have been identified in culture-negative AF from women in PTL.[29,31,32] Further, microbial colonization of the chorioamnion was shown to be twice that of the amniotic cavity.[33,34]

Microbial Invasion of the Amniotic Cavity

In patients with PTL and intact membranes, the mean rate of positive AF cultures for microorganisms is 12.8% (379/2963), based on a review of 33 studies.[8] Women with positive AF cultures generally do not have clinical evidence of infection at presentation, but are more likely to develop clinical chorioamnionitis (37.5% vs. 9%), be refractory to tocolysis (85.6% vs. 16.3%), and rupture their membranes spontaneously (40% vs. 3.8%) than women with negative AF cultures.[8] Neonates born to women with MIAC have more complications than those born to women without infection.[27] Moreover, the earlier the gestational age at birth, the more likely MIAC is present.[35]

In patients with PPROM, the rate of positive AF cultures for microorganisms is 32.4% (47/142).[8] Clinical chorioamnionitis is present in only 29.7% of those with proven MIAC.[8,9] The rate of MIAC in PPROM is probably an underestimate. In addition to the reasons cited with PTL, women with oligohydramnios and those with PPROM admitted in labor are less likely to have an amniocentesis. Yet, women with PPROM and severe oligohydramnios have a higher incidence of intra-amniotic infection/inflammation (IAI)[36] than those without oligohydramnios and those admitted in labor have a higher rate of MIAC than those admitted without labor (39% vs. 25%; $P < .05$).[37] Finally, 75% of women who are not in labor on admission have a positive AF culture at the time of the onset of labor.[37] This means that patients with PPROM acquire MIAC and that they often go into labor when IAI is present. Antibiotic administration to patients with PPROM does not always eradicate IAI, and MIAC may be acquired while receiving antibiotics.[38]

Women presenting with a dilated cervix, intact membranes, and few, if any, contractions before 24 weeks' gestation are considered to have clinical cervical insufficiency. In one study, 51.1% of these patients had a positive AF culture for microorganisms.[39] The outcome of patients with MIAC was uniformly poor because these individuals developed subsequent complications (rupture of membranes, clinical chorioamnionitis, or pregnancy loss). Therefore, infection is frequently associated with dysfunctional cervical ripening. The contribution of subclinical inflammation to dysfunctional cervical ripening has been investigated.[40] In women with dysfunctional cervical ripening undergoing rescue cerclage between 15 and 27 weeks' gestation, the median AF IL-6 concentration (prior the cerclage placement) was higher

than in controls (women undergoing amniocentesis for karyotyping at 16–27 weeks' gestation). Moreover, an inverse relationship was found between the AF IL-6 concentration and the latency interval from cerclage to delivery.[40] Among patients with dysfunctional cervical ripening between 17 and 29 weeks' gestation, the prevalence of IAI was reported to be 81%.[41] Among those with dysfunctional cervical ripening and IAI, in the absence of infection, preterm delivery within 7 days occurred in 50% of cases, 84% of patients delived at less than 34 weeks' gestation, and 55% of newborns died immediately after birth (<1 day). It is possible that clinically silent cervical dilation with protrusion of the membranes into the vagina leads to a secondary intrauterine infection.

A sonographic short cervix is considered a powerful predictor of spontaneous preterm delivery.[42–45] The shorter the sonographic cervical length (CL) in the mid trimester of pregnancy, the higher the likelihood of spontaneous preterm delivery.[42–45] Hassan and associates[46] conducted a retrospective study of 57 patients with a CL less than 25 mm at 14 to 24 weeks' gestation. The prevalence of IAI was 9% (5/57). Among these patients, the rate of preterm delivery less than 32 weeks was 40% (2/5), suggesting that a short cervix may be the only manifestation of subclinical MIAC. A CL of 5 mm or less at 16 to 24 weeks' gestation is associated with higher AF concentrations of inflammatory cytokines, even in the absence of proven infection or labor.[47] An inverse correlation was found between AF concentrations of proinflammatory cytokines and sonographic CL. Of 25 cytokines assayed, monocyte chemotactic protein (MCP)-1 was the most differentially regulated.[47]

Microbial invasion of the amniotic cavity occurs in 11.9% to 13% of twin gestations presenting with PTL and delivery[20,48] compared with a 21.6% culture-positive rate in singleton gestations with PTL and delivery.[5] Microorganisms are more frequently isolated from the presenting sac (55.6%) or both sacs (33.3%) rather than from the upper sac alone (11.1%).[48] These data suggest that IAI is a possible cause of PTL and delivery in twin gestation, but does not support the hypothesis that IAI is responsible for a large part of the excessive rate of preterm delivery observed.

CHORIOAMNIOTIC INFECTION, HISTOLOGIC CHORIOAMNIONITIS, AND PRETERM BIRTH

Inflammation of the placenta and chorioamniotic membranes is a nonspecific host response to a variety of stimuli, including infection. Acute inflammation of the chorioamniotic membranes has traditionally been considered an indicator of AF infection.[15–17,19,49,50] Indeed, several studies demonstrated an association between acute inflammatory lesions of the placenta and the recovery of microorganisms from the subchorionic plate and chorioamniotic space. Furthermore, there is a strong correlation between positive AF cultures for microorganisms and histologic chorioamnionitis.[49,50] Cassell and coworkers[33] reported an association between positive microbial cultures obtained from the chorioamniotic interface and histologic chorioamnionitis. The presence of inflammation in the umbilical cord (funisitis) represents evidence of a fetal inflammatory response.[51] Collectively, the evidence indicates an association between preterm birth and the occurrence of acute chorioamnionitis;

it also indicates that the lower the gestational age at birth, the higher the frequency of histologic chorioamnionitis and funisitis.[52]

The rate of microbial colonization in the chorioamniotic space is higher than that observed in the amniotic cavity. If the infection is localized to the decidua or the space between the amnion and the chorion, microorganisms may not be detected in the amniotic cavity. Thus, intrauterine infection can be present without a positive AF culture for microorganisms or a positive polymerase chain reaction (PCR).[53] Patients with positive membrane cultures, but negative AF cultures, often have elevated AF concentrations of inflammation indicators, such as IL-6.[53] Therefore, some patients with IAI but negative cultures in the AF may have intrauterine infection in the extra-amniotic space. Fluorescence in situ hybridization (FISH) with a DNA probe specific for conserved regions of bacterial DNA (the 16S ribosomal RNA) has detected bacteria in the fetal membranes of up to 70% of women undergoing elective cesarean section at term.[54] Organisms were also detected in fetal membranes after preterm delivery without labor.[54] Inflammatory cells were found frequently in the amnion or chorion of preterm fetal membranes but not in term tissues. These findings suggest that the presence of bacteria alone is not sufficient to cause PTL and delivery and that microbial colonization of the chorioamniotic membranes may not always elicit a fetal or maternal inflammatory response. In recent studies, we were unable to identify bacteria in the fetal membranes of normal patients at term using FISH for the 16S ribosomal DNA. Moreover, even in the cases of IAI, most of the organisms were in the amnion rather than in the chorion. These observations challenge the conventional view of ascending intrauterine infection.[55]

INTRAUTERINE INFECTION/INFLAMMATION AS A CHRONIC PROCESS

Microbial invasion of the amniotic cavity has been reported at the time of genetic amniocentesis. Cassel and colleagues[56] recovered genital mycoplasmas from 6.6% (4/61) of AF samples collected by amniocentesis between 16 and 21 weeks. Two patients with *M. hominis* delivered at 34 and 40 weeks without neonatal complications, whereas two with *U. urealyticum* had premature delivery, sepsis, and neonatal death at 24 and 29 weeks. Subsequently, Gray and associates[57] reported a 0.37% prevalence (9/2461) of positive cultures for *M. hominis* or *U. urealyticum* in AF samples. Except for 1 woman who had a therapeutic abortion, all patients with a positive AF culture had either a fetal loss within 4 weeks of the amniocentesis (*n* = 6) or preterm delivery (*n* = 2). Horowitz and coworkers[58] detected *U. urealyticum* in 2.8% (6/214) of AF samples obtained between 16 and 20 weeks' gestation. The rate of adverse pregnancy outcome was higher in patients with a positive AF culture than in those with a negative culture (50% vs. 12%; P = .04).[58] In a retrospective study, Berg and colleagues[59] found 1.8% (49/2718) positive cultures for *Ureaplasma/Mycoplasma*, and 34 patients were treated with oral erythromycin. Mid-trimester pregnancy loss was lower in the 34 patients treated with erythromycin than in the untreated group (11.4% vs. 44.4%; P = .04). However, no differences were observed in the rates of preterm delivery (19.4% vs. 20%) and adverse pregnancy

outcome (28.6% vs. 55.6%).[59] In summary, these observations suggest that MIAC may be clinically silent in the mid trimester of pregnancy and that pregnancy loss/preterm delivery can take weeks to occur.

AF IL-6 concentration is a marker of IAI and is frequently associated with microbiologic infection in either the AF or the chorioamniotic space.[60,61] Romero and associates[62] conducted a case-control study in which IL-6 was measured in the stored AF of women who had a pregnancy loss after a mid-trimester amniocentesis and compared them with a control group who delivered at term. Patients who lost their pregnancies had a higher median AF IL-6 concentration. Similar findings were reported by Wenstrom and coworkers.[63] In contrast, maternal plasma IL-6 concentration is not associated with adverse pregnancy outcome. Chaiworapongsa and colleagues[64] measured AF MCP-1 at the time of genetic amniocentesis and reported higher concentrations in 10 patients who had a pregnancy loss after the procedure compared with 84 patients with a normal pregnancy outcome. An MCP-1 concentration greater than 765 pg/mL was strongly associated with pregnancy loss (odds ratio [OR] 7.35; 95% confidence interval [CI] 1.7–31.0).

An association can also be demonstrated between markers of inflammation (matrix metalloproteinase [MMP]-8,[65] IL-6,[66] tumor necrosis factor-α [TNF-α],[67] angiogenin,[68] and C-reactive protein[69]) in mid-trimester AF samples and preterm delivery. Goldenberg and associates[70] demonstrated that the maternal plasma concentration of granulocyte colony-stimulating factor (G-CSF) at 24 and 28 weeks' gestation was associated with early preterm birth, suggesting that a chronic inflammatory process, identifiable in the maternal compartment, is associated with early preterm birth. Collectively, the evidence suggests that a chronic IAI process is associated with both spontaneous abortion and spontaneous preterm delivery.

IS THE RELATIONSHIP BETWEEN INTRAUTERINE INFECTION AND SPONTANEOUS PRETERM BIRTH CAUSAL?

An association of intrauterine infection with spontaneous preterm delivery does not mean that infection *causes* preterm delivery. Indeed, it has been argued that MIAC is merely a consequence of labor.[71,72] The evidence supporting a causal role for infection in preterm parturition includes (1) biologic plausibility, (2) temporal relationship, (3) consistency and strength of association, (4) dose-response gradient, (5) specificity, and (6) animal experimentation. Administration of bacterial products or microorganisms to pregnant animals can lead to premature labor and delivery. Three sets of observations suggest that infection precedes the spontaneous onset of PTL and delivery: (1) subclinical MIAC or intrauterine inflammation in the mid trimester of pregnancy leads to either spontaneous abortion or premature delivery, (2) patients with PPROM who had a positive AF culture for genital mycoplasmas on admission have a shorter amniocentesis-to-delivery interval than those with sterile AF,[73] and (3) abnormal colonization of the lower genitourinary tract with microorganisms is a risk factor for preterm delivery. These conditions include asymptomatic bacteriuria, bacterial vaginosis, and infection with *N. gonorrhoeae*. The

consistency and strength of association between infection and preterm delivery is demonstrated by the many studies in which AF was cultured in women with PPROM and PTL; the relative risk for preterm delivery in patients with PTL and MIAC is high (>2) and the hazard ratio for the duration of pregnancy after PPROM is also high.

The likelihood of a causal relationship is increased if a dose-response gradient can be demonstrated. Evidence supporting the existence of this includes (1) the median concentration of bacterial endotoxin is higher in patients in PTL than in patients not in labor,[74] (2) a microbial inoculum greater than 10^5 CFU/mL is more common in women with PPROM admitted with PTL than in those admitted without labor (41.6% vs. 15%; P = .03),[37] and (3) the rate of abortion/preterm delivery after administration of *E. coli* bacterial endotoxin to pregnant mice exhibits a clear dose-response gradient.

One criterion for causality that is not met is specificity. Although intrauterine infection appears sufficient to induce PTL and delivery, it is not specific because many patients have a preterm delivery in the absence of evidence of IAI. However, the formulation of "the necessary and sufficient cause" can inappropriately restrict the conceptualization of cause. Although the causal relationship between smoking and lung cancer is accepted, it is also nonspecific; lung cancer occurs in nonsmokers and smoking causes other diseases. Microbiologic, cytologic, biochemical, immunologic, and pathologic data indicate that PTL is a syndrome and infection is but one of its causes.[9]

An important criterion for causation is whether eradication of the agent decreases the frequency of outcome or illness. There is evidence that treatment of patients with asymptomatic bacteriuria reduces the rate of prematurity/low birth weight[75] and that antibiotic treatment of patients with PPROM prolongs the latency period and reduces the rate of maternal and neonatal infection.[76] However, antibiotic treatment in patients with PTL has not yielded positive results in most trials.[77–80] The reasons for this are complex and are probably related to the syndromic and chronic nature of preterm parturition and the inclusion of many patients who do not have intrauterine infection and, thus, cannot benefit from antimicrobial treatment.

DETECTION OF MICROBIAL FOOTPRINTS IN THE AMNIOTIC FLUID WITH SEQUENCE-BASED TECHNIQUES

Estimates of the frequency and type of microorganisms participating in intrautering infections are based on standard microbiologic techniques (e.g., culture). Surveys of terrestrial and aquatic ecosystems indicate that more than 99%[81] of existing microorganisms may not be cultivated using standard microbiologic techniques (e.g., culture) and that only molecular diagnosis can provide identification of these microorganisms.[82] Sequenced-based methodologies are likely to demonstrate how insensitive conventional microbiology methods are for the detection of already known and potentially "new" microorganisms in perinatal medicine. However, application of these techniques to clinical practice poses clinical, technological, and conceptual questions and challenges.

Two strategies have been used to detect microorganisms in the AF with PCR. The broad-range PCR uses primer pairs designed to anneal with highly conserved DNA regions of all bacteria, such as the 16S ribosomal DNA. A positive result indicates the presence of bacteria, but identification of the specific organism requires subsequent sequencing of the PCR products. The second approach is to use specific primers for a particular microorganism. Four studies used primers for the conserved sequence,[29,31,83,84] five used specific primers to recover bacterial DNA from AF,[85–89] while one applied both approaches.[90] Blanchard and coworkers[87] were the first to report the recovery of *U. urealyticum* from AF using specific primers for the urease structural genes. Ten of 293 AF samples collected at cesarean section were PCR-positive but only 4 were also culture-positive. Others have applied broad-spectrum bacterial 16S rDNA PCR for the detection of bacteria in AF.[31,29,83] Hitti and colleagues[29] studied 69 women in PTL with intact membranes. PCR was positive in 94% of the culture-positive AF samples (15/16) and in 36% of the patients with a negative culture. Five of the 14 women with an elevated IL-6 concentration had bacteria detected by PCR. In Markenson and associates' study,[83] 55.5% of the 54 women with PTL but without clinical evidence of infection were PCR-positive, whereas only 9.2% of the cultures recovered a microorganism ($P < .05$). Two thirds (6/9) of the AF samples with an elevated IL-6 were also PCR-positive.

Oyarzun and coworkers[85] described a PCR amplification technique aimed at detecting the 16 microorganisms most commonly cultured from the AF of patients in PTL. AF samples were examined with bacterial culture and PCR in 50 patients with PTL and 23 patients not in labor. All control samples were both culture- and PCR-negative. A higher proportion of samples were positive by PCR than by culture (46% vs. 12%; $P < .05$). The sensitivity of PCR for the prediction of PTL before 34 weeks was better than culture (64% vs. 18%; $P < .05$). However, there were patients with positive PCR who delivered at term without maternal or neonatal complications.

The clinical implications of detecting *U. urealyticum* in AF by PCR in patients with PPROM[86] or PTL[88] were evaluated by Yoon and colleagues. Patients with a positive PCR assay, but a negative culture, had a stronger AF inflammatory reaction (higher AF white blood cell [WBC] count and IL-6 concentration), a shorter interval to delivery, as well as a higher rate of histologic chorioamnionitis, funisitis, and neonatal morbidity than those with a negative AF culture and negative AF PCR assay. These studies reveal that patients with PPROM or PTL and a positive PCR assay for *U. urealyticum* (but a negative culture) have worse pregnancy outcomes than those with a sterile AF culture and negative PCR.

Gerber and associates[89] used PCR to detect *U. urealyticum* DNA in the AF of asymptomatic patients undergoing genetic amniocentesis. Test results were positive in 11.4% (29/294) of the pregnancies and, among these, 58.6% delivered preterm. In contrast, only 4.4% of the PCR-negative patients delivered prematurely ($P < .0001$). This study is consistent with the premise of chronic *U. urealyticum* infection because women with a positive *U. urealyticum* DNA in the AF had a higher frequency of preterm birth in previous pregnancies than women with PCR-negative AF (20.7% vs. 2.7%; $P = .0008$). In a smaller study of women undergoing genetic amniocentesis, bacterial 16S ribosomal DNA was detected in

18% (14/78) of AF samples.[90] No samples tested positive for *Mycoplasma* spp. DNA using a PCR/enzyme-linked immuno-sorbent assay. No association was found between the recovery of bacteria at the time of amniocentesis and either increased IL-6 concentration in the AF or preterm delivery. Nguyen and coworkers[91] identified *M. hominis* in 6.4% (29/456) of AF samples obtained at 15 to 17 weeks' gestation. The rate of PTL and delivery less than 37 weeks' gestation was higher in women with a positive PCR for *M. hominis* than in those with negative PCR (14.3% vs. 3.3%; $P = .01$; and 10.7% vs. 1.9%; $P = .02$, respectively). Perni and colleagues[92] detected *M. hominis* and *U. urealyticum* by PCR in 6.1% (11/179) and 12.8% (22/172) of asymptomatic women at 15 to 19 weeks' gestation, respectively. PPROM occurred in 2.8% (5/179) of women, and the same proportion of patients had a spontaneous preterm birth with intact membranes. All women with PPROM were positive for either *M. hominis* or *U. urealyticum*, whereas none of those with spontaneous preterm birth. Finally, Wenstrom and associates[93] compared AF samples from a group of 62 pregnancy losses following mid-trimester amniocentesis with 60 controls. PCR was performed for the presence of adenovirus, parvovirus, cytomegalovirus (CMV), Epstein-Barr virus (EBV), herpes simplex virus (HSV), β-actin DNA, enterovirus, and influenza A. No difference in the prevalence of viruses was observed between cases and controls (8% vs. 15%). Adenovirus was identified in 6% of cases but also in 8% of controls.

We have recently compared the results of culture and molecular techniques[84] and demonstrated that the AF of women in PTL and intact membranes harbors DNA from a greater diversity of microbes than previously suspected. This includes uncultivated, previously uncharacterized taxa (bacteria, fungi, and archea). The combined use of molecular and culture methods revealed a greater prevalence (15%) and diversity (18 taxa) of microbes in AF than did the culture alone (9.6%, 11 taxa). A positive PCR was associated with histologic chorioamnionitis (adjusted OR 20; 95% CI 2.4–172), and funisitis (adjusted OR 18; 95% CI 3.1–99). Moreover, the positive predictive value of PCR for preterm delivery was 100%.[84]

MOLECULAR MECHANISMS FOR PRETERM PARTURITION IN THE SETTING OF INTRAUTERINE INFECTION

A considerable body of evidence supports a role for inflammatory mediators in the mechanisms of preterm parturition associated with infection.

Prostaglandins and Lipoxygenase Products

Intrauterine prostaglandins (PGs) are considered by many to be the key mediators of the biochemical mechanisms regulating the onset of labor. They can induce myometrial contractility[94,95] as well as changes in the extracellular matrix metabolism associated with cervical ripening[96] and are thought to participate in decidual/fetal membrane activation.[9] The evidence invoked in support of a role for PGs in the initiation of labor includes (1) administration of PGs induces early and late termination of pregnancy (abortion or labor),[97,98] (2) treatment with indomethacin or aspirin delays

the spontaneous onset of parturition in animals,[99,100] (3) PG concentrations in plasma and AF increase during labor,[101,102] and (4) intra-amniotic injection of arachidonic acid can induce abortion.[103]

Infection can increase PG production by amnion, chorion, or decidua through the activity of bacterial products, pro-inflammatory cytokines, growth factors, and other inflammatory mediators. Indeed, AF concentrations of PGE_2 and PGF_2 and their stable metabolites, PGEM and PGFM, are higher in women with PTL and MIAC than in women with PTL without infection.[104] Similar observations have been made in patients with labor and high AF concentrations of IL-1β, TNF, and IL-6. Moreover, amnion obtained from women with histologic chorioamnionitis produces higher amounts of PGs. More recent evidence also suggests that PGD_2 and its active metabolites are involved in the mechanism leading to term and preterm parturition.[105,106]

Metabolites of arachidonic acid derived through the lipoxygenase pathway, including leukotrienes (LTs) and hydroxyeicosatetraenoic acids (HETEs), are also implicated in the mechanisms of spontaneous preterm and term parturition. Concentrations of 5-HETE, LTB_4, and 15-HETE are increased in the AF of women with PTL and MIAC.[107,108] Similarly, amnion from patients with histologic chorioamnionitis releases more LTB_4 in vitro than amnion from women delivering preterm without inflammation.[109] 5-HETE and LTB_4 can also stimulate uterine contractility, and LTB_4 is thought to play a role in the recruitment of neutrophils to the site of infection.[110]

Inflammatory Cytokines

Strong evidence suggests that pro-inflammatory cytokines (IL-1, TNF, IL-18) and chemokines (IL-8, MCP-1, macrophage inflammatory protein [MIP]-1α, requested on activation, normal T cell expressed and secreted [RANTES], and epithelial cell-derived neutrophil-activating peptide-78) are involved in the mechanisms responsible for PTL associated with infection. IL-1β and TNF-α are the most extensively investigated pro-inflammatory cytokines in the context of PTL: (1) IL-1β and TNF-α stimulate PG production by amnion, decidua, and myometrium[111–114]; (2) human decidua produces IL-1β and TNF-α in response to bacterial products[112,114]; (3) AF IL-1β and TNF-α bioactivity and concentrations are elevated in women with PTL and IAI[113,114]; (4) in women with PPROM and IAI, IL-1β and TNF-α concentrations are higher in the presence of labor[116,117]; (5) IL-1β and TNF-α induce preterm parturition when administered systemically to pregnant animals[118,119]; (6) pretreatment with the natural IL-1 receptor antagonist prior to the administration of IL-1 to pregnant animals prevents preterm parturition[120]; and (7) fetal plasma IL-1β is elevated in the context of PTL with intrauterine infection.[121] However, there is considerable redundancy in the cytokine network, and it remains unclear whether a particular cytokine signals the onset of labor.

Adipocytokines

Adipose tissue is a highly active endocrine organ[122,123] that can orchestrate a metabolic response to insults and mount an inflammatory response via the production of soluble adipocytokines (cytokines that are produced mainly, but not exclusively, by adipose tissue). Adipocytokines such as resistin[124] and visfatin[125] participate in the modulation of the innate immune responses, whereas leptin and adiponectin regulate the innate[126] and adaptive[127] immune responses.

Adiponectin, the most abundant gene (AMP1) product of adipose tissue, has profound insulin-sensitizing and anti-inflammatory properties. Our group[128] has recently reported that PTL is characterized by a change in the maternal serum profile of adiponectin multimer concentrations that favors insulin resistance and a pro-inflammatory state. These changes were more pronounced in the presence of IAI.[128] Consistent with these observations, preterm parturition and IAI were associated with alterations of AF concentrations of adiponectin.[129] Visfatin is produced preferentially by visceral adipose tissue and exerts insulin-mimicking and pro-inflammatory and immunomodulating effects. PTL and MIAC[130] were both associated with alterations in maternal plasma[131] and AF[130] concentrations of visfatin. Resistin is mainly produced by circulating monocytes and macrophages. AF concentrations of resistin are higher in patients with PTL and in those with PPROM with IAI than in those without IAI.[132] This evidence suggests that adipocytokines may play a role in maternal metabolic adaptations to PTL in the presence of IAI as well as in the regulation of the host response against infection.

Anti-inflammatory Cytokines and Preterm Labor

The resolution of the inflammatory response is an active process that encompasses the removal of the inflammatory stimulus, a decrease in bioavailability of pro-inflammatory mediators with a switch to an anti-inflammatory milieu, followed by tissue repair. Several cytokines have anti-inflammatory properties, including IL-4, IL-10, and IL-27.[133,134]

IL-10 is a cytokine highly expressed in the uterus and placenta and is implicated in pregnancy maintainence.[135] Down-regulation of placental IL-10 has been implicated in the onset of spontaneous labor at term.[133] In addition, IL-10 plays an important role in controlling inflammation-induced pathologies of pregnancy,[136] and it has been implicated in the preterm parturition associated with inflammation.[135] Women with PTL and IAI have higher median AF IL-10 concentrations than those without IAI, suggesting that IL-10 is present to dampen the inflammatory response associated with severe infection.[137] The abundance of endogenous IL-10 in gestational tissues has been identified as a determinant of resistance to PTL, because IL-10 is thought to modulate resistance to inflammatory stimuli by down-regulating pro-inflammatory cytokines.[136] Evidence that IL-10 confers resistance to PTL includes (1) IL-10 knock-out mice experience pregnancy loss in response to very low doses of lipopolysaccharide (LPS)[138]; (2) the IL-10 -1082A/-819T/-592A (IL-10 ATA)-haplotype, associated with low IL-10 production, was found to be independently associated with early preterm birth[139]; (3) administration of IL-10 to pregnant rhesus monkeys results in a reduction of IL-1β–induced uterine contractility as well as the TNF-α and WBC count in the AF[140]; and (4) the administration of IL-10 in animal models of infection has been associated with improved pregnancy outcome.[141]

Pattern Recognition Receptors Identify Microorganisms

The first line of defense against infection is provided by the innate immune system. One of the mechanisms by which the innate immune system recognizes microorganisms is by using pattern recognition receptors (PRRs), which bind to patterns of molecular structures present on the surfaces of microorganisms.[142] Toll-like receptors (TLRs) are a group of transmembrane PRRs.[143] Ten different TLRs have been identified in humans. TLR-2 recognizes peptidoglycans, lipoproteins, and zymosan (gram-positive bacteria, mycoplasmas, and fungi); TLR-4 recognizes LPS (produced by gram-negative bacteria); and TLR-3 recognizes double-stranded RNA (viruses).[143,144] Ligation of TLRs results in activation of nuclear factor κB (NF-κB), which, in turn, leads to the production of cytokines, chemokines, and antimicrobial peptides. Moreover, activation of the Toll pathway also induces surface expression of costimulatory molecules required for the induction of adaptive costimulatory immune responses, such as CD80 and CD86. In combination with antigenic microbial peptides, these molecules presented by major histocompatability complex class II proteins in dendritic cells and macrophages can activate naïve CD4 T cells that initiate an adaptive immune response.[142]

Expression of TLRs has been reported in the fetal membranes,[145] placenta,[146,147] and placental bed.[148] Expression of TLRs within the placenta is not restricted to the infiltrating immune cells and Hoffbauer cells,[147] but it is a feature of human trophoblasts as well.[146,147,149] This suggests a participation of the placenta itself in the induction of immune responses against pathogens.[149] Expression of TLR-2,[149] TLR-4,[149] and TLR-3[150] has been demonstrated by immunohistochemistry in first-trimester trophoblasts. Abrahams and coworkers[149,150] observed that cytotrophoblast and extravillous trophoblast, but not syncytiotrophoblasts, expressed TLR-2 and TLR-4 during the first trimester, suggesting that the placenta is able to respond only to those pathogens that breached the syncytiotrophoblast layer and entered either the placental villous or the decidual compartments.[151] Ligation of TLR-2 in first-trimester trophoblast cells by bacterial product results in the activation of the apoptotic pathway.[149] In contrast, ligation of TLR-4 by LPS results in the production of both pro- and anti-inflammatory cytokines.[150] TLR-3 mediates responses to viral dsRNA.[152] Ligation of TLR-3 in first-trimester trophoblasts is followed by up-regulation of a cytokine profile that is distinct from that induced following bacterial stimulation.[153]

Accumulating evidence suggests that TLRs participate in the onset and/or maintenance of infection-induced PTL[154] and that the innate immune system plays a role in parturition. Because TLRs are crucial for the recognition of microorganisms, it could be anticipated that defective signaling through this PRR would impair bacteria-induced PTL. Indeed, mice that have a spontaneous mutation for TLR-4 are less likely to deliver preterm after intrauterine inoculation of heat-killed bacteria or LPS administration than wild-type mice.[155,156] More recently, it was been demonstrated that preterm delivery in the mouse can be induced by TLR-2 stimulation with peptidoglycans and TLR-3 stimulation with polyinosinic acid.[157] In humans, spontaneous labor at term or preterm with histologic chorioamnionitis is associated with an increased mRNA and protein expression of TLR-2 and TLR-4 in the chorioamniotic membranes.[145] Further evidence for the role of TLRs in the infection-associated PTL comes from genetic studies; a polymorphism, which is known to confer impaired TLR-4 function and higher likelihood of gram-negative sepsis, is carried more often by preterm infants than by term infants and by mothers delivering preterm than at term.[158]

Matrix-Degrading Enzymes

The mechanisms responsible for PPROM are only partially understood. The tensile strength and elasticity of the chorioamniotic membranes are attributed to extracellular matrix proteins. Matrix-degrading enzymes have therefore been implicated in PPROM and there is now compelling evidence of increased availability of MMP-1, MMP-8, MMP-9, and neutrophil elastase, but not MMP-2, MMP-3, MMP-7, and MMP-13, in PPROM. Proposed mechanisms to regulate the expression and activity of matrix-degrading enzymes in fetal membranes include apoptosis[159] and increased availability of superoxide anions,[160] respectively.

Fetal carriage of functional polymorphisms that lead to overproduction of MMP-1, MMP-9, and MMP-8 in response to microorganisms have been associated with PPROM.[161–163] In addition to genetic variation, epigenetic mechanisms (DNA methylation) play a role in controlling MMP-1 expression in the human amnion and the risk of obstetric adverse outcome.[164]

Our group has proposed that the management of patients with PTL[165] or PPROM[166] should be based on the diagnosis of intra-amniotic inflammation rather than the diagnosis of IAI, because (1) the outcome of patients with MIAC is similar to that of patients with intra-amniotic inflammation and a negative AF culture and (2) results of AF culture are not available for 48 hours. MMP-8 is an excellent marker of intra-amniotic inflammation[167] and a bedside test is now available to detect elevated concentrations of MMP-8 in AF. The MMP-8 PTD (preterm delivery) Check test (SK Pharma Co, Ltd, Kyunggi-do, Korea) requires only 20 μL of AF and no laboratory equipment. The results are available within 15 minutes. Nien and colleagues[168] performed the MMP-8 rapid test in 331 patients admitted with increased preterm uterine contractions and intact membranes; the positive predictive values for spontaneous delivery within 48 hours and 7 days were 70% and 94%, respectively. Kim and associates[169] retrieved AF from 141 women with PPROM. Patients with a positive MMP-8 rapid test had a higher rate of IAI, proven AF infection, and adverse outcome than those with negative test results. A positive MMP-8 rapid test had a sensitivity of 90%, a specificity of 80%, a positive predictive value of 77%, and a negative predictive value of 92% in the identification of IAI.[168] In another study of 139 patients who delivered at less than 35 weeks, Park and coworkers[170] reported a positive MMP-8 rapid test that had a sensitivity of 97%, a specificity of 63%, a positive predictive value of 50%, and a negative predictive value of 99% in the identification of funisitis. Further clinical trials are needed to determine whether treatment with antibiotics and/or anti-inflammatory agents based on the MMP-8 rapid test results improves pregnancy outcome.
THE FETAL INFLAMMATORY RESPONSE SYNDROME

The term *fetal inflammatory response syndrome (FIRS)* was coined to define a subclinical condition originally described in fetuses of women presenting with PTL as well as those presenting with PPROM.[11,12] The definition was an elevation of fetal plasma IL-6 above 11 pg/mL.[11] The original work was based on fetal blood samples, but the association with elevated pro-inflammatory cytokines and sepsis has since been confirmed in umbilical cord blood at the time of birth.[14] Pathologic examination of the umbilical cord is an easy approach to determine whether fetal inflammation was present before birth. Funisitis and chorionic vasculitis are the histopathologic hallmark of FIRS.[51] Neonates with funisitis are at increased risk for neonatal sepsis[171] as well as long-term handicap such as bronchopulmonary dysplasia (BPD)[14] and CP.[13] Among women with PPROM, FIRS is associated with the impending onset of PTL, regardless of the inflammatory state of the AF (Fig. 26–2).[12] This suggests that the human fetus plays a role in initiating the onset of labor. However, maternal cooperation must be present for parturition to occur.

Fetal Target Organs during Fetal Inflammatory Response Syndrome

Fetuses with FIRS are frequently born to mothers with subclinical MIAC.[12] Affected fetuses have evidence of multiorgan involvement with a higher rate of severe neonatal morbidity after adjustment for gestational age[12] and cases of PPROM had a shorter cordocentesis-to-delivery interval.[11] Fetal microbial invasion results in a systemic fetal inflammatory response that can progress toward multiple organ dysfunction, septic shock, and death in the absence of timely delivery.

Hematopoietic System

Neutrophilia is present in two thirds of fetuses with FIRS, whereas neutropenia is observed in 7%.[172] FIRS has also been associated with changes in the immunophenotype of monocyte and granulocytes consistent with activation.[173] Numbers of circulating nucleated red blood cells are also increased. IL-6 has been proposed to have a role in elevating the fetal nucleated red blood cell count.[174]

Lung

FIRS is associated with BPD.[175] Amniotic fluid and its contents can be inhaled by the fetus and reach the distal parts of the airways and the alveoli. Ghezzi and colleagues[176] reported that fetuses who subsequently developed BPD had a higher AF IL-8 concentration than those who did not. These observations were confirmed in another study that reported higher AF concentrations of IL-6, TNF-α, and IL-8 in fetuses who eventually developed BPD,[177] suggesting that antenatal exposure to pro-inflammatory cytokines is also a risk factor for the development of BPD. As for whether fetal systemic inflammation is a risk factor for chronic lung disease, neonates who develop BPD have a higher IL-6 concentration in umbilical cord plasma at birth than those who do not (68.3 pg/mL vs. 6.9 pg/mL; $P < .001$).[14] The same group[175] has also found FIRS in 76% on infants with atypical chronic lung disease (defined as chronic lung disease in the absence of respiratory distress syndrome).

Kidneys

Yoon and associates[36] reported an association between oligohydramnios and fetal infection/inflammation in patients with PPROM. In view of the antimicrobial properties of the AF, oligohydramnios may reduce the protective effect of this component of innate immunity. Alternatively, oligohydramnios may be the result of a redistribution of blood flow away from the kidneys occurring during the host response to microbial products.[36]

Heart

In the presence of IAI, fetuses show changes in cardiac function consistent with a high left ventricular compliance.[178] In cases of overwhelming fetal sepsis, myocardial depression may lead to fetal death. In the context of FIRS, bacterial products and cytokines may contribute to the myocardial depression. Fetuses that are unable to modify their cardiac compliance or maintain ventricular cardiac output may suffer an inadequate brain perfusion, predisposing to hypotension and brain ischemia in utero.[179] This could create conditions for the development of periventricular leukomalacia (PVL) and brain injury.

Adrenal Glands

FIRS is associated with endocrine evidence of "stress," which is expressed by an elevated cortisol–to–dehydroepiandrosterone sulfate (DHEA-S) ratio.[180] These endocrine changes may contribute to the onset of spontaneous PTL. Indeed, Yoon and coworkers[180] reported that in patients with PPROM, there is an association between the fetal plasma

cortisol-to-DHEA-S ratio and a shorter interval from cordocentesis to delivery (hazards ratio 2.9; 95% CI 1–8.4). Patients with PPROM who went into spontaneous labor and delivered within 7 days of cordocentesis had a higher fetal plasma cortisol than those delivered after 7 days ($P < .0001$). Fetal plasma cortisol, but not maternal cortisol, was an independent predictor of the duration of pregnancy. These endocrine changes may have short- and long-term implications given the recent observations about the effect of glucocorticoids in fetal programming of several metabolic functions.[181,182]

Skin

Fetal dermatitis is a new entity described in FIRS. Skin samples from fetuses delivered between 21 and 24 weeks' gestation had histologic evidence of dermatitis.[183] TLR-2 expression in the skin was dramatically increased in fetuses born from mothers with histologic chorioamnionitis. Moreover, TLR-2 and TLR-4 were also expressed in the mononuclear inflammatory infiltrate of the dermal-epidermal junction, suggesting that microorganisms are recognized by the fetal skin through PRRs and, thus, participate in the fetal inflammatory response to microbial products.[183]

Thymus

Subclinical chorioamnionitis has been associated with a small thymus,[184] and thymus involution has been demonstrated antenatally with ultrasound in fetuses exposed to IAI in patients with PTL[185] and in those with PPROM.[186] In another study, infants born at less than 28 weeks' gestation and with ultrasonographic signs of cerebral white matter damage (WMD) were more likely to have undergone thymic involution.[187]

CONTRIBUTION OF FETAL INFECTION/ INFLAMMATION TO LONG-TERM HANDICAP

Cerebral Palsy

CP is a symptom complex characterized by aberrant control of movement or posture that appears in early life and can lead to costly lifelong disability. The estimated annual prevalence of CP ranges from 1.5 to 2.5 per 1000 live births, depending on the cohort studied.[188,189] Prematurity has a strong association with CP[190]; one third of all neonates who later have signs of CP weigh less than 2500 g.[191] Newborns with birth weights less than 1500 g have a rate of CP 25 to 31 times higher than those with a normal birth weight.[191] The most common form of CP affecting preterm babies is spastic diplegia.[191] In turn, preterm babies that subsequently develop spastic diplegia have a high rate of PVL.[190,192,193] Strong evidence links brain injury and infant exposure to perinatal infection and inflammation.[194–196] In 1955, Eastman and Deleon[197] observed that intrapartum maternal fever was associated with a sevenfold increase in the risk of CP. In 1978, Nelson and Ellenberg[198] showed, using data from the Collaborative Perinatal Project, that among low–birth weight infants, chorioamnionitis increased the risk of CP from 12 in 1000 to 39 in 1000 live births. The general view is that an initiator event (either systemic or intrauterine infection) leads to maternal and fetal inflammatory responses that, in turn, contribute to adverse outcomes such as preterm

delivery, IVH, WMD, and neurodevelopmental disability (mainly CP).

PVL describes foci of coagulation necrosis of the white matter near the lateral ventricles. This condition is frequently associated with the subsequent development of CP,[199,200] is more common in infants born between 28 and 31 weeks, and is nine times more common among those with documented bacteremia.[190] Among preterm neonates, the frequency of IVH and PVL is higher for those born after spontaneous PTL or PPROM than for infants delivered for fetal or maternal indications.[201,202]

Experimental Evidence Linking Infection with White Matter Damage

WMD is more common among children of pregnancies complicated by chorioamnionitis[202] and purulent AF[192] as well as among neonates with bacteremia.[190] Experimental evidence indicates that intrauterine infection results in WMD and neuronal lesions.[203–205] Yoon and coworkers[203] experimentally induced ascending intrauterine infection with E. coli rabbits. Histologic evidence of WMD was identified in 12 fetuses born to 10 E. coli–inoculated rabbits compared with none in the control group ($P < .05$). All cases with WMD had evidence of intrauterine inflammation. Similar findings were reported by Debillon and colleagues.[204]

Fetal Cytokinemia Is Associated with Intraventricular Hemorrhage, White Matter Damage, and Long-Term Disability

Leviton[206] proposed that inflammatory cytokines (TNF-α) released during the course of intrauterine infection could play a central role in the pathophysiology of WMD. TNF could participate in the pathogenesis of PVL by four different mechanisms: (1) induction of fetal hypotension and brain ischemia[207]; (2) stimulation of tissue factor production and release, which activates the hemostatic system and contributes to coagulation necrosis of white matter[208]; (3) release of platelet-activating factor, which could act as a membrane detergent causing direct brain damage[209]; and (4) a direct cytotoxic effect on oligodendrocytes and myelin.[210]

The hypothesis that fetal inflammation is linked to brain injury is supported by studies documenting higher concentrations of IL-6 in the umbilical cord plasma[201] and AF[195] of fetuses who subsequently develop WMD. Moreover, increased expression of TNF-α and IL-6 is observed in hypertrophic astrocytes and microglia cells obtained from subjects with PVL.[211] Yoon and associates[195] advanced one mechanism to explain how inflammatory cytokines might lead to WMD and CP. According to their theory, MIAC (which occurs in 25% of preterm births) results in congenital fetal infection/inflammation that stimulates fetal mononuclear cells to produce IL-1β and TNF-α. These cytokines increase the permeability of the blood-brain barrier, facilitating the passage of microbial products and cytokines into the brain.[212] Microbial products then stimulate the human fetal microglia to produce IL-1 and TNF-α with subsequent activation of astrocyte proliferation and production of TNF-α. Oligodendrocytes, the cells responsible for the deposition of myelin, are damaged by TNF-α.

Fetal Vasculitis, Intraventricular Hemorrhage, White Matter Damage, and Cerebral Palsy

Yoon and coworkers[13] observed in a study of 123 preterm infants followed to age 3 years that the odds of developing CP were higher in the presence of funisitis (OR 5.5; 95% CI 1.2–24.5), increased AF IL-6 concentrations (OR 6.4; 95% CI 1.3–33.0), and increased AF IL-8 concentrations (OR 5.9; 95% CI 1.1–30.7). All 14 children who developed CP had evidence of WMD and 11 had evidence of intrauterine inflammation. Fifty percent of the children had positive AF cultures. Histologic chorioamnionitis was not associated with subsequent development of CP after adjusting for gestational age at birth, suggesting that it is the fetal, rather than the maternal, inflammatory response that predisposes to CP. Nonetheless, neither infection nor inflammation was considered a sufficient causal factor for WMD or CP, because the latter did not develop in 82% of fetuses with documented MIAC and in 76% of those with evidence of intrauterine inflammation. Factors implicated in the genesis of brain injury include (1) gestational age, (2) virulence of the microorganisms, (3) fetal attack rate, (4) the nature of the fetal immunoresponse, and (5) vulnerability of the central nervous system.

APPROACHES TO FETAL IINFLAMMATORY RESPONSE SYNDROME

Three approaches can be used to interrupt the course of FIRS: (1) delivery, (2) antimicrobial treatment of women in whom the FIRS is due to microbial invasion of susceptible bacteria, and (3) administration of agents that down-regulate the inflammatory response. Preterm delivery places the unborn child at risk for complications of prematurity. Therefore, the risks of prematurity and intrauterine infection must be balanced.

The administration of antimicrobial agents may eradicate MIAC in cases of PPROM. The results of the ORACLE I trial suggest that antibiotic administration may not only delay the onset of labor but also improve neonatal outcome.[76] These findings are supported by experimental evidence in pregnant rabbits inoculated with *E. coli*. Antibiotic administration within 12 hours of microbial inoculation (but not after 18 hours) effectively prevented maternal fever, reduced the rate of preterm delivery, and improved neonatal survival.[213] It is tempting to postulate that this was accomplished by improving or preventing a fetal inflammatory response. It is important to note that the 7-year follow-up of infants in ORACLE trial I did not demonstrate any reduction in the rate of CP in infants given antibiotics.[214]

Agents that down-regulate the inflammatory response, such as anti-inflammatory cytokines, antibodies to macrophage migration inhibitory factor, and antioxidants, may also play a role in preventing preterm delivery, neonatal injury, and long-term perinatal morbidity. A combination of antibiotics and immunomodulators (dexamethasone and indomethacin) given to nonhuman pregnant primates was effective in eradicating infection, suppressing the inflammatory response, and prolonging gestation in experimental premature labor induced by intra-amniotic inoculation with group B streptococci.[215] The administration of magnesium sulfate as a neuroprotective agent has also been found to be beneficial for fetuses of less than 34 weeks' gestation.[216–221]

Hepatitis Virus Infections

JANET I. ANDREWS

INTRODUCTION

Viral hepatitis is one of the more commonly diagnosed viral infections in pregnancy. Six subtypes of the hepatitis virus have been identified (A, B, C, D, E, and G). These viral subtypes differ according to structure, routes of transmission, and implications for management during pregnancy and the neonatal period (Table 27–1). In general, diagnosis of viral hepatitis is based on specific clinical symptoms (malaise, fever, abdominal pain, and/or jaundice) and virus-specific laboratory criteria including serology. The purpose of this chapter is to describe each of the viral hepatitis subtypes and their maternal and perinatal implications as they relate to prevention and treatment.

HEPATITIS A
General

Although person-to-person contact resulting in "infectious jaundice" was described in a review of hepatitis epidemics published by Blumer in 1923,[1] the hepatitis A virus (HAV) was not identified until 1973, when Feinstone and colleagues,[2] using immunofluorescent electron microscopy, described virus-like particles in filtered stool samples that stained positively when mixed with HAV convalescent serum. Subsequent work by this group then demonstrated a temporal link between detectable shedding of the HAV antigen in feces and symptomatic illness in experimentally infected subjects.[3]

As a member of the Picornaviridae family, HAV is non-enveloped and resistant to organic solvent dissolution owing to its lipid-poor coating. Compared with other picornaviruses such as poliovirus, HAV is relatively stable in the environment. The virus is resistant to heat and inactivation by drying for up to 1 month.[4] Autoclaving, heating food to above 185°F for 1 minute, or disinfecting surfaces with dilute chlorine bleach will inactivate the virus.[5] This latter effect helps explain the propagation of HAV in areas of poor sanitation.

The distribution of HAV is global, though outbreaks are typically seen in areas with crowded conditions, inadequate water supplies, or poor hygiene and sanitation. The virus is highly contagious and can be isolated from the feces of all infected persons, which facilitates the fecal-oral route of person-to-person transmission. Outbreaks and sporadic cases also can occur from exposure to contaminated food and water. Contaminated food needs to be cooked to the appropriate temperature to kill the virus. Parenteral transmission is rare, because the virus is present only transiently in serum.

Prior to the introduction of the HAV vaccine in 1995, HAV accounted for approximately one third of cases of hepatitis in the United States. Since 1995, HAV rates in the United States have declined by 89%. In 2006, 3579 acute symptomatic cases of HAV were reported, the lowest rate recorded. After adjusting for underreporting bias and asymptomatic cases, the estimated number of cases in 2006 was 32,000.[6] The rate of HAV infection during pregnancy is unknown, but retrospective reviews estimate that HAV is a rare cause of acute hepatitis in pregnancy. In large retrospective case series from Ireland and Isreal, the incidence of HAV infection during pregnancy was extremely low with reported rates of 1/13,181 and 13/79,458 pregnant women, respectively.[7,8]

Major risk factors for HAV infection in pregnant women in developed countries include (1) travel to developing countries (especially Southeast Asia, Africa, central America, Mexico, and the Middle East), (2) household or sexual contact with infected individuals, and (3) contact with contaminated food or water. In the United States, person-to-person transmission is the primary means of HAV transmission via a close personal contact with a household member or sex partner. Because most HAV-infected children are asymptomatic, they serve a key role in the transmission of the virus.[9,10]

Bivalve mollusks such as clams and oysters can act also as reservoirs for HAV within contaminated waters; crustaceans such as shrimp do not seem to carry the same infectious risk. Infected food handlers have also been implicated in HAV outbreaks, especially when they are from global areas with endemic HAV infection rates.[11]

Although HAV infection tends to be clinically less severe than infection with other viral hepatitides, and serious complications are uncommon, distinction between infection with HAV and other viruses can only be made serologically. Conversely, not all HAV infections are symptomatic. Before immune globulin was available for preventive passive immunization, 80% to 95% of infected adults in HAV epidemics were symptomatic, two thirds of whom were icteric.[12]

TABLE 27–1

Comparison of Hepatitis Virus Subtypes

	HEPATITIS A	HEPATITIS B	HEPATITIS C	HEPATITIS D	HEPATITIS E
Virus family	Picornaviridae	Hepadnaviridae	Flaviviridae	Deltavirus genus	Similar to Calciviridae
Diagnosis	Anti-HAV	HBsAg, anti-HBs, anti-HBc, HBeAg	Anti-HCV by ELISA (see text for confirmatory testing)	Anti-HDV and D antigen	Anti-HEV
Primary route of transmission	Fecal-oral	Blood/body fluids	Blood/body fluids	Blood/body fluids (requires HBV for replication)	Fecal-oral
Average incubation period in days (range)	28 (15–50)	90 (60–150)	28–84 (14–168)	21–49	40 (21–56)
Incidence rate* (United States)	1.2/100,000	1.6/100,000	0.3/100,000	N/A	N/A
Rate of vertical transmission risk	Rare	10%–20% if no immunoprophylaxis	2%–7% (unless high HCV-RNA and/or HIV-positive)	Rare	Rare
Vaccine available?	Yes	Yes	No	No	No
Breast-feeding contraindicated?	No	No (risk unknown if HBeAg-positive mom)	No (unless nipples cracked or bleeding)	No	No

* Centers for Disease Control and Prevention: Surveillance for Acute Viral Hepatitis—United States, 2006. MMWR Surveill Summ March 21, 2008. MMWR 2008;57/No. SS-2.

ELISA, enzyme-linked immunosorbent assay; HAV, hepatitis A virus; HBeAg, hepatitis Be antigen; HBsAg, hepatitis B surface antigen; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; N/A, not applicable.

Severity of illness with HAV infection appears to be directly related to the patient's age (older patients are more severely ill) as well as to the size of the viral inoculum. Virus transmissibility is of greatest concern during the incubation period, which has a mean of 28 days and range of 15 to 50 days.

Diagnosis

The initial clinical symptoms of acute HAV infection are nonspecific, consisting of fatigue, malaise, fever, nausea, and anorexia. Significant weight loss may be a presenting complaint in pregnant women. The classic picture of icteric illness becomes apparent within 10 days of the generalized symptoms and is usually preceded by palpable hepatosplenomegaly. Liver function abnormalities, typically characterized by elevations in serum alanine aminotransferase (ALT) higher than aspartate aminotransferase (AST), peak prior to the appearance of jaundice. They may remain elevated for over a month in adults. Prolonged illness, with elevations in liver functions tests (LFTs) lasting over 12 months, has been reported in 8% to 10% of older patients, and jaundice and pruritus may persist despite an overall improving trend in symptoms and LFTs. Fulminant hepatitis, resulting in death, occurs in fewer than 1% of cases.[13]

HAV-specific immunoglobulin M (IgM) is the serologic marker for acute infection and can be reliably identified with an automated enzyme-linked immunosorbent assay (ELISA).[14,15]

By the time a patient is symptomatic, she will almost uniformly be seropositive for IgM anti-HAV. IgM levels drop below the detectable range within 4 to 6 months in most patients and parallel a concomitant normalization of LFTs in 80% to 85% of cases.[16] HAV-specific IgG, however, will remain positive for years after acute infection.

Maternal and Fetal Risks

As an almost entirely self-limited illness, acute HAV infection usually does not confer an increased risk of adverse outcome to a pregnant woman. Supportive care for the woman is essential, and in areas where the virus may be endemic as the result of sanitation or housing issues, the availability of such care might not exist. Nutritional needs should be addressed, and infected pregnant women may require hospitalization with strict contact isolation precautions. A chronic carrier state for HAV does not exist. Perinatal transmission of HAV is rare.[17–19]

Administration of immune globulin is recommended for neonates born within 2 weeks of acute maternal illness with HAV conferring protection for up to 3 months at 80% to 90% efficacy level.[20]

Management Options

No specific antiviral treatment of HAV is currently available. However, both preventive vaccination and postexposure prophylaxis with immunoglobulin are available. The current HAV vaccine is available either as a single-agent vaccine (Havrix and Vaqta) or as one combined with hepatitis B virus (HBV) vaccine (Twinrix). Single-agent HAV vaccine is given as two doses, 6 to 12 months apart. Currently, the Advisory Committee on Immunization Practices (ACIP) recommends a single-antigen vaccine series for all children at age 12 to 23 months, catch-up vaccination of older children in selected areas, and vaccination of persons at increased risk for HAV (e.g., travelers to endemic areas, users of illicit drugs, or men who have sex with men).[21] As an inactivated-virus vaccine, there is no contraindication to the use of HAV vaccine during pregnancy.

Individuals who have close personal or sexual contact with an HAV-infected person should receive postexposure

prophylaxis unless they have been immunized. Until recently, immune globulin was the recommended choice for postexposure prophylaxis. The 2007 ACIP guidelines were revised to recommend the HAV vaccine be given following exposure, based on the data indicating that immune globulin and vaccine have similar postexposure efficacy among healthy persons younger than 40 years of age.[22] The current recommendations state that for healthy persons aged 1 to 40 years, single-antigen HAV vaccine at the age-appropriate dose is preferred to immune globulin for postexposure prophylaxis because of vaccine advantages that include long-term protection and ease of administration. For persons older than 40 years, immune globulin is preferred because of the absence of information regarding vaccine performance and the more severe manifestations of HAV in this age group. A single intramuscular dose of 0.02 mL/kg should be given as soon as possible after contact with the infected individual, within 2 weeks of exposure. The efficacy of immune globulin after 2 weeks from exposure is unknown.[21] Administration of immune globulin is still recommended for neonates born to mothers with recent HAV infection.[23]

HEPATITIS B

General

According to the World Health Organization (WHO), approximately 2 billion people have been infected with worldwide and 350 million are chronically infected.[24] HBV infection is a major global health problem with 600,000 annual deaths attributable to the consequences of HBV infection.[24] In areas of Asia, 8% to 10% of the adult population is chronically infected with HBV, and liver cancer attributable to HBV is a major cause of cancer in women. High rates of chronic infections are also found in the Middle East and the Indian subcontinent, with an estimated 2% to 5% of the adult population infected.[24] In many of these endemic areas, perinatal and childhood infections exist as a primary route for perpetuating the reservoir of carriers. The likelihood that a person infected with HBV will develop a chronic infection depends upon the age at which the person is infected. The earlier in life that a person is infected, the higher the risk of being a chronic carrier. This finding is especially significant because the risk of chronic HBV infection for a child infected in the newborn period, in the absence of prophylactic therapy, is 70% to 90%.[25,26]

In areas of low endemicity for HBV carriage, such as the United States, screening programs for the general population have been targeted to decrease household, transfusion, sexual, and perinatal transmission risks among contacts of hepatitis B surface antigen (HBsAg)–positive individuals. Population subsets have been identified that are at increased risk for HBV acquisition, and HBV vaccination is recommended for individuals within those groups who are serologically negative for HBsAg and hepatitis B surface antibody (HBsAb). The efficacy of a serum-derived HBV vaccine was demonstrated initially on a large scale in a cohort of more than 1000 homosexual men in the United States; this trial showed an antibody (HBsAb) response in 96% of those vaccinated, with an overall protective efficacy of 88% against all HBsAg-positive events for vaccine compared with placebo.[27]

More recently, two single-antigen and three combination vaccines were developed and licensed in the United States. These vaccines are prepared from yeast culture and utilize a recombinant HBsAg protein dose.

In 2006, an estimated 46,000 persons in the United States were newly infected with HBV after taking into account asymptomatic infections and underreporting. This estimate represents a decline by approximately 81% since 1991.[6] Among pregnant women, Asian American women from urban areas have the highest HBsAg prevalence rate of 6%, followed by blacks (1%), whites (0.6%), and Latinos (0.14%).[28] Blood and blood products are the most thoroughly established sources of HBV infection, although HBsAg has been demonstrated in a variety of body fluids. Of those, however, only serum, saliva, and semen have been associated consistently with transmission in experimental models.[29] Percutaneous transfer of the virus is the most obvious route of transmission in the medical setting, through either blood products or needle-stick accidents. Contact of infectious material with broken skin or mucous membranes also can result in effective transmission.

Compared with other transmissible viruses, such as HIV, HBV is a fairly stable virus and remains infectious on household surfaces up to 7 days. Although transmission in households is more common through sexual contact than through fomite contact,[30] nonsexual household transmission has been established as a route for HBV infection.[31] Therefore, any surfaces potentially contaminated with infectious blood should be cleaned with 1 : 10 dilution of bleach solution. In areas of the world with higher HBV carrier rates than the United States, nonparenteral transmission would be expected to constitute the major route of person-to-person HBV infection. Vertical transmission is a major source; investigators in Taiwan estimated that 40% to 50% of HBsAg carriers became infected in the perinatal period.[25,32]

Children born to carrier mothers who escape the neonatal period without evidence of infection are still at risk for childhood acquisition of HBV. One of the early vaccine trials conducted in Senegal showed that among children seronegative at the beginning of a randomized HBV vaccination trial, almost 10% acquired HBV infection in the absence of vaccination by the end of a 12-month follow-up period.[33]

Diagnosis

HBV is distinguished from the other viral hepatitides by its long incubation period (1–6 mo), by the presence of extrahepatic symptoms in up to 20% of patients (arthralgia, rash, and myalgia thought to be a result of antigen-antibody complex deposition),[34] and by the detection of HBV-specific serum markers (Table 27–2).

HBV consists of three structural antigens: surface, core, and e antigen. The appearance of surface antigen (HBsAg) in the serum usually predates any clinical symptoms by 4 weeks on average and remains detectable for 1 to 6 weeks in most patients.[35] In the 90% to 95% of patients in whom chronic infection does not develop, HBsAg titers decrease as symptoms diminish. The appearance of HBsAb defines the absence of the carrier state; titers increase slowly during the clinical recovery period and may continue to increase up to 10 to 12 months after HBsAg is no longer detectable. In most patients with self-limited, acute HBV, HBsAb is

Interpretation of Hepatitis B Panel

TESTS	RESULTS	INTERPRETATION
HBsAg	Negative	Susceptible
Anti-HBc	Negative	
Anti-HBs	Negative	
HBsAg	Negative	Immune due to natural infection
