Anti-HBs	Negative	2. False-positive anti-HBc, thus susceptible
		3. "Low level": chronic infection
		4. Resolving acute infection

HBc, hepatitis B core antigen; HBs, hepatitis Bs; HBsAg; hepatitis B surface antigen; IgM, immunoglobulin M.

Adapted from A comprehensive immunization strategy to eliminate transmission of hepatitis B virus infection in the United States: Recommendations of the Advisory Committee on Immunization Practices (ACIP) part 1: Immunization of infants, children, and adolescents. MMWR Recomm Rep 2005;54(RR-16):1–31.

detectable only after HBsAg titers in serum disappear.[36] A "window" of time has been described in which a patient still with clinical hepatitis is negative for both HBsAg and HBsAb. During this time, HBV infection still can be diagnosed by the detection of hepatitis B core antibody (HBcAb), which begins to appear 3 to 5 weeks after HBsAg does. HBcAb titers may drop off in the first 1 to 2 years after infection, although the antibody is still detectable years after acute disease in most patients.[36] The appearance of hepatitis Be antigen (HBeAg) parallels that of HBsAg; in self-limited infections, HBeAb is detectable shortly after the time that HBeAg disappears. The chronic HBV carrier state usually can be predicted by HBsAg seropositivity for 20 weeks or longer. HBcAb is detectable in the serum of carriers at levels higher than those seen in either acute or recovering self-limited infections, and e antigen markers are variable. The presence of HBsAb in the absence of HBsAg and HBcAb differentiates vaccine-mediated immunity from natural-infection–mediated immunity.

Maternal and Fetal Risks
Risks during Pregnancy

Acute HBV infection during pregnancy is usually a mild illness with only up to 30% of patients reporting icterus, nausea, vomiting, and right upper quadrant discomfort.[37] Treatment during pregnancy is mainly supportive, as in the nonpregnant state. Symptoms generally resolve within several weeks; however, 0.5% to 1.5% of infective individuals will develop fulminant liver failure.[38] Hospitalization

should be considered for pregnant women with acute HBV infection if they have encephalopathy, coagulopathy, or severe fluid and nutritional imbalances. The diagnosis of acute HBV during the later stages of pregnancy can be differentiated from preeclampsia or HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome using normal blood pressure criteria and presence of jaundice. Encouragement is necessary to maintain adequate nutrition during the early symptomatic phase, and liver-metabolized drugs, if not avoidable, need to be monitored carefully through blood levels. In addition, household and sexual contacts of patients should be offered appropriate immunoprophylaxis. No teratogenic association has been established for maternal HBV infections,[39,40] despite evidence of viral infection within the placenta.[41,42]

The rate of vertical transmission during acute maternal HBV infection depends on the gestational age of the fetus. When maternal infection occurs during the first trimester, up to 10% of neonates will be infected. In contrast, 80% to 90% of neonates are HBsAg-positive when maternal infection occurs during the third trimester.[20,43] Although evidence is limited, there is an association between prematurity and acute HBV infection (32% vs. 11% in controls).[39]

Chronic HBV is endemic in certain areas of Asia where the estimated prevalence among women of reproductive age is 10% to 20%. Studies from these areas indicate that the presence of HBsAg does not appear to increase the risk of adverse pregnancy outcomes.[44] In addition, pregnancy does not exacerbate chronic HBV infection or alter HBV viral levels.[45]

Hepatitis B Screening in Pregnancy

The opportunity to provide almost complete protection against perinatally acquired HBV infection makes antenatal identification of HBV carriers critical so that combined neonatal prophylaxis can be administered in a timely fashion. Previously, in nonendemic areas such as the United States, risk factor–based prenatal screening protocols were implemented, but these protocols detected only up to 60% of HBV carriers. Therefore, the American College of Obstetricians and Gynecologists and the Centers for Disease Control and Prevention (CDC) recommended routine prenatal screening with HBsAg for all pregnant women regardless of risk factors.[20,43] Furthermore, the CDC recommends that pregnant women who are HBsAg-negative and at high risk for HBV infection (including >1 sex partner in past 6 mo, evaluation or treatment for sexually transmitted infection, recent or current injection drug use, or HBsAg-positive sex partner) should be retested upon admission to labor and delivery.

Management Options
Prevention of Hepatitis B Virus Infection

Immunoprophylaxis regimens to prevent HBV transmission in the perinatal period were a direct extension of the success of these therapies in high risk adult populations. Postexposure immunization was first demonstrated through the use of immunoglobulin preparations with high titers of HBsAb, when given within 4 hours of experimental infection with HBV.[46] Before the development of an effective HBV-specific vaccine, transient preexposure prophylaxis was demonstrated using hepatitis B immunoglobulin (HBIG),[47] although such use of HBIG is now of purely historical interest in terms

of understanding the evolution of therapeutic standards. Currently, postexposure treatment consists of a single dose of HBIG administered as temporally as possible to the exposure. Immediate therapy is optimal for maximal protection, although 75% efficacy has been shown when HBIG is given within 7 days of exposure.[48]

Although it does not increase the efficacy of HBIG therapy, a series of HBV vaccinations also should be initiated if the exposure was within a setting of ongoing risk, such as a health care or institutional setting. This regimen consists of injections at 0, 1, and 6 months and results in high antibody titers in more than 90% of those younger than 60 years of age. Administration of HBV vaccine simultaneously with HBIG does not diminish the immunologic response to the vaccine.[49] Still, the currently available HBV vaccine's efficacy is conferred by stimulating production of HBsAb by exposure to HBsAg; vaccine-related immunity can be distinguished from natural immunity in most cases by the absence of HBcAb in the serum of successfully vaccinated patients.

Prevention of Hepatitis B Virus in Utero Infection

In utero HBV infection is determined by multiple potential factors including HBV DNA level, gestational age, placenta integrity, and possibly genetic susceptibility of fetus.[50] Several prophylactic therapies (including hyperimmunoglobulin, HBV vaccine, and lamivudine) have been proposed to possibly reduce the risk of in utero transmission. Lamivudine is approved for treatment and can achieve suppression of HBV replication and remission.[20,51–53] Although well-controlled, large studies are needed, several reports have shown potential benefit from maternal lamivudine therapy to reduce the risk of in utero infection.[52,53] However, there is currently no effective, well-studied prophylactic treatment aimed at prevention in utero transmission.[54–57]

Preventing Perinatal Hepatitis B Virus Transmission

Although there may be a theoretical risk of HBV transmission, a lack of data exists regarding risk of transmission with fetal scalp monitoring and operative vaginal delivery. The route of delivery has not demonstrated to influence of the risk of perinatal HBV transmission.[20] According to the CDC, an HBsAg-positive mother can breast-feed even prior to the infant receiving the HBV vaccine and HBIG. The potential for vertical transmission of HBV at birth is significant. Most infants born to carrier mothers are HBsAg-negative at birth but seroconvert in the first 3 months after delivery, suggesting acquisition of the virus at birth.[58] Early attempts at interrupting the perinatal transmission cycle employed HBIG alone, administered in the neonatal period. Globulin alone had a protective efficacy against the carrier state of 70% to 75%, although the protection was not permanent, and many children eventually became infected after the passively acquired antibody was cleared, undoubtedly through household contact.[59,60]

With the advent of the HBV vaccine, trials were established to test its efficacy when administered in the newborn period, both alone and in conjunction with HBIG. A combination of HBIG and vaccine in the newborn period conferred significantly greater protection against perinatally transmitted HBV than even the vaccine alone, increasing efficacy from a range of 75% to 85% up to 90% to 95%.[59] The small but identifiable percentage of infants who become infected, despite even combined HBV therapy at birth, is believed to represent in utero infection.[61,62]

Combination HBV-specific immunotherapy provides the best opportunity to prevent the chronic carrier state in the offspring of HBsAg-positive mothers. CDC guidelines have been changed recently to reflect timing of the vaccine based on infant birth weight. Infants born to HBsAg-*positive* women should receive HBIG (0.5 mL) intramuscularly (IM) and HBV vaccine concurrently at a different site (0.5 mL, IM) within 12 hours of birth. For infants weighing less than 2000 g, the vaccine dose does not count as the first dose in the vaccine series and the full vaccine series should be initiated at 1 to 2 months. Infants (>2000 g) born to women of HBsAg-*negative* status receive the HBV vaccine prior to discharge. Infants (<2000 g) receive the first dose of vaccine 1 month after birth or at hospital discharge. If the mother's HBV status is unknown, the infant will receive HBIG and HBV vaccine within 12 hours of birth. The timing of HBIG appears to be more critical than that of vaccine in achieving maximal effectiveness of passive-active therapy. Subsequent vaccination is performed, also 0.5 mL IM, at 1 month and 6 months of age. Follow-up for these infants is crucial, because one study confirmed the concern that in the United States, groups at highest risk for HBV infection are also least likely to be compliant with follow-up care.[63]

Impact of Perinatal Hepatitis B Virus Vaccination Programs

The efficacy of perinatal HBV vaccination programs in preventing infection in children born to carrier mothers has led to the inclusion of the HBV vaccine series in the American Academy of Pediatrics' current recommendations for childhood vaccines for the general population.[64] Since 1982, over 1 billion doses of HBV vaccine have been administered worldwide. At the end of 2006, 164 countries had instituted HBV vaccination programs for infants in comparison with 31 countries in 1992 according WHO.

The beneficial impact of adequate childhood vaccination for HBV has been demonstrated dramatically in reports from Taiwan, where large-scale mass vaccination programs were begun in 1984. Researchers there have conclusively proven a link between HBV and hepatocellular carcinoma (HCC) by showing a significant decrease in the average annual incidence of HCC since the institution of the program.[65,66] The decline in the rate of HCC was also paralleled by a drop in the rate of HBsAg carriage among children born before the vaccination program was started, suggesting a herd immunity effect from the mass inoculation of children in the much more infectious younger birth cohorts, and resulting in a lower rate of horizontal HBV infection among the older unvaccinated children.[65] These results even further bolster the need to identify HBsAg carrier mothers and provide timely and complete HBV vaccination to their children.

HEPATITIS C VIRUS

General

Hepatitis C virus (HCV) is the most common bloodborne infection in the United States, although the incidence of

acute infection has been decreasing steadily since 1992.[67] In 2006, an estimated 3.2 million persons were chronically infected with HCV, largely due to infection during the 1970s and 1980s when the rates were highest.[43] Since 2003, HCV rates in the United States have remained stable with intravenous drug (IV) use being the most commonly identified risk factor.[6] The prevalence of HCV infection in pregnant women with IV drug use approaches 70% to 95%[68] As the risk of HCV infection resulting from blood transfusions has diminished, a result of the mass screening of blood products since 1992, the proportion of HCV infections attributable to drug use has markedly increased.[67] Transfusion-associated HCV infection is now extremely rare, with an estimated risk of less than 1 in 2 million units transfused.[69]

The significance of sexual transmission of HCV is controversial, though the overall rate of infection between HCV-discordant sexual partners appears to be rare.[70] It is likely that the observed association of HCV with high risk sexual practices is a result of the confounding effect of injection drug use associated with high risk sexual practices.[71] In addition, an interaction increasing the risk of concomitant transmission of HCV and HIV has been described. Heterosexual men with HCV and HIV infection were five times more likely to transmit both viruses to a female partner than would have been expected by chance.[72] This potential interaction of HIV and HCV to increase transmissibility of either or both agents also has become important in describing issues surrounding maternal-fetal HCV transmission.

Another important risk factor for HCV infection is transmission in the health care setting. With the introduction of standard precautions, nosocomial transmission has decreased dramatically with three exceptions: sharp injuries, hemodialysis, and iatrogenic therapeutic practices.[73] Needle-stick or sharp injuries from an HCV-positive source confer an estimated risk of HCV seroconversion of 1.8%.[73] Effective October 2008, all dialysis facilities are directed to follow CDC guidelines[74] for prevention of iatrogenic infection in hemodialysis patients as a condition for receiving Medicare payment for services.[75] Overall, prevention of nosocomial HCV transmission is targeted at minimizing the use of multiple-use vials, bottles, and/or IVs fluids where contaminated therapeutic injections can occur.

Acute HCV infection occurs after an incubation period of 30 to 60 days. Asymptomatic infection occurs in 75% of patients; the remaining 25% of infected individuals present with fatigue, abdominal pain, anorexia, or jaundice. Fulminant hepatitis and hepatic failure attributable to HCV are uncommon.

Chronic liver disease (defined as persistent infection for >3 mo) occurs in 75% to 85% of acutely infected individuals. Chronic HCV infection is the leading cause of liver transplantation in the United States.[69]

Diagnosis

Laboratory tests for diagnostic confirmation of acute HCV include at least a sevenfold increase in serum ALT levels, IgM anti-HAV–negative, IgM anti-HBc– or HBsAg–negative, and either a positive anti-HCV screening test with a cut-off predictive of a true positive OR anti-HCV–positive screening test verified with a more specific assay.[6] In a patient at high risk for HCV infection with a positive anti-HCV test result, the chance of a false-positive ELISA is exceedingly low. However, recognizing that most clnical laboratories report positive anti-HCV results using screening assays alone despite previous recommendations, the CDC expanded its HCV testing algorithm to include an option for supplemental testing based on "signal-to-cut-off (s/co)" ratios of positive commercial assay results.[76] The s/co of anti-HCV screening test positive results can be used minimize the number of specimens that require supplemental testing while providing results that have high probability of reflecting the person's true antibody status. Because pregnant women without risk factors do not constitute a high risk group requiring HCV screening by CDC guidelines, it is critical for clinicians to understand the limitations and interpretations of the currently available HCV screening assays.

At least six HCV genotypes and 50 subtypes have been identified. Viral genotyping is valuable to help guide therapy.[77] Genotype 1 is the most common HCV genotype found in the United States and is less responsive to treatment than genotypes 2 and 3. Genotypes 2 and 3 are almost three-fold more likely than genotype 1 to respond to therapy with interferon-α (IFN-α) or IFN-α and ribavirin.[77] This variation may limit the reproducibility of results in clinical trials, and therefore, genotyping information should be included for subjects enrolled in these trials. HCV genotype has not been determined to be an independent risk factor for perinatal HCV transmission, although data are very limited.[78,79]

Maternal and Fetal Risks

The prevalence of HCV infection among pregnant women ranges from approximately 0.3% to 2% in the United States and Europe, with higher rates in urban settings.[64,80,81] Routine prenatal screening for HCV is not recommended because of the lack of proven cost-effectiveness and available safe treatment.[82] However, screening is recommended for the subset of women with known risk factors for HCV infection as listed in Table 27–3.[20] Identifying HCV-seropositive pregnant women is important to guide postnatal follow-up and potential therapy for both women and neonates.

Overall, pregnancy does not significantly affect the clinical course of acute or chronic HCV infection. Studies have demonstrated decreases in transaminase levels as pregnancy progresses in HCV-infected women, although there are conflicting results regarding whether pregnancy alters viral load.[83–85] It is postulated that immunomodulatory factors play a role in these findings. Conversely, HCV infection may lead to adverse maternal or neonatal outcomes. Several studies have suggested that maternal HCV reactivity is associated with an increase risk of cholestasis of pregnancy and increased neonatal methadone withdrawal in those infants born to women taking methadone.[86,87] Therefore, clinicians should be aware of the increased risk of cholestasis and its associated morbidity.

Vertical HCV transmission rates range between 2% and 7%.[77,78,80,88,89] Although reported rates of transmission have been variable, overall it is encouraging that most series show the risk to be generally less than 5%. Maternal viremia (HCV RNA detected in maternal blood) near the time of delivery is a key determinant for vertical HCV transmission, regardless of maternal HIV status.[90–92] If an HCV-infected pregnant woman has no detectable HCV RNA, the risk of

TABLE 27–3

Risk Factors Warranting Hepatitis C Screening: Centers for Disease Control and Prevention Guidelines

Individuals Who Should Be Screened Routinely?

- Persons who ever injected illegal drugs (even once)
- Persons notified that they received blood/blood products from a donor who later tested positive for HCV
- Recipients of transfusions or organ transplants, particularly if received before July 1992
- Persons ever on long-term hemodialysis
- Persons with persistently elevated alanine aminotransferase (ALT) levels or other evidence of liver disease
- Persons seeking evaluation or care for a sexually transmitted infection, including HIV

Individuals for Whom Routine Testing Is of Uncertain Need

- Recipients of tissue transplants (e.g., corneal, skin, sperm, ova)
- Users of intranasal cocaine or other illegal noninjected drugs
- Persons with a history of tattooing or body piercing
- Persons with a history of sexually transmitted diseases or multiple sexual partners
- Long-term steady sex partner of an HCV-infected individual

HCV, hepatitis C virus.
From Centers for Disease Control and Prevention (CDC): Recommendations for prevention and control of hepatitis C virus (HCV) infection and HCV-related chronic disease. MMWR 1998;47(RR-19):1–33; and CDC: Sexually transmitted diseases treatment guidelines, 2006. MMWR 2006;55(RR-11):1–94.

transmission is approximately 0% to 3%.[80,93] In a recent study of over 500 HCV-infected women, the vertical transmission rate was 7.1% (95% confidence interval [CI] 6.3%–7.9%) in those women with detectable HCV RNA and 0% in those women who were HCV RNA–negative.[80] In contrast to HIV, the critical titer predictive of perinatal transmission remains unknown.

Women coinfected with HCV and HIV have consistently higher rates of perinatal transmission than women infected with HCV alone. Recent series have demonstrated that the risk may be lower that previously reported, ranging from 5.4% to 13.6% [80,88,94] The interaction between maternal and fetal humoral and immunologic factors is thought to be a critical contributor to both the occurrence and the persistence of perinatally acquired neonatal HCV infection. The fact that maternal or neonatal co-infection with HIV increases the risk of vertical HCV infection suggests that HIV-infected infants, who are known to have early deficits in cell-mediated and humoral immunity, may be less able to clear small amounts of perinatally presented HCV than HIV-uninfected infants.[95,96] Although no large-scale longitudinal follow-up studies exist into the natural history of perinatal HCV infection through childhood, at least one published case report has documented clearance of neonatally documented HCV RNA by 24 months of age in a child born to an HIV-negative, HCV RNA–positive mother.[72] Therefore, an intact neonatal immune system may allow for HCV clearance in early infancy, as can occur in HIV-uninfected adults.

Management Options

Similar to HBV, invasive monitoring during labor should be avoided if possible in HCV-infected women. Internal fetal heart rate monitoring is associated with a 6.7-fold (95% CI 1.1–35.9) increased risk of transmission.[79] Optimal route of delivery, in the context of maternal HCV infection, has been an area of controversy. This debate, to some degree, parallels the one that evolved regarding maternal HIV infection. However, unlike with HCV infection, maternal HIV viral load was a clearly established independent predictor of vertical transmission[97] and had a direct bearing on the current guidelines regarding route of delivery and maternal HIV infection, specifically when maternal HIV viral load is durably suppressed to greater than 1000 RNA copies/mL.[98] Several studies indicate that route of delivery is much less clearly associated with an increased risk of HCV transmission.[68,80,89] Current consensus opinions, therefore, recommend cesarean delivery in HCV-infected women only for usual obstetric indications.[20,80]

The experience with antiretroviral treatment in decreasing both maternal viral load and the risk of neonatal HIV infections raises the question of potential comparable treatment options in the context of maternal HCV infection. Currently, there is no safe treatment for chronic HCV infection during pregnancy. The standard combination therapy for nonpregnant adults consists of weekly injections with pegylated IFN-α and daily ribavirin.[99] Ribavirin is contraindicated during pregnancy and in male partners of pregnant women due to potential teratogenic effects.[73,100,101]

Finally, questions surrounding the safety of breast-feeding frequently arise from HCV-infected women. Many of these women have other risk factors, such as ongoing substance addiction or coexisting HIV infection, which preclude breast-feeding in general and override concerns about transmission of HCV through breast milk. For those women who have no other obstetric or medical issues that prevent nursing, data have failed to demonstrate breast milk as an effective route for HCV transmission. Although most of these studies were not designed to specifically address this topic, the authors' evaluation of mother-infant pairs enrolled in some of the published vertical HCV transmission studies failed to document any neonatal HCV infection in breast-fed infants, even when the mother was HCV RNA–positive. One study from China that did look at breast milk specifically found a correlation between maternal HCV serum titer and detection of HCV by means of polymerase chain reaction (PCR) in breast milk; however, no infants in this small series (n = 15) became infected with HCV.[102] Additional studies from Australia,[103] United Arab Emirates,[104] and Switzerland[105] examined 100 pregnancies in HCV-infected women who breast-fed (up to two thirds of whom were HCV RNA–positive in sera), with no detectable impact of breast-feeding on the risk of neonatal infection. As a result of the available supporting data, consensus opinions do not view maternal HCV infection as a contraindication to breast-feeding except, perhaps, in cases in which a mother experiences cracked or bleeding nipples.[20,77,106]

A survey study, in fact, did demonstrate that that the majority of community-based obstetricians are questioning patients about issues that could relate to HCV infection risk. However, the authors showed that HCV screening practices and counseling provided were discrepant with CDC recommendations up to 53% of the time, particularly in the area of counseling against breast-feeding in the face of maternal HCV infection.[107]

D. HEATHER WATTS

INTRODUCTION

The management of HIV infection continues to evolve rapidly. Amazing advances have been made in therapy of primary infection, prevention of opportunistic infections, and prevention of perinatal transmission since the first cases of AIDS were described in 1981. Perinatal transmission rates have decreased from 20% to 30% early in the epidemic to 1% to 2% in developed countries with the use of antiretroviral therapy and scheduled cesarean delivery. While reducing transmission, these interventions have increased the complexity of prenatal care for HIV-infected women. As standards of care evolve rapidly, providers are urged to access resources available on the Internet such as www.aidsinfo.nih.gov or www.WHO.int/hiv/topics/arv/ for the most recent update.

Women represent the fastest growing group of persons with new HIV infections. In the United States, over 130,000 women are estimated to be infected, and worldwide, the number is over 15 million.[1,2] Approximately 6000 HIV-infected women deliver annually in the United States, with approximately 144 to 236 infants acquiring HIV infection compared with 2 million deliveries to HIV-infected women worldwide resulting in over 600,000 HIV-infected infants.[2,3] Improvements in availability of prenatal care, HIV counseling and testing, antiretroviral therapy, and strategies to reduce HIV transmission through breast-feeding are vitally needed in areas of the world most affected by HIV to improve maternal health and survival and reduce perinatal transmission.[4] This chapter focuses on interventions currently available to maximize maternal health and minimize perinatal transmission in resource-rich countries.

DIAGNOSIS

All pregnant women should be tested for HIV infection to allow optimal care for maternal health and prevention of perinatal transmission. A policy of universal HIV testing, with patient notification and right of refusal, is recommended.[5] All pregnant women should be encouraged to be tested regardless of perceived risk factors or local seroprevalence, because many HIV-infected women were infected heterosexually and are unaware of their risk. If women decline testing, the reasons for declining should be explored and further education provided regarding the benefits and risks of testing. Federal policy recommends universal HIV testing along with other prenatal laboratory studies unless the woman refuses testing, but state laws may require detailed pretest counseling and written informed consent. Providers should be aware of their own local and state requirements while striving for universal testing for pregnant women.

HIV testing should be repeated in the third trimester for all women in high-prevalence areas (HIV incidence >17/100,000[5]) and for those with ongoing risk factors in pregnancy including injection drug use, an HIV-infected partner, or new or multiple partners during pregnancy.[5] In addition, pregnant women with symptoms suggestive of acute HIV infection, such as fever, rash, sore throat, and myalgias, should undergo both antibody testing and HIV RNA testing to diagnose infection as early as possible.

The recommended algorithm for HIV testing consists of initial screening with a U.S. Food and Drug Administration (FDA)–licensed enzyme immunoassay (EIA) or rapid test followed by confirmatory testing with an FDA-licensed supplemental test, usually a Western blot (WB), if the initial test is repeatedly reactive.[6] If the EIA is repeatedly reactive and the WB is positive, HIV infection is confirmed, because false-positive WB results are rare.[7] However, given the implications of a positive HIV test result, repeat testing on a separate blood sample is recommended to rule out any possibility of mislabeling or other clerical error. A more common, though still infrequent, event is an indeterminate WB. Indeterminate WB results can be caused by incomplete antibody response seen with recent HIV infection or late-stage disease or by nonspecific reactions in uninfected persons, possibly related to recent immunizations or current or previous pregnancy. Although indeterminate results are more common among pregnant or parous women, they are estimated to occur during pregnancy at a rate of fewer than 1 per 4000 samples based on a study of over 1 million specimens.[8,9] Pregnant women with indeterminate WB results should be queried regarding potential recent exposures to HIV through occupational, sexual, or needle-sharing activity; have repeat testing to evaluate for evolving infection versus resolution of nonspecific reactivity; and consider testing of sexual partners to clarify risk. For women with repeatedly indeterminate testing, alternate testing for HIV itself using an approved HIV RNA test may be helpful,

*This chapter is in the public domain.

although these tests are not approved for diagnosis of HIV infection. If no recent high-risk exposures are identified, women with repeatedly indeterminate WB results should be reassured that HIV infection is unlikely.

Women delivering with no prenatal care represent a group at high risk for perinatal HIV transmission. During the period 1993 to 1996, approximately 15% of HIV-infected pregnant women in the United States received no prenatal care, compared with 2% in the general population.[10] Given the reduction in transmission achieved with several different intrapartum/neonatal prophylaxis regimens[11–14] and the increased risk of HIV infection among women presenting without prenatal care, rapid HIV testing should be offered to all pregnant women presenting in labor without prenatal care or documentation of previous testing during pregnancy.[5] Testing should be done only after pretest counseling, including discussion of the need for confirmatory testing if rapid assays are positive, and informed consent. Rapid testing may be done using approved rapid tests or EIA testing.[15] Because of the relatively low prevalence of HIV even in this setting, the negative predictive value of a single negative rapid test is high, so no further testing is required to confirm a negative rapid test.[15] All positive rapid tests should be confirmed by supplemental testing with either a WB or an immunofluorescence assay but decisions regarding use of antiretrovirals for prevention of perinatal transmission may need to be made pending confirmatory test results because initiation of therapy during labor or shortly after birth is required to reduce risk of transmission.[15]

MATERNAL AND FETAL RISKS

Disease Progression

Studies in the United States and Europe have been consistent in not demonstrating an effect of pregnancy on HIV disease progression.[16–18] More recently, a report from the Women and Infants Transmission Study (WITS) did not show a difference in CD4+ lymphocyte count or HIV RNA trajectory or clinical AIDS rate between women with one or multiple pregnancies after HIV diagnosis.[19] Studies in developing countries suggest that pregnancy may enhance disease progression, but they included small numbers and might have had selection bias in HIV testing.[20,21]

Increased Toxicity of Antiretroviral Therapy

The hormonal effects of pregnancy may increase the risk of toxicity of antiretroviral therapy, especially the nucleoside reverse transcriptase inhibitors. Several cases of lactic acidosis and hepatic failure, some resulting in maternal deaths, have been reported among women on long-term nucleoside therapy during pregnancy, most frequently stavudine and didanosine in combination.[22,23] Clinical findings were similar to those seen in acute fatty liver of pregnancy, which occurs more frequently among women with heterozygous defects of mitochondrial fatty acid metabolism carrying fetuses homozygous for the defect.[24] Similar enhancement of mitochondrial toxicity due to reduced fatty acid oxidation has been shown in pregnant mice and in mice treated with high doses of estrogen and progesterone to simulate pregnancy.[25,26] The potential for lactic acidosis and hepatic

failure is present with the use of any nucleoside agent, with the binding affinity for mitochondrial polymerase gamma, the key enzyme, highest for zalcitabine, then decreasing for didanosine, stavudine, lamivudine, zidovudine, and abacavir.[27] Thus, all pregnant women on nucleoside antiretroviral therapy should be educated regarding the signs and symptoms of lactic acidosis and hepatic dysfunction including nausea, vomiting, fatigue, tachycardia, dyspnea or hyperventilation, and abdominal pain, and clinicians should be vigilant for these signs and symptoms that might be difficult to distinguish from normal pregnancy symptoms.

Impact on Future Therapy

Current indications for initiation of antiretroviral therapy in nonpregnant adults are a CD4+ lymphocyte count below 500 cells/μL or opportunistic infections.[28] Many pregnant women do not meet these criteria for therapy but will take antiretrovirals to reduce the risk of perinatal transmission and stop therapy after delivery. As discussed in more detail later, these women should receive highly active therapy with a combination of three or more drugs to minimize HIV RNA levels and risk of transmission.[29] Although aggressive combination therapy with suppression of HIV RNA to undetectable levels during pregnancy should minimize the risk of resistance, the impact of short-term highly active antiretroviral therapy on future response to therapy and maternal health has not been well studied. Although studies following women postpartum after zidovudine monotherapy and dual nucleoside therapy in pregnancy have not suggested an increased risk of disease progression with stopping therapy,[30,31] studies of structured treatment interruption have raised concern about stopping highly active antiretroviral therapy (HAART) once initiated.[32] However, most subjects in treatment interruption studies had lower nadir CD4+ cell counts, longer duration of antiretroviral therapy, and older age than the pregnant women using HAART during pregnancy for interruption of transmission, making extrapolation of results difficult. More research is needed on the risks of stopping or continuing HAART after use in pregnancy among women with higher CD4+ lymphocyte counts.

Pregnancy Complications

The effect of HIV infection and antiretroviral therapy on pregnancy outcome is another issue for consideration. The majority of studies in developed countries done before the availability of antiretroviral therapy did not demonstrate an increased rate of adverse pregnancy outcomes such as preterm birth and stillbirth among HIV-infected women compared with uninfected women with similar risk profiles.[33–35] Conversely, most studies in developing countries have suggested an increased risk of preterm birth, low birth weight, intrauterine growth restriction, stillbirth, and infant death among infants born to HIV-infected women, with increasing risk with more advanced HIV infection.[33,36] Factors associated with an increased risk of preterm birth and low birth weight among HIV-infected women included previous adverse pregnancy outcome, hypertension, multiple gestation, smoking, bleeding, alcohol use, low maternal weight, *Trichomonas vaginalis* infection, and other sexually transmitted infections, similar to risk factors in

HIV-uninfected women.[35,37,38] Low CD4+ percentage was an additional risk factor for adverse outcome among women not receiving antiretroviral therapy,[37] but neither CD4+ lymphocyte count nor HIV RNA levels were associated with adverse outcomes among women receiving zidovudine therapy.[38]

Zidovudine monotherapy has not been associated with an increased risk of preterm birth or low birth weight in any study to date, but the potential impact of combination antiretroviral therapy on pregnancy outcome is less clear.[39,40] In the early HAART era, a small study from Europe[41] and an analysis of the European Collaborative Study[42] found an increased risk of preterm birth with increasing numbers of drugs, with the highest rate occurring among women receiving protease inhibitor (PI) therapy. A combined analysis of several cohorts in the United States did not find an increased risk of preterm delivery among women on dual therapy or regimens including PIs, although there was a slight increase in risk of very low–birth weight infants born to women receiving PI therapy compared with those on no therapy or zidovudine.[43] A meta-analysis published in 2007 incorporating 14 studies found no increase in risk of preterm birth with antiretroviral therapy compared with no therapy.[44] HAART regimens including PIs did not increase the risk of preterm birth compared with the no therapy group, but were associated with an increased risk compared with combination regimens without PIs (odds ratio [OR] 1.35; 95% confidence interval [CI] 1.08–1.70).[44] Among the subset starting any HAART before pregnancy or in the first trimester, the risk of preterm birth was increased compared with those starting HAART later in pregnancy (OR 1.71; 95% CI 1.09–2.67).[44] Subsequent studies have found an increased risk of preterm birth with HAART, in some cases specifically with PI therapy. A large, population-based study from the United Kingdom and Ireland found an adjusted odds ration (AOR) of 1.51 (95% CI 1.19–1.93) for preterm birth with HAART compared with mono- or dual therapy, regardless of whether a PI was included in the HAART.[45] A Brazilian study found in increased rate of preterm birth (AOR 5.0; 95% CI 1.5–17.0) with HAART started preconception compared with therapy started later in pregnancy.[46] Recent studies from the United States, Germany/Austria, and Italy have found increased risks of preterm delivery with PI-based HAART in pregnancy, with AORs ranging from 1.21 to 3.40.[47–49] Clinicians should be aware of a possible increased risk of preterm birth with PI use, but given the clear benefits for maternal health and reduction in perinatal transmission, these agents should not be withheld because of these concerns.

Perinatal Transmission

A major concern with HIV infection in pregnancy is the risk of perinatal transmission of HIV to the infant. Among untreated women who do not breast-feed, transmission will occur in 20% to 30%.[50] Estimates are that about two thirds of transmissions from untreated women occur at delivery and one third occur in utero, many late in pregnancy.[51] An additional transmission risk of 15% to 20% occurs during breast-feeding.[52] Maternal HIV RNA levels appear to be the factor most predictive of transmission.[53,54] Antiretroviral therapy during pregnancy and in the neonatal period clearly reduces the risk of perinatal transmission of HIV. The first study demonstrating this benefit was the Pediatric AIDS Clinical Trials Group (PACTG) 076 study[39] with a transmission rate of 8.3% among those receiving oral antepartum, intravenous intrapartum, and oral neonatal zidovudine for 6 weeks compared with 25.5% among those receiving placebo. The PACTG 185 trial[55] found no benefit from addition of HIV immunoglobulin to the PACTG 076 regimen but demonstrated benefit of zidovudine among women with CD4+ lymphocyte counts under 500 cells/μL at enrollment, with a transmission rate of 4.6%. Subsequent trials have demonstrated benefit from shorter courses of antepartum/intrapartum or antepartum/intrapartum/neonatal zidovudine or zidovudine/lamivudine compared with placebo, but no benefit was seen from intrapartum zidovudine/lamivudine alone.[14,56–61] In addition, the HIVNET 012 trial[11] demonstrated the benefit of a two-dose nevirapine regimen (one dose intrapartum to the mother and one dose to the infant at 48 hr of age) compared with oral intrapartum and 1 week of neonatal zidovudine. A subsequent trial demonstrated that intrapartum and 1 week of neonatal zidovudine/lamivudine therapy was similar in efficacy to the HIVNET 012 nevirapine regimen.[14] These trials provide data for implementation of shorter, less complex regimens for reduction of transmission of HIV in resource-limited settings or for women diagnosed in the peripartum period as being HIV-infected.

A trial in the United States, Europe, and Latin America (PACTG 316) evaluating addition of the HIVNET 012 nevirapine regimen to established antiretroviral therapy demonstrated no benefit of adding nevirapine to ongoing therapy.[62] However, this trial provides updated data regarding transmission of HIV with the use of combination antiretroviral therapy. The transmission rate overall was 1.5%, with rates of 2.1% for women on zidovudine alone, 1.1% with combination nucleoside therapy, and 1.6% with combination with PI.[62] Similarly, an analysis from WITS, including women enrolled from 1990 through 2000, observed transmission rates of 20.0% for women not receiving antiretroviral agents, 10.4% for women receiving zidovudine monotherapy (not necessarily the complete 076 regimen), 3.8% for those receiving dual nucleoside therapy, and 1.2% for those receiving highly active antiretroviral regimens.[50] These low rates of transmission with highly active regimens occurred despite potential confounding by indication in which women with the highest HIV RNA levels and lowest CD4+ lymphocyte counts were most likely to be treated with highly active regimens, especially early in the period of availability. More recent data from a study of HIV transmission among women delivering in the United Kingdom and Ireland from 2000 to 2006, transmission occurred in 0.7% of 2845 women on HAART, regardless of mode of delivery.[63] Thus, current data demonstrate significant fetal benefit from combination antiretroviral regimens, which would require significant evidence of harm to negate.

Antiretroviral Therapy

Teratogenesis

Another concern with the use of antiretroviral drugs in pregnancy is the potential for birth defects, especially with first-trimester exposure. Limited data from animal studies are available for most of the drugs (Table 28–1). Of concern,

TABLE 28–1

Preclinical and Clinical Data Relevant to the Use of Antiretrovirals in Pregnancy

DRUG	FDA PREG CAT	NEWBORN:MATERNAL DRUG RATIO	ANIMAL STUDIES	MAJOR TOXICITIES	HUMAN STUDIES; CONCERNS SPECIFIC TO PREGNANCY
Nucleoside/Nucleotide Reverse Transcriptase Inhibitors				**Class effect: Rare, but potentially fatal, lactic acidosis with hepatic steatosis.**	
Zidovudine (Retrovir, AZT, ZVD)	C	~0.8 human	No effect on rodent fertility, but cytotoxic to mouse embryos. Positive teratogenicity in rodents only at near-lethal doses.	Bone marrow suppression, myopathy	ARV agent most used in pregnancy, safe in short term. See discussion of rodent tumors, mitochondrial toxicity in text.
Emtricitabine (Emtriva, FTC)	B	0.4–0.5 mice, rabbits	Negative teratogenicity studies in mice and rabbits.	Hyperpigmentation of palms/soles. Possible hepatitis B flare when stopping.	Pk study shows slightly lower levels in third trimester compared with postpartum but no clear need to increase dose. Alternate NRTI for use in pregnancy.
Didanosine (Videx, ddI)	B	0.5 human	No effect on rodent fertility or mouse embryos. No teratogenicity in mice, rats, rabbits.	Pancreatitis, peripheral neuropathy, nausea, diarrhea	Pk study (n = 14) shows no need for dose modification, well-tolerated. Alternate NRTI for use in pregnancy. Do not use with d4T in pregnancy because of enhanced toxicity.
Stavudine (Zerit, d4T)	C	0.76 rhesus monkey	No effect on rodent fertility, but cytotoxic to mouse embryos. No evidence of teratogenicity. Ossification delay at high doses in rats.	Peripheral neuropathy	Phase I/II study indicated no change in pk in pregnancy; well-tolerated. Do not use with ddI in pregnancy because of enhanced toxicity. Antagonizes ZDV, do not use together.
Lamivudine (Epivir, 3TC)	C	~1.0 human	No effect on rodent fertility or mouse embryos. No teratogenicity.	Pancreatitis increased in children. Possible hepatitis B flare when stopping.	Pk study (n = 20) shows no need for dose modification, well-tolerated. Preferred NRTI in pregnancy based on experience with use.
Abacavir (Ziagen, ABC)	C	Passage in rats	No effect on fertility in rodents. Anasarca, skeletal abnormalities at 35 times human dose in rodents, not seen in rabbits.	Potentially fatal hypersensitivity reactions, symptoms: fever, rash, fatigue, nausea, vomiting, diarrhea, abdominal pain in 2%–9%.	No change in pk in pregnancy. Alternate NRTI for use in pregnancy. Screen for HLA-B*5701 before use to reduce risk of hypersensitivity reaction.
Tenofovir (Viread)	B	0.6–1.0 human	No effect on fertility. No birth defects, but growth restriction, reversible bone changes with chronic use in monkeys.	Asthenia, nausea, vomiting, diarrhea, headache, flatulence. Possible hepatitis B flare when stopping.	Limited data in human pregnancy thus far. Use only after careful consideration of alternatives.
Non-nucleoside Reverse Transcriptase Inhibitors				**Class effects: rash with rare cases of Stevens-Johnson syndrome; increased transaminase levels.**	
Nevirapine (Viramune)	C	~0.9 human	Impaired fertility in female rats. Not teratogenic in rats, rabbits.	Rash, drug interactions, potential for fulminant hepatitis and hepatic failure, especially among women with CD4 counts >250 cells/mL at initiation.	No change in pk in pregnancy. Not recommended for women initiating therapy with CD4 count >250 cells/mL due to increased risk of potentially fatal liver toxicity. Single dose at delivery not associated with increased risk. See text for use of NRTI "tail" after single dose in labor.
Delavirdine (Rescriptor)	C	Unknown	No effect on fertility in rodents. Embryotoxic in rabbits. VSD in rats, maternal toxicity, developmental delay, decreased pup survival.	Rash, drug interactions.	No studies. Not recommended for use in pregnancy.
Efavirenz (Sustiva)	D	0.13 human	Increased fetal resorptions in rats. Defects (anencephaly, anophthalmia, cleft palate) in 3/20 monkeys treated with human doses.	Rash, drug interactions, CNS symptoms such as dizziness, insomnia, confusion.	Avoid use in first trimester. May be considered for use later in pregnancy. Ensure adequate contraception postpartum.
Etrvirine (Intelence)	B	Unknown	Negative in rats, rabbits.	Rash, rare hypersensitivity reactions; drug interactions	No data on use in human pregnancy so not currently recommended.
Protease Inhibitors				**Class effects: Hyperglycemia, possible fat redistribution and lipid abnormalities, increased bleeding episodes in hemophiliacs.**	
Indinavir (Crixivan)	C	Minimal	No effect on fertility in rodents. No teratogenicity in rats, rabbits or dogs. Extra ribs in rats.	Kidney stones, hyperbilirubinemia, drug interactions, nausea.	Use with low-dose ritonavir boosting to assure adequate dosing in pregnancy. Alternate PI for use in pregnancy.

TABLE 28–1

Preclinical and Clinical Data Relevant to the Use of Antiretrovirals in Pregnancy—cont'd

DRUG	FDA PREG CAT	NEWBORN:MATERNAL DRUG RATIO	ANIMAL STUDIES	MAJOR TOXICITIES	HUMAN STUDIES; CONCERNS SPECIFIC TO PREGNANCY
Ritonavir (Norvir)	B	Minimal	No effect on fertility in rodents at half the human dose. Hepatotoxicity at higher doses. Developmental toxicity at toxic doses but no teratogenicity in rats, rabbits.	Nausea, vomiting, diarrhea; increased triglycerides, transaminases; drug interactions, paresthesias.	Use only at low doses to boost levels of other PIs in pregnancy.
Saquinavir hard gel capsules (Invirase)	B	Minimal	No effect on fertility in rodents. Negative teratogenicity.	Nausea, diarrhea, elevated transaminases.	Use with low-dose ritonavir boosting to ensure adequate dosing in pregnancy. Alternate PI for use in pregnancy.
Nelfinavir (Viracept)	B	Minimal	No effect on fertility in rodents. Studies negative in rats, rabbits.	Diarrhea, drug interactions	Extensive experience in pregnancy but not recommended for treatment in nonpregnant adults. May be used as part of triple-agent regimen for pregnant women receiving HAART for prophylaxis rather than therapy.
Fosamprenavir (Lexiava)	C	Unknown	No effect on fertility in rodents. Negative teratogenicity studies.	Nausea, vomiting, diarrhea, rash, oral paresthesias, increased liver function tests. Drug interactions.	No studies in human pregnancy, not recommended.
Lopinavir/ ritonavir (Kaletra)	C	0.20 human	No effects on fertility. No teratogenicity in rats, rabbits.	Nausea, vomiting, diarrhea, asthenia, elevated transaminase levels.	Preferred PI in pregnancy based on experience. Pk studies of new tablet under way; increased dosing in third trimester required with capsule. Monitor virologic response in third trimester with standard dosing. Once-daily dosing not recommended in pregnancy.
Atazanavir (Reyataz®-)	B	Minimal (<10%)/ variable in humans.	No effect on fertility. No teratogenicity in rats, rabbits.	Drug interactions, prolonged PR interval, hyperbilirubinemia, rash.	Limited experience in human pregnancy. Theoretical concern of hyperbilirubinemia in neonate from maternal exposure. May be considered as alternate PI.
Darunavir	C	Unknown	Negative teratogenicity studies; decreased pup weight after prenatal exposure.	Headache, nausea, diarrhea, hypertriglyceridemia, nasopharyngitis, drug interactions.	No studies in human pregnancy, not recommended.
Entry Inhibitors					
Enfurvitide (Fuzeon, T-20)	B	None based on limited human data	No effect on fertility. No teratogenicity in rats, rabbits.	Injection site reactions, eosinophilia, rare systemic hypersensitivity	No studies in human pregnancy. Consider use only as salvage therapy.
Maraviroc (Selzentry)	B	Unknown	Negative teratogenicity studies in rats, rabbits.	Hepatoxicity, allergic rash, increased upper respiratory infections, possibly other infections, dizziness, drug interactions.	No experience in human pregnancy, not recommended.
Integrase Inhibitors					
Raltegravir (Isentress)	C	2.0 in rats, 0.02 in rabbits	Negative in rabbits, supernumerary ribs in rats.	Creatine kinase elevations, possible myopathy.	No experience in human pregnancy. Consider use only as salvage therapy.

FDA preg cat, U.S. Food and Drug Administration pregnancy category: A, adequate and well-controlled studies of pregnant women fail to demonstrate a risk to the fetus during the first trimester of pregnancy (and there is no evidence of risk during the later trimesters); B, animal reproduction studies fail to demonstrate a risk to the fetus, and adequate and well-controlled studies of pregnant women have not been conducted; C, safety in human pregnancy has not been determined, animal studies are either positive for fetal risk or have not been conducted, and the drug should not be used unless the potential benefit outweighs the potential risk to the fetus; D, positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experiences, but the potential benefits from the use of the drug in pregnant women may be acceptable despite its potential risks; X, studies in animals or reports of adverse reactions have indicated that the risk associated with the use of the drug for pregnant women clearly outweighs any possible benefit.

ABC, abacavir; ARV, antiretroviral; AZT, azidothymidine; CNS, central nervous system; ddI, dideoxyinosine; d4T, stavudine; FTC, emtricitabine; HAART, highly active antiretroviral therapy; HLA, human leukocyte antigen; NRTI, nucleoside/nucleotide reverse transcriptase inhibitor; PI, protease inhibitor; pk, pharmacokinetic; 3TC, lamivudine; VSD, ventricular septal defect; ZVD, zidovudine.

From Panel on Antiretroviral Guidelines for Adults and Adolescents: Guidelines for the Use of Antiretroviral Agents in HIV-1-infected Adults and Adolescents. Washington, DC, Department of Health and Human Services. December 1, 2009, pp 1–144. Available at http://www.aidsinfo.nih.gov/ContentFiles/Adultand-AdolescentGL.pdf (accessed March 25, 2010); and Public Health Service Task Force Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1–infected Women for Maternal Health and Interventions to Reduce Perinatal HIV-1–Transmission in the United States. April 29, 2009. Available at http://aidsinfo.nih.gov/guidelines/ (accessed March 25, 2010).

birth defects, including anencephaly, anophthalmia, micro-ophthalmia, and cleft palate, were seen in 3 (20%) of 15 monkeys exposed to efavirenz in the first trimester.[29] Several cases of meningomyelocele after first-trimester efavirenz exposure have been reported retrospectively to the Antiretroviral Pregnancy Registry (APR), an important source for data on birth defects among infants born to antiretroviral-exposed pregnant women.[64] Among prospective cases with first-trimester efavirenz exposure reported to the APR, defects have occurred among 13 (3.2%) of 407 live births, not different from the overall rate of 2.7% among all prospective cases reported to APR or the rate of 2.9% among all prospective cases with first-trimester exposure to antiretroviral agents.[64] Of note, however, the defects after first-trimester efavirenz exposure include one case of sacral meningomyelocele with hydrocephalus and one case of bilateral facial clefts, anophthalmia, and amniotic band, indicating that further surveillance is required. Based on animal data and concerning case reports, favirenz use should be avoided during the first trimester of pregnancy, and women of reproductive potential on efavirenz should be counseled regarding potential risks and provided with effective contraception. No increase in birth defects associated with first-trimester antiretroviral therapy has been noted among prospective cases reported to the APR, with adequate numbers to rule out a twofold or greater increased risk of overall birth defects reported for the following drugs: zidovudine, lamivudine, stavudine, nelfinavir, nevirapine, abacavir, efavirenz, didanosine, ritonavir, lopinavir, tenofovir, indinavir, emtricitabine, and atzanavir.[64] Providers caring for pregnant women receiving antiretroviral drugs are urged to report cases as early in pregnancy as possible to the Registry (1–800–258–4263 or http://www.apregistry.com) to allow better assessment of risks.

Additional data are available from prospective cohorts, some of which overlap with cases reported to the APR. A report from the WITS found no increase in birth defects after first-trimester exposure to antiretrovirals compared with later exposure or no exposure, but did find a marginally significant increase in risk of hypospadias in male infants after first-trimester zidovudine exposure.[65] An analysis of data from the European Collaborative Study,[66] including women and infants enrolled between 1986 and 2003, did not find an increase in birth defects with first-trimester antiretroviral exposure compared with later or no exposure, and there was no discernible pattern of defects related to type or timing of therapy. Likewise, an analysis of births in the United Kingdom and Ireland to HIV-infected women between 1990 and 2007 did not find an increased risk of birth defects related to timing or class of antiretroviral exposure in pregnancy.[67] Thus, with the exception of animal data and case reports for efavirenz, data are reassuring so far that use of antiretrovirals in pregnancy does not increase the risk of birth defects overall. Continued vigilance is indicated, though, as new drugs become available and expanded access leads to treatment of more pregnant women.

Mitochondrial Toxicity in Offspring

Another concern, potential mitochondrial toxicity in the children of women treated with antiretrovirals, was first raised by French researchers. Eight children with clinical or laboratory abnormalities, including two who died, were reported from a cohort of 1754 HIV-uninfected children exposed to zidovudine or zidovudine/lamivudine during pregnancy and the neonatal period.[68,69] Findings were consistent with mitochondrial pathology seen in HIV-infected adults on nucleoside analogue therapy and in animal studies and have since been confirmed in other cohorts.[70,71] Two different syndromes of mitochondrial dysfunction have been described in infants after perinatal antiretroviral exposure.[72] The first is hyperlactatemia, usually asymptomatic, occurring in up to one third of antiretroviral-exposed newborns and reversible with cessation of therapy. The long-term impact of this transient hyperlactatemia is unknown. The second includes severe neurologic symptoms manifesting in the first 2 years of life and associated with biochemical and ultrastructural changes characteristic of mitochondrial dysfunction. This severe manifestation has been seen at a rate of 0.3% or less, depending on the cohort and the intensity of surveillance.[72] The risk of clinically apparent mitochondrial toxicity related to antiretroviral therapy is low and must be balanced against the known benefits in reduction of perinatal transmission. However, long-term follow-up of children exposed to antiretrovirals is required to assess for toxicity.

Transplacental Carcinogenesis

Another concern requiring long-term surveillance of children exposed to antiretrovirals is transplacental carcinogenesis. One study in rats treated with zidovudine in utero at about 30 times the human dose found an increase in liver, lung, and reproductive system tumors, yet a similar study using lower doses did not find an increased rate[73,74] No cancers were seen in a follow-up study of PACTG 076 and WITS, including 727 children or among 1859 antiretroviral-exposed but uninfected children in PACTG 219/219C.[75,76] A study of HIV-infected children with malignancies did not identify zidovudine exposure, either in utero or after birth, as a risk factor for developing cancer.[77] A study linking HIV, cancer, and death registries in England and Wales found no cases of cancer among 2612 HIV-exposed children born between 2001 and 2004.[78] Therefore, human data thus far do not support zidovudine use as a risk factor for carcinogenesis, but long-term follow-up of exposed children is required.

MANAGEMENT OPTIONS

Prepregnancy

Ideally, all HIV-infected women would have a preconceptional visit to optimize their status before pregnancy.[29] Issues to be discussed include current maternal status and indications for antiretroviral therapy and opportunistic infection prophylaxis, choice of antiretroviral drugs to minimize risk of birth defects and toxicity, risk of perinatal transmission and strategies to reduce transmission, immunization status, optimal nutritional status and use of folate supplements, and assessment of other preconceptional issues such as family history pertinent to genetic screening, screening for other infectious diseases, and assessment for other medical or psychological conditions. The risk of perinatal transmission is most strongly related to HIV RNA levels, with the lowest transmission risk associated with undetectable HIV RNA.[53,54]

For women planning pregnancy or currently on antiretroviral therapy or with indications for antiretrovirals based on current guidelines (CD4+ lymphocyte count <500 cells/μL), a highly active regimen that does not include efavirenz should be used. Pregnancy should be delayed until HIV RNA levels are undetectable, if possible. For women not meeting criteria for therapy for their own health, initiation of therapy to prevent transmission after the first trimester should be discussed. Need for opportunistic infection prophylaxis should be assessed.[79] Ideally, if CD4+ lymphocyte counts are in the range at which opportunistic infection prophylaxis is indicated, highly active antiretroviral therapy should be initiated to enhance immunity and obviate the need for prophylaxis during pregnancy. Pregnancy should be delayed until sustained CD4+ lymphocyte counts over 200 cells/μL are achieved to minimize the number of drugs needed during pregnancy. Any indicated immunizations should be provided before pregnancy to avoid the theoretical risk of increased transmission risk related to HIV RNA rebound after immunization. If the HIV-infected woman has not previously been tested for antibodies to *Toxoplasma gondii*, hepatitis C virus, or cytomegalovirus, antibody status should be documented at the preconceptional visit to establish risk for seroconversion or reactivation. Tuberculin skin testing should be done if not done within the past year. The range of transmission risks based on maternal HIV RNA levels and antiretroviral therapy should be discussed, and the woman must understand that, although the risk is now low, there is no guarantee that transmission will not occur. If the HIV-infected woman's sexual partner is HIV-uninfected, there should be discussion of methods to avoid unprotected intercourse including the use of male condoms and alternate methods for conception, such as artificial insemination.

Prenatal

The same principles as outlined for preconceptional care should be followed for HIV-infected women presenting already pregnant. Women newly diagnosed with HIV infection during pregnancy should be assessed for any signs or symptoms suggestive of acute HIV infection or opportunistic infection and undergo laboratory testing (HIV RNA and CD4+ lymphocyte testing) to establish the stage of HIV infection. HIV infection should be confirmed by repeat testing if not previously done. In general, highly active combination antiretroviral therapy is indicated during pregnancy to prevent perinatal transmission and may also be indicated for maternal health.[29] A regimen recommended as first-line or alternate therapy for nonpregnant adults, generally including two nucleoside reverse transcriptase inhibitors with either one or more PIs or a non-nucleoside reverse transcriptase inhibitor, should be chosen.[28] However, nevirapine should not be initiated in women with CD4+ lymphocyte counts over 250 cells/μL because the risk of potentially fatal hepatotoxicity is greatly increased in this group compared with women with lower CD4+ lymphocyte counts.[29] Highly active antiretroviral therapy is indicated to lower HIV RNA levels to undetectable levels to minimize transmission risk and also to minimize the risk of development of resistant virus. Extensive discussions with the woman should emphasize the importance of complete adherence to the regimen to prevent development of

resistance. Unless contraindicated or not tolerated, the regimen should include zidovudine, which has the most data on efficacy in reducing transmission. Intravenous zidovudine should be given during labor, and the infant should receive zidovudine for 6 weeks after birth. For women with HIV RNA levels below 1000 copies/mL off antiretroviral therapy who want to minimize their exposure to antiretrovirals, monotherapy with the PACTG 076 zidovudine regimen can be offered. In an analysis of data from several studies, transmission among women with HIV RNA levels below 1000 copies/mL during pregnancy was 9.8% among 368 untreated women and 1% among 834 women receiving zidovudine.[80] Zidovudine monotherapy during pregnancy was not associated with a difference in disease progression postpartum among women in several studies.[30,31,81] The risk of developing resistance to zidovudine among women with HIV RNA below 1000 copies/mL is expected to be low given limited viral replication. The option of stopping therapy after delivery should be discussed with women who initiate therapy solely for prevention of perinatal transmission.

Indications for resistance testing during pregnancy should be the same as for nonpregnant adults.[29] Technical aspects of resistance testing have been reviewed elsewhere.[82] The use of resistance testing to optimize therapy during pregnancy and to reduce the rate of perinatal transmission has not been studied specifically, but resistance testing in adults has been shown to be cost-effective in both treatment-naïve patients and those on failing antiretroviral regimens.[82] Pregnant women not on antiretroviral therapy should have genotypic resistance testing obtained before initiation of therapy unless results from previous testing with no intervening therapy are available.[82] Therapy may be started pending receipt of test results and modified if indicated. If the expected response of at least a one log drop in HIV RNA in the first 8 weeks is not obtained, specimens for resistance testing should be obtained while the woman is on therapy before switching to an alternate regimen. For women entering pregnancy already on therapy, resistance testing is indicated if persistently detectable HIV RNA levels are present despite adequate adherence to the regimen and adequate dosing or if HIV RNA levels become persistently detectable after a period of undetectable levels. The specimen for resistance testing should be drawn while still on the failing regimen to maximize detection of resistance. An HIV RNA level above 500 copies/mL is required for resistance testing. Pregnant women with virologic failure after multiple treatment regimens should have both genotypic and phenotypic resistance testing obtained and should be managed in consultation with an HIV expert.[82]

The majority of studies evaluating the impact of resistance on risk of perinatal transmission have not found the presence of zidovudine, lamivudine, or nevirapine resistance to increase the risk of transmission.[83] Given the currently observed rates of transmission of under 2% among women on highly active antiretroviral therapy during pregnancy, antiretroviral resistance does not appear to be a major issue in perinatal transmission. However, as the prevalence of resistant HIV increases among those with recent infection[82] and as women have repeat pregnancies, the chance of coexistent resistant HIV and pregnancy will increase and might become a larger problem. Resistance patterns among

pregnant women and among infected infants must be monitored to allow adaptation of treatment guidelines.

For women presenting during pregnancy already taking antiretroviral therapy, management will depend on gestational age, regimen, HIV levels before starting therapy and time to response, and current symptoms such as nausea that may interfere with adherence during pregnancy. Women presenting after the first trimester should continue on their current regimen as long as HIV RNA levels are below the level of detection. Women presenting early in the first trimester should be counseled regarding the potential teratogenic risks of antiretroviral exposure in the first trimester versus the competing risk of rebound in HIV RNA levels if therapy is stopped, with potential risk for perinatal transmission. Women on efavirenz-containing regimens should be switched to alternate regimens if they choose to continue therapy in the first trimester. In general, women on other regimens should be encouraged to continue therapy. If a woman chooses to discontinue therapy during the first trimester, she should stop and restart all agents concurrently to minimize the risk of development of resistance, unless a drug with a long half-life, such as nevirapine or efavirenz, is included in the regimen. These drugs should be stopped first and the additional drugs stopped in 7 to 10 days to minimize the potential for resistance.[29]

If not previously documented, antibody status for *T. gondii*, hepatitis C, and cytomegalovirus should be obtained. Tuberculin skin testing should be performed if not done within the past year. Prophylaxis and treatment of opportunistic infection in pregnant women is generally the same as for nonpregnant women.[79] Ideally, use of highly active antiretroviral therapy should optimize the immune status so that prophylaxis is not indicated. For more detailed information regarding prophylaxis of opportunistic infections in pregnancy, providers should consult current guidelines at http://aidsinfo.nih.gov/guidelines

HIV-infected pregnant women should receive counseling regarding issues of HIV and pregnancy and should be provided with psychosocial support during pregnancy and the postpartum period. Women can be reassured that pregnancy per se does not appear to have an impact on the progression of HIV infection. Women should be educated regarding signs and symptoms such as rash, nausea, vomiting, extreme fatigue, and muscle aches that may indicate toxicity related to antiretroviral drugs. The risks of perinatal transmission of HIV and the evaluation of the infant for infection should be discussed. The need for careful adherence to therapy to maximize response and minimize the development of resistance should be emphasized.

In addition to use of antiretroviral therapy to lower HIV RNA levels and reduce transmission, performance of cesarean delivery before the onset of labor and membrane rupture has been shown to reduce transmission among women on no antiretrovirals or on zidovudine.[84,85] In a meta-analysis of data from 15 cohorts, the AOR for transmission was 0.43 (95% CI 0.33–0.56) for those with cesarean delivery before labor or membrane rupture compared with those with other modes of delivery.[84] A similar benefit was seen among the subset receiving zidovudine. In a randomized trial of planned cesarean section compared with vaginal delivery, transmission occurred in 1.8% of infants assigned to planned cesarean group and 10.5% of 200 who delivered vaginally ($P <$

.001).[85] A similar magnitude in reduction of transmission was seen among the subset receiving zidovudine, although small numbers did not reach statistical significance. Given transmission rates of less than 2% among women receiving highly active antiretroviral therapy or with HIV RNA below 1000 copies/mL receiving zidovudine, it is difficult to assess for any additional benefit of planned cesarean delivery. In the most recent data, the rate of transmission among women on HAART was 0.7% among 2286 women with planned cesarean delivery and 0.7% among 559 women with planned vaginal delivery.[63] Currently, cesarean delivery before labor or membrane rupture is recommended for women with HIV RNA levels above 1000 copies/mL in the third trimester.[86] Women with HIV RNA levels below 1000 copies/mL should have the option of planned cesarean delivery discussed with them, along with the lack of clear data regarding benefit in this setting. All HIV-infected pregnant women should be informed of the increased risks, primarily infectious, associated with cesarean compared with vaginal delivery. Despite early case-control studies suggesting increased rates of morbidity among HIV-infected compared with uninfected women undergoing cesarean delivery, more recent cohort studies suggest that the increased risk is similar in magnitude to that observed in similar HIV-uninfected women.[29,87] Cesarean delivery may be scheduled at 38 weeks' gestation without amniocentesis, rather than the usually recommended 39 weeks, to minimize the risk of labor or membrane rupture, although this increases the risk of respiratory distress in the newborn.[88] To minimize risks of perioperative infection, genital infections such as bacterial vaginosis should be treated, and the use of antibiotic prophylaxis should be considered, although these interventions have not been specifically evaluated in HIV-infected women. Scheduled cesarean delivery also appears to confer a reduced risk of hepatitis C transmission to the infant among HIV-infected women with detectable hepatitis C viremia.[89]

HIV-infected women should undergo baseline testing of renal and hepatic function. The schedule of testing for drug toxicity will vary with drugs chosen. In general, visits for assessment for any new symptoms and laboratory testing should occur about every 2 to 4 weeks during the first 1 to 2 months of therapy. An optimal schedule of testing for early diagnosis of such complications as hepatic toxicity or lactic acidosis has not been established, but clinicians should consider evaluating hepatic function and electrolytes monthly in the third trimester and certainly in the presence of any new symptoms. Accurate blood lactate levels are difficult to obtain, and normal values in pregnancy have not been established. Routine testing of lactate levels is not recommended, but may be helpful during pregnancy if values are elevated above nonpregnant adult levels in the presence of suggestive symptoms. CD4+ lymphocyte counts should be done every 3 months during pregnancy. HIV RNA levels should be monitored as per guidelines in nonpregnant adults (i.e., every 4 wk after initiating or changing therapy until undetectable, then every 3 mo on stable therapy).[28] A drop of at least one log on HIV RNA levels should be seen after 4 to 8 weeks of therapy.

PI therapy has been associated with an increased risk of glucose intolerance and diabetes in nonpregnant adults.[90] Most studies in pregnancy have not found differences in gestational diabetes, glucose intolerance, and insulin

resistance among HIV-infected women on PIs compared with other regimens, although rates of glucose intolerance were high in both groups related to other risk factors such as obesity and ethnicity.[91,92] Clinicians may consider early 50-g glucose load testing in pregnant women on PI therapy with repeat testing at 24 to 28 weeks of gestation if earlier testing is normal.

Clinicians caring for HIV-infected pregnant women on methadone should be aware of potential drug interactions when initiating or changing therapy. Nevirapine, efavirenz, and PIs other than indinavir may decrease methadone levels and precipitate drug withdrawal so pregnant women should be monitored for symptoms in this setting.[28]

Counseling regarding options for prenatal diagnosis is complicated by HIV infection. Amniocentesis and other invasive procedures such as scalp electrode placement increased the risk of transmission by two- to fourfold in early studies among women not receiving antiretrovirals.[93,94] In more recent cohort studies among women receiving antiretroviral therapy, invasive testing has not been identified as a risk factor for transmission, but amniocentesis is uncommon and chorionic villus sampling is rare among HIV-infected women. Thus, specific risk figures are not available to use in counseling. Further complicating the discussion is the recent suggestion that median serum human chorionic gonadotropin and α-fetoprotein values may be higher among HIV-infected women and elevations may correlate with increasing disease severity, although more recent, larger studies have not found clinically relevant differences in levels.[95–97] If an invasive prenatal diagnostic procedure is planned for an HIV-infected woman, she should be on optimal antiretroviral therapy with an undetectable HIV RNA level beforehand to minimize the risk of transmission.

Labor and Delivery

Ideally, the decision regarding mode of delivery should be made after discussions throughout pregnancy, based on HIV RNA results obtained at 34 to 36 weeks' gestation. If the decision is made to attempt vaginal delivery, zidovudine infusion at a dose of 2 mg/kg of body weight over 1 hour, followed by a continuous infusion of 1 mg/kg/hr should be given until delivery.[39] Other antiretroviral drugs should be continued as scheduled during labor, except stavudine, which may antagonize zidovudine and should be discontinued when zidovudine infusion is begun. If the woman is unable to tolerate zidovudine, then stavudine may be continued during labor. During labor, artificial rupture of membranes should be avoided if possible, and labor should be augmented as needed to minimize the duration of ruptured membranes. Fetal scalp electrodes, scalp blood sampling, and instrumented delivery should be avoided to limit fetal exposure to maternal blood. Infants should be washed before undergoing blood draws, injections, or other procedures.

If cesarean delivery is planned, it should be scheduled at or after 38 weeks' gestation.[86] Infusion of intravenous zidovudine as described earlier should be begun at least 3 hours before surgery and continued until cord clamping. Other medications should be continued as scheduled. For women who had planned on a scheduled cesarean delivery presenting with ruptured membranes, management must be individualized based on HIV RNA levels, time since rupture, stage of labor, and patient preference. The benefit of cesarean delivery shortly after rupture of membranes or onset of labor is unclear. Among women not receiving antiretrovirals or receiving zidovudine monotherapy, transmission rates increase with increasing duration of rupture before delivery.[98,99] However, in most studies, transmission rates were similar among women delivering vaginally and those delivering by cesarean after labor or rupture. Women with a short duration of ruptured membranes and an unripe cervix in whom a prolonged labor is anticipated may benefit from urgent cesarean delivery, and those progressing rapidly in labor may be less likely to benefit. In the setting of ruptured membranes without labor before 34 weeks' gestation, expectant management with continuing antiretroviral therapy, potentially including intravenous zidovudine, should be offered to attempt to prolong gestation and reduce complications of prematurity.[100] HIV-infected women with preterm labor should be treated the same as HIV-negative women, with a decision regarding delivery mode based on obstetric considerations and recent HIV RNA levels once delivery is deemed to be inevitable.

For HIV-infected women presenting or diagnosed in labor or postpartum without antiretroviral therapy during pregnancy, several options are available. Observational data from Wade and associates[12] demonstrated transmission rates of 6.1% with zidovudine begun prenatally and continued intrapartum and to the neonate for 6 weeks, 10.0% given intrapartum and to the neonate for 6 weeks, 9.3% when started within 48 hours of birth and continued for 6 weeks, 18.4% when started after 48 hours, and 26.6% with no zidovudine for mother or infant. Subsequent studies have demonstrated transmission rates at 14 to 16 weeks of 13.1% with a single dose of 200 mg nevirapine to mother and 2 mg/kg to the infant compared with 25.1% with oral zidovudine during labor and for 1 week for the infant,[11] a rate at 6 weeks of 10.8% with oral zidovudine/lamivudine in labor and for 1 week in mother and infant compared with 17.2% for placebo,[13] and a rate at 8 weeks of 13.3% with the maternal/infant nevirapine regimen compared with 10.9% for zidovudine/lamivudine orally in labor and for 1 week in the infant.[14] The latter three trials were done in predominantly breastfeeding populations. Thus, any of these three regimens (intravenous zidovudine in labor and oral for the infant for 6 wk; the maternal/infant nevirapine dosing; or oral zidovudine/lamivudine in labor and for 1 wk in the infant) could be used for women presenting in labor without therapy during pregnancy. Some clinicians would choose to use a combination of zidovudine and nevirapine in this setting, although a trial comparing this regimen has not been studied specifically. If single-dose nevirapine is used in the mother, 1 week of dual nucleoside therapy, usually zidovudine/lamivudine, should be provided for the mother to minimize the risk of nevirapine resistance mutations developing with the prolonged nevirapine levels occurring after dosing.[101,102] One trial has compared neonatal therapy–only regimens, finding that single-dose nevirapine compared with oral zidovudine for 6 weeks in the infant had similar transmission rates overall and in formula-feeding infants, but nevirapine had a significantly lower transmission rate among breastfeeding infants.[103] Some clinicians might choose to add additional drugs to the 6 weeks of infant zidovudine to mimic postexposure prophylaxis recommendations, although

formulations and dosing recommendations for neonates are limited.

Postnatal

The postpartum period is a very demanding period for all women, but HIV-infected women have the added stresses of administering medication to the infant and waiting to discern the infant's infection status. Additional psychosocial support is needed during this period. If the woman plans to continue antiretroviral therapy after delivery, measures to enhance adherence are indicated.[28] For women stopping antiretroviral therapy, all drugs should be stopped simultaneously to minimize the development of resistance unless nevirapine or efavirenz are included, in which case the nucleoside agents should be continued for 7 to 10 days after stopping the non-nucleoside reverse transcriptase inhibitor to decrease the risk of resistance development.[29] HIV-infected women should be counseled against breast-feeding because it increases the risk of transmission by 15% to 20%, based on studies of women not receiving antiretrovirals.[52]

Follow-up care for the woman, both reproductive and HIV-specific, and her infant should be ensured before hospital discharge. During prenatal care, women should be counseled regarding contraceptive options. Condom use should be reinforced. Hormonal contraceptives may be used by HIV-infected women, although estradiol levels are reduced by nevirapine, ritonavir, nelfinavir, rifampin, rifabutin, and possibly amprenavir.[27] The impact on contraceptive efficacy of these interactions is unknown, although these changes may increase the risk of irregular bleeding. No significant interactions were found between depomedroxyprogesterone acetate (DMPA) and nucleosides, nevirapine, efavirenz, or nelfinavir, suggesting that DMPA can be used safely among HIV-infected women on antiretroviral therapy.[104] Studies in HIV-infected women suggest that intrauterine contraceptive devices may be used safely by HIV-infected women at low risk of sexually transmitted infections without severe immune compromise.[105]

Infants born to HIV-infected women require HIV-specific as well as routine pediatric care. Infants should receive zidovudine syrup 2 mg/kg of body weight every 6 hours, or equivalent dosing schedule, for 6 weeks after birth.[29] A complete blood count should be obtained from the neonate before starting zidovudine because anemia is the primary side effect of the zidovudine. Use of additional antiretrovirals in the infant may be considered in some situations, such as for an infant born to women not receiving antiretrovirals during pregnancy.[29] Observational data suggest that transmission is reduced with 6 weeks of oral zidovudine in the infant if started within 24 hours of birth, even in the absence of antepartum and intrapartum use.[12] Testing of the infant should be done at 14 to 21 days of age, 1 to 2 months, and 4 to 6 months of age or as soon as any positive result is obtained. Some providers also perform at test shortly after birth.[106] HIV DNA or RNA polymerase chain reaction (PCR) are the preferred methods for infant diagnosis. Infants with two positive HIV virologic tests on separate samples are considered to be HIV-infected. Infants with two or more negative virologic tests, wtih one sample drawn at or after age 14 days and at least one sample at or after 1 month, can be considered to be HIV-uninfected if not exposed through ongoing breast-feeding. Many experts also perform an HIV antibody test at 12 to 18 months to confirm seroreversion among infants with negative PCR testing. Infants should be started on prophylaxis for *Pneumocystis carinii* pneumonia at 4 to 6 weeks of age unless infection has been presumptively excluded with two negative tests by then, with prophylaxis continued until the infant is confirmed to be HIV-uninfected.[106] HIV-infected children should be managed by or in consultation with a specialist in pediatric HIV infection.

The Summary of Management Options Box contains recommendations for appropriate care for HIV-infected pregnant women to maximize maternal health and minimize the risk of perinatal transmission. Although huge advances have been made in management of HIV infection and prevention of transmission in developed countries, the greater challenge is to translate these interventions into practical and sustainable interventions throughout the world. Ultimately, the goal must be to prevent transmission of HIV to avoid the coexistence of HIV infection in pregnancy.

SUMMARY OF MANAGEMENT OPTIONS
Human Immunodeficiency Virus

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Counsel regarding HIV prevention and offer testing for HIV to all reproductive-age women.	Ia/A	29
Assess indications for antiretroviral therapy and opportunistic infection prophylaxis with HIV RNA, and CD4+ cell counts. Initiate highly active antiretroviral therapy if CD4+ cell count <500/µL. Avoid regimens containing efavirenz because of teratogenicity concerns.	Ia/A	28,29,79

Management Options	Evidence Quality and Recommendation	References
Recommend against conception until HIV RNA level undetectable and no indication for opportunistic infection prophylaxis (CD4+ cell count >200/mm^3 for >6 mo).	IIa/B	29,79
Complete other routine preconception assessments such as genetic screening, evaluation for other medical conditions.	IIa/B	29
If partner is HIV-negative, discuss methods to avoid unprotected intercourse: male condoms for all intercourse and artificial insemination for conception.	GPP	
Recommend folate supplementation.	Ia/A	29
Prenatal Screening Policy		
Offer opt-out testing for HIV to all pregnant women, rescreen in third trimester in high-prevalence areas and in women with ongoing risk.	—/GPP	—
Prenatal HIV-positive Patients		
Assess immunization status and update as needed for pneumococcus, influenza, hepatitis A and B, tetanus.	Ia/A	79
Assess antibody status to hepatitis C, *Toxoplasma gondii*, and CMV if not previously documented.	IIa/B	79
Perform tuberculin skin test if not done in past year.	Ia/A	79
Counsel regarding risk of transmission, methods to minimize risk (antiretroviral therapy with scheduled cesarean delivery if HIV RNA >1000 copies/mL after 34 wk), lack of impact of pregnancy on maternal disease progression, symptoms of drug toxicity, possible effects of therapy on infant, evaluation of infant after birth for HIV status.	Ia/A	29
Assess indications for antiretroviral therapy and opportunistic infection prophylaxis with HIV RNA level, CD4+ lymphocyte count. For women already on therapy, discuss risks/benefits of continuing or stopping. Modify regimen if first trimester and on efavirenz. If not on therapy, recommend highly active antiretroviral regimen including zidovudine for all women starting after first trimester, regardless of HIV RNA and CD4+ cell count. Provide opportunistic infection prophylaxis according to adult guidelines.	Ia/A	29,79
Monitor HIV RNA levels monthly after changing or initiating therapy. Level should drop by ≥1 log in first 4–8 wk.	II/B	28
Monitor CD4+ lymphocyte counts each trimester.	Ia/B	29
Perform complete blood count, liver enzymes, renal function frequently (every 2–4 wk) on new regimen, monthly in third trimester.	Ia/A	29
Perform HIV resistance testing for women with detectable HIV RNA levels before initiating therapy or if not responding appropriately to therapy or if rebound from undetectable.	II/B	28,82
Perform ultrasound at 18–20 wk' gestation to rule out anomalies and confirm dates	—/GPP	—
Discuss risks versus benefits of scheduled cesarean delivery. Recommend for HIV RNA levels >1000 copies/mL after 34 wk. Schedule at or after 38 wk' gestation if dating criteria adequate. Perform vaginal delivery only if on antiretroviral therapy with undetectable HIV RNA.	Ia/A	29,86

Human Immunodeficiency Virus—cont'd

Management Options	Evidence Quality and Recommendation	References
Routine prenatal care. If indicated, discuss unknown risk of transmission with amniocentesis or chorionic villus sampling.	III/B	29
Labor and Delivery		
Start intravenous zidovudine infusion:	Ia/A	29,39
a. For those choosing vaginal delivery 2 mg/kg over 1 hr followed by 1 mg/kg/hr until delivery with onset of labor. b. Same regimen at least 3 hr before scheduled cesarean delivery.		
Continue other medications orally except stavudine, which may antagonize zidovudine.		
If vaginal delivery, minimize duration of ruptured membranes as much as possible.	II/B	29,98,99
Avoid scalp electrodes, scalp sampling, instrumented delivery.	II/B	93,94
Wash infant before blood draws, injections.		
Postnatal		
Discuss option of stopping or continuing antiretroviral therapy if initiated solely for transmission prophylaxis. Reinforce adherence if continuing therapy.	Ia/A	29
Counsel against breast-feeding.	Ia/A	29
Provide contraception and ensure continued HIV and reproductive health care. If partner is HIV-negative, advise male condom to avoid unprotected intercourse.	Ia/A	29
Provide psychosocial support as infant infection status assessed.	Ia/A	29
Ensure routine and HIV-specific care for infant including zidovudine 2 mg/kg every 6 hr or equivalent until 6 wk of age, HIV DNA PCR testing, initiation of prophylaxis against *Pneumocystis carinii* pneumonia beginning at 4–6 wk of age unless infant presumptively HIV-infected based on serial testing.	Ia/A	106

CMV, cytomegalovirus; GPP, good practice point; PCR, polymerase chain reaction.

RUBELLA

Maternal and Fetal Risks

Rubella (German measles or third disease) is an exanthematous disease caused by a single-stranded RNA virus of the togavirus family.[1] Like rubeola, rubella is acquired via respiratory droplet exposure. After a 2- to 3-week incubation period, symptomatic patients develop a rash that spreads from the face to the trunk and extremities, lasting about 3 days. Fever, arthralgias, and postauricular, posterior cervical, and suboccipital lymphadenopathy are characteristic. Severe complications such as encephalitis, bleeding diathesis, and arthritis are rare. Overt clinical symptoms occur in only 50% to 75% of rubella-infected patients, and thus, clinical history is not a useful marker of prior illness.[2]

Rubella infection is usually a mild illness in both adults and children. However, fetal infection may be devastating. Congenital rubella syndrome (CRS) may produce transient abnormalities, including purpura, splenomegaly, jaundice, meningoencephalitis, and thrombocytopenia, or permanent anomalies such as cataracts, glaucoma, heart disease, deafness, microcephaly, and mental retardation. Long-term sequelae might include diabetes, thyroid abnormalities, precocious puberty, and progressive rubella panencephalitis.[2,3] Defects involving virtually every organ have been reported (Table 29–1).[4] A 50-year follow-up of 40 survivors of CRS born between 1939 and 1943 revealed that all had hearing impairment; 23 had eye defects related to the rubella.[5]

The results of one large survey of maternal rubella infection in pregnancy are summarized in Table 29–2.[6] The rate of fetal infection is highest at 11 weeks and greater than 36 weeks. However, the overall rate of congenital defects is greatest in the first trimester (90%) and declines steadily in the second and third trimesters.

Rubella vaccine became available in the United States in 1969. Vaccination given as a trivalent preparation of measles, mumps, and rubella (MMR) vaccine produces long-term immunity in 95% of vaccinees. The rates of rubella dropped precipitously after introduction of the vaccine. Ten years later, the annual incidence of rubella infections, including CRS, had decreased by 99.6%.[7] However, in the 1990s, there were several outbreaks in groups of adults with unknown vaccination status living in close quarters.[8] The largest outbreak in the United States occurred in Nebraska in 1999 and involved 125 cases; 87% of these patients were born in Latin America.[9] In this outbreak, 7 pregnant women were infected and 1 child was born with CRS. Almost half of these women had prior births in the United States and had missed prior vaccination opportunities. Since then, the number of CRS cases has steadily declined in part due to rubella immunization campaigns in Latin America and Mexico.[10,11]

Diagnosis

The clinical diagnosis of rubella infection is difficult. Most infections are subclinical, and the rash is nonspecific. Serologic testing is the primary mode of diagnosis using enzyme-linked immunoassay (ELISA). In a woman with exposure or suspected illness, seroconversion demonstrated by paired acute and convalescent specimens is indicative of acute infection. Acute infection may also be diagnosed by isolation of virus from the blood, nasopharynx, urine, or cerebrospinal fluid. Serologic testing for immunity is based on the assumption that rubella-specific antibodies of the immunoglobulin G (IgG) class are present for life after natural infection or vaccination.

Management Options

Prepregnancy

Vaccination of all children and susceptible adults will help prevent outbreaks of rubella. All children should receive a single dose of live attenuated rubella vaccine at 12 to 15 months of age in a trivalent preparation of MMR strains. The second dose of MMR may be administered at least 1 month after the first dose but before 6 years of age. Susceptible young women should be vaccinated and refrain from pregnancy for 1 month following vaccination.[12] Evidence of immunity is required of health care workers and women of childbearing age.[13] Studies on a MMR-vaccinated cohort followed for 20 years shows that rubella antibodies remain elevated for at least that long in many individuals.[14] However, individuals with low levels of antibody after vaccination may be susceptible to viremia and clinical infection.[15] CRS after previous maternal rubella vaccination has been rarely reported.[16]

The rubella vaccine is a live virus preparation, which may cross the placenta; thus, it should not be administered to

TABLE 29–1

Abnormalities in Congenital Rubella: Triad of Gregg

ABNORMALITY	DESCRIPTION
Eye	
Cataract	Usually bilateral and present at birth.
Retinopathy	"Salt and pepper" appearance, may have a delayed onset, frequently bilateral, visual acuity is not affected.
Microphthalmia	Often associated with cataract.
Glaucoma	Rare but leads to blindness if not recognized.
Heart	
Patent ductus arteriosus	Common, often associated with persistence of the foramen ovale.
Pulmonary valvular stenosis	Common, due to intimal proliferation and arterial elastic hypertrophy.
Pulmonary artery stenosis	
Coarctation of the aorta	Infrequent.
Ventricular septal defects	Rare.
Atrial septal defects	Rare.
Ear	
Commonly damaged	Injury of cells of the middle ear leading to sensorineural deafness may also have a central origin.
Bilateral and progressive	May be present at birth or develop later in childhood. Severe enough for the child to need education at a special school; rare when maternal rubella occurs after the fourth mo of pregnancy.

Adapted from Freij BJ, South MA, Sever JL, et al: Maternal rubella and the congenital rubella syndrome. Clin Perinatol 1988;15:247–257.

pregnant women. However, the Centers for Disease Control and Prevention (CDC) have monitored inadvertent rubella vaccination during pregnancy, collecting over 500 cases. No case of CRS due to vaccination was documented, although virus was isolated from the conceptus in several cases.[17] Thus, patients inadvertently vaccinated during pregnancy, or becoming pregnant shortly after vaccination, should be reassured and counseled that the risk of fetal infection is negligible.[18,19] Furthermore, follow-up studies on fetuses inadvertently exposed to rubella vaccine RA27/3 in pregnancy in Costa Rica did not have increased rates of miscarriage or stillbirth.[20]

Prenatal

A pregnant woman infected with rubella is at little risk. However, depending on the gestational age at infection, the fetus may be at great risk for congenital anomalies. Methods for in utero diagnosis include fetal blood sampling measurement of rubella-specific IgM,[21] rubella-specific reverse transcriptase polymerase chain reaction (RT-PCR), and virus isolation from amniotic fluid or products of conception.[22,23] RT-PCR can detect the presence of viral RNA even when the fetal rubella virus–specific IgM obtained by fetal blood sampling is negative.[24] Although these tests may indicate fetal infection, the counseling is largely based on the gestational age–related risk of congenital abnormalities due to CRS. No treatment other than pregnancy termination is available.

Treatment for acute maternal rubella is generally symptomatic. Rarely, patients who develop thrombocytopenia or encephalitis may benefit from glucocorticoids or platelet transfusion. Immunoglobulin for pregnant women with acute infection is controversial. Furthermore, no data suggest that immunoglobulin will prevent fetal anomalies.

Labor, Delivery, and Postnatal

Acute infection during these time periods is unlikely. If suspected, appropriate infection control measures should be instituted. The neonate should be evaluated for infection following birth.

TABLE 29–2

Fetal Consequences of Symptomatic Maternal Rubella during Pregnancy

STAGE OF PREGNANCY (WK)	INFECTION		DEFECTS		OVERALL RISK OF DEFECT (RATE OF INFECTION × RATE OF DEFECTS) (%)
	NO. TESTED	NO. POSITIVE	NO. FOLLOWED	RATE (%)	
<11	10	9 (90%)	9	100	90
11–12	6	4 (67%)	4	50	33
13–14	18	12 (67%)	12	17	11

SUMMARY OF MANAGEMENT OPTIONS
Rubella

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Prevent by childhood vaccination.	III/B	13
Vaccination programs for girls in their early teens contribute to prevention.	III/B	13
Serologic evaluation and, if negative, vaccination of woman inquiring about status.	III/B	13
Prenatal		
Routine check of rubella immunity status at first visit for all women is standard practice in many centers.	III/B	13,19
Accidental vaccination in early pregnancy is not an indication for termination.	IIa/B	13,16–20
If suspected exposure in woman with immunity:	—/GPP	—
• Confirm presence of rubella-specific IgG (if immediately after exposure).		
• Confirm failure of appearance of IgM (acute phase) antibodies with two serum samples 2–3 wk apart.		
• Reassure patient.		
If suspected exposure in susceptible woman:		
• Establish validity of diagnosis serologically in index case if possible.	III/B	13
• Check for appearance of IgM (acute-phase) antibodies.	III/B	13
• If there is no serologic evidence of infection, reassure patient.	—/GPP	—
If maternal infection is confirmed serologically, options will depend on gestation at time of infection:		
• In early pregnancy, termination should be discussed; it may be performed immediately or only after confirmation by invasive procedure.	IIb/B	5,6
• In late pregnancy, confirmation of fetal infection by invasive procedure can be considered; fetal growth and health should be monitored if infection is suspected or confirmed.	—/GPP	—
Labor, Delivery, and Postnatal		
If fetal infection is suspected, cord blood should be sent for serologic confirmation.	III/C	13
If fetal infection is confirmed, careful pediatric assessment and follow-up are needed.	—/GPP	—

RUBEOLA

Maternal and Fetal Risks

Rubeola (red measles or first disease), caused by a paramyxovirus, is highly infectious and commonly attacks children. The illness is spread by respiratory droplet and may include high fever, rash, cough and rhinorrhea, conjunctivitis, and the pathognomonic Koplik spots on the oral buccal epithelium. The incubation period is generally 10 to 14 days. The infection is usually self-limited in children.[25] Rarely, the disease might be severe and might be complicated by bronchopneumonia, hepatitis, otitis media, diarrhea, or death.[13,26] Encephalitis occurs in 1 of every 1000 reported cases and may lead to permanent brain damage and mental

retardation. Death, usually due to pneumonia or encephalitis, is reported to occur in 1 to 2 per 1000 cases in the United States. The fatality rate is greater in infants, young children, and adults. In addition, subacute sclerosing panencephalitis, an extremely rare degenerative disease of the central nervous system, is caused by this virus presenting years after the initial measles infection.

The number of cases of measles in the United States and other industrialized countries has decreased markedly since the introduction of an effective vaccine in 1963.[13,27] Still, in 1990, there were 55,000 cases and 120 measles-related deaths. This resurgence was largely due to an increase in unvaccinated preschool children, particularly in urban areas.[27,28] Although data from the National Health and Nutrition Examination Survey show that the overall seroprevalence of measles IgG antibody was 95.9% between 1999 and 2004, outbreaks continue to occur.[29,30]

Some report that measles during pregnancy is not associated with increased maternal or fetal death rates.[31] Others find higher rates of measles-related hospitalization, pneumonia, and death for infected pregnant women.[32] Placental damage from the infection has been implicated in stillbirths.[33] Furthermore, measles infection of mothers in developing countries is associated with an increase in the perinatal mortality rate.[34] As with any febrile illness, measles infection may precipitate premature uterine activity and lead to premature delivery.[35]

No specific syndrome is attributed to intrauterine measles infection. However, the newborn delivered to a woman with active disease is at high risk for severe neonatal measles. Pneumonia is the primary cause of death and is more common in the premature newborn. Some reports suggest an association between in utero measles infection and postnatal development of Crohn's disease.[36] This potential relationship has yet to be confirmed and does not warrant prenatal diagnosis in the fetus.

Diagnosis

The clinical diagnosis of rubeola is based on the presence of a maculopapular rash occurring 1 to 2 days after a specific exanthematous rash (Koplik's spots), photophobia, and upper respiratory symptoms. Serologic tests can provide a definitive diagnosis. In addition, a diagnosis can also be confirmed by isolating the virus or using RT-PCR from serum or throat swabs.[37]

Management Options

Prepregnancy

Prevention is the best available mechanism to protect against measles. All children should receive one dose of the live measles virus vaccine as part of MMR between 12 and 15 months of age, followed by a second dose at age 6. Vaccination results in long-lasting immunity in over 95% of recipients.

Likewise, immunity to natural infection is lifelong, and the high infectivity of the virus during childhood leaves few susceptible adults. Women contemplating pregnancy with a negative or questionable history of measles illness or vaccination or laboratory evidence of susceptibility should receive the live attenuated virus vaccine followed by a second dose not less than 1 month later. Women vaccinated before 1967 (and likely to have received a heat-killed viral vaccine), or who were vaccinated before 1 year of age, or those with equivocal serology should also receive two doses of vaccine.[13] Pregnancy should be delayed 1 month after receiving MMR vaccine.

Prenatal

The upper respiratory symptoms of acute measles can be ameliorated with cough suppressants. Fever, especially if high, should be treated aggressively with antipyretics. Measles pneumonia may require respiratory support, and if superimposed bacterial pneumonia develops, antibiotic therapy is required. Even when there is no life-threatening disease, pregnant women should be closely monitored during the acute illness for evidence of uterine activity.

Although pregnant women are not candidates for vaccination with any live virus vaccine, accidental vaccination with rubeola vaccine is not a cause for alarm or an indication for pregnancy termination. Immune serum globulin (ISG) may be given to susceptible pregnant women exposed to rubeola in an attempt to prevent or modify the clinical expression of the disease. The intramuscular preparation (0.25 mL/kg, maximum 15 mL) should be given within 6 days of exposure.[13]

Labor, Delivery, and Postnatal

There are no specific management recommendations for these intervals because acute disease is unlikely. Clinicians, however, should be aware of appropriate isolation precautions instituted for rubeola in the hospital. Observation of the neonate for infection is mandatory.

MUMPS

Maternal and Fetal Risks

Mumps is a contagious acute viral illness caused by a paramyxovirus, primarily infecting children and young adults. Human beings are the only recognized natural host for this pathogen. The classic presenting symptom for mumps is either unilateral or bilateral parotitis, which usually develops 14 to 18 days after exposure. Respiratory droplets typically transmit the virus. Prodromal symptoms include fever, chills, malaise, and myalgias. The disease can also remain asymptomatic in 20% of cases. Persons are considered infectious from 2 days before the onset of symptoms to approximately 9 days after the parotitis is noted.

Although generally a self-limited disease with symptoms resolving within 5 to 7 days, mumps can result in significant complications, particularly in the adult population. Orchitis occurs in up to 38% of cases in postpuberal males and may lead to infertility.[13] Conversely, mastitis and oophoritis have been reported in women, but infertility is rare.[38] Other complications include aseptic meningitis, pancreatitis, and thyroiditis. Mumps meningoencephalitis can cause permanent sequelae such as sensorineural hearing loss, seizures, nerve palsies, and hydrocephalus.[13]

There are limited data on mumps in pregnancy. In a cohort study of measles, mumps, and rubella, Siegel[39] reported an increased incidence of first-trimester pregnancy loss with acute mumps infection. No data suggest mumps specifically increases the incidence of stillbirths or preterm deliveries. Early studies suggested an association between endocardial fibroelastosis and mumps virus antigen; however, a clear relationship of mumps to this or other congenital malformations has not been confirmed.[40]

The number of reported cases of mumps in the United States has decreased dramatically since the broad institution of effective vaccination. In 1968, over 180,000 cases of mumps were reported in the United States compared with 266 cases reported in 2001.[41] Most cases occurred in persons younger than 20 years. Although the presumption was that these outbreaks were due to failure to vaccinate, surveillance data suggested that there may be a waning of vaccine-induced immunity over time, allowing for susceptibility to wild virus infection.[42] Hence, current recommendations, which were enacted in 1989, include a second dose of MMR vaccine given at age 6 years. This practice has resulted in a further decline in mumps infection.[43] A remaining concern is that only 38% of countries worldwide use routine mumps vaccination. Still, outbreaks occur intermittently such as the outbreak in Iowa among 605 18- to 25-year-olds in which the source is unknown but the G genotype of mumps was isolated. The latter is the same strain found in a large outbreak (>70,000 cases over 3 yr) in the United Kingdom.[44] The importation of mumps into previously protected communities has become increasingly recognized.

Diagnosis

The diagnosis of mumps is usually suspected based on presenting features of the disease in the appropriate clinical setting. Although the virus can be isolated in culture or by RT-PCR detection from a clinical specimen (saliva, cerebrospinal fluid, urine, or other infected organ system), the diagnosis is more typically established by serologic techniques. Enzyme immunoassay (EIA) is the most widely used methodology and is more sensitive than complement fixation or hemagglutination inhibition. Both IgM and IgG antibody testing is available. A positive mumps-specific IgM result from a reliable laboratory or a significant rise between acute and convalescent titers of IgG antibody helps establish the diagnosis of acute infection. After acute infection, it is presumed that one has lifelong immunity and persistent IgG titers.

Management Options

Prepregnancy

Two doses of mumps vaccine in combination with measles and rubella (MMR) are routinely recommended for children in the United States. Therefore, adequate protection against infection should be established prior to a woman reaching her reproductive years. There are no current routine recommendations to test for mumps immunity prior to conception. However, if there is reasonable concern that prior vaccination is not adequate, IgG testing can be obtained. If susceptible, a dose of MMR vaccine should be administered at least 1 month prior to attempting pregnancy.[45]

Prenatal

Because the mumps component in MMR is a live attenuated virus, the vaccine is contraindicated in pregnancy. Because no data indicate that mumps vaccination is associated with congenital malformations or other specific adverse outcomes, the inadvertent administration of the vaccine during pregnancy is not an indication for pregnancy termination.

During pregnancy, if exposure to an infected individual is reported, immediate testing for IgG antibody will in most cases confirm immunity and can be used to reassure the patient. In those individuals who lack proven immunity, postexposure immunoglobulin has not been shown to be beneficial as a prophylactic agent. Careful surveillance and symptomatic care should be instituted. Appropriate infection control procedures should be undertaken. These procedures can be rapidly procured from hospital infection control authorities and via the CDC website.

Labor, Delivery, and Postpartum

There are no specific recommendations for these periods of time because an acute outbreak is unlikely to occur. However, in suspected cases in the laboring gravida, the previously mentioned infection control measures should be started as the diagnostic workup is begun. The neonate should be carefully observed for early signs of infection manifested by parotitis or aseptic meningitis. Pediatric infectious disease consultation should be sought.

VARICELLA

Maternal and Fetal Risks

Varicella-zoster virus (VZV) is a member of the herpesvirus family and is the causative agent of varicella (chickenpox) and herpes zoster (shingles). Varicella is generally a mild, self-limited illness in healthy children. It is transmitted by infected secretions from the nasopharynx, by direct contact with vesicular fluids, or by airborne spread of the virus. This is followed by viral replication in regional lymph nodes and the tonsils. Viral replication continues for approximately 4 to 6 days. Primary viremia develops and virus spreads to internal organs. When the virus replicates again and is released into the bloodstream, it invades the skin, resulting in the classic viral exanthem by 14 days. Therefore, patients are infectious 1 to 2 days prior to developing this rash.

The incubation period of chickenpox is 10 to 12 days. Many patients have a prodrome of fever, malaise, or myalgia a few days prior to the rash, which is vesicular and erupts in crops over the trunk, face, oropharynx, and scalp. Several crops erupt every 2 to 3 days and last 6 to 10 days. Complications are rare but may include bacterial superinfection of vesicles, pneumonia, arthritis, glomerulonephritis, myocarditis, ocular disease, adrenal insufficiency, and central nervous system abnormalities.[46]

Retrospective studies suggest that varicella pneumonia in pregnant women is more severe than in nonpregnant adults.[47] In a case-control study, smoking and the occurrence of 100 or more skin lesions were risk factors for developing pneumonia.[48] A pregnant woman with varicella and cough, dyspnea, fever, or tachypnea warrants immediate attention. Pneumonia generally develops within a week of the rash and may rapidly progress to hypoxia and respiratory failure. The mortality rate in untreated varicella pneumonia in pregnancy exceeds 40%.[49] If treated aggressively with intravenous acyclovir and supportive measures, reported mortality rates are less than 15%, but patients may still require intubation and ventilatory support.[50]

Congenital varicella syndrome (CVS) is characterized by dermatomal scarring; ocular abnormalities such as cataracts, chorioretinitis, and microphthalmia; low birth weight; cortical atrophy; and mental retardation (Table 29–3). Most cases occur in infants whose mothers were infected between 8 and 20 weeks' gestation. However, the number of cases is low. Data compiled from multiple retrospective cohort studies have determined the rate of embryopathy is approximately 2%.[51–54] In fact, in a prospective study of 347 varicella-infected mothers, the incidence of CVS was 3 per 231 births (1.3%; 95% confidence interval [CI] 0.3–0.7) where follow-up was complete.[55] In a study of babies who were

Early childhood zoster

exposed in utero to primary varicella and did not develop CVS, there appeared to be no differences in neurobehavioral outcomes when compared with uninfected controls.[56]

Neonatal varicella generally occurs in neonates born to mothers who are infected with varicella within 2 weeks of delivery.[57] It is a serious illness characterized by fever and vesicular rash, which resolves, but in some cases, disseminated disease or visceral involvement may ensue. In the latter, the mortality rate may be as high as 25%.

Herpes zoster or shingles, which arises from reactivated VZV, which had been dormant in the dorsal root ganglia, does not lead to CVS.

Diagnosis

Varicella is usually diagnosed clinically based on the characteristic exanthem. Culture of the vesicular fluid is a lengthy process. Serologic tests are useful to document immunity (when IgG is present) in a patient immediately following exposure. IgM antibody specific to VZV may be identified as soon as 3 days after the onset of symptoms in an acutely infected gravida. IgG seroconversion can be seen by 7 days after VZV symptom onset. Paired sample analysis for IgG may be useful to establish the diagnosis of primary infection.

Prenatal diagnosis of varicella is possible. Ultrasonography may detect limb abnormalities, and fetal blood or amniotic fluid may be tested for VZV antibody or DNA.[58,59]

However, despite detection of virus, the presence of embryopathy cannot be predicted.

Management Options

Prepregnancy

Varivax, a live attenuated varicella vaccine, is recommended for susceptible children under age 13 and susceptible adults.[60] The vaccine is given in two doses 4 to 8 weeks apart, and approximately 82% of adults will seroconvert. Women should avoid pregnancy for at least 1 month after vaccination. Results from a voluntary registry of Varivax administered in early pregnancy gathered between 1995 and 2005 revealed no cases of CVS among 131 live births.[61] Thus, inadvertent Varivax exposure should not prompt medical recommendations for pregnancy termination.

Pregnancy

Varicella zoster immunoglobulin should be administered to pregnant women who are susceptible to VZV and are exposed to varicella or herpes zoster. The only product currently available is VariZIG, an investigational varicella immune globulin product that may be obtained under expanded access following patient consent.[62] VariZIG should be administered with 48 hours of exposure but may be effective up to 96 hours. Although it diminishes the severity of maternal disease, there is no evidence that VariZIG prevents congenital varicella.

If a pregnant woman becomes infected with chickenpox, she may be offered oral acyclovir to decrease the number of febrile days and shorten the duration of active lesions.[63] As previously noted, parenteral antiviral therapy is indicated in cases of varicella complicated by pneumonia or central nervous system involvement.

Labor, Delivery, and Postnatal

There are no specific management recommendations for labor. Infected pregnant women should be placed in a negative-pressure room for labor, delivery, and the postpartum period in accordance with infection control protocols. Neonates should be given VariZIG after birth and monitored closely because the neonate at greatest risk for chickenpox is born within 4 days prior to or 2 days after maternal chickenpox.[62] A small study of 24 prenatally infected newborns suggests that VariZIG in conjunction with intravenous acyclovir is a more effective prevention strategy than VariZIG alone.[64]

PARVOVIRUS B19

Maternal and Fetal Risks

Human parvovirus B19 (erythema infectiosum, fifth disease) is an infectious exanthematous childhood illness transmitted by droplet. Parvovirus B19 viremia occurs 6 to 8 days after exposure and may persist for up to a week. An infected individual is contagious before the onset of symptoms, and the virus can be detected in the blood or secretions as early as 5 to 10 days after exposure. Parvovirus B19 infection is characterized by fever, rash, and arthropathy. The rash has a "slapped cheek" appearance on the face and a "lacelike" appearance on the trunk and extremities. The arthropathy may affect the joints of the hands, wrist, knees, and ankles. In addition, the virus may cause aplastic crisis in patients with sickle cell disease[65] and other hemolytic states,[66] chronic bone marrow failure in patients with immunodeficiency,[67] a chronic arthropathy,[68] and the childhood illness fifth disease (erythema infectiosum).[69]

Parvovirus B19 infection preferentially infects rapidly dividing cells and is cytotoxic for erythroid progenitor cells.[70,71] As a result, B19 virus also may stimulate a cellular process involving programmed cell death.[72] Parvovirus B19 infections during pregnancy might rarely be associated with fetal loss or hydrops fetalis. The risk of fetal loss appears highest in the first 20 weeks of pregnancy. In a prospective study of 186 pregnancies with confirmed parvovirus B19 infection, there were 27 first-trimester spontaneous abortions versus 7 abortions or fetal deaths in the second trimester and only 1 death in the third trimester.[73] Several additional series of parvovirus infection in pregnancy have been reported. When these series are summarized, the risk of fetal loss among pregnancies infected prior to 20 weeks' gestation is approximately 10%.[74–76] The risk of loss after 20 weeks' gestation is less than 1% and the risk of hydrops is 0.3%.[77] A prospective study of 618 exposed pregnancies showed no hydrops or fetal death attributable to B19 in 52 babies born to infected mothers.[78] The hydrops may develop rapidly within 7 to 14 days and can either lead to fetal death or resolve spontaneously.[79] In the largest prospective study of 1018 women with acute parvovirus infection, 6.3% of pregnancies ended with fetal death, and all were infected prior to 20 weeks' gestation.[80] The rate of death in the first trimester was 13% (34/256 < 12 weeks' gestation); 9% (30/222 13–20 weeks' gestation); and 0/439 after 20 weeks' gestation. There were a total of 6 stillbirths, 4 prior to 24 weeks' gestation and 2 at term. These term deaths were not attributed to B19.

Although B19 infection appears to be teratogenic in fetal animals (cerebellar hypoplasia and ataxia in cats and anencephaly, microcephaly, facial defects, and ectopic hearts in hamsters have been described), epidemiologic studies do not suggest that B19 infection is teratogenic in human fetuses.[81] Furthermore, long-term follow-up of offspring of women with B19 infections suggests the children are normal.[82,83]

Parvovirus B19 infection is distributed worldwide. Antibody to B19 virus occurs in 30% to 60% of adults.[84,85] Secondary attack rates for household contacts may be as high as 50% but as low as 20% to 30% for classroom contacts.[86] Serologic surveys of pregnant women revealed that 35% to 65% are B19-seropositive.[75,78] In one large study during an epidemic, the risk of seroconversion for pregnant women was highest in those with the greatest exposure to young children.[87]

Diagnosis

B19 virus is difficult to culture, and clinical manifestations are often lacking. Serology is the easiest method to detect infection using either IgM antibody capture radioimmunoassay or ELISA. These tests will detect between 80% and 90% of B19 seropositive individuals.[88] IgM, indicating acute infection, can be detected approximately 10 days after exposure and can last for 3 months or longer.[89,90] IgG antibodies may be detected several days after IgM and can persist for years as markers of past infection. Polymerase chain reaction

(PCR) to detect small amounts of B19 virus is useful to diagnose in utero infection from amniotic fluid.[91–93] In cases of unexplained hydrops, the presence of B19 DNA in maternal blood is useful for diagnosis, although avidity testing and EIA for specific parvovirus IgG epitope might be more useful for timing of infection.[94] Additional methods such as electron microscopy, detection of viral DNA, and hybridization assays for nucleic acids may be useful for pathologic specimens in the evaluation of stillbirths.

Management Options

Prepregnancy

Immunocompetent adults rarely need treatment; however, patients at risk for hemolysis may need multiple transfusions.

Prenatal

Pregnant women following exposure to B19 virus should have immediate serologic testing. Presence of IgG and absence of IgM suggests prior exposure to B19 virus and that the fetus is protected from infection. If the IgG is negative or positive and the IgM is positive, this finding is consistent with acute infection. Women should be counseled about the low risk of fetal loss in the first trimester and low risks of hydrops or stillbirth in the second and third trimesters. Prior to 20 weeks' gestation, no further action is required. However, after 20 weeks' gestation, periodic ultrasound examinations may be useful to identify hydrops. In addition,

Doppler studies of the fetal middle cerebral artery peak velocity may yield an accurate reflection of fetal anemia.[95] In some reported cases, hydrops did not appear until 8 weeks following maternal infection; hence, the recommendation to continue monitoring for 8 to 12 weeks after infection.[96] If hydrops is noted, percutaneous umbilical blood sampling may be warranted to determine fetal hematocrit and provide transfusion.[97,98] Although some small series show improvement following transfusion, other reports note spontaneous resolution in the absence of intervention.[99,100] Further discussion of fetal hydrops can be found in Chapter 24.

The pregnant woman who is IgG-negative and IgM-negative is susceptible to infection. She should be counseled that repeat testing may be required if her serologic results were obtained within 2 weeks of her exposure. Preventive measures include minimizing contact with known parvovirus infection and good contact precautions. According to the CDC, there is no proven benefit to removing seronegative women from high risk employment for the duration of the pregnancy.

Labor, Delivery, and Postpartum

Onset of signs and symptoms suggesting acute infection during these time periods requires appropriate infection control measures. The neonate should be carefully observed for vertical transmission of the infection. Neonatal IgG levels immediately after birth reflect transplacentally passed maternal immunoglobulin.

Cytomegalovirus, Herpes Simplex Virus, Adenovirus, Coxsackievirus, and Human Papillomavirus

THOMAS ROOS and DAVID ALLAN BAKER

INTRODUCTION

Viral infections can pose a serious threat to the fetus and the newborn. In the healthy adult, infections might be asymptomatic or cause only mild unspecific symptoms. Some viruses may reside dormant for prolonged periods, and asymptomatic virus shedding may occur unnoticed. Viruses can be transmitted by trivial interpersonal contacts such as occurs when handling a baby (cytomegalovirus [CMV], herpes simplex virus [HSV], adenovirus, coxsackievirus) or in a swimming pool (adenovirus). Sexual activities with multiple partners confer a high risk for infection with some viruses associated with severe disease in the adult and in the infant. Pregnancy is associated with decreased maternal cell-mediated immunity to viral infections; thus, the pregnant woman and her fetus are theoretically at increased risk for serious illness. Depending on gestational age, transplacental viral infection may range from asymptomatic to severe, causing fetal or neonatal death or long-term sequelae in the survivors. Intrauterine growth restriction (IUGR), nonimmune hydrops, isolated ascites, intracranial calcifications, microcephaly, and hydrocephaly are common ultrasound findings associated with some in utero viral infections. The possible severe impact of viral infections and the lack of specific antiviral treatment options in the fetus and newborn available to date imply that prevention is the most important approach to disease containment. The development of antiviral drugs and vaccines in progress holds the promise of a reduced incidence of fetal viral infections and of their sequelae in the future.

CYTOMEGALOVIRUS

General

CMV, a DNA virus, is a member of the herpes family of viruses, which causes a number of infectious syndromes in humans. However, because CMV is highly efficient in remaining dormant or silent in the host, the most common manifestation of CMV infection in humans is the lack of demonstrable disease. Three disease states are particularly important: intrauterine and neonatal infection, heterophil-negative mononucleosis, and infection in the immunocompromised patient.

Diagnosis

Human CMV is readily grown in cell lines of human fibroblasts. In patients with symptoms suggestive of acute CMV infection, viral culture from urine, nasopharynx, or blood may document the presence of the organism. Direct immunofluorescence tests in combination with a limited culture can detect the virus more rapidly. More recently, nucleic acid amplification systems using polymerase chain reaction (PCR) techniques have been used to identify the virus in amniotic and other fluid samples and in dried newborn blood.[1–4] High numbers of virus copies in the amniotic fluid can possibly signal a fetus at risk for severe CMV disease; however, this relationship remains controversial.[5–7] Viral load detected in newborn dried blood spot test might indicate children at increased risk of sensoneurinal hearing loss.[8] Tissue specimens (biopsy, necropsy) may also be evaluated for virus by immunofluorescence, in situ hybridization, or PCR techniques,[9] thus, providing a better understanding of fetal CMV infection mechanisms.[10,11]

Because many previously infected patients excrete CMV intermittently throughout their lives depending on certain circumstances (e.g., pregnancy, immunosuppression), the presence of CMV in a specimen does not automatically confirm that the illness in question is caused by this particular virus. The physician must be extremely careful with the interpretation of these results.

Approximately 50% of reproductive age women have antibody to CMV. Thus, paired specimens are necessary if seroconversion from negative to positive has not been documented. A significant rise in titer is usually consistent with

a primary infection. Immunoglobulin M (IgM)–specific antibody is usually present 4 to 8 weeks after a primary infection but can increase periodically or persist at a low titer for years. IgM and, less frequently, IgA are of use in distinguishing transplacental transfer of maternal antibodies in the diagnosis of congenital infection.[12]

Serologic testing consists of the older complement fixation test or the more current indirect fluorescent antibody (FA) and anticomplement immunofluorescent tests. In a primary infection, these tests become positive sooner than the complement fixation test.[13] Enzyme immunoassay (EIA) methods also have been used to detect CMV-specific IgG, IgM, IgA, and IgE antibodies.[14] This is important because reactivation of latent CMV during pregnancy may be accompanied by either an increase or a reappearance of IgM antibodies (depending on the methodology used), which theoretically would help differentiate it from new infection.[15] More recently, more labor-intensive EIA assays have been used to detect low-avidity IgG antibodies that are produced early in infection.[16–18] In one study, CMV immediate-early messenger RNA in maternal blood was detected only in cases of primary CMV infection and not in immune subjects; thus, this later EIA test has been suggested to be helpful in differentiating primary from recurrent infection.[19]

Isolation of the virus or DNA from amniotic fluid and demonstration of viral DNA, immunologic response, or non-specific markers in fetal blood collected by cordocentesis have all been used to supplement antenatal diagnosis.[20–23] A prospective evaluation of 1771 pregnant Belgian women by serial serology and culture of urine, saliva, and cervical secretions at each prenatal visit revealed a seronegative rate of 49%.[24] Of this group, seroconversion occurred in 20 susceptible women (2.3%). Five of the 7 who agreed to cordocentesis and amniocentesis had positive amniotic fluid cultures for CMV; 3 had a positive fetal IgM for CMV. The presence of CMV in fetal tissue was confirmed after termination, supporting the authors' contention that amniotic fluid culture is superior to fetal IgM in diagnosing fetal infection.[24] Others have reported either a lack of fetal CMV seropositivity for IgM in culture-positive fetuses or the failure of the fetus to sustain the IgM response. Thus, amniotic fluid culture or PCR analysis of amniotic fluid is superior to fetal CMV-specific IgM.[25,26] There have been a few reports of false-negative amniotic fluid cultures, as ascertained by neonatal shedding, but the relationship of these apparently negative results to the timing of infection and to long-term sequelae is unclear. Culture failure may be related to performance of amniocentesis too close to the time of initial maternal infection or too early in gestation, that is, before the fetal kidneys produce sufficient amounts of urine containing shedded virus.[27,28] The best results for detecting congenital CMV infection by testing amniotic fluid samples occur when amniocentesis is performed after 21 weeks' gestation and after an interval of at least 6 weeks from the first diagnosis of maternal infection.[29,30] Sensitivity to CMV can be enhanced using PCR or nested PCR assays.[16,31] Nested PCR technique has effectively been applied in a dried blood spot test of newborn Guthrie card in a trial evaluating newborn CMV screening.[4] Because all of these techniques can produce false-negative results, a negative diagnostic workup does not guarantee absence of infection.

Detection of specific IgM in fetal blood has been found to be associated with severe CMV disease.[29] Some, but not all, infected fetuses have sonographic abnormalities (e.g., intracranial calcifications, growth restriction), anemia, thrombocytopenia, and elevated liver function test results.[20,32] The natural history of the disease was followed antenatally by serial ultrasound and cordocentesis in at least one reported case.[33] Hyperechoic bowel may precede development of ventriculomegaly, IUGR, nonimmune hydrops, and fetal death in infected fetuses.[34] In a group of 50 pregnant women (51 fetuses) with primary CMV infection and confirmed in utero transmission, abnormal fetal ultrasound findings could be demonstrated in 22% (11 of 51 fetuses). In the same study, 3 out of 16 newborns (19%) with normal ultrasound findings had neurologic abnormalities.[35] Thus, normal mid-trimester ultrasound findings in infected fetuses can exclude neither an abnormal ultrasound later in pregnancy or the birth of a severely affected child. Recently, in addition to ultrasonography, magnetic resonance imaging (MRI) in proven CMV-infected fetuses has demonstrated to be helpful in providing additional information on gyration, cerebellar hypoplasia, and changes in the white matter of the fetal brain. However, MRI may not detect brain anomalies in cases of normal ultrasound findings; thus, MRI is not recommended as a first-line diagnostic procedure in evaluating CMV-infected fetuses.[36,37]

Maternal and Fetal Risks

Approximately 10% of healthy adults infected with CMV for the first time may develop a syndrome of fever, atypical lymphocytosis, malaise, and mild lymphadenopathy, which generally follows a benign course. This illness is clinically indistinguishable from Epstein-Barr virus (EBV) mononucleosis, save that the heterophil-antibody test is negative in patients with CMV infection. Patients with CMV mononucleosis tend to be slightly older than patients with EBV infection. This syndrome is generally self-limiting, although the fever may last for over a month. Serious complications of the acute infection rarely occur, including interstitial pneumonitis, hepatitis, Guillain-Barré syndrome, meningoencephalitis, myocarditis, thrombocytopenia, and hemolytic anemia.[38] The virus may be excreted in tears, saliva, breast milk, cervical secretions, and urine for weeks, months, or years after a primary infection. A latency period eventually occurs, but reinfection and reactivation are common.[39]

CMV infection in the immunosuppressed patient can be serious, depending on the type and degree of immunosuppression.[40] Patients on immunosuppressive drugs because of organ transplantation or patients with AIDS most commonly exhibit the mononucleosis syndrome. The next most frequent manifestation is interstitial pneumonia, which may progress rapidly from asymptomatic to fatal disease (often in association with *Pneumocystis* infection in AIDS patients). A large percentage of persons suffering primary CMV infection exhibit hepatitis; severely immunosuppressed patients may develop clinical symptoms, including malaise, nausea, and vomiting. Gastrointestinal disease, including ulceration leading to hemorrhage and perforation, is another effect of CMV in the immunocompromised patient. The AIDS patient may suffer coexistent CMV infection with other infections such as cryptosporidiosis and *Mycobacterium*

avium-intracellulare. In fact, endoscopic examination of the AIDS patient with colitis due to CMV may demonstrate lesions that resemble Kaposi's sarcoma. Finally, in the AIDS patient specifically, CMV infection of the eye may produce retinitis, typically noted in neonates with the disease, and miscellaneous effects on endocrine organs, including adrenals, pancreas, parathyroids, pituitary, and ovaries.

Venereal spread of CMV is conceptually attributed to the presence of virus in the semen and to cervical shedding. CMV has been isolated from semen of both homosexual and heterosexual men.[41] Heterosexual transmission has been demonstrated by outbreaks of CMV mononucleosis among populations of sexual partners.[42] Aside from the fact that differences in rates of cervical shedding are noted in different patient groups throughout the world, it is fairly clear that sexual activity, in particular higher numbers of sexual partners and earlier age at onset of sexual activity, is positively correlated with CMV isolation from the cervix.[43]

Whereas CMV is transmitted by such routes as transfused blood[44] and bone marrow,[45] a common route of acquisition is through perinatal transmission. The fetus may be infected either transplacentally or by exposure to the virus from the cervix and birth canal. The neonate may also be infected by virus excreted in breast milk[46]; however, the risk appears to be low.[47,48] Another source of childhood infection is exposure to other babies in nurseries and daycare centers,[49–51] because infected children tend to shed virus from the urine and respiratory tract for a prolonged time (unlike infected but otherwise healthy adults).

The rate of seropositivity varies by age and multiple demographic factors. The rate increases steadily after the first year or two of life. The prevalence is higher in underdeveloped countries[52] and in lower socioeconomic patient populations.[53] One study of over 21,000 women attending a prenatal clinic in London revealed marked variation by race (white, 46%; Asian, 88%; black, 77%), parity (increasing seropositivity with increasing parity), and socioeconomic status.[54,55] Among most middle-income women in Alabama, 54% were seropositive, with whites having a lower rate than blacks.[53] The incidence of seroconversion in women of childbearing age approximates 2% in high socioeconomic groups and up to 6% in lower socioeconomic groups. The higher infection rate in young adults (hence mothers) does not necessarily lead to higher congenital infection rates.[56]

Primary infection occurs in 1% to 3% during pregnancy, with approximately 40% to 50% of women of childbearing age being serologically determined to be susceptible to such primary infection.[53,57] Estimates are that each year in the United States, approximately 340,000 non-Hispanic white persons, 130,000 non-Hispanic black persons, and 50,000 Mexican American women of childbearing age experience a primary CMV infection.[58] Serologic or culture evidence of in utero CMV infection is present in 0.2% to 2.2% of all liveborns. Thus, congenital CMV infection is a major health problem; CMV is still thought to be the most common congenital infection in the United States based on serologic study.[39,59,60]

Unlike other viral infections, CMV, on the basis of its latency and intermittent shedding from the female genital tract, may infect a fetus or neonate despite the presence of maternal antibody. Virus is shed from the cervix more

readily as gestation progresses and occurs in approximately 0% to 2% of women in the first, 6% to 10% in the second, and 11% to 28% in the third trimester.[13] The infection rates at birth are higher in newborns whose mothers excrete virus. The most severe neonatal disease usually occurs in children born to women who experience primary infection during pregnancy. Vertical transmission of CMV occurs in 21% to 50% of fetuses following primary maternal infection.[29,30,61] A study of preconceptional and periconceptional primary CMV infection in 25 women identified a 9% risk for congenital fetal infection in the preconceptional group (1 of 12 newborns) and a 31% risk in the periconceptional group (4 of 13 newborns).[62]

Naturally acquired immunity results in a 69% reduction in the risk of congenital CMV infection in future pregnancies.[63] In addition, severe transplacental infection is not usually seen in children of women with preexisting antibody.[64] However, maternal preconceptional immunity to CMV does not provide complete fetal protection, and secondary CMV infection might cause severe sequelae in the fetus.[65–67] Thus, sonographic findings suggestive of CMV infection should prompt further investigation even if maternal serology does not support recent maternal infection.

CMV infection occurs in approximately 1 of 150 newborn infants. In the United States, this results in an estimated 33,000 infected newborns annually[68–70]; in the United Kingdom, CMV causes much more neonatal disease than rubella.[59] Approximately 5% to 10% of infected newborns are clinically symptomatic at birth. This is one of the classic TORCH (toxoplasmosis, other infections, rubella, CMV infection, and HSV) syndromes, consisting of hepatosplenomegaly, hyperbilirubinemia, petechiae, thrombocytopenia, intracranial calcifications, microcephaly, and often growth restriction. In primary infection, mortality may be as high as 20% to 30%, with 90% of survivors suffering late complications (Fig. 30–1) using "averaged" published data.[71] Of the asymptomatic infected neonates, 5% to 15% develop some abnormality attributable to CMV before their second birthday, primarily sensorineural hearing loss.[60,72] Vertical transmission may also occur in recurrent CMV infection[73]; however, the percentage of symptomatic children at birth or of those developing sequelae is much lower (Table 30–1).[74]

CMV is the most common cause of congenital sensorineural hearing loss, developing in 30% of neonates symptomatic at birth.[75] Hepatosplenomegaly is the most common clinical finding. Microcephaly, frequently associated with paraventricular cerebral calcifications, is also common.[76] Chorioretinitis, optic atrophy, mental and psychomotor delay, learning disabilities, and dental abnormalities are reported. Overall, congenital CMV infection leads to severe sequelae in 1 of 750 newborn infants, affecting close to 8000 children annually. Thus, congenital CMV infection is the most common cause of birth defects and childhood disabilities. Better-known childhood disabilities such as Down syndrome affect approximately 4000 children per year, fetal alcohol syndrome approximately 5000 infants per year, and spina bifida approximately 3500 newborns annually. Public and physicians awareness of these conditions are high compared with congenital CMV disease.[68–70] In a recent survey, 44% of obstetrician-gynecologists counseled their patients on preventing CMV infection, emphasizing the need for

additional training.[68] In a different study, only 14% of women had heard of CMV, indicating the potential of preventional behavior education.[77]

Management Options

Treatment of acute, symptomatic CMV infection in the immunocompetent normal individual is palliative. The vast majority of infections are asymptomatic; the remainder are mild. Currently, eradication of the virus is beyond the capacity of modern medicine. In the patient with compromised immunity, such as the transplant patient or the patient with AIDS, the antiviral drug ganciclovir provides temporary relief from such severe effects as retinitis.[13] To date, there is no accepted therapy for acute maternal or neonatal infection.[78]

There is progress in the development of a specific CMV vaccine,[79] although a number of real and theoretical obstacles remain.[80] Even though complete eradication of the virus may appear unlikely, antibody presence similar to that after primary human infection could reduce the rate of congenital fetal infection and its sequelae. Thus, an effective CMV vaccine will be a significant step forward. Passive immunization with specific anti-CMV immunoglobulins appears to be useful as prophylaxis in cases of renal and marrow transplantation.[81] Thus, prevention of maternal infection is clearly the strategy to avert intrauterine infection. Three different areas offer potential to reduce the likelihood of maternal CMV infection in pregnancy: patient education, physician education, and vaccine development. CMV is typically spread by interpersonal contact with transmission of infected secretions from person to person, so, in particular, pregnant women working in high risk situations (e.g., daycare centers) should be counseled to wash their hands carefully after changing diapers and after any contact with children's secretions (e.g., saliva).[78,82] Mouth-to-mouth kissing with children should be discouraged. Physicians need to be aware of the risk of transfusion-related CMV transmission.[83] Thus, when transfusing women of childbearing age who could potentially be or soon become pregnant, CMV-negative blood products should be used whenever possible. Any fetal transfusion in utero must use CMV-negative washed packed cells to avoid fetal CMV contamination. It is not appropriate, however, to screen all pregnant women for either anti-CMV IgG or viral excretion with the aim of isolating them for the duration of the pregnancy. The most reasonable course is to serologically screen all women in high risk areas (e.g., daycare workers) and recommend to susceptible individuals

that they pay attention to hygiene measures. For prevention of CMV as well as other sexually transmitted diseases (STDs), all women with nonmonogamous relationships should be strongly encouraged to use condoms during sexual contact.[78]

No effective fetal therapy is yet available. Ganciclovir has been administered into the umbilical vein of a fetus at about 27 weeks. The dosage was 10 mg/day for 5 days, 15 mg/day for 3 days, and 20 mg/day for 4 days. Several episodes of bradycardia were noted after administration. Although the viral load in amniotic fluid decreased dramatically over the time of treatment and liver function tests improved, a fetal demise was noted at 32 weeks.[84] Antiviral treatments in pregnant women have been performed only on a small scale and with moderate effect.[85,86] Toxicity and cost-effectiveness are the main concerns. CMV hyperimmuno-globulin therapy in women with primary CMV infection during pregnancy appears to be promising in reducing CMV disease in the infants; however, the effectiveness and safety of this treatment await results of an international trial under way.[87–89]

Therapy of severely infected newborns with antiviral drugs had only a moderate effect.[90] In the absence of safe and effective treatment of fetal CMV infection, prevention through education of patients and physicians remains the most effective means to reduce the incidence of congenital CMV disease to date.

Assessment of effective newborn screening is the next step in order to early identify infants at risk for CMV disease and to reduce sequelae. Advances in the development of vaccines are promising; however, a licensed CMV vaccine appears to be years away.

SUMMARY OF MANAGEMENT OPTIONS
Cytomegalovirus

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Advise women working in high risk environment (e.g., child care) about risks.	III/B	50,78,82
Counsel pregnancy planning in women with history of proven CMV infection	—/GPP	—
• Establishing their "shedding status" may help.	—/GPP	—
Encourage use of condoms in nonmonogamous relationships.	IV/C	78
Use CMV-negative blood products in transfusions.	IV/C	83
Prenatal		
Advise women working in high risk environment (e.g., child care) about risks.	III/B	50,78,82
Use CMV-negative blood products in transfusions.	IV/C	83
If patient is diagnosed to have CMV infection in pregnancy:	—/GPP	—
• Offer careful counseling about fetal risks.		
• Consider invasive procedure to establish fetal risk.		
• Check fetal growth and health.		
• Consider pregnancy termination (if early gestational age).		
• No effective treatment, although acyclovir, ganciclovir, valaciclovir, CMV-specific hyperimmunoglobulin have been used.	IV/C	13,84,85, 88,89
Labor, Delivery, and Postnatal		
If patient is diagnosed to have CMV infection in pregnancy:	—/GPP	—
• Put infection control measures in place.		
• Conduct clinical and serologic evaluation of the newborn with pediatric follow-up if infection confirmed.

HERPES SIMPLEX VIRUS

General

HSV is a DNA virus of the herpes family. HSV-1 has classically been considered the cause of orolabial herpes, referred to commonly as *fever blisters*; HSV-2 has been considered the cause of genital herpes infection, a well-known STD. Although these two types of HSV are generally thought to be segregated in this way, there is a great deal of overlap, that is, of HSV-2 causing oral disease and HSV-1 causing genital infection. In fact, up to a third of genital infections may be due to HSV-1. However, HSV-1 is somewhat less prone to produce recurrent infection than HSV-2. Generally, the two viruses may be considered identical in the clinical circumstance of a patient with characteristic ulcerative lesions.[91]

Diagnosis

HSV is relatively easy to culture; viral culture is the preferred test of genital HSV infection in patients who present with genital ulcers. The sensitivity of culture declines rapidly as lesions begin to heal, usually within a few days of onset. When more rapid diagnosis is desirable, FA staining performed on short-incubation tissue culture slides allows identification within 48 hours, especially when the original specimen contains large numbers of virus. In high-inocula situations, direct FA staining of the original specimen may give the diagnosis, though it is neither as sensitive nor as specific as tissue culture.[92,93] PCR assays for HSV DNA are highly sensitive and can be used to rapidly detect HSV DNA in pregnant women.[94]

Type-specific antibodies to HSV develop during the first 6 to 8 weeks after infection and persist indefinitely. Accurate type-specific assays must be based on the HSV-1–specific glycoprotein G1 for diagnosis of infection with HSV-1 and on the HSV-2–specific glycoprotein G2 for diagnosis of infection with HSV-2.[95,96] Sensitivity of serology tests vary between 80% and 90%, and false-negative results may occur, especially at early stages of infection. Specificity is greater than 96%, and false-positive results can occur. Thus, repeat testing may be indicated in some settings. Type-specific serology in combination with HSV culture and DNA testing by PCR might prove helpful in confirming a clinical diagnosis of genital herpes, especially in patients with healing sores or recurrent episodes of genital herpes when HSV culture provides false-negative results.[97] Clinical examination is likely to miss many cases of genital herpes,[98] and antepartum cultures do not predict viral shedding at the time of delivery.[99]

The Centers for Disease Control and Prevention (CDC)[95] provides guidelines on the use of type-specific serologic tests. The CDC recognize the significance of using serologic testing: (1) to confirm clinical diagnoses, (2) to diagnose people with unrecognized infection, and (3) to manage sex partners of persons with genital herpes. Because cultures are frequently false-negative, serologic tests can be useful in confirming a clinical diagnosis. The guidelines note that some specialists believe that type-specific serologic tests are useful to identify pregnant women at risk for HSV infection and to help them with counseling regarding the risk of acquiring genital herpes during pregnancy. There is no place for using IgM antibody testing to determine primary versus recurrent HSV infection.

There are three stages of HSV infection based on clinical presentation and serology.

Primary Infection

Primary HSV infection is confirmed when no HSV-1 or HSV-2 IgG antibodies are present. Primary genital infection, due to HSV-2 or HSV 1, when symptomatic, presents with mild to severe symptoms and numerous genital lesions. Genital lesions occur on the vulva, vagina, and cervix, between 2 and 14 days, and are multiple and more numerous than those observed in recurrent disease. Vaginal discharge, dysuria, and vaginal burning can be presenting symptoms. Regional lymphadenopathy is caused by virus replication in the sites of lymphatic drainage. Systemic symptoms (malaise, myalgia, and fever) are found during primary herpetic

infection. It is important to appreciate that primary infection may be asymptomatic.

Nonprimary First-episode Disease

In nonprimary first-episode disease, HSV-1 antibodies are present in the woman who acquires genital HSV-2 infection for the first time. If the infected person possesses preexisting anti-HSV 1 antibody, there are fewer constitutional symptoms, lesions, and complications, and the duration of the lesions and the time of viral shedding are reduced.[91]

Recurrent Infections

In recurrent infections, homologous antibodies are present.[100] Routine screening in the general population appears not to be cost-effective[101] and is not recommended.[95] However, identification of seronegative women provides the opportunity to properly address the risk of primary transmission during pregnancy and counsel serologically discordant couples, in particular.[102]

In recurrent genital herpes, lesions tend to be limited in size and number. They recur usually on one area of the external vulva, and no more than three lesions are found with clinical examination. A diffuse cervicitis or a single large ulcer may demonstrate cervical involvement. Local irritation or pain is the presenting complaint, and there may be an increase in vaginal discharge or dysuria. The external genital tract is the site of intermittent virus replication. Virus shedding without a lesion (asymptomatic shedding) can occur from the vulva and cervix intermittently in subsequent years after primary infection. Asymptomatic shedding of virus lasts an average of 1.5 days.

Epidemiology and Transmission of Herpes Simplex Virus-1 and Herpes Simplex Virus-2

A susceptible partner can acquire this virus during times of asymptomatic shedding.[103] Shedding of virus without any symptoms or signs of clinical lesions (asymptomatic shedding) makes this viral STD difficult to control and prevent. Patients will experience recurrent disease after clinical or asymptomatic primary HSV genital infection. Recurrences of genital HSV infection can be symptomatic or asymptomatic, and there is significant variation from patient to patient in the frequency, severity, and duration of symptoms and viral shedding. Young adult women typically acquire the first episode of genital herpes between the ages of 20 and 24 years.

Primary orolabial herpes is mainly a disease of childhood, children acquiring the infection from family members through close contact. Although 90% to 95% of primary oral infections are asymptomatic, a few may consist of a rather florid vesiculoulcerative outbreak in the oropharynx and lips about a week after exposure. Adenopathy and viremia, along with fever and malaise, may persist for a week or two, with viral shedding for up to 6 weeks. Thereafter, antibody production limits the virus such that it remains dormant, occasionally flaring up as localized blisters on the lips in times of stress, sunburn, or febrile systemic illness (hence the term *fever blisters*). During recurrent disease, viral shedding lasts up to a week.[104]

Genital herpes may occur after sexual contact, either genital-genital or orogenital, with an infected person. The

incubation period is 2 to 14 days. Persons transmitting the virus may be asymptomatic themselves,[105] confusing identification of the origin of the infection. In one study, 10% of pregnant women were at risk for contracting primary HSV-2 infection from their HSV-2–seropositive husbands.[102] Asymptomatic cervical and vulvar shedding following a primary HSV infection occurs in 2.3% of women with HSV-2 infection and 0.65% with HSV-1 infection.[106] In the absence of circulating antibody, primary HSV genital infection can be severe, with symptoms of fever, malaise, myalgias, and aseptic meningitis. HSV encephalitis[107] and hepatitis[108] have proved fatal. Lower motor neuron and autonomic dysfunction may lead to bladder atony and urine retention. Increased viral shedding occurs for nearly 3 weeks in severe cases if untreated. Local disease may recur weeks or months later if the offending virus is HSV-2, in particular, which recurs much more frequently than does HSV-1, especially in the genital area.[109]

Genital herpes infection is common in the United States, with 45 million people ages 12 and older, or one out of five of the total adolescent and adult population, infected with HSV-2.[110] Since the late 1970s, the number of people in the United States with genital herpes infection has increased by 30%. HSV-2 infection is more common in women (~1 of 4) than in men (~1 of 5), and more in blacks (45.9%) than in whites (17.6%). The largest increase is now occurring in young white teens. HSV-2 infection is now five times more common in 12- to 19-year-old whites, and it is twice as common in young adults ages 20 to 29 than it was in the late 1980s.[110] Among sexual partners discordant for HSV infection, the annual risk of acquisition of genital HSV infection was 31.9% among women who were both HSV-1– and HSV-2–negative versus 9.1% among women who were HSV-1–positive.[111] Approximately 1.6 million new HSV-2 infections are acquired yearly, and approximately 2% of women seroconvert to HSV-2 during pregnancy.[112,113]

Maternal and Fetal Risks

Because of the relative immunosuppression during pregnancy,[114] dissemination of HSV may lead to death from hepatitis, encephalitis, and general viral dissemination.[115] Primary infection early in pregnancy, perhaps due to a viral endometritis ascending from cervical infection, may end in spontaneous abortion. However, there are no consistent reports of a congenital syndrome due to intrauterine infection with HSV. The spectrum of fetal/neonatal infection includes abortion, prematurity, and intrapartum infection with resultant disseminated HSV infection.[116]

Primary HSV infection in the second or third trimester increases the risk for preterm delivery as well as the risk of virus transmission to the newborn.[117] The fetus acquiring HSV, especially if the mother suffers an acute, primary infection, may sustain severe neonatal morbidity, including chorioretinitis, meningitis, encephalitis, mental retardation, seizures, and death.[118]

Since the late 1980s or 1990s, industrialized countries have reported a decrease in seropositivity rates of HSV-1, due perhaps to increasing sanitation measures, and increasing rates of HSV-2, due to increasingly permissive sexual behavior.[119] The rates of clinical genital HSV infection have risen dramatically since the 1960s in the United States,[120] United Kingdom, and other parts of Europe.[119]

The incidence of a positive culture in laboring women is 0.5% in the general population.[121] Rates of 0.96%[99] to 2.4%[122] have been reported in asymptomatic women with known histories of genital HSV infection. The rate of neonatal disease is in the range of 0.01% to 0.05%. The variability is due to differences in maternal antibody (and thus passively acquired fetal antibody) levels and the size of the viral inoculum (i.e., primary, severe infection versus mild, recurrent infection in the mother). The majority of infants developing neonatal HSV infection are born to mothers without symptoms or even a history of genital herpes infection and who test seronegative for specific HSV antibodies.[99,121,123] In Seattle, a prospective study was conducted in a cohort of 58,362 pregnant women, of whom 40,023 had genital HSV cultures at the time of labor and 31,663 had HSV specific serology; 202 women (0.5%) had a positive HSV culture, of whom 10 (5%) had neonates with HSV infection.[121] Women without a history of genital herpes were more likely to shed HSV asymptomatically than women with such a history. However, women with a history of genital herpes were more likely to have cesarean deliveries. The rate of vertical HSV transmission was 31.3% (5/16) in HSV-1–culture-positive mothers, and 2.7% (5/186) in HSV-2–positive mothers. Neonatal HSV infection rates per 100,000 live births were 54 among HSV-seronegative women, 26 among women who were HSV-1–seropositive only, and 22 among all HSV-2–seropositive women. Thus, the highest rate of neonatal HSV infection occurred in women who were seronegative and had no specific HSV antibodies. Heterologous antibody in this study did not seem to protect against transmission for primary versus nonprimary first-episode as, in contrast, did homologous antibody. The results emphasize the need for counseling seronegative women, in particular, to reduce the risk of neonatal HSV infection.

Most neonatal HSV infection is the consequence of delivery of a neonate through an infected birth canal. Most infants have localized skin, eye, and mouth disease, which usually is a mild illness. However, localized disease may progress to encephalitis or disseminated disease. Disseminated disease is associated with a 57% mortality rate; central nervous system (CNS) disease has 15% mortality; and localized disease shows no mortality.[124] In a group of 202 women from whom HSV was isolated, HSV transmission occurred in 9 of 117 (7.7%) infants after vaginal delivery, and in 1 of 85 (1.2%) newborns delivered by cesarean section.[121] Thus, cesarean section could reduce the rate of HSV transmission from mother to infant, but cannot completely prevent HSV infection in the newborn.

Management Options
Prepregnancy

The consistent, correct use of latex condoms can help protect against infection, particularly in women.[125] However, condoms do not provide complete protection because the condom may not cover the herpes sore(s) and viral shedding may nevertheless occur, which makes this STD difficult to prevent. In case of symptomatic genital herpes, it is best to abstain from sex and to use latex condoms between

outbreaks. More recently, daily valacyclovir (500 mg) suppressed overt acquisition of HSV-2 in susceptible sexual partners. Overall acquisition, symptomatic and asymptomatic, was reduced by 48% in the valacyclovir group compared with the placebo group. Treatment with valacyclovir 500 mg daily decreases the rate of HSV-2 transmission in discordant, heterosexual couples in which the source partner has a history of genital HSV-2 infection. Such couples should be encouraged to consider suppressive antiviral therapy as part of a strategy to prevent transmission, in addition to consistent condom use and avoidance of sexual activity during recurrences.[95,103]

Prenatal

It is important that women avoid contracting herpes during pregnancy because a primary infection during pregnancy causes a greater risk of transmission to the newborn. All pregnant women should be asked whether they have a history of genital herpes. However, history is an unreliable method for identifying women at risk of acquiring genital herpes or those who are already infected.[110] Women without known genital herpes should be counseled to avoid intercourse during the third trimester, in particular, with partners known or suspected of having genital herpes. In addition, women with no history of orolabial herpes should be advised to avoid cunnilingus during the third trimester with partners known or suspected to have orolabial herpes.[95] When a woman's sex partner has a history of HSV infection, serologic testing for HSV-1 and HSV-2 antibodies might prove to be helpful to identify and consequently counsel seronegative women at risk for primary HSV infection during pregnancy. Pregnant women with a significant primary HSV infection may need to be hospitalized and monitored closely for evidence of sequelae. Premature labor should be appropriately treated when identified. Evidence of severe, disseminated disease such as hepatitis (elevated hepatic transaminase levels) and encephalitis (abnormal neurologic testing) should trigger the administration of intravenous acyclovir to prevent serious morbidity.[115] Treatment of primary genital herpes with oral antiherpetic agents is indicated to reduce viral shedding, reduce pain, and heal lesions faster.[126] Different studies have demonstrated that the use of acyclovir and valacyclovir is safe during pregnancy and does not impose an increased risk to the developing fetus even during the first trimester.[126–128] Dosing schedules are presented in Table 30–2. No induction of acyclovir-resistant HSV strains was noted in immunocompetent patients.[129] However, the extent to which suppressive therapy prevents HSV transmission to the infant is unknown.[95] In severe HSV disease, intravenous acyclovir is given at 5 to 10 mg/kg body weight every 8 hours for 2 to 7 days or until clinical improvement is observed. Oral antiviral therapy should follow to complete at least 10 days total therapy.[95] Oral acyclovir or valacyclovir and intravenously administered acyclovir reached therapeutic concentrations in the breast milk, the amniotic fluid, and the fetus.[130] Topical treatment with acyclovir offers no clinical benefit and should not be used to treat genital herpes.[95] Newer antiherpetic drugs, valacyclovir and famciclovir, demonstrate increased bioavailability over acyclovir and thus require less frequent dosing.

Antiviral prophylaxis of the mother to prevent maternal symptomatic and asymptomatic viral shedding during the

TABLE 30–2

Treatment Recommendations for Genital Herpes in the Nonpregnant Patient

CLINICAL SETTING	RECOMMENDED REGIMEN
First clinical episode of genital herpes	Acyclovir 400 mg orally three times a day for 7–10 days* OR Acyclovir 200 mg orally five times a day for 7–10 days OR Famciclovir 250 mg orally three times a day for 7–10 days OR Valacyclovir 1 g orally twice a day for 7–10 days
Suppressive therapy for recurrent genital herpes	Acyclovir 400 mg orally twice a day OR Famciclovir 250 mg orally twice a day OR Valacyclovir 500 mg orally once a day OR Valacyclovir 1.0 g orally once a day
Episodic therapy for recurrent genital herpes	Acyclovir 400 mg orally three times a day for 5 days OR Acyclovir 800 mg orally twice a day for 5 days OR Acyclovir 800 mg orally three times a day for 2 days OR Famciclovir 125 mg orally twice daily for 5 days OR Famciclovir 1000 mg orally twice daily for 1 day OR Valacyclovir 500 mg orally twice a day for 3 days OR Valacyclovir 1.0 g orally once a day for 5 days

* Treatment might be extended if healing is incomplete after 10 days of therapy.

From Centers for Disease Control and Prevention, Workowski KA, Berman SM: Sexually transmitted diseases treatment guidelines, 2006. MMWR Recomm Rep 2006;55(RR-11):1–91.

intrapartum period is now recommended by the American College of Obstetricians and Gynecologists.[131–134] Acyclovir, valacyclovir, and famciclovir are class B medications as categorized by the U.S. Food and Drug Administration. Starting in 1984, an acyclovir pregnancy registry has been compiled. The CDC published data in 1993 showing there was no increase in fetal problems in women who received acyclovir in the first trimester of their pregnancy.[135] Ongoing studies examining newer recommendations to reduce the number of newborns infected with HSV are focused on identifying pregnant women susceptible to HSV infection.[135] The strategy is to test all pregnant women for antibodies to HSV-1 and HSV-2 (using a type-specific glycoprotein G-based testing) and to initiate the antiviral prophylaxis starting at 36 weeks' gestation in selected cases. Intervention is aimed at preventing primary infection in those at risk.

Labor and Delivery

On admission to the delivery suite, all women should be questioned carefully about symptoms of genital herpes, and all women should be examined carefully for herpetic

lesions.[95] In the absence of visible lesions in the genital area at the onset of labor, vaginal delivery is permitted. If active genital lesions or prodromal symptoms of vulvar pain or burning (which may indicate an impending outbreak) are present, cesarean delivery is indicated. The incidence of infection in newborns whose mothers have recurrent infection is low, but cesarean delivery is warranted because of the serious nature of the disease.

The extent to which maternal antibodies will protect a neonate from an infection during a recurrence has not been determined with certainty. Cesarean delivery is not recommended in women with a history of HSV infection but no active disease during labor.[95,136]

In women with premature rupture of membranes (PROM) near term and active HSV infection, cesarean delivery should be performed as soon as possible. It should not, however, be assumed the fetus is infected just because of prolonged rupture of membranes. Women with preterm PROM and active lesions are considered individually, taking into account gestational age and other relevant factors.

Remote from term, expectant management and use of glucocorticoids are increasingly supported, and antiviral therapy is indicated because premature neonates are at greatest risk of infection.[136]

Fetal HSV infection has been attributed to the use of fetal scalp electrodes even in the absence of active lesions.[121,137] Thus, fetal scalp monitoring should be used cautiously even in women with a history of recurrent HSV and no active lesions.

Postnatal

Postpartum, endometritis due to HSV infection has been reported[138] and is responsive to acyclovir. Postnatally acquired HSV infections in the newborn can be severe, and mothers with skin or oropharyngeal lesions should use caution when handling their babies. HSV-1 is more likely to cause nosocomial infections in the infant than is HSV-2. Breast-feeding is unlikely to cause infection in the infant; only in the case of an obvious lesion on the breast is breast-feeding contraindicated.[130]

SUMMARY OF MANAGEMENT OPTIONS
Herpes Simplex Virus

Management Options	Evidence Quality and Recommendation	References
Prepregnancy and Prenatal		
Inform about nature of the disease and that sexual transmission can occur during asymptomatic periods; counsel about condom protection during asymptomatic intervals and sexual abstinence during active disease.	IV/C	95,125
Perform HSV type-specific serology testing; allows more specific advice by identifying seronegative women at risk for HSV acquisition.	IV/C	95
• Advise HSV-2–negative women to abstain from intercourse during third trimester with men who have genital herpes.		
• Advise HSV-1–negative women to avoid intercourse with a partner who has genital HSV-1 infection; no cunnilingus with a partner who has orolabial herpes.		
Provide symptomatic treatment of infections (primary and recurrent); hospitalize for severe cases.	—/GPP	—
Give acyclovir for active disease:		
• Oral (7–14 days) for primary local infection.	Ib/A	126
• IV (for 2–7 days then oral) for primary systemic disease.	IV/C	115
• Oral (5 days) for recurrent disease.	III/B	136
Provide prophylactic acyclovir (400 mg bid) for last trimester in patients with previous HSV to reduce recurrence risk (no known effect on fetal/neonatal transmission).	Ib/A	131,132
No information about newer anti-HSV drugs; not recommended for pregnancy.	—/GPP	—
Remain vigilant for dissemination.	—/GPP	—
Remain vigilant for preterm uterine activity.	—/GPP	—
Serial viral cultures are no longer recommended in the last trimester for patients who are asymptomatic; culture only to document a new case.	IV/C	95
Consider delivery with septicemic cases.	—/GPP	—

SUMMARY OF MANAGEMENT OPTIONS
Herpes Simplex Virus—cont'd

Management Options	Evidence Quality and Recommendation	References
Labor and Delivery		
Inquire and inspect perineum, vagina, and cervix for HSV in all women at onset of labor (especially those with history of HSV).	IV/C	95
Allow vaginal delivery if no active lesions and no prodromal symptoms at time of labor.	—/GPP	—
Active lesions at time of labor is considered an indication for cesarean section by most obstetricians, though the risk of fetal infection is less with recurrent disease.	—/GPP	—
Counseling about the benefits of cesarean section in preventing fetal infection with membrane rupture is controversial, although most would still advise cesarean section. Expectant approach with suspected preterm labor and PROM is reasonable.	—/GPP	—
Avoid fetal electrodes and fetal scalp sampling.	Ib/A	121,137
Postnatal		
Maintain infection control measures if mother has active lesions.	—/GPP	—
Treat maternal infection; reduces dissemination and morbidity.	III/B	136
Perform clinical, microbiologic, and serologic evaluation of the newborn if active maternal lesions are present.	—/GPP	—
Give IV acyclovir to HSV-infected newborns.	III/B	136

GPP, good practice point; HSV, herpes simplex virus; PROM, premature rupture of the membranes.

ADENOVIRUS

General

Adenoviruses are medium-sized (90- to 100-nm) double-stranded DNA viruses. There are 6 subgenera (A through F) with 49 immunologically distinct types that can cause infection in the human. Most commonly, in the healthy adult, adenovirus infection causes gastrointestinal and respiratory tract illness with a wide range of symptoms.

There has been considerable interest in developing adenoviruses as defective vectors to deliver and express foreign genes for therapeutic purposes.[139–141] Furthermore, adenovirus vectors have been used to better understand mechanisms of intrauterine inflammation and fetal programming.[142,143] Adenovirus is relatively easy to manipulate in vitro, and the coupled genes are effectively expressed in large amounts. Direct administration of adenovirus gene vectors to the fetus can be achieved by fetoscopy or ultrasonographic guidance.[144,145] However, repeated prenatal exposure to an adenovirus vector was associated with pulmonary inflammation as reported in newborn sheep.[146] Alternatively, selective placental and maternal intravenous adenovirus vector application has demonstrated only low numbers of adenovirus replication in the fetus, thus reducing the risk of fetal exposure to the virus.[147] In addition, intraplacental adenovirus-mediated gene delivery showed only low numbers of virus in the mother, thus possibly providing a suitable strategy for basic studies of placental function or even a method of correcting placental dysfunction in the future.[148] Amniotic fluid–derived stem cells have been effectively transduced by adenovirus vectors, thus possibly providing pluripotent stem cells for use in gene therapy treatment.[149]

Diagnosis

Conventional virus culture, electronmicroscopy and serology tests,[150,151] and modern laboratory techniques such as antigen detection by immunofluorescence tests[152] and PCR assay[23] are all suitable means to identify adenovirus disease. Adenovirus typing requires the use of type-specific antisera in hemagglutination-inhibition and/or neutralization tests.[150,151] Adenovirus infection in tissues or cell smears can be identified using in situ hybridization technique.[153] The presence of adenovirus does not necessarily mean disease because viruses can be shed for a prolonged time. Adenovirus genome could be identified in amniotic fluid of 30 of 91 (33%) fetuses with ultrasound evidence of nonimmune hydrops. However, concomitant infection with parvovirus, CMV, enterovirus, HSV, and respiratory syncytial virus was found in the majority of cases by PCR technique.[23]

Maternal and Fetal Risks

In healthy adults, adenoviruses commonly cause respiratory illness with symptoms that range from the common cold to pneumonia, croup, and bronchitis. However, depending on the serotype or route of infection (inhalation or ingestion), adenoviruses might cause febrile disease and keratoconjunctivitis, rash illness, gastroenteritis, or cystitis. Immunocompromised patients are susceptible to severe complications of adenovirus infections.

Transmission is by direct contact and the fecal-oral route. Adenoviruses are unusually stable in adverse conditions. Occasionally, waterborne transmission occurs, often centering around swimming pools and small lakes. Infection is usually acquired during childhood and at a higher incidence in late winter, spring, and early summer. Depending on the serotype, adenovirus infection can persist in either the tonsils, the adenoids, or the intestines of infected patients. Virus shedding can continue for years. Adenovirus types 40 and 41 are known to cause gastroenteritis, primarily in children. Inhalation of adenovirus type 7 is known to cause severe lower respiratory tract infection, and acute respiratory disease is most often associated with types 4 and 7.[150,151]

Adenovirus infection of the infant might occur transplacentally or at delivery via birth canal or contact with feces. Amniotic fluid obtained from 303 pregnancies with abnormal ultrasound findings tested positive for adenovirus infection in 124 cases (41%). PCR technique could demonstrate adenovirus to be the only viral genome present in the amniotic fluid of oligohydramnios in 18% (2/11; 2 additional patients positive for CMV), hydrothorax/pleural effusion in 22% (4/18; 2 additional patients positive for enterovirus and CMV), ventriculomegaly in 23% (6/26; 1 additional patient positive for CMV), microcephaly in 20% (1/5), and echogenic bowel in 5% (1/22; 5 additional patients positive for CMV and HSV). In the control group of 154 structurally normal fetuses, viral infection of the amniotic fluid was detected in 4 cases (3%), and adenovirus was the only microorganism in 2% (3/154; 1 additional patient positive for CMV). Intrauterine adenovirus infection might cause fetal myocarditis with tachyarrhythmia, dilated cardiac chambers, poor ventricular function, and subsequent hydrops fetalis.[154,155]

Severe neonatal adenovirus illness is rare, but is most often manifested as necrotizing pneumonitis.[152,153,156,157] Within 10 days of birth, infected infants demonstrate rapidly progressing pneumonia, thrombocytopenia, disseminated intravascular coagulopathy, hepatomegaly, and hepatitis. Respiratory failure might require extracorporeal membrane oxygenation in the newborn.[158] Case fatality might be as high as 84% and death often occurs around day 16.[156,159,160] Neonatal infection may also be seen in epidemic proportions in neonatal nurseries.[161] Severity of the disease in newborns seems to be less pronounced in the presence of maternal antibodies.

Management Options

Prepregnancy and Prenatal

To date, no specific therapy is available for adenovirus infections in pregnancy or for the infected newborn, although new antiviral drugs (cidofovir, ribavirin) show promising results in pediatric patients.[162,163] Thus, the best treatment of adenovirus infection is prevention. Women should be counseled on proper hygiene measures to avoid fecal-oral transmission. Also, inadequately chlorinated swimming pools should be avoided. Most infections are mild and require no therapy.

Severe adenovirus infection can be managed only by treatment of symptoms and complications. Fetal tachyarrythmia and associated fetal hydrops may be treated by maternal oral digoxin and other agents (see Chapter 15). Maternal therapy with oral digoxin at 0.5 mg loading, and 0.125 to 0.25 mg/day maintenance dose has shown to convert fetal tachyarrhythmia to normal sinus rhythm and to produce spontaneous resolution of hydrops. Transplacental transfer of digoxin is at an estimated rate of 60% to 100%. Maternal digoxin levels or persistent fetal tachyarrhythmia might require adjustment of the daily administered digoxin dosage. Vaccines for adenovirus types 4 and 7 were developed for military use only. Risk to the general population is so low that vaccination is not a viable proposition.

Labor, Delivery, and Postnatal

Strict attention to good infection control practices is effective in stopping nosocomial outbreaks of adenovirus disease such as epidemic keratoconjunctivitis.

COXSACKIEVIRUS

General

Coxsackievirus is a single-strand RNA virus, a member of the picornaviridae, which includes human enteroviruses and rhinoviruses. The enterovirus serotypes are determined by type-specific antisera and are traditionally grouped into four classes: poliovirus, group A coxsackievirus, group B coxsackievirus, and echovirus. Newly discovered serotypes are assigned enteroviral numbers (e.g., hepatitis A virus: enterovirus 72).

In northern latitudes, enterovirus infections are more firmly associated with a seasonal periodicity (pronounced in summer and fall) than can be observed in more tropical climates. However, infections may occur at any time of the year. Group B coxsackievirus serotypes 2 to 5 are isolated more frequently, whereas other serotypes are rarely reported. Group A coxsackievirus infections have been identified less frequently, possibly owing to poor growth in routine cell culture.

Enteroviruses are transmitted by direct contact with nose and throat discharge or feces of infected humans. Because many infections are clinically not apparent, spread of coxsackievirus infection may occur accidentally; the incubation period is 3 to 5 days (range 2–15 days).[164]

In healthy, nonpregnant adults, enterovirus infections either are asymptomatic or cause simple febrile illness with or without signs of upper respiratory tract infection or rash. However, some clinical syndromes are characteristically associated with enterovirus infection, including aseptic meningitis, pleurodynia, and the hand-foot-and-mouth disease. The rate of infection is higher in young children than among older children and adults.

Diagnosis

Coxsackievirus infection can be identified by virus culture from the oropharynx, stool, blood, urine, cerebrospinal fluid, and amniotic fluid. After virus isolation by culture, virus typing is performed by conventional neutralization tests. More rapid specific virus identification techniques using immunofluorescence assay (IFA) or enzyme-linked immunosorbent assay (ELISA) have not proved to be useful because of the large number of different serotypes.[165] However, development of monoclonal group-specific antibodies that can be used for rapid identification of enterovirus groups by IFA and ELISA is in progress.[166–168] Modern laboratory methods provide accurate and fast diagnosis of coxsackievirus infection by PCR technique.[23,169] In addition, PCR seems to be more suitable for detection of group A coxsackievirus that grows poorly in culture, which has led to a possible clinical underrecognition of this virus as a cause of disease.

Serology using hemagglutination-inhibition, complement fixation, and ELISA tests can readily identify IgG, IgM, IgA, and IgE classes of specific antibodies; however, the large number of different enterovirus type-specific antigens requires the performance of large numbers of serologic tests. Gene-sequencing technology has identified a common epitope in a number of enteroviruses, which might prove to be helpful for serology tests in the future.[168] When case serology is performed, paired specimens should be obtained to ensure proper diagnosis.

Tissue samples can be examined for specific enteroviral antigens by immunofluorescence or PCR technique.[170]

Maternal and Fetal Risks

The prevalence of enterovirus infection is inversely related to socioeconomic status and age, whereas individual factors, including age, sex, immune status, and pregnancy, are important determinants of the severity of infection.[171]

In pregnancy, most maternal coxsackievirus infections either are not apparent or cause only minimal symptoms similar to a viral upper respiratory tract infection or viral gastroenteritis[172]; however, hepatic failure has been reported.[173] The exact incidence of coxsackievirus infections in pregnancy is not known. There is no direct virologic evidence available that suggests that coxsackievirus infections in pregnancy may result in miscarriage.[165] However, an increased frequency of coxsackievirus IgM in women with spontaneous abortion has been reported.[174] In a collaborative study, serologic evidence of coxsackievirus B (types 1–6) infection during pregnancy was demonstrated in 9% of 198 women[175]; during peak enterovirus season, a seroconversion rate of 25% was noted during the last 2 to 6 weeks of pregnancy among 55 women.[176] Most women either were asymptomatic or had only mild symptoms, and no newborn had signs of severe enterovirus infection. The incidence of neonatal coxsackievirus B infection, based on laboratory records, was estimated at a minimum of 50 per 100,000 liveborn children.[177] Thus, enterovirus infection during late pregnancy might be a rather common event; however, most infections did not produce a significant maternal or neonatal morbidity. Alternatively, in women delivering newborns with evidence of group B coxsackievirus infection, 59% to 65% had symptomatic illness during the perinatal period with febrile disease and upper respiratory symptoms, pleurodynia, myocarditis, and aseptic meningitis.[171,177]

In animal studies, pregnant mice experimentally infected with different strains of enterovirus have a shorter incubation period, develop higher titers in blood and various organs, and remain viremic longer. Susceptibility increases with advancing gestation and rapidly reverts to that of nonpregnant animals within days of delivery. In nonpregnant female mice, administration of corticosterone or estrogen reduced the resistance to encephalomyocarditis virus infection, but this resistance was not altered by exogenous progesterone. Group B coxsackievirus infection of the pregnant mouse may also result in infection of the fetus before delivery or in infection of the mouse intrapartum.[171]

In humans, in vitro experiments demonstrated that vertical infection from mother to fetus rarely happens through transplacental passage.[178] However, 22% to 25% of neonatal group B coxsackievirus infections have been attributed to antepartal transmission.[172,177] The mechanisms of intrauterine coxsackievirus infection are poorly understood. Evidence of congenital disease is inconsistently related to recovery of virus from the placenta and the respective fetus,[165,176,179] and it is assumed that besides hematogeneous transmission involving the placenta, a number of fetuses might be infected by ingesting coxsackievirus contained in the amniotic fluid.[180] Transplacental infection of the fetus occurs in the

absence of maternal immunity and is unrelated to the clinical severity of the disease in the mother. Viral shedding from the cervix has been reported; however, ascending viral infection seems to be a rare event.[181] At the time of delivery, infection of the infant might occur by cervical or fecal contamination. Fecal carriage rates of coxsackievirus was reported to range from 0% to more than 6% in different population groups.[165,166]

In a study of 630 infants with 778 anomalies of different organ systems, intrauterine infection with coxsackievirus B2 and B4 was associated with urogenital anomalies and coxsackievirus B3 and B4 with cardiovascular anomalies. The likelihood of congenital heart disease was increased by maternal infection with two or more coxsackievirus B serotypes rather than one. Also, first-trimester infection with coxsackievirus B4 occurred more frequently in mothers of infants with any anomaly than in the control group.[182] In 28 newborns with severe congenital defects of the CNS, neutralizing antibody to coxsackievirus B6 was demonstrated in 4 cases (14%); 2 had hydranencephaly, 1 had occipital meningocele, and 1 had aqueductal stenosis.[183] In a stillborn infant with calcific pancarditis and hydrops fetalis, coxsackievirus B3 antigen could be demonstrated.[179]

Newborns who acquire coxsackievirus infection in the immediate peripartum period are more likely to experience severe disease in the absence of protecting maternal antibodies. Neonatal infection might range from asymptomatic viral shedding to severe and rapidly fatal illness. Infection that occurs more than 5 days before delivery is likely to induce production of maternal IgG that can cross the placenta and protect the newborn from severe disease, but not necessarily from infection. In the newborn, coxsackievirus infection may cause benign neonatal arrhythmias[184]; fever[177]; oral vesicular lesions[185]; vesiculopapular rash[186]; severe respiratory failure[187]; pneumonitis[172]; fatal pulmonary hemorrhage[177,188]; hepatitis, hepatomegaly, jaundice, bleeding diatheses, hepatic failure, and necrosis[165,177]; aseptic meningitis[177]; meningoencephalitis, fatal encephalomyocarditis, and encephalohepatomyocarditis[172,189]; acute aseptic and interstitial myocarditis[190]; and result in heart disease.[191] A study of 16 neonates with enterovirus hepatitis and coagulopathy demonstrated hemorrhagic complications in 10 of 16 cases (63%); 5 infants had intracranial bleeding.[192] The overall fatality rate was 31% (5/16). In the group of 5 neonates with intracranial bleeding, 4 (80%) died. Overall, mortality rates are highest in children with myocarditis, encephalitis, or sepsis-like illness with liver involvement. In addition, prognosis seems to be related to the infecting viral strain. In general, infection with coxsackievirus B1 to B4 seems to carry the most ominous prognoses. Long-term sequelae are mostly reported with regard to heart and CNS-related impairment. Animal studies of coxsackievirus myocarditis demonstrated a T-cell–mediated immunopathic process and a virus-induced autoimmunity. In a study of 7 newborn infants with neurodevelopmental delays, coxsackievirus was retrieved from the respective placenta in 6 of the 7 cases (86%).[187] A 28-year follow-up study of 145 patients, particularly those with coxsackievirus B5 CNS infection during childhood, demonstrated an increased risk for adult onset of schizophrenia or other psychoses.[193] In a group of 15 children who had meningoencephalitis due to coxsackievirus B5, 2 were reported to have developed spasticity, and

their intelligence was low.[194] Epidemiologic and serologic studies suggest a role for intrauterine coxsackievirus infection for the onset of insulin-dependent diabetes mellitus (IDDM) in childhood.[195–197] However, conflicting serologic data exist that do not indicate an association of coxsackievirus infections during pregnancy with the development of islet autoantibodies; these results do not support a major role of fetal coxsackievirus infection in the development of IDDM.[198,199]

Infection with coxsackievirus A in neonates has been reported less frequently than with coxsackievirus B. Coxsackievirus A infection has been associated with small–for–gestational-age newborns,[172] sudden infant death,[200–202] anorexia, fever, bronchopneumonia, pericarditis, and meningitis.[165]

A number of reports have confirmed that coxsackieviruses may be responsible for outbreaks of apparent infections with fatalities among neonates in obstetric wards and maternity homes.[203–205] Most commonly, mild nonspecific febrile illness is observed in full-term infants. A careful history frequently reveals a trivial illness in a family member. Feeding difficulties are frequently observed, and short periods of vomiting and diarrhea may occur. The most consistent source of original nursery infection is coxsackievirus transmission from mother to her child, but introduction of the virus into the nursery by personnel also occurs. After infection of the pharynx and lower alimentary tract, minor viremia with spread to regional lymph nodes and secondary infection sites (CNS, heart, liver, pancreas, respiratory tract, skin) occurs on the third day. Major viremia ceases with the appearance of antibodies on day 7. Infection can continue in the lower intestinal tract for prolonged periods, and isolation measures are warranted.[165]

Management Options

Prenatal, Labor, and Delivery

Coxsackievirus infections during late pregnancy seem to be a common event, in particular during late summer and early autumn in temperate climates. Epidemics in the region may be signaled by the occurrence of aseptic meningitis, pleurodynia, or Bornholm's disease (myalgia epidemica). Unseasonal respiratory tract infection or symptoms of fever, muscle pain, neck stiffness, skin rashes, and vesicular lesions (mouth, hand, foot) are suggestive of an enteroviral infection. Ultrasound examination in some cases may reveal an enlarged fetal heart with dilated chambers and unusually thick myocardium. Fetal arrythmias and congestive heart failure in combination with nonimmune hydrops may be treated by maternal digoxin or other agents (see Chapter 15) (oral digoxin at 0.5 mg loading, and 0.125–0.25 mg/day maintenance dose). Conversion of fetal arrhythmia to normal sinus rhythm and, consequently, spontaneous resolution of hydrops may be observed. If a woman is suspected of having an acute coxsackievirus infection, she is a potential risk for transmitting coxsackievirus in the obstetric wards. Isolation measures for delivery, newborn care, and postpartum care are warranted.[165] Coxsackievirus infection in the adult usually takes a benign course. If delivery occurs within 4 days of maternal infection, the newborn is at risk for severe disease.

Postnatal

No specific therapy is available to treat coxsackievirus infection in the newborn. Commercially available immune serum globulin contains titers of antibodies to coxsackievirus; however, no beneficial clinical effect has been observed when administered to an infected infant.[206,207] However, viremia and viruria ceased earlier in treated infants than in the control group. Some studies with new antiviral drugs (e.g., pleconaril) seem promising.[208]

In most cases, transmission of coxsackievirus occurs by direct contact from mother or staff members to the newborn or by mouth and gavage feeding. Coxsackievirus B and echoviruses have been recovered from specimens obtained from nurses and physicians caring for infected patients.[205]

Rigorous attention to hygienic measures and handwashing after handling each baby are imperative to avoid the transmission of enteroviruses. Infected newborns should be isolated, and closure on the neonatal unit to new admissions has been advocated.[165]

In sudden and virulent nursery outbreaks passive immunization by intramuscular or intravenous immunoglobulin can be useful in preventing disease.[206,209]

A vaccine to prevent coxsackievirus infection is not available. However, an experimental attenuated vaccine has been developed.[210] Because of the considerable morbidity and mortality associated with coxsackievirus B infection in neonates (and in older persons as well), these agents should be candidates for vaccine development.

SUMMARY OF MANAGEMENT OPTIONS
Coxsackievirus

Management Options	Evidence Quality and Recommendation	References
Prenatal, Labor, and Delivery		
Suspect coxsackievirus infection if unseasonal respiratory tract infection and/or clinical signs of meningitis.	—/GPP	—
Treat infections symptomatically (hospitalize severe cases).	—/GPP	—
Evaluate hydropic fetuses for tachyarrhythmia, congestive heart failure; see Chapters 15, 16, and 24 for management options.	—/GPP	—
Deliver women suspected for acute coxsackievirus infection in an isolated unit.	IV/C	165
Postnatal		
Isolate women known to have coxsackievirus infection during postpartum care.	IV/C	165
Maintain strict attention to infection control measures.	IV/C	165
Provide clinical, microbiologic, and serologic evaluation of the newborn if acute maternal infection is present within the peripartum period.		
Isolate newborns of mothers suspected of having coxsackievirus infection.	IV/C	165
Consider passive immunization of newborns in case of sudden virulent coxsackievirus infection outbreak.	III/B	206,209

GPP, good practice point.

HUMAN PAPILLOMAVIRUS

General

Human papillomavirus (HPV) is a double-stranded DNA virus that can persist as a latent provirus in epithelial cells after infection. Nucleotide sequencing of the DNA has identified more than 100 genotypes of HPV associated with epithelial neoplasias of the skin and mucosa. More than 30 different HPV types can infect the genital tract, and 8 HPV types are predominantly identified in the most common HPV-associated genital diseases.

HPV types 6 and 11 are detected in more than 90% of condylomata acuminata (genital warts), and also in laryngeal papillomatosis, and conjunctival, oral, and nasal warts. HPV types 16, 18, 31, 33, 51, and 54 have been designated high risk HPV types because they have been strongly associated with cervical intraepithelial neoplasia (CIN) and cervical cancer.[211] Genital warts are contagious and are spread during oral, genital, or anal sex. About two thirds of people who have sex with a partner with genital warts will develop warts, usually within 3 months after contact.

Diagnosis

The diagnosis of condylomata acuminata can be made visually by the appearance of white or pink verrucous friable

growths. However, most cases of HPV infection are subclinical. Cytologic evaluation of the Pap smear may reveal evidence of infection in 31% to 71% of cases, depending on age.[212] If koilocytosis is noted on the Pap smear, liberal use of colposcopy is warranted, given the association of HPV infection and CIN. Colposcopy may identify up to 70% of infected cases; however, colposcopy during pregnancy is challenging. Directed biopsies can support diagnostic evaluation in certain cases (e.g., unresponsiveness to therapy, uncertain clinical diagnosis). During pregnancy, limiting biopsy to lesions suspicious for CIN 2 or 3 or cancer is preferred, but biopsy of any lesion is acceptable. Biopsy during pregnancy has not been linked to fetal loss or preterm delivery, whereas failure to perform biopsy during pregnancy has been linked to missed invasive cancer.[95,212] The goal of cytology and colposcopy during pregnancy is to identify invasive cancer that requires treatment before or at the time of delivery. However, unless cancer is identified or suspected, treatment of CIN is contraindicated during pregnancy.[212] HPV isolation in culture is difficult to accomplish. Highly specific and sensitive DNA methods utilizing type-specific HPV gene probes can identify HPV infection in vaginal washings, Pap smears, and amniotic fluid. In situ hybridization technique is useful to demonstrate type-specific HPV infection in tissues and cervical cell scrapings. PCR methods can identify even the lowest levels of HPV infection in blood and other kinds of fluids or in tissue samples. Identification of high risk HPV types might prove helpful for follow-up strategies of women in whom cervical cytology has demonstrated atypical squamous cells of undetermined significance (ASCUS).[212] The usefulness of DNA technology in the clinical diagnosis of genital warts is not supported by any data.[95] Routine screening for subclinical HPV infection by DNA tests should be reserved for women aged 30 years and older.[95,212]

Maternal and Fetal Risks

Epidemiologic data suggest that HPV infection is the most prevalent STD. Although the occurrence of grossly visible genital warts is infrequent, sensitive detection tests utilizing dot blot DNA analysis or PCR for detection of HPV DNA indicate that as many as 30% of sexually active adults in the United States may be infected,[213] with a similar rate seen in pregnancy.[214] The highest rates of genital HPV infection (71%) are detected in adults aged 18 to 28. Many adolescents experience multiple sequential HPV infections; thus, repetitively positive HPV DNA tests in this group may represent consecutive incident infections rather than a single persistent infection. Consequently, routine subclinical HPV screening should not be used in this age group, and if inadvertently performed, a positive result should not influence management.[212] Major risk factors to acquiring genital HPV infection include multiple sex partners, younger age at first intercourse and first pregnancy, oral contraceptive use, pregnancy, and impairment of cell-mediated immunity.[213,215,216] Estimates indicate that approximately 1% of the sexually active population have clinically apparent genital warts.[213] Controversial data exist on a possible increase in the prevalence of HPV infections during pregnancy. A threefold increase in HPV DNA–positive women during the third trimester compared with nonpregnant controls has been

reported.[217,218] Possible underlying reasons to facilitate HPV infection during late pregnancy could involve hormonal changes inducing virus transcription and the transient immunosuppression experienced by pregnant women.

Genital HPV infections in pregnant women have long been suspected to cause genital warts or laryngeal papillomatosis in the respective infants.[219] Juvenile laryngeal papillomatosis represents the most common neoplasm of the larynx in infants and young children and usually occurs by age 5.[220] The symptoms range from hoarseness to complete upper airway obstruction. A history of genital warts can be obtained from over 50% of women whose infants subsequently develop laryngeal papillomatosis.[221] However, the absolute risk of laryngeal papillomatosis following exposure to maternal infection is extremely low. Conservative estimates suggest the risk of papillomatosis developing in an offspring of a mother with HPV genital infection is approximately 1 in 400.[220] Surgical excision is the mainstream therapy, and most afflicted patients experience spontaneous remission. However, some endure several hundred surgical procedures. Further development of new antiviral drugs (e.g., cidofovir) and preventive and therapeutic vaccines hold promise for reducing the incidence of recurrent respiratory papillomatosis and, at best, eliminating the virus.[222,223] Genital warts in children show spontaneous resolution in up to 75% of cases. In a cohort of 41 children, overall resolution of condylomata was noted in 31 infants (76%), with spontaneous resolution in 22 of 41 (54%); girls were affected three times more often than boys.[224] HPV vaccination should reduce the incidence of vertical HPV transmission.[225]

Vertical transmission and persistence of high risk cancer-associated HPV in the infant is of great concern.[226] Amniotic fluid samples of 37 women with cervical lesions tested positive for HPV in 24 cases (65%) using PCR technique.[227] HPV type 16 amniotic fluid infection was present in 54% (13/24), and HPV type 18 was detected in 21% (5/24). A correlation was noted between viral DNA amplification and grade of the cervical lesions. In a group of 11 women carrying HPV type 16, 7 infants of 11 (64%) tested positive for HPV type 16.[228] Viruses were detected in buccal or genital swabs collected 24 hours after delivery, demonstrating infection rather than contamination. Persistence of HPV type 16 infection after a 6-month interval was noted in 83% of infants. In 270 healthy children between the ages of 3 and 11, 131 (49%) buccal swabs tested positive for HPV type 16. Serologic study performed on 229 children demonstrated IgM seropositivity rates indicative of acute infection that peaked between ages 2 and 5, and again between ages 13 and 16.[228] Thus, given the lack of demonstrable disease in children, consequences of perinatal high risk HPV transmission need to be clarified in long-term studies to establish whether perinatal acquisition of high risk HPV types predisposes for an increased risk of cervical neoplasia later in life.

The frequency of perinatal HPV transmission is a controversial subject. Transmission rates may be as low as 2.8%–12.2%,[228–230] whereas other studies demonstrate vertical transmission in up to 73% of newborns.[231] Discrepancies in infection rates of the newborn may be due to different PCR techniques, with up to a 100-fold difference in sensitivity, differences in study population (e.g., concomitant STDs), sampling technique (nasopharyngeal, buccal, genital), and

timing (immediately after birth, contamination versus infection). HPV is thought to cause infection in the infant by direct contact during the passage through the birth canal. However, several studies have shown infants being infected with different strains of HPV despite being delivered by cesarean section.[232,233] In a study of 68 HPV-positive women, 35 delivered vaginally and 33 by cesarean section,[234] at 3 to 4 days of age, buccal and genital swabs were collected. In the group of vaginally born infants, 18 of 35 (51%) had a positive HPV test, whereas in 9 of 33 (27%) infants delivered by cesarean section, HPV was detected. Although the study did show a lower incidence of HPV infection in infants delivered by cesarean section, the study also demonstrated that cesarean section did not consistently protect from vertical HPV transmission. In addition, the presence of HPV has been demonstrated in amniotic fluid, placenta, and cord blood; thus, the fetus is at risk for exposure to the virus prior to delivery.[227,230,231,233,235]

Management Options

Prepregnancy

Parents and women should be advised on HPV vaccination. Two vaccines, a bivalent (HPV 16, 18) and a quadrivalent (HPV 6, 11, 16, 18) are available. Vaccine efficacy for the prevention of the primary composite endpoint (CIN grades 2–3, adenocarcinoma in situ, or cervical cancer related to HPV-16 or HPV-18) was greater than 90%. The quadrivalent vaccine also demonstrated high efficacy against HPV-6 and HPV-11 related external genital lesions. Maximum efficacy is suggested in girls receiving the vaccine prior to sexual activity. However, women who were already infected with one or more of the respective HPV types targeted by the vaccine were protected from clinical disease caused by the remaining HPV types in the vaccine.[236] The recommended age for vaccination of girls is 11 to 12 years, with catch-up vaccination for females aged 13 to 26 years who have not been previously vaccinated. Vaccination during pregnancy is not advocated; however, it appears to be safe.[237] Finishing trials on HPV vaccination of women aged 30 to 45 years are under way. Vaccination of males has been approved in 40 countries worldwide, including a recent permissive approval for the quadrivalent vaccine in the United States.

Widely applied HPV vaccination holds the promise of greatly reducing the incidence of genital warts, precancerous lesions, vulvovaginal and cervical cancer, as well as penile and anal cancer. In addition, reduction of severe respiratory problems due to a laryngopapillomtosis in children infected by vertical transmission from their mothers during pregnancy is expected to occur. Vaccination is not a substitute for routine cervical cancer screening, and vaccinated females should have cervical cancer screening as recommended.[225]

Patients should be counseled on the nature of genital warts and advised on using protection (e.g., latex condoms) when having sex with an infected partner.[216] Some genital warts may resolve spontaneously; however, treatment should be considered for expanding genital warts. Treatment for genital warts reduces but does not eradicate infectivity. In nonpregnant women, podophyllum resin 10% to 25% antimitotic solution, podofilox 0.5% solution, and 5-fluorouracil are commonly used for topical treatment.

However, they should not be applied during pregnancy because of the potential for fetal toxicity. All treatments show a 10% to 40% probability of recurrence. Intralesional injections of different types of interferon have demonstrated efficacy comparable with other modalities for the treatment of genital warts; however, use of interferons has been frequently associated with systemic adverse effects.[238] Interferons should not be used during pregnancy.[239] Although some HPV types are associated with CIN and cervical cancer, HPV infection does not necessarily progress to cancer. It is important for women with a history of abnormal Pap smears to receive appropriate cytologic testing on a regular basis so that early treatment, if necessary, can be instituted.

Prenatal

There is no single definitive treatment for HPV infection in pregnancy. Treatment is dependent on the size, location, and number of identified lesions and entails the removal or ablation of all visible warts. Owing to the subclinical and multifocal nature of HPV infection, recurrences are common. Certain treatment modalities that are effective in the nonpregnant patient are contraindicated during pregnancy.

In pregnant women, topical application of 80% to 90% trichloroacetic acid (TCA) can be used for small lesions and is the least expensive treatment.[240] TCA is not absorbed systemically and can be used in pregnancy. However, it has a cure rate of only 20% to 30% after a single application; therefore, weekly applications may be required until the lesions are resolved. TCA solutions have a low viscosity and can spread rapidly, thus damaging adjacent tissues. If an excess amount is applied, the treated area should be powdered with talc, sodium bicarbonate, or liquid soap preparations to remove unreacted acid.[95] Cryotherapy with liquid nitrogen has also been successfully used in pregnancy and is a reasonable first-line treatment option. Cryotherapy is not recommended for use in the vagina because of the risk of vaginal perforation and fistula formation.[95,238] Surgical removal by tangential scissor excision, tangential shave excision, curettage, or electrosurgery has the advantage of eliminating warts at a single visit in most cases.[238] Carbon dioxide laser vaporization has been used successfully in pregnancy, although recurrence rates of 10% to 14% have been reported. In particular, laser therapy is recommended for those patients with large or multiple lesions or with lesions refractory to TCA application or cryotherapy.[240] Recurrences usually occur during the first 3 months after treatment, and a follow-up evaluation should be offered.

Imiquimod 5% cream, an immune-response modulator that induces host T helper-1 (Th-1) cytokines, including interferon-γ, has been demonstrated to be effective in eradicating genital warts when applied topically three times weekly in nonpregnant patients. Although not yet recommended in pregnancy, imiquimod may represent an effective alternative to other topical or destructive therapies during pregnancy. New antiviral drugs (e.g., cidofovir) have not been evaluated for safety and efficacy during pregnancy.[241]

Labor and Delivery

Elective debulking of genital warts should not be done at the time of delivery for two reasons: first, these lesions may

be very vascular and obstetric hemorrhage may ensue; second, most lesions regress to some extent after delivery.

Because of the lack of substantial evidence for the preventive value of cesarean delivery, cesarean section should not be performed solely to prevent transmission of HPV infection to the newborn.[95] However, cesarean section may be indicated in women with genital warts obstructing the pelvic outlet or when vaginal delivery would result in excessive bleeding.

Postnatal

Large lesions should be observed for secondary infection, if they involve an episiotomy site. Sitz baths may be particularly useful in comforting and cleansing the perineal area with multiple HPV lesions.

Parents should be counseled on HPV vaccination in order to reduce HPV infection and related disease in the future.[225,236]

SUMMARY OF MANAGEMENT OPTIONS
Human Papillomavirus

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Counsel about HPV vaccination	IIa/B	225
Identify and treat lesions:	—/GPP	—
• Topical therapy (podophyllum, podofilox, 5-fluorouracil).		
• Ablation (e.g., cryocautery).		
• Removal.		
Counsel about risks (infectious condition) and use of condoms if partner infected.	IIa/B	216,226
Advise that treatment does not eradicate infectivity.	—/GPP	—
Implications from cervical smear screening programs:	—/GPP	—
If Pap smear reports ASCUS but no other types of abnormalities:		
• Consider HPV testing.	Ib/A	212
If Pap smear reports ASCUS, and high risk HPV types are detected:		
• Perform colposcopy, consider biopsy.	Ib/A	212
• Perform pelvic examination, Pap smear on a regular basis.	Ib/A	212
Screening for subclinical HPV infection is not recommended in women aged 29 and younger.	IV/C	212
Prenatal		
Topical 80% TCA.	III/B	240
Cryotherapy.	IV/C	238
Electrodiathermy.	IV/C	238
Laser vaporization (carbon dioxide).	III/B	240
Excision (tangential scissors, excision, curettage).	IV/C	238
Contraindicated preparations:		
• Podophyllum.	IV/C	238
• Podofilox.	—/GPP	—
• 5-Fluorouracil.	—/GPP	—
• Interferon	IV/C	237
Counsel about low newborn risk, and about nature of HPV infection in the infant.	—/GPP	—

SUMMARY OF MANAGEMENT OPTIONS
Human Papillomavirus—cont'd

Management Options	Evidence Quality and Recommendation	References
Labor and Delivery		
Avoid treatment at delivery, especially debulking, because of risk of hemorrhage.	—/GPP	—
Cesarean section may be indicated in women with genital warts obstructing labor or vaginal delivery that would result in excessive bleeding; not recommended solely to prevent HPV transmission to the infant.	III/B	95
Postnatal		
Maintain vigilance for secondary infection, especially in episiotomy site.	—/GPP	—
Offer sitz baths.	—/GPP	—

ASCUS, atypical squamous cells of undetermined significance; GPP, good practice point; HPV, human papilloma virus; TCA, trichloroacetic acid.

Other Infectious Conditions

MARK H. YUDIN

INTRODUCTION

Infections are an important contributor to maternal and perinatal morbidity and mortality rates. The relative immunosuppression that occurs during pregnancy may alter the natural course of many infectious diseases. Higher attack rates for a variety of bacterial and viral infections are seen in pregnancy. Furthermore, many of these infections may be associated with adverse outcomes, including preterm labor and delivery, low birth weight, and stillbirth. This chapter addresses a large group of infectious diseases and conditions not discussed in other chapters, including streptococcal infections, listeriosis, common sexually transmitted infections (STIs), and vaginitis.

GROUP A STREPTOCOCCUS

Group A streptococcus (GAS; *Streptococcus pyogenes*) has been associated with obstetric and neonatal infections since the 16th century. It is probable that GAS was responsible for much of puerperal sepsis, or "childbed fever," described by Semmelweis in 19th-century Vienna.[1] However, with the advent of the antibiotic era, GAS infections became increasingly infrequent until the 1980s, when GAS infections dramatically increased again for poorly understood reasons.[2] GAS causes a broad spectrum of invasive and noninvasive diseases, including bacterial pharyngitis, impetigo, scarlet fever, necrotizing fasciitis, and the more recently recognized streptococcal toxic shock syndrome (STSS), as outlined in Table 31–1.[2,3]

S. *pyogenes*, the etiologic agent for GAS infections, was first described by Louis Pasteur in 1879. The *Streptococcus* genus is classified into groups, based upon polysaccharide capsular antigens and the cell wall M protein, as first described by Lancefield.[4] S. *pyogenes* is divided into serotypes according to the M protein, and to date, more than 80 M protein serotypes have been identified. Different serotypes are associated with different forms of infection, and M1 and M3 have been the most common serotypes identified in serious infection in more recent years.[5]

M protein is also important as a virulence factor because of its antiphagocytic properties. Other significant virulence factors are the streptococcal pyrogenic exotoxins (SPE), which act as superantigens. Superantigens are able to bind to T-cell receptors and the class II major histocompatibility complex (MHC) without first undergoing antigen processing and presentation. The cross-linking of a T-cell receptor with a class II MHC molecule by a superantigen stimulates the proliferation and activation of T cells and macrophages, causing them to release large amounts of cytokines, which can cause shock or inflammation and tissue damage.[2,6] A large number of SPE superantigens have been identified, but SPE A, SPE B, SPE C, SPE F, and streptococcal superantigen (SSA) are among the best characterized. By stimulating cytokine production, these streptococcal exotoxins likely play an important role in the pathogenicity of invasive GAS infections by exacerbating the onset of clinical signs and symptoms of infection.

Maternal and Fetal Risks

GAS may be recovered from the skin or mucous membranes of asymptomatic colonized patients. GAS may gain entry to the body via the skin, mucosa, pharynx, and vagina and cause infections with both suppurative and nonsuppurative complications.[2,7] The most notable GAS infections encountered during pregnancy are presented in Table 31–2 and include bacteremia without a focus of infection and endometritis, but invasive infections including STSS and necrotizing fasciitis also occur. The reasons for the increased susceptibility seen during the puerperium include the breach of integrity in the integumentary system associated with either vaginal delivery or cesarean section. Invasive infections are characterized by hypotension and shock, multiple organ failure, systemic toxicity, severe local pain, rapid necrosis of subcutaneous tissues and skin, renal dysfunction, and fever.[2,7] GAS invasive disease is characterized by a rapid, often fatal course and by difficulties in the early diagnosis, when intervention may be more successful.

Postpartum invasive GAS infection occurs in approximately 1 in 11,000 to 1 in 17,000 births, with an average of 220 cases occurring in the United States every year.[8,9] The rate of invasive GAS infection is 1.6- to 2.0-fold greater among black patients than white patients.[8] Maternal case fatality rate ranges from 3.5% to 30% in postpartum invasive GAS. Maternal GAS disease has also been associated with stillbirth.

TABLE 31–1

Classification of Group A Streptococcal Infections

1. Streptococcal toxic shock syndrome (streptococcal TSS)
2. Other invasive infections (isolation of *Streptococcus pyogenes* from a normally sterile site in patients not fulfilling criteria from streptococcal TSS)
   a. Bacteremia with no identifiable focus
   b. Focal infection with or without bacteremia (meningitis, pneumonia, peritonitis, puerperal sepsis, osteomyelitis, septic arthritis, necrotizing fasciitis, surgical wound infections, erysipelas, cellulitis)
3. Scarlet fever
4. Noninvasive infections (recovery of *S. pyogenes* from a nonsterile site)
   a. Mucous membranes (pharyngitis, tonsillitis, otitis media, sinusitis, vaginitis)
   b. Cutaneous (impetigo)
5. Nonsuppurative sequelae (specific clinical findings with evidence of a recent group A streptococcal infection)
   a. Acute rheumatic fever
   b. Acute glomerulonephritis

Adapted from The Working Group on Severe Streptococcal Infections: Defining the group A streptococcal toxic shock syndrome. JAMA 1993;269:390–391.

TABLE 31–2

Diseases Seen among Patients with Postpartum Group A Streptococcus Infection

INFECTION	NUMBER OF PATIENTS (*N* = 87)
Bacteremia without focus	40 (46%)
Endometritis	24 (28%)
Peritonitis	7 (8%)
Septic abortion	6 (7%)
Cellulitis	3 (3%)
Septic arthritis	3 (3%)
Necrotizing fasciitis	3 (3%)
Streptococcal toxic shock syndrome	3 (3%)
Chorioamnionitis	3 (3%)
Pneumonia	1 (1%)
Other	3 (3%)

TABLE 31–3

Diagnostic Criteria for Streptococcal Toxic Shock Syndrome

I. Isolation of *Streptococcus pyogenes*
   A. From a normally sterile site
   B. From a nonsterile site (throat, sputum, vagina, superficial skin lesion)
II. Clinical evidence of severity
   A. Hypotension (systolic blood pressure ≤ 90 mm Hg in adults or ≤ 5th percentile for age in children) and
   B. Two or more of the following:
      1. Renal impairment (serum creatinine ≥ 2.0 mg/dL or a twofold elevation over baseline level in patients with preexisting renal impairment)
      2. Coagulopathy (platelets ≤ 100 × 10^6/L or disseminated intravascular coagulation)
      3. Liver involvement (AST, ALT, or total bilirubin ≥ two times upper limits of normal)
      4. Adult respiratory distress syndrome
      5. Generalized erythematous macular rash
      6. Soft tissue necrosis (necrotizing fasciitis, myositis, or gangrene)

ALT, alanine aminotransferase; AST, aspartate aminotransferase.
Adapted from The Working Group on Severe Streptococcal Infections: Defining the group A streptococcal toxic shock syndrome. JAMA 1993;269: 390–391.

Neonatal invasive GAS has also been reported and has a case fatality rate of up to 30%.[9–11] Although the neonate may be colonized following horizontal transmission within the nursery, vertical transmission from a colonized mother has also been demonstrated.[10,12] Furthermore, 50% of neonatal cases of invasive GAS disease occur within the first week of life, suggesting that vertical transmission from a colonized parturient may be the most important route of infection. The most frequent manifestation of neonatal GAS disease is omphalitis, but cellulitis, meningitis, sepsis, and fasciitis may also occur. Fortunately, neonatal GAS disease is rare, with an estimated incidence of 1 in 18,000 births.

Diagnosis

GASs can be readily recovered from most patients with evidence of GAS disease. GASs are catalase-negative gram-positive cocci that are β-hemolytic on blood agar. The colonies may appear as highly mucoid to nonmucoid, and the organisms are usually 1 to 2 mm in diameter. Although cultures may be helpful in confirming the diagnosis of GAS disease, they are seldom available when considering the initial diagnosis. GAS disease may progress rapidly, and therapy must be initiated before cultures are generally available.

Therefore, the diagnosis of GAS disease depends upon a high index of suspicion. Fever is the most common presenting sign, and 20% of patients have a flulike syndrome with fever, chills, myalgia, nausea, vomiting, and diarrhea.[13] Confusion or altered mental status is present in over one half of patients. Renal dysfunction occurs in 80% of patients and may precede hypotension or shock. The presence of hemaglobinuria or an elevated serum creatinine is evidence of renal involvement. Hemoconcentration, as a result of a fluid shift to the extravascular compartment, and leukocytosis (often > 20,000/mm^3), with a predominance of immature neutrophils, are common. Respiratory failure and adult respiratory distress syndrome occur in approximately 50% of patients but usually develop after the onset of clinically recognized shock. Criteria for the diagnosis of STSS are outlined in Table 31–3.

Eighty percent of patients have evidence of soft tissue infection characterized by induration and erythema, which progress to necrotizing fasciitis in 70% of cases.[13] The hallmark of these soft tissue infections is the abrupt onset of severe pain, which usually precedes physical findings or is out of proportion to physical findings. Any patient suspected of having GAS-associated necrotizing fasciitis must have the

diagnosis confirmed by immediate wound exploration and débridement. A purulent discharge is usually not present, and a limited wound inspection may fail to confirm the diagnosis. When the wound is opened, a thin, watery, non-malodorous discharge is frequently present. The diagnosis of necrotizing fasciitis can be easily confirmed by the blood-less blunt dissection of the superficial fascia and by pathologic frozen section.

In summary, the diagnosis of GAS disease should be considered in any patient with the sudden onset of hypotension and shock, the abrupt onset of severe pain in a wound, or systemic signs and symptoms such as confusion, renal impairment, or respiratory distress in a patient with a wound or episiotomy infection. Aggressive intravenous fluid resuscitation, antibiotic therapy, and wound débridement are necessary in these patients.

Management Options

Prepregnancy

No current evidence suggests that the identification of GAS carriers prior to pregnancy is predictive of subsequent pregnancy outcome or effective in reducing puerperal infectious morbidity. Therefore, prepregnancy screening is not recommended.

Prenatal

Women may be identified as being GAS carriers as a result of routine screening for group B streptococcus (GBS) near the end of pregnancy. In one study, 0.03% of women screened at 35 to 37 weeks' gestation were found to have vaginal colonization with GAS.[14] At present, there are not sufficient data to make a recommendation regarding management of asymptomatic carriers. However, there are published case reports of women identified as carriers during pregnancy who then developed GAS sepsis after delivery.[15] A case of puerperal sepsis in a woman with a strain of GAS identical to that identified in her husband's throat swab has also been reported.[16]

A high index of suspicion is necessary for the early diagnosis of GAS infection. Unfortunately, diagnosis may be difficult in the early stages of GAS infection, and delays in therapy may be associated with increased morbidity and mortality rates. Many patients die within 24 to 48 hours of infection.[17] In general, treatment must be directed at hemodynamic stabilization with intravenous fluids and vasopressors, antibiotic therapy, and in the case of soft tissue infections, surgical exploration and aggressive débridement of involved tissues. Massive amounts of intravenous crystalloids, in the range of 10 to 20 L/day, are often necessary to maintain blood pressure and tissue perfusion. Vasopressors such as dopamine are also frequently required. In soft tissue GAS infections such as necrotizing fasciitis, antibiotic therapy alone, without surgical débridement, usually results in maternal death. Intraoperative Gram stain and histologic frozen section may be necessary to fully delineate the extent of involved tissues. Hyperbaric oxygen therapy has no role in the treatment of necrotizing fasciitis but might be a useful adjunct in delineating necrotic tissue that must be surgically débrided.

Broad-spectrum parenteral antibiotics should be administered promptly. Penicillin G (200,000–400,000 U/kg/day) is the drug of choice for GAS invasive infections. However, studies in mice have demonstrated that even a short delay of 2 hours after initiation of infection dramatically reduces the efficacy of penicillin G.[17] Some studies indicate that clindamycin may be more efficacious than penicillin when therapy is delayed. In an experimental model with mice, survival was 70% even when initiated 16 hours after GAS infection.[17] Several potential advantages to clindamycin therapy (900 mg IV q8h) have been identified.[7] First, in contrast to penicillins, clindamycin is not affected by bacterial inoculum size or rate of growth. Second, clindamycin suppresses the synthesis of bacterial toxins. Third, clindamycin facilitates phagocytosis of *S. pyogenes* by inhibition of M protein synthesis. Fourth, clindamycin has a longer postantibiotic effect than penicillin. Last, clindamycin suppresses lipopolysaccharide-induced monocyte synthesis of tumor necrosis factor-alpha (TNF-α), a cytokine that contributes to hypotension and shock. However, a small proportion of GAS infections are resistant to clindamycin, and clindamycin should not be used alone until the organism is demonstrated to be susceptible by susceptibility testing. Therefore, initial therapy usually includes a combination of both penicillin G and clindamycin.

Some data also indicate that intravenous immunoglobulin (IVIG) (1–2 g/kg given once) may be a useful adjunct to antibiotic therapy in the treatment of STSS. Commercial preparations of IVIG have been shown to contain neutralizing antibodies to several streptococcal virulence factors.[18] Recently, investigators reported a significant reduction in mortality rate among patients with GAS disease treated with IVIG when compared with a historical cohort.

Thus, the optimal treatment for invasive GAS disease includes a high index of suspicion, aggressive fluid resuscitation and hemodynamic support, surgical exploration and aggressive débridement, parenteral antibiotics including penicillin G and clindamycin, and possibly IVIG.

Labor and Delivery

GAS may be associated with intra-amniotic infection and with stillbirth. However, most patients with invasive GAS disease usually present in the postpartum period, frequently within the first 24 to 48 hours. Treatment should follow the general guidelines provided earlier.

Postnatal

There are no current recommendations for screening for or treating asymptomatic parturients colonized with GAS. However, careful attention should be given to any parturient with the sudden onset of systemic signs such as hypotension or shock or to parturients with severe pain out of proportion of physical findings or rapidly progressive soft tissue infections, as noted earlier. Although these findings, which are consistent with necrotizing fasciitis, usually suggest a polymicrobial infection, GAS should be considered in the diagnosis, and broad-spectrum antibiotics including penicillin and clindamycin should be utilized in the initial management.

SUMMARY OF MANAGEMENT OPTIONS
Group A Streptococcal Infection

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
No benefit to screening.	—/GPP	—
Prenatal, Labor, and Delivery		
No benefit to screening.	—/GPP	—
May cause intra-amniotic infection.	—/GPP	—
Diagnosis requires a high index of suspicion:	III/B	13
• Severe pain.		
• Hypotension or shock.		
• Altered mental status.		
• Renal or respiratory impairment.		
Treatment requires prompt intervention:	Ib/A	17,18
• IV antibiotics (penicillin G, clindamycin).		
• IV fluids and circulatory support including vasopressors.		
• IVIG in nonresponsive cases.		
• Surgical débridement if appropriate		
Postnatal		
Infection may cause toxic shock syndrome or soft tissue infection.	—/GPP	—
Diagnosis requires a high index of suspicion:	III/B	13
• Severe pain.		
• Hypotension or shock.		
• Altered mental status.		
• Renal or respiratory impairment.		
Therapy:	Ib/A	17,18
• Broad-spectrum antibiotics (penicillin and clindamycin).		
• Surgical wound exploration and débridement.

GROUP B STREPTOCOCCUS

GBS (*Streptococcus agalactiae*) has become recognized since the 1980s as one of the most important causes of neonatal infection and is currently considered one of the leading infectious causes of neonatal morbidity and death. Although early reports in the 1930s and 1940s linked GBS with postpartum infections and neonatal meningitis, it was not until the early 1960s that the scope of perinatal and neonatal GBS infections became evident.[19] Initial case series reported case fatality rates as high as 50%. In the 1980s, trials of empirical intrapartum antibiotics to women at risk of transmitting infection to their newborns demonstrated a protective benefit against neonatal infection in the first week of life (early-onset disease). In the 1990s, these efforts led to the implementation of guidelines for intrapartum antibiotic prophylaxis of at-risk mothers, endorsed and issued by the American College of Obstetricians and Gynecologists (ACOG),[20] the Centers for Disease Control and Prevention (CDC),[21] and the American Academy of Pediatrics (AAP).[22]

This practice has resulted in a significant reduction in early-onset disease, as well as a smaller impact on maternal morbidity. Based upon these results, updated guidelines were issued by the CDC in 2002[23] to recommend optimization of screening and treatment of pregnant women in an attempt to improve upon the success already demonstrated.

GBSs are one of many serologically distinct species within the genus *Streptococcus*. Streptococci are facultatively anaerobic gram-positive cocci, usually arranged in chains on Gram stain. The most important pathogenic streptococcal species for humans include group A (*S. pyogenes*), group B (*S. agalactiae*), group D (enterococci), *Streptococcus pneumoniae*, and *Streptococcus viridans*. Definitive identification is based on the presence of a polysaccharide group-specific antigen common to all group B streptococcal strains as determined by serologic testing. GBSs can be further subdivided into eight distinct serotypes (Ia, Ib, Ia/c, II, III, IV, V, and VI) on the basis of distinctive type-specific polysaccharide antigens. About 99% of strains can be typed into one of these six antigen types. GBSs can be recovered from the vagina or

cervix in 10% to 30% of pregnant women at some point during gestation.[24] The colonization may be transient, chronic, or intermittent, and the rate of colonization does not vary with gestational age. Women with GBS colonization in one pregnancy are at increased risk, relative to women who are negative in the initial pregnancy, for colonization in a subsequent pregnancy.[25] There is evidence that the gastrointestinal tract is the major primary reservoir and that vaginal or cervical contamination and colonization occur from a gastrointestinal source. The frequency of GBS isolation increases as one proceeds from the cervix to the introitus, and GBS can be recovered twice as frequently from rectal cultures as from vaginal cultures. GBSs can also be recovered from the urethra of 45% to 63% of the male consorts of female carriers, implying that sexual transmission may also occur.

Neonatal GBS colonization may occur either by vertical transmission from a colonized mother as the neonate passes through the birth canal or by horizontal transmission, including both nosocomial spread in the nursery from colonized personnel or other colonized neonates and acquisition from community sources. Overall, 3% to 12% of all neonates are colonized with GBS in the first week of life. Forty percent to 70% of neonates born to colonized mothers become colonized, usually with the same serotype that is present in the mother. In contrast, only 1% to 12% of neonates born to noncolonized mothers will become culture-positive. Several additional factors may modify or enhance the risk of GBS vertical transmission. Higher neonatal transmission rates occur when women are persistently culture-positive carriers or when women are heavily colonized with GBS as demonstrated by semiquantitative vaginal cultures.[26] The site of maternal carriage is also important; vertical transmission is more likely to occur with cervical GBS carriage than with rectal carriage.

The most important determinant of susceptibility to invasive infection after colonization may be maternal antibodies directed against the capsular polysaccharide antigens of GBS. Immunity to GBS is mediated by antibody-dependent phagocytosis. Mothers of infants with type III GBS invasive disease have lower serum levels of type-specific antibodies than women giving birth to asymptomatically colonized infants. This antibody, which has some broad reactivity to all GBS types, is an immunoglobulin G (IgG) that readily crosses the placenta. When measured in mother-infant pairs, an excellent correlation exists between maternal and cord antibody levels. Baker and associates[27] demonstrated that 73% of 45 GBS-colonized mothers with healthy neonates had high serum levels of type III antibody in contrast to only 19% of 32 GBS-colonized mothers whose neonates developed early-onset septicemia or meningitis ($P < .001$). Strain virulence is also an important determinant of disease. Although type III strains of GBS represent approximately one third of isolates from symptomatically colonized infants, they account for over 85% of the isolates from early-onset meningitis or late-onset disease. Overall, type III strains account for more than 60% of isolates from infants with all varieties of invasive GBS infections.

Maternal and Fetal Risks

Although most research has focused on GBS neonatal infection, GBS is also an important pathogen for maternal

intrapartum, postpartum, and occasionally prenatal infections. Data from an early report suggest puerperal septicemia due to GBS occurs with an incidence of approximately 1 to 2 per 1000 deliveries and accounts for up to 15% of positive blood cultures from postpartum patients.[28] Postpartum endometritis is reported to be more frequently observed among GBS-colonized parturients than among noncolonized parturients. GBS is also associated with clinical intra-amniotic infection and is a frequent isolate from amniotic fluid of patients with intra-amniotic infection. Finally, GBS has been isolated from the urine of pregnant women, with or without symptoms of urinary tract infection. Untreated antepartum GBS bacteriuria has been associated with intrapartum chorioamnionitis.[29]

GBS has also been associated with premature rupture of membranes (PROM) and with preterm delivery prior to the 32nd gestational week in some, but not all, studies.[30] Previous studies have indicated that this association may be strongest for patients with GBS bacteriuria.[31] Thomsen and coworkers[32] have demonstrated significant reductions in PROM and preterm labor among patients with asymptomatic GBS bacteriuria who were treated with penicillin. However, antepartum antibiotic treatment to eradicate GBS from patients with asymptomatic vaginal colonization without bacteriuria has not been demonstrated to alter pregnancy outcome. Thus, a causal relationship between GBS colonization and prematurity remains to be established.

Since the 1970s, GBS has become a leading cause of septicemia and meningitis during the first 3 months of life in neonates. Early surveillance data in the 1990s suggested an incidence of 1.8 cases per 1000 live births. Two distinct clinical syndromes occur among neonates with GBS infections. These differ in the age at onset, pathogenesis, and outcome. The first clinical syndrome, early-onset infection, occurs within the first 7 days of life and represents nearly three fourths of all cases in infants younger than 3 months. The mean age at onset is 20 hours of life, and 72% will present within the first 24 hours of life.[33] A significant portion of these infections are apparent at birth or become symptomatic within the first 90 minutes of life, indicating that in utero GBS exposure and infection often occur. Early infection attack rates were estimated at 1.5 per 1000 for all live births prior to widespread use of intrapartum antibiotics. Among offspring of maternal GBS carriers, however, the attack rate is much higher, ranging from 10 to 60 per 1000 live births.

Early neonatal infection is presumed to result from vertical transmission of GBS from a colonized mother. There is a direct relationship between neonatal attack rates and the size of the inoculum and number of colonized neonatal sites. In one epidemiologic review, early-onset infection presented as bacteremia (80%), pneumonia (7%), or meningitis (6%).[33] Eighty-three percent of cases were in term infants (≥37 wk' gestation). The overall case fatality rate was approximately 4% but was significantly higher in preterm infants, approaching 30% in infants of 33 weeks' gestation or less.

The second type of disease (late-onset infection) occurs in infants after the first week of life until 3 months of age, with a typical range of 3 to 4 weeks. The overall attack rate is estimated to be 0.5 cases per 1000 live births, and these cases represent 28% of infections in infants younger than 3 months.[33] In contrast to early-onset infection, nosocomial transmission may be as important as vertical transmission,

although it is believed that some infants are colonized at birth, with subsequent development of invasive disease. The serotype distribution of strains recovered from late-onset infection does not reflect the serotypes present in the maternal genital tract; over 90% of late-onset infection is caused by type III GBS. Late-onset disease also presents most commonly as bacteremia (63%), but may appear as meningitis (24%, relative risk [RR] 4.3 vs. early-onset disease; $P < .001$) and may demonstrate other sites of infection, such as septic arthritis or osteomyelitis. The overall case fatality rate for late-onset disease is 2.8%.[33] Approximately 50% of meningitis survivors will have neurologic sequelae, including cortical blindness, diabetes insipidus, deafness or other cranial nerve deficits, and spasticity.

Diagnosis

The recommended technique for collecting specimens for culture of GBS in pregnant women involves obtaining a combined vaginal-rectal swab. Although some studies have shown that the GBS detection rate is not significantly different when comparing vaginal-rectal specimens with vaginal-perianal specimens,[34,35] the current standard of care is still to obtain a combined vaginal-rectal swab. A speculum is not necessary, and there is no difference in detection rates or accuracy if the culture is collected by the patient or the health care provider.[36]

GBS can be easily grown on selective or nonselective media. Most GBS colonies appear on blood plates as small, 1- to 2-mm, gray-white colonies surrounded by a zone of β-hemolysis, although 2% of strains are nonhemolytic. Preliminary identification and distinction of GBS from other streptococci is based on biochemical reactions including resistance to bacitracin, hydrolysis of sodium hippurate, and the production of a soluble hemolysin that acts synergistically with B-lysin of *Staphylococcus aureus* to produce hemolysis (CAMP [Christie-Atkins-Munch-Petersen] test). Although GBS can be recovered after overnight growth on nonselective media, such as blood agar, the use of a selective broth medium such as Todd-Hewitt broth or Lim broth greatly enhances the isolation rate of GBS from any culture site.

A major limitation of cultures is the length of time necessary for growth and identification. Therefore, research has been focused on developing a more rapid screening test that could be used at the time of labor and delivery to identify colonized women. A number of rapid screening tests have been developed to directly detect GBS in either body fluids or cervical-vaginal secretions. These culture-independent tests include Gram stain, latex particle agglutination (LPA), optical immunoassay, enzyme immunoassay, DNA hybridization, and polymerase chain reaction (PCR). A large number of studies have evaluated the ability of these indirect tests to rapidly detect GBS colonization of the maternal lower genital tract. Such identification is important to interrupt maternal-neonatal vertical transmission that leads to early-onset neonatal disease. Initial results were encouraging,[37,38] although subsequent studies have demonstrated that these tests do not always perform well.[39,40] PCR tests appear to have the most promise and the best test performance characteristics relative to culture.[41–43] Recent studies from the United States and Canada have used PCR

assays that demonstrate excellent sensitivity and specificity compared with traditional culture methods, but these assays await further testing to determine the feasibility of widespread application.[43–45] A cost-benefit analysis showed that the use of a rapid PCR test resulted in fewer courses of maternal antibiotics, fewer perinatal GBS infections, and fewer infant deaths compared with culture.[46] However, only culture techniques currently allow for antibiotic sensitivity profiling of positive cultures, which is particularly important in cases of maternal penicillin hypersensitivity.

Management Options

Prepregnancy

No current evidence suggests that the identification of GBS carrier status prior to pregnancy is predictive of subsequent pregnancy outcome. Similarly, treatment of asymptomatic women found to be colonized with GBS prior to pregnancy does not impart any recognized benefit, with the possible exception of women with asymptomatic bacteriuria.

Prenatal, Labor, and Delivery

GBS rarely causes maternal symptoms in the prenatal period, but may cause symptoms of urinary tract infection. However, GBS bacteriuria (whether symptomatic or not) provides a significant risk factor for neonatal disease, as previously mentioned. When detected, GBS bacteriuria should be treated according to current standard of care for urinary tract infections during pregnancy. Pregnant women with documented GBS bacteriuria at any time during their prenatal course do not require routine screening cultures and should receive intrapartum antibiotics, which are discussed in further detail later.

Although the attack rate for neonatal GBS infection is low, a variety of prevention strategies have been advocated because of the high mortality and morbidity rates seen in neonatal GBS disease. These strategies have involved chemoprophylaxis, aimed at eradicating the organism from the mother or the neonate, or immunoprophylaxis, aimed at inducing humoral immunity.

Antibiotic chemoprophylaxis has been advocated for the pregnant patient in either the antepartum or the intrapartum period or for the neonate in the immediate neonatal period. Attempts to eradicate GBS colonization with antepartum treatment have been unsuccessful, and early neonatal prophylaxis is also frequently unsuccessful because many neonates are already septic at birth as a result of in utero infection.[47] Initial chemoprophylactic prevention strategies released in the 1990s focused upon selective intrapartum treatment based on either the presence of risk factors associated with neonatal infection, the maternal genital tract colonization, or both.

Major risk factors for neonatal early-onset GBS disease include low birth weight (<2500 g), premature delivery (<37 wk' gestation), prolonged duration of rupture of membranes (≥18 hr), and intrapartum fever (≥38.0°C). Boyer and colleagues[47] have demonstrated that 74% of neonates with early-onset infection and 94% of those infections with a fatal outcome occur among those neonates with one or more of these risk factors. Additional risk factors include having previously had a neonate with invasive GBS disease and maternal GBS bacteriuria during the current pregnancy. A study

in 1985 documented that the overall attack rate for early-onset neonatal GBS disease increased from the then-observed 3.0 per 1000 births in the total population to 8.4 per 1000 births among those pregnancies in which risk factors were present.[48] The attack rate rose even more dramatically to 40.8 per 1000 births if risk factors were present and the mother was colonized with GBS.

Several studies utilizing the presence of risk factors, maternal colonization status, or both, as a determinant for prophylaxis have documented the efficacy of intrapartum chemoprophylaxis in reducing neonatal early-onset GBS disease.[49–55] A meta-analysis of these studies demonstrated a 30-fold reduction in early-onset disease with intrapartum chemoprophylaxis.[56] The two alternative approaches to intrapartum chemoprophylaxis were proposed in the United States by the CDC in 1996[21] and have been endorsed by both ACOG[20] and AAP.[22] The first approach is based upon universal screening for maternal GBS colonization at 35 to 37 weeks' gestation. Cultures remote from term might not be accurate and should not be used. Intrapartum chemoprophylaxis is offered to all pregnant women identified as GBS carriers. In addition, intrapartum chemoprophylaxis is offered to women with a previous neonate with GBS infection, GBS bacteriuria during the current pregnancy, or delivering prior to 37 weeks' gestation, regardless of maternal colonization status. Women with an unknown carrier status are offered prophylaxis in the event of an intrapartum fever of 38.0°C or higher or rupture of membranes at 18 hours or before. It was estimated that this screening-based approach would result in intrapartum chemoprophylaxis of 26.7% of all deliveries and prevent 86% of early-onset neonatal GBS disease (Table 31–4).[21]

An alternative prophylactic strategy, also initially endorsed by the CDC, is based upon offering intrapartum chemoprophylaxis only in the presence of risk factors. In this risk-factor approach, antepartum cultures are not obtained, and prophylaxis is offered only to those women with delivery prior to 37 weeks' gestation, rupture of membranes for greater than 18 hours, an intrapartum fever at or above 38.0°C, a previously infected neonate, or with GBS bacteriuria in the current pregnancy. With this approach, 18.3% of pregnancies were estimated to merit chemoprophylaxis and 68.8% of early-onset neonatal disease would be potentially prevented.[21]

The impact of implementing these guidelines has been studied extensively in the period following their initial recommendation. In the surveillance areas studied, the incidence of early-onset disease declined from 1.7 per 1000 in 1993 to 0.6 per 1000 in 1998, a 65% reduction, with the steepest decline occurring in 1996 following the initial release of consensus guidelines from the CDC. Schrag and associates[57] published the first comprehensive study directly comparing the two management strategies and found that the universal screening-based approach was greater than 50% more effective in preventing perinatal GBS disease. This result was felt to stem from two main factors. First, the screening-based approach identified mothers who were GBS-positive but did not exhibit risk factors during pregnancy or labor, a group representing 18% of all parturients during the study period. Second, women identified as being GBS-positive were more likely to receive intrapartum antibiotics than women who qualified on the basis of risk factors (89% vs. 61%, $P < .001$), indicating improved compliance with the guidelines utilizing the screening-based approach. In this study, similar numbers of patients (24%) in each group received intrapartum prophylaxis, negating previous concerns that the screening-based approach would result in a significant increase in the use of antibiotics and potential contribution to antibiotic resistance. Also, other studies have suggested that the increased cost of performing routine cultures on all eligible pregnant women would be offset by the impact of disease prevention. This idea led to the release of new guidelines by the CDC in 2002,[23] recommending a universal screening-based approach (Fig. 31–1). The risk-based approach should be used only for women who arrive in labor with no documented culture results. In addition, a new algorithm was provided for the management of women with preterm delivery, summarized in Figure 31–2. An evaluation of the universal antenatal screening approach for GBS was recently published, highlighting the efficacy achieved and areas in which further improvements in management might result in the additional reductions in neonatal disease.[58]

Vaginal and rectal GBS screening cultures at 35–37 weeks' gestation for ALL pregnant women (unless patient had GBS bacteriuria during pregnancy or a previous infant with invasive GBS disease)

Intrapartum prophylaxis indicated
• Previous infant with invasive GBS disease
• GBS bacteriuria current pregnancy
• Positive GBS screening culture during current pregnancy (unless a planned cesarean delivery, in the absence of labor or amniotic membrane rupture, is performed)
• Unknown GBS status (culture not done, incomplete or results unknown) and any of the following:
  ➤ Delivery at ≤37 weeks' gestation
  ➤ Amniotic membrane rupture ≥18 hours
  ➤ Intrapartum temperature ≥100.4° F (≥38.0° C)

Intrapartum prophylaxis not indicated
• Previous pregnancy with a positive GBS screening culture (unless a culture was also positive during the current pregnancy)
• Planned cesarean delivery performed in the absence of labor or membrane rupture (regardless of maternal GBS culture status)
• Negative vaginal and rectal GBS screening culture in late gestation during the current pregnancy, regardless of intrapartum risk factors

FIGURE 31–1
Indications for intrapartum antibiotic prophylaxis to prevent prenatal group B streptococcus (GBS) disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures collected at 35 to 37 weeks' gestation from all pregnant women. (From Centers for Disease Control and Prevention [CDC]: Prevention of perinatal group B streptococcal disease: Revised guidelines from CDC. MMWR Morb Mortal Wkly Rep 2002;51[RR-11]:1–18.)

Onset of labor or rupture of membranes at <37 weeks' gestation with significant risk for imminent preterm delivery

No GBS culture → Obtain vaginal and rectal GBS culture and initiate IV penicillin → (GBS +) Penicillin IV for ≥48 hrs

Obtain vaginal and rectal GBS culture and initiate IV penicillin → No growth at 48 hrs → Stop penicillin

GBS + → Penicillin IV for ≥48 hrs → Intrapartum antibiotic prophylaxis

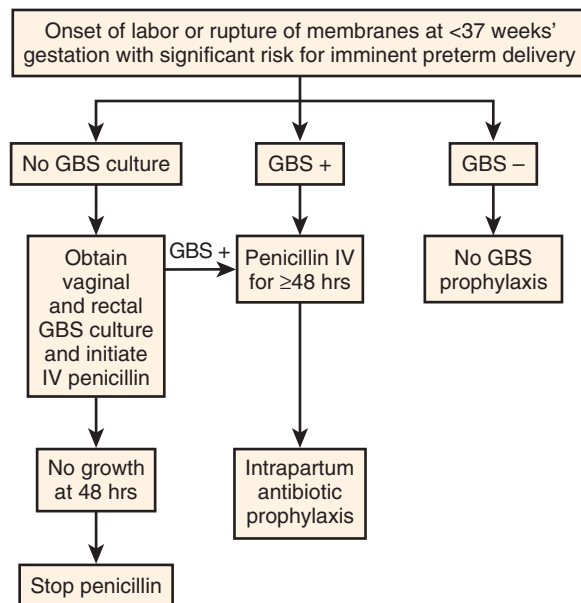
GBS – → No GBS prophylaxis


FIGURE 31–2
Sample algorithm for GBS prophylaxis for women with threatened preterm delivery. This algorithm is not an exclusive course of management. Variations that incorporate individual circumstances or institutional preferences may be appropriate. (From Centers for Disease Control and Prevention [CDC]: Prevention of perinatal group B streptococcal disease: Revised guidelines from CDC. MMWR Morb Mortal Wkly Rep 2002;51[RR-11]:1–18.)

Intravenous penicillin G (5 million units IV initially, then 2.5 million units q4h until delivery) is preferred for intrapartum chemoprophylaxis. Ampicillin (2 g IV initial dose, then 1 g q4h until delivery) is an acceptable alternative, but penicillin G is preferable because its narrower spectrum of activity may be less likely to select for antibiotic-resistant microorganisms. Previous debate had centered on the minimum duration of therapy for effective prophylaxis, in terms of length of therapy versus number of doses of antibiotics administered prior to delivery. Vaginal GBS colony counts fall rapidly after intrapartum penicillin administration.[59] Some evidence has confirmed that an initial dose of antibiotics at least 4 hours prior to delivery is as effective as two or more doses of antibiotics in preventing GBS transmission[60] and early-onset disease,[61] and this emphasis is maintained in the current guidelines.

If penicillin resistance is documented but the risk of anaphylaxis is judged to be low, cefazolin (2 g IV initial dose, then 1 g q8h) may be used. Clindamycin (900 mg IV q8h) or erythromycin (500 mg IV q6h) may be used in the severely penicillin-allergic patient. However, increasing resistance to both of these agents has led to the recommendation of routine susceptibility testing of positive cultures if penicillin allergy is suspected or documented. In surveillance studies in the United States covering the time period 1999 to 2005, 32% of isolates were resistant to erythromycin and 15% were resistant to clindamycin.[62] In cases of resistant organisms (or unknown susceptibility) and high risk for anaphylaxis to penicillins and cephalosporins, vancomycin (1 g q12h) is the preferred treatment. This underscores the need to accurately determine true β-lactam allergy as well as risk for anaphylaxis.

An alternative approach to intrapartum chemoprophylaxis is to immunize pregnant women. As noted previously, women delivering neonates with invasive early-onset disease usually have very low (<2 μg/mL) serum concentrations of type III GBS antibody.[27] More recent preliminary trials have been conducted among nonpregnant adults utilizing monovalent protein-conjugate vaccines containing capsular polysaccharide antigens against serotypes Ia and Ib,[63] type II,[64] and type III.[65] Further work is needed in this area prior to the implementation of a vaccination strategy toward women of childbearing age and pregnant women.

Postnatal

In the asymptomatic parturient receiving intrapartum chemoprophylaxis, there is no need to continue antibiotics following delivery. Conversely, in the symptomatic patient with intra-amniotic infection, therapy should be continued as described previously. Because GBS may also be associated with postpartum endometritis, known carriers should be observed closely for this and treated accordingly. Of note, Schrag and associates[57] reported a modest but significant reduction in invasive GBS disease, including postpartum endometritis, among pregnant women following implementation of the original guidelines for intrapartum prophylaxis, from 0.29 cases per 1000 live births in 1993, to 0.23 per 1000 in 1998 ($P < .03$). It should be recognized that postpartum endometritis is frequently a polymicrobial infection and broad-spectrum antibiotics should be utilized, even among those patients known to be colonized with GBS.

SUMMARY OF MANAGEMENT OPTIONS
Group B Streptococcal Infection

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Treatment of GBS carriers before pregnancy has no benefit.	—/GPP	—
Immunization strategies are being evaluated currently.	—/GPP	—
Prenatal, Labor, and Delivery		
Treat symptomatic bacteriuria during prenatal period.	IIa/B	29
Recommended universal screening–based approach:	IIa/B	23,57
• Perform combined vaginal and rectal cultures on all pregnant women at 35–37 wk' gestation. (Exception: women with documented GBS bacteriuria during current pregnancy or history of previous GBS-infected infant warrant intrapartum prophylaxis and do not require screening.)		
• IAP is recommended for all women with positive culture unless delivery by cesarean section prior to rupture of membranes and onset of labor.		
• If culture status is unknown at time of delivery, administer IAP for gestation < 37 wk, rupture of membranes ≥ 18 hr, or intrapartum temperature ≥ 38.0°C.		
Suggested management of threatened preterm delivery:	III/B	21
• No culture done: obtain cultures and initiate IAP for 48 hr until results obtained or delivery occurs.		
• Culture positive prior to or during labor: IAP for 48 hr or until delivery occurs.		
• Culture negative prior to labor (or after 48 hr): no IAP (or stop IAP).		
Recommended prophylaxis regimens:	Ia/A	23,56,60,61
• Penicillin G 5 million U IV followed by 2.5 mU IV q4h until delivery (ampicillin 2 g IV initially followed by 1 g IV q4h until delivery is acceptable but less preferred owing to broader-spectrum activity).		
• For penicillin allergic (low anaphylaxis risk), cefazolin 2 g IV initial dose followed by 1 g IV q8h until delivery.		
• For penicillin allergic (high anaphylaxis risk, documented susceptibility of GBS), clindamycin 900 mg IV q8h, or erythromycin 500 mg IV q6h.		
• For penicillin allergic (high anaphylaxis risk and resistance to clindamycin and erythromycin or susceptibility unknown), vancomycin 1 g IV q12h.		
Postnatal		
Antibiotic prophylaxis need not be continued after delivery.	—/GPP	—
Diagnosis of postpartum endometritis in a GBS-positive woman should be treated with broad-spectrum antibiotics.	—/GPP	—

GBS, group B streptococcus; GPP, good practice point; IAP, intrapartum antibiotic prophylaxis.

METHICILLIN RESISTANT STAPHYLOCOCCUS AUREUS

Maternal and Fetal Risks

Staphylococcus aureus is a commonly encountered organism, colonizing the anterior nares, other mucus membranes and skin surfaces. Resistance to penicillin, and later methicillin, has made these bacteria of particular concern as a nosocomial pathogen. Over the last decade, methicillin resistant strains (MRSA) have been increasingly isolated from patients in the community setting, without typical risk factors such as recent antibiotic treatment, ICU admission, known contact with an infected individual or surgical exposure.[66] Community acquired MRSA usually has chromosomal DNA restriction patterns that are different from the hospital-associated strains, commonly contain the Panton Valentine Leukocidin (PVL) virulence toxin, and are generally less resistant to multiple antibiotic classes of drugs.[67] Whereas hospital-acquired strains most commonly present within the bloodstream, urinary tract, or in association with device or surgical site infections, community associated MRSA presents as "spider bite" lesions, localized skin or other soft tissue infections or as necrotizing pneumonia after an influenza episode.[67] Community associated MRSA has now been identified as an emerging concern among pregnant and postpartum women, with infections in the breast, buttocks, vulva and groin reported.[68,69] More invasive disease has also been noted, including nonmenstrual toxic shock syndrome and neonatal sepsis due to this organism.[67] Recent United States national surveillance data have documented an MRSA nasal colonization rate of 1.5%.[66] Prevalence studies specific to pregnancy have reported recto-vaginal colonization rates of 0.5–3.5%.[68,69] Fortunately only a small fraction of those who are colonized go on to develop clinical disease. Vertical transmission to the neonate has been suggested in isolated case reports, although the frequency of this event must be exceedingly low.

Management Options

Prenatal, Labor, and Delivery

Regardless of the source of infection, antibiotic treatment usually begins with systemic vancomycin for invasive disease. Incision and drainage of any localized abscess collection is required. These infections are often slow to respond, and sensitivity testing should be initiated early to assess adequacy of therapy. Alternative or adjunctive agents include daptomycin, linezolid and tigecycline. Few data, and much debate, surround the discussion of the merits of these latter agents; consultation with a health care provider with expertise in this area would likely be beneficial.[67]

Mild to moderate skin and soft tissue infection due to community associated MRSA begins with incision and drain. Again, despite a paucity of data, the CDC has published guidelines for the outpatient antimicrobial theraphy of MRSA (www.cdc.gov/ncidod/dhqp/ar_mrsa_ca_skin.html) not specific to pregnancy.

Whether to perioperatively decolonize the nose, genital tract or skin to prevent MRSA infection before vaginal or cesarean delivery remains controversial.[67] At the present time, the cumulative data do not support routine screening for MRSA carriers or decolonization with mupirocin ointment (for nasal site) or oral or vaginal chlorhexidine (genital site). An exception may be if the patient has a prior history of MRSA infection, or is at particularly high risk for postoperative infection. This latter consideration would also apply to perioperative antimicrobial prophylaxis prior to cesarean delivery, where an agent that is active against MRSA should be considered for those known to carry or be at risk for MRSA.

MRSA carriage or infection is not a contraindication to breast feeding. As with other types of mastitis, breast feeding may be continued as antimicrobial therapy is instituted. Any draining lesion should be covered to limit infant exposure. If a significant breast abscess is identified, temporary cessation of feeding on that side may be needed for a few days after surgical drainage.[67]

SUMMARY OF MANAGEMENT OPTIONS
Methicillin Resistant Staphylococcus Aureus

Management Options	Evidence Quality and Recommendation	References
Prenatal, Labor, and Delivery		
For Severe Invasive Disease		
Systemic vancomycin (alternative or adjunctive agents include daptomycin, linezolid and tigecyline).	IV/C	67
Incision and drainage of abscess.	IV/B	67
For Mild to Moderate Skin and Soft Tissue Infection		
Incision and drain.	IV/C	67

For recommendations pertaining to oral antimicrobial therapy, see www.cdc.gov/ncidod/dhqp/ar_mrsa_ca_skin.html.

Management Options	Evidence Quality and Recommendation	References
General		
Decolonization of nose (mupirocin), genital tract (oral or genital chlorhexidine) or skin (chlorhexidine) to prevent MRSA infection before vaginal or cesarean delivery is controversial.	IV/C	67
Current cumulative data do not support routine screening for MRSA carriers or decolonization. Exceptions: Prior history of MRSA infection High risk for infection	IV/C	67
MRSA and its associated antimicrobial treatment are not contraindications to breast feeding. Cover any draining lesion to limit infant exposure. Temporary cessation of feeding on relevant side if abscess occurs.	IV/C	67

LISTERIOSIS

Listeriosis is caused by the organism *Listeria monocytogenes*, an aerobic and facultatively anaerobic, non–spore-forming, motile, gram-positive bacillus. This bacterium is widespread in the environment in soil, vegetation, water, and sewage. It is also found in humans and has been isolated in the stool of 1% to 5% of healthy adults. It is a relatively uncommon infection, although there is a predilection for populations with relative immunosuppression, including infants, the elderly, and the pregnant woman, with the latter group demonstrating an incidence of 12 per 100,000 (compared with 0.7 per 100,000 in the general population, a 17-fold increase).[70] Most cases of human listeriosis during pregnancy are sporadic with occasional epidemic common-source outbreaks. It can contaminate a variety of foods including uncooked meat and vegetables, raw milk, and processed foods that become contaminated after processing, such as soft cheeses and cold cuts at the deli counter. In certain ready-to-eat foods such as hot dogs and deli meats, contamination can occur after cooking but before packaging. Contaminated food looks, tastes, and smells normal. Unlike most bacteria, *Listeria* can survive on food stored in the refrigerator. It is killed with proper cooking and pasteurization procedures.

Maternal and Fetal Risks

Listeria exhibits an unusual life cycle, demonstrating obligate intracellular replication and spread, without significant exposure to the extracellular environment and its defense mechanisms. Thus, cell-mediated immunity is the primary host defense, and this may explain the unique susceptibility of humans to this infection during periods of relative suppression of cell-mediated immunity, including pregnancy.[71]

Listeria infection is well established as a cause of pregnancy loss in domestic and wild animals. Subsequently, it was implicated as a possible cause for recurrent spontaneous abortion in pregnant women. An Israeli study reported a significantly increased rate of multiple positive cervical cultures for *Listeria* in women with a history of recurrent losses compared with a control group without such history.[72] However, subsequent studies failed to replicate this association, and at this time, the association is controversial.[73–75] Multiple gestation pregnancies may also be at increased risk for listeriosis, as reported by Mascola and coworkers.[76]

Pregnant women with listeriosis most commonly suffer from a flulike illness, with fever, general malaise, and other nonspecific symptoms. Rarely, it might cause meningoencephalitis or sepsis-like manifestations. In one large series, 65% of patients had fever (defined usually as temperature ≥ 38.2°C), 32% a "flulike" illness, 21.5% abdominal or back pain, and less commonly, headache, myalgia, or sore throat.[77] The average duration of symptoms prior to diagnosis was 6.6 days. Of note, 29% of patients were asymptomatic.

The primary mode of transmission to the fetus or newborn has not been proved, but is suspected to occur either via ascending infection through the vagina or transplacentally secondary to maternal bacteremia.[70] Neonatal listeriosis might present as respiratory distress, fever, neurologic symptoms, or skin rash, or it might be asymptomatic. Rarely, the infant might present with granulomatosis infantisepticum, which classically exhibits disseminated granulomatous reaction in the lung, skin, liver, and other locations. Similar to GBS infection in the neonate, there is a bimodal distribution of disease. Early-onset infection (usually defined as < 5 days of life) is more commonly associated with maternal illness and produces a sepsis-like illness, with onset of disease exhibited within hours of birth. Late-onset disease presents more commonly as meningitis, is less commonly associated with maternal symptoms or positive *Listeria* cultures, and may be associated with nosocomial or environmental acquisition.[78]

Outcomes of pregnancies complicated by listeriosis vary. In the study by Mylonakis and colleagues,[77] one in five pregnancies resulted in spontaneous abortion or stillbirth. In the remainder, 68.3% of the infants demonstrated infection with a positive culture from one or more sites. Of these infants for which follow-up was available, 62.8% recovered completely, 24.5% died, and 12.7% recovered with neurologic sequelae or other long-term complications. The worst prognosis occurred in patients with meningeal involvement. Similar data were reported in a British review of 248 perinatal cases of listeriosis from 1967 to 1985 in which 19% of cases in which the outcome was known resulted in abortion or stillbirth.[78] Of the remaining infants in which gestational age was known, 58% were delivered prematurely (defined as < 38 wk). The overall neonatal mortality rate in known outcome cases was 35%.

Diagnosis

Listeria grows well on most routine media, although the use of selective media may be required when cultures are obtained from sites of heavy bacterial colonization such as the vagina or rectum. Owing to morphologic similarity, it may be confused with nonpathogenic diphtheroids. However, the organism produces a characteristic tumbling motion when viewed on wet preparation, allowing it to be distinguished. Of the four serotypes, subtypes 1/2a, 1/2b, and 4b are responsible for the vast majority of infections, and serotype analysis may be useful in epidemic settings.[70]

The diagnosis depends upon clinical suspicion and isolation of the organism from a culture of appropriate source. In the large series mentioned previously, *Listeria* was most commonly isolated from cultures of the blood (43%), cervix/vagina (34%), and placenta (12%). It may also be cultured from amniotic fluid obtained by amniocentesis performed for suspected intra-amniotic infection. Staining of amniotic fluid by meconium, especially in the preterm infant, may increase clinical suspicion for listeriosis, because this was observed in 12 of 23 infants in a reported series from Australian authors.[79]

Management Options

Prepregnancy

Treatment of listeriosis in the nonpregnant woman is identical to that of other adult patients and dependent on the site of the infection (i.e., bacteremia vs. meningitis or other location). As mentioned, the possibility of *Listeria* colonization or carriage as a risk factor for subsequent pregnancy loss has been previously evaluated with inconclusive results. Thus, the role of *Listeria* as a cause of poor obstetric outcome in asymptomatic patients is questionable, and routine screening is not recommended at this time.[70]

Prenatal, Labor, and Delivery

Prevention of maternal listeriosis has been targeted as a primary objective following epidemiologic data confirming the role of contaminated food products as a major source for listeriosis, in both epidemic and sporadic cases. The first outbreak confirming an indirect transmission from animals to humans was reported in 1983 in Canada's Maritime Provinces.[80] A subsequent large outbreak occurred in 1985 in the Los Angeles area, in which 65.5% of all cases were pregnant women or their offspring.[81] In 2008, a large outbreak occurred in several Canadian provinces resulting in 56 confirmed cases and 20 deaths.[82] A surveillance project followed the Los Angeles outbreak, beginning in 1986, coordinated between the U.S. Food and Drug Administration (FDA) and CDC over multiple diverse demographic areas throughout the United States. This effort led to identification of many at-risk food sources and implementation of more stringent regulations for these food groups over the next several years.[83] In 1992, multiple agencies including the CDC, FDA, and Food Safety and Inspection Service (FSIS) issued dietary recommendations for persons at increased risk, including pregnant women. Results of this project resulted in a decrease of perinatal listeriosis in the surveillance areas from 17.4 per

---

> ### TABLE 31–5
> **Dietary Recommendations for Pregnant Women**
>
> **Do not eat** hot dogs, luncheon meats, or deli meats **unless they are reheated** until steaming hot.
>
> **Do not eat** soft cheeses such as feta, Brie, Camembert, blue-veined cheeses, and Mexican-style cheeses such as "queso blanco fresco." Hard cheeses, semisoft cheeses such as mozzarella, pasteurized processed cheese slices and spreads, cream cheese, and cottage cheese can be safely consumed.
>
> **Do not eat** refrigerated pâté or meat spreads. Canned or shelf-stable pâté and meat spreads can be eaten.
>
> **Do not eat** refrigerated smoked seafood **unless** it is an ingredient in a **cooked** dish such as a casserole. Examples of refrigerated smoked seafood include salmon, trout, whitefish, cod, tuna, and mackerel, which are most often labeled as "nova-style," "lox," "kippered," "smoked," or "jerky." This fish is found in the refrigerated section or sold at deli counters of grocery stores and delicatessens. Canned fish such as salmon and tuna or shelf-stable smoked seafood may be safely eaten.
>
> **Do not drink** raw (unpasteurized) milk **or eat** foods that contain unpasteurized milk.

100,000 (1989) to 8.6 per 100,000 (1993), ($P <$ .003).[83] A list of at-risk food substances has been summarized in a handout for pregnant women on the FSIS website and may be viewed in Table 31–5.[84]

For women with suspected or confirmed listeriosis during pregnancy, intravenous antibiotics are indicated. Multiple cases have been reported of successful antepartum treatment of listeriosis with normal neonatal outcome, including cases diagnosed in the first and second trimesters.[84–86] First-line therapy consists of ampicillin 2 g given every 6 hours for 10 to 14 days. The addition of gentamicin for synergistic activity has been recommended in some cases but lacks adequate study to determine a conclusive advantage. Because of its bactericidal activity and excellent intracellular concentration, trimethoprim/sulfamethoxazole (20 mg/kg/day TMP component IV divided into four daily doses) is the recommended second-line therapeutic agent in cases of penicillin-allergic patients.[71] However, because of fetal effects, its utility must be evaluated in each case individually, weighing the potential risks and benefits. This underscores the necessity of accurately determining true penicillin-allergy status and consideration of desensitization therapy. Other second-line considerations include erythromycin, vancomycin, or the carbapenems, but experience is limited. Cephalosporins are not effective against *Listeria*.

Postnatal

For mothers with proven listeriosis, antibiotic therapy should be continued for a total of 10 to 14 days for bacteremia or superficial infections or 14 to 21 days for meningitis. Care of the neonate should involve obtaining blood and cerebrospinal fluid (CSF) cultures to assess potential infection and empirical treatment with ampicillin and gentamicin pending culture results. Antibiotic therapy is recommended for a minimum of 14 days in cases of bacteremia or pneumonia and 21 days in cases involving the central nervous system.

SUMMARY OF MANAGEMENT OPTIONS
Listeriosis Monocytogenes

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
No benefit to screening.	III/B	70
Treatment of documented infection depending on the site (see later).	IV/C	84–86
Prenatal, Labor, and Delivery		
Avoid unpasteurized dairy products and certain meat products (see Table 31–5)	III/B	83,84
Culture appropriate sites if listeriosis suspected (blood, CSF, cervix, amniotic fluid).	—/GPP	—
Treatment	IV/C	84–86
• **First-line therapy**: IV ampicillin 200 mg/kg/day (divided into four doses), max = 12 g/day.		
• **For penicillin-sensitive patients**: trimethoprim/sulfamethoxazole (20 mg/kg/day in three or four doses).		
• **Other antibiotics**: erythromycin, vancomycin. *Note*: cephalosporins not effective.		
• **Duration of therapy**: 10–14 days for superficial infection/bacteremia; 14–21 days for meningitis.		
Postnatal		
Evaluate neonate with blood and CSF cultures.	—/GPP	—

CSF, cerebrospinal fluid; GPP, good practice point.

SEXUALLY TRANSMITTED INFECTIONS

Gonorrhea

Gonorrhea is the second most commonly reported bacterial STI in the United States. It is caused by *Neisseria gonorrhoeae*, a gram-negative diplococcus. The prevalence of gonococcal infection in pregnancy varies, depending upon the population studied, from 0.5% to 7.4% in the United States.[87,88] Nationally reported gonorrhea rates have been roughly stable since 1996, although the rate increased in 2005 for the first time since 1999 to 115.6 cases per 100,000 population.[89] Risk factors for gonococcal infection include multiple sexual partners, young age, nonwhite race, low socioeconomic status, and being unmarried.

Maternal and Fetal Risks

The most prevalent type of gonococcal infection in pregnancy is asymptomatic infection of the cervix. *N. gonorrhoeae* may also cause acute cervicitis, proctitis, pharyngitis, and disseminated systemic infection. The rate of pharyngeal gonococcal infection increases during pregnancy, possibly as a result of altered sexual practices.[90] Disseminated gonococcal infection (DGI) also occurs more frequently in pregnant than in nonpregnant women.[91] DGI is characterized by a bacteremic phase associated with malaise, fever, and a pustular hemorrhagic rash and a secondary septic arthritis stage usually with asymmetrical involvement of the knees, wrists, or ankles. Acute salpingitis secondary to gonococcal infection may occur during the first trimester but is rare after the 12th week of gestation because obliteration of the endometrial cavity by the pregnancy prevents ascending infection. In pregnancy, gonococcal cervicitis has been associated with PROM, premature delivery, chorioamnionitis, and both postabortion and postpartum endometritis.[92,93] In addition, gonococcal ophthalmia neonatorum may develop in up to 40% of newborns exposed to maternal infection who did not receive ocular prophylaxis.

Diagnosis

It is estimated that up to 80% of women with gonococcal infection of the cervix are asymptomatic; for this reason, prevention of sequelae of gonorrhea depends upon prenatal screening to detect infected parturients. Screening should occur during pregnancy, and late pregnancy rescreening is advised for patients in a high-prevalence population.[94] Diagnosis depends upon the demonstration of gram-negative intracellular diplococci within leukocytes of a smear obtained from an exudate, if present, or upon culture. Cultures should be inoculated immediately after collection onto a selective medium such as Thayer-Martin. Culture-independent identification of *N. gonorrhoeae* by immunoassay or DNA detection assays are also available and have been demonstrated to be highly specific and sensitive for the detection of gonococcal infections.

Treatment of Uncomplicated Gonococcal or Chlamydial Infections in Pregnancy

Gonococcal Infection

Recommended:
    Cefixime 400 mg orally in a single dose or
    Ceftriaxone 125 mg IM in a single dose

Alternative:
    Spectinomycin 2 g IM in a single dose
    All regimens followed by azithromycin 1 g orally in a single dose or
        amoxicillin 500 mg orally three times daily for 7 days

Chlamydial Infections

Recommended:
    Azithromycin 1 g orally in a single dose or
    Amoxicillin 500 mg orally three times daily for 7 days

Alternative:
    Erythromycin base 500 mg orally four times daily for 7 days
    Erythromycin base 250 mg orally four times daily for 14 days
    Erythromycin ethylsuccinate 800 mg orally four times daily for 7 days
    Erythromycin ethylsuccinate 400 mg orally four times daily for
        14 days

From Centers for Disease Control and Prevention (CDC): Sexually transmitted diseases treatment guidelines, 2006. MMWR Morb Mortal Wkly Rep 2006; 55(RR-11):1–94.

Management Options

PREPREGNANCY

The CDC published new guidelines for the treatment of STIs in 2006.[95] Guidelines are similar for most STIs with regard to the identification and treatment of these diseases prior to pregnancy, with partner notification and treatment an important component to prevent reinfection. For nonpregnant women, recommended antibiotics for treatment of gonorrhea include cephalosporins and quinolones.[95]

PRENATAL

Uncomplicated gonorrhea in pregnancy should be treated with cefixime 400 mg orally in a single dose, ceftriaxone 125 mg intramuscularly in single dose, or spectinomycin, 2 g intramuscularly in a single dose (Table 31–6). Because concurrent cervical infection with *Chlamydia trachomatis* occurs frequently,[96,97] azithromycin 1 g orally in a single dose or amoxicillin 500 mg orally three times daily for 7 days should also be administered, unless specific testing for *C. trachomatis* has been done and the results are negative. For DGI, hospitalization and parenteral therapy are recommended for initial therapy. Recommended regimens include ceftriaxone 1 g intramuscularly or intravenously once daily, ceftizoxime 1 g intravenously every 8 hours, or cefotaxime 1 g intravenously every 8 hours. Parenteral therapy should be continued until 24 to 48 hours after symptoms resolve and then converted to oral therapy for a total of 1 week of antibiotics. Identification, screening, and treatment of sexual contacts of patients with gonococcal infection are recommended.

Tetracyclines and the quinolone antibiotics may be used in the nonpregnant population, although they are contraindicated in pregnancy because of potential adverse fetal effects. As well, because of the emergence of quinolone resistance in some areas of the United States, quinolones are not recommended for areas with increased prevalence of quinolone-resistant *N. gonorrhoeae*.

LABOR AND DELIVERY

Rapid diagnostic screening tools such as Gram stain, immune-based assays, and DNA detection assays are available. These tests can be useful in evaluating the intrapartum patient at risk for infection. Intrapartum treatment of the mother may reduce the neonate's risk for infection, although specific treatment and ocular prophylaxis of the infant after delivery are usually done.

POSTNATAL

Treatment guidelines for the postpartum patient are similar to those outlined previously. However, doxycyline or the quinolone antibiotics may be used in nonlactating women.

Chlamydia Trachomatis

C. trachomatis is the cause of one of the most prevalent sexually transmitted bacterial infections in the world and is the most prevalent sexually transmitted bacterial organism in the United States.[75] Chlamydiae are obligate intracellular organisms. *C. trachomatis* may be differentiated into 15 serotypes. Serotypes A, B, and C cause endemic trachoma, a chronic ocular infection considered to be the leading cause of blindness in the world. Serotypes L1, L2, and L3 cause lymphogranuloma venereum, discussed later in this chapter. Serotypes D through K cause genital and ocular infections, discussed in this section. The prevalence of genital infection in pregnant women in the United States has been reported as between 2% and 37%, with an average estimate of 5% to 7%.[98–100] Risk factors for cervical infection include young age, single marital status, multiple sexual partners, and previous history of sexually transmitted disease.[101]

Maternal and Fetal Risks

The majority of infected patients have asymptomatic cervical infection. In the nonpregnant female, chlamydial infections may cause mucopurulent cervicitis, endometritis, acute salpingitis, infertility and ectopic pregnancy, and acute urethral syndrome. The role of maternal chlamydial infection in pregnancy is more controversial. Several studies have found an association between maternal cervical infection and preterm delivery, PROM, low birth weight, perinatal death, and late-onset postpartum endometritis.[102–106] Two prospective studies have found that only those women with recently acquired infection, as detected by the presence of IgM serum antibody to *C. trachomatis*, are at increased risk for PROM, preterm delivery, and low birth weight.[100,107] Treatment and eradication of maternal cervical chlamydial infection reduces the risk of PROM and premature delivery.[108–110] Thus, the available data suggest an association between maternal chlamydial infection and adverse pregnancy outcome and that screening and treatment in pregnancy is warranted.

Maternal chlamydial infection also poses significant risk to the neonate. Approximately 50% to 60% of the neonates delivered vaginally to women with chlamydial cervicitis will be colonized with *C. trachomatis*.[99] The most common manifestations of neonatal infection are inclusion conjunctivitis

and pneumonia. Eighteen percent to 50% of exposed infants develop conjunctivitis within the first 2 weeks of life, and 11% to 18% will develop pneumonia in the first 4 months of life.

Diagnosis

The diagnosis of chlamydial infections is based upon isolation of the organism, or culture-independent detection by immunoassay and DNA detection by PCR and serologic testing. Because chlamydiae are obligatory intracellular bacteria, isolation by culture requires inoculation onto a susceptible tissue culture cell line. Cell cultures are both labor-intensive and expensive and are not readily available to most clinicians. Antigen detection kits are widely available to detect chlamydia and represent a less costly alternative to culture. More recently, detection of *C. trachomatis* DNA from the genital tract, or from urine, by PCR or ligase chain reaction (LCR) has been demonstrated to be greater than 90% sensitive and specific for the detection of *C. trachomatis* and has largely replaced cultures and antigen detection assays. A serum microimmunofluorescent antibody test is also available to detect recent or past infection but is more useful as a research tool than for the clinical diagnosis of chlamydial infection.

Management Options

PREPREGNANCY

C. trachomatis is susceptible to a wide range of antibiotics including azithromycin, erythromycin, doxycycline, tetracycline, and ofloxacin. For the nonpregnant patient, azithromycin 1 g orally in a single dose or doxycycline 100 mg orally two times a day for 7 days is the recommended regimen.[95] Alternate regimens include erythromycin base 500 mg orally four times daily for 7 days, erythromycin ethylsuccinate 800 mg orally four times daily for 7 days, ofloxacin 300 mg orally twice a day for 7 days, or levofloxacin 500 mg orally once daily for 7 days. For nonpregnant women, test of cure is not required, but follow-up testing approximately 3 months after treatment is recommended.[95]

PRENATAL

In pregnancy, azithromycin 1 g orally in a single dose or amoxicillin 500 mg orally three times a day for 7 days is recommended. Alternate regimens include erythromycin base 500 mg orally four times a day for 7 days or 250 mg orally four times daily for 14 days, or erythromycin ethylsuccinate 800 mg orally four times a day for 7 days or 400 mg four times daily for 14 days (see Table 32–6).[95] Erythromycin estolate should probably not be used because it may be associated with hepatotoxicity when given during pregnancy. Because erythromycin therapy is frequently associated with gastrointestinal intolerance in pregnancy, regimens avoiding erythromycin might be preferable. Therapy with either amoxicillin, 500 mg orally three times a day for 7 days, or clindamycin, 450 mg orally four times a day for 14 days, results in cure rates (98% and 93%, respectively) comparable with cure rates with erythromycin base therapy and are better tolerated by the patient.[111,112] Sexual contacts should be examined and treated.

LABOR AND DELIVERY

See the section on "Gonorrhea."

POSTNATAL

The incidence of neonatal inclusion conjunctivitis can be reduced by ocular prophylaxis at birth with 0.5% erythromycin ocular ointment or 1% tetracycline ointment, but not as well by 1% silver nitrate drops. Conjunctivitis that does occur, or pneumonia, should be treated with oral erythromycin for 2 weeks.

Genital Mycoplasmas

Maternal and Fetal Risks

Mycoplasmas are a ubiquitous group of microorganisms that inhabit the mucosa of the genital and respiratory tracts. They differ from bacteria in that they lack a cell wall, but they are susceptible to antibiotics that inhibit protein synthesis. The two most common genital mycoplasmas are *Mycoplasma hominis* and *Ureaplasma urealyticum*. The prevalence of these two microorganisms in the lower genital tract in sexually active women has been reported to be 40% to 95% for *U. urealyticum* and 15% to 70% for *M. hominis*. Their high prevalence rates among otherwise healthy women make it difficult to determine their role in adverse pregnancy outcomes. In general, *M. hominis* has been associated in some, but not all, studies with septic abortion, postpartum endometritis, and postpartum fever.[107,108,114] *U. urealyticum* has been associated with histologic chorioamnionitis, low birth weight, and perinatal death.[115–119]

Serologic evidence of infection with *M. hominis* has been found in 50% of febrile abortions versus 17% of afebrile abortions.[113] In one study of early postpartum endometritis among women, genital mycoplasmas, including *M. hominis*, accounted for 30% of the total endometrial isolates and 19% of the total blood isolates, but were usually recovered in association with other pathogenic bacteria, suggesting a mixed infection.[114] *M. hominis* has also been isolated from amniotic fluid of patients with amniotic fluid infection, but almost always in association with other bacteria, again implying a mixed infection.[28] Significantly, infected patients from whom *M. hominis* is recovered almost always respond to therapy with β-lactam antibiotics, which have no activity against genital mycoplasmas.

A number of studies have found an association between *U. urealyticum* and chorioamnionitis[116,117,119] and with perinatal death.[117,120] In one study, *U. urealyticum* was isolated as the sole isolate from fetal lungs in 24 (8%) of 290 perinatal deaths.[120] Twenty-two of these deaths occurred in utero and all but 1 were associated with pneumonia and chorioamnionitis, implying an ascending intrauterine infection. Some studies have also found decreased birth weight among offspring of women colonized with *U. urealyticum*,[115] but this association has not been confirmed by others.[106] Intervention treatment trials have also been inconclusive. McCormack and associates[121] demonstrated an increase in birth weight among the offspring of women colonized with *U. urealyticum* treated with erythromycin in the third trimester compared with colonized women treated with placebo. Because the presence of potential genital pathogens was not ascertained, their potentially confounding influence upon birth weight cannot be excluded. In

contrast, Eschenbach and coworkers[122] found no beneficial effect of erythromycin taken for up to 14 weeks by a large cohort of women colonized for *U. ureaplasma* on birth weight, gestational age at delivery, frequency of PROM, or neonatal outcome. In this study, women also colonized with either *C. trachomatis* or GBS were excluded from analysis, eliminating any potential confounding bias from co-infection.

Management Options

Taken collectively, the data linking either *M. hominis* or *U. urealyticum* to adverse pregnancy outcome are inconclusive. At present, antenatal vaginal cultures for either of these mycoplasmas cannot be recommended. Current evidence does not support the treatment of colonized patients for the prevention of adverse pregnancy outcomes. If treatment is deemed necessary, tetracycline is effective against both *M. hominis* and *U. urealyticum* but should not be used in pregnancy. *U. urealyticum* is also sensitive to erythromycin but is resistant to clindamycin; *M. hominis* is resistant to erythromycin but sensitive to clindamycin. Because the mycoplasmas lack a cell wall, they are resistant to β-lactam antibiotics.

Chancroid

Chancroid is an acute ulcerative disease, usually of the genitals, caused by infection with *Haemophilus ducreyi*, a facultative gram-negative bacillus. Although rare in North America and Europe, it remains an important public health concern in developing countries and can potentially be introduced into other geographic areas as a result of travel. Chancroid may occur more frequently in individuals infected with HIV, genital herpes, or syphilis. Chancroid is spread only through sexual contact with individuals with ulcers and is much more prevalent in men than in women. The incubation period after transmission is usually between 4 and 7 days. A painful chancre then develops at the site of entry, beginning as a small papule that over the course of 1 to 2 days, becomes eroded and ulcerated. Multiple ulcers are common, with the majority occurring on the external genitals and only rarely on the cervix or vagina. The classic ulcer of chancroid is shallow with an irregular border surrounded by erythema. The base of the ulcer is frequently covered with a necrotic exudate. Painful inguinal adenopathy develops in about 50% of cases and may lead to suppuration and spontaneous rupture if untreated. These buboes appear 7 to 10 days after the initial ulcer and are unilateral in two thirds of cases.

Maternal and Fetal Risks

H. ducreyi has not been shown to cause systemic infection or spread to distant sites and poses no special risk to pregnancy.

Diagnosis

The diagnosis of chancroid is based upon clinical characteristics (the presence of a painful ulcer and tender adenopathy) and Gram stain and culture of the ulcer or aspirated bubo. The Gram stain may reveal gram-negative rods that form chains but has a sensitivity of only 50%.[123] Cultures should be taken from the base of the ulcer and placed on selective media. Cultures are both sensitive and specific in the diagnosis of *H. ducreyi* infection, but might not be readily available from commercial sources. An enzyme-linked immunosorbent assay has been developed that is both sensitive and specific and may represent a good alternative when culture is not available.

Management Options

H. ducreyi is susceptible to a variety of antibiotics, although resistance to sulfonamides and tetracycline has emerged that precludes their use. Quinolones, which are very active against *H. ducreyi*, are contraindicated during pregnancy. Current recommended regimens that may be given in pregnancy include (1) azithromycin 1 g orally in a single dose; (2) erythromycin base 500 mg three times daily for 7 days; and (3) ceftriaxone 250 mg intramuscularly as a single dose. Azithromycin and ceftriaxone offer the advantage of single-dose therapy. It is recommended that patients are tested for HIV at the time of diagnosis, and retested for syphilis and HIV 3 months after diagnosis, and that sexual partners of patients are examined and treated.[95]

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is a sexually transmitted disease caused by *C. trachomatis* serovars L1, L2, and L3. Transmission occurs through vaginal, anal, or oral sexual contact with mucosal damage. It is characterized by inguinal lymphangitis, anogenital lesions, and fibrosis with gross distortion of the perineal tissues. LGV is endemic in certain parts of the world, including Africa, India, Southeast Asia, and parts of South America.[124] It occurs sporadically in other geographic locations and was very rarely seen in industrialized countries in North America, Europe, or Australia until more recently. Beginning in 2003, clusters of cases have been identified in Europe, Canada, and the United States.[125] LGV is predominantly a disease of lymphatic tissue characterized by thrombolymphangitis and spread of the inflammatory process into the adjacent tissues. Three stages of infection are recognized: primary, secondary, and tertiary. The primary lesion is characterized by a small shallow genital papule or ulcer that appears at the site of infection after an incubation period of 3 to 12 days, heals rapidly, and is often associated with few symptoms. The secondary stage occurs 10 to 30 days later and is characterized by systemic symptoms and painful inguinal lymphadenitis or buboes, loculated abscesses, and anorectal symptoms such as pain and bleeding. The tertiary stage is characterized by a chronic inflammatory response with progressive tissue destruction, ulceration, fistula formation, and lymphatic obstruction. Antibiotic treatment during the secondary stage will prevent these tertiary complications.

Maternal and Fetal Risks

The course of the disease is not dramatically altered by pregnancy, and transmission to the fetus does not occur. However, infection may be acquired during birth and passage through the infected birth canal.

Diagnosis

The diagnosis of LGV is based upon clinical appearance, serologic tests, and recovery of *C. trachomatis* from infected tissue or its identification by the direct immunofluorescent antibody test. Serology showing complement fixation titers greater than 1:64 support the diagnosis. Routine testing for *C. trachomatis* is not specific enough, and confirmatory serovar-specific testing using DNA sequencing techniques is necessary to confirm the diagnosis.

Management Options

A variety of antibiotics have been used to treat LGV. First-line treatment for nonpregnant patients and sexual partners of pregnant patients is doxycycline 100 mg orally two times a day for 21 days.[95] An alternative regimen is erythromycin base 500 mg orally four times a day for 21 days. Pregnant women should be treated with erythromycin.[95] Azithromycin may be an alternative, but there are not yet any published studies regarding its efficacy and safety. Late sequelae such as fistulas or strictures may require subsequent surgical repair.

Granuloma Inguinale (Donovanosis)

Granuloma inguinale (GI) is a rare, chronic genital infection characterized by granulomatous ulcers. It is common in tropical climates and developing countries, but extremely rare in temperate climates.[126] GI is caused by infection with *Klebsiella granulomatis*, formerly known as *Calymmatobacterium granulomatis*, a facultative, gram-negative bacillus. Although most infections probably result from sexual transmission, autoinoculation and nonsexual transmission also occur. The infection is only mildly contagious, and repeated close physical contact is necessary for transmission.[127] Following acquisition of infection, the incubation period varies from 8 to 80 days. The disease begins as a subcutaneous nodule that erodes through the skin and slowly enlarges to form an exuberant, granulomatous heaped ulcer, which is usually painless. Redundant, beefy-red granulation tissue may be present, giving an exophytic appearance to the lesion. These lesions are highly vascular and may bleed on contact. In the female, these lesions are found most commonly on the labia.

Maternal and Fetal Risks

Pregnancy may accelerate the growth of these lesions. The effects of GI upon the fetus are not completely understood, but perinatal transmission at the time of birth through an infected birth canal has been reported.[128]

Diagnosis

The diagnosis of GI is based upon the clinical appearance of the disease. The diagnosis is readily confirmed by examination of a smear of a crushed tissue preparation of the lesion. The smear is stained with Wright or Giemsa stain and examined for Donovan bodies. Donovan bodies are the darkly stained organisms within cytoplasmic inclusions contained in infected mononuclear cells. Their presence is diagnostic for GI. Neither cultures nor serologic tests are available.

Management Options

The recommended treatment of GI for nonpregnant patients is doxycycline 100 mg orally twice daily for a minimum of 3 weeks and until all lesions have completely healed.[91] Chloramphenicol and gentamicin have been used successfully for resistant cases. Pregnant women should be treated with erythromycin base 500 mg orally four times a day for at least 3 weeks. Azithromycin may also be effective, but published data are currently lacking. The addition of a parenteral aminoglycoside should be considered if improvement is not evident within the first few days of therapy. Treatment should continue for a minimum of 3 weeks and until lesions are completely healed to prevent recurrence. Treatment of asymptomatic sexual partners is generally not recommended.

GPP, good practice point.

VAGINITIS

Vaginal discharge is one of the most common complaints of pregnant patients. The discharge may be the result of normal physiologic adaptations of pregnancy or may result from infectious vaginitis, with possible increased risk for pregnancy complications. The vagina has both a nutrient-rich biochemical milieu and a complex microbial flora. Normal vaginal discharge consists of water (primarily as a serum transudate), desquamated epithelial cells, microorganisms, electrolytes, and organic compounds including organic acids, fatty acids, proteins, and carbohydrates (primarily glycogen).[129] Normal vaginal fluid contains two to nine species of facultative and anaerobic bacteria in concentrations of 10^9 colony-forming units/mL.[130] Normally, facultative *Lactobacillus* species account for the majority of the total organisms present. These microorganisms utilize the available glycogen, producing lactic acid, which serves to acidify the vaginal pH to less than 4.5, inhibiting the growth of non–acid-tolerant, potentially pathogenic microorganisms. They also produce hydrogen peroxide, a potent antimicrobial toxin to other microorganisms including *Candida albicans*, *Gardnerella vaginalis*, and anaerobic bacteria.[130,131] When this complex relationship is changed, potentially pathogenic microorganisms indigenous to the vagina such as *C. albicans* or *G. vaginalis* and anaerobes may proliferate and cause vaginal discharge. Alternatively, sexually transmitted exogenous microorganisms, such as *Trichomonas vaginalis*, may disrupt the normal vaginal ecosystem and lead to symptomatic vaginitis.

Pregnancy itself may also lead to physiologic changes of the lower genital tract, which may predispose to vaginitis. During pregnancy, the vaginal walls become engorged with blood, leading to increased transudation, and the glycogen content of the vagina increases.[130] Elevated levels of progesterone seen during pregnancy enhance the adherence of *C.*

albicans to vaginal epithelial cells. Finally, cell-mediated immunity is impaired during pregnancy, predisposing to candidal infections.

The three most commonly occurring causes of infectious vaginitis in pregnancy are bacterial vaginosis, candidiasis, and trichomoniasis. Although frequently asymptomatic, these infections have been implicated in a variety of adverse pregnancy outcomes.

Bacterial Vaginosis

Bacterial vaginosis is the most common lower genital tract disorder among women of reproductive age (pregnant and nonpregnant) and the most prevalent cause of vaginal discharge and malodor.[132,133] It is a polymicrobial syndrome resulting in a decreased concentration of lactobacilli and an increase in pathogenic bacteria (mainly anaerobic). Specifically, there is an increased prevalence of *G. vaginalis*, selected anaerobes (*Bacteroides*, *Peptostreptococcus*, and species), and *M. hominis* and a decreased prevalence of hydrogen peroxidase–producing *Lactobacillus*.[131,134] In addition, there is a 100-fold increase in the intravaginal concentration of *G. vaginalis* and a 1000-fold increase in the concentration of anaerobes.[134] Thus, the diagnosis of bacterial vaginosis does not depend upon the recovery or identification of any single microorganism from the vagina, but rather requires the recognition of an altered vaginal microbial milieu.

Maternal and Fetal Risks

The presence of bacterial vaginosis has consistently been shown to be a risk factor for adverse pregnancy outcomes such as preterm labor and delivery, preterm PROM, spontaneous abortion, chorioamnionitis, and postpartum infections such as endometritis and cesarean section wound infections.[118,135–139] Table 31–7 presents a summary of studies demonstrating an association between bacterial vaginosis and preterm birth. Despite this evidence, the strategy of screening for and treatment of bacterial vaginosis in large-scale studies of women at low risk of adverse obstetric outcomes has not resulted in a reduction in the incidence of prematurity. Thus, the U.S. Preventive Services Task Force published a statement in 2001 concluding that the available evidence was insufficient to recommend for or against routinely screening women at high risk preterm birth for bacterial vaginosis and recommending against screening average risk asymptomatic pregnant women.[139]

Little is known about the mechanisms by which bacterial vaginosis may cause prematurity. The increased intravaginal concentrations of bacteria may simply overwhelm the local host defenses, allowing for ascending infection. Alternatively, these bacteria could also produce protease or phospholipases, which weaken the membranes or stimulate prostaglandin production.[140] Although the magnitude of the increased risk for prematurity noted in these studies is modest (approximately a twofold increased risk compared with patients without bacterial vaginosis), the total impact upon prematurity may be much greater given the high prevalence of 20% for bacterial vaginosis in pregnancy. It has been estimated that as many as 6% of preterm deliveries of infants with low birth weight may be attributable to bacterial vaginosis.[135]

Diagnosis

The most common symptom among women with bacterial vaginosis is a thin, watery, nonpruritic discharge with a fishy odor. However, one half of women with bacterial vaginosis are asymptomatic.

Criteria for the clinical diagnosis of bacterial vaginosis are well established, with the diagnosis confirmed if three of the four following signs are present[141]: (1) an adherent and homogeneous vaginal discharge; (2) a vaginal pH above 4.5; (3) detection of clue cells on saline wet mount; and (4) the release of an amine (fishy) odor after the addition of 10% potassium hydroxide (positive whiff test). The diagnosis of bacterial vaginosis can also be made by direct Gram stain of the vaginal discharge. The Gram stain is the most widely used and evaluated microbiologic diagnostic method for this condition. Most laboratories use an objective diagnostic scheme that quantifies the number of *Lactobacillus* morphotypes and pathogenic bacteria, resulting in a score that is used to determine whether the infection is present. The most commonly used system is the Nugent score.[142] The criterion for bacterial vaginosis is a score of seven or higher. A score of four to six is considered intermediate, and a score of zero to three is considered normal.

Management Options

The treatment of choice for symptomatic bacterial vaginosis in pregnancy is metronidazole given orally in a dose of 500 mg twice daily for 7 days or 250 mg three times daily for 7 days.[95] This results in cure rates of 90%. A single 2-g oral dose of metronidazole is also effective. Oral clindamycin 300 mg twice a day for 7 days may be used as an alternative. Nitroimidazoles cross the placenta and are mutagenic in bacteria and carcinogenic in some animals. However, there is no evidence that metronidazole is teratogenic or

mutagenic in human studies, and it is considered safe for use in pregnancy.[143,144] Cure rates utilizing topical therapy are comparable with those of systemic therapy.[145] However, vaginal preparations such as metronidazole vaginal gel 0.75%, given intravaginally once daily for 5 days, or clindamycin cream 2.0%, given intravaginally once daily for 7 days have not been shown to be effective for preterm birth prevention, and therefore, oral agents are preferred. Further studies are necessary to address this important consideration.

The results of trials examining whether the treatment of bacterial vaginosis in pregnancy can affect the frequency of adverse pregnancy outcomes, especially preterm birth, have been inconsistent. In trials enrolling women from the general population who are not at increased risk for preterm birth, there does not appear to be any benefit to screening for and treating bacterial vaginosis. These results have been replicated in many studies from different countries, enrolling women at a range of gestational ages, and using both oral and vaginal medications (metronidazole and clindamycin).[146–151] However, in women at increased risk for premature birth (often defined as having a history of a previous preterm delivery), there have been more promising results. Several studies have shown that women randomized to treatment with oral metronidazole had lower rates of adverse outcomes, including preterm labor and delivery, than women randomized to placebo.[150,152,153] In a Cochrane Collaboration review[154] of 15 treatment trials involving 5888 women, there was a statistically significant decrease in the rate of preterm prelabor rupture of membranes and low birth weight in treated women with a history of previous preterm birth, but no effect on preterm delivery rates. However, in the same review, there was a statistically significant decreased risk of preterm birth in five trials of 2387 women treated before 20 weeks' gestation.[154]

In published studies, vaginal therapy has not been shown to be effective in preventing preterm birth in women with bacterial vaginosis.[146–149] The one exception to this is a trial by Lamont and colleagues[155] that demonstrated a statistically significant reduction in preterm birth (4% vs. 10%) in women randomized to clindamycin vaginal cream at 13 to 20 weeks' gestation compared with placebo. A meta-analysis exploring the issue of oral or vaginal treatment in women at low risk versus those at high risk for preterm birth found no significant reduction in preterm delivery by treatment of all women, women with a previous preterm birth, or women at low risk for preterm birth.[156] However, in the subgroup of women who had a previous preterm delivery and who had received oral treatment for at least 7 days, there was a highly significant decrease in preterm delivery (odds ratio [OR] 0.42; 95% confidence interval [CI] 0.27–0.67). There was no benefit seen in the group of women receiving vaginal treatment.

Candida Vaginitis

Maternal and Fetal Risks

Candida vaginitis may be caused by many species of *Candida*, but the predominant species is *C. albicans*, which is responsible for 80% to 90% of infections. The remainder of cases are caused by *Candida (Torulopsis) glabrata* and other *Candida* species. These organisms are saprophytic fungi, which may

be recovered from the vagina in 25% to 40% of asymptomatic women. *Candida* also accounts for approximately 25% of all symptomatic vaginitis among nonpregnant patients and up to 45% of vaginitis in pregnancy. In pregnancy, alterations in the vaginal microflora, glycogen availability, and a depression in maternal cellular immunity may all contribute to increase the risk of *Candida* overgrowth leading to vaginitis. Although rare, *C. albicans* has been reported as a cause of amniotic fluid infection and congenital cutaneous candidiasis of the newborn.[157]

Diagnosis

Women with vaginal candidiasis experience vulvar and vaginal pruritus, external dysuria, and a nonmalodorous flocculent discharge. Examination usually reveals an erythematous vulvar rash and a characteristic white "cottage cheese" discharge that adheres to the vaginal walls. The vaginal pH is usually normal (<4.5) and no odor is present. Microscopic examination of material suspended in 10% potassium hydroxide reveals typical mycelial forms and pseudohyphae in 80% of patients with symptomatic infection. Because *Candida* species may exist in the vaginal flora in low concentrations among normal asymptomatic patients, cultures are usually not indicated. Cultures should be limited to women in whom candidiasis is suspected but cannot be confirmed by microscopic examination.

Management Options

Treatment by local application of antifungals results in relief of symptoms and eradication of yeast in 70% to 90% of patients. The mainstay of treatment has been with imidazoles. These broad-spectrum antifungals include miconazole, clotrimazole, teraconazole, and butaconazole. These agents inhibit fungal ergosterol synthesis, resulting in disruption of the cell membrane. They are available as a one-time intravaginal suppository or as either 3-day or 7-day courses of intravaginal suppositories or creams given once daily at bedtime. These imidazoles are not absorbed systemically and are safe to use in pregnancy. In pregnant women, the 7-day course is recommended.[95] Boric acid powder, in 600 mg vaginal suppositories, placed intravaginally daily for 14 days is also 90% effective in eradicating symptomatic vaginal candidiasis and has the advantage of being very inexpensive.[158] Although borate is poorly absorbed systemically in nonpregnant women, its absorption during pregnancy is uncertain, and therefore, alternative therapies with topical imidazoles are preferable. Two other antifungal agents that are systemically absorbed after oral or intravenous administration are ketoconazole, an imidazole, and fluconazole, a triazole. These both have superb activity against *Candida* species and are useful in the treatment of systemic fungal infections or vaginal candidiasis in nonpregnant women.

Trichomoniasis

Trichomoniasis is caused by *T. vaginalis*, a sexually transmitted anaerobic protozoan. *T. vaginalis* may be recovered from 40% of women screened in sexually transmitted disease clinics and from the prostatic fluid of 70% of the male

contacts of the women with symptomatic trichomoniasis.[159,160] The prevalence of trichomoniasis in pregnancy ranges from 6% to 22%. Risk factors associated with *T. vaginalis* colonization include black race, cigarette smoking, greater number of sexual partners, and a history of gonorrhea.[161] It is estimated that approximately 50% of women harboring *T. vaginalis* are asymptomatic.[159]

Maternal and Fetal Risks

Pregnant women with *T. vaginalis* infection may be asymptomatic or may have clinical vaginitis. *T. vaginalis* may also cause other infections of the lower genitourinary tract including bartholinitis, urethritis, periurethral gland infection, and cystitis. Although the risk of infection to the neonate is low (<1%), vaginitis and cystitis may occur as manifestations of neonatal disease. *T. vaginalis* has also been rarely suspected as a cause of neonatal pneumonitis. Although the relationship between vaginal trichomoniasis and adverse pregnancy outcome has not been well studied, two prospective studies have found a decrease in mean gestational age at delivery and an increase in PROM among women infected with *T. vaginalis*.[99,136] Further studies are necessary to confirm these relationships.

Diagnosis

Women with symptomatic trichomoniasis characteristically complain of a profuse and malodorous vaginal discharge. Vulvar pruritus, dysuria, dyspareunia, and lower abdominal tenderness may also be present. On examination, a gray or yellow-green frothy discharge is frequently present. The pH of the discharge is usually higher than 4.5 and may have an amine odor after addition of 10% potassium hydroxide. Small submucosal punctate hemorrhages of the cervix, the so-called strawberry cervix, are sometimes present. Microscopically, motile trichomonads may easily be identified on a saline wet mount by their characteristic pear shape, flagella, and rapid, jerking motility. Polymorphonuclear leukocytes are also present on saline wet mount microscopy and may be so abundant that they obscure the trichomonads. The sensitivity of the saline wet mount, when compared with culture, is 60%, but its specificity is near 100%.[162] *Trichomonas* cultures are easily performed utilizing Diamond's medium and are highly sensitive (92%–95%) and specific.

However, cultures have limited practicality in the clinical setting because 3 to 7 days are needed for growth before the diagnosis can be confirmed. Trichomonads can also be seen on a Pap smear with a similar sensitivity to the wet mount, but with a higher rate of false-positive results. Other sensitive and specific rapidly performed diagnostic tests have recently been developed, including direct immunofluorescence assay, enzyme-linked immunoassay, and LPA. These are not, however, in widespread use currently. All women with trichomoniasis, whether symptomatic or not, should have a culture taken for *N. gonorrhoeae* because of the frequency of coinfection.

Management Options

Because *T. vaginalis* resides not only in the vagina but also in the urethra and bladder, systemic therapy is necessary for treatment. The only effective therapy for trichomoniasis are the nitroimidazole antibiotics, including metronidazole, ornidazole, and tinidazole. For pregnant women who are symptomatic, treatment is recommended. However, it is important to note that, although trichomoniasis has been associated with adverse pregnancy outcomes, treatment has not been shown to reduce the incidence of these adverse events,[135] and some studies have even documented an increased risk with treatment. Therefore, treatment is not indicated in asymptomatic *T. vaginalis* infection in pregnancy. In a randomized, controlled trial of pregnant women with asymptomatic trichomoniasis, the preterm birth rate was 19% in those given two 2-g doses of oral metronidazole and 10% in the placebo group (RR 1.8; 95% CI 1.2–2.7; P = .004).[163] In another randomized trial, children of women treated with several antibiotics including metronidazole had an increased risk of low birth rate, preterm delivery, and 2-year mortality.[164] Finally, a meta-analysis of 14 studies revealed that metronidazole treatment increased the incidence of preterm birth.[165]

For pregnant women in whom treatment is chosen, the preferred regimen is a single 2-g dose of oral metronidazole. Simultaneous treatment of sexual partners is required to prevent reinfection. As previously mentioned, there is no evidence that metronidazole is teratogenic or mutagenic in human studies, and it is considered safe for use in pregnancy.[143,144]

Parasitic Infections

ALBERT FRANCO and JOSEPH M. ERNEST

INTRODUCTION

In the developing world, pregnant women frequently experience a cycle of undernutrition and parasitic infections, resulting in adverse pregnancy outcomes, including abortion, malformation, and neonatal death. Although malnutrition in general and parasitic infections specifically are less common in developed countries, no society is immune from their potential effects during pregnancy. Six parasitic infections that have major health, financial, or combined consequences worldwide are Lyme disease, malaria, tuberculosis (TB), syphilis, toxoplasmosis, and schistosomiasis.

LYME DISEASE

General

In the early 1970s, a mysterious clustering of juvenile rheumatoid arthritis–like cases occurring in children in and around Lyme, Connecticut, was subsequently recognized as a distinct disease and named Lyme disease. Further investigation revealed that tiny deer ticks infected with a spirochetal bacteria, later named *Borrelia burgdorferi*, were responsible for the outbreak.[1] Subsequent research has discovered additional vectors, three distinct stages of the disease, and multiple therapy options.

Ticks are divided into two families of medical importance: the Ixodidae (hard ticks) and Argasidae (soft ticks). Family Ixodidae contains ticks of the genera Ixodes which are responsible for transmitting spirochetal bacteria responsible for Lyme disease.[2] Black-legged ticks (*Ixodes scapularis*) are responsible for transmitting *B. burgdorferi* to humans in the northeastern and north central United States; on the Pacific Coast, the bacteria are transmitted to humans by the western black-legged tick (*Ixodes pacificus*). The life cycle of ticks is 2 years and includes egg, larva, nymph, and adult. *Ixodes scapularis* nymphs appear to be the most important vector for transmission of *B. burgdorferi*. *Ixodes* ticks are much smaller than common dog and cattle ticks and usually feed and mate on deer during the adult part of their life cycle. The larvae (or seed ticks) are six-legged, whereas adult and nymphs are eight-legged. In their larval and nymphal stages, these ticks are no bigger than a pinhead. According to laboratory studies, a minimum of 36 to 48 hours of attachment of the tick is required for transmission,[3] presumably because of the time required for the bacteria to travel from the midgut of the tick to its salivary glands.

In the United States, Lyme disease is mostly localized to states in the northeastern, mid-Atlantic, and upper north central regions and to several counties in northwestern California, although it has been reported in all 50 states. In 2000, 17,730 cases of Lyme disease were reported to the Centers for Disease Control and Prevention (CDC), making it the most common vector-borne illness in the United States.[4] In 2007, 27,444 cases of Lyme disease were reported yielding a national average of 9.1 cases per 100,000 persons. Ninety-two percent of these were from the states of Connecticut, Rhode Island, New York, Pennsylvania, Delaware, New Jersey, Maryland, Massachusetts, and Wisconsin. In these states, the average was 34.7 cases per 100,000 persons. Most cases occur in the United States between May and August, corresponding with increased outdoor human activity and nymphal activity.

Diagnosis

Clinically, Lyme disease has three stages:
- Early-localized.
- Early-disseminated.
- Late-stage disease.

Only the early-localized stage contains a hallmark unique to Lyme disease—the erythema migrans rash—which is present in 60% to 80% of patients at the site of the bite.[5] Adding to this difficulty in diagnosis is the frequent absence of notable tick bites in many individuals who subsequently have symptoms of Lyme disease.

Although the gold standard for diagnosis of an infectious disease is isolation of the causative organism, this confirmation is often difficult in Lyme disease, and the reliability of other methods currently available is questionable.[6] The diagnosis of Lyme disease is, therefore, based on the history of a tick bite in an endemic area and on characteristic clinical findings. Serology using enzyme-linked immunosorbent assay (ELISA) is the most common laboratory test to screen for antibodies to *B. burgdorferi*, but the test is not standardized and results may vary between laboratories, with false-negatives and false-positives commonly seen.[7] Given the high rate of false-positive serology associated with ELISA, a positive or equivocal ELISA should be followed by an

immunoblot (Western blot) on the same specimen to detect immunoglobulin M (IgM) and IgG antibodies. If positive, the diagnosis is confirmed.[6] IgM antibodies appear 2 to 4 weeks following onset of rash and decline to low levels at 4 to 6 months. IgG antibodies appear at 6 to 8 weeks, peak at 4 to 6 months, and remain elevated even with treatment. In patients with only cutaneous disease (erythema migrans rash), laboratory testing is neither necessary nor recommended because laboratory studies may be negative at this early stage; in suspected cases of extracutaneous Lyme diseases, laboratory studies are essential.

Diagnosis of Early-Localized Disease

The hallmark of Lyme disease—the erythema migrans rash—typically occurs within 1 week of infection, but can develop as late as 16 weeks after the tick bite. The rash develops centrifugally as an erythematous, annular, round to oval, well-demarcated plaque and can reach a diameter of more than 30 cm. Occasionally, the lesion might be hemorrhagic or nonmigratory. The rash may be accompanied by constitutional symptoms such as myalgia, arthralgia, low-grade fever, and regional lymphadenopathy. Untreated, the lesions usually resolve within 3 to 4 weeks. Within days to a few weeks after the infection, hematogenous and lymphatic dissemination of the organism to distant sites occurs, leading to the early-disseminated stage.

Diagnosis of Early-Disseminated Disease

The most characteristic manifestations of this stage occur in the skin, musculoskeletal system, and neurologic system.[8] Skin manifestations during this stage include the development of other annular plaques resembling erythema migrans, found in up to half of patients. About 6 months after infection, approximately 60% of patients develop musculoskeletal symptoms, including arthralgias and myalgias early in the process, and asymmetrical, oligoarticular arthritis primarily of the large joints (especially the knee) later in the disease. The most common neurologic feature is cranial neuropathy, including unilateral or bilateral facial paralysis. Cardiac involvement, a less common component of this stage, may include atrioventricular block (in ≤ 8% of patients), left ventricular dysfunction, pericarditis, or fatal pancarditis.[9]

Diagnosis of Late-Stage Disease

Manifestations of late-stage disease can occur months to years after the initial infection and most commonly involve the skin, musculoskeletal system, and neurologic system. Localized scleroderma-like lesions may involve the skin, and approximately 10% of patients in the United States with untreated disease will develop chronic Lyme arthritis, an asymmetrical oligoarticular or monoarticular arthritis. Permanent joint disease is unusual. The central and peripheral nervous system can be affected, most commonly with intermittent distal paresthesias or radicular pain.[7]

Maternal and Fetal Risks

Although transplacental transmission of *B. burgdorferi* has been reported, it seems to be infrequent.[10,11] In a report by Markowitz and colleagues,[12] in which 19 cases of Lyme disease were collected retrospectively, 5 had adverse outcomes, including syndactyly, cortical blindness, intrauterine fetal death, prematurity, and rash. Neither trimester of acquisition nor therapy administered seemed to be associated with the outcome. Weber and Pfister[13] collected 58 cases from Slovenia, including 13 in the first trimester, 27 in the second trimester, and 18 in the third trimester, and concluded that the outcomes of 1 missed abortion and 5 preterm infants revealed no causal connection between the organism and adverse fetal effects. Likewise, Williams and Strobino[14] divided a group of 463 infants after birth into those serologically positive and negative to *B. burgdorferi* and found no difference in the incidence of malformations based on the infant's serology or geographic location. Therefore, recommendations for therapy during pregnancy are similar to those for nonpregnant individuals, with the exception of avoidance of tetracyclines and doxycycline in pregnancy.

Management Options

Prepregnancy and Prenatal

With the exception of the avoidance of tetracyclines during pregnancy, management options are similar before and during pregnancy. Four clinical situations can occur during which the practitioner may need to consider Lyme disease and the need for therapy:

- Tick bites without signs of infection.
- Early-localized.
- Early-disseminated.
- Late-stage disease.

TICK BITES WITHOUT SIGNS OF INFECTION

The best method of preventing Lyme disease is to avoid exposure to the vector ticks. If the patient resides in an endemic area, most practitioners recommend the use of DEET (*N,N*-diethyl-3-methylbenxamide). There is no evidence of risk in pregnancy with its use.[15]

The Infectious Disease Society of America recommends antibiotic prophylaxis only in those who meet four specific criteria: (1) attached tick identified as an adult or nymphal *I. scapularis* tick (deer tick), (2) it is estimated that the tick has been attached for 36 hours or longer, (3) prophylaxis is begun within 72 hours, and (4) doxycycline is not contraindicated.[16] As a result, pregnant patients are not candidates for prophylactic antibiotics. However, pregnant patients who remove attached ticks should be monitored closely for signs and symptoms of tick-borne diseases for up to 30 days and should be especially observant for the occurrence of a skin lesion at the site of the tick bite (which might suggest Lyme disease) or a temperature higher than 38°C (which may suggest other tick-related illnesses). Persons who develop a skin lesion or other illness within 1 month after removing an attached tick should promptly seek medical attention. Owing to the early appearance of both IgM and IgG antibodies, there is no utility in these serologic tests at the time of a tick bite.

EARLY-LOCALIZED STAGE

Identification of the bull's-eye rash of erythema migrans should prompt early oral treatment for nonpregnant adults

with doxycycline 100 mg PO twice a day for 10 to 21 days. Pregnant women should be given amoxicillin 500 mg PO three times a day for 21 days, or if allergic to penicillin, cefuroxime axetil 500 mg PO twice a day for 14 to 21 days. Macrolides have been shown to be less effective. As a result erythromycin 250 to 500 mg PO four times a day for 21 days may be substituted only if the patient is intolerant to cefuroxime, and these patients should be monitored closely for evidence of treatment failure.[16] More than 90% of infected individuals respond to antibiotic therapy; when prompt and complete response is not seen the practitioner should consider a later or underdiagnosed stage of disease (such as unsuspected neurologic disease) or co-infection with other tick-borne infections, such as ehrlichiosis or babesiosis.

A Jarisch-Herxheimer–type reaction may occur in the first 24 hours of treatment, consisting of fever, chills, myalgia, headache, tachycardia, increased respiratory rate, and mild leukocytosis.[17] Defervescence usually takes place within 12 to 24 hours, and the patient can be managed by bedrest and appropriate antipyretics.

EARLY-DISSEMINATED AND LATE-STAGE DISEASE

In the absence of neurologic involvement or third-degree atrioventricular heart block, oral doxycycline or amoxicillin are recommended for early-disseminated disease. Cefuroxime axetil is an acceptable alternative when the patient is unable to take either doxycycline or amoxicillin. Parenteral antibiotics such as ceftriaxone 2 g IV daily for 14 to 28 days may be used for acute neurologic disease and third-degree atrioventricular heart block.

Labor and Delivery

No specific recommendations apply to the intrapartum period.

Postnatal

Women who develop Lyme disease during pregnancy should be monitored for up to 1 year for symptoms that may represent late-stage disease. These include localized scleroderma-like lesions of the skin, chronic Lyme arthritis involving single large joints such as the knee, and intermittent distal paresthesias or radicular pain.

SUMMARY OF MANAGEMENT OPTIONS
Lyme Disease

Management Options	Evidence Quality and Recommendation	References
Prepregnancy and Prenatal		
Tick bites: Avoid tick-infested areas when possible and carefully remove all ticks as soon as recognized.	IV/C	16
Observe skin after tick bites for up to 30 days for signs of infection.	IIb/B	16
Prophylactic antibiotics are usually not warranted in absence of infection.	Ib/A	15
Early-stage disease: Doxycycline 100 mg PO bid for 10–21 days for nonpregnant or amoxicillin 500 mg PO tid for 21 days for pregnant adults are comparable therapies.	Ib/A	13,16
Late-stage disease: Intravenous therapy should be considered.	III/B	13,16
Postnatal		
Observe the patient for up to 12 mo for signs of chronic Lyme disease.	IV/C	13,16

TUBERCULOSIS

General

TB is a disease with enormous worldwide implications. There were approximately 8.3 million cases of TB and 1.8 million deaths due to TB in 2000. The highest incidence rate exists on the African continent where approximately 290 of 100,000 persons contract TB on a yearly basis.[18–20]

TBs may be caused by any one of three mycobacterial pathogens: *Mycobacterium tuberculosis* (the most common), *Mycobacterium bovis*, and *Mycobacterium africanum*. *Mycobacterium microti*, also a tubercle bacilli, does not cause disease in humans.

TB is spread from person to person through the air by droplet nuclei, particles 1 to 5 μm in diameter, that contain *M. tuberculosis* complex.[21] Droplet nuclei are produced when persons with pulmonary or laryngeal TB cough, sneeze, speak, or sing. Droplet nuclei, containing two to three *M. tuberculosis* organisms, are so small that air currents normally present in any indoor space can keep them airborne for long periods of time.[22] These particles are small enough to reach the alveoli within the lungs, where the organisms replicate.[23] Organisms deposited on intact mucosa or skin do not invade tissue. After inhalation, the droplet nuclei are carried down the bronchial tree, where the tubercle bacilli are ingested by alveolar macrophages. The organisms can multiply there, growing for 2 to 12 weeks until a critical number of 10^3 to 10^4 is reached, which is sufficient to elicit a cellular immune response that can be detected by a reaction to the tuberculin skin test (TST).[24]

Before the infected individual develops cellular immunity, tubercle bacilli spread via the lymphatics to the hilar lymph nodes and through the bloodstream to more distant sites. After cellular immunity develops, granulomas are formed that limit multiplication and further spread.

Diagnosis

In non–HIV-infected patients, the majority of reported TB cases are limited to the lungs. Advanced infection with HIV, however, results in extrapulmonary involvement over 60% of the time.[25]

Systemic effects of TB include fever (present in ≤ 80% of patients),[26] weight loss, increases in peripheral leukocyte count and anemia (present in ~10% of patients),[27] and hyponatremia, occurring in as many as 11% of patients.[28]

Cough is the most common symptom of pulmonary TB, beginning as nonproductive but subsequently becoming sputum-producing. Hemoptysis is uncommon early in the disease process. Physical findings in pulmonary TB are generally unhelpful, although the chest film almost always reveals abnormalities, generally seen as a middle or lower lung zone infiltrate, often associated with ipsilateral hilar adenopathy when the disease is primary and is occurring as a result of a recent infection. TB that develops as a result of endogenous reactivation of latent infection usually causes abnormalities in the upper lobes of one or both lungs and may also involve cavitation.[29]

Pending confirmatory cultures, which may take several weeks, pulmonary TB can be diagnosed with sputum samples that show the presence of acid-fast bacilli (AFB), identified in 50% to 80% of patients with pulmonary TB.[29] A series of at least three single specimens should be collected on different days. Specimens should be transported to the laboratory and processed as soon as possible. If delay is inevitable, the specimen should be refrigerated until prompt delivery can be ensured. No fixative or preservative agents should be used. Direct amplification tests using gene probes or polymerase chain reaction (PCR) testing and high-performance liquid chromatography may also be useful in some circumstances in evaluating the patient. Regardless of the method used to diagnosis TB, cultures of the organism are essential for confirmation and to allow for drug susceptibility testing, a critical component of TB infection management.

Extrapulmonary TB can present as a disseminated form or in the lymph nodes, pleural cavity, genitourinary system, skeleton, central nervous system, abdomen, or pericardium. The ease and accuracy of diagnosis of extrapulmonary TB depend on the system involved.

In addition to symptomatic TB, patients who may have asymptomatic latent infection require careful consideration and thoughtful diagnosis as well. Current recommendations discourage screening of low risk populations because of false-positive results and subsequent inappropriate and potentially hazardous drug administration.

Annual TST administration is recommended in the following asymptomatic individuals:

- Potential close contact with infected individuals (health care workers, prison guards, laboratory personnel).
- Persons who are HIV-infected or who have another medical condition placing them at high risk for infection (chronic illness, immune deficient, homeless, medically underserved).
- Long-term care facility resident.
  A one-time TST is indicated in the following situations:
- Single exposure with low risk for repeated exposures (if recent exposure, repeat TST 6–12 wk later).
- Recent visit to an endemic area in which the person was in a health care, relief, or refugee setting.
- Less than 5 years after arrival of a foreign-born individual from an endemic area.
- Incidental finding of a fibrotic lung lesion.

When screening for latent infection is considered, the preferred skin test for *M. tuberculosis* is the intradermal, or Mantoux, method. It is administered by injecting 0.1 mL of 5 tuberculin units (TU) PPD (purified protein derivative) intradermally into the dorsal or volar surface of the forearm. Tests should be read 48 to 72 hours after test administration, and the transverse diameter of induration (not inflammation) should be recorded in millimeters. Multiple puncture tests (Tine and Heaf) and PPD strengths of 1 TU and 250 TU are not sufficiently accurate and should not be used.

Three cutoff levels have been recommended for defining a positive tuberculin reaction: 5 mm or greater, 10 mm or greater, and 15 mm or greater of induration, depending on the risk group in which the patient resides. If there is no underlying disease causing immunosuppression, 75% to 95% of individuals with active TB will have a positive TST (≥10 mm). Specificity is 98% to 99%. For persons who are at highest risk for developing TB disease if they become infected with *M. tuberculosis*, a cutoff level of 5 mm or greater is recommended. This group contains immunosuppressed patients, those with recent close contact with a patient with infectious TB, and individuals with fibrotic changes on chest x-ray consistent with prior TB. A reaction of 10 mm or greater of induration should be considered positive for those persons with an increased probability of recent infection or with other clinical conditions that increase the risk of TB, such as recent immigrants from endemic areas, intravenous drug users, or those with normal or mildly impaired immunity including groups with poor access to health care. This level is reasonable for pregnant patients. A reaction of 15 mm or greater of induration should be used for groups at low risk for latent infection, should that group be tested.[30] In most individuals, PPD skin test sensitivity persists throughout life. Over time, however, the size of the skin test may diminish or disappear. If a PPD test is administered in this situation, the initial test result may be small or nonidentifiable. However, there may be accentuation of response on repeated testing. This is called the *booster effect* and does not represent a skin test conversion. This two-step method is commonly used in health care workers who undergo repeated tests and involves an initial test that, if negative, is followed in 1 to 3 weeks by a second and similar TB skin test, administered at a different site. The second test should be considered the "correct" one and the results from its induration measurement used. Because of the small amount of antigen administered, repeated skin testing with tuberculin will not induce a positive skin test reaction in individuals who have no cellular immunity to the antigens in PPD.[31]

Previous immunization with bacillus Calmette-Guérin (BCG) has been shown to protect against disseminated TB

and meningitis in children, but has not been conclusively demonstrated to have protective effects against pulmonary disease in children or adults.[32] Millions of people around the world have been vaccinated with this attenuated strain of *M. bovis*, which frequently causes a false-positive Mantoux skin test. However, to avoid undertreatment of those truly infected, it is considered prudent by many experts to consider induration of more than 5 mm as indicating infection with *M. tuberculosis*, even with a history of BCG immunization.

Maternal and Fetal Risks

TB during pregnancy appears to progress in a similar fashion as in the nonpregnant individual. There appears to be no risk to the fetus with maternal exposure or positive skin testing in the absence of active pulmonary or extrapulmonary disease, although the tubercle bacillus has been reported to cross the placenta and granulomas rarely are found in the placenta.[33–35] Because of these reassuring findings, the risks to the mother are similar to those of the nonpregnant individual, and both mother and fetus share potential medication side effect risks.

Management Options

Prepregnancy and Prenatal

A positive TST in a low risk asymptomatic pregnant patient should prompt a chest radiograph to be performed after the 12th week of pregnancy to exclude asymptomatic pulmonary TB.[36] The main points about prepregnancy and prenatal care in patients with TB are
- Pregnancy does not affect the course of TB.[30,34]
- TB is unlikely to have fetal effects, and maternal effects of latent disease are primarily related to side effects of medications.[34]
- Latent disease should be treated with isoniazid and pyridoxine during pregnancy if risk factors such as HIV infection or known contact with an infected individual are present or immediately postpartum in the absence of risk factors.[30,34]
- If active disease is suspected, a chest radiograph should be performed regardless of gestational age and, if present,

TB should be treated aggressively during pregnancy, with a combination of isoniazid, rifampin, and ethambutol for 9 months. Addition of pyrazinamide should be included only if a multiresistant strain is suspected.[34,36]
- Streptomycin should be avoided during pregnancy.[34]

Labor and Delivery

Factors that should be considered when managing an intrapartum patient with TB include
- Masks worn by persons exposed to an infectious source are less effective than are masks worn by patients with TB, because most airborne droplet nuclei are much smaller than their parent droplets.
- Droplet nuclei do not settle but remain suspended in the air for long periods of time.[22]

Asymptomatic patients under appropriate medical therapy do not pose a risk to health care providers. However, patients with untreated or undiagnosed disease may pose a serious threat to the health care team. In labor and delivery, any coughing patient who comes in contact with the health care team should immediately be provided a surgical mask, tissues, and a container to collect tissues. Patients with any of the following symptoms should be evaluated for the presence of TB: persistent cough for 3 weeks or more, bloody sputum, night sweats, weight loss, or fever. If any of these are noted, a chest x-ray should be obtained and sputum sent for AFB. If active TB is suspected, use of an isolation room with airborne transmission precautions should be implemented until further workup is complete. Health care workers should wear respirators capable of filtering particles to 1 μm in diameter with facial leak of 10% or less. Health care workers exposed to patients with active disease should have a PPD administered immediately and again in 12 weeks. Nursery personnel should be alerted when a newborn has an actively infected mother.

Postpartum

Patients with recent skin test conversion who have not been treated during pregnancy should be considered for therapy in the postpartum period. Although anti-TB drugs can be measured in breast milk, breast-feeding is safe during therapy for TB. Some anti-TB drug may reduce the efficacy of the oral contraceptive pill.

MALARIA

General

Malaria is produced by intraerythrocytic parasites of the genus *Plasmodium* that are transmitted by the bite of the infective female anopheline mosquito. One billion people worldwide are estimated to carry parasites at any one time and approximately 50 million are pregnant.[37,38] It is estimated that between 10,000 to 200,000 newborns die as a result of infection in pregnancy.[38] Its name is derived from the belief of the ancient Romans that *mal-aria* was due to the bad air of the marshes surrounding Rome.

Four plasmodia produce malaria in humans: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, and *Plasmodium malariae*. Most deaths are the result of *P. falciparum* and occur in children younger than 5 years, although pregnant women are also at increased risk for severe disease. Early treatment usually results in cure without recurrence, although *P. ovale* and *P. vivax* may remain dormant and recur months or years after the initial infection. Once infected, partial immunity may develop.

Human infection begins when sporozoites in the salivary gland of the female *Anopheles* mosquito are inoculated into the human host as the insect feeds. These parasites infect human hepatocytes within 30 minutes of entering the human body.[39] In the hepatocyte, each sporozoite divides and differentiates to form up to 30,000 merozoites, which rupture the hepatocyte and enter the bloodstream to infect erythrocytes.[40] Sporozoites of *P. vivax* and *P. ovale* may also form hypnozoites, dormant forms that remain in hepatocytes and may lead to recurrent infection months or years later. Merozoites actively enter the host erythrocytes, where they differentiate into ring-shaped trophozoites. These trophozoites develop into a schizont, which fills with merozoites, subsequently rupturing the erythrocyte and infecting other red blood cells (RBCs). Periodically, merozoites differentiate into male or female gametocytes, sexual forms that are ingested by *Anopheles* mosquitoes feeding on the infected human host. In the mosquito midgut, gametocytes merge to form a diploid zygote that differentiates into a motile ookinete that enters the gut wall to form an oocyst. Sporozoites released from the oocyst migrate to the salivary glands of the mosquito to repeat the cycle.[39]

Rupture of erythrocytes by proliferating merozoites occurs with a periodicity related to the species of plasmodia. This cycle repeats every 72 hours for *P. malariae* (*quartan malaria*) and every 48 hours for other malaria species (*tertian malaria*). Fever greater than 40°C is lethal to schizonts; consequently, the life cycle tends to be synchronized over the course of the infection, leading to periodic fever spikes rather than continuous fever.[41] Anemia develops in the infected human as a result of erythrocyte rupture by merozoite proliferation and by sequestration of normal uninfected RBCs by an engorged liver and spleen. Iron stores are depleted as hemoglobin from lysed RBCs is lost in urine.

Renal failure can result from a number of causes, including the rigidity of RBCs filled with merozoites that fail to pass through venules and capillaries, leading to microvascular sludging and ischemia in the kidneys. Cerebral malaria (the most common cause of death in this disease) occurs only with *P. falciparum* infection, because clumps of erythrocytes

occlude the cerebral microvasculature, causing diffuse cerebral ischemia.

Acutely ill patients with malaria typically have either *P. falciparum* or *P. vivax* infections.[41] Partial resistance to malaria occurs in the presence of sickle cell trait (owing to decreased intraerythrocytic adenosine triphosphatase [ATPase] activity, which decreases surplus energy available to support parasite proliferation[39]) and in the absence of the Duffy antigen (owing to the propensity of merozoites of *P. vivax* to invade erythrocytes by binding to that antigen).

Diagnosis

Fevers, chills, and headaches are the hallmark of malarial infection. The chills can last for periods of 1 to 2 hours. Concomitant with lysis of RBCs, the febrile stage is characterized by rigors, flushing, headache, and muscle aches with temperatures of 39°C to 42°C. This stage can last for up to 6 hours, followed by profuse sweating and, as these symptoms disappear, excessive fatigue. Although most cases of malaria are classified as mild or uncomplicated, as the degree of parasitemia in patients with *P. falciparum* rises above 2%, the risk of severe malaria grows. Severe malaria is characterized by renal failure (sometimes accompanied by gross hemoglobinuria from lysed RBCs, termed *blackwater fever*), noncardiogenic pulmonary edema, severe anemia, jaundice, seizures, parasitemia of greater than 5%, coma, circulatory collapse, or hypoglycemia, in the presence of either recent exposure to malaria or *P. falciparum* on smear.[42]

For the past 100 years, confirmation of the diagnosis of malaria has been made with the demonstration of intraerythrocytic parasites by Giemsa-stained thick and thin smears of fresh fingerprick blood. All four *Plasmodium* species may be identified in this fashion. Although the thin smear is easier to read, the thick smear is 10 to 40 times more sensitive and can detect as few as 50 parasites/μL.[43] Detectable parasitemia may lag behind aches, fevers, and chills by 2 days. If malaria is suspected, thick and thin smears should be done every 8 to 12 hours on at least three occasions, the collection of which should not be tied to fever spikes. Persistently negative smears after this time period argue against the presence of malaria.[41]

Several alternative laboratory methods have been developed, including the quantitative buffy-coat centrifugal hematology system, immunofluorescence, ELISA tests for the detection of the *P. falciparum* antigen, and the PCR technique. Because of cost and complexity, none of these tests is used routinely.[44] Rapid blood tests using a dipstick or test strip with monoclonal antibodies directed against the target parasite antigen histidine-rich protein 2 (Pf HRP2) or parasite-specific lactate dehydrogenase (pLDH) are currently commercially available. Limitations in these methods include persistent Pf HRP2 antigenemia despite microscopic and clinical cure and positivity of pLDH only when viable parasites are present.[41]

Maternal and Fetal Risks

Pregnant women have an increased risk of malarial infection compared with their nonpregnant adult counterparts,[45] the difference being most marked during the first pregnancy and after the first trimester. In one study in Malawi, the incidence of parasitemia in primigravidas was 66%, falling to 29% in the second and 20.9% in subsequent pregnancies.[46] This increased susceptibility may be due to a number of reasons. Pregnant women seem to be more attractive to the female *Anopheles* mosquito than nonpregnant women and incur a significantly greater number of bites.[47] Sequestration of *P. falciparum* in the placenta may be another; in one case in which a woman's peripheral blood parasitemia was 3% at presentation (and presumably less after treatment), her placenta at delivery showed a local parasitemia of 70%.[48]

Although the major adverse effect of malaria in pregnancy on the mother is anemia, the risk of developing severe and complicated malaria is three times higher in pregnancy[49] and that of developing hypoglycemia is seven times more likely.[50] Malaria presents a significant risk for morbidity and mortality in pregnancy. Intrauterine growth restriction, miscarriage, preterm birth, congenital infection, and perinatal death have been seen in pregnancies infected with malaria. Studies have demonstrated an increased incidence of intrauterine growth restriction when parasitemia is found during the antenatal period and an increased incidence of premature birth when cord blood parasitemia (probably reflecting recent active infection) is seen.[50–53]

Management Options

Prepregnancy

Malaria chemoprophylaxis and therapy before pregnancy is similar to that administered to other adults, and can be reviewed at www.cdc.gov. Management principles are similar to those discussed in the following sections, with the exception that additional drugs are available to the nonpregnant adult that are not appropriate for the pregnant woman.

Prenatal

Management of the pregnant patient involves two components: prevention of infection and treatment of disease. To prevent serious infection in pregnancy, pregnant women should be advised to avoid travel into areas where there is chloroquine-resistant *P. falciparum* malaria. There are an increasing number of chloroquine-resistant strains worldwide. When travel is unavoidable into these regions, use of pyrethroid-containing flying-insect spray in living and sleeping areas during evening and nighttime hours is advisable. Bednets, especially those sprayed with the insecticide permethrin, are effective in limiting mosquito bites, and use of the insecticide DEET is a safe and effective means to minimize bites during pregnancy as well.[54] Recommended chemoprophylaxis in areas *without* chloroquine-resistant *P. falciparum* is chloroquine phosphate (Aralen) 500 mg/wk (300 mg chloroquine base) once weekly beginning 2 weeks before travel and during exposure and for 4 weeks after leaving the endemic area. Recommended chemoprophylaxis in areas *with* chloroquine-resistant *P. falciparum* is mefloquine (Lariam) 250 mg/wk, following the same schedule as chloroquine. It is critical that the patient continue the medication for 4 weeks after leaving the endemic area because

infection is not prevented by the chemoprophylaxis, because sporozoites released into the bloodstream by the biting mosquito still reach the liver even in the presence of these medications. As the developing merozoites are released into the bloodstream, the infection succumbs to the drugs at this point.[55]

Before treating a pregnant patient with malaria, one should consider the place where the infection occurred, the trimester of pregnancy, and whether the clinical and parasitologic situation is severe. Consideration of the place where the infection occurred allows the clinician to use drugs that should meet with the least chance of resistance in the parasite. Consideration of the trimester of pregnancy allows the clinician to use drugs with the least chance of fetal toxicity, and consideration of the clinical and parasitologic situation allows the clinician to determine the aggressiveness and length of therapy. The drug or drugs chosen should be effective in the reduction of the asexual forms in the blood and in the placenta in order to prevent or reduce the severe clinical forms. Although the latest recommendations regarding specific treatment from certain regions may be obtained from the CDC, we review concepts of malaria therapy and drugs useful in the pregnant patient. Of note, CDC clinicians are available 24 hours a day to help with questions of diagnosis and treatment of malaria through the Malaria Hotline (770-488-7788 or 770-488-7100 on holidays, weekends, and off-hours).[43]

CHLOROQUINE

Although in many areas of the world, 80% or more of *P. falciparum* infections exhibit a high degree of chloroquine resistance,[56] chloroquine is still considered one of the safest antimalarials. It is not considered to be a cause of spontaneous abortion or teratogenesis when used for chemoprophylaxis or in recommended dosages for treatment,[57] but when given in large doses, it has been reported to cause alterations of the eighth cranial nerve and retinal pigmentation in the fetus.[58]

QUININE AND QUINIDINE

Quinine and quinidine remain effective therapies for malaria, and a quinine-tetracycline combination cures nearly 100% of *P. falciparum* infections no matter in which region of the world the disease is contracted.[41] Unfortunately, although quinine may be used during pregnancy, tetracyclines should be avoided because of adverse fetal effects. Quinine may cause cinchonism (headache, tinnitus, nausea, vision disturbances) and, if glucose-6-phosphate dehydrogenase deficiency is present, hemolysis. Quinidine may be used intravenously with caution because of its cardiosuppressant effects and its tendency to cause severe hypotension when administered rapidly. It can also cause hypoglycemia in the pregnant patient because of its tendency to stimulate the β cells to produce insulin.[42]

Quinine has been shown to be safe in therapeutic doses in the first trimester of pregnancy.[59]

ANTIFOLATE DRUGS

The drug combinations sulfadoxine/pyrimethamine and sulfamethoxazole/trimethoprim work synergistically on two enzymes of the *Plasmodium* organism: dihydropteroate synthase and dihydrofolate reductase. Pyrimethamine has produced a teratogenic effect in laboratory test animals (which can be avoided by the administration of folinic acid), and sulfa administration to the mother near delivery has a theoretical risk to the fetus of kernicterus. Because of these concerns, these combinations should be limited to the second or early third trimester.

MEFLOQUINE

Mefloquine is critical for chemoprophylaxis or therapy in areas of chloroquine-resistant *P. falciparum*. Studies have not shown significant adverse effects on the mother or fetus when mefloquine is administered in the second or third trimester of pregnancy. Observations made on a group of 1627 women who used mefloquine before conceiving or during pregnancy failed to demonstrate an increased risk of toxic or teratogenic effects on the embryo.[60] Side effects in general may include the induction of neuropsychiatric alterations including anxiety, affective disorders, hallucinations, psychosis, and convulsions.[61]

CLINDAMYCIN

Clindamycin is useful in the treatment of resistant *P. falciparum* and is an alternative to tetracycline or doxycycline, because it does not produce important adverse effects in the pregnant patient or fetus. Clindamycin in combination with quinine has been used since 1982 in Brazil and has been found to be an effective therapy for multiresistant strains of malaria, with no observed significant side effects in mother or fetus.[45]

ARTEMISININS

These antimalarials, isolated by Chinese scientists from *Artemisia annua*, currently are the fastest acting of all antimalarial drugs and have not shown significant toxicity.[62]

Resistance is rare, and although experimental studies with laboratory animals showed that doses above 10 mg/kg weight cause fetal resorption,[63] preclinical studies did not show any mutative or teratogenic effects. Increasing evidence of their safety has prompted the WHO to release a statement allowing the use of these compounds in the second and third trimesters of pregnancy. Their use is also allowed in the first trimester in complicated, severe, or recurrent cases in which no other medicines are effective.[64]

Labor and Delivery

No specific recommendations are needed for labor and/or delivery in these patients.

Postpartum

Breast-feeding patients should use the same chemoprophylaxis schedule and medication regimen for therapy as the pregnant patient.

Malaria Vaccines

Owing to the various life cycles of the protozoan and other features of the infection, development of a malaria vaccine remains elusive.[65]

SYPHILIS

General

Syphilis is a complex systemic illness caused by the spirochete *Treponema pallidum*. Debate about the origin of syphilis has continued for nearly 500 years, with 16th-century Europeans blaming each other, referring to it variously as the Venetian, Naples, or French disease. Evaluations of several hundred skeletons from archaeological sites in the United States and Ecuador ranging in age from 400 to 6000 years favor a New World origin.[66] Syphilis currently is a worldwide malady that can lead to serious maternal and fetal complications. The nickname "lues" came from the Latin *lues venereum*, which means "disease," "sickness," or "pestilence," and originally was loosely applied to any venereal disease. It became a synonym for syphilis at the beginning of the 20th century.

Despite continued declines among African Americans and women of all races, overall rates of primary and secondary syphilis have recently increased for the first time in more than a decade. After declines from 1992 to 2003, the rate of

primary and secondary syphilis among women increased from 0.8 cases per 100,000 population to 1.1 cases per 100,000 population in 2007.[67]

The causal agent of syphilis is *T. pallidum* spp. *pallidum*, which belongs to the family Spirochaetaceae. Other members of the genus *Treponema* that can infect humans are *Treponema pallidum* spp. *pertenue* (yaws), *Treponema carateum* (pinta), and *Treponema pallidum* spp. *endemicum* (bejel, nonvenereal, or endemic syphilis). A number of nonpathogenic treponemes have also been isolated from humans, particularly from the oral cavity. Other pathogenic organisms of the family Spirochaetaceae belong to the genera *Borrelia* and *Leptospira*.[68]

Syphilis can be acquired by sexual contact, by the fetus during pregnancy or birth, by kissing or other close contact with an active lesion, by transfusion of fresh human blood (banked < 24–48 hr), or by accidental direct inoculation. The overwhelming majority of cases of syphilis are transmitted by sexual intercourse, but for all practical purposes, a patient cannot spread syphilis by sexual contact 4 years or more after acquiring the disease.[68] Clinically, syphilis can be divided into five stages: incubating, primary, secondary, latent, and late syphilis. Diagnosis, therapy, and risk to the fetus vary with the stage of the disease.

Within hours or days after *T. pallidum* penetrates the intact mucous membrane or gains access through abraded skin, it enters the lymphatics or bloodstream and disseminates through the body. Virtually any organ, including the central nervous system, may be invaded. The minimum dose for human infection is not known, but in rabbits, an inoculum containing as few as four spirochetes can establish an infection. The incubation period is directly related to the size of the inoculum.[69] The median incubation period is 21 days, but can range from 3 to 90 days. During this stage, a spirochetemia develops that sets the stage for subsequent multiple organ invasion. The first symptomatology to develop occurs in the primary stage, which can last for 4 to 6 weeks (range 2–8 wk) and which usually includes development of the chancre. This painless ulcer (which may be slightly tender to the touch) occurs at the site of inoculation. A small inoculum produces only a papular lesion; a larger inoculum produces the ulcerative chancre. Persons with a history of previous syphilitic infection fail to develop any lesion or develop only a small, darkfield-negative papule.[69] Multiple chancres may occur.[70] Chancres heal spontaneously in 3 to 6 weeks (range 1–12 wk), leaving no trace or a thin atrophic scar. The manifestations of secondary syphilis often develop while the chancre is still present,[71] especially in HIV-infected patients.

The secondary or disseminated stage becomes evident 2 to 12 weeks (mean 6 wk) after contact. The generalized nature of this stage becomes evident as parenchymal, constitutional, and mucocutaneous manifestations may develop. The greatest number of treponemes is present in the body during this stage, and the classic and most commonly recognized lesions involve the skin. Macular, maculopapular, papular, or pustular lesions, and combinations and variations thereof, all may occur.[71] Vesicular lesions are notably absent. In warm, moist intertriginous areas, the papules enlarge, coalesce, and erode to produce painless, broad, moist, gray-white to erythematous, highly infectious plaques called *condylomata lata*. Constitutional symptomatology is also frequently present during the secondary stage and may include low-grade fever, malaise, pharyngitis, laryngitis, anorexia, weight loss, arthralgias, and generalized painless lymphadenopathy. The central nervous system may be involved in up to 40% of patients—headache and meningismus are common. The differential diagnosis of secondary syphilis is extensive—hence, the name "the great imitator."

Latent syphilis is by definition that stage of the disease during which a specific treponemal antibody test is present but during which there are no clinical manifestations of syphilis. It does not imply a lack of progression of disease. Early latent syphilis distinguishes the first year of that period, and late latent syphilis begins after 1 year. Only during the first 4 years of latent syphilis may a relapse occur; thus, the patient must continue to be considered infectious during those 4 years. After 4 years of late latent syphilis, the patient develops host resistance to reinfection and to infectious relapse. However, a pregnant woman with late latent syphilis can transmit the infection vertically to her fetus.

Late or tertiary syphilis is a slowly progressive, inflammatory disease that may affect any organ system and is usually subdivided into neurosyphilis, cardiovascular syphilis, and gummatous syphilis.

Diagnosis

Unlike many nonpathogenic treponemas, the virulent treponemes, including *T. pallidum*, cannot be cultivated in vitro.

Direct Examination for Spirochetes

In primary, secondary, and early congenital syphilis, the darkfield examination (a wet-preparation method for direct visualization of living *T. pallidum* spirochetes) or immunofluorescence staining of mucocutaneous lesions are the quickest and most direct laboratory methods of establishing the diagnosis.[72] Examination of a serous transudate from moist lesions such as a primary chancre or condyloma latum is productive because these lesions contain the largest number of treponemes. *T. pallidum* may be demonstrated from dry skin lesions or from lymph nodes by saline aspiration, if the saline is free of bactericidal additives. Specimens from mouth lesions are not accurate because *T. pallidum* cannot be distinguished from nonpathogenic treponemes with certainty.

Serologic Tests

Two different types of antibodies are measured in the evaluation of syphilis: the *nonspecific* nontreponemal reaginic antibody and the *specific* antitreponemal antibody.

Syphilis reaginic antibodies are IgG and IgM directed against a lipoidal antigen resulting from the interaction of host tissues with *T. pallidum* or from the organism itself. The earliest antigens used to measure reaginic antibody were phospholipid extracts made from beef livers and subsequently from beef hearts (hence, the name *cardiolipin*). The standard nontreponemal test is the VDRL (Venereal Disease Research Laboratories) slide test, although most laboratories have adopted a modification for routine screening called the rapid plasma reagin (RPR) test or other similar method. The quantitative RPR test should become nonreactive 1 year after successful therapy in primary syphilis and 2 years after successful therapy in secondary syphilis.[73] A patient with late

syphilis should have a negative response after 5 years.[74] However, the longer the disease has been present before treatment, the longer the VDRL takes to become nonreactive. In many cases after the secondary stage, it will never become nonreactive, even with adequate treatment (this is called *Wasserman fastness*). A prozone phenomenon occurs in about 2% of infected patients, especially in secondary syphilis and pregnancy, and appropriate dilutions should be performed whenever the index of suspicion is high.[75]

The principal specific antitreponemal antibody tests done today are the fluorescent treponemal antibody absorption test (FTA-abs), the *T. pallidum* particle agglutination (TPPA) test, *T. pallidum* hemagglutination assay (TPHA), and the microhemagglutination assay–*T. pallidum* (MHA-TP) test. The FTA-abs is a standard indirect immunofluorescent antibody test that uses *T. pallidum* harvested from rabbit testes as the antigen. Because of the difficulty with standardization between laboratories and with quantifying results and the meticulousness with which the test must be performed, the TPHA, which uses a sorbent for increased specificity, or the MHA-TP, an adaptation of the TPHA, is commonly used today. Once positive, the patient usually remains positive for life, although patients treated early may revert to a nonreactive state in up to 10% of cases.[68] Acute or transient false-positive nontreponemal reaginic test reactions may occur whenever there is a strong immunologic stimulus, such as with an acute bacterial or viral infection, vaccination, or early HIV infection. Positive reactions that last for months may occur with parenteral drug abuse, in those with autoimmune or connective tissue diseases, and in patients in hypergammaglobulinemic states. Syphilis may be excluded if a biologic false-positive (BFP) test is suspected by obtaining a negative specific treponemal antibody test, such as the FTP-abs or MHA-TP. Other spirochetal illnesses, such as relapsing fever (*Borrelia* spp.), yaws, pinta, leptospirosis, or rat-bite fever (*Spirillum minus*) may also yield a positive nontreponemal test. Infection with *B. burgdorferi* (Lyme disease) results in a positive FTA-abs test but does not cause a positive nontreponemal reaginic reaction with either the VDRL or the RPR.

Because of expense and ease of performance, screening large numbers of patients such as in pregnancy is usually done with reaginic antibody tests (RPR, VDRL), and confirmation is done with the specific treponemal tests (FTA-abs or MHA-TP).

Ultrasound

The prenatal diagnostic test with the greatest potential for identifying the severely infected fetus is ultrasound. Ultrasound findings suggestive of in utero infection include placentomegaly, intrauterine growth restriction, microcephaly, hepatosplenomegaly, anemia, and hydrops.

Maternal and Fetal Risks

Maternal risks of syphilis acquired during pregnancy are similar to those for acquisition in the nonpregnant state. *T. pallidum* readily crosses the placenta and up to 75% of infants born to mothers with active syphilitic infections will become infected in utero.[76] It is critical to identify infections as early in pregnancy as possible to reduce this risk. Although vertical transmission can occur during any stage of infection in the untreated or inadequately treated gravida, infection of the fetus before 16 weeks' gestation is rare; therefore, early abortion is unlikely to be the result of syphilis. Perinatal transmission occurs in approximately 50% of patients with primary or secondary syphilis. This decreases among women with latent infection (40%) or late latent/tertiary disease (10%). Treatment of the mother decreases risk of infection to approximately 1%. Later in pregnancy, depending on the severity of the maternal infection, abortion, stillbirth, neonatal death, neonatal disease, or latent infection may be seen.[72] More recent evidence indicates that these manifestations appear to be caused largely by dysfunction of the maternal-fetal endocrine axis, resulting in decreased levels of dehydroepiandrosterone produced by the fetal adrenal glands.[77] Neonatal manifestations of congenital syphilis include rhinitis (snuffles), which may be followed by a diffuse maculopapular, desquamative rash with extensive sloughing of the epithelium, particularly on the palms, on the soles, and around the mouth and anus. Hepatic involvement with associated splenomegaly, anemia, thrombocytopenia, and jaundice is also common. Neonatal death is usually caused by liver failure, severe pneumonia, or pulmonary hemorrhage. Renal involvement and a generalized osteochondritis and perichondritis may be seen as well.

Management Options

Prepregnancy

Although the efficacy of penicillin in the treatment of syphilis is well established, there remains uncertainty regarding optimal dose and duration of therapy, especially during pregnancy.[78] Therefore, treatment regimens must be viewed with this in mind and with the understanding that treatment failures do occur and must be recognized and retreated. From work with experimental infections, it is known that penicillin concentrations as low as 0.018 µg/mL sustained for 7 days in the nonpregnant adult results in almost 100% treponemicidal activity.[79] It has also been recognized that *T. pallidum* has been isolated from the cerebrospinal fluid (CSF) of patients with only a chancre.[80] Therefore, to adequately treat this infection that may affect the central nervous system, one must treat the parasite in the CSF. However, despite the fact that benzathine penicillin does not reliably achieve treponemicidal levels in the CSF[81] and that retreatment may be required in as many as 1 in 33 cases,[82] clinical experience continues to suggest that benzathine penicillin remains a mainstay of therapy. When an early diagnosis is made, fewer treponemes exist and the likelihood of a complete cure is greatly enhanced. Because of the high risk of infection, treatment should be given to anyone exposed to infectious syphilis within the preceding 3 months. Serologic studies must be done to establish the diagnosis and monitor success of therapy.

Prenatal

Pregnant patients should receive penicillin in the same dosage schedules as nonpregnant adults for comparable stages of the disease. When a well-documented penicillin allergy exists, desensitization (which can be accomplished in as few as 3–4 hr) is recommended.[83,84]

For primary and secondary syphilis and for early latent syphilis, administer benzathine penicillin G 2.4 million units

IM once. For late latent syphilis or for latent syphilis of unknown duration, administer benzathine penicillin G 7.2 million units total, as three doses of 2.4 million units IM each at 1-week intervals. Regimens for syphilis in pregnancy that do not include penicillin have not been documented to be adequate therapy to prevent congenital syphilis. Pregnant patients with concomitant HIV infections should be considered for treatment as if they have neurosyphilis, regardless of their clinical findings. The only effective treatment demonstrated for penicillin-allergic pregnant patients is desensitization followed by penicillin therapy. True penicillin allergy (except in those with history of an anaphylactic reaction) can be demonstrated by skin allergy testing.[85]

All women should be screened serologically for syphilis at the first prenatal visit. In populations in which prenatal care is not optimal, RPR test screening and treatment (if the RPR test is reactive) should be performed at the time a pregnancy is confirmed. For communities and populations in which the prevalence of syphilis is high or for patients at high risk, serologic testing in addition to routine early screening should be performed twice during the third trimester: at 28 weeks' gestation and at delivery.

The fetus with hepatomegaly or ascites is more likely to fail prenatal therapy and may benefit from a more extended course than usual and more intense monitoring throughout the remainder of the pregnancy.[86]

The Jarisch-Herxheimer reaction is a systemic reaction that occurs 1 to 2 hours after the initial treatment of syphilis with effective antibiotics. It consists of the abrupt onset of fever, chills, myalgia, headache, tachycardia, hyperventilation, vasodilation with flushing, and mild hypotension. Additional findings at or beyond 24 weeks' gestation include uterine contractions (42%) and recurrent variable fetal heart rate decelerations (38%).[87] It lasts for 12 to 24 hours and may be treated in pregnancy with antipyretics or prednisone, although no studies have documented a clearly effective prophylaxis.

Labor and Delivery

In the United States, some states mandate screening for syphilis at delivery for all women. Any woman who delivers a stillborn infant after 20 weeks' gestation should be tested for syphilis.

Postpartum

No infant should leave the hospital if maternal serologic status has not been determined at least once during pregnancy and preferably again at delivery. All patients with early or congenital syphilis should have repeat quantitative nontreponemal tests at 3, 6, and 12 months. All patients with secondary syphilis or syphilis of more than 1 year's duration should also have a nontreponemal serologic test 24 months after treatment. Many experts recommend examination of the CSF for those patients treated with benzathine penicillin because of its poor ability to penetrate the CSF. Retreatment should be considered whenever clinical signs and symptoms of syphilis persist or recur, whenever there is a sustained level or an increase in the titer on the nontreponemal test, or whenever a positive RPR reaction persists beyond 12 months in primary syphilis, 24 months in secondary or latent syphilis, or 5 years in late syphilis.[68]

SUMMARY OF MANAGEMENT OPTIONS
Syphilis

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Identify and treat with penicillin (provided not allergic) before pregnancy.	IV/C	78
Initiate contact tracing and treatment.	—/GPP	—
Confirm response with serial serology.	—/GPP	—
Prenatal		
Provide routine serologic screening in early pregnancy.	IV/C	78
Treat with penicillin (provided not allergic) all with *Toxoplasma palladum*–positive lesions (rare).	IV/C	78
Treat all women with positive serology with penicillin (provided not allergic) even if history suggests they have been treated in the past	IV/C	78
If significant penicillin allergy is determined, the pregnant patient should be desensitized.	III/B	83,84
Initiate contact tracing and treatment.	—/GPP	—
Confirm response with serial serology.	IV/C	78

Management Options	Evidence Quality and Recommendation	References
Labor and Delivery		
Some states in the United States require testing of all women at delivery.	—/GPP	—
Evaluate all cases of stillbirth > 20 wk for the presence of syphilis.	IV/C	68
Inform pediatricians of prenatal syphilis.	IV/C	86
Postnatal		
Alert pediatricians to the presence of syphilis during pregnancy so that they can properly evaluate the neonate for early (snuffles, rash, hepatosplenomegaly, jaundice) and late (deafness, hydrocephalus, optic nerve atrophy, mental retardation) manifestations of congenital syphilis.	IV/C	86
Follow-up tests should occur up to 2 yr after treatment, with concomitant fall in titers during that period.	III/B	68,76

GPP, good practice point.

TOXOPLASMOSIS

General

Toxoplasmosis is caused by the obligate intracellular parasite *Toxoplasma gondii*. Its name is derived from "toxon" (Greek for *arc*, the shape of the parasite during its acute infectious phase in humans) and "gundi" (the North African rodent from which the parasite was originally identified). Infections in immunocompetent individuals are frequently subclinical and innocuous unless the individual is pregnant, during which time, vertical transmission can occur and lead to significant disease and possibly death in the fetus or neonate. The organism has three distinct forms: the tachyzoite, or arc form, found in the parasitemic or acute phase of infection; the tissue cyst, found in the quiescent or latent phase in many organs of humans and animals; and the oocyst, which originates only in the digestive tract of members of the family Felidae (including domestic and feral cats).

Toxoplasmosis can be transmitted to humans by three principal routes. It is estimated that approximately 50% of the toxoplasmosis cases in the United States are caused by eating inadequately cooked meat[88] (especially pork, mutton, and wild game meat) containing the tissue cyst form of the organism.[89] A second means of acquiring toxoplasmosis is by inadvertently ingesting the oocysts that cats have passed in their feces, either from a cat litter box, from infected soil where a cat has defecated, or from unwashed fruits or vegetables that have contacted infected soil. Under favorable conditions (i.e., in warm, moist soil), oocysts can remain infectious for approximately 1 year. A third means of transmission is transplacentally, when a primary infection occurs during pregnancy. Other than vertical transmission and the rare incidence of blood or organ donation between individuals, it is not possible to acquire toxoplasmosis from either a neonate or another adult. In adults, the incubation period ranges from 10 to 23 days from ingestion of undercooked meat and from 5 to 20 days from ingestion of oocysts from cat feces.[90]

Since the 1960s, rates of infection with *Toxoplasma* in the United States appear to have declined from 14% (in a study of U.S. military recruits at that time)[91] to a seroprevalence of 9.6% in a second study of recruits in 1989.[92] In the Third National Health and Nutrition Examination Survey (NHANES III) conducted in the United States from 1988 to 1994, 17,658 individuals were tested for *Toxoplasma*-specific IgG antibodies; 23% were found to be positive. Of 5988 women of child-bearing age (12–49 yr) in that series, 14% were seropositive.[93]

Determining the number of cases of congenital toxoplasmosis is more difficult than estimating seroprevalence, although prospective studies in the United States from the 1970s[94,95] and from the period 1986 to 1992[96] indicate an infection rate of between 1 in 10,000 to 10 in 10,000 live births. With an estimated 4 million births annually in the United States, 400 to 4000 neonates yearly will be born with congenital toxoplasmosis.

Although some studies identify cleaning the cat litter box[97] or owning a cat[98] as risk factors, the presence of a cat has not been a consistent risk factor for *T. gondii* infection. Owning a cat was not shown to be a risk factor for *T. gondii* infection in two studies of pregnant women[99,100] and in a study of HIV-infected persons.[101] Cats generally only shed oocysts for several weeks during their lives if they become infected with *T. gondii*. Cats kept indoors that do not hunt prey or are not fed raw meat are not likely to acquire *T. gondii* infection and, therefore, pose little risk. Because of their grooming habits, fecal matter has not been found on the fur of clinically normal cats, and adult cats are not diarrheal during the period in which they are shedding oocysts.[88] Therefore, the possibility of transmission to human beings via touching cats is minimal to nonexistent.[88] Because cats may not develop antibodies to *T. gondii* during the oocyst-shedding period, serologic examination of cats does not provide useful information regarding the ability of a particular cat to transmit the infection.[88]

Outbreaks of toxoplasmosis in humans have been attributed to ingestion of raw or undercooked ground beef, lamb, pork, or venison[102-107]; unpasteurized goat's milk[108]; contaminated unfiltered drinking water[109-110]; soil exposure[111]; and aerosolized soil exposure.[112]

Diagnosis

Because most acute *Toxoplasma* infections are relatively asymptomatic, a universal challenge for obstetricians is how to identify acute infections during pregnancy. In France and Austria, where the incidence of toxoplasmosis is much higher than in the United States, universal screening is mandatory.[113] In the United States, although universal screening has frequently been discussed, it is not generally practiced. An article using decision analysis estimated that universal screening with medical treatment would result in 18.5 additional pregnancy losses for each case of toxoplasmosis avoided (12.1 additional pregnancy losses were estimated to occur if infected pregnancies underwent termination rather than treatment).[114]

When screening is performed or when a pregnant woman's clinical presentation leads the practitioner to suspect acute toxoplasmosis, the diagnosis may be established by serologic tests, amplification of specific nucleic acid sequences (using PCR), histologic demonstration of the parasite and/or its antigens (immunoperoxidase stain), or isolation of the organism. Ultrasound also has an important role in the evaluation of this infection.

Serologic Tests

The use of serologic tests for demonstration of specific antibody to *T. gondii* in maternal blood is the initial and primary method of diagnosis. IgG antibodies usually appear within 1 to 2 weeks of acquisition of an infection, peak within 1 to 2 months, decline at various rates, and usually persist for life. The most common methods of measurement of IgG include the Sabin-Feldman dye test, the ELISA, the immunofluorescence assay (IFA), and the modified direct agglutination test.[115] IgM antibodies, conversely, may appear earlier and decline more rapidly than IgG antibodies. They are measured by ELISA, IFA, and the immunosorbent agglutination assay.[115] False-positive results for the presence of IgM may occur when rheumatoid factor or antinuclear antibodies are present. Commercial kits often have low specificity, and positive results must be interpreted with great caution. Although IgM antibodies usually decline rapidly after the onset of infection, they may persist for years in some individuals, further complicating the interpretation of a positive serologic test.

A combination of serologic tests is usually required to establish whether an individual has most likely been infected in the distant past (which should pose minimal to no risk to an ongoing pregnancy) or has been recently infected. The traditional acute and convalescent titers of IgM and IgG are most helpful when either both are negative in two samples 3 or more weeks apart (no acute or chronic infection) or IgG is positive and IgM is negative in both samples (distant infection but no acute infection). When IgM is positive in either (especially when titers are drawn after the first trimester of pregnancy) or when IgG is negative in the first and positive in the second (or with a greater than fourfold rise in IgG

antibody titer from the first sample) with or without positive IgM, concern about a recent infection must be raised. Owing to lack of standardization, serologic diagnosis should be confirmed by a reference laboratory such as the Palo Alto Medical Foundation Research Institute's Toxoplasma Serology Laboratory (650-853-4828).[116] Another reported means by which acute and chronic infections may be distinguished is by measuring the binding strength of specific IgG antibodies to multivalent *Toxoplasma* antigen. This binding strength, or IgG avidity, increases as the duration of infection lengthens. Thus, higher IgG avidity indicates a more long-standing infection and may be useful in early pregnancy when other tests are inconclusive.[117]

Polymerase Chain Reaction

PCR amplification for detection of *T. gondii* DNA in amniotic fluid has been used to accurately and rapidly diagnose intrauterine infection with the parasite. The sensitivity is high (81%–88%),[118,119] and the overall accuracy is comparable with or better than fetal blood testing by cordocentesis[118,119] with less risk to the fetus.

Histology

Demonstration of tachyzoites in amniotic fluid or placental tissue establishes the diagnosis of an acute infection. This is best accomplished with the immunoperoxidase technique with antisera to *T. gondii*.[120]

Isolation of Toxoplasma gondii

Isolation of the organism from tissue or fluid establishes the infection as acute. Mouse inoculation coupled with PCR analysis of amniotic fluid has sensitivities of 91% to 94%.[118,121]

Ultrasound

Ultrasound findings of fetal infection with *T. gondii* are generally nonspecific; however, ventricular dilation (the most common finding), intracranial calcifications, increased placental thickness, hepatic enlargement, and ascites may be seen in over one-third of cases of fetal infection and may be useful in evaluation.[122] In highly suspicious cases in which serology or PCR is nonconclusive, follow-up ultrasound has been found to be valuable in confirming a diagnosis of congenital toxoplasmosis.[123]

Maternal and Fetal Risks

Maternal risks of toxoplasmosis in the immunocompetent gravida are minimal, and 90% of infections are asymptomatic and self-limited. Symptoms most commonly resemble infectious mononucleosis with posterior cervical or axillary lymphadenopathy that is discrete, nontender, and nonsuppurative. Other maternal symptoms may include malaise and muscle pain.

Fetal risks, conversely, vary widely, depending on the trimester of acquisition and presence or absence of maternal treatment. In general, the earlier the infection is acquired, the lower the risk of fetal transmission, but the greater the risk of serious sequelae to the fetus when congenital infection does develop.[124] A recent meta-analysis by Thiebaut and coworkers[125] estimated the risk of transmission at 13 weeks, 26 weeks, and 36 weeks to be approximately 15%, 44%, and 71%, respectively. As many as 85% of congenitally infected

neonates have subclinical infections that will later surface as chorioretinitis, hearing loss, or developmental delays. Serious sequelae noted at or after birth, including intrauterine death, neurologic abnormalities, hydrocephalus and cerebral calcifications, and chorioretinal scars with or without severe visual impairment, may be reduced by the use of prenatal antibiotic therapy even though the rate of congenital infection may not change.[118,126]

Management Options

Prepregnancy

Preconception infection with toxoplasmosis generally conveys immunity to subsequent pregnancies against congenital toxoplasmosis. Reports exist describing preconception seroconversion and subsequent fetal infection, but these are extremely rare,[127] and gravidas with IgG positivity at the onset of pregnancy should be considered at low risk for subsequent congenital infection.

Prenatal

Prevention of acute infection during pregnancy is much preferred to treatment of toxoplasmosis. Pregnant women, especially those determined to be IgG-negative during pregnancy, should be advised of appropriate preventive measures to use. When acute toxoplasmosis is suspected during pregnancy, appropriate laboratory testing is critical (see "Diagnosis"). If serologic testing confirms acute *maternal* toxoplasmosis, amniocentesis with PCR testing of amniotic fluid should be performed to document presence of *fetal* infection. Cordocentesis is no longer considered an essential component of the evaluation of fetal infection, having been replaced by PCR owing to its simplicity and relative safety. Spiramycin 3 g/day should be administered as soon as maternal infection is documented, adding pyrimethamine/sulfadiazine if fetal infection is confirmed by PCR testing. Doses and dosing schedules and the addition of folinic acid with pyrimethamine vary, taking into consideration the trimester and local preferences. Pyrimethamine is not recommended for use in the first trimester.[128,129] In the United States, spiramycin may be obtained through special permission from the CDC after confirmation of acute maternal infection by a reputable reference laboratory.[130]

Labor and Delivery

Patients with ongoing or recent toxoplasmosis infection pose a transmission risk only to their fetus and do not require isolation for themselves or for their newborn. The pediatrician caring for the neonate should be alerted to the possibility of congenital toxoplasmosis so appropriate follow-up studies can be performed on the infant. Congenital infection can be excluded if IgG does not persist in the infant beyond age 12 months.

Postpartum

After delivery, the parturient may be managed routinely, again emphasizing to the health care team that neither she nor the newborn poses a risk of transmission to others.

SUMMARY OF MANAGEMENT OPTIONS
Toxoplasmosis

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Toxoplasmosis infection before conception (documented by the presence of IgG antibodies) conveys a relative immunity to the gravida and makes congenital infection extremely unlikely.	III/B	127
Prenatal–Prevention		
Teach patient to prevent *Toxoplasma* infection: • Cook meat to well done (industrial deep-freezing also seems to destroy parasites efficiently). • When handling raw meat, avoid touching mouth and eyes. • Wash hands thoroughly after handling raw meat or vegetables soiled by earth. • Wash kitchen surfaces that come into contact with raw meat. • Wash fruit and vegetables before consumption. • Avoid contact with items that are potentially contaminated with cat feces. • Wear gloves when gardening or handling cat litter box. • Disinfect cat litter box for 5 min with boiling water.	—/GPP	—
The policy of routine screening for toxoplasmosis varies between countries; it is not practiced universally in the United States.	III/B	114

SUMMARY OF MANAGEMENT OPTIONS
Toxoplasmosis—cont'd

Management Options	Evidence Quality and Recommendation	References
Prenatal–Diagnosis		
Maternal infection should be confirmed by an appropriate laboratory using reliable testing, which may include Sabin-Feldman dye test for IgG and ELISA; testing for IgM, IgA, and IgE along with IgG avidity testing; or differential agglutination test for chronicity of infection.	III/B	116
IgM antibodies for toxoplasmosis are frequently false-positive or may represent chronic infection, and should *always* be confirmed by a reference laboratory.	IIb/B	116
Prenatal–Treatment		
When maternal infection is confirmed, begin spiramycin as soon as possible.	IIa/B	122,129
Fetal infection may be diagnosed by PCR testing of amniotic fluid, obviating the need for cordocentesis (though not possible to determine prognosis).	IIa/B	118,121
Documented fetal infection necessitates addition of pyrimethamine/sulfadiazine.	IIa/B	122,129
Serial ultrasound will give an identification of signs of fetal infection.	IIa/B	121,123
Labor and Delivery, Postpartum		
Neither the mother nor the infant is infectious to the health care team and may be handled normally.	IV/C	120

ELISA, enzyme-linked immunosorbent assay; GPP, good practice point; Ig, immunoglobulin; PCR, polymerase chain reaction.

SCHISTOSOMIASIS

General

Schistosomiasis, also known as bilharziasis, is caused by a parasitic trematode blood fluke[131] first discovered by Theodor Bilharz in 1852. Schistosomiasis is endemic to 74 countries. This disease infects more than 200 million people, of which 40 million are women of childbearing age. At any one time, 120 million have symptoms of the disease and approximately 20 million have severe disease.[132–134] Estimates indicate that global deaths as a result of schistosomiasis may be as high as 200,000 per year and serious disability results in up to 15% of those infected.[135,136]

Five species of schistosomes have been reported to infect the intestines or urinary tract of humans. In Africa, the Eastern Mediterranean, the Caribbean, and South America, intestinal schistosomiasis is caused by *Schistosoma mansoni*. In central Africa, another species, *Schistosoma intercalatum*, has been found to cause intestinal schistosomiasis. In Asia and Western Pacific countries, intestinal schistosomiasis is caused by *S. japonicum* and *S. mekongi*. Urinary schistosomiasis, caused by *S. haematobium* is endemic to Africa and the Eastern Mediterranean region. 85% of persons with the disease are infected by either *S. mansoni* or *S. haematobium* and live in sub-Saharan Africa.[132]

Schistosomes have a complex life cycle and require two hosts in their development. The parasite's eggs are released into fresh water by way of defecation or, in the case of *S. haematobium*, by urination. The hypotonic environment of fresh water triggers the eggs to mature and release a male or female miracidia. The miracidium swims searching for a sus-ceptible, species-specific snail. Miracidia do not feed and if a suitable host is not found, their life span is limited. Once a suitable snail is found, the miracidium enters through the foot process and subsequently transforms into a primary sporocyst and matures in either the foot process or the snail's digestive gland. Within the primary sporocyst, germinal cells replicate, mature, and bud off as many secondary spo-rocysts, which migrate to the snail liver and mature into cercariae.[131] Most infected snails are not significantly injured by this process and can survive for prolonged periods of time.

Cercariae are fork-tailed, infective larval forms of the schistosoma and are free-swimming. They exit the snail in search of a host and, like the miracidia, do not feed. Once in water, their ability to optimally infect a host diminishes significantly after 4 hours, although they may survive for as long as 48 hours. The cercariae attach to human skin using an oral sucker containing glands that release enzymes allow-ing migration through the skin epidermis. During migration,

the forked tail is discarded and the larva develops a double-lipid bilayer tegument that effectively protects it from the host's immune system by mimicking the host and inhibiting the immune system. At this point, the cercariae has developed into a schistosomula.[137]

Over several days, the schistosomula (parasite stage) uses lytic enzymes to migrate through the dermis and access the venous system. It is then pumped through the right side of the heart and into the lungs where it migrates along pulmonary capillaries and enters the systemic circulation through the left side of the heart. At this point, the schistosomula travels to the mesenteric arteries and splanchnic capillaries and, finally, through the portal veins where it gains access to the liver. In the liver, the organism matures and pairs with a schistosomula of the opposite sex (a trait that is unique among trematodes). The thin female schistosomula resides within the gynecophoric canal of the male. The female is carried by the male, and they migrate against portal blood flow to either the mesenteric or the vesical veins. At this point, the pair migrates along the veins and deposits eggs.[131,137]

Although the average life span of the schistosomula is 3 to 5 years, cases have been reported of adult schistosomula living up to 30 years.[138] The adult causes little direct damage to the host, clinical sequelae being the result of the immune response to the deposited eggs. Whereas the parasite effectively evades the immune system, the eggs lodged in the host tissue elicit an aggressive T helper-2 (Th-2)–mediated immune attack. Despite this robust immune reaction, the eggshell is extremely resistant to proteases. This results in a granulomatous reaction that may be used by the egg to migrate across the intestinal or urinary bladder wall and allow deposition into stool or urine where the life cycle begins again.[131,138–142]

Acute infection is usually asymptomatic and if clinical symptoms do occur, they usually manifest among individuals who are new to an endemic area and who have no prior immunity. The most common clinical symptom is generalized fatigue. Acute infection can also manifest in the form of "swimmer's itch" or Katayama fever. Swimmer's itch is caused by a local dermatologic reaction to the cercariae that starts as local itching at the site of entry and progresses to an intense pruritic papular or urticarial rash within 24 hours of exposure. The pruritus and itching can last for up to a week.[143,144]

Katayama fever is believed to be a result of a hypersensitivity reaction to the migrating parasite. Onset begins approximately 35 to 40 days following contact with infested water. Clinical symptoms include fever, malaise, diarrhea, arthralgia, myalgia, and cough. Eosinophilia is a component of the acute infection. Although transaminases are not elevated, hepatic tenderness and enlargement are commonly present.[131,145,146] Symptoms usually resolve after a few weeks as the infection enters the chronic stage, although there have been cases of coma and even death reported, especially with *S. japonicum*.[144,147]

Chronic schistosomiasis and its clinical sequelae are the result of egg deposition followed by granuloma formation and scarring. The granulomas that form around the schistosomula egg are composed of eosinophils (50%), mast cells, macrophages, lymphocytes, and fibroblasts. Burden of disease is related to the number of eggs deposited in tissue.

Symptoms begin slowly but are progressive without treatment. They commonly involve the intestinal, hepatic, and urinary systems, but in some cases, neurologic, pulmonary, and genital involvement may occur.[131,143]

The most common presenting symptom of intestinal schistosomiasis is bloody diarrhea, which can lead to iron deficiency anemia. Patients also may have abdominal tenderness and tenesmus. In some asymptomatic cases, patients may present with guaiac-positive stools. Rarely, intestinal schistosomiasis will present with inflammatory colonic polyps or intestinal obstruction.[148–150]

Hepatic schistosomiasis may have two clinical presentations. In children and adolescents, there may be hepatomegaly and/or splenomegaly due to an inflammatory response to deposited eggs.[151] The more common form occurs years after infection and is defined by portal hypertension as a result of granulomas that have healed and formed fibrotic scars. Before healing and resolution of one fibrotic lesion is completed, another granuloma is formed, initiating a pattern that can lead to Symmer's pipestem fibrosis. Symmer's pipestem fibrosis results from the portal vein and its tributaries becoming fibrotic, causing impediment of portal blood flow, thus producing portal hypertension. Although hepatic function remains largely unaffected, ascites and esophageal varices can form and lead to hemorrhage.[131,151,152]

Urinary schistosomiasis is caused by *S. haematobium*. The pathophysiology involves deposition of eggs in the mucosa of the genitourinary system. Presentation may be asymptomatic or the infection may manifest as hematuria severe enough to cause anemia, dysuria, and frequency. If untreated, the infection may progress to obstruction, hydroureter, and hydronephrosis. As a result, susceptibility to serious bacterial infections can occur leading to kidney damage.[153] Kidney damage may also occur as a result of deposition of immune complexes leading to proteinuria and nephrotic syndrome.[154] *S. haematobium* can also induce squamous cell metaplasia of the urinary bladder and urethral mucosa and may increase the risk of developing squamous cell carcinoma of the bladder.[131,154]

In some cases of schistosomiasis, neurologic sequelae may occur as a result of deposition of eggs in the spinal cord and its resulting granulomatous inflammatory reaction. This can cause a myelopathy. There may also be migration of the parasite to cerebral or cerebellar tissue manifesting in seizures, focal neurologic impairment, or increased intracranial pressure.[155,156]

Pulmonary complications may occur as an extension of hepatic disease and portal hypertension. The portosystemic collaterals that develop in this scenario allow embolization of schistosome eggs into the pulmonary circulation. This can lead to a granulomatous pulmonary endarteritis, which can cause pulmonary hypertension.[157] Clinical signs may include coughing and wheezing, and a chest x-ray may show infiltrates, military nodules, and heart enlargement with dilated pulmonary arteries.[158,159]

Possible gynecologic involvement includes ulcerative and hypertrophic lesions of the cervix, uterus, vagina, and vulva. In rare cases, ectopic pregnancies have been reported, as has infertility.[151,160,161]

Ultrasound imaging in acute schistosomiasis usually demonstrates normal or nonspecific findings such as hepatomegaly, splenomegaly, or periportal adenopathy. In chronic

schistosomiasis, periportal fibrosis and signs of portal hypertension such as an increase in caliber of the portal vein and its tributaries may develop. Ultrasound is mainly helpful for tracking long-term changes and directing further therapy.

Diagnosis

Suspicion of a possible acute schistosomal infection in a patient should develop with a history of recent travel to an endemic area and with recent onset of fatigue, fever, bloody diarrhea, hematuria, abdominal pain, arthalgias, or cough. On physical examination, the addition of hepatosplenomagaly should increase suspicion for the infection. Nonspecific laboratory abnormalities commonly seen with schistosomiasis include eosinophilia in approximately 50% of patients[162] and iron deficiency anemia, which may be present owing to chronic blood loss. Thrombocytopenia may also be present owing to splenic sequestration.[131] Seventy-eight percent of those infected with *S. haematobium* in the bladder will have positive hematuria on dipstick.[163]

Diagnosis of schistosomiasis is usually made by parasitologic (microscopic detection of eggs) or antibody and antigen detection. Demonstrating eggs in the feces or urine indicates the presence of the organism. The classic method used for detecting parasite eggs in the stool is the Kato-Katz thick smear preparation, which uses glycerol to allow for visualization of entrapped eggs. This smear is not routinely used by many laboratories as part of their standard ova and parasite evaluation, necessitating the notification of the microbiology laboratory about a specific concern for schistosomiasis when stool is submitted for evaluation.[131] Disadvantages of searching for parasite eggs in the feces or urine directly include the large fluctuations in egg counts resulting in infections during the nadir of egg release being easily missed and the time-consuming nature of these tests.[164]

Immunologic methods such as ELISA measurement of circulating anodic antigen (CAA) or circulating cathodic antigen (CCA) on serum or urine samples have a higher sensitivity and maintain high specificity.[164] In addition, these methods allow for demonstration of active infections and can be used to monitor the effects of treatment. A disadvantage is the need for sophisticated laboratory equipment that is often not available in the field, and attempts are being made to develop a rapid field-applicable test for the detection of these antigens.[164,165]

Maternal and Fetal Risks

There are little data addressing the pregnancy-related burden of schistosomiasis. The morbidity experienced by pregnant mothers and their newborns remains unclear.[134] In Africa, where greater than 85% of people with schistosomiasis live, it is estimated that 10 million women per year have schistosomiasis during pregnancy. However, the number of pregnant women who are infected worldwide is unknown.[136] Many of the morbidities in pregnancy are likely the cause of the profound undernutrition and anemia caused by schistosomiasis.[166–168]

There is also evidence of potential fetal effects of schistosomiasis. A cross-sectional survey of 972 women in Tanzania demonstrated that heavy infection with *S. mansoni* was associated with increased risk of anemia and reduced hemoglobin levels (adjusted odds ratio 1.82; P = .026). The effects persisted after controlling for potential confounders.[169] A prospective study in Ghana compared births outcomes of 41 infected pregnant women with a control group of 500 noninfected women. Delivery data were available for 23 of these infected cases. They demonstrated a larger percentage of preterm births (34.8% vs. 23.8%) among infected females and lower birth weight among the preterm infants (1768 g vs. 2457 g).[170] Another study from an endemic region of China compared 244 infected women with 236 healthy controls. They also showed significant differences in weight among infants born to infected women (3229 g vs. 3355 g).[171] Unfortunately, these two studies were not adjusted for potential confounders such as prepregnancy weight, nutritional status, and socioeconomic status, making their results inconclusive. Vertical transmission has been demonstrated in one study in which schistosoma infection was diagnosed in 3 of 22 newborns who were examined for infection.[134,172] Infection and inflammation has been demonstrated in the placenta of women infected with schistosomiasis, demonstrating a potential mechanism for placental insufficiency.[173,174]

Management Options

Prepregnancy

Owing to the importance of prepregnancy nutritional status, all patients with evidence of infection should be treated. The treatment of choice for all schistosoma species is praziquantel. Praziquantel paralyzes the adult schistosome by increasing calcium ion influx across the tegument membrane and also by exposing parasite antigens to the host immune system.[175] For most schistosoma species, a dose of 40 mg/kg in one or two doses is adequate. When treating *S. japonicum* or *S. mekongi*, a dose of 60 mg/kg divided in two or three doses is recommended.[176] Cure rates approach 85% to 90%[177] and at present, no vaccine is available.

After therapy, monitoring mainly involves examination of the stool or urine, depending on species of schistosmiasis, and monitoring of eosinophil count in cases with eosinophilia.

In endemic areas, follow-up evaluation of specimens is performed approximately 6 weeks after treatment. In nonendemic areas, reexamination is recommended 3 to 6 months after treatment owing to the low risk of reinfection.[143]

Unfortunately, praziquantel is ineffective in early infection or Katayama fever. In these situations, supportive care with the addition of prednisone (40 mg daily for 5 days), if needed, can be used to relieve some of the host symptoms as a result of hypersensitivity. Praziquantel can then be given 6 to 10 weeks later, once adult worms have developed.[178]

Prenatal

If pregnant women plan on visiting an area endemic to schistosomiasis, care should be taken to avoid swimming in fresh water that may not have proper sewage control and to use footwear when coming into contact with water sources. Nutrition status should be assessed with close monitoring of hemoglobin levels.

The World Health Organization in 2003[136] gave an informal recommendation that pregnant and lactating women

should not be excluded from treatment. Although the toxicity of praziquantel has not been formally evaluated, more recent reports have supported its safety in pregnancy. In a report of 88 pregnancies with inadvertent exposure to praziquantel in the first trimester that were compared with 549 pregnant controls, there were no differences between the two groups in rates of abortion and preterm deliveries. In addition, no congenital anomalies were observed.[179] In a separate study conducted in the Sudan, 25 pregnant infected women were treated with a single dose of praziquantel during different semesters. There were no differences in the abortion rate when compared with the background rate of the community.[180]

Labor and Delivery

Schistosomiasis cannot be transmitted from human to human. As a result, patients in labor do not need to be isolated. The pediatrician should be notified of the mother's infection status owing to some reports of vertical transmission.

Postpartum

Routine postpartum management can be continued. No adverse effects of the use of praziquantel during lactation have been reported. Lactating women with evidence of infection should not be excluded from treatment, particularly if they are being treated in endemic areas.[136]

SUMMARY OF MANAGEMENT OPTIONS
Schistosomiasis

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Owing to importance of prepregnancy nutritional status, all patients with evidence of infection should be treated with praziquantel.	IIa/B	176
Prenatal–Prevention		
Teach patient to prevent *Schistosoma* infection: • Avoid visiting endemic areas during pregnancy if possible. • Avoid swimming in fresh water that may not have proper sewage control. • Use footwear when coming into contact with water sources.	—/GPP	—
Prenatal–Diagnosis		
Maternal infection should be suspected if history of recent travel to an endemic area with recent onset of fatigue, fever, bloody diarrhea, hematuria, abdominal pain, arthralgias or cough.	—/GPP	—
Diagnosis is usually made by detecting parasite eggs in the stool or urine.	IIb/B	131
Immunologic methods using ELISA measurement of CAA or CCA on serum or urine samples demonstrate higher sensitivity but are not yet commercially available.	IIb/B	164,165
Prenatal–Treatment		
The World Health Organization has given an informal recommendation that pregnant and lactating women should not be excluded from treatment.	IV/C	136
Praziquantel is generally considered safe in pregnancy.	IIb/B	179,180
No increased risk for congenital anomalies or abortion rate with the use of praziquantel in pregnancy.	IIb/B	179,180
Labor and Delivery; Postpartum		
Schistosomiasis cannot be transmitted from human to human. As a result, patients in labor do not need to be isolated.	IIb/B	130,136
The pediatrician should be notified of the mother's infection status owing to some reports of vertical transmission.	IV/C	134,172
Lactating women with evidence of infection should not be excluded from treatment, particularly if they are being treated in endemic areas.	IV/C	136

CAA, circulating anodic antigen; CCA, circulating cathodic antigen; ELISA, enzyme-linked immunosorbent assay; GPP, good practice point.

Substance Abuse

JAMES J. WALKER and ANN M. WALKER

INTRODUCTION AND OVERVIEW

Substance abuse is common in our society, including the widespread use of tobacco and alcohol as well as illicit drugs. Substance abuse is increasing in young women,[1] and this produces significant maternal and fetal morbidity during pregnancy. The complication for the clinician is that the mother is complicit with the problem and there are often associated legal, social, and environmental problems[2] that can complicate the provision of care as well as the woman's ability to care for her child after birth. The aim of service provision is to provide an environment that is nonjudgmental and supportive to minimize the risk to the mother and her baby, not only during pregnancy and the neonatal period but also in the long term. Care does not necessarily require abstinence from drug use because the ultimate goal is to keep the mother within the care system and encourage her to take responsibility for herself and her child. To achieve this goal, the caregivers must be multidisciplinary, supportive, and tolerant.[3,4]

Programs of comprehensive antenatal care that provide social and behavioral support along with medical care do not universally improve maternal health and pregnancy outcome.[3,5] The specifics of the care provided are probably less important than the quality of care given and the degree of engagement of the individual.[6,7]

Major life events, such as pregnancy, can be a turning point allowing the women to take control of her life to the benefit of herself and her infant. It is often the first time she has been given any attention or responsibility. She may not be interested in harm reduction for herself, but she is likely to wish to protect her child. Unfortunately, the associated social problems of poor hygiene, nutrition, and social deprivation are responsible for much of the risk, rather than the abuse itself. The use of drugs or alcohol is often a symptom of these problems. Because most users abuse more than one substance and have multiple social complications, it is often difficult to evaluate the risk of any given substance.

TOBACCO SMOKING

Background

Smoking is a legal and socially tolerated form of substance abuse. Although it is accepted that smoking is harmful to general health and to pregnancy in particular, the incidence of smoking in the pregnant population has increased in recent decades to between 16.3% and 52%, depending on the characteristics of the patient group.[8–11] However, there is evidence that it is declining in some populations.[9,11] Smoking is more common in the socially deprived population and varies with race. It is also heavily dependent on family and partner influences.[7,12] Although the incidence of smoking decreases throughout pregnancy, this is largely due to voluntary cessation[8,13] because most intervention programs are only marginally successful.[14,15] As with many addictions, of those who do stop, most relapse in the first year.[14,16]

Maternal and Fetal Risks

Maternal smoking increases almost all placental complications and is dose-related.[14,17] These include placental abruption, placental insufficiency, placenta previa, and low birth weight.[11,14,18,19] Many infants are admitted to the neonatal unit,[11] largely owing to an increase in premature birth.[20] However, the increased risk is eliminated when women with proven placental pathology are excluded, suggesting that smoking produces most of its effects through placental damage.[21] There is also an increased risk of neonatal death and sudden infant death syndrome,[11,14] but this is partly due to secondhand smoke after birth rather than prenatal exposure.[14] Interestingly, smoking in pregnancy is a significant protective factor against preeclampsia, reducing the incidence by up to 50%[22]; however, women with preeclampsia who smoke have a worse outcome, which can be reduced by smoking cessation.[23] Data on miscarriage are contradictory, with some evidence of an increased incidence[14] but large cohort studies found no link.[24,25] However, there is an increased risk of ectopic pregnancy.[14,26] There are also varied data on the role of smoking and cleft lip and palate, but the increase in incidence appears to be small,[14] especially with heavy use.[27] No evidence links maternal smoking to childhood cancer.[14,28]

The risk of growth restriction increases with the number of cigarettes smoked per day. Although the average effect is 200 g,[14] heavy smokers deliver babies up to 458 g lighter than those of nonsmokers.[29] The effect of smoking on birth weight also increases with maternal age. Passive smoking produces risks similar to those seen in women who smoke 1

to 5 cigarettes/day. The effect on growth is largely in the second and third trimesters, so women who stop smoking during pregnancy deliver babies that are, on average, 120 g larger than babies of those who do not stop smoking, although these infants are still 39 g smaller than infants of those who never smoked. Interestingly, the offspring of women who smoke tend to be overweight during infancy. This effect is reduced in those mothers who cease smoking during pregnancy.[30]

Complications do not stop at birth, with neonatal neurobehavioral abnormalities[31] and reduced arousal reflexes seen in infants of mothers who smoke, which may explain the increase in sudden infant death syndrome in these infants. There is evidence that children whose mothers smoked during pregnancy have early neurodevelopmental impairment and behavioral problems,[32] but these effects appear to decrease with age.[33] However, some long-term effects remain, with maternal smoking increasing the risk of conduct disorders and criminal behavior in male offspring.[34] This effect can be alleviated if the mother is responsive to the child in infancy,[35] suggesting that at least some of these changes depend on the social environment and not just the effect of intrauterine exposure to smoking.

There is some evidence that women who smoke breast-feed for less time and produce less milk,[14] although nicotine patches do not produce the same effect.

Management Options

Prepregnancy and Prenatal

Although the strategy appears simple, most smoking cessation programs only have a minimal effect.[14] Most women who stop do so voluntarily, often prior to or early after conception.[14] This is not due to a lack of awareness of the risks to the unborn child as shown by a study which targeted high risk women.[36] After the campaign, more people understood the risks to the unborn child, but there was no significant change in smoking prevalence or consumption. Therefore, information itself does little to change practice, and more active intervention is required. Cessation can be increased by partner's support.[37]

Despite this recognized failure of intervention strategies, smoking cessation is a major drive in most prenatal health care provision. Various studies of the role of a specially designed self-help manual to help stop smoking show that some women had already stopped before recruitment and the effect of the intervention ranges from 10% to 20%.[38,39] Better results (38%) occurred with a more intensive program targeting the specific psychological problems the women have.[40]

Therefore, although smoking cessation is beneficial, intervention programs have limited effect because some women do not comply,[41] partly because of environmental,[42] and psychological[40] factors.

Most studies used patient histories to assess smoking habits. If smoking status in pregnancy is determined by a serum cotinine assay, the rate correlates well with declared smoking.[43] However, in studies in which the percentage of self-reported quitting was higher with intervention programs compared with control groups, cotinine-verified quit rates were not significantly different. These results suggest that as with any addiction program, biochemical verification is essential to evaluate smoking cessation interventions[44] and that previously reported successful intervention programs might have overestimated their success.

Originally, nicotine replacement therapy was not approved for use in pregnancy, but some studies suggest that this therapy may be safe because the amount of nicotine transferred to the baby may be reduced compared with smoking itself[45] and the U.S. Food and Drug Administration (FDA) no longer states pregnancy as a contraindication to its use.[46] However, nicotine is cleared more quickly during pregnancy, and the effects of replacement may be minimal.[14]

Therefore, no particular approach or advice appears to prevent smoking relapse during pregnancy, but repeated support and encouragement provided to women who quit early in pregnancy may be beneficial[47] by encouraging them not to relapse. The effect of family and peer pressure is important, with increasing success occurring when there is family or peer support.[7,48]

In the nonpregnant population, other interventions have been tried including antidepressants. These have mixed results, although bupropion, which is an atypical antidepressant that acts as a norepinephrine and dopamine reuptake inhibitor and nicotinic antagonist, appears to be effective. Initial reports suggest safety in pregnancy, but no trials in smoking cessation in pregnancy have been undertaken.[14]

Therefore, if smoking cessation programs are going to be cost-effective, it is in the high risk group of heavy smokers where most benefits can be achieved but where intervention programs appear to fail. An additional factor is that women find it more difficult to stop smoking compared with men.[14] It may be that greater benefits may be achieved by programs to prevent nicotine addiction among adolescent girls or by encouraging cessation before pregnancy, when cessation may be easier. There is some evidence that this is occurring because the rate of smoking in pregnancy appears to be decreasing in some populations.[49]

Labor and Delivery

Women who smoke are more likely to have preterm prelabor rupture of the membranes and preterm birth, possibly because of increased oxytocin sensitivity,[50] but there is no difference in management. Because the risk of placental insufficiency is increased, the infant may have growth restriction, with an increased possibility of fetal distress. Therefore, close vigilance in labor is recommended, with assessment of the fetal heart rate on admission and again near the end of labor, when the risks to the fetus are greatest. Interestingly, because of the effect on fetal growth, smoking is protective against macrosomia.

If a general anesthetic is required, women who smoke are at increased risk. Normally, smokers are asked to stop at least 24 hours before the anesthetic is administered, but labor is not predictable. Women should be told not to smoke once contractions have started.

Postnatal

Cigarette smoking during pregnancy is a significant health risk to the fetus, but most women continue to smoke during pregnancy, and most who quit relapse postpartum. This can have a significant effect on the future health of the child as well as on subsequent pregnancies.[12] Smoking cessation is easier in the nonpregnant state, but cessation appears to be

more closely related to environmental and social factors than to any medical intervention. Failure to stop smoking also has a detrimental effect on long-term maternal health. A 28-year follow-up study of women who smoked during pregnancy in northern Finland showed that the mortality ratio, adjusted for age, place of residence, years of education, and marital status, in women who smoked during pregnancy was more than twice that in nonsmokers.[51] The difference was related to an increase in expected smoking-related diseases.[51]

SUMMARY OF MANAGEMENT OPTIONS
Cigarette Smoking

Management Options	Evidence Quality and Recommendation	References
Train staff to give advice and support.	III/B	179
• Tell women that smoking puts their baby at risk.	III/B	180
• Stopping smoking by midpregnancy will improve the outcome.	III/B	180,181
• Reducing smoking is better than not reducing but not as good as stopping.	III/B	180
• Repeated encouragement and specially designed programs increase the chance of success and reduce relapse.	Ia/A	181
• Low risk, more educated, lighter smokers are more likely to stop.	III/B	181
• Specific targeted intervention programs have benefit for both the mother and the newborn.	Ia/A	181,182
• Women underreport failure to stop smoking and smoking relapse.	Ia/A	183
• Nicotine patches can be beneficial and are safe for use in pregnancy	IIa/B	46

ALCOHOL

Background

The consumption of excessive amounts of alcohol is detrimental to health. After many historical references to the harmful effects of alcohol consumption in pregnancy, Lemoine and colleagues[52] described defects in fetal growth and development associated with maternal alcohol abuse in 1968. Further studies described the range of fetotoxicity attributed to both heavy and social maternal alcohol consumption.[53] Although the risk depends on the level and frequency of alcohol use, therapy is dependent on the degree of maternal dependency. In women who are not dependent, there is a high success rate with simple educational and motivational methods.[54] However, those who are dependent need greater supportive input and often require pharmacologic intervention.[55]

Maternal and Fetal Risks

Excessive Alcohol Consumption

Jones and Smith[56] were the first to coin the phrase "fetal alcohol syndrome" to describe the features associated with heavy maternal alcohol consumption, but the signs had been described before.[57] The main features include

- Growth deficiency, both prenatally and postnatally.
- Central nervous system disturbance that affects intellect and behavior.
- Abnormal facial characteristics, particularly low-set, unparallel ears; a short, flattened philtrum; an elongated midface; a small head; and a short, upturned nose.
- Malformation of major organs, especially the heart, and skeletal deformities.

Newborns with the syndrome may be irritable, with hypotonia, severe tremors, and withdrawal symptoms. The main physical and cerebral signs are usually apparent at birth. Mild mental retardation, the most common and serious deficit, and other anomalies may accompany fetal alcohol syndrome, and the degree of facial abnormality is directly related to the long-term physical and intellectual deficits.[58] Sensory deficits include optic nerve hypoplasia, poor visual acuity, hearing loss, and receptive and expressive language delays. Atrial and ventricular septal defects as well as renal hypoplasia, bladder diverticula, and other genitourinary tract abnormalities may occur. Only complete abstinence during pregnancy is considered safe. Alcohol consumption in each trimester is associated with abnormalities, and the lowest innocuous dose of alcohol is not known.[59] However, abnormal facial features are apparent only at the highest levels of exposure.[59]

Fetal alcohol syndrome is relatively rare, with an incidence of less than 1 in 1000 live births, increasing to 4.3% among "heavy" drinkers. The general incidence is more than 20 times higher in the United States (1.95 in 1000) than in Europe and other countries (0.08 in 1000). Therefore, relatively few women who drink alcohol during pregnancy give birth to children with fetal alcohol syndrome. The problem would appear to be multifactorial including genetic factors, social deprivation, nutritional deficiencies, and tobacco and other drug abuse.[60,61] Intrauterine growth restriction (IUGR) is also more frequent in women who drink alcohol during pregnancy. This effect is aggravated by maternal smoking.[59]

Maternal alcohol intake of more than 20 g/day is associated with an increase in preterm delivery and neonatal jaundice.[62] Therefore, these effects are associated with excessive consumption, poor diet, and smoking.

"Social" Alcohol Consumption

The evidence against more moderate consumption is controversial. Although effects are seen at all intake levels, the results are not conclusive.[63] Approximately 50% of women consume alcohol on a moderate and occasional basis during pregnancy, although more abstain in the first trimester.[64] This behavior is socially acceptable and considered normal. The consequences on pregnancy are difficult to assess because quantification of alcohol consumption is difficult to assess accurately. In addition, there are confounding factors, particularly socioeconomic group and tobacco consumption.

Far more studies have reported no significant effects of mild alcohol intake than have reported problems. The effect of smoking on birth weight is three times greater than the effect of alcohol.[59] When data are stratified by smoking status, moderate maternal alcohol consumption usually has no significant effect on birth weight in nonsmokers, but among smokers, there is a significant linear trend, with a threshold for decreased birth weight at an average of approximately two drinks per day (14 units/wk).[65] Lower consumption levels are associated with an increase in birth weight, suggesting an inverted J-shaped function between drinking during pregnancy and birth weight.[66] On its own, moderate intake of alcohol during pregnancy of less than 12 to 14 units/wk has no apparent detrimental effect on fetal growth.[66]

Although some studies show that children exposed to alcohol prenatally had significantly lower weight, height, head circumference, and palpebral fissure width at 6 years,[67] most show that the effect on growth is transient and the differences are not measurable after 8 months of age.[68]

So low alcohol intake in pregnancy may not have a substantial effect on child development, but there is concern about long-term neurodevelopment. Dose-dependent effects on neurobehavioral function from birth to 14 years have been established and are described as "fetal alcohol effects".[69] Specific problems include attention deficit,[70] slower information processing, and learning problems, especially with arithmetic,[71] as well as slower reaction times, suggesting an alcohol-related deficit in "speed of central processing." Reaction time deficits were dose-dependent,[72] as were attention and memory deficits.[70] The number of drinks per occasion was the strongest predictor of deficits. Fluctuating attention states, problems with response inhibition, and spatial learning also showed a strong association.[71] The higher the average number of drinks per occasion, the poorer the performance of the adolescent offspring on tasks believed to underlie numeric problem-solving and reading proficiency.[73] As with fetal alcohol syndrome, not all exposed offspring studied showed neurodevelopmental deficits. The effects appear to increase with advancing maternal age[74] and associated maternal smoking.[70]

However, because the lower safe limit cannot be determined with any surety, many agencies including the American College of Obstetricians and Gynecologists recommend abstinence for all pregnant women.[75]

Management Options

Prepregnancy and Prenatal

Because most women are not addicted to alcohol, they often take a "better safe than sorry" approach and reduce or stop drinking in pregnancy.[64] A successful previous pregnancy experience or a previous alcohol-related problem can influence this decision.[76] However, it is not the social drinker who concerns the obstetrician because these women are relatively easily educated about risks and tend to reduce their intake.[64] The few heavy drinkers, either dependent or binge drinkers, are more likely to harm their unborn child and are difficult to manage. Smokers and older women are particularly at risk because of the associated additive effects.

Formalized questionnaires on alcohol use can be used to screen either the entire population or targeted at-risk groups. The T-ACE questionnaire has been validated and appears to be accurate in detecting women who drink more than 1 oz of absolute alcohol/day (~25 g, or 2.5 units). Screening is most sensitive during the first 15 weeks of pregnancy.[77] This has been adapted for use in pregnancy.[75]

T-ACE is an acronym for the following:
- T: TOLERANCE
  How many drinks does it take to make you feel "high"?
- A: ANNOYED
  Have people ANNOYED you by criticizing your drinking?
- C: CUT DOWN
  Have you felt you should CUT DOWN on your drinking?
- E: EYE OPENER
  Have you ever had a drink first thing in the morning?

Scoring of the test is straightforward. If the answer to the tolerance question is more than 2, a score of 2 is given. A score of 1 is assigned to a positive answer to all of the other questions. A total score of more than 2 is considered positive for problem drinking, and this score correctly identifies more than 70% of women who drink heavily during pregnancy. Although this questionnaire is better than traditional alcohol questionnaires, its sensitivity can be improved with the use of a further test.[78]

An alternative is the Leeds Dependence Questionnaire, which is a 10-item, self-completion questionnaire designed to measure dependence on a variety of substances. It is understood by users of alcohol and opiates. The questionnaire is sensitive to changes over time from severe to mild dependence. Test-retest reliability is 0.95.[79]

Biochemical markers, such as blood γ-glutamyltransferase, alcohol concentration, thiocyanate, and mean corpuscular volume, can be used as surrogates of excessive alcohol consumption, but they are not accurate and can be used only to identify potential at-risk women. Abnormalities of liver enzymes in women who drink heavily should be taken into account if these tests are used during pregnancy to monitor other diseases, such as preeclampsia.

As with smoking, studies show that approximately one third of women who drink alcohol before pregnancy stop drinking during pregnancy and those who continue to drink tend to reduce their consumption.[64] A few women continue high levels of alcohol intake, and if they can be identified, preventive efforts should be focused on this group.[80] In

contrast to smoking, many of these women are in higher socioeconomic groups.[81]

Adults have a significantly higher average daily intake of alcohol than adolescents. However, adults are more likely to reduce their intake in pregnancy and have a reduced incidence of binge drinking during the first trimester, which puts the offspring of adolescents at greater risk.[82]

If intervention programs are established, help from outside agencies, such as the local addiction unit, is invaluable. As with smoking, these programs are more likely to be successful in women who want to stop and when supportive care is provided. Motivational intervention with close monitoring of alcohol consumption with a planned reduction program is of benefit, often with the help of friends, family, and organizations such as Alcoholics Anonymous, with their 12-step program.[83] Because the effects of alcohol are associated with dietary deficiencies, the importance of a good diet and vitamin supplementation should be discussed.[84] Many complications of alcohol abuse may be attenuated by these measures.

If there is continued dependent drinking and the women is motivated to stop, planned detoxification should be considered, possibly with hospitalization or regular daily monitoring of withdrawal symptoms. Sudden withdrawal can lead to acute maternal symptoms, including convulsions, which may be detrimental to the fetus. Detoxification is normally undertaken with benzodiazepines, such as chlordiazepoxide, with the possible addition of phenobarbitone, if required, to manage convulsions.[85] These are given by reducing the regimen over 7 to 10 days. Benzodiazepines given in the first trimester may be associated with cleft palate abnormalities.[86] However, the benefits of stopping alcohol use outweigh this risk because alcohol is by far the greater teratogen. If delivery is likely within the next few days, benzodiazepines should be given with care because neonatal sedation and "floppy baby syndrome" can occur.[87] Disulfiram (Antabuse) should not be used because it is considered a potential teratogen, although the evidence is conflicting.[88] These women should also be given vitamin B supplementation.

Labor and Delivery

There are no problems with labor and delivery, except for the occasional need for higher levels of opiate analgesia or problems with general anesthesia because of induced liver enzymes. Alcohol withdrawal occurs after 48 hours and may be a problem postnatally. Appropriate sedation can be used with vitamin, particularly thiamine, supplementation. Symptoms subside after a few days. Women may appear agitated and have difficulty caring for their infant during this time.

If alcohol abuse continues after delivery, breast-feeding should be discouraged. Alcohol crosses over to the baby, and there may be continued effects of alcohol on the neonate.[59] Alcohol abuse during breast-feeding can cause drowsiness in the baby and may aggravate existing nutritional problems, increasing the need for dietary supplementation. However, alcohol may interfere with milk production, necessitating artificial feeding.

Postnatal

In most follow-up studies, a significant percentage of women relapsed. In one study of adolescents, more than 30% reported using alcohol within 3 months of delivery. These women are more depressed, are under greater stress, and report a greater need for social support. Therefore, the use of alcohol, as with other drugs of abuse, may be a marker for other problems that would benefit from intervention.

There is increasing concern about children of parents who abuse alcohol. These children have a higher risk of psychiatric disorders, cognitive deficits, and substance abuse that may be genetic or a long-term effect of in utero alcohol exposure.[89] Significant alcohol use affects family functioning, and children of alcohol-abusing parents are at risk for abuse and neglect.[90] Family drinking patterns are associated with adolescent alcohol abuse.[89] Children of alcohol-abusing parents have a higher incidence of emotional and behavioral disturbances and are at risk of future adult morbidity other than alcoholism. Therefore, women who abuse alcohol during pregnancy require careful follow-up from the appropriate agencies.

DRUG ABUSE: GENERAL

Maternal and Fetal Risks

The effects of maternal drug abuse on the mother and infant are difficult to assess because most users are low-income women with multiple drug use along with social and psychological problems.[91–94] When matched for social factors, mothers who use heroin have similar birth outcomes to non–drug-using mothers.[3] Therefore, many effects attributed to maternal drug abuse may be related to socioeconomic deprivation or associated factors, such as smoking, rather than to in utero drug exposure. The only effects that can be definitely blamed on drug abuse are neonatal withdrawal. However, some specific complications are associated with particular substances (discussed later).

Management Options

Prepregnancy and Prenatal

ESTABLISHING A SPECIAL CLINICAL SERVICE FOR THE PREGNANT ADDICT

The social factors are made worse by the fact that the drugs used are illegal. The women often live in a subculture of illegal behavior, including theft and prostitution.[95] Many mothers attempt to hide their lifestyle and claim fictitious support. They are often reluctant to be honest and may fear criticism, legal action, or removal of the child. They may resist antenatal care and must believe that the care is beneficial.[96] The service must be flexible and understanding enough to cope with these problems. In Glasgow, Scotland, a multidisciplinary approach was used to provide economic, social, and antenatal care during pregnancy.[3] This model has been copied elsewhere.[4] However, these approaches may not lead to great improvements in outcome,[5] but do support issues related to social problems and substance misuse that, because they persist after delivery, require close collaboration with local addiction services.[97]

Care programs that have been developed attempt to modify the external influences as much as possible to stabilize the mother's substance misuse.[4] Some women can stabilize their habit, detoxify, leave the drug culture, become healthy and responsible, and keep and care for their infant. However, others struggle to stay within the system, and care should be directed at the best possible outcome for each individual rather than optimal outcome. These care systems may change the pattern of abuse, but not necessarily the neonatal outcome.[5,98]

The systems that work best are multidisciplinary, with input from obstetricians, midwives, pediatricians, community-based health workers, social workers, drug abuse counselors, and others who can offer support.[3,4]

Caregivers should not be judgmental, although they must establish boundaries and maintain discipline. It is important to keep the trust of women and encourage them to obtain care, regardless of whether they still use drugs. A system based on rewards structure is better than one based on punishment. The ultimate reward for the mother is to be able to keep and care for the infant after birth. Care programs are more successful when friends and family are supportive.[99]

It is difficult to believe addicts, and urine screening is beneficial to assess program compliance.[100] Inpatient care can be useful to detoxify the patient; remove her from an unhealthy, stressful street environment; and provide adequate nutrition. However, the patient may be disruptive, cause stress to other women, and continue to abuse substances. In an attempt to overcome these problems, some hospitals have a segregated area for the care of addicts.[101] Our approach in Leeds, has been to treat them as normally as possible and to house them in the regular areas,[4,97] although the need for admission is now rare because the current approach is to reduce narcotic use in a gradual way in their normal environment along with psychosocial support and counseling which helps to maintain success.[97] Protocols must be in place and sympathetic staff available.

In Leeds, a special pregnancy addiction service was set up within an antenatal clinic.[97] This allows women to have all of their needs met at a single site. The clinic is coordinated by a liaison midwife with an obstetrician and an addiction worker. This ensures access to necessary antenatal care and addiction advice. The service provides a regular clinic that is available by appointment as well as on a drop-in basis. Providing care at a single site avoids the potential stigma of a separate clinic as well as possible loss of confidentiality. The availability of the service is promoted in health centers, hospitals, and local relevant organizations.

To achieve this, a close working relationship was developed between the obstetric and the addiction services, with links with community midwives, general practitioners, pediatricians, health visitors, child protection services, social services, and general support services, such as housing, probation, and community care projects. With so many individuals involved, regular meetings are held to exchange information and discuss concerns. Treatment protocols are available for all staff, particularly those who share responsibility with other services.

Regular reviews of the women are important. The Standing Conference on Drug Addiction guidelines are followed.* An initial assessment is performed at presentation, and a full review of progress made and work outstanding is completed at 32 weeks. By that time, a care plan should be in place to deal with outstanding issues. Other professionals, usually social services or housing authorities, can be contacted at that time. This process occurs with the consent of the woman, unless the infant is considered "at risk". In this case, authorities must be involved, even if the woman fails to give consent. When significant concern is present, a full prebirth assessment by social services may be needed. The 32-week meeting generates a report that is circulated to all relevant professionals involved in the care of the mother or child. A postnatal review at 3 months is scheduled to assess the progress of the mother and infant.

Labor and Delivery

The labor and delivery unit must be prepared to provide the care required. As with alcohol, problems include issues of

drug withdrawal and complications with analgesia, but also include the possibility of HIV and hepatitis infection. Specific problems depend on the drugs used.

Postnatal

The neonatal unit should be ready to care for an infant with withdrawal symptoms. The incidence and severity of these symptoms are related largely to the type and amount of drug used. In the past, babies of drug-using women were usually admitted routinely to the special care nursery and often treated for or in anticipation of withdrawal symptoms. These symptoms are a source of distress to the mother, but separation can cause further distress. In the United Kingdom, most infants do not require admission to a neonatal unit and can be cared for in a transitional care area, where the mother is directly involved.[4] At delivery, a "cause for concern" sheet is made up for the neonatal and other staff involved in the postdelivery care. This lists all relevant details of drug use, infection status, current care plans, and child protection issues.

Drug abuse was formerly considered incompatible with adequate child care, but it is now realized that drug cessation and postnatal abstinence is largely unachievable. An attempt to enforce drug cessation is likely to drive the women away from the supportive environment that was carefully established during pregnancy. However, harm reduction and stabilization should be the goal, and this goal is compatible with maternal and child health. In the United Kingdom, methadone maintenance is the main treatment for opiate addicts who are unable or unwilling to stop using drugs.[97] This approach may allow the women to live a reasonably stable life and care for her children. Many studies show that infants who remain with their biologic parents do better than those who do not.[102] To achieve these outcomes, a good working relationship with the local addiction unit is necessary to ensure that adequate follow-up and support are available.[4,97]

The success of these policies is varied. More than 50% of women who stop abusing drugs resume drug use within 6 months of delivery. Many of their infants are cared for by extended family members on a voluntary basis; others enter foster care or are adopted. This outcome may be upsetting to staff working in this area, but one success can lead to long-term benefit to at least two people (i.e., the mother and her child), and even a temporary success might reduce the long-term effects on the infant.

HEROIN ADDICTION: SPECIFIC PROBLEMS

Background

Heroin is processed from morphine, a naturally occurring substance extracted from the seedpod of the Asian poppy plant. Heroin usually appears as a white or brown powder. Street names for heroin include "smack," "H," "skag," and "junk." Other names refer to types of heroin produced in a specific geographic area, such as "Mexican black tar."

Most addiction services see more users of heroin than of any other illicit drug.[103] It is a highly physically addictive substance, and its use is a serious worldwide problem. It can be injected, snorted, or smoked, and like many drugs of abuse, the ritual of preparation is an important part of the attraction. After heroin injection, there is a surge of euphoria ("rush") accompanied by warm flushing of the skin, dry mouth, and a heavy sensation of the extremities. A drowsy state occurs, and mental functioning becomes clouded as a result of central nervous system depression. This leads to a lack of motivation and reduced social interaction.

Maternal and Fetal Risks

The main clinical problems related to heroin use are direct drug effects on the fetus and neonate and the reduced ability of the mother to care for the child.[102] Opiates are

not teratogenic.[104] However, their use is associated with IUGR and premature delivery,[102,105] a higher incidence of fetal distress, and a greater need for neonatal care.[106] Although other factors, such as poor antenatal attendance, poor nutrition, mixed drug use, and cigarette smoking, are undoubtedly involved, it is important to realize that these pregnancies are at risk, regardless of whether the drug is primarily responsible.[107] Longitudinal studies found an increased incidence of deficits in cognitive development and more behavioral problems but no differences in motor development. It is difficult to separate the effects of in utero exposure to heroin from the problems of deficient child care.[108] Children who are adopted at an early age into nurturing families develop normally, suggesting that there is no inherent problem in these babies, and if the mother is stabilized and succeeds in changing her lifestyle, the long-term outcome for the infant can be good. However, these mothers have child care problems, and there is an increased risk of sudden infant death syndrome.[5,109] Pregnancy care is only the starting point, and there is a need for ongoing support after delivery, requiring collaboration with addiction services.[97]

Management Options

Prepregnancy and Prenatal

The main aim of care for the pregnant drug-abusing woman is engagement. With this, the rest of the care follows. She should be cared for by a multidisciplinary team (including the addiction service), with the goal of risk reduction and regular follow-up.[4,97,110] The core of risk reduction is the drug substitution program; methadone is the therapy most often used, although there is increasing interest in the use of buprenorphine.[107,111–113]

METHADONE USE IN PREGNANCY

Methadone use in pregnancy varies. In the United States, higher doses are used to block opiate receptors and reduce cravings, whereas in the United Kingdom, the approach is often to find the lowest dose to prevent withdrawal symptoms. Studies show that reducing the dose to a minimum improves birth weight and prolongs gestation.[114] It is difficult to determine whether these benefits result from the use of methadone, the reduction of other drug use, an improved lifestyle, or a combination of these factors.[114] However, the risk and severity of neonatal abstinence syndrome (NAS) appear to be increased by methadone compared with heroin,[115] but methadone stabilization has considerable overall benefits for the mother and infant. The purpose of substitution therapy is to reduce illegal heroin use as well as the crime, disease, and other consequences of street use. Reducing intravenous injection has the added benefit of reducing the risk of HIV infection and hepatitis B and C infection as well as other health risks. Because methadone, at therapeutic levels, does not create euphoria, sedation, or analgesia and has no adverse effects on motor skills, mental capability, or employability, it is compatible with a reasonably normal lifestyle. Therefore, it is suitable for stabilization during pregnancy and for short- to medium-term use after delivery to maintain stability. Although many patients reduce their opiate use, only a few (10%–25%) become drug-free,[104,105] and many of these return to heroin use after

delivery. So the aim should be to maintain rather than abstain.[111]

The amount of methadone required should be assessed in the usual way. Women who are not regular (daily) users do not need substitution therapy. Those who are given methadone should have a clear history of daily use, withdrawal symptoms, and positive urine toxicology findings. The amount of methadone required can be assessed by the declared amount of heroin used or the amount of money spent per day. However, because the cost and purity of street heroin vary considerably, this guidance can only be approximate. Dosage is then titrated against withdrawal scores until stabilization is achieved. The aim is to find the lowest dose of methadone that is compatible with an absence of withdrawal symptoms or cravings. The dosage regimens in pregnancy are the same as those used in the nonpregnant user. In Leeds, it is rare to require a dose of methadone above 100 mg/day. If a higher dose is required, an electrocardiogram should be undertaken to exclude cardiac conduction defects.[116] Because the metabolism of methadone is increased in pregnancy, leading to a shorter half-life, the dose may need to be split into a twice-daily dose in later pregnancy to maintain a satisfactory steady state.[117] This dosing can increase compliance without the need to increase the total dose. Methadone maintenance treatment is more successful within a supportive environment and is largely independent of methadone dose or plasma concentration.[100] Therefore, the supportive nature of the service is more important than the drug regimen used.[97]

Once stabilization is achieved and lifestyle issues are addressed, the main aim is to maintain a stable state.[97] However, if the woman is motivated and wishes to, a gradual dose reduction can begin. Because of the danger of miscarriage, this is more safely carried out between 12 and 30 weeks' gestation. After this point, it is better simply to stabilize the patient at the lowest possible dose in preparation for labor and delivery. However, because of the changes in maternal metabolism, the maintenance dose may need to be increased to sustain maternal stability. Reduction should be done slowly, by decreasing the daily dosage by 5 mg, no more often than every 2 weeks, and then, from 20 mg/day, by 2 mg every 2 weeks, to achieve the lowest sustainable dose without the mother resorting to street heroin or suffering withdrawal symptoms.[105] It is important to aim for the lowest maternal dose to reduce the possibility of NAS. Although not strictly dose-related, a dose of less than 20 mg is not usually associated with significant NAS, unless there is concurrent street drug use. Regular urine toxicology testing allows accurate assessment of the success of the treatment program and assists in the planning of dose adjustments.[100]

ALTERNATIVES TO METHADONE

Because of the well-recognized limitations of methadone treatment, alternatives have been sought. Buprenorphine appears to be a potential option,[107,112,113,118–121] and studies showed that stabilization is as good as methadone and the risk of NAS lower. Studies show that NAS still occurs in 40% to 60% of cases, usually within 12 to 48 hours, peaks at approximately 72 to 96 hours, and lasts for 5 to 7 days.[120,122] However, NAS appears to be of less duration and severity than methadone and is related to polydrug use in at least

40% of cases.[109,122] The infants appear to have normal physical and psychological development. Also buprenorphine taken at the time of conception has been reported with no teratogenic effects.[123] It would appear buprenorphine offers a real alternative to methadone, with a reduced risk profile, although good-quality randomized trials are lacking.

Labor and Delivery

The attendant staff must be trained in the care of pregnant drug users and treat them in the same way as other women in labor. On admission, a history of recent drug use (i.e., before admission) must be obtained. Many mothers use heroin before hospital admission to help them tolerate labor.

No specific problems are associated with labor or delivery, except for maternal analgesia. Methadone should be continued, with additional opiate analgesia as required. Because high doses of narcotic analgesia may be necessary because of tolerance, epidural analgesia has advantages. At delivery, the infant should not be given naloxone (Narcan) because it causes a severe withdrawal reaction.

Postnatal

After delivery, normal support should be continued, ideally in a transitional unit. This allows the mother and infant to be together, which is important for bonding and establishment of parenting skills. This is the ideal time for staff to promote support and assess possible risk.

The incidence and severity of NAS are partially related to the type and amount of drug used and the degree of polydrug and street drug use.[124,125] Both benzodiazepines and cocaine delay the onset of NAS, but cocaine also appears to reduce the severity of symptoms.[125] The pediatric unit should be alerted to the potential clinical problems and involved in the case discussion and the development of management protocols.

In Leeds, a modified Finnegan scale is used to monitor the infant for signs of NAS.[126] This is initially carried out every 4 hours, and monitoring is reduced when appropriate. Three scores of 8 or more should be used for the diagnosis. It is useful for the mother to be involved in these assessments because many drug-using mothers have strong feelings of guilt and want to feel that they can make a useful contribution. They can also improve the continuity of assessment. Withdrawal from heroin occurs over 1 to 3 days, whereas methadone has a longer clearance time, and symptoms in the newborn may not occur for up to 7 days after delivery. Buprenorphine would appear to fall in between these lengths. Assessment should last at least 7 days, although some centers advocate earlier discharge if there are no signs by 72 hours.[127] The classic symptoms are restlessness, jitteriness, failure to feed, tremors, a high-pitched cry, arching of the back, yawning, sneezing, and sweating.[126] Convulsions may also occur. Narcotics, either morphine or methadone, are the best drugs for the treatment of NAS, although phenobarbitone may be required if convulsions occur or appear imminent.[127,128] Although most babies show some withdrawal symptoms, fewer than 50% require treatment and most can be safely cared for in a transitional unit.[4,127] Of 200 babies born in Glasgow in the 1980s and early 1990s to mothers using illicit drugs or legal methadone, only 7% required treatment for withdrawal and even fewer required admission

to the special care nursery.[101] However, other centers, including more recent figures from Glasgow, quote incidences of 10% to 80% of cases, depending on the amount of antenatal drug used and the success of the clinic maintenance program.[113,124,125,127]

Continuing supportive care, including methadone maintenance, may allow the new mother to live a reasonably stable life and care for her child, which is the best outcome for the child. This requires a continued good working relationship with general practitioners, health visitors, community pediatricians, and the local addiction service. However, many babies are eventually cared for by extended family members, placed in foster care, or released for adoption.[129]

BREAST-FEEDING

If the mother is stable on methadone, is not supplementing with street drugs, and is believed to be HIV-negative, breast-feeding should be encouraged. The secretion of methadone in breast milk is variable,[130] but it may help to reduce withdrawal symptoms.[131] A stable lifestyle helps successful breast-feeding. However, if the mother is still injecting street heroin, is known to be or is at risk for being HIV-positive, or is using other street drugs (e.g., cocaine), breast-feeding is not advisable.

HUMAN IMMUNODEFICIENCY VIRUS AND OTHER INFECTIOUS DISEASES (see also Chapters 27, 28, 30, and 31)

HIV infection is associated with drug abuse because of needle sharing and heterosexual spread from associated prostitution. The danger, particularly in the United Kingdom, has been overstated, although in some areas, the incidence of HIV infection is particularly high. In Edinburgh, in 290 at-risk pregnancies, 93 (32%) of the women were HIV-positive. However, of these 93 pregnancies, only 8 (8.7%) resulted in an HIV-infected child.[132] Since then, the prevalence of HIV has declined from 0.5% of all pregnancies in 1986 to 0.1% in the 1990s.[133] The risk of vertical transmission has been significantly reduced by the use of antiviral drugs and obstetric intervention.[134] Targeting of antiviral treatment is difficult because not all HIV-positive women are known to the medical authorities.[135,136]

Because many HIV-positive patients are not known to the service, single-tier management of all pregnant women is important to minimize the risk of transmission to health care workers. This also helps to reduce discrimination against substance-misusing women. In the United Kingdom, HIV testing is offered to all pregnant women after appropriate counseling. The benefits of testing must be explained to the mother. Current therapy improves maternal health and significantly reduces vertical transmission to the baby with the opportunity for a vaginal delivery.[134]

Intravenous drug users are also at risk for hepatitis B and C infection, and screening is routinely offered. The most common infection found is hepatitis C, which is found in approximately 40% to 60% of women who abuse intravenous drugs.[103] Evidence suggests that hepatitis C does not adversely affect the pregnancy and the pregnancy does not worsen the viral load or prognosis of the disease, although many women have a slight rise in alanine aminotransferase levels postpartum.[137] Vertical transmission of hepatitis C infection occurs in approximately 1% to 6% of cases and is

usually in women with detectable hepatitis C virus RNA in the peripheral blood.[138] It is increased by concurrent HIV infection[139,140] and longer labors. Breast-feeding is not a risk because hepatitis C virus RNA is not detected in breast milk. Infants who are hepatitis C virus–positive should be followed up for at least 1 year because some become seronegative over time. No treatment or vaccination is available.

Less frequently, women are hepatitis B–positive.[103] Pregnancy does not appear to affect the course of the disease in the mother, but the rate of vertical transmission without intervention is 80% to 90%. Of these infants, more than 85% become clinical carriers of the virus. Infection in the baby usually occurs at or directly after delivery, so the babies are candidates for post-exposure prophylaxis. An at-risk infant should be given HepB immunoglobulin within 12 hours of delivery while concurrently being given the first dose of HepB vaccination.[141] This should be completed with follow-up vaccinations at 1 month and 6 months. This intervention is safe and provides 90% protection against infection. One study suggested that maternal lamivudine treatment may also help to reduce neonatal infection.[142]

COCAINE ADDICTION: SPECIFIC PROBLEMS

Background

Cocaine is a vasoactive drug and can cause specific problems in the baby as a result of placental damage[143] and direct fetal vascular effects. Unlike alcohol, cocaine has no specific associated syndrome or cluster of signs.[144] Its effects are varied and may be more closely related to other drug use and associated social problems.[143,145]

It comes in the following two forms:

- Pure cocaine, or "coke," which is a white powder that is generally snorted through the nasal mucosa.
- "Crack," which is more addictive and dangerous. Crack is produced by mixing cocaine crystal or powder with water and baking soda or sodium bicarbonate. The mixture is boiled until the water evaporates, leaving brown and white rocks. It is usually smoked with special glass pipes or silver foil, although it can be injected after a solution is made with water.

The use of crack cocaine has been reducing since the late 1980s, but overall cocaine use has increased greatly due to the widespread use of powder cocaine.[146] Many studies, particularly in the United States, found higher rates of cocaine abuse than of heroin abuse, with an incidence of between 0.8% to 31%.[143,146] Radioimmunoassay of hair samples obtained immediately postpartum show much underreporting of cocaine use. Underreporting is more common among women who are unmarried, African American, and multiparous.

Maternal and Fetal Risks

Cocaine is absorbed rapidly into the bloodstream, producing a high in approximately 6 to 8 minutes. Unlike the physical addiction of heroin, cocaine addiction is more psychological. Users often do not eat or sleep while under the influence of the drug and often become dehydrated. Although these effects may not present problems with occasional use, heavy use may be associated with exhaustion, dehydration, and poor nutrition. Some people use heroin to "come down" from cocaine highs, further complicating the medical problems. Because crack can be smoked, it can affect other people nearby; this has implications for children and babies in the room with a user.

Heavy usage of cocaine is associated with an increase in preterm delivery, low birth weight, the need for resuscitation at birth, and prolonged postnatal stay, although significant problems are rare.[147,148] The effect of cocaine on birth weight may be related to shorter gestation and poor maternal nutrition. Women who use cocaine use prenatal care less often, smoke more cigarettes, and drink more alcohol, all of which are associated with poor growth.[72] When these variables are excluded, identifiable differences in birth weight between cocaine-using mothers and control subjects are no longer present.[145] However, peripartum exposure to cocaine is associated with an increased frequency of abruptio placentae; thick, meconium-stained amniotic fluid; and prelabor rupture of the membranes.[143] There is also an association with fetal abnormalities, including genitourinary anomalies and abdominal wall defects.[143]

Cocaine-exposed infants with very low birth weight had an increased incidence of mild intraventricular hemorrhage. The incidence of developmental delay was significantly higher, even after controlling for the effects of intraventricular hemorrhage and gestational age,[149] although there is no place for routine neonatal brain ultrasonography.[150] Cocaine-exposed infants with very low birth weight were also more likely to be living with relatives or in foster homes, which further affects their development.[149] Long-term assessment showed reduced head circumference, low Stanford-Binet Intelligence Scale (SBIS) verbal reasoning, and low SBIS abstract/visual reasoning. These children were also more aggressive.[151] These findings are similar to those associated with alcohol.

Binge cycles are a particular problem and reflect the chaotic lifestyle of many drug abusers. Binges range from 26.4 to 34.4 hours.[152] Bingeing is associated with preterm birth and an increased incidence of acute problems, such as vaginal bleeding (21.8%), abruptio placentae (14.3%), and stillbirth (20.5%). Erratic use of cocaine or crack results in perinatal complications that are as severe as those occurring with daily use.[152]

Like heroin, maternal cocaine exposure during pregnancy is associated with acceleration of amniotic fluid and fetal lung maturity, which may reflect increased fetal stress.[153]

Not all substance-exposed children have the same poor prognosis, suggesting that maternal and environmental factors modify the damage.[151] Surveys show that most cocaine users also use alcohol.[154] Comparison with alcohol shows that alcohol is the more potent teratogen. Those who use both agents are more likely to have troubled backgrounds, indulge in antisocial behavior, and drop out of treatment programs than those who use only alcohol. Good nutrition is very important in preventing congenital anomalies and fetal death, and cocaine use during pregnancy is more dangerous to the street person who uses multiple drugs and alcohol than to the middle-class woman who takes antenatal vitamins.[155]

Management Options

Prepregnancy and Prenatal

Again, the basis of care is trust between the woman and her caregivers. The true nature of cocaine or crack abuse may not be easily divulged, and support may be rejected. The risk to the fetus must be made clear and the particular risk of binge use emphasized. No substitute drug is available to help with stabilization in pregnancy. However, sudden cessation is not associated with adverse fetal effects. Although the desire for a healthy baby may be an incentive to stop using cocaine, success is rare because psychological addiction is usually strong. If a woman wishes to stop using cocaine or crack, hospital admission may be beneficial to remove her from her usual environment. Constant social support and encouragement increases the chance of success. If use is stopped at any time during pregnancy, the outcome is improved.

Labor and Delivery

There is no major problem with labor or delivery other than an increased need for narcotic analgesia. There can be specific problems in anesthetizing a woman who uses cocaine or crack.[156] Drug-related hypertension may mimic preeclampsia. Excessive uterine activity may result in fetal compromise or acute separation of the placenta.

Postnatal

After birth, the symptoms of fetal cocaine withdrawal may not reach a peak until 3 days of life, and they may persist for 2 to 3 weeks. Many babies are discharged home before symptoms occur, so community midwives should be vigilant. Common signs are irritability, tremulousness, mood alterations, and hypertonia; in addition, the infants may be difficult to console.

As with heroin, relapse to drug abuse may occur in the postpartum period. Close community support from the relevant agencies can help women to stay drug-free and develop parenting skills.

CANNABIS: SPECIFIC PROBLEMS

Background

Marijuana is the most prevalent illicit drug used in pregnancy (4%–30%).[94,157–159] Despite this, there are few reports on fetal effects.

Maternal and Fetal Risks

Studies suggest that there is no increase in the rate of morphologic anomalies, low birth weight, preterm delivery, or abruptio placentae.[67,108,160,161]

A study in Jamaica assessed newborns exposed to marijuana antenatally in a blinded fashion and compared them with nonexposed babies from socioeconomically matched mothers. At 1 month, marijuana-exposed infants scored higher on autonomic stability, reflexes, general irritability, and weight. No ill effects from marijuana were found, and there may have been dose-related positive effects. The Jamaican mothers reported that cannabis increased their appetite during pregnancy and relieved pregnancy-related nausea.[161] More recent studies suggest the possibility of more subtle problems.[70]

Therefore, the use of marijuana is not a major problem and may even be beneficial in pregnancy. However, some may see marijuana as a gateway drug that potentially leads to harder drugs because of its association with the drug culture. Users should be warned against progression to drugs that are more harmful. It is also associated with other substances of abuse including alcohol and tobacco that are far more dangerous. There is a recent trend of medicinal use of marijuana for the treatment of nausea in pregnancy. This may increase the exposure of the early fetus to this substance.[162]

Management Options

No management problems are specifically associated with cannabis use, although a careful drug history should be taken and a reduction of use encouraged.

BENZODIAZEPINES: SPECIFIC PROBLEMS

Background

Benzodiazepines are commonly used as anxiolytics and sedatives.[163] Their legitimate use in pregnancy has varied over the years, including the management of preeclampsia.[164] However, because of the fear of harmful effects, many women and their physicians recommend stopping their medication acutely, often with adverse maternal effects.[165] There are no apparent fetal effects, although the fetus may be at risk if the mother has a convulsion. These substances are also taken as part of polydrug abuse,[166] making assessment of their risk difficult.

Maternal and Fetal Risks

Large epidemiologic studies show no teratogenic effects and no obvious problems related to withdrawal from various benzodiazepines. However, some abnormalities, particularly cleft palate,[86] are associated with its use. This finding is not conclusive, and other studies found no link.[167] Further, cleft palate is a common abnormality that occurs with other drug use.[168] However, there is evidence of hypotonia and problems with feeding because of its sedative effect when taken immediately before delivery.[87]

Management Options

No specific management in pregnancy is needed, except to discourage its use or stabilize the patient to the lowest level tolerated. Further reduction and cessation is possible in motivated patients. However, stopping suddenly can produce severe maternal side effects such as convulsion, but it is safe for the baby. Benzodiazepines are excreted in breast milk, but the levels are low and should not cause neonatal problems.[87]

AMPHETAMINES: SPECIFIC PROBLEMS

Amphetamines are synthetic amines that are similar to the body's own adrenaline (epinephrine). They exaggerate the

normal reaction to emergency or stress. Common slang terms for amphetamines include "speed," "wizz," "crystal," "meth," "bennies," "dexies," "A," "uppers," "pep pills," "diet pills," "jolly beans," "truck drivers," "co-pilots," "eye openers," "wake-ups," "hearts," and "footballs." The stimulating effects of amphetamines have been widely used to counteract fatigue. These drugs are also used by athletes to increase performance and by others for general stimulation, pleasure, or fun. Their use in pregnancy varies but is usually less than 1%.[169] In the younger age group, approximately 9% describe past use.[158] Overall, its use appears to be decreasing.

The drug is usually taken orally but can be injected or sniffed. It is sometimes used interchangeably with cocaine. Because amphetamine use produces undesirable personality changes, "speed freaks" are highly unpopular with other addicts. They may be aggressive and violent. Most drug users consider amphetamines extremely dangerous and do not use them.

After continued administration of moderate doses, recovery is associated with fatigue, drowsiness, and often depression. The increased energy produced by the drug merely postpones the need for rest. Regular users rely on the drug when fatigued and often do not get proper rest for long periods. Near the end of such a "run" (usually < 1 wk), toxic symptoms dominate and the effects become intolerable. If the drug is discontinued, fatigue sets in and prolonged sleep follows, sometimes lasting days. After wakening, the user feels lethargic, sometimes depressed, and extremely hungry. These effects can be overcome by further drug use, which restarts the cycle. To stop runs, or "downers" opiates are sometimes used. Amphetamines do not produce a physical dependence, and psychological and environmental factors appear to be the motivating factors in the addiction.

Maternal and Fetal Risks

The effect on the baby is not well documented, but it appears to be associated with congenital abnormalities, particularly an increased occurrence of cleft palate.[170] Because amphetamine use is associated with hypertension, the incidence of preeclampsia and convulsions is also increased, with associated IUGR and death. Preterm labor is also more common, but this may be due to associated lifestyle factors. The long-term growth of infants born to mothers who were addicted to amphetamines during pregnancy was found to be impaired.[171] This reduction appeared to be global, suggesting symmetrical growth impairment, which is usually associated with direct injury to the developing fetus rather than placental insufficiency.

Management Options

Amphetamines are dangerous and should be discontinued. There is no drug substitute. Success in stopping the use of this drug is poor, and these addicts are probably the most difficult and problematic to treat. They value their sick appearance and often claim that they will die. Death as a result of amphetamine use is relatively rare. The best approach is to provide close, supportive care and constant encouragement to stop using the drug. The problem is that few engage in care, and if they do, stopping is relatively easy, but so is restarting.

D-LYSERGIC ACID DIETHYLAMIDE-25: SPECIFIC PROBLEMS

Background

D-Lysergic acid diethylamide-25 is an unusual, controversial drug better known as "LSD" or simply "acid." It is usually taken orally but may be sniffed or injected. LSD is one of the most potent biologically active substances known. It is well absorbed from the gastrointestinal tract, is distributed in the blood, easily diffuses into the brain, and crosses the placental barrier.

The psychological effects are not predictable and are affected by the user's personality and current thoughts. However, its use is compatible with a reasonably normal life and is not necessarily associated with the normal drug culture. In the younger age group, approximately 7% describe past use.[158]

Maternal and Fetal Risks and Management Options

High doses of LSD given to pregnant animals produce deformities in the offspring of some species and not others.[172,173] There are little data on LSD use in human pregnancy.[174] Until more information is known, the most sensible approach is to recommend that pregnant women avoid LSD use. No other particular care is required.

BARBITURATES: SPECIFIC PROBLEMS

Background

The incidence of barbiturate use in pregnancy is relatively low and is falling.[175,176] There do not appear to be specific fetal effects, except for fetal dependence. Acute withdrawal during pregnancy can affect the fetus in utero and is not recommended, although the precise risk is unknown. Gradual withdrawal can be achieved with reducing doses of short-acting barbiturates, such as pentobarbitone.

Maternal and Fetal Risks

The main risk to the mother and neonate is associated with withdrawal. This can be alleviated with a gradually reducing regimen that includes supplementary drugs. Acute withdrawal is associated with seizures and mental instability, usually occurring approximately 48 hours after the last dose. The neonate may take longer to show symptoms because the clearance of barbiturates is slower in the newborn.

Management Options

Slow reduction and cessation of drug use is the mainstay of management.

SOLVENT ABUSE: SPECIFIC PROBLEMS

Background

Solvent abuse is extremely common, and up to 19% of schoolchildren in parts of the United States have used them.

Along with alcohol, marijuana, and tobacco, they are considered gateway drugs. There are many types of inhalants, including spray paint, liquid correction fluid, hair spray, nail polish remover, paint thinners, felt-tip markers, air fresheners, octane booster, glues and adhesives, fabric protectors, acetone products, carburetor cleaner, gasoline, propane gas, gas inside Ping-Pong balls, VCR head cleaner, and vegetable cooking sprays. Other examples are butyl nitrates, called "locker room" or "rush," and amyl nitrate capsules, called "snappers" or "poppers."

Maternal and Fetal Risks

Solvent abuse produces clinical signs, such as irritation and sores around the mouth and nose, nausea and headache, coughing, memory loss, lack of concentration and coordination, and odd behavior or irritability.

Sniffing leads to rapid entry of the drugs into the brain and organ systems, producing a high that lasts 15 to 45 minutes. Inhaling from a plastic or paper bag ("bagging") or inhaling from a soaked rag placed in the mouth ("huffing") greatly increases these effects. Damage can occur to the brain, liver, kidneys, blood, and bone marrow, and unconsciousness is common. In a study in pregnant solvent users, renal tubular acidosis was diagnosed in 5.3%, and 3.6% had adverse neurologic sequelae. One patient was diagnosed with brain damage, including expressive aphasia. The incidence of premature delivery was 21.4%. The substances in solvents can cross the placenta and enter the fetal bloodstream. In the same study, 16.1% of infants had major anomalies. Most of these had facial abnormalities similar to those seen in fetal alcohol syndrome, and a further 10.7% had hearing loss.[177]

In another study of infants exposed to toluene, there was a 10% incidence of neonatal death as well as an increased incidence of prematurity (42%), low birth weight (52%), and microcephaly (32%). In addition, some infants had craniofacial features similar to those seen in fetal alcohol syndrome as well as other minor anomalies.[178]

Management Options

Solvent use is associated with erratic behavior, is dangerous for the mother and fetus, and should be strongly discouraged. Close observation and monitoring are required because of the high incidence of premature delivery and IUGR. Because there is evidence of neonatal abnormalities similar to those seen with alcohol and there may be developmental problems, the babies require close long-term follow-up.

SUMMARY OF MANAGEMENT OPTIONS
Specific Drugs of Abuse (e.g., Heroin, Cocaine, Barbiturates)

Management Options	Evidence Quality and Recommendation	References
Use a multidisciplinary approach.	IIb/B	4,187
Explain the risks of low birth weight, intrauterine growth restriction, and preterm delivery and the need for neonatal care, especially if withdrawal symptoms occur.	III/B	106
Explain the risk of developmental abnormality in infants.	III/B	102
In women using heroin, encourage detoxification or substitution with methadone or buprenorphine.	III/B	110
Encourage cessation with cocaine and amphetamines.	IIb/B	190
Solvent abuse produces effects similar to those of alcohol.	III/B	178
Screen for fetal abnormality, growth, and well-being.	III/B	106
The patient may need an increased dose of narcotic analgesia (an epidural is preferable).	IV/C	191
Provide fetal monitoring if intrauterine growth restriction occurs.	—/GPP	—
If the patient is HIV-positive or is still injecting, discourage breast-feeding (see also Chapter 28).	IV/C	134
Watch for symptoms of withdrawal in the infant (starting at 3 days with heroin, cocaine, and solvents; 7 days with methadone, barbiturates, and amphetamines).	IV/C	127,192
Provide follow-up by an addiction team.	IV/C	193,194

GPP, good practice point.

Medication

CATALIN S. BUHIMSCHI and CARL P. WEINER

INTRODUCTION

Drug use during pregnancy and lactation remains one of the least developed areas of clinical pharmacology and drug research. Pregnancy risk factors together with an increased incidence in chronic diseases and a rise in the average maternal age predict medication use will increase during gestation. Common primary exposure categories include over-the-counter medication, psychiatric agents, gastrointestinal medications, herbals, vitamins, antibiotics, and topical products. Sadly, only a few medications have been tested specifically for safety and efficacy during human gestation. Profound physiologic changes occur during both normal and pathologic pregnancy that may dramatically alter drug clearance, efficacy, and safety. In such an environment, the danger of a drug to mothers, their fetuses, and nursing infants cannot be determined with any confidence until it is widely used. It is important that women with medical disorders such as diabetes, hypertension, epilepsy, and inflammatory bowel disease continue necessary therapy while pregnant. Unfortunately, many physicians stop or delay medically important agents precisely because of the lack of information. Innovative research in genomics and proteomics should facilitate the development of medications exponentially as part of the new scientific field of "theranostics." Theranostics holds great potential for personalized medicine in order to tailor medical treatments for individual patients. Perhaps we should start with a whole class of patients—pregnant women—in desperate need of tailored products.

In this chapter, we seek to provide a general but concise resource of drugs commonly used during pregnancy and lactation. It is critical that clinicians become familiar with all the aspects of the drugs they recommend and consult with a maternal-fetal medicine specialist, when appropriate, so that the best possible evidence-based counseling and treatments are provided.

MATERNAL PHYSIOLOGIC ADAPTATION TO PREGNANCY

Pregnancy is characterized by profound changes in the cardiovascular, respiratory, renal, gastrointestinal, and endocrine systems.[1] These changes begin early and evolve steadily. By 6 to 8 weeks' gestation, the plasma volume begins to rise, reaching 50% above the nonpregnant level by the end of the third trimester.[2,3] Given this increase in the extracellular space and total body water, physiologic dilution occurs and may explain some of the effects of pregnancy on drug efficacy. The efficacy of any medication used is highly dependent on the dose and route of delivery, absorption, plasma level achieved, engagement of the receptors, functionality of the effector mechanisms, and clearance of the drug by liver and kidneys.[4] The physiologic increase in the maternal blood volume provides a rationale for the clinical observation that the doses of many medications must be adjusted during pregnancy to maintain efficacy.

Cardiac output increases during pregnancy by 30% to 50% and begins to do so by 8 weeks' gestation. It is caused by an elevation in both stroke volume and heart rate.[5,6] In addition, there is a significant redistribution of this increased cardiac output.[7] The impact of this on drug clearance might be great because glomerular filtration rate increases while the percentage of the cardiac output delivered to the liver, the organ crucial for drug disposal, declines. Therefore, adaptation to normal pregnancy might increase renal clearance but decrease hepatic clearance. In addition, gastric and intestinal transit is prolonged during pregnancy owing, at least in part, to progesterone-induced inhibition of intracellular calcium movement within smooth muscle cells.[8] This adaptation will alter the bioavailability of oral agents. Further, up to 80% of pregnant women experience nausea and vomiting at least during the first trimester, which can influence compliance with treatment.[9]

Numerous medications are bound by albumin, which declines during pregnancy. Decreased albumin and α_1-acid glycoprotein concentrations increase the free drug concentration of drugs that are normally highly bound, shortening their elimination half-life.[10,11] Pregnancy causes a partially compensated respiratory alkalosis, which also may affect the protein binding of some drugs.

Knowledge of pharmacokinetics and the application of mechanism-based approaches will improve our ability to predict the effects of pregnancy on medications with limited experience.[10] In pharmacology, "bioavailability" describes the fraction of an administered dose of unchanged drug that reaches the systemic circulation. It measures the extent to which a therapeutically active compound reaches the

systemic circulation and is present at the site of action. The good news is that despite the many physiologic changes that occur during pregnancy that could affect absorption, drug bioavailability does not appear to be profoundly altered.[10]

GENERAL PRINCIPLES OF TERATOLOGY

Teratology—Definition

Teratology is the study of the biologic mechanisms and causes of abnormal human development coupled with the development of preventive strategies.[12] According to Shepard and Lemire,[12] the following conditions are required to establish proof of teratogenicity:

- Established exposure of the embryo or fetus at a critical time during development.
- Consistent dysmorphic findings recognized in well-conducted epidemiologic studies.
- Specific defects or syndromes consistently associated with a specific teratogen.
- Association of environmental exposure with rare anatomic defects (e.g., carbamazepine with facial dysmorphism and nail hypoplasia).
- Proven teratogenicity in experimental animal models.

Teratogen—Definition

A *teratogen* acts to irreversibly alter growth, structure, or function of the embryo or fetus and refers to any agent that causes an anatomic structural abnormality. This definition can reasonably be expanded to include alterations in function. Although 2% to 3% of all pregnancies are complicated by congenital abnormalities, less than 10% can be associated with a particular drug exposure. Known teratogens include viruses (e.g., rubella, cytomegalovirus, congenital lymphocytic choriomeningitis virus), parasites (toxoplasmosis), spirochetal bacterium (*Treponema pallidum*), environmental factors (e.g., hyperthermia, irradiation), chemicals (e.g., mercury, alcohol), and therapeutic agents (e.g., *lithium*, *methotrexate*, inhibitors of the renin-angiotensin system, *thalidomide*, *streptomycin*, *isotretinoin*, *warfarin*, *valproic acid*, *phenytoin*, *carbamazepine*).[1,13]

Embryonic versus Fetal Exposure to Teratogens

The extent of embryonic and fetal exposure depends on factors such as gestational age, dose, route of administration, absorption of the drug, maternal serum levels, and/or liver or kidney clearance system.[14] Placental passage is also critical for a drug medication to exercise its specific embryonic or fetal teratogenic effect.

Based on the gestation at exposure, a teratogen can induce either an *embryopathy* or a *fetopathy*. From this perspective, several critical periods of embryonic or fetal development are described:

1. "Preimplantation" (fertilization to implantation).
2. "Embryonic" (the second through the ninth week).
3. "Fetal" (the ninth week to term).

The preimplantation period is generally characterized as "all or nothing," meaning that injury to a large number of cells will predictably cause an embryonic loss. In turn, if only

a small number of cells are disrupted, the embryo is protected through a phenomenon called "compensation" that facilitates survival without birth defects.[15]

The period of organogenesis (2–8 wk postconception) is the time of maximal vulnerability, and each embryonic system has a period of maximum susceptibility (e.g., the heart is typically affected if the teratogen acts between 6 and 8 wk' gestation). Conversely, the fetus might be affected by alterations in the structure and function of organs that initially develop. For example, a variety of central nervous system (CNS) malformations (e.g., anencephaly, spina bifida, encephalocele, craniorachischisis) arise owing to the failure of closure of the neural tube during the process of neurulation (17th–30th postfertilization days). Other neural tube defects (e.g., encephaloceles) may occur postclosure during the fetal period.[14,16]

Human teratogens may act and induce a different spectrum of malformations during specific stages of fetal developmental. For instance, nonsteroidal anti-inflammatory drugs (NSAIDs; e.g., *indomethacin*, *ibuprofen*) are associated with vascular disruptions (e.g., gastroschisis) if the embryo is exposed early in gestation.[17] In contrast, closure of the ductus and/or kidney failure might occur when the fetus is exposed to an NSAID after 32 weeks.[18] Similarly, *warfarin* is a well-recognized teratogen that carries a 4% to 10% risk of a dose-dependent and specific embryopathy if used during the first trimester.[19,20] Whereas first-trimester exposure to *warfarin* leads to embryopathy, exposure of the fetus during the second and third trimesters causes abnormalities related to hemorrhage, primarily in the CNS and skeleton.[21]

Placenta and Teratogenicity

Placental transfer depends greatly on maternal metabolism, gestational age, protein binding and storage, charge, pH, drug ionization, liposolubility, and molecular size (e.g., most substances <500 daltons diffuse rapidly across the placenta).[22,23] Probably the most eloquent example of this phenomeon may be found in anticoagulation therapy. Whereas the relatively low-molecular-weight *warfarin* is transported across the placenta, the high-molecular-weight *heparin* is not, explaining in part why *warfarin* but not *heparin* is a teratogen agent.[24] The increased circulating sex hormone levels characteristic of pregnancy have a profound impact on at least some placental drug-metabolizing enzymes, drug bioavailability, and receptor coupling. Steroid hormones directly influence the expression and function of placental transporters involved in drug passage to the fetus.[25] Of particular interest in the future is the manipulation of placental transporter activity (either increasing or decreasing) to optimize the fetal therapeutic impact. Lastly, differences in placentation are likely to be a key factor responsible for interspecies variability in response to many agents and might explain why a drug may act as a teratogen in humans but not in animals and vice versa.[22]

Genetic Variation and Teratogenicity

Genetic variation is a relevant determinant of drug clearance in pregnant women. Likewise, the effect of pregnancy on systems subject to genetic variation is likely to affect the efficacy and teratogenic effect of a specific drug. Several

drug groups whose metabolic pathways are known to be greatly affected by genetic heterogeneity are widely used during pregnancy, and changes in their clearances are reported.[26–29] For example, developmental effects of certain anticonvulsants (e.g., *phenytoin*) suggest that prenatal exposure may result in gender-determined developmental changes and deficits.[30] Clearly, the fetal genotype determines susceptibility of the fetus to a given agent. Furthermore, all vertebrates carry a group of highly conserved genes—the homeobox genes. These regulatory genes (especially the HOX family) encode for transcriptional factors that control the expression of several other regulatory genes.[31] The HOX genes are essential to establish positional identity of various body structures from the head to the tail. For example, upper arm development is regulated by genes in the 9 to 10 group; the lower arm by the 10, 11, 12 groups; and the digits by the 11, 12, and 13 groups.[32] Several teratogenic agents (e.g., retinoids) activate homeobox genes, causing chaotic gene expression at different times of development. Several patterns of malformations are explained by such pathways, including spina bifida associated with *valproic acid*.[33] The world painfully learned in the 1970s that in utero exposure to diethylstilbestrol (DES) induces various abnormalities in the müllerian duct. Animal studies suggest that organ-specific gene expression patterns in the mouse müllerian duct are altered by in utero DES exposure.[34] DES-induced changes in expression of genes include Dkk2 (Dickkopf gene family), Nkd2 (naked cuticle drosophila), and sFRP1 (secreted frizzled related protein 1) as well as changes in genes of the HOX family that, in the female fetal reproductive tract, could be the basis for various abnormalities.[34]

Drug Risk Classification in Pregnancy

Physicians in the United States rely almost routinely on U.S. Food and Drug Administration (FDA) drug classification (A, B, C, D, or X) (Table 34–1) to ascertain risks and counsel patients regarding the safety of a drug during pregnancy. Other classifications are used worldwide (see Table 34–1). All differ in their conclusions on the safety of numerous agents commonly used during pregnancy.[35] In one comparison, only 61 (26%) of the 236 drugs common to all three systems in Table 34–1 were placed under the same risk factor category. Though these classifications seek simplicity, they are often difficult to interpret and are only rarely updated after a drug is marketed.

Under the FDA taxonomy, less than 1% of drugs are classified as category A (controlled studies in women fail to demonstrate a risk for the fetus and the possibility of fetal harm appears remote).[36] In point, the majority (66%) of all drugs marketed in the United States are classified category C (risks cannot be ruled out in humans, but the benefits of the medication may outweigh the potential risks).[36] Many angiotensin-converting enzyme (ACE) inhibitors are or were initially classified as such. In the same FDA risk classification, some category X drugs (7%; evidence that the medication causes abnormalities in the fetus) are not absolutely contraindicated during pregnancy. One such example is *ribavirin*, which is used in combination with *interferon*, for the treatment of chronic hepatitis C.[37] Although *ribavirin* is considered contraindicated in pregnancy, there is no

adequate study demonstrating a teratogenic effect of this drug in human pregnancy.[38]

Given these limitations, the FDA has proposed to revise the content and format of labeling for human prescription drug and biologic products. Detailed information about this proposal can be found at http://www.fda.gov/cber/rules/frpreglac.htm. The new categorization will eliminate the alphabetical (A, B, C, D, and X) category of risk. Two major subsections of the drug labeling are proposed:

- Pregnancy.
- Lactation.

These subsections will replace the existing "Pregnancy," "Labor and Delivery," and "Nursing Mothers" sections of the current drug labeling scheme and include three main components: risk summary, clinical considerations, and data available from animal and human studies. This layout approximates that used by our text *Drugs for Pregnant and Lactating Women*.[36] It is encouraging that under the new rules, postmarketed experience will be provided.

Pregnancy Registries and Case-Control Surveillance Studies as a Resource for Identification of Drug Teratogenicity

Unfortunately, manufacturers, physicians, and patients are often reassured and believe that the most serious short-term adverse effects of a drug were identified in premarketing studies. The reality is that many human teratogenic effects were discovered only after a drug received marketing approval and was used broadly. Although the endorsement of a drug by the FDA requires comprehensive animal and human studies, such surveillance models are limited in their ability to accurately predict whether an agent is a human teratogen. Factors such as dose and route of administration, gestational age at exposure, maturation of the fetus, and its genotype all are important in limiting the identification of drug teratogenicity prior to commercialization. Variations in placentation, species-specific effects, and even between mammalian species are described.[15,22]

Identification of a de novo birth defect is always problematic, given that the caregiver should provide answers to two main questions:

- Was this defect the consequence of a genetic defect?
- Was this defect the result of exposure to a teratogen during gestation?

Most congenital defects associated with prenatal exposure to a drug are identifiable by their pattern of major and minor malformations, rather than a single major malformation. Thus, traditional epidemiologic methods are not always effective in identifying new teratogens.[39] Therefore, two main strategies for the identification of teratogens are proposed:

- Pregnancy registries.
- Case-control surveillance.[40]

The FDA defines a "pregnancy exposure registry" as a prospective observational study that collects information on women who take medicines and receive vaccines during pregnancy. Recruitment of large numbers of exposed pregnancies and successful long-term follow-up of the patients coupled with the complete and accurate ascertainment of pregnancy outcomes are critical attributes of a well-designed

TABLE 34–1

Pregnancy Drug Categories from Different Countries

FDA CATEGORY (USA)	PREGNANCY CATEGORY DEFINITION
A	Adequate, well-controlled studies in pregnant women have not shown any risk to the fetus in the first 3 months of pregnancy, and there is no evidence of later risk either. *Very few medications have been tested to this level.*
B	There have been no adequate, well-controlled studies in women, but studies using animals have not found any risk to the fetus, or animal studies have found risk that was not confirmed by adequate studies in pregnant women. *Not many adequate studies have been performed in pregnant women, so the first situation (not enough information) usually applies if a medication is assigned to this category.*
C	There have been no adequate, well-controlled studies in women, but studies using animals have shown a harmful effect on the fetus, or there have not been any studies in either women or animals. Caution is advised, but the benefits of the medication may outweigh the potential risks.
D	There is clear evidence of risk to the human fetus, but the benefits may outweigh the risk for pregnant women who have a serious condition that cannot be treated effectively with a safer drug.
X	There is clear evidence that the medication causes abnormalities in the fetus. The risks outweigh any potential benefits for women who are (or may become) pregnant.

FASS CATEGORY (SWEDEN)	PREGNANCY CATEGORY DEFINITION
A*	Drugs taken by a large number of pregnant women with no proven increase in the frequency of malformations or other observed harmful effects on the fetus
B1*	Limited experience in pregnant women, no increase observed in the frequency of malformations or other observed harmful effects on the fetus. Animal studies reassuring.
B2*	Limited experience in pregnant women, no increase observed in the frequency of malformations or other harmful effects on the fetus. Animal studies inadequate or lacking.
B2*	Limited experience in pregnant women, no increase observed in the frequency of malformations or other harmful effects on the fetus. Animal studies inadequate or lacking.
B3[†]	Limited experience in pregnant women, no increase observed in the frequency of malformations or other harmful effects on the fetus. Animal studies have shown evidence of an increased occurrence of fetal damage.
C[†]	May cause pharmacologic adverse effects on the fetus or neonate.
D[‡]	Suspected or proven to cause malformations or other irreversible damage.

ADEC CATEGORY (AUSTRAILIA)	PREGNANCY CATEGORY DEFINITION
A–D	Categories A,a B1,a B2,a B3,b C,b Dc similar to the FASS definitions.
Xc	Limited experience in pregnant women, no increase observed in the frequency of malformations or other observed harmful effects on the fetus. Animal studies reassuring.

* Drugs grouped as probably safe.
[†] Drugs grouped as potentially harmful.
[‡] Drugs grouped as clearly harmful.
ADEC, Australian Drug Evaluation Committee (Australian categorization); FASS, Farmaceutiska Specialiteter i Sverige (Swedish categorization); FDA, U.S. Food and Drug Administration (U.S. categorization).

In Queenan JT, Spong CY, Lockwood CJ (eds): Management of High Risk Pregnancy, 5th ed. An evidence based approach. Malden, Mass: Blackwell Publishing, 2007, pp 38–58.

registry.[41] There is consensus that pregnancy registries are a useful resource of information, and the FDA has required some pharmaceutical manufacturers to maintain a pregnancy exposure registry. The most up-to-date *List of Pregnancy Exposure Registries* is available at the FDA website (http://www.fda.gov/womens/registries/). Recently, the Research Committee for the Organization of Teratology Information Specialists (OTIS) concluded that more specific information on the timing and the dose of drug was necessary in pregnancy birth defect registries sponsored by pharmaceutical companies to improve the accuracy of risk estimates for developmental toxicity.[42] Specifically, the Committee recommended that

• The exposure should be stated in gestational weeks and days rather than simply weeks.
• The exposure dose should be stated in patient-specific terms, such as body weight (milligrams per kilogram) or body surface area (milligrams per square meter), rather than simply the dose strength. OTIS maintains a specialized telephone information service that is a valuable resource available to patients and health care practitioners (http://www.OTISpregnancy.org).

Other online databases about the effect of exposure to a significant number of medications during pregnancy are

- REPROTOX (http://www.reprotox.org).
- TERIS (http://depts.washington.edu/terisweb).

REPROTOX offers information on the effects of medications, chemicals, infections, and physical agents on pregnancy, reproduction, and development. It includes more than 4000 agents along with references. Likewise, TERIS is designed to help physicians assess the risks of possible teratogenic exposures during pregnancy based on a thorough review of published clinical and experimental literature.

Given that randomized studies are in most cases impossible to conduct for detection of teratogenicity, physicians must rely on case-control studies.[43] Even so, case-control studies are used mainly to identify possible associations and their interpretation should be cautious.[44]

Similar to our recent publications,[1,45] the objective of this chapter is to provide a general overview of selected drugs with a large or small potential for teratogenicity. First, we present a list of the most common drugs or drug groups (in alphabetical order) known or strongly suspected to cause developmental defects (Table 34–2). Second, we list and provide information on some of the most common medications or medication groups with minimal or no known

human teratogenic effect (Table 34–3). Because information changes rapidly, it is critical that clinicians become familiar with the most up-to-date aspects of the drugs they recommend and consult, when appropriate, with a maternal-fetal medicine specialist so that patient counseling and decisions are based on the best possible evidence. For detailed information regarding all medication drugs, the interested readers should consult a text such as *Drugs for Pregnant and Lactating Women*[36] or a continuously updated database such as REPROTOX, OTIS, or ENTIS.

HUMAN TERATOGENS (see Table 34–2)

Angiotensin-converting Enzyme Inhibitors (Enalapril [Vasotec], Captopril [Capoten, Lopurin], Lisinopril [Prinivil; Zestril])

MATERNAL CONSIDERATIONS

There are no adequate reports or well-controlled studies in pregnant women in great part because ACE inhibitors are generally contraindicated throughout pregnancy. This prohibition would include women receiving renoprotective medications.[46] In extremely rare cases, ACE inhibitors may be indicated for the control of severe hypertension in a woman refractory to other medications.[47,48] In this scenario, close consultation with a cardiologist and/or a nephrologist coupled to the serial monitoring of amniotic fluid and fetal well-being is recommended.[49] Should oligohydramnios be detected, the ACE inhibitor must be discontinued immediately unless it is deemed life-saving for the mother.

FETAL CONSIDERATIONS

Both *lisinopril* and *enalapril* cross the human placenta.[50–52] It was long held that exposure of the embryo to ACE inhibitors was safe during the first trimester and that only second- and third-trimester exposure resulted in oligohydramnios,

---

TABLE 34–2

Drugs or Drug Groups Known or Strongly Suspected to Cause Developmental Defects, and Their Pregnancy Safety Categorization*

DRUG	FDA
Agents acting on renin-angiotensin system (enalapril, captopril, lisinopril)	C (1st trimester) D (2nd and 3rd trimesters)
Antidepressants (paroxetine—only)	D
Antiepileptic drugs (valproic acid, carbamazepine, phenytoin)	D
Anxiolytics (diazepam)	D
Alkylating agents (cyclophosphamide)	D
Hormone androgens (methyltestosterone, medroxyprogesterone acetate, danazol)	X
Antimetabolites (methotrexate)	D, X
Antithyroid (methimazole)	D
Coumarin derivatives (warfarin)	X
Estrogens (diethylstilbestrol)	X
Antifungals (fluconazole)	C
Antipsychotics (lithium)	D
Prostaglandins (misoprostol)	X
Oral contraceptives	X
Penicillamine	D
Retinoids (isotretinoin)	X
Radioactive iodine (sodium iodide-131)	X
Dermatologics; immunomodulators (thalidomide)	X

* See Table 34–1 for an explanation of the safety categories.

TABLE 34–3

Drugs or Drug Groups with Minimal or Not Known Human Teratogenic Effect*

DRUG	FDA
Analgesics (aspirin, acetaminophen, ibuprofen)	B–D (see class)
Antibiotics (penicillin G, tetracyclines, ciprofloxacin, metronidazole, tetracycline, nitrofurantoin, azithromycin)	B–D (see class)
Anticholinergics (albuterol, atropine, dimenhydrinate)	B–C (see class)
Antihypertensive agents (methyldopa, hydralazine, labetolol, propranolol)	B–C (see class)
Antihistamines (cetirizine, diphenhydramine)	B
Antivirals (acyclovir)	B
Corticosteroids (prednisone, betamethasone, dexamethasone)	B
Tumor necrosis factor modulators (infliximab)	C

* See Table 34–1 for an explanation of the safety categories.
FDA, U.S. Food and Drug Administration. These categories change on occasion. Please review before prescribing any drug you are unfamiliar with.
Modified from Blackwell Lippincott Williams & Wilkins, Baltimore, Md USA. Buhimschi CS, Weiner CP: Medications in pregnancy and lactation: Part 2. Drugs with minimal or unknown human teratogenic effect. Obstet Gynecol 2009;113:417–432.

hypocalvaria, anuria, renal failure, patent ductus arteriosus, aortic arch obstructive malformations, or death.[53–55] However, one report concluded that infants exposed to ACE inhibitors during the first trimester have an increased risk for cardiovascular (pulmonic stenosis, atrial and ventricular septal defects) and CNS (microcephaly, eye anomaly, spina bifida, coloboma) malformations.[56] Although the strength of this conclusion is limited by the relatively small number of fetuses in the final analysis and its retrospective design, we suggest avoidance of ACE inhibitors in the first trimester until there is evidence of safety. Antenatal surveillance must be initiated should inadvertent exposure occur and the fetus is potentially viable. Oligohydramnios may not appear until after the irreversible renal injury. Fetal exposure to ACE inhibitors is associated with increased neonatal morbidity and mortality. Neonates exposed to ACE inhibitors in utero should be observed closely for hypotension, oliguria, and hyperkalemia. Long-term follow-up after fetal ACE exposure reveals impaired renal function, severe hypertension, and proteinuria.[57]

BREAST-FEEDING CONSIDERATIONS

ACE inhibitors are considered compatible with breast-feeding. Trace quantities of ACE inhibitors (*captopril, enalapril*) are excreted into breast milk, though the kinetics remains to be clarified.[58,59] It is unknown whether *lisinopril* enters human breast milk. For this reason, the lowest effective dose should be used, infants should be monitored for possible adverse effects, and breast-feeding should be avoided at times of peak maternal drug levels.

Antidepressant (Fluoxetine [Prozac, Sarafem], Sertraline [Zoloft, Lustral], Paroxetine [Paxil])

MATERNAL CONSIDERATIONS

The use of psychotropic medications during pregancy is increasing and a matter of concern for the physicians and patients. Because depression is common and typically unrecognized, universal screening is recommended at the time of the first prenatal visit, each trimester, and postpartum.[60,61] Pregnancy is not a reason a priori to discontinue psychotropic drugs.[62] Discontinuation of needed antidepressant medication during pregnancy exchanges the risk of embryopathy/fetopathy for debilitating depression. Recently, the manufacturer of *paroxtine* changed its classification from C to D (see Table 34–1). In response, the American College of Obstetricians and Gynecologists (ACOG) issued both a Commitee Opinion and a Practice Bulletin to provide guidelines for the use of selective serotonin-reuptake inhibitor (SSRIs) and psychiatric medications during pregnancy and lactation.[60,61] It recommended that the treatment of depression with SSRIs be in the context of an increased risk of maternal relapse following discontinuation of antidepressive medication. ACOG suggests that a team composed of a psychiatrist and an obstetrician work together to decide on the need for continuing treatment and to discuss the known risks with the mother. *Fluoxetine* is effective treatment for postpartum depression and is as effective as a course of cognitive-behavioral counseling in the short term.[63] There are no adequate reports or well-controlled studies of *sertraline*

in pregnant women, though there is growing experience with its use for the treatment of postpartum depression.[63] In general, women taking SSRIs during pregnancy require a higher dose to maintain euthymia.[64] If possible, *paroxetine* should be avoided during gestation and in women planning pregnancy.[61] Other alternatives should be sought in collaboration with the mental health provider.

FETAL CONSIDERATIONS

Most data related to the use of antidepressants in pregnancy are derived from the use of SSRIs (*fluoxetine, sertraline, paroxetine*). *Fluoxetine, sertraline,* and *paroxetine* cross the human placenta and there is evidence of teratogenicity.[65–68] The teratogenic effect of SSRIs has been examined in two other large case-control studies suggesting a 1.5 to 2-fold increased risk of congenital cardiac malformations (atrial and ventricular septal defects) after first-trimester exposure to *paroxetine*.[69,70] In the Slone Epidemiology Center Birth Defects Study, *paroxetine* use was associated with right ventricular outflow defects and *sertraline* use was associated with omphalocele and atrial and ventricular septum defects.[69] Not all studies find the same risks from SSRI use in pregnancy. There was no significant association between SSRIs and congenital heart defects in the National Birth Defects Prevention Study.[70] They did observe an association between *paroxetine* and anencephaly, craniosynostosis, and omphalocele. The small number of exposed infants for each individual malformation and identification of these risks only after performance of more than 40 statistical tests represent the major drawbacks of the studies. An FDA public health advisory note highlighted concerns about a possible association between SSRI use during gestation and newborn persistent pulmonary hypertension.[71]

In summary, exposure to SSRIs, specifically *paroxetine*, during early pregnancy may be associated with an increased risk of cardiac defects. A more recent study did not confirm that *paroxetine* is associated with an increased risk of congenital cardiovascular defects.[72] The absolute risk is small and generally not greater than 2 per 1000 births. Although caution should be exercised (mostly with the use of *paroxetine*), these agents are not considered major teratogens.[73] Late exposure to SSRIs is linked with transient neonatal complications, including jitteriness, mild respiratory distress, transient tachypnea of the newborn, weak cry, poor tone, and neonatal intensive care unit admission.[74–76]

BREAST-FEEDING CONSIDERATIONS

Most psychotropic medications are transferred to breast milk in varying amounts and potentially passed on to the nursing infant. Breast-feeding is not contraindicated in women using either *fluoxetine, sertraline,* or *paroxetine*.[77] Maternal serum and peak breast milk concentrations of *fluoxetine* and its active metabolite norfluoxetine predict nursing infant serum norfluoxetine concentrations. Limited data suggest that *paroxetine* is not detectable in the neonates who are exclusively breast-fed.[78] The infant should be monitored for possible adverse effects if breast-fed; the drug should be given at the lowest effective dose; and breast-feeding should be avoided at times of peak drug levels if possible. In theory, discarding breast milk obtained at the time of peak drug concentration could allow the mother to reduce the infant's exposure to her medication.[77]

Anticonvulsants (Valproic acid [Depakene], Carbamazepine [Tegretol, Atretol, Convuline, Epitol], Phenytoin [Dilantin, Aladdin, Dantoin], Lamotrigine [Lamictal])

MATERNAL CONSIDERATIONS

Almost half a million women in the United States have a medical condition that requires psychiatric care, ensuring that the use of such medications during pregnancy would receive much attention.[61] Several anticonvulsants (*valproate, carbamazepine, lamotrigine*) are used for the treatment of epilepsy as well as mood stabilization (bipolar disorders). Many anticonvulsants induce hepatic enzymes that decrease the serum concentrations of estrogen and progesterone, a potential problem for women using oral contraceptives.[79] The risk for contraceptive failure appears greatest with cytochrome P-450 enzyme-inducing agents, such as *carbamazepine* or *phenytoin*. Conversely, the available information suggests that *valproic acid* does alter steroid levels in women taking oral contraceptives.[80] There is no reliable information to assess the relationship between *lamotrigene* and combined hormonal contraceptive failure.[61] Clinicians frequently recommend contraceptives with a higher ethinyl estradiol level (50 μg) to avoid first-trimester exposure, although there is no real experience to support such a practice. Despite the lack of supportive data, ACOG recently suggested that women taking anticonvulsants proven to reduce oral contraceptive steroid levels be switched to a 30- to 35-μg estrogen oral contraceptive.[61] Patients planning pregnancy should be counseled on the risks and the importance of periconceptual folate supplementation (4 mg/day).[81] Some authorities recommend measuring serum concentrations of old- and new-generation antiepileptic drugs.[82]

Valproate is the sodium salt of *valproic acid*. Although there is a long clinical experience with *valproate* and *carbamazepine*, there are no adequate reports or well-controlled studies of these medications in pregnant women. *Phenytoin* is a first-generation, enzyme-inducing anticonvulsant. Stable *phenytoin* serum levels are achievable in most pregnant women, though there is wide variability on equivalent doses.[83] It is unknown whether women with unusually low levels of *phenytoin* are noncompliant subjects or hypermetabolizers. Unusually high levels can result from hepatic disease, congenital enzyme deficiency, or other drugs that interfere with metabolism. To reduce the risk of a seizure, dosage adjustments should be based on clinical symptoms, and not solely on serum drug concentrations. *Phenytoin* may impair the efficacy of corticosteroids, coumadin, digitoxin, doxycycline, estrogens, furosemide, oral contraceptives, quinidine, rifampin, theophylline, and vitamin D.[84]

Lamotrigene is a new-generation antiepileptic drug also useful for the treatment of bipolar depression.[85] It is generally well tolerated, and its reproductive safety profile is superior to that of other antiepileptics. There are no adequate reports or well-controlled studies of *lamotrigene* in pregnant women. *Lamotrigene* levels vary widely during pregnancy, and patients may experience a loss of seizure control without close monitoring.[86–88]

The most common treatment strategy is to use the appropriate antiepileptic drug for the woman's seizure disorder as monotherapy at the lowest effective dosage throughout pregnancy. If necessary, a single medication at a higher dose is preferable to a multidrug regimen.[61] The goal is to use antiepileptic drugs in such a way that generalized tonic-clonic seizures are avoided in hopes of minimizing risk to the fetus.

FETAL CONSIDERATIONS

Valproic acid is a recognized human teratogen.[89,90] The likelihood of an affected offspring is dose-dependent, and the risk is enhanced by a low serum folate level. A recent analysis indicates that the risk of congenital abnormalities in children exposed in utero to anticonvulsant therapy is reduced but not eliminated by folic acid supplementation between 5 and 12 weeks after the last menstrual period.[91] *Valproic acid* is rapidly and actively transported across the human placenta, reaching an fetal-to-maternal ratio exceeding 2.[92] The fetal *"valproate* syndrome"[93] includes a distinct craniofacial appearance, limb abnormalities, and heart defects, coupled with a cluster of minor and major anomalies and CNS dysfunction.[94,95] Affected fetuses may have an increased nuchal translucency measurement between 11 and 13 weeks.[96] After delivery, 10% die in infancy, and 1 of 4 survivors has either developmental deficits or mental retardation.

Carbamazepine crosses the human placenta and is also a teratogen.[97] The fetal *"carbamazepine* syndrome" includes facial dysmorphism, developmental delay, spina bifida, and distal phalanx and finger nail hypoplasia.[98,99]

Phenytoin is also a teratogen specifically associated with congenital heart defects and cleft palate (fetal *hydantoin* syndrome).[100,101] As with most psychotropic drugs, monotherapy and the lowest effective quantity given in divided doses to lower the peak levels can theoretically minimize the risks to the fetus.[102]

Lamotrigene crosses the human placenta.[103] Fetal exposure to *lamotrigene* does not appear to increase the risk of major fetal anomalies.[104] However, because *lamotrigene* crosses the placenta, close monitoring of both mother and newborn is receommended.[105]

BREAST-FEEDING CONSIDERATIONS

Valproic acid enters human breast milk. Fortunately, the peak neonatal serum concentration is less than 10% of the maternal level.[106] *Carbamazepine* is also excreted into human breast milk. Limited study suggests that *carbamazepine* is safe for breast-feeding women, although rare cases of neonatal cholestatic hepatitis have been previously reported.[107] Little *phenytoin* and *lamotrigene* are excreted into human breast milk, and both drugs are considered safe for breast-feeding.[108] Infants of mothers treated with anticonvulsant drugs should be monitored for possible adverse effects; the lowest effective dose should be given; and breast-feeding should be avoided at the time of peak drug levels.

Anxiolytics (Diazepam [Valium], Alprazolam [Xanax], Clonazepam [Klonopin])

MATERNAL CONSIDERATIONS

Anxiety disorders include panic disorders, generalized anxiety disorders, post-traumatic stress disorder, social anxiety, and phobias.[61] Collectively, these disorders are the

most common psychiatric conditions, with a prevalence in the United States of approximately 18%.[109] Treatment options include benzodiazepines, antidepressants, and psychotherapy. Currently available information is insufficient to determine whether the potential benefits of benzodiazepines to the mother outweigh the risks to the fetus.[110]

There are no adequate reports or well-controlled studies of *diazepam* use in pregnant women. Although not an integral part of the ACOG protocol for the treatment of nausea and vomiting of pregnancy, *diazepam* may be a beneficial adjunct to intravenous fluids and vitamins for the treatment of hyperemesis gravidarium. *Diazepam* is a useful anxioloytic for women undergoing fetal therapy procedures. It has been used for both prophylaxis and treatment of eclamptic convulsions, but it is clinically inferior to *magnesium sulfate* and is not recommended as first-line therapy.[111–113]

Alprazolam is rarely indicated during pregnancy. There are only few reports of its use during pregnancy.[114,115] Abrupt cessation of therapy is associated with a discontinuation-emergent syndrome that includes neuropsychiatric, gastrointestinal, dermatologic, cardiovascular, and visual symptoms.

Clonazepam is a widely used benzodiazepine for the treatment of seizures and conditions such as panic attack and anxiety disorder. Unfortunately, there is limited study of its safety during pregnancy.[116] Several investigators have used *clonazepam* to treat dystonia gravidarium[117] (muscle contractions, frequently causing twisting and repetitive movements) and seizure prophylaxis in women with severe preeclampsia.

FETAL CONSIDERATIONS

Benzodiazepine use during pregnancy does not appear to carry a significant risk for teratogenesis. *Diazepam* rapidly crosses the human placenta.[118] Though several studies suggested an increased risk of oral clefts if used during the first trimester,[119] these findings were not confirmed in long-term follow-up studies.[115,120] Nor is there convincing evidence of an adverse effect on neurodevelopment. Intravenous *diazepam* may decrease fetal movement; thus, it may be used in select cases as an adjuvant to fetal therapy. Prolonged CNS depression may occur in neonates exposed to *diazepam* in utero. Symptoms vary from mild sedation, hypotonia, reluctance to suck to apneic spells, cyanosis, impaired metabolic responses to stress, floppy infant syndrome, and marked neonatal withdrawal symptoms[121] and may persist for hours to months after birth. Thus, the shortest course and the lowest dose should be used when indicated.

There is no evidence that *alprazolam* is a human teratogen.[122] Neonatal withdrawal syndrome may occur following exposure, and the measurement of *alprazolam's* main metabolite (α-hydroxyalprazolam) may be useful to differentiate between a drug effect and neonatal sepsis.[123]

Clonazepam also crosses the human placenta.[124] Although congenital anomalies are reported in 13% of infants whose mothers took clonazepam during pregnancy in combination with other antiepileptic drugs, there is no pattern of anomalies. Exposure in the late third trimester and during labor seems to carry the greatest risks to the perinate. Although the neonatal withdrawal syndrome is rare, children born to treated women may have symptoms varying from mild

sedation, hypotonia, and reluctance to suck to apnea spells, cyanosis, and impaired metabolic responses to cold stress. These symptoms can persist from hours to months after birth.

BREAST-FEEDING CONSIDERATIONS

Benzodiazepines are excreted into human breast milk, but the maximum neonatal exposure is estimated at 3% of the maternal dose.[125] Neonatal lethargy, sedation, and weight loss are each reported and special attention should be paid if the neonate was premature or the maternal dose particularly high.

Alprazolam enters breast milk by passive diffusion.[126] It should be avoided during lactation because of its potential to alter neurodevelopment and because of the documented risks of withdrawal.[110,123]

Clonazepam is excreted into breast milk, but the detected levels in milk are low. The nursing infant is unlikely to ingest significant amounts of the drug. However, special attention should be paid if the infant is premature or has been exposed to high concentrations of drug either during pregnancy or at delivery.[125]

Alkylating Agents (Cyclophosphamide [Cytoxan])

MATERNAL CONSIDERATIONS

Cyclophosphamide is an integral part of numerous multiagent regimens to treat cancer of the ovary, breast, blood, and lymph systems. The most common complications reported following *cyclophosphamide* treatment are transient sterility and secondary malignancy. Several case reports note that *cyclophosphamide* can be used during pregnancy with a good outcome.[127–129]

FETAL CONSIDERATIONS

Cyclophosphamide crosses the human placenta, and neonatal hematologic suppression and secondary malignancies are reported.[130,131] The spectrum of malformations associated with in utero exposure to *cyclophosphamide* is highly variable (high-arched palate, microcephaly, flat nasal bridge, syndactyly, hypoplasia of the fingers). Growth deficiency and anomalies of the craniofacial region and limbs are most common.[132]

BREAST-FEEDING CONSIDERATIONS

Cyclophosphamide is not safe with breast-feeding because it enters human breast milk in high concentration. Neonatal neutropenia is common.[133,134]

Hormones-Androgens (Methyltestosterone [Androral, Testred], Medroxyprogesterone Acetate [Depo-Provera, Med-Pro, Provera], Danazol [Danocrine, Danatrol])

MATERNAL CONSIDERATIONS

Methyltestosterone is used for the treatment of endometriosis and for palliation of advancing inoperable breast cancer.[135] Some recommend *methyltestosterone* with estrogens to enhance libido in women, though its efficacy is unclear.[136] There are

no indications for *methyltestosterone* during pregnancy. Inadvertent pregnancy exposures are reported because many pregnancies escape recognition until after the first trimester.[137] Progestational agents such as *medroxyprogesterone* have long been prescribed during early pregnancy to prevent first-trimester spontaneous abortion. This practice continues in some locales despite the failure of well-conducted studies to show effectiveness. Fortunately, epidemiologic studies are reassuring and there is no demonstrable increase in the prevalence of ectopic pregnancy following treatment with *medroxyprogesterone*.

Danazol, a derivative of the synthetic steroid 17-α-ethinyltestosterone is considered one of the most effective treatments for endometriosis.[138] *Danazol* is not an effective contraceptive, and it should be discontinued immediately should the patient become pregnant. There are no indications for *danazol* during pregnancy.

FETAL CONSIDERATIONS

Whether or not *methyltestosterone* crosses the human placenta is unknown. Animal studies reveal pseudohermaphroditism in female fetuses exposed to *methyltestosterone*.[139] Similarly, in utero exposure of male fetuses to *methyltestosterone* increases the risk of hypospadias.[140,141] Although there are insufficient human data to quantify the risk to the female fetus, some synthetic progestins have reportedly caused mild virilization of the external genitalia.[142,143]

It is unknown whether *danazol* crosses the human placenta. In addition, although the FDA classifies *danazol* as category X, there is no a priori reason to terminate an exposed pregnancy. *Danazol* may have an androgenic effect on female fetuses (vaginal atresia, clitoral hypertrophy, labial fusion, ambiguous genitalia).[144,145] First-trimester exposure to androgen-"like" hormones is an indication for a detailed anatomic ultrasound between 18 and 22 weeks' gestation.

BREAST-FEEDING CONSIDERATIONS

It remains unknown whether *methyltestosterone* enters human breast milk. In addition, although small quantities of *medroxyprogesterone* are excreted into human breast milk, it does not suppress lactation or adversely affect the newborn.[146,147] *Medroxyprogesterone* is typically given as a contraceptive 3 days after delivery because progesterone withdrawal may be one stimulus for the initiation of lactogenesis. It is unknown whether *danazol* enters human breast milk, and perhaps as a result, it is generally considered contraindicated during breast-feeding.

Antimetabolites (Methotrexate [Folex, Mexate, Rheumatrex, Tremetex])
MATERNAL CONSIDERATIONS

Methotrexate is an antimetabolite with multiple uses in reproductive-age women, including the treatment of ectopic pregnancy, neoplastic disease, autoimmune disorders, and inflammatory conditions (Crohn's disease, rheumatoid arthritis).[148] It is also considered an efficient medical abortifacient. It is even more efficient when combined with misoprostol (the efficacy ranges from 70% to 97%).[149,150] However, because *methotrexate* is not 100%

effective, women must be followed until their serum β-human chorionic gonadotropin (β-hCG) titer returns to normal.[151,152]

FETAL CONSIDERATIONS

First-trimester exposure to *methotrexate* increases the risk of several malformations including craniofacial, axial skeletal, cardiopulmonary, and gastrointestinal abnormalities and developmental delay, though most pregnancies exposed to low doses are unaffected.[153,154] But even a single dose of *methotrexate* and *misoprostol*, used for medical termination of pregnancy, is associated with multiple congenital anomalies.[153] Exposure to *methotrexate* later in pregnancy seems to be reasonably safe.[133]

BREAST-FEEDING CONSIDERATIONS

Methotrexate is generally considered contraindicated in nursing mothers,[155] but it is unknown whether *methotrexate* is excreted into human breast milk. Women with rheumatoid arthritis often experience a disease flare within 3 months of delivery, and drug treatment is required. Experts differ regarding the use of *methotrexate* during lactation, in part because of varying views on the potential for short- and long-term adverse effects.[156]

Antithyroid (Propylthiouracil [PTU], Methimazole [Favistan, Mercazole, Tapazole])
MATERNAL CONSIDERATIONS

Graves' disease is the most common cause of hyperthyroidism during pregnancy. Medical treatment involves either *propylthiouracil* (*PTU*) or *methimazole*.[157,158] Hyperthyroid women should have their thyroid function checked every 3 to 4 weeks throughout pregnancy. There is a general consensus among clinicians that the lowest dose of *PTU* or *methimazole* needed to keep free triiodothyronine (T_3) and free thyroxine (T_4) within the upper normal range for these women should be used.[159,160] Improvements in thyroid-stimulating hormone assay methodology have resulted in accurate identification of high thyroid-stimulating antibodies in pregnancy. Because women previously ablated with either a radioactive iodine (^{131}I) or a thyroidectomy may still be producing thyroid-stimulating antibodies (even though they are themselves euthyroid) the fetus remains at risk. The fetal status, whether the mother is receiving antithyroid medication or previously received definitive treatment, cannot be accurately predicted by ultrasound. The selection of *PTU* versus *methimazole* for the treatment of Graves' disease during pregnancy should not be based solely on the assumptions that *PTU* crosses the placenta less than *methimazole*, or that *PTU* causes less fetal hypothyroidism, or that exposure to *methimazole* leads to decreased intellectual function in the offspring. Rather, *PTU* is preferred because *methimazole* is more likely than *PTU* to be associated with fetal anomalies such as aplasia cutis, esophageal atresia, and choanal atresia.[161] *Methimazole* is a reasonable choice if the patient is allergic to *PTU* or fails to have a therapeutic response to *PTU*.[161] Agranulocytosis remains a major clinical concern when antithyroid drugs are used.[162] In 2009, the FDA

issued a warning of increased risk of hepatotoxicity with *PTU* compared with *methimazole* (see http://www.fda.gov/Safety/MedWatch/SafetyInformation/SafetyAlertsforHumanMedicalProducts/ucm164162.htm).

FETAL CONSIDERATIONS

PTU crosses the human placenta, which in the case of Graves' disease, may be desirable. Fetal evaluation is recommended to directly confirm that the fetus is neither severely hyper- or hypothyroid.[163] A hypothyroid fetus can be given T_4 intra-amniotically. If hyperthyroid, the *PTU* can be increased and the mother supplemented with oral thyroxine if necessary. Aplasia cutis is a rare complication of maternal therapy. *Methimazole* also crosses the human placenta and is an alternative to *PTU* for the treatment of fetal hyperthyroidism.[164] The detailed placental kinetics for either agent is unknown. Both *methimazole* and *PTU* can induce fetal goiter and even cretinism in a dose-dependent fashion. Fortunately, long-term follow-up studies of exposed children reveal no deleterious effects on either thyroid function or physical and intellectual development with doses up to 20 mg daily.[165] At least for now, *PTU* remains a first-line treatment for Graves' disease during pregnancy because of the more frequent association of *methimazole* with fetal anomalies such as aplasia cutis, esophageal atresia, and choanal atresia.[161,166,167]

BREAST-FEEDING CONSIDERATIONS

Methimazole and *PTU* are excreted in the human breast milk at low concentrations.[168,169] No deleterious effects on neonatal thyroid function or physical and intellectual development of breast-fed infants have been described when mothers are treated with either *methimazole* or *PTU*.[170,171]

Coumarin Derivatives (Warfarin [Coumadin])

MATERNAL CONSIDERATIONS

Despite significant preventive efforts, thromboembolic disease remains a major cause of maternal morbidity and mortality. *Warfarin* is a teratogen and contraindicated in pregnancy with but a few exceptions, the principal one being a mechanical heart valve in which an International Normalized Ratio (INR) of 2.3 to 3.0 is recommended for either prophylaxis or treatment of venous thromboembolism. The risk of a bleeding complication during pregnancy approximates 18%. It is believed an INR of 2.3 to 3 will minimize the risk of hemorrhage.[172] Women requiring a dose above 5 mg/day have a greater risk of an adverse outcome. Previous studies consistently show that maternal morbidity is higher in women with bioprosthetic valves.[173] One therapeutic approach to minimize risk in a woman receiving therapeutic-dose anticoagulation with *warfarin* before pregnancy owing to a hereditary or acquired condition is to convert her to therapeutic doses of unfractionated *heparin* or low-molecular-weight *heparin* within the first 6 weeks of gestation.[174] When used in this fashion, coumarin derivatives are safe and effective and avoid embryopathy. Therapeutic *heparin* may not be as effective for prophylaxis, though most physicians recommend *heparin* or low-molecular-weight *heparin* for the first 6 to 12 weeks.[175]

If the mother's condition requires anticoagulation with *warfarin*, it should be substituted with *heparin* at 36 weeks to decrease the risk of epidural/spinal anesthesia (subdural hematoma).[176] *Warfarin* treatment should be resumed postpartum.

FETAL CONSIDERATIONS

Warfarin is a recognized teratogen. Exposure from 6 to 10 weeks' gestation is associated with an embryopathy and subsequent exposure with a fetopathy. The fetal "*warfarin* syndrome" consists of a varied spectrum of manifestations that include nasal hypoplasia, microphthalmia, hypoplasia of the extremities, intrauterine growth restriction, heart disease, scoliosis, deafness, and mental retardation.[177,178] In one large series of women treated with *warfarin* throughout pregnancy for a prosthetic valve, the incidence of fetal *warfarin* syndrome was 5.6%, the pregnancy loss rate was 32%, and the stillbirth rate was 10% of pregnancies achieving at least 20 weeks. It is proposed that the embryopathy occurs secondary to vitamin K deficiency and the fetopathy results from microhemorrhages. Agenesis of the corpus callosum, Dandy-Walker malformation, and optic atrophy are the most common CNS malformations. Long-term follow-up studies reported that school-age children exposed in utero have an increased frequency of mild neurologic dysfunction and an IQ less than 80.[179]

BREAST-FEEDING CONSIDERATIONS

Warfarin is not excreted to any degree into breast milk and is compatible with breast-feeding.[180,181]

Antipsychotics (Lithium [Calith, Lithocarb, Lithonate])

MATERNAL CONSIDERATIONS

Lithium is used for the treatment of psychiatric disorders (prevention of recurrent mania and bipolar depression and to reduce the risk of suicidal behavior), but not typically for the rapid control of acute mania.[182] The decision to discontinue *lithium* therapy during pregnancy because of fetal risks must be balanced against the maternal risks of exacerbation.[61] In addition, although pregnancy and especially the puerperium are high risk times for the recurrence of bipolar disease, physicians should be aware that sudden discontinuation of *lithium* is associated with a high rate of disease relapse.[183]

In 2008, ACOG issued a series of recommendations regarding the use of *lithium* during pregnancy or in women who are planning to conceive:

- In women who experience mild and infrequent episodes of illness, *lithium* should be gradually tapered before conception.
- In women who have more severe episodes but are only at moderate risk of relapse, *lithium* should be tapered before conception but restarted after organogenesis.
- In women who have especially severe and frequent episodes of illness, *lithium* should be continued throughout pregnancy and the patient counseled regarding the risks.[61,184]

When *lithium* is indicated, the serum levels should be maintained between 0.5 and 1.2 mEq/L.[185] As delivery approaches,

several authorities recommend that the drug be tapered gradually beginning at 36 weeks or decreased by one quarter 2 to 3 days before delivery.[61,102,184,185]

FETAL CONSIDERATIONS

Lithium crosses the placenta. Fetal exposure to *lithium* may be associated with fetal and neonatal cardiac arrhythmias, hypoglycemia, nephrogenic diabetes insipidus, polyhydramnios, changes in thyroid function, premature delivery, large–for–gestational age infant, and floppy infant syndrome.[61,186] There may also be a small increase in congenital cardiac malformations.[187] Several studies have reported an increased prevalence of Ebstein's anomaly, though this was not confirmed in a prospective, multicenter study.[188] The risk ratio for cardiac malformations is approximately 1.2 to 7.7, and the overall risk ratio for congenital malformations 1.5 to 3.[189] Fetal echocardiography is recommended in women exposed to *lithium* during the first trimester.[190]

BREAST-FEEDING CONSIDERATIONS

Lithium is excreted into human milk, and detectable levels can be measured in the nursing newborn.[191] Whether nursing mothers should continue *lithium* therapy while breast-feeding is controversial.[192] The neonatal clearance rate is slower than in the adult, and the circulating level may be higher than expected. If *lithium* must be continued during breast-feeding, neonatal levels should be measured if any apparent adverse effects are noted.[193]

Prostaglandins (Misoprostol [Cytotec])

MATERNAL CONSIDERATIONS

Misoprostol is a prostaglandin E_1 analogue. Though approved by the FDA only for the treatment and prevention of intestinal ulcer disease secondary to NSAID use, there is compelling evidence that *misoprostol* is effective in ripening the cervix and inducing labor during either the second or the third trimester.[194,195] Combined with *mifepristone, misoprostol* provides for safe and effective medical termination during early pregnancy.[196] In August 2000, the manufacturer (Pfizer) issued a warning letter to American health care providers on the appropriate use of *misoprostol*. In that letter, the manufacturer cautioned against the use of *misoprostol* during pregnancy because of a perceived lack of safety data for use in obstetric practice. In 2003, the ACOG Committee Opinion on Obstetric Practice[197] concluded that the risk of uterine rupture during vaginal birth after cesarean section is substantially increased by the use of *misoprostol* as well as other prostaglandin cervical-ripening agents. In 2003, ACOG issued specific recommendations in regard to the use of *misoprostol* for labor induction[197]:

- If *misoprostol* is used for cervical ripening or labor induction in the third trimester, 25 μg should be considered for the first dose.
- Higher doses (50 μg q6h) can be used in some situations. Uterine tachysystole and uterine hyperstimulation and meconium staining of amniotic fluid are recognized complications.
- *Misoprostol* should not be given more frequently than every 3 to 6 hours.
- *Oxytocin* should not be administered sooner than 4 hours after the last *misoprostol* dose.

- Fetal heart rate and uterine activity should be monitored when *misoprostol* is used for labor induction in a hospital setting.
- *Misoprostol* is contraindicated in women with prior uterine scar.

FETAL CONSIDERATIONS

Misoprostol is associated with a higher rate of fetal variable decelerations and likely a higher prevalence of meconium.[198] Even though such complications occur more frequently with *misoprostol* than with *oxytocin*, there is no increase in the incidence of cesarean delivery for fetal distress or umbilical artery acidemia. Congenital defects (skull defects, cranial nerve palsies, facial malformations, limb defects) occur following unsuccessful first-trimester medical termination.[153]

BREAST-FEEDING CONSIDERATIONS

Misoprostol is secreted in the breast milk. The levels rise and then decline rapidly, becoming essentially undetectable by 5 hours, significantly lowering infant exposure.[199]

Oral Contraceptives

MATERNAL CONSIDERATIONS

Numerous studies have confirmed the relative safety and effectiveness of hormonal contraceptives in healthy women. The data are far less robust for women with underlying medical problems.[200] Decisions regarding contraception, especially for women with medical problems, may be complicated. Age, tobacco use, hypertension, diabetes, dyslipidemia, and migraine headaches are important risk factors to consider before recommending any form of hormonal contraception. In some cases, medications taken for certain chronic conditions might alter the effectiveness of hormonal contraception, and pregnancy in these cases might pose substantial risks to the mother and her fetus. For details, the reader is referred to the most recent ACOG Practice Bulletin—2006, where this topic is extensively reviewed.[200] Although there are many anecdotal reports of oral contraceptive failure in women taking concomitant antibiotics, pharmacokinetic evidence of lower serum steroid levels exists only for *rifampin*.[201] In addition, although several studies demonstrate reduced serum levels of contraceptive steroids in women treated with anticonvulsants, investigators have not been able to demonstrate an excess of ovulation cycles or accidental pregnancy during anticonvulsant use.[200] However, there is a higher risk of oral contraceptive failure in obese women. This does not preclude their use in overweight women motivated to use these methods in preference to other less effective techniques.[200]

FETAL CONSIDERATIONS

About 1% of pregnant women unknowingly use oral contraceptives during the first part of their pregnancy and expose their fetus to estrogens. However, exposure to specific estrogens or progestogens seems unrelated to the prevalence of malformations. A causal relationship was reported between a syndrome of multiple congenital anomalies (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or esophageal atresia, renal agenesis

and dysplasia, and limb defects [VACTERL]) and maternal progesterone/estrogen exposure.[202] However, this link remains weak and may more reflective of other simultaneous exposures. For example, the likelihood of delivering a malformed infant to a woman who used an oral contraceptive at the beginning of pregnancy is increased by concomitant tobacco use.[203] One study concluded that early, high-dose in utero exposure to *medroxyprogesterone* may affect fetal growth.[204] Others notes that *medroxyprogesterone* does not have a measurable teratogenic risk, especially for congenital heart disease and limb reduction defects.[205] Several studies addressed the issue related to fetal exposure to *levonorgestrel* in women who seek emergency contraception. It appears neither the woman nor the fetus will be harmed if hormonal emergency contraception is inadvertently used in early pregnancy.

BREAST-FEEDING CONSIDERATIONS

Women remain in a hypercoagulable state during the puerperium. Product labeling for combination oral contraceptives recommends they not be used until 4 weeks postpartum, and then only in non–breast-feeding women. Because progestin-only oral contraceptives and *depomedroxyprogesterone acetate* do not contain estrogen, these methods may be started safely immediately postpartum.

Retinoids (Isotretinoin [Accutane])

MATERNAL CONSIDERATIONS

Isotretinoin is contraindicated during pregnancy. Before prescribing, physicians must assure themselves that the woman is capable of complying with mandatory contraceptive measures. Two reliable forms of birth control must be used at the same time (unless abstinence is the chosen method) for 1 month before, during, and for at least 1 month after concluding treatment with *isotretinoin*. The most recent, and most stringent, system aimed to avoid exposure to *isotretinoin* is an Internet-based, performance-linked system called iPLEDGE (http://www.fda.gov/cder/drug/infopage/accutane/iPLEDGEupdate).[206] Only manufacturer-approved physicians may prescribe it.[207]

FETAL CONSIDERATIONS

Isotretinoin and its active metabolites cross the human placenta. *Isotretinoin* is one of the strongest human teratogens known today. The prevalence of birth defects after exposure during embryogenesis is estimated to be as high as 30%.[208] Multiple organ systems are affected, including CNS, cardiovascular, and endocrine organs, and the damage can be severe.[209] Mental retardation without malformation has also been reported.

BREAST-FEEDING CONSIDERATIONS

It is unknown whether *isotretinoin* is excreted into human breast milk. Considering its potential adverse impact on the fetus, breast-feeding is contraindicated.

Iodine 131

MATERNAL CONSIDERATIONS

Radioactive iodine (sodium iodide 131) is a cost-effective, safe, and reliable treatment for hyperthyroidism in nonpregnant women.[210] However, radioactive iodine is contraindicated during pregnancy. Although all of the ^{131}I is excreted within 1 month, the current recommendation is that women avoid pregnancy for 4 to 6 months after treatment.[160]

FETAL CONSIDERATIONS

There are no adequate reports or well-controlled studies in human fetuses. Treatment during pregnancy after the first trimester can result in fetal thyroid destruction.[211] Fetal thyroid damage may be ameliorated by treating the mother as soon as the pregnancy is diagnosed with large doses of solution of potassium iodide (SKI) to dilute the effect of the I[131].

BREAST-FEEDING CONSIDERATIONS

Breast-feeding should be avoided for at least 120 days after ^{131}I treatment.[212]

Dermatologics; Immunomodulators (Thalidomide [Thalomid])

MATERNAL CONSIDERATIONS

Thalidomide is a known human teratogen and contraindicated during pregnancy.[213] After normal reproductive studies in rodents, *thalidomide* was prescribed to treat morning sickness in Canada and Europe during the early 1960s. Reports of defects followed and *thalidomide* was banned from the market. In 1998, the FDA approved *thalidomide* for use in treating erythema nodosum leprosum. Its potential indications (Behçet's disease, lupus erythematous, Sjögren's syndrome, rheumatoid arthritis, AIDS, inflammatory bowel disease, cancer) are growing, increasing the likelihood of an inadvertent pregnancy.[214–216] *Thalidomide* is excreted in the semen of treated males, necessitating the use of a condom during coitus.[217]

FETAL CONSIDERATIONS

Thalidomide crosses the human placenta and is a potent human teratogen, causing limb abnormalities after first-trimester exposure. A common effect of *thalidomide* is either duplication (preaxial polydactyly of hands and feet) or deficiency (absence of thumbs).[218] No other human teratogen identified to date has this effect on the developing limb. If pregnancy occurs, the drug should be discontinued and the patient referred to a fetal medicine expert for evaluation and counseling. In the United States, any suspected fetal exposure to *thalidomide* must be reported to the FDA, which is controlling *thalidomide's* marketing in the United States via the System for Thalidomide Education and Prescribing Safety (S.T.E.P.S.) Program. This mandatory registry includes authorized patients, prescribers, and pharmacies, offers extensive patient education regarding *thalidomide's* safety, and is designed to prevent fetal exposure (see http://www.fda.gov/cder/Offices/OODP/whatsnew/thalidomide.htm).

BREAST-FEEDING CONSIDERATIONS

There is no published experience with *thalidomide* in breast-feeding women. It is unknown whether *thalidomide* is excreted into human breast milk.

DRUGS WITH MINIMAL OR NO KNOWN HUMAN TERATOGENIC EFFECT
(see Table 34–3)

Analgesics (Aspirin, Acetaminophen [Tylenol, Apacet], Ibuprofen [Advil, Alaxan, Brofen, Motrin, Paduden])

MATERNAL CONSIDERATIONS

Our understanding of the action of *aspirin* remains incomplete. Considerable individual variation in the pharmacokinetics of *aspirin* in both nonpregnant and pregnant women increases the task. It is believed that the cyclooxygenase-1 (COX-1) and COX-2 pathways are most frequently involved.[219] Gastrointestinal lesions, renal or hepatic dysfunction, asthma, hypoprothrombinemia, tachypnea, hyperthermia, and lethargy are the most significant risks associated with *aspirin* use.[220] A large cohort study concluded the antenatal use of NSAIDs such as *ibuprofen, naproxen*, and *aspirin* but not *acetaminophen* increased the risk of spontaneous abortion.[221] *Aspirin* treatment after the first trimester may provide a small but significant reduction in the rate of preterm birth but not perinatal death.[222]

Aspirin is used to improve pregnancy outcomes in women who have both antiphospholipid antibodies *and* a history of recurrent pregnancy loss. At the base of this practice is an assumption that *aspirin* interferes with the ability of antiphospholipid antibodies to compromise implantation and placental angiogenesis.[223,224] *Aspirin* is also frequently prescribed to reduce the risk of maternal thrombosis. However, *aspirin* alone is not sufficient to prevent thrombosis. Further, this medication is not risk-free. *Aspirin* may increase the risk of fetal malformation and contribute to maternal bleeding due to its effect on platelet COX enzymes. Many clinicians do not recommend its use in the third trimester.

The optimal approach for women with obstetric manifestations of antiphospholipid syndrome is uncertain. *Aspirin* plus *heparin* remains the most effective treatment[225] for women with a history of at least two spontaneous miscarriages or one intrauterine fetal death without apparent cause other than inherited or acquired thrombophilia.[226] Perhaps one explanation for the lack of consensus regarding management reflects the wide range of clinical manifestations. Yet, in a 2002 randomized, controlled trial of *aspirin* alone versus low-dose *aspirin* plus low-molecular-weight *heparin* prophylaxis for the prevention of recurrent pregnancy loss associated with antiphospholipid syndrome and recurrent miscarriage, low-molecular-weight *heparin* did not improve the outcome achieved with low-dose *aspirin* alone.[227]

The benefit of low-dose *aspirin* for the prevention of preeclampsia also remains controversial.[228,229] The most recent meta-analysis available at this writing indicates that antiplatelet agents produce a moderate but consistent reduction in the relative risk of preeclampsia.[230]

Collectively, large trials demonstrate low-dose *aspirin's* relative safety during pregnancy (especially after the first trimester) and generally positive effects on reproductive outcomes.

Acetaminophen is a component of a long list of over-the-counter medications and is one of the most widely used medications during pregnancy. The most common maternal problems relate to overdose and chronic abuse. The tissue damage is thought to be secondary to free radical toxicity with the consumption of glutathione during the *acetaminophen* metabolism. *N-Acetylcysteine* is the treatment of choice for an acute overdose.[231] *Ibuprofen* remains the drug of choice for management of postabortal pain and acute postoperative and postpartum pain.[232,233]

FETAL CONSIDERATIONS

Aspirin crosses the human placenta,[234] and its use is associated with an increased risk of fetal vascular disruptions, particularly gastroschisis, small intestinal atresia, and possibly premature closure of the ductus arteriosus.[17,223,235] It should be avoided in the first trimester.

Use of *acetaminophen* to treat the fever of chorioamnionitis during labor is associated with improved umbilical blood gases (improvements in the umbilical cord bicarbonate concentration and base deficit)[236] apparently by reducing fetal oxygen demand as the maternal core temperature declines. A prior suggestion that first-trimester exposure to *acetaminophen* in combination with *propoxyphene* is associated with clubfoot and digital abnormalities was not sustained by large series.[237] However, there is a link between *acetaminophen*, gastroschisis, and small bowel atresia. One recent study concluded that genetic variation represents a risk factor for the development of gastroschisis in the offspring of mothers exposed to *acetaminophen* early in pregnancy.[238] Unlike *aspirin*, *acetaminophen* has no antiplatelet activity and does not pose a hemorrhagic risk to the fetus.[239]

Ibuprofen crosses the human placenta. Fetal levels are dependent on maternal excretion since NSAIDs are not efficiently metabolized by the fetal kidney. *Ibuprofen* is as effective as *indomethacin* in closing the ductus arteriosus, but may have less impact on fetal renal function.[240] Thus, chronic exposure of the fetus to *ibuprofen* requires fetal surveillance for evidence of fetal right heart decompensation following critical constriction of the ductus arteriosus.

BREAST-FEEDING CONSIDERATIONS

Low-dose *aspirin*, *acetaminophen*, and *ibuprofen* are considered compatible with breast-feeding.[241–243] Patients often question the safety of cough and cold preparations during breast-feeding.[244] Some experts suggest that breast-feeding mothers use the lowest effective dose and for the shortest duration taken after a feeding. Women requiring high doses of *aspirin* such as that used for arthritis or rheumatic fever should avoid breast-feeding because neonatal salicylate levels may reach toxic levels.

Antibiotics (Penicillin G, Tetracycline [Achromycin, Telmycin, Tetocy, Tetracap], Ciprofloxacin [Ciloxan, Cipro], Metronidazole [Flagyl], Nitrofurantoin [Furadantin, Furatoin, Macrodantin, Macrobid], Azithromycin [Aruzilina, Zithromax])

MATERNAL CONSIDERATIONS

Penicillin and its derivatives (ampicillin, cephalosporins) are considered safe during pregnancy.[245–248]

Tetracycline is a broad-spectrum antibiotic avoided during pregnancy for fetal considerations.[249] *Tetracyclines* are alternative treatment for gonorrhea, syphilis, *Listeria monocytogenes*, *Clostridium* species, *Bacillus anthracis*, *Fusobacterium fusiforme* (Vincent's infection), and *Actinomyces* species.

Ciprofloxacin is a bactericidal antibiotic belonging to the fluoroquinolone group. It is recommended when penicillin-class agents have no effect on gram-negative rods (e.g., gonorrhea). It has the best safety profile of any second-line drugs for drug-resistant tuberculosis.[250] *Ciprofloxacin* is the drug of choice for prophylaxis among asymptomatic pregnant women exposed to *B. anthracis* and for the treatment of Q fever during pregnancy.[251,252] Because the prevalence of fluoroquinolone-resistant gonorrhea is growing, the U.S. Centers for Disease Control and Prevention (CDC) no longer recommends fluoroquinolones as first-line therapy (http://www.cdc.gov/std/treatment/2006/updated-regimens.htm). When penicillins and fluoroquinolones are contraindicated, *erythromycin* (a tetracycline-class agent without the fetal sequelae) is an alternative for the treatment of gonorrhea and syphilis.[253,254] A test for cure is indicated in both adolescents and pregnant women.[255]

Metronidazole is widely used during pregnancy for such indications as bacterial vaginosis (BV), trichomoniasis, inflammatory bowel disease, *Clostridium difficile* colitis, and anaerobic and protozoal infections.[256,257] Several large randomized trials to determine whether the treatment of BV reduced the prevalence of adverse outcomes, such as preterm birth,[258–261] had mixed results. Treatment has no effect on the prevalence of preterm birth in women with asymptomatic BV but no prior preterm birth.[262] Women who experienced a prior preterm birth in association with symptomatic BV appear to have a lower risk of recurrent preterm birth if treated with *clindamycin* and *erythromycin*, but not *metronidazole*.[263] Similarly, *metronidazole* failed to prevent preterm birth in women with asymptomatic trichomoniasis.[264] One major concern is the observation that in most randomized trials, *metronidazole* was actually associated with an increased rate of preterm birth.[260,265] The absence of benefit coupled with a potentially serious complication indicates that *metronidazole* should be avoided in preterm women unless there is no option. High risk conditions that require the treatment of BV with oral *clindamycin* and *erythromycin* include women with prior preterm birth associated with symptomatic cervicitis, those with a body mass index (BMI) less than 19.8 kg/m^2, and those with evidence of endometritis before pregnancy. A test of cure is obtained 1 month later.[266]

Nitrofurantoin is safe and effective for the treatment of asymptomatic bacteriuria as well as acute and recurrent urinary tract infections. Resistance rates are less than 10%. Women with recurrent urinary tract infections are candidates for long-term antibiotic prophylaxis. Acute pulmonary reactions to *nitrofurantoin*, presumably immune-mediated, are uncommon but potentially life-threatening. Patients with glucose-6-phosphate dehydrogenase (G-6-PD) deficiency may experience hemolytic reactions. It remains unclear how long a woman with asymptomatic bacteriuria should be treated. Some suggest that short-term administration combined with continued surveillance for recurrent bacteriuria

is sufficient. Pyelonephritis occurs in about 7% of women despite adequate treatment.

Azithromycin is probably the treatment of choice for *Chlamydia*. It is also used in combination with *artesunate* for malaria prophylaxis. It is ineffective for delaying preterm birth when given to reduce lower genital tract colonization with *Ureaplasma urealyticum* in women with preterm labor.

FETAL CONSIDERATIONS

Most penicillins cross the human placenta.[267,268] A large clinical experience is reassuring.[269]

Tetracycline crosses the human placenta and may cause a yellow-gray-brown discoloration of the permanent adult tooth.[270] It is unlikely that topically applied *tetracycline*, such as that used to prevent acne, achieves a relevant systemic level. Another tetracycline, *oxytetracycline* (but not *doxycycline*), is associated with an increased risk of neural tube defects, cleft palate, and cardiovascular defects. Treatment with *tetracycline* derivatives such as *doxycycline* has little, if any, teratogenic risk.[271]

Only a small number of fluoroquinolones (*ciprofloxacin*, *ofloxacin*, *levofloxacin*) are known to cross the human placenta.[272] Short-duration treatment with *ciprofloxacin* appears free of adverse fetal effect. As a class, the new quinolones (*irloxacin*, *trovafloxacin*, *sparfloxacin*) are not associated with an increased risk of malformation or musculoskeletal abnormalities in either animals or humans.[272,273] There are no clinically significant musculoskeletal problems reported in children exposed to fluoroquinolones in utero.[273,274] Because these studies include a relatively low number of children exposed during the first trimester, a longer period of follow-up coupled with magnetic resonance imaging of the joints at 1 or 2 years of age may be warranted to exclude subtle cartilage and bone damage.

Metronidazole crosses the human placenta and does not appear to have a teratogenic risk when used at recommended doses.[275]

It is unknown whether *nitrofurantoin* crosses the human placenta, but it is considered compatible with pregnancy. There are no well-documented cases of hemolytic reactions in neonates despite its use either during labor or in the neonate. It is typically avoided for that express reason.

Less than 3% of maternally administered *azithromycin* crosses the placenta. There have been no adverse effects reported in humans.

BREAST-FEEDING CONSIDERATIONS

Trace amounts of *penicillin G* are excreted into human breast milk,[276] and it is believed the infant has little exposure when the mother is treated with a *penicillin*.[277]

Tetracycline is excreted into human breast milk but is considered compatible with breast-feeding.[278]

Ciprofloxacin is concentrated in human breast milk,[279] and neonatal *C. difficile* pseudomembranous colitis is reported in neonates breast-fed by mothers treated with *ciprofloxacin*.[280] There are alternative agents with a superior safety profile.

Metronidazole is excreted into human breast milk but is considered compatible with breast-feeding.[281]

Nitrofurantoin is actively transported into human milk. However, maternal ingestion of *nitrofurantoin* is not associated with adverse neonatal events with the possible exception of a family with a G-6-PD deficiency.

Small amounts of *azithromycin* are excreted in breast milk in a dose-dependent fashion. No neonatal adverse effects have been reported.

Anticholinergics (Albuterol [Proventil, Ventolin], Atropine [Atropen, Atropinol, Atropisol, Borotropin], Dimenhydrinate [Amosyt, Biodramina, Dimetabs, Wehamine])

This class of pharmaceuticals antagonizes the actions of acetylcholine in the central and peripheral nervous systems.

Albuterol

MATERNAL CONSIDERATIONS

Albuterol has been used in the past for the control of asthma during pregnancy. There are superior agents.[282] The mean maternal blood pressures and heart rates are unaffected. In some countries, *albuterol* is used as a tocolytic agent, but there is no evidence to support this practice.

FETAL CONSIDERATIONS

Albuterol crosses the human placenta, though the detailed kinetics of transfer remains to be elucidated. Less than 10% is absorbed when administered by inhalation. There is no convincing evidence of teratogenicity after first-trimester exposure, and long-term follow-up studies of infants exposed to betamimetic tocolytic agents in general are reassuring.

BREAST-FEEDING CONSIDERATIONS

It is unknown whether *albuterol* enters human breast milk, but it is considered compatible with breast-feeding.

Atropine

MATERNAL CONSIDERATIONS

There are no adequate reports or well-controlled studies of *atropine* use in pregnant women. It is used for the treatment of symptomatic bradycardia and organophosphate poisoning or as an adjunct to anesthesia.

FETAL CONSIDERATIONS

Atropine rapidly crosses the human placenta, and the tachycardic fetus will respond to the direct administration of *atropine*.

BREAST-FEEDING CONSIDERATIONS

It is unknown whether *atropine* is excreted into human breast milk.

Dimenhydrinate

MATERNAL CONSIDERATIONS

Dimenhydrinate is a popular agent for the relief of nausea and vomiting during pregnancy. A recent randomized trial concluded that ginger is as effective as *dimenhydrinate* for the treatment of hyperemesis gravidarum and has fewer side effects.[283] Both *dimenhydrinate* and *diphenhydramine* are treatment options for severe migraine headache during pregnancy.[284] Some caution is warranted, however, because several investigators have noted an increase in uterine activity with *dimenhydrinate*.[285]

FETAL CONSIDERATIONS

It is unknown whether *dimenhydrinate* crosses the human placenta. There is no indication that *dimenhydrinate* increases the risk of fetal abnormalities when given at any stage of pregnancy.

BREAST-FEEDING CONSIDERATIONS

Dimenhydrinate is excreted in small quantities into human breast milk. In addition, though the kinetics remains to be elucidated, a long clinical experience is reassuring.

Antihypertensives (Methyldopa [Aldomet, Alfametildopa], Hydralazine [Apresoline], Labetolol [Coreton, Normodyne, Trandate], Propranolol [Inderal])

MATERNAL CONSIDERATIONS

Approximately 3% of the women take an antihypertensive agent during pregnancy.[286] ACOG recommends the treatment of women with a systolic blood pressure higher than 170 mm Hg and/or a diastolic blood pressure above 109 mm Hg. There is no consensus whether lesser degrees of hypertension require treatment during pregnancy because antihypertensive therapy does not improve the fetal outcome in women with mild to moderate chronic hypertension.[287] Not treating requires the assumption that untreated mild to moderate hypertension in the short term has no lasting effect on the mother.

Methyldopa is one of the best-studied antihypertensives during pregnancy and remains a popular agent for the treatment of moderate to mild hypertension despite it being a particularly effective agent.[288,289] *Methyldopa* acts through the sympathetic nervous system (both centrally and peripherally) via an α_2-receptor negative feedback mechanism. Oral *methyldopa* requires 48 to 72 hours to act. *Methyldopa* is less effective than *metoprolol*, but is similar to *nifedipine*, *labetalol*, and *ketanserin* in decreasing both systolic and diastolic blood pressure in women with chronic hypertension in whom speed of control is not critical.[290]

Hydralazine and *labetolol* are the most widely used drugs for the treatment of acute hypertension during pregnancy.[291] The mechanism of action for *hydralazine* is poorly understood. It is thought that *hydralazine* works through a cyclic guanosine monophosphate–mediated mechanism, resulting in smooth muscle relaxation. In two recent randomized trials, *hydralazine* was as safe and as effective as *diazoxide* and *labetalol* for the treatment of hypertensive emergencies during the antenatal and in the postpartum periods.[292,293]

Labetalol combines α- and β-adrenoceptor antagonist properties. Despite its popularity, *labetalol* is associated with

a higher risk of hypotension and cesarean section than *diazoxide* when given intravenously.[294]

Propranolol has been used extensively during pregnancy for the treatment of maternal hypertension, arrhythmia, and migraine headache and is generally considered safe unless the dose given decreases maternal cardiac output.[295] It is also used to provide symptomatic relief of symptoms from thyrotoxicosis and pheochromocytoma.[296,297] Although the studies of *propranolol* use for hypertension are small, it appears as effective as *methyldopa* and is often coupled with other hypotensive agents such as *hydralazine* with which its actions are synergistic.[298]

FETAL CONSIDERATIONS

Most antihypertensive agents cross the placenta. *Methyldopa* is considered safe for use during the first trimester.[299] It neither alters fetal cardiac activity nor produces fetal hemodynamic changes as measured by Doppler velocimetry.[300] The effects of various antihypertensive medications on fetoplacental circulation were studied in vitro.[301] *Hydralazine*, *nifedepine*, and *methyldopa* had little or no direct effect on the fetal vasculature in contrast to *labetalol*, which was a vasodilator.

Clinical experience suggests *hydralazine* is safe during the first trimester. Large doses of *labetalol* given intravenously can cause fetal bradycardia, hypoglycemia, bradycardia, hypotension, pericardial effusion, myocardial hypertrophy, and fetal death due to acute hypotension.[302,303] Based on these risks, an initial intravenous dose of 5 to 10 mg is recommended. Similar responses are unlikely with oral therapy. Overall, neonatal outcome is similar to that achieved with *hydralazine*.[304] Simultaneous occurrence of maternal and fetal thyrotoxicosis is not rare, and in this instance, *labetalol* may be useful for symptomatic treatment of the thyrotoxicosis.[305]

BREAST-FEEDING CONSIDERATIONS

Although most antihypertensive medications (*methyldopa*, *hydralazine*, *labetolol*, *propranolol*) are excreted into human breast milk, breast-fed neonates are normotensive.[306] *Labetalol* increases the risk of neonatal hypoglycemia, but this effect is blunted by supplementing with glucose-fortified formula.[307]

Antihistamines (Cetirizine [Zyrtec], Diphenhydramine [Benadryl])

MATERNAL CONSIDERATIONS

Despite a long clinical experience in obstetrics, neither *cetirizine* nor *diphenhydramine* has been adequately studied during human pregnancy. Allergic rhinitis is the most common indication for *cetirizine* during pregnancy. The advantage of *cetirizine* over many other antihistamines is that it does not cause clinically significant cardiac QT interval prolongation.[308] The product label frequently states that medications for allergic rhinitis are to be avoided during pregnancy owing to lack of fetal safety. The human data refute this position.

Diphenhydramine is a useful adjunct for women who have allergic reactions to local anesthetic agents, laminaria, and serum albumin or for the treatment of severe migraine headaches.[309,310]

FETAL CONSIDERATIONS

It is unknown whether *cetirizine* crosses the human placenta. *Cetirizine* is not incriminated as a human teratogen. *Diphenhydramine* crosses the human placenta, but the detailed kinetics remains to be elucidated. There is no evidence of increased fetal risk when administered at any stage of pregnancy. *Diphenhydramine* may cause neonatal depression if administered during labor.[311]

BREAST-FEEDING CONSIDERATIONS

Cetirizine is excreted into human breast milk. It is unknown whether *diphenhydramine* does so. Irritability is the most common adverse reaction reported in the newborns of women using antihistamines while breast-feeding.

Antivirals (Acyclovir)

MATERNAL CONSIDERATIONS

All suspected herpesvirus infections should be confirmed by viral or serologic testing.[312] Treatment of genital herpes with *acyclovir* during pregnancy is not curative but does reduce the duration of symptoms and viral shedding.[313] Extensive clinical experience with *acyclovir* is reassuring. Based on several studies, ACOG recommends prophylactic *acyclovir* from 36 weeks until delivery to reduce the risks of recurrent genital herpes and thus potentially avoid cesarean delivery.[314] Suppression therapy is both effective and cost-effective whether or not the primary infection occurs during the current pregnancy.

FETAL CONSIDERATIONS

Acyclovir crosses the human placenta and is concentrated in the amniotic fluid. However, there is no evidence of preferential drug accumulation in the fetus.[315] Long-term follow-up studies have not revealed any increase or pattern of malformations after first-trimester exposure.[316]

BREAST-FEEDING CONSIDERATIONS

Acyclovir is excreted into human breast milk, reaching a milk concentration higher than maternal serum.[317] It is considered safe with breast-feeding.

Corticosteroids (Prednisone [Cortan, Dacortin], Betamethasone [Celestone], Dexamethasone [Decadron])

MATERNAL CONSIDERATIONS

There are no adequate well-controlled studies of *prednisone* use during pregnancy. The authors of several trials conclude that women with antiphospholipid syndrome treated with *prednisone* and *aspirin* have higher loss rates than women treated with *heparin* and *aspirin*.[318]

Betamethasone and *dexamethasone* are used routinely to accelerate fetal lung maturation. Their administration is standard of care in women with threatened preterm birth.[319,320] A recent multicenter, randomized, double-blind, placebo-controlled trial demonstrated that the administration of a

single "rescue course" of corticosteroids before 33 weeks improves neonatal outcome without apparent increased short-term risk.[321]

Corticosteroids may increase the risk of maternal infection in women with preterm premature rupture of the fetal membranes, though most large studies reveal no such increased risk.[322] They can transiently cause an abnormal glucose tolerance test,[323] worsen existing diabetes mellitus, and are associated with pulmonary edema when given with a tocolytic agent in the setting of an underlying infection.[324] Repeat doses of corticosteroids do not reduce the maternal perception of fetal movement.[325,326]

Dexamethasone is an effective postoperative antiemetic following general anesthesia for pregnancy termination.[327] There are reports that intravenous *dexamethasone* modifies the clinical course of the HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome during both the antenatal and the postpartum periods,[328] though a more recent study contradicts that conclusion.[329]

FETAL CONSIDERATIONS

The human placenta metabolizes *prednisone*, reducing fetal exposure to less than 10% of the maternal level.[330] Evidence that corticosteroids are human teratogens is weak and confined to cleft lip.[331–334] *Betamethasone* and *dexamethasone* cross the human placenta and are two of the few drugs proven to enhance perinatal outcome after preterm birth.[335] An increased risk of neonatal sepsis has been suggested but remains unconfirmed despite large prospective trials with thousands of deliveries. Multiple courses of glucocorticoids for fetal lung maturation are not recommended.[336] Adverse effects noted in animal and/or human studies include profound suppression of fetal breathing and movement (altering the biophysical profile score), impaired myelination, intrauterine growth restriction, and microcephaly.[337,338] The fetal heart rate pattern may also become transiently nonreactive.[339] There is controversy as to the earliest gestational age at which corticosteroids effective.[340] The National Institute of Child Health and Human Development and the Office of Medical Applications of Research of the National Institutes of Health recommend a single course of glucocorticoid to all pregnant women between 24 and 34 weeks' gestation at risk for preterm delivery within 7 days.[341] Repeat corticosteroid courses should not be used routinely. Recently, it was demonstrated that repeat courses of corticosteroid were accompanied by a reduction in birth weight and an increase in the prevalence of small–for–gestational age infants.[326] Some studies suggest that *betamethasone* can alter fetal breathing when administered for the enhancement of lung maturation.[342] Apparently, this does not occur with *dexamethasone*.[325] Complete fetal heart block has been treated successfully with *dexamethasone*.[343] *Dexamethasone* can prevent or diminish virilization due to congenital adrenal hyperplasia if administered early during the first trimester.[344,345]

BREAST-FEEDING CONSIDERATIONS

Although it is unknown whether *prednisone* is excreted into human breast milk, a long clinical experience suggests that this drug is safe during breast-feeding. It is still unclear whether maternal treatment with *betamethasone* or *dexamethasone* increases the concentration of cortisone in breast milk.

Infliximab (Remicade)

MATERNAL CONSIDERATIONS

Infliximab is a monoclonal antibody that specifically binds to tumor necrosis factor-α (TNF-α), blocking its activity. Given the evidence that TNF-α is involved in the pathogenesis of many conditions with an inflammatory component, *infliximab* has been used for treatment of psoriasis, inflammatory bowel disease, spondylarthropathies, rheumatoid arthritis, and juvenile idiopathic arthritis.[346–348] There are only limited data on the use of *infliximab* during pregnancy. Most studies examining the effects of *infliximab* on pregnancy in women with inflammatory bowel disease are confounded by the fact that most of these patients are on multiple medications and have varying levels of disease activity.[349] There is consensus that women on remission therapy can continue their *inflixumab*, given that the disease may flare if the therapy is stopped.

FETAL CONSIDERATIONS

Most of the available data suggest that the benefits of achieving and maintaining remission in mothers with Crohn's disease using *infliximab* outweigh the potential fetal risk.[350] To date, there is no evidence that TNF-α antagonists are associated with embryotoxicity, teratogenicity, or increased pregnancy loss.[351] However, caution continues to be advised because human experience is still extremely limited.

BREAST-FEEDING CONSIDERATIONS

Studies monitoring the level of *infliximab* in human breast milk suggest that targeted monoclonal antibodies and other biologic agents can be used with caution in breast-feeding patients.[352] *Infliximab* is considered compatible with breast-feeding.

CONCLUSIONS

- The decision to prescribe a medication to a pregnant woman must take into consideration many factors such as the risk of teratogenicity, previous experience with that medication, gestational age, route of drug administration, and whether or not the drug crosses the placenta or is excreted into breast milk.
- Comprehensive information on currently prescribed drugs with unknown teratogenicity or classified as nonteratogenic is essential for physicians recommending drug treatment for pregnant and breast-feeding women.
- Up-to-date information about the effect of exposure to a large number of medications during pregnancy can be obtained from textbooks or in electronic format through consultation of pregnancy exposure registries and several databases such as REPROTOX, OTIS, or ENTIS.

SUMMARY OF MANAGEMENT OPTIONS
Medication during Pregnancy

Management Options	Evidence Quality and Recommendation	References
Preconceptual counseling can minimize the risk for the mother and her fetus.	GPP	
During first prenatal visit, obtain a thorough medical, allergy, and drug medication history of the mother.	GPP	
Recommend first-trimester ultrasound surveillance of the fetus for early detection of fetal anomalies.	GPP	
Counseling of the patients should include the background risk for fetal anomalies.	GPP	
Team approach for care of pregnant women with medical conditions is the best strategy.	GPP	
Be aware of known teratogens.	GPP	
Provide the best counseling and treatment recommendations by consulting a text or a continuously updated database such as ReproTOX, OTIS, or ENTIS.	GPP	
Advise that for most drug medications, there are no adequate reports or well-controlled studies in human fetuses.	GPP	
In general, monotherapy with the lowest effective dosage is recommended.	GPP	
Medication should be used during pregnancy and lactation only if the benefit justifies the potential risk.	GPP	
Recommend medications with known safety records rather than new or untested drugs.	GPP

Hypertension

GUSTAAF DEKKER

Videos corresponding to this chapter are available online at www.expertconsult.com.

INTRODUCTION

Some form of hypertension occurs in approximately 15% to 20% of pregnancies. According to the World Health Organization, hypertensive disease during pregnancy is a major cause of perinatal mortality and morbidity. However, in developed countries, nonproteinuric hypertension arising late in pregnancy is associated neither with any increase in perinatal mortality or morbidity nor with a decreased birth weight. In this chapter, these cases are designated *gestational hypertension*. It appears that an increase in blood pressure (BP) is in some way an adaptive phenomenon of intrinsic survival value that, in some women, breaks down, converting a physiologic process into one of pathology, that is, preeclampsia.[1–3] Preeclampsia, occurring in 3% to 8% of pregnancies, is a major cause (15%–20%) of maternal mortality (in developed countries) and of (often iatrogenic) preterm birth, intrauterine growth restriction (IUGR), and perinatal mortality. The main maternal and fetal risks are listed in Table 35–1.[1]

DEFINITION, CLASSIFICATION, AND RISK

Classification schemes of hypertensive disorders can overemphasize the importance of hypertension in the pathophysiology so that patients with other signs of preeclampsia but without an increase in BP may be mismanaged. Historically, a range of definitions has served to confuse clinicians and researchers as to the most appropriate definition to use.[4] More recent classifications are more closely aligned.

Definition of Hypertension

BP changes throughout normal pregnancy, with a fall in the first and second trimesters and a rise toward term to levels similar to those in the nonpregnant level. The concept of hypertension is artificial, with an arbitrary threshold used to divide a continuously distributed variable into two artifactual categories of "normotension" and "hypertension." The conventional dividing line is 140/90 mm Hg. Any definition of hypertension is inevitably arbitrary, but the use of diastolic BP of 90 mm Hg or greater throughout pregnancy as originally proposed by Nelson[5] has as advantages that (1) readings above this level are beyond 2 standard deviations

in normal pregnant women[6] and (2) it corresponds with the point of inflexion of the curve relating diastolic BP to perinatal mortality with a significant increases above a diastolic BP of 85 mm Hg.[7] The criterion of a rise in BP to diagnose pregnancy-induced hypertensive disorders is usually unreliable, because a gradual increase in BP from the second to the third trimester is seen in most normotensive pregnancies.[8] Currently, the following thresholds to define "hypertension" have been accepted by most national bodies and international organizations.[9–11] Thus, **hypertension in pregnancy** is defined as

- Systolic BP greater than or equal to 140 mm Hg and/or
- Diastolic BP greater than or equal to 90 mm Hg (Korotkoff 5 [K5]).

These measurements should be confirmed by repeated readings over 4 to 6 hours. Where K5 is absent, K4 (muffling) should be accepted.

Severe hypertension in pregnancy is defined as

- Systolic BP greater than or equal to 170 mm Hg and/or
- Diastolic BP greater than or equal to 110 mm Hg.

This represents a level of BP above which cerebral autoregulation is overcome in normotensive individuals, with the risk of cerebral hemorrhage and hypertensive encephalopathy. It is important to acknowledge that systolic as well as diastolic hypertension increases the risk of cerebral hemorrhage.[9,10]

Classification of Hypertensive Disorders in Pregnancy

The classification adopted by the International Society for the Study of Hypertension in Pregnancy (ISSHP) reflecting both the pathophysiology of the condition and the risks and potential outcomes for both mother and baby is[9–11]

- **Gestational hypertension.**
- **Preeclampsia.**
- **Chronic hypertension**
  - Essential.
  - Secondary.
- **Preeclampsia superimposed on chronic hypertension.**

Gestational hypertension is diagnosed when there is new-onset hypertension after 20 weeks without any systemic

TABLE 35–1

Maternal and Fetal Complications in Severe Preeclampsia

Maternal Complications

Abruptio placentae (1%–4%)
Disseminated coagulopathy/HELLP syndrome (10%–20%)
Pulmonary edema/aspiration (2%–5%)
Acute renal failure (1%–5%)
Eclampsia (<1%)
Liver failure or hemorrhage (<1%)
Stroke (rare)
Death (rare)
Long-term cardiovascular morbidity

Neonatal Complications

Preterm delivery (15%–67%)
Fetal growth restriction (10%–25%)
Hypoxia-neurologic injury (<1%)
Perinatal death (1%–2%)
Long-term cardiovascular morbidity associated with low birth weight (fetal origin of adult disease)

Magnitude of risk depends on gestational age at time of diagnosis, delivery, severity of disease process, and presence of associated medical disorders.
HELLP, hemolysis, elevated liver enzymes, and low platelets.
Modified from Sibai B, Dekker G, Kuperminc M: Preeclampsia. Lancet 2005;365:785–799, with permission.

TABLE 35-2

Society for Obstetric Medicine Australia and New Zealand Definition of Preeclampsia

A clinical diagnosis of preeclampsia can be made when hypertension arises after 20 wk' gestation and is accompanied by one or more of the following:
- Renal involvement:
  - Proteinuria ≥ 300 mg/24 hr or a urine protein/creatinine ratio ≥ 30 mg/mmol
  - Serum/plasma creatinine ≥ 0.09 mmol/L or oliguria (< 500 mL/24 hr)
- Hematologic involvement
  - Thrombocytopenia
  - Disseminated intravascular coagulation
  - Hemolysis
- Liver involvement
  - Abnormal liver function (AST and/or ALT > 50 IU/L, raised bilirubin > 25 IU/L)
  - And/or severe epigastric or right upper quadrant pain.
- Neurologic involvement
  - Convulsions (eclampsia)
  - Hyperreflexia with sustained clonus
  - Severe headache (persisting, atypical)
  - Persistent visual disturbances (photopsia, scotomata, cortical blindness, retinal vasospasm)
  - Stroke
- Pulmonary edema
- IUGR and/or signs of fetal distress
- Placental abruption

ALT, alanine aminotransferase; AST, aspartate aminotransferase; IUGR, intrauterine growth restriction.
From Lowe SA, Brown MA, Dekker G, et al: Guidelines for the management of hypertensive disorders of pregnancy. Aust N Z J Obstet Gynaecol 2009;49:242–246.

features of preeclampsia and BP levels return to normal within 3 months postpartum. This diagnosis will include some women who are in the process of developing preeclampsia but do not yet have proteinuria or other manifestations. Some women initially diagnosed in this category will have BP elevation that persists beyond 12 weeks postpartum and may eventually be classified as having chronic hypertension. Gestational hypertension near term is associated with little increase in the risk of adverse pregnancy outcome. The earlier the gestation at presentation and the more severe the hypertension, the higher the likelihood that the woman with gestational hypertension will progress to develop preeclampsia or have an adverse pregnancy outcome, in particular IUGR, placental abruption, and (often iatrogenic) preterm birth.[12,13]

Preeclampsia is a pregnancy-specific syndrome characterized by variable degrees of placental dysfunction and a maternal response featuring systemic inflammation. Most consider hypertension and proteinuria to be the hallmarks of preeclampsia,[9–11] but the clinical manifestations of this syndrome are very heterogeneous.

Urinary protein excretion increases in normal pregnancy, with the upper 95% confidence limit of total protein excretion being 200 to 260 mg/24 hr and urinary albumin excretion of 29 mg/24 hr.[14,15] The gold standard for determining proteinuria remains the 24-hour urinary protein excretion. Proteinuria, as used in the classification of hypertensive disorders of pregnancy, is defined as excretion of 300 mg/24 hr or a urine protein/creatinine ratio of 30 mg/mmol, or if these methods are not available, as a concentration of 30 mg/dL (≥1+ on dipstick) or more in at least two random urine samples collected at least 4 to 6 hours apart.[1,10,11,14,15] Urinary tract infection should be excluded. Dipstick testing for proteinuria is a screening test with very high false-positive and, more important, false-negative rates.[16–18] The use of automated dipstick readers can improve false-positive and false-negative rates for the detection of proteinuria.[16,17]

Dipstick testing should really be used only in scenarios in which access to more reliable methods of establishing the degree of proteinuria is absent. In all women presenting with gestational hypertension, the presence of proteinuria should be confirmed with at least a urine protein-to-creatinine ratio or, preferably, a 24-hour urine collection; for clinical screening purposes, there is a reasonable correlation between these two methods. The protein-to-creatinine ratio has not been found to be an accurate method of quantifying protein excretion and should not be used to track progression of proteinuria in preeclampsia. Centers will need to evaluate local performance of the protein-to-creatinine ratio, because performance may be influenced by the method of measuring protein.[4,16–18]

The traditional criteria to confirm a diagnosis of preeclampsia (new onset of hypertension and new onset of proteinuria after 20 wk' gestation) are appropriate to use in the majority of healthy nulliparous women. However, hypertension and/or proteinuria may be absent in 10% to 15% of women who develop the HELLP (hemolysis, elevated liver enzymes, or low platelets) syndrome[19,20] and in 38% of those who develop eclampsia.[21] In recognition that severe disease may occur in the absence of proteinuria, the Society for Obstetric Medicine Australia and New Zealand (SOMANZ) has widened these criteria to include the presence of other multisystem manifestations, whether or not proteinuria is present[10] (Table 35–2).

The ISSHP[11] has adopted the following research definition of preeclampsia: (1) de novo hypertension after 20 weeks' gestation, (2) properly documented proteinuria of

greater than 300 mg/24 hr, and (3) both hypertension and proteinuria disappearing postpartum.

Severe preeclampsia is defined by the presence of

- Severe hypertension in association with proteinuria
  or
- If there is hypertension in association with severe proteinuria (≥5 g/24-hr period)[1,2,10,11]
  or
- If there is multiorgan involvement such as pulmonary edema, seizures, oliguria (<500 mL/24-hr period), thrombocytopenia (platelet count < 100,000/mm³), abnormal liver enzymes in association with persistent epigastric or right upper quadrant pain, or persistent severe central nervous system symptoms (altered mental status, headaches, blurred vision, or blindness).[1,2,10]

The course of disease in an individual preeclamptic patient is highly unpredictable and a patient's status can evolve from apparently mild preeclampsia to fulminating severe preeclampsia in hours. It should be noted that

- Edema is not included in the diagnostic features of preeclampsia, though rapid development of generalized edema should alert the clinician to screen for preeclampsia.
- Many disorders may present with similar features to preeclampsia, such as acute fatty liver of pregnancy, hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, autoimmune thrombocytopenia, severe folate deficiency, and exacerbation of systemic lupus erythematosis or cholecystitis.[19,20]
- The HELLP syndrome represents a particular presentation of severe preeclampsia.[10,19,20]
- Hyperuricemia is a common feature of preeclampsia. The degree of hyperuricemia may correlate with fetal risk,[22,23] although some studies have questioned its utility.[24,25] A rapidly rising plasma urate in a hypertensive patient can indicate herald progressive preeclampsia.

Chronic hypertension: *Essential hypertension* is defined by a BP of 140 mm Hg or greater systolic and/or 90 mm Hg or greater diastolic diagnosed preconception or in the first half of pregnancy without an apparent underlying cause. It may also be diagnosed in women presenting in the pregnancy on antihypertensive medications in whom no secondary cause for hypertension has been determined.[26] *Secondary hypertension* may be caused by renal parenchymal disease or scarring, renovascular disease, endocrine disorders, or aortic coarctation. Chronic hypertension is a strong risk factor for the development of preeclampsia.[1,10,26]

Preeclampsia superimposed on chronic hypertension is diagnosed when one or more of the features of preeclampsia develop after 20 weeks' gestation. In women with chronic renal disease, the diagnosis of superimposed preeclampsia is often difficult because preexisting proteinuria normally increases during pregnancy. In such women, sudden dramatic increases in proteinuria and hypertension should raise suspicion of preeclampsia, but the diagnosis is not secure without the development of other systemic features.

PREECLAMPSIA

Epidemiology

The frequency of preeclampsia is between 2% and 7% in healthy nulliparous women.[2,27,28] In these women, the disease

---

TABLE 35–3

Risk Factors for Preeclampsia

Couple-related Risk Factors

Primipaternity[36-38]
Limited sperm exposure[36-39]
Pregnancies after donor insemination; oocyte donation; embryo donation[36,37,40]
Protective effect of "partner change" in case of previous preeclamptic pregnancy[36-38]
"Dangerous male partner" (paternal effects)[41]

Maternal- or Pregnancy-related Risk Factors

Extremes of maternal age[36]
Multifetal gestation[29,30]
Preeclampsia in a previous pregnancy[31,32]
Chronic hypertension and/or renal disease[26,31]
Maternal chronic inflammatory conditions (e.g., rheumatologic disease, systemic lupus erythematosus)[42]
Maternal (chronic) infections[43,44]
Maternal low birth weight[36]
Obesity and insulin resistance (with and without the polycystic ovary syndrome; the risk proportionate to BMI)[45-47]
Pregestational diabetes mellitus[31]
Preexisting thrombophilias[33-35,48-50]
Maternal susceptibility genes[51-53]
Family history of preeclampsia[54]
Smoking (reduced risk)[36]
Hydropic degeneration of the placenta[36]

BMI, body mass index.
Modified from Sibai B, Dekker G, Kupferminc M: Preeclampsia. Lancet 2005;365:785–799, with permission.

---

is mostly mild, the onset is mostly near term or intrapartum (75% of cases), and it conveys only a negligible increased risk for adverse pregnancy outcome. By contrast, frequency and severity of the disease are substantially higher in women with multifetal gestation,[29,30] chronic hypertension,[26,31] previous preeclampsia,[31,32] pregestational diabetes mellitus,[31] and preexisting thrombophilias.[33-35] Maternal and couple-specific risk factors for preeclampsia are listed in Table 35–3. Preeclampsia is a disease of first pregnancy within a couple (primipaternity). A previous abortion (spontaneous or induced) or healthy pregnancy with the same partner is associated with a reduced risk of preeclampsia, although this protective effect is lost with a change of partner.[36–40] The risk increases in those who have limited sperm exposure with the same partner before conception.[55,56] Also, men who fathered one preeclamptic pregnancy are nearly twice as likely to father a preeclamptic pregnancy in a different woman, irrespective of whether or not she had already had a preeclamptic pregnancy.[41,54] Advances in assisted reproductive technology have also increased the risk of preeclampsia. These include women who are older than 40 years, obese with polycystic ovaries syndrome, and/or pregnant by donated gametes. In addition, many of these women will have multifetal gestations.[39,40,57] Obesity is a definite risk for preeclampsia. The worldwide increase in obesity is probably one of the main reasons for the increased frequency of preeclampsia in many developed countries with a "western" lifestyle.[36,45,46] Factors triggering or augmenting a maternal systemic inflammatory response (e.g., chronic infections and autoimmune disorders) are also known to increase the preeclampsia risk.[43,44,58,59]

Pathogenesis

Shallow, endovascular cytotrophoblast (CTB) invasion in the spiral arteries, inappropriate endothelial cell activation, and an exaggerated inflammatory response are key features in the pathogenesis of preeclampsia.[1,58] The clinical findings of preeclampsia can manifest as a maternal syndrome (hypertension and proteinuria with or without other multisystem abnormalities) and/or as a fetal syndrome (IUGR, reduced amniotic fluid, and abnormal oxygenation).[1,58] The syndrome "preeclampsia" probably encapsulates more than one disease process. Thus, near-term preeclampsia without demonstrable fetal involvement is different from preeclampsia associated with low birth weight and preterm delivery,[28,60] and preeclampsia in nulliparous women may be different from that in women with preexisting vascular disease, multifetal gestation, diabetes mellitus, or previous preeclampsia.[1,2,10,60,61] The main pathogenetic processes demonstrated to be involved in the development of preeclampsia are discussed in the following sections.

Inflammation

Pregnancy imposes a substantial systemic inflammatory stress on all pregnant women in the second half of pregnancy. The inflammatory stimulus may arise from "debris" shed into the maternal circulation from the syncytiotrophoblast (STB), which, if excessive, may signal "danger" to the maternal innate immune system. Preeclampsia occurs when this response is increased to the point of decompensation.[58,62] These features, which are clinically apparent, form the so-called second stage of preeclampsia. The two-stage model of preeclampsia (Fig. 35–1), originally proposed more

than a decade ago by Redman and coworkers,[63,64] envisages that preeclampsia arises in various ways including from placental ischemia-reperfusion injury[65] secondary to deficient placentation. Whereas some consider abnormal placentation to be the start and invariable cause of preeclampsia, it is much more likely that it is a completely separate but predisposing condition. Some, but certainly not all, cases of preeclampsia are associated with poor placentation. Poor placentation defines the first stage, which would appear to have a different origin; first-stage decidual immune responses account for the primipaternity and possible partner specificity of preeclampsia.[1,64] Second-stage responses,[58,64] all secondary to the systemic inflammatory response, could also explain why women bearing pregnancies with unusually large placentas are susceptible to preeclampsia. In a completely normal woman, although normal pregnancy stimulates a systemic inflammatory response, it is not intense enough to generate the signs of preeclampsia. To do that requires the abnormal stimulus from an oxidatively stressed placenta ("placental preeclampsia").[66] In a woman with a chronic systemic inflammatory response associated with conditions such as chronic hypertension, diabetes, or obesity, the starting point is abnormal enough that even a normal placenta can stimulate a systemic response of an intensity to give the signs of preeclampsia ("maternal preeclampsia") (Fig. 35–2). In clinical practice, there are many mixed presentations with maternal constitution and placental ischemia-reperfusion contributing to the presentation. Based on the "inflammatory" paradigm,[58,64] preeclampsia is not a separate entity but the extreme end of a range of maternal systemic inflammatory responses engendered by pregnancy itself. The corollary is that any factor enhancing this response would predispose to preeclampsia. Indeed, recent studies have shown that, not only auto-immune disorders, but also certain maternal infections (e.g., urinary tract,[59] periodontal disease,[44] chlamydia,[43] and certain viruses[67]) are associated with preeclampsia.[59] Inflammation is

probably also an important part of the causal pathway through which obesity predisposes to preeclampsia.[68]

Endothelial Cell Activation

Endothelial cell activation is part of the generalized inflammatory reaction also involving leucocytes as well as the clotting and complement systems.[58,64] The endothelium is one of the key organs involved in the pathophysiology of preeclampsia, as evidenced by the prostacyclin (PGI_2)/thromboxane A_2 (TXA_2) imbalance, impairment of the nitric oxide–cyclic guanosine monophosphate (NO-cGMP) pathway and a series of markers indicating endothelial activation.[68–76] Glomerular endotheliosis, but also ultrastructural changes in the placental bed and uterine boundary vessels, provides morphologic evidence of endothelial cell "injury" in preeclampsia.[72,73] Absence of normal stimulation of the renin-angiotensin system, despite relative hypovolemia in severe preeclampsia, increased vascular sensitivity to vasoconstrictors, and increased endothelial cell permeability can all be explained on the basis of this endothelial cell activation.[76] Endothelial cell activation fits the selective platelet activation and consumption (sometimes accompanied by microangiopathic hemolysis) and the resulting reduction in uteroplacental blood flow due to spiral artery thrombosis and placental infarction. An inadequate production of either antiaggregatory PGI_2 or NO, or both, increased platelet-derived TxA_2 and serotonin,[76,77] and increased local tissue factor[78,79] provide an attractive explanation for surface-mediated platelet activation occurring on the inner lining of spiral arteries. Platelets adhere to and release α- and dense granule constituents, specifically, TxA_2 and serotonin, contributing to platelet aggregation and inducing fibrin formation in particular in the uteroplacental circulation.[76,77] In preeclampsia, endothelial cell dysfunction and platelet aggregation precede the increase in thrombin and fibrin formation.[80]

Impaired Cytotrophoblast Invasion in Spiral Arteries and Placental Pathology in Preeclampsia

In normal pregnancies, endovascular CTBs replace endothelial cells in the spiral arteries; this invasion results in the destruction of the medial elastic, muscular, and neural tissue. These so-called physiologic changes normally reach the inner third of the myometrium.[81] These physiologic changes create a low-resistance arteriolar system and the absence of maternal vasomotor control, which allows the dramatic increase in blood supply necessary to serve the growing fetus. Fetal and maternal bloods are, at all times, separated by a layer of STB, a variable layer of CTB and mesenchyme, and the walls of the fetal capillaries. Therefore, the fetus can secrete substances directly into the maternal blood, but maternal products must cross trophoblast membranes and cytoplasm before they reach fetal blood.[81] A true intervillous blood flow is established by about 12 weeks' gestation. Initially, CTB plugs in the spiral arteries may act as valves and may protect the early gestation from the forces of arterial blood flow.[82,83] Uterine natural killer (NK) cells produce a series of cytokines involved in angiogenesis and vascular stability, including vascular endothelial growth factor (VEGF), placental growth factor (PLGF) and angiopoietin 2,[84] and play a pivotal role in regulating trophoblast invasion

and the maternal placental bed vascular changes.[81,84] The end result is that 100 to 120 spiral arteries are remodeled by the invading "foreign" CTBs into dilated, inelastic tubes without maternal vasomotor control. Only humans have such extensive placental invasion, arguably because of the long intrauterine period required for the development of the fetal brain.[84,85]

In preeclampsia, physiologic changes in many but not all spiral arteries are confined to the decidual portion of the arteries. In these arteries, the myometrial segments remain anatomically intact, do not dilate, and the adrenergic nerve supply to the spiral arteries remains intact. About 30% to 50% of placental bed spiral arteries escape entirely from the endovascular invasion of trophoblast.[81] In addition, many vessels are occluded by fibrinoid material and exhibit adjacent foam cell invasion (atherosis). Acute atherosis is characterized by fibrinoid necrosis of the vessel wall, with an accumulation of lipid-laden macrophages (foam cells) and a perivascular mononuclear cell infiltrate. Acute atherosis and the associated thrombosis are the cause of placental infarctions, which are more common in preeclampsia.[81] Preeclamptic patients are also at higher risk for abruption. Placental abruption in preeclamptic patients probably results from thrombotic lesions in the placental vasculature, leading to decidual necrosis, separation, and hemorrhage. A vicious circle then continues as the decidual hemorrhage results in further separation.[86] Similar pathologic vascular changes exist in a significant proportion of normotensive pregnancies complicated by IUGR and/or preterm labor and are certainly not specific for preeclampsia.[87]

Pro- and Antiangiogenic Proteins in Normal and Preeclamptic Pregnancies

VEGF and PLGF induce vasodilator autocoids including NO and PGI_2 in endothelial cells and play a major role in pregnancy-associated vasodilation and the pregnancy-associated increase in glomerular filtration rate. VEGF-A and PLGF are produced by villous and extravillous CTBs, STBs, and decidual leukocytes. The receptors for VEGF-A, fms-like tyrosine kinase-1 (Flt-1) and kinase-insert domain-containing receptor (KDR),[88] are both expressed on human trophoblasts in addition to endothelial cells. In the placental bed, at time of implantation, VEGF is expressed dominantly in the epithelial cells. Later, expression increases in the decidual leukocytes, which remain a major source of VEGF in placental tissues.[84,88–92] The production of VEGF and PLGF by decidual NK cells and macrophages and the presence of Flt-1 on human intermediate and extravillous trophoblasts are an important part of the complex interplay between the immunologically driven expression of growth factors by decidual leukocytes and trophoblast receptors.[1,84,93] VEGF is up-regulated by hypoxia. The control is homeostatic; neovascularization induced by hypoxia corrects tissue oxygenation and VEGF release is down-regulated. The up-regulation of VEGF by hypoxia may provide an important mechanism through which the placenta develops according to its metabolic requirements. This mechanism may have particular relevance in the first 10 weeks of pregnancy, when oxygen tension of trophoblastic villi is particularly low.[91,94,95] In contrast to VEGF, PLGF is down-regulated by hypoxia in trophoblastic cell cultures grown in vitro.[96,97]

Soluble Flt-1 (sFlt-1), a soluble version of the VEGF receptor generated by alternative splicing of the Flt-1 gene, is a major endogenous angiogenesis inhibitor because it retains the ability to bind to VEGF and PLGF while preventing VEGF and PLGF binding to cell-surface receptors. The subsequent deficiency of free VEGF and PLGF leads to a state of endothelial dysfunction.[93] Early in pregnancy, pro-angiogenic proteins are overexpressed (placental angiogenesis and increasing placental mass), whereas toward the end of pregnancy, antiangiogenic factors increase in expression, possibly in preparation for delivery[88,93]; as such, sFlt-1 might be involved in the return to booking BP often observed near term. Messenger RNA for sFlt-1 is up-regulated in pre-eclamptic placentas, leading to increased systemic levels of sFlt-1 falling to baseline 48 hours after delivery.[90,93] These increased sFlt-1 levels result in decreased circulating levels of free VEGF and PLGF in preeclampsia and endothelial cell dysfunction.[88,90,93,98] Excessive levels of sFlt-1 are not the only player causing the antiangiogenic state in preeclampsia.[99] A novel soluble form of endoglin (sEng) of placental origin is present in the sera of pregnant women, is elevated in preeclamptic individuals, and correlates with disease severity.[99] Notably, sEng acts in concert with sFlt-1 to amplify endothelial dysfunction and induce clinical signs of severe preeclampsia, including HELLP syndrome and IUGR. Analogous to sFlt-1, circulating sEng starts rising 6 to 10 weeks before clinical symptoms of preeclampsia.[99] A recent development was the discovery of a human-specific splicing variant of VEGF receptor 1, designated sFlt1-14, qualitatively different from the previously described sFlt-1 and a potent VEGF inhibitor.[100] The fact that preeclampsia is a human-specific disease and that sFlt1-14 is a human-specific protein raises the speculation that a unique aspect in sFlt1-14 regulation or a unique, yet unidentified, biologic property of this protein is responsible for this disease.[100]

Immunology of Preeclampsia

The invasion of trophoblasts into the decidua and myometrium appears to be primarily controlled by immune mechanisms. STBs do not express class human leukocyte antigen (HLA) mRNA. Whereas all of the classic class I HLA antigens are absent, apart from HLA-C, the invading CTBs express the nonclassic HLA-G and HLA-E. Initially, it was thought that the presence of HLA-G, being monomorphic, played an important role in the afferent arm of maternal tolerance to the fetus, through failing to be perceived as "foreign" while still protecting the trophoblast from NK cell–mediated cytotoxicity. Today, we know that HLA-G expressed on the invading CTB plays an even more important role in the required vascular adaptations in the placental bed.[84] Because T cells were believed to be the unique immune cells required for adaptive immune responses, absence of major T-cell interaction in preeclampsia appeared to negate the immune maladaptation hypothesis.[76] This concept was radically changed by the realization of the major role played by the decidual NK cells. The predominant population of lymphoid cells in the decidua consists of NK cells; T and B cells are rare. NK cells express inhibitory and activatory killer cell immunoglobulin-like receptors (KIRs) capable of recognizing HLA-class I molecules. Uterine NK cells influence both trophoblast invasion and the maternal placental bed vascular changes by producing a series of cytokines

involved in angiogenesis and vascular stability, in particular VEGF, PLGF, and angiotensin-2.[84,89] Moffett-King and colleagues[84] changed our understanding of the importance of the HLA-C–NK cell receptor interaction. HLA-C loci are dimorphic for residues 77 to 80 and these two HLA-C groups interact with different NK cell receptors. There is great diversity of NK KIR haplotypes in humans with variations in the number of genes as well as polymorphisms at individual loci. All women express KIRs on decidual NK cells for both groups of HLA-C alleles, and because HLA-C is polymorphic, each pregnancy will involve different combinations of paternally derived fetal HLA-C and maternal KIRs. Therefore, each pregnancy is based on a unique couple-specific immune interaction not necessarily involving T cells but NK cells interacting with "paternal" HLA. Mothers lacking most or all activating KIRs (AA genotype) when the fetus had HLA-C, belonging to the HLA-C2 group, are at a substantial risk of preeclampsia.[101] Interestingly, recent studies have also shown that regulatory T cells are involved in specific immune tolerance to fetal alloantigens during pregnancy.[102–104] A major part of the protective effect of previous sperm exposure[55,56] is conveyed by sperm cells.[39] Intercourse provokes a cascade of cellular and molecular events that resemble a classic inflammatory response. The critical seminal factor appears to be seminal vesicle derived transforming growth factor-b1 (TGF-b1). By initiating a postmating inflammatory reaction, TGF-b1 increases the ability to sample and process paternal antigens (HLA-C?) contained within the ejaculate. The processing of paternal antigens by antigen-presenting cells in an environment containing TGF-b1 will initiate a "type 2" immune response. By initiating a type 2 immune response toward paternal ejaculate antigens, seminal TGF-b1 may inhibit the induction of type 1 responses against the semiallogenic conceptus that are thought to be associated with poor placental and fetal development.[40,105,106]

Placental Ischemia/Placental Debris Hypothesis

Circulating placental debris (STB microvillous membrane particles, free fetal DNA, and cytokeratin) is likely to be an important part of the systemic inflammatory stimulus associated with normal and preeclamptic pregnancies. Increased deportation of placental tissue in future preeclamptics is already detectable at 16 to 18 weeks.[107–109] The increased STB deportation in preeclampsia is explained by the presence of syncytial sprouds that may be elongated on long pedicles—interestingly, also the source for sFlt-14.[100] Apoptosis plays a central role in the formation of STB from the underlying villous CTB. Apoptosis, causing controlled cell fragmentation and allowing continuous renewal of the syncytial surface, is increased in preeclampsia.[110–112] In maternal blood, there are more apoptotic microparticles than trophoblastic microparticles, particularly in preeclampsia. The maternal inflammatory response is the likely cause of the increased endothelial cell and leukocyte apoptosis.[113] In the earlier stages of a preeclamptic pregnancy, increased apoptosis could be explained by the maternal-fetal immune maladaptation (tumor necrosis factor [TNF], interferon-γ [IFN-γ], Fas-FAS ligand)[114,115]; later on, placental ischemia-reperfusion probably plays a major role.[113] Not only "placental debris" but many other placental factors are found in the maternal circulation in normal pregnancy, with increased

levels in preeclampsia. These include several inflammatory cytokines, corticotropin-releasing hormone (CRH), and activin A; all could be potential stimulators of the maternal inflammatory response.[113] The maternal inflammatory response syndrome and placental ischemia-reperfusion injury are also responsible for the oxidative stress in preeclampsia.[66,116]

Genetic Conflict Hypothesis

According to Haig's genetic conflict theory,[117] fetal genes will be selected to increase the transfer of nutrients to the fetus, and maternal genes will be selected to limit transfers in excess of some maternal optimum. The phenomenon of genomic imprinting means that within fetal cells, a similar conflict exists between genes that are maternally derived and genes that are paternally derived. The conflict hypothesis predicts that placental factors (fetal genes) will act to increase maternal BP, whereas maternal factors will act to reduce BP. Placental factors have this opportunity to preferentially increase nonplacental resistance because the uteroplacental arteries are highly modified and unresponsive to vasoconstrictors. The intrinsic effects of a high maternal systemic BP are ultimately beneficial to the fetus. Thus, the genetic conflict hypothesis[117] predicts that fetal genes will enhance the flow of maternal blood through the intervillous space by increasing maternal BP (perfusion pressure). The genetic conflict hypothesis predicts that a mother's BP, as a continuum, is determined by the balance between fetal factors increasing BP and maternal factors decreasing BP. Causing maternal endothelial cell activation may have evolved as a high risk fetal strategy to increase nonplacental resistance when the uteroplacental blood supply is inadequate. Small increments in birth weight of semistarved fetuses may often have caused major increases in subsequent survival despite substantial costs to the mother. The balance between angiogenic growth factors and sFlt-1 (and the human-specific sFlt-14) provides a prime example of the molecular pathways predicted by Haig.[117] The magnitude of increase in sFlt-1 levels correlates with disease severity, lending further support that the VEGF–sFlt-1 (sFlt-14) balance represents a major final common pathophysiologic pathway.[118]

Maternal Susceptibility

There is a well-described maternal predisposition to preeclampsia, a clear and important maternal contribution that is of pivotal importance in determining the individual disease phenotype.

Maternal Susceptibility Genes

It is unlikely that there is just one major critical "preeclampsia" gene. Such a gene should have committed "evolutionary" suicide, unless it also carried a major reproductive advantage. More likely, we will see a rapidly growing number of susceptibility genes, many of these interacting with the maternal cardiovascular/hemostatic system and/or regulation of maternal inflammatory responses. Current models suggest a heritability estimate of 30% for preeclampsia.[119]

Thrombophilias

After initial studies[50,120,121] showed a clear association between maternal thrombophilias and early-onset preeclampsia,

several studies were unable to reproduce these findings.[122,123] However, systematic reviews[48,49,124,125] have confirmed an overall higher rate of acquired (primarily antiphospholipids) and genetic thrombophilias in women with severe early-onset preeclampsia compared with controls. The apparent controversy probably reflects the heterogeneous nature of preeclampsia and the heterogeneity of the patients being studied.[125] In a "two-hit" type model of preeclampsia in which a triggering event is exacerbated by other factors, thrombophilias clearly function as the exacerbating factor or "second hit." The surface of apoptotic cells is highly procoagulant activity.[126] Apoptotic CTBs in spiral arteries could elicit fibrin deposition as well as platelet activation. Any underlying thrombophilia will greatly augment this pathophysiologic process.[1]

Age

Extremes of age are known risk factors for preeclampsia. A short period of sperm exposure is the most likely explanation for the high risk of preeclampsia among teenagers.[55,56] For the more advanced maternal age categories, the significant positive relation between age (as a continuum) and the incidence of preeclampsia probably reflects a combined effect of "ageing" endothelium and the higher incidence of other adverse factors, in particular increased booking BP and body mass index (BMI).[127]

Chronic Hypertension

Increased booking BP is a major risk factor for preeclampsia.[26,128]

Obesity

Obesity is a definite risk for both gestational hypertension and preeclampsia. The risk of preeclampsia typically doubles with each 5 to 7 kg/m^2 increase in prepregnancy BMI.[45,46] In addition to the increased cytokine-mediated inflammation and oxidative stress,[68] possible explanations[76] include increased shear stress, dyslipidemia,[68] and increased sympathetic activity.[129] Figure 35–3 provides an overview of the major processes involved in the pathogenesis of preeclampsia.

Maternal Changes and Risks

Cardiovascular System

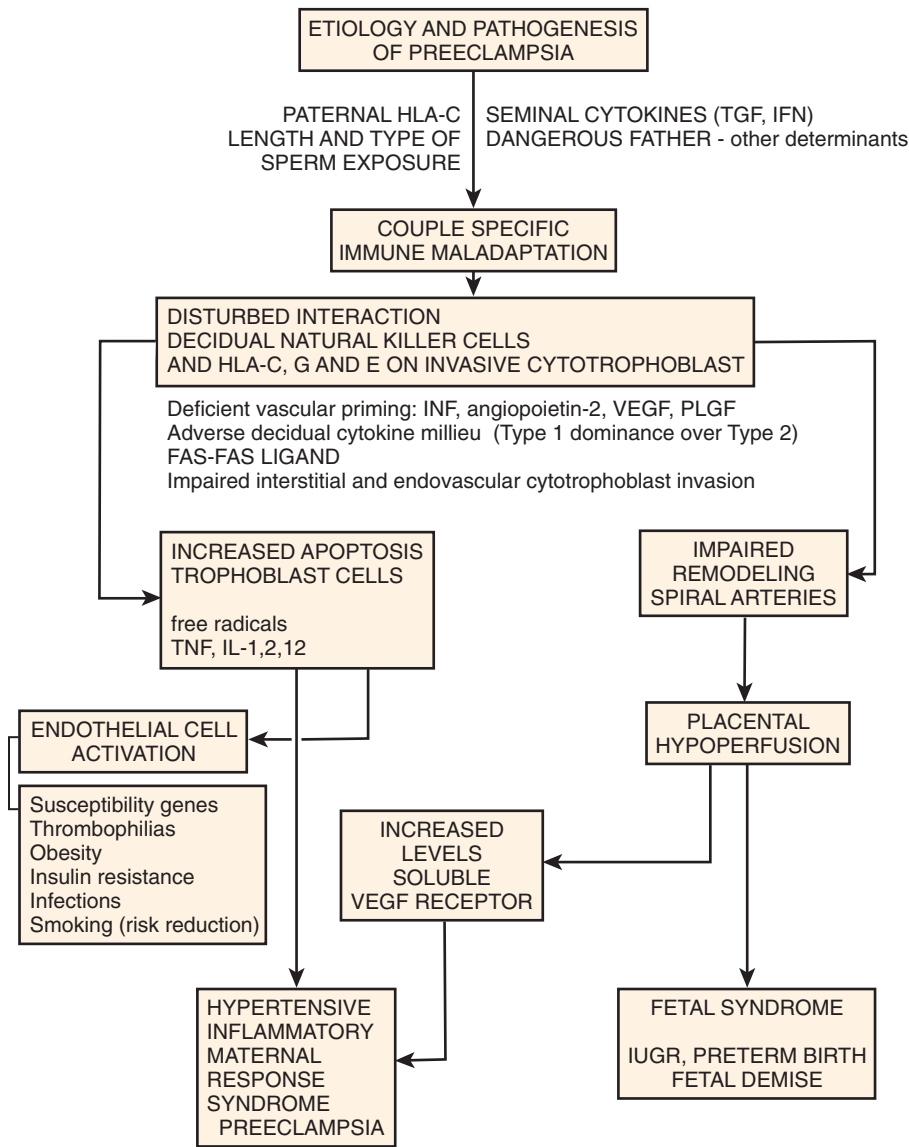
Total body water increases by 6 to 9 L during normal pregnancy, equally divided between the fetus and the mother. Expansion of the plasma volume accounts for 20% to 25% of the increase in extracellular space; the other 75% to 80% are increments in interstitial fluid. The greatest increase in interstitial fluid occurs in the third trimester, contrasting with the increment in plasma volume, taking place primarily in the first and second trimesters. The increase in blood volume is already detectable at 6 weeks. It reaches a level about 40% higher than that in nonpregnant values at 30 weeks and then remains stable until term.[130,131] The increase in plasma volume correlates closely with newborn weight, even if fetal growth is impaired.[130] The average plasma volume in women with established pregnancy-induced hypertensive disease is about 9% below expected values and as much as 30% to 40% below normal in cases of severe preeclampsia. Hypovolemia in pregnancy-induced


FIGURE 35–3

hypertensive disorders has been identified in particular in cases associated with IUGR, oligohydramnios, and preterm labor.[132–136]

Whereas the mean red cell mass rises during pregnancy, the relatively greater increase in plasma volume results in a gradual fall of the hematocrit until week 30, followed by a gradual rise. The physiologic hemodilution is associated with a decreased viscosity, which may be beneficial for intervillous space perfusion.[130]

Severe preeclampsia is characterized by vasoconstriction and a "leaky" microcirculation, resulting in fluid moving into the extracellular interstitial space and relative hypovolemia. The red cell volume in preeclampsia is no different than in normotensive pregnancy. Thus, the hemoglobin concentration or hematocrit is a reasonable surrogate measure of plasma volume in preeclampsia. Abnormally high hemoglobin levels correlate with adverse perinatal outcome including low birth weight, low placental weight, increased incidence of prematurity and perinatal mortality, and

hypertension.[137–142] Hemoglobin concentrations may be elevated in the first and second trimesters in advance of clinical disease.[142–144] Edema and swelling, although not reliable signs of pregnancy-induced hypertensive disorders, are the clinical expression of this shift in the distribution of extracellular fluid. Pathologic edema is not caused by an increased intracapillary hydrostatic pressure, as is the case in normal pregnancy. Because of the increased precapillary resistance in preeclampsia, the intracapillary hydrostatic pressure is actually decreased. Pathologic edema is caused by increased microvascular permeability to plasma proteins, a reduction in plasma colloid osmotic pressure, and an increase in interstitial protein mass.[141] Pathologic edema appears suddenly and is associated with an accelerated rate of weight gain. Chesley[132,133] stated that if pedal edema does not regress overnight, the pregnant woman bears careful watching. Sudden swelling linked with a gain greater than 1 kg/wk over 2 to 3 weeks or greater than 2 kg in 1 week should warn the clinician. A woman with established

preeclampsia will often have facial and particularly periorbital edema in contrast to the physiologic pedal edema.

BP falls in the first and second trimesters, followed by a rise to levels similar to the nonpregnant level close to term. By 6 to 8 weeks' gestation, mean arterial blood pressure (MAP) is already decreased relative to the preconceptional reference levels.[145] Cardiac output begins to rise shortly after conception; 50% of the final increase in cardiac output is realized by 8 weeks' gestation. Cardiac output reaches a peak of 35% to 50% higher than resting, nonpregnant levels at the end of the second trimester. The increase in cardiac output is due to an increase in both stroke volume (10%) and pulse rate (5%–15%) and is accompanied by enlargement of the left ventricle. The sequential rise in heart rate before, and in stroke volume after, the fifth week is related to the underfilled state of the vascular bed and is triggered in an attempt to maintain cardiac output in a state of relative underfill. Cardiac output remains elevated until delivery, if not measured in the supine position. In the third trimester, about 65% of the additional cardiac output is distributed to the uteroplacental and renal circulation.[146–149] Because BP falls and cardiac output increases in pregnancy, systemic vascular resistance (SVR) must decrease. In the average woman, SVR falls from 1700 dynes/sec/cm^{-5} before pregnancy to about 900 dynes/sec/cm^{-5} in midpregnancy, rising to 1300 dynes/sec/cm^{-5} toward term. A decrease in SVR is one of the earliest maternal adjustments to pregnancy and is already observed during the luteal phase in women that subsequently become pregnant. The fall in arterial BP and afterload leads to a rise in cardiac output, primarily through an increase in heart rate.[150,151] The fall in arterial BP, together with the concomitant fall in venous tone, activates the volume-retaining mechanisms such as the renin-angiotensin-aldosterone system (RAAS) and the osmoregulatory system. The induced volume retention enhances preload and stroke volume.[150,151]

In preeclampsia, cardiac output, as measured with thermodilution, has been described as decreased, unchanged, and increased, and likewise, there are conflicting data regarding alterations in SVR and pulmonary capillary wedge pressure (PCWP).[152–156] Visser and Wallenburg[154] compared results of pulmonary artery catheter measurements in 87 preeclamptic women who had received no treatment with those obtained in 47 preeclamptic women who had received various drugs and intravenous fluids; 10 normotensive pregnant women served as controls. All measurements were performed between 25 and 34 weeks' gestation. The median (range) cardiac index in the untreated patients of 3.3 (2.0–5.3) L · min^{-1} · min^{-2} was significantly lower than that in the treated patients of 4.3 (2.4–7.6) L · min^{-1} · min^{-2}. The median (range) PCWP in the untreated group was 7 (1–20) mm Hg and did not differ from that of 7 mm Hg (0–25) in the treated group. The variability of all hemodynamic variables was much lower in untreated than in treated patients. Thus, the majority of the extremes in dynamic profiles in severe established preeclampsia, as reported in the literature, are probably related to a combination of iatrogenic artifacts, differences in disease severity, obesity, and the presence of underlying chronic hypertension and/or renal disease. Untreated patients with severe established early-onset preeclampsia, mostly associated with IUGR, show a rather uniform pattern of a low cardiac index, a high SVR index,

and low-normal filling pressures.[154] Longitudinal ultrasound studies have demonstrated, however, that preeclampsia is characterized by a high cardiac output before the onset of clinically severe disease; so patients may cross over from a high cardiac output–low SVR state in earlier stages to one of lower output and higher SVR in cases with severe early-onset established disease.[156]

Renal System

Glomerular endotheliosis, swollen intracapillary endothelial cells in the glomeruli, the hallmark renal lesion of preeclampsia, represents the primary renal manifestation of the aforementioned systemic endothelial cell activation. An increase in renal vascular resistance causes a reduction of renal blood flow. The excess sFlt-1 (sFlt-14) probably plays a major role in the causation of glomerular endotheliosis.[93] Glomerular filtration rate, ERPF (effective renal plasma flow), and filtration fraction all decrease in preeclampsia. After delivery, the functional decrements usually reverse quickly but can sometimes progress to acute tubular necrosis (ATN).

In 1983, MacGillivray[157] stated that "oliguria or anuria is a most important sign to look for in preeclampsia, as is an indication that the baby and placenta should be delivered promptly." Although oliguria is indeed a serious sign, it is not, as such, an indication for immediate delivery. Oliguria/anuria may be classified as prerenal, renal, and postrenal. In preeclampsia, hypovolemia, without serious intrarenal vasoconstriction, may cause oliguria. However, in most patients, oliguria/anuria is a consequence of a combination of glomerular endotheliosis, intrarenal vasoconstriction, and hypovolemia. Although acute renal failure (ARF) is a rare complication of preeclampsia (1 in 10,000–15,000),[158] preeclampsia is a major cause of obstetric ARF. ARF in preeclampsia is mostly caused by ATN, but sometimes, it is caused by the more ominous bilateral cortical necrosis variety. Relative oliguria in the early postpartum period is common, but this generally resolves spontaneously and can be treated conservatively, providing that the serum creatinine and urea levels do not increase alarmingly. ARF in a preeclamptic patient who is otherwise well has a good prognosis, with full recovery being the norm. Patients who develop renal complications of preeclampsia superimposed upon preexisting renal disease are at increased risk of bilateral renal cortical necrosis, which is associated with increased maternal mortality and persistent renal compromise. Renal failure due to preeclampsia in antenatal patients will almost always prompt delivery.

Abnormal Hemostasis

Platelet activation, a feature of normal pregnancy, is exaggerated in preeclampsia.[159] Abnormalities of the hemostatic system in preeclampsia are compatible with a local grade of compensated intravascular coagulation, secondary to platelet adherence at sites of endothelial cell damage, instead of the fibrinogen depletion and thrombocytopenia that occur in case of disseminated intravascular coagulation (DIC). Only in certain sites (such as uteroplacental vascular bed, liver, and kidneys) is there a local increase of thrombin formation and fibrin deposition. Vascular damage and platelet aggregation precede an increase in thrombin and fibrin formation.[80,160,161]

Thrombocytopenia (platelet count < 150,000 μL⁻¹) is common (5%–7%) in late pregnancy.[162] The most common cause of isolated thrombocytopenia in pregnancy is gestational thrombocytopenia. Gestational thrombocytopenia characteristically has its onset earlier in gestation than does preeclampsia, it is commonly detected as part of routine prenatal screening, and platelet counts rarely fall below 70,000 μL⁻¹. Thrombocytopenia is the most frequent hemostatic abnormality in established preeclampsia; 20% of all patients with a pregnancy-induced hypertensive disorder develop mild thrombocytopenia (>50,000 μL⁻¹) varying between 7% in mild disease to 30% to 50% in severe preeclampsia and eclampsia.[132,163–165] Preeclamptic patients, in particular when IUGR is present, may show a marked day-to-day variability in platelet counts as well as in platelet volume distribution.[166] The thrombocytopenia in severe preeclampsia does not commonly fall below 50,000 μL⁻¹,[165] and when it does, other diagnoses should be considered (see Chapter 40).

The key features of the HELLP syndrome[167] are shown in Table 35–4.[19] Most patients with HELLP syndrome show decreasing platelet counts until 24 to 48 hours after delivery. Although more than 90% of cases of thrombocytopenia associated with preeclampsia should resolve by postpartum day 4, women with severe thrombocytopenia (platelet count < 50 × 10⁹/L) may require more than 10 days to achieve a platelet count greater than 100,000 μL⁻¹. Recovery is typically followed by a marked thrombocytosis. HELLP syndrome is a manifestation of a microangiopathic process and not a form of DIC, although there are often signs of locally increased localized coagulation (uteroplacental vascular bed, kidney, and liver). The localized increase in intravascular coagulation is secondary to endothelial cell injury. The high incidence of DIC reported by some authors is probably caused by the fact that the patients in these studies are already in the (pre) terminal stage of their disease process. In general, only if a patient's platelet count falls consistently lower than 80,000 μL⁻¹, an increasing percentage of patients with HELLP syndrome show evidence of increased intravascular thrombin production and accelerated fibrin consumption that can be documented with more or less sophisticated coagulation studies, such as antithrombin (AT), thrombin-antithrombin (TAT) complexes, fibrininopeptide A, and D-dimer measurements. Only in well-advanced cases of HELLP syndrome with platelets lower than 50,000 μL⁻¹ and lactate dehydrogenase (LDH) levels greater than 600 IU/L do routinely available clinical laboratory tests of fibrinogen and fibrinogen degradation products (FDPs) become abnormal, occasionally with some prolongation of the prothrombin time (PT) and activated partial thromboplastin time (aPTT). In case of HELLP syndrome, microangiopathic hemolytic anemia (MAHA) and severe thrombocytopenia precede the appearance of fibrin consumption and DIC and not the reverse, as seen, for instance, in patients with placental abruption.[80] The corollary of all of this is that a HELLP syndrome patient with DIC is really in the very advanced stage of the disease process.

The Liver

Hepatic involvement in the HELLP syndrome is not caused by excessive vasoconstriction of the hepatic arterial circulation,[168] but related to excessive fibrin-fibrinogen deposition in the hepatic sinusoids. In severe preeclampsia, large deposits of fibrin-like material obstruct blood flow in sinusoids and cause hepatic capsular distension, which may cause upper epigastric pain.[1] This is a problem in 90% of HELLP syndrome patients. In addition, 50% have nausea and/or vomiting, and others have nonspecific viral syndrome–like symptoms.[19,169] The majority of patients (90%) will have a history of malaise for a few days prior to presentation. On physical examination, 80% will have right upper quadrant tenderness and 60% significant weight gain with generalized edema. Hypertension may be absent (20%), mild (30%), or severe (50%).[169] Some patients may present with gastrointestinal bleeding, hematuria, flank or shoulder pain, and jaundice. Such patients are often misdiagnosed as having various medical and surgical disorders. Cholelithiasis, cholecystitis, hepatitis, acute fatty liver of pregnancy, pancreatitis, perforated peptic ulcer, severe hiatus hernia, pyelonephritis, and Budd-Chiari syndrome should be included in the differential diagnosis of epigastric or right upper quadrant pain during pregnancy and ,thus, in the differential diagnosis of HELLP syndrome. Subcapsular hematoma and liver rupture are further extensions of the HELLP syndrome with patients presenting with severe epigastric pain, shoulder pain, shock, evidence of massive ascites (hemoperitoneum), respiratory difficulties, or pleural effusions. When the rupture is contained within the capsule, the patient experiences severe pain but is hemodynamically stable. Subcapsular hematomata are clearly visible by ultrasonography and computed tomography (CT) scanning. The CT scan is likely more useful, because it is less operator-dependent and can visualize the entire abdomen. Ultrasonography, however, is more practical to perform, because the equipment is often on hand in an obstetric unit. Most often, the hematoma is on the anterior or inferior surface of the right lobe of the liver. A right pleural effusion may occur in some cases. A peritoneal tap may be used to differentiate between ascites and peritoneal blood.[19,169]

The Brain

Eclampsia is defined as the onset of convulsions and/or coma in women who have either gestational hypertension or preeclampsia. However, a series in the 1990s demonstrated that at the onset of convulsions, 23% had minimal or absent hypertension, 19% did not have proteinuria, and edema was absent in 32%.[170] This said, eclampsia occurs seven to eight

times more commonly in the context of proteinuric than in nonproteinuric pregnancy-induced hypertensive disease, and the average BPs of women with eclampsia are higher than those with severe preeclampsia.[171] In general, eclamptic seizures are grand mal in character with tonic/clonic phases; focal seizures have been described occasionally. Cerebral signs and symptoms of preeclampsia-eclampsia are headache, dizziness, tinnitus, hyperreflexia, clonus, drowsiness, mental changes, visual disturbances, paresthesias, and seizures. Headache has long been recognized as a harbinger of eclampsia. The headache is unrelieved by salicylates or phenacetin and is frequently described as "throbbing." The precise mechanism of these headaches is not certain, although hypertensive encephalopathy, cerebral vasospasm, and abnormal cerebral perfusion pressure are intimately involved.[172] To distinguish eclampsia from preeclampsia by the occurrence of at least one convulsion is too restrictive. For instance, cortical blindness is excluded even though the pathology is identical to the lesions causing convulsions. Furthermore, preeclamptic patients can become comatose without convulsing.[173] Hyperreflexia and clonus are hallmarks of severe preeclampsia. However, seizures may occur in the absence of hyperreflexia, and many young subjects have a consistent physiologic hyperreflexia. Clonus is "always" a pathologic sign and must warn the obstetrician of impending eclampsia.[174]

The most frequent symptoms preceding convulsions are headache (82.5%), visual disturbances (44.4%), and upper abdominal pain (19%).[174] Visual symptoms include scintillation (scotomata), chromatopsia, blurring of vision, diplopia, homonymous hemianopsia, and amaurosis. Visual disturbances in severe preeclampsia may be similar to the "aura" preceding migraine attacks, may include flashing or multicolored lights, and may range from blurring to scotomata and temporary blindness. Retinal arteriolar spasm, ischemia, and edema are believed to produce these visual disturbances.[175] Blindness is uncommon (1%–3% incidence in eclampsia). Chesley[132] reported an incidence of amaurosis of 4.3% among 330 eclamptic women. Women with amaurosis usually recover completely within 1 week. Retinal detachment also may cause altered vision, although it is usually one-sided and seldom causes total loss of vision. Without surgical treatment, vision returns to normal within approximately 1 week.[176] Magnesium intravenously is known to cause neuroophthalmic effects, which may thus cause a differential diagnostic problem. However, there are significant differences between preeclamptic visual complaints and those induced by magnesium. Preeclampsia-eclampsia is associated with positive and negative scotomata and/or segmental visual blurring; use of magnesium intravenously is associated with blurred vision and diplopia.[177]

Current data suggest that hypertensive encephalopathy and overperfusion of the brain occur in women with preeclampsia. Middle cerebral artery (MCA) and posterior cerebral artery (PCA) blood flow (as determined by magnetic resonance imaging [MRI]) and MCA velocity and cerebral perfusion pressure are increased in women with severe preeclampsia when compared with normotensive pregnant women.[178] These women are different from normotensive women, who have decreases in the MRI-calculated blood flow in large arteries (MCA and PCA) and Doppler-calculated velocities with increasing gestational age.[179] This

overperfusion is coupled with capillary leak and vasogenic edema in most cases of eclampsia and may, in some cases of severe eclampsia, result in local areas of infarction (cytotoxic edema). MRI findings of focal and generalized vasogenic edema are more apparent in eclampsia than in severe preeclampsia, and permanent infarction with the development of cytotoxic edema was demonstrated in about 20% of women with eclampsia in whom MRI of the brain is performed. The role of vasospasm as the primary mechanism of eclampsia in women with severe preeclampsia is challenged by the more recent data that suggest hypertensive encephalopathy as the initiating injury. Secondary vasospasm may well then follow the primary pathophysiology, and the reported vasospasm in cases of eclampsia may be a reflection of the severity of the case, the long interval between the seizure and the imaging, and the development of cytotoxic edema and cerebral infarction. In the future, it may be possible to delineate different groups of patients with predominant vasogenic or cytotoxic edema, and this may significantly influence management.[178–181] Cortical blindness in preeclampsia-eclampsia is caused by multiple microinfarctions and microhemorrhages with edema in the occipital gray matter. Each flash or streak of light experienced in cases of severe preeclampsia could signal the occurrence of another small lesion. In aggregate, these lesions cause cortical blindness, although the syndrome may not be complete because light is perceived. The pupils continue to react to light (midbrain reflex), but the ability to blink in response to a threat is lost. If the lesion is complete, optokinetic nystagmus is absent, and the patient is indifferent to the blindness (Anton's symptom).[173] The so-called posterior reversible encephalopathy syndrome (PRES), with cortical blindness as its cardinal clinical feature, should have the same clinical significance as eclamptic seizures, because the pathology is probably more or less identical.[182] Papilledema in eclampsia signifies cerebral edema.

Fetal/Neonatal Risks and Overall Outcome

Maternal and perinatal outcomes in preeclampsia are dependent on gestational age at time of onset and/or at time of delivery, severity of disease process, quality of management used, and presence or absence of preexisting medical conditions.[1–4,61,183] Maternal and perinatal outcomes are usually favorable in women with mild preeclampsia developing beyond 36 weeks' gestation.[2,9] In contrast, maternal and perinatal morbidities and mortalities are increased in women who develop preeclampsia before 33 weeks' gestation,[2,184] in those with preexisting medical conditions,[19,26,32,34,48–50,183] and in those from the developing countries.[185]

Approximately 1 in 6 babies born to mothers with preeclampsia is very preterm (<32 weeks' gestation), and often severely growth-restricted. In contrast, two thirds are delivered after 37 weeks, most of whom are normally grown, healthy babies.[1,4] The increased risk of prematurity is both iatrogenic and spontaneous. Several studies have shown that term and post-term preeclampsia is associated with an increased mean birth weight.[1] The rate of neonatal complications is markedly increased in those who develop severe preeclampsia in the second trimester, whereas it is minimally increased in those with severe preeclampsia beyond 35 weeks' gestation. Perinatal risks relate largely to the

gestational age at delivery, and also to the degree of IUGR.[184] Neonatal complications are also worse if there is associated perinatal hypoxia.

Severe preeclampsia is also associated with an increased risk of maternal mortality (0.2%) and increased rates of maternal morbidity (5%) with conditions such as convulsions, intracranial hemorrhage/infarction, pulmonary edema, acute renal or liver failure, liver hemorrhage, pancreatitis, and DIC. These complications are usually seen in women who develop preeclampsia before 32 weeks' gestation and in those with preexisting medical conditions.[2,169]

Management Options

Prepregnancy

PRIMARY PREVENTION

Several factors known to increase the risk of preeclampsia can be addressed before pregnancy and are, therefore, at least potentially amenable to intervention before attempts at conception.[186] Lengthier sexual relationships preceding the first pregnancy would be expected to translate in a lower risk for preeclampsia,[55,56] but for mostly pragmatic reasons, it will difficult to introduce this as primary preventive strategy. Weight control might offer the potential for affecting gestational outcomes. Women who are overweight or obese should be encouraged to achieve an ideal body weight before conception in an attempt to reduce their risk of preeclampsia. There are no randomized studies, however, to prove this benefit.[187,188] Pre-, periconception, and first-trimester vitamin B supplementation, in particular folate and B_{12}, might reduce the risks not only for neural tube defects, congenital cardiac defects, and cleft palates but also for preeclampsia (risk reduction > 50%).[189,190] Interestingly, this "preventive" effect appears to be limited to lean, multivitamin users.[189] It is not certain whether or this preventive effect operates via lowering maternal homocysteine levels.

Women with Chronic Hypertension and/or Diabetes

Women with chronic hypertension should achieve control of their BP before conception. Again, there are no randomized studies to prove such a benefit. Women with pregestational diabetes mellitus should be encouraged to complete childbearing as early as possible and before vascular complications develop and to aggressively control their diabetes and hypertension (if present) for at least several months before conception and throughout the pregnancy.[191]

Prenatal

PREDICTION

Increased vigilance is advisable in patients a increased risk factors (e.g., chronic hypertension, renal disease, connective tissue disorder, diabetes mellitus, previous preeclampsia).[189,191]

Numerous clinical and biochemical markers have been proposed to predict which women are destined to develop preeclampsia, and a detailed overview of this extensive literature is outside the scope of this chapter. For many of these tests, low predictive values have been established convincingly (e.g., mean BP in second trimester; rollover test;

isometric exercise test; platelet count; microalbuminuria, hematocrit; and serum uric acid and magnesium, calcium, and total proteins); others are too invasive as well as costly (e.g., intravenous infusion of angiotensin II).[185] Most biochemical markers were chosen on the basis of specific pathophysiologic abnormalities that have been reported in association with preeclampsia.[185,192] Thus, these markers have included markers of placental dysfunction,[59,193] endothelial and coagulation activation,[70,185,192] renal involvement, and markers of systemic inflammation.[60,64,194] These biomarkers have been reported to be either elevated or reduced in the maternal circulation early in gestation before the onset of preeclampsia. Table 35–5 presents a list of those markers studied intensively since the 1980s.[185] However, the results of various studies evaluating the reliability of these markers in predicting preeclampsia have been inconsistent, and many of these markers suffer from poor specificity and predictive values for routine use in clinical practice.[185,192]

Not surprisingly, there has been a search of interest in circulating antiangiogenic and angiogenic factors before and after the onset of preeclampsia.[193] PLGF is reduced whereas sFLt-1 and endoglin levels are elevated before and after the onset of preeclampsia.[193] Some studies also have found that the magnitude of the imbalance between serum sFLt-1 and serum PLGF (sFLt-1/PLGF ratio) correlates with disease severity as well as early onset of preeclampsia.[90,99,193,195] However, a 2006 systematic review[90] concluded that the evidence is insufficient to recommend these markers for use as screening tests because of differences among the various studies regarding gestational age at time of measurements, methods used for analysis, study population, and reporting of results.[90] More recent studies[196–198] have evaluated first-trimester levels of angiogenic factors as predictors for preeclampsia; only two of these studies found that reduced levels of PLGF are associated with subsequent preeclampsia,[196,197] whereas two found that sFlt-1 levels are not associated with preeclampsia.[197,198] Three other studies evaluated second-trimester levels of angiogenic factors for the prediction of preeclampsia.[199–201] One found that PLGF levels were lower but that sFLt-1 levels were not elevated in women who later developed severe preeclampsia.[199] Another study found serum-soluble endoglin levels were elevated in the second trimester in women who later developed severe, particularly early-onset, preeclampsia.[200] Moore Simas and associates[201] measured serial serum levels of PLGF and sFLt-1 from 22 to 36 weeks in 94 high-risk women and found the sFLt-1/PLGF ratio at 22 to 26 weeks to be highly predictive of early-onset preeclampsia.

Another novel biomarker, placental protein-13, is produced in the placenta and involved in implantation and maternal vascular remodeling. First-trimester placental protein-13 levels are significantly lower in preeclampsia compared with controls; placental protein-13 alone or in combination with the slope between the first and the second trimester may be a promising marker for preeclampsia.[202,203]

Currently, Doppler ultrasound of uterine artery velocity waveforms is the only method used in clinical practice, either as a general screening or in selected patients with a high a priori risk for preeclampsia and/or IUGR.[204,205] An abnormal uterine artery velocity waveform is characterized by a high resistance index and/or by the presence of an early

TABLE 35–5

Screening Tests for Preeclampsia Identified in the Literature

Placental Perfusion and Vascular Resistance Dysfunction–related Tests

Mean blood pressure in second trimester
Rollover test
Isometric exercise test
Intravenous infusion of angiotensin II
Platelet angiotensin II binding
Platelet calcium response to arginine vasopressin
Renin
24-hr ambulatory blood pressure monitoring
Doppler ultrasound

Fetoplacental Unit Endocrinology Dysfunction–related Tests

Human chorionic gonadotropin
α-Fetoprotein
Estriol
Inhibin A
Pregnancy-associated plasma protein-A
Activin A
Corticotropin release hormone

Renal Dysfunction–related Tests

Serum uric acid
Microalbuminuria
Urinary calcium excretion
Urinary kallikrein
Microtransferrinuria
N-Acetyl-β-glucosaminidase

Endothelial and Oxidant Stress Dysfunction-related Tests/Inflammatory Markers

Platelet count
Fibronectin
Platelet activation and endothelial cell adhesion molecules
Endothelin
Prostacyclin
Thromboxane
Cytokines
Homocysteine
Isoprostanes
Asymmetrical dimethylarginine
Serum lipids
Insulin resistance
Antiphospholipid antibodies
Plasminogen activator inhibitor
Placenta growth factor
Leptin
Hematocrit
Total proteins
Antithrombin III
Magnesium
Calcium
Ferritin
Transferrin
Haptoglobin
Atrial natriuretic peptide
β_2-Microglobulin
CRP

Genetic Markers

diastolic notch (unilateral or bilateral). Pregnancies complicated by abnormal uterine artery Doppler findings in the second trimester are associated with more than a three- to sixfold increase in the rate of preeclampsia.[204,205] However, the sensitivity of an abnormal uterine artery Doppler for predicting preeclampsia and/or IUGR, as reported in systematic reviews, ranges from 20% to 60% with a positive predictive value of 6% to 40%.[185,204,205] Current data do not support this test for routine screening of pregnant women for preeclampsia, but uterine artery Doppler could be beneficial as a screening test in women at high risk for preeclampsia if an effective preventive treatment is available. Most authors and researchers agree that uterine artery Doppler has quite a high sensitive for early-onset preeclampsia associated with IUGR.[185,204,205] If overall test performance could be enhanced by the addition of clinical data, biomarkers, or both, 20 weeks would be the best time to perform uterine artery Doppler studies.[206]

SECONDARY PREVENTION

The overall risk for recurrence of preeclampsia is in the range of 14% for preeclampsia and the same for developing gestational hypertension in a next pregnancy,[207] whereas women with prior early-onset preeclampsia and/or significant chronic hypertension have recurrence rates exceeding 50%.[191,208] A number of agents have been studied for their ability to reduce the risk of preeclampsia and improve maternal and fetal outcomes. These include antiplatelet agents, vitamins, calcium, and heparin. Table 35–6 presents an overview of current strategies to prevent preeclampsia with the degree of supportive evidence.[1]

Antiplatelet Agents

The majority of randomized trials for the prevention of preeclampsia have used low-dose aspirin (LDA; 50–150 mg/dL). The rationale for recommending LDA prophylaxis is the theory that LDA in pregnancy inhibits platelet TxA_2 biosynthesis with minimal effects on vascular PGI_2 production, thus altering the balance in favor of PGI_2, and thus preventing the development of preeclampsia.[209] LDA has been the subject of a large number of studies and various statistical reassessments. The Perinatal Antiplatelet Review of International Studies (PARIS) Collaborative Group[209] performed a meta-analysis of the effectiveness and safety of LDA for the prevention of preeclampsia; 31 randomized trials involving 32,217 women are included in this review. For women assigned to LDA, the relative risk (RR) of developing preeclampsia was 0.90 (95% confidence interval [CI] 0.84–0.96). For women with a previous history of hypertension or preeclampsia ($n = 6107$) who were assigned to LDA, the RR for developing preeclampsia was 0.86 (95% CI 0.77–0.97). The reviewers concluded that LDA has small to moderate benefits when used for prevention of preeclampsia and is also safe. Results from a meta-analysis suggested that LDA improves pregnancy outcome in women with persistent increases in uterine Doppler resistance index at both 18 and 24 weeks' gestation.[210] However, in other studies with abnormal Doppler measurements of uterine arteries at 22 to 24 weeks' gestation, LDA after 23 weeks' gestation did not prevent preeclampsia.[211,212] A large, multicenter study including 2539 high-risk women with pregestational insulin-treated diabetes mellitus, chronic hypertension, multifetal

TABLE 35–6
Prevention of Preeclampsia

	PREGNANCY OUTCOME	RECOMMENDATION
Diet and exercise (I)	No reduction in preeclampsia	Insufficient evidence to recommend.*
Protein or salt (II) restriction	No reduction in preeclampsia	Not recommended.
Magnesium or zinc supplementation (I)	No reduction in preeclampsia	Not recommended.*
Fish-oil supplementation and other sources of fatty acids (I)	No effect in low risk or high risk populations	Insufficient evidence to recommend.*
Calcium supplementation (I)	Reduced preeclampsia in those at high risk and with low baseline dietary calcium intake No effect on perinatal outcome	Recommended for women at high risk of gestational hypertension and in communities with low dietary calcium intake.
Low-dose aspirin (I)	19% reduction in risk of preeclampsia, 16% reduction in fetal or neonatal deaths	Consider in high risk populations.
Heparin or low-molecular-weight heparin (III-3)	Reduced preeclampsia in women with renal disease and in women with thrombophilia	Lack of randomized trials, not recommended.
Antioxidant vitamins (C, E) (I)	No reduction in preeclampsia	Number of adverse effects including increased risk of stillbirth and of birth weight < 2.5 kg. Not recommended.
Antihypertensive medications in women with chronic hypertension (I)	Risk of women developing severe hypertension reduced by half, but not risk of preeclampsia	No evidence to recommend for prevention.

* Insufficient evidence = small trials or inconclusive results.

gestation, or preeclampsia in a previous pregnancy showed no beneficial effects from LDA.[31] However, almost all studies on the prevention of preeclampsia so far focus on poor or inconsistent definitions of the disorder and not on actual perinatal outcome.[213] LDA use should be based on individualized risk assessment for preeclampsia.[36,209,214] In translating these results into clinical practice, the underlying risk of preeclampsia in the population being treated must be taken into consideration. If the baseline risk is 8%, treating 114 women will prevent 1 case of preeclampsia. In a population with a 20% risk of preeclampsia, the number needed to treat to prevent 1 case of preeclampsia is 50. In view of this potential benefit, and the relative absence of maternal or neonatal complications, LDA is indicated for the secondary prevention of preeclampsia in women at increased risk. In most cases, LDA may be ceased at 37 weeks' gestation, although continuation beyond this period is not unsafe.[209]

Calcium Supplements

A possible mode of action for calcium supplementation is that it reduces parathyroid and/or renin release, thereby decreasing intracellular calcium, and as such, reducing smooth muscle contractility. Calcium might also have an indirect effect on smooth muscle function by increasing magnesium levels. A theoretical risk of increased renal tract stone formation with calcium has not been substantiated, and no other adverse effects of calcium supplementation have been documented. Twelve clinical studies compared the use of calcium versus no treatment or a placebo in pregnancy.[215] These trials differ in the populations studied (low risk or high risk for hypertensive disorders of pregnancy), study design (randomization, double-blind, or use of a placebo), gestational age at enrollment (20–32 weeks' gestation), sample size in each group (range 22–4151), dose of elemental calcium used (156–2000 mg/day), and definition

of hypertensive disorders of pregnancy used. These 12 trials involving 15,206 women were included in a Cochrane review.[215] For women assigned to calcium, the RR for developing preeclampsia was 0.48 (95% CI 0.33–0.69). This systematic review concluded that calcium supplementation reduces the risk of preeclampsia and hypertensive disorders during pregnancy, particularly in populations that have diets deficient in calcium.[215] In contrast, a recent evidence-based review by the U.S. Food and Drug Administration (FDA)[216] concluded that "the relationship between calcium and risk of hypertension in pregnancy is inconsistent and inconclusive, and the relationship between calcium and the risk of pregnancy induced hypertension and preeclampsia is highly unlikely." None of the published randomized trials with calcium supplementation included women with a history of previous preeclampsia; therefore, the benefit of calcium supplementation for recurrent preeclampsia prevention remains unclear.[191] Calcium supplementation has also not been shown to have a significant beneficial effect on fetal and neonatal outcomes including preterm birth, low birth weight, IUGR, stillbirth or death before discharge from hospital.[191,215] The ideal patient to consider calcium supplementation appears to be the obese patient with a mildly elevated booking BP and a low dietary calcium intake.[215]

Other Therapies

Randomized, placebo-controlled trials of antioxidant vitamins C and E failed to demonstrate any significant effect on the incidence of preeclampsia. Of concern, a number of adverse effects were seen including an increased risk of stillbirth and of birth weight less than 2.5 kg, but there were fewer fetal deaths due to immaturity. Prophylactic antioxidant therapy with vitamins C and E is, therefore, not recommended.[217,218]

To date, there are no large randomized trials assessing the effect of heparin with or without aspirin in prevention of preeclampsia. As discussed previously, women with thrombophilias have an increased incidence of preeclampsia, and there has been enthusiasm for prophylactic treatment with anticoagulants, particularly low-molecular-weight heparin, with or without aspirin. Other than in the specific case of antiphospholipid antibody syndrome (for prevention of recurrent pregnancy loss), there is no randomized study to support this practice.[219]

PRENATAL CARE AND GENERAL MANAGEMENT PRINCIPLES

Most patients with a pregnancy-induced hypertensive disorder have no clinical symptoms. So it can be reliably detected only by screening for the early signs and symptoms in the second half of pregnancy. Adequate and proper prenatal care is the most important part of management of preeclampsia.[2,10,61,205] Maternal prenatal monitoring includes identifying women at increased risk, early detection of preeclampsia by recognizing clinical signs and symptoms, and observing progression to the severe form.[2,10,20,61]

The only effective treatment is to deliver the infant and placenta; ancillary therapy is predominantly symptomatic and not directed at underlying causes. Once the diagnosis of preeclampsia is made, subsequent therapy will depend on the results of initial maternal and fetal evaluation. The primary objective of management of preeclampsia must always be the safety of the mother. Although delivery is always appropriate for the mother, it may not be optimal for the fetus that is extremely premature. The decision between delivery and expectant management depends on fetal gestational age, maternal and fetal status at time of initial evaluation, presence of labor or rupture of fetal membranes (Fig. 35–4), and level of available neonatal and maternal services. The proposed management algorithm[1] and the following recommendations are based on observational studies and expert opinion. The individual components have not been subjected to appropriate large prospective, randomized, controlled clinical trials.

In general, women with mild preeclampsia developing at 38 weeks' gestation or longer have a pregnancy outcome similar to that found in normotensive pregnancy. Those patients should undergo induction of labor for delivery.[1,2,9] Induction of labor and/or delivery is also recommended for those at or beyond 34 weeks' gestation in the presence of severe preeclampsia, labor or rupture of membranes, or non–reassuring tests of fetal well-being (see Fig. 35–4) because the mother is at slightly increased risk for development of placental abruption and progression to eclampsia.[2,61] In women who remain undelivered, close maternal and fetal evaluation is essential. The type of test and frequency of evaluation will depend on fetal gestational age as well as severity of maternal condition and presence or absence of IUGR.[2,9,10,61]

EXPECTANT MANAGEMENT OF SEVERE PREECLAMPSIA

The clinical course of severe preeclampsia may be characterized by progressive deterioration in both maternal and fetal conditions.[220] There is universal agreement that such patients be delivered if the disease develops after 34 weeks' gestation.[1,2,9,10,61,220] Delivery is also indicated when there is

FIGURE 35–4
Overall management plan of preeclampsia.

imminent (persistent severe symptoms) or actual eclampsia, multiorgan dysfunction, severe IUGR, and/or placental abruption with non-reassuring fetal testing before 34 weeks' gestation.[1,2,61,220] There is disagreement, however, about treatment of patients with severe preeclampsia before 34 weeks' gestation in which the maternal condition is stable and the fetal condition is reassuring.[2,220] The Cochrane review on interventionist versus expectant care[221] states that it is not possible to draw firm conclusions, because there are only two small trials (133 women) that have compared a policy of early elective delivery with a policy of delayed delivery, and the CIs for all outcomes are wide. However, the evidence is promising that short-term morbidity for the baby may be reduced by a policy of expectant care.[221–223] A recent review on expected management of severe preeclampsia remote from term concluded that the results of all these studies suggest that expectant treatment in a select group of women with severe preeclampsia between the beginning of the 24th week and 33 weeks' gestation in a suitable hospital is safe and improves neonatal outcome.[224] Most studies on expectant management report 7 to 10 days of prolongation. For gestational age less than 24 weeks, expectant treatment

was associated with high maternal morbidity with limited perinatal benefit.[224] Ganzevoort and coworkers[225] studied expectant management in 216 patients presenting with early-onset hypertensive disease (24–34 wk′ gestation). In this study, 74% of the women with HELLP syndrome improved after inclusion and had a low risk of major complications, which did not differ from the other inclusion groups. All three inclusion groups (HELLP syndrome, severe preeclampsia, and gestational hypertension combined with IUGR) had a similar rate of major complications, and the median prolongation of pregnancy was of a similar duration. These authors concluded that prolongation of pregnancy in early-onset hypertensive disorders results in the development of further HELLP syndrome episodes and reversible major maternal morbidity but may improve perinatal healthy survival.[225]

If expectant management is undertaken, this should include serial investigation of maternal platelet count, hepatocellular enzymes, and renal function.

ANTIHYPERTENSIVE THERAPY

Although hypertension is only one manifestation of the disease, it is directly related to the cerebral complications.[184,223,226,227] The benefits of acute pharmacologic control of severe hypertension prior to delivery are generally accepted. The more contentious issues are the role of pharmacologic therapy in allowing prolongation of pregnancy and the ability of such therapy to modify the course of the underlying systemic disorder and affect fetal and maternal outcome. Some antihypertensive drugs affect the mother, some the fetus or newborn, some both mother and fetus/neonate.[228] The effects of antihypertensive drugs on the fetus may be indirect, by impairing uteroplacental perfusion, or direct, by influencing the fetal cardiovascular circulation. Although never formerly subjected to randomized, controlled trials, there is consensus that pregnant women with severe hypertension, that is, with diastolic BP values greater than 110 mm Hg, should receive pharmacologic treatment and that the goal in treatment of hypertension in pregnancy is to keep the systolic BP between 140 and 160 mm Hg and the diastolic BP between 90 and 105 mm Hg. Decreasing BP below 130/80 mm Hg is to be avoided. A sudden severe decrease in BP may cause poor uteroplacental perfusion and, therefore, fetal distress.[228,229]

Although the use of antihypertensive agents in women with preeclampsia and severe elevations in BP may prevent cerebrovascular accident, such treatment does not prevent preeclampsia or alter the natural course of the disease in women with mild preeclampsia.[2,230] Use of antihypertensive drugs for mild to moderate hypertension during pregnancy is still controversial. The most recent Cochrane review[231] included 40 studies (3797 women), 24 of which compared an antihypertensive drug with placebo/no antihypertensive drug (2815 women). The risk of developing severe hypertension associated with the use of antihypertensive drugs (17 trials, 2155 women; RR 0.52, 95% CI 0.41–0.64) was halved, but there was no difference in the risk of preeclampsia (19 trials, 2402 women; RR 0.99, 95% CI 0.84–1.18). Similarly, there was no clear effect on the risk of the baby dying (23 trials, 2727 women; RR 0.7, 95% CI 0.46–1.09), preterm birth (12 trials, 1738 women; RR 0.98, 95% CI 0.85–1.13), or small–for–gestational age babies (17 trials, 2159 women;

RR 1.13, 95% CI 0.91–1.42). In addition, 17 trials (1182 women) compared one antihypertensive drug with another. There was no clear difference between any of these drugs in the risk of developing severe hypertension and proteinuria/preeclampsia. The reviewers concluded that it remains unclear whether antihypertensive drug therapy for mild to moderate hypertension during pregnancy is worthwhile.[231] A meta-regression of antihypertensive drugs in pregnancy suggested that excessive lowering BP in women with mild disease may increase the risk of a small–for–gestational age baby.[232]

DRUGS FREQUENTLY USED IN THE MANAGEMENT OF PREECLAMPSIA

Methyldopa

Methyldopa lowers BP by reducing overall sympathetic outflow. Methyldopa reduces systemic vascular resistance without causing significant physiologic changes in heart rate or cardiac output.[233] Methyldopa is effective in mild to moderate hypertension, but a fall in arterial BP is achieved only 4 to 8 hrs after an oral dose. As monotherapy, it is not effective in severe hypertension.[233] Although methyldopa when administered to pregnant women with mild or moderate hypertension will reduce the risk of developing severe hypertension, it has no effect on the incidence of proteinuria, IUGR, preterm birth, or cesarean section. Methyldopa is, however, a very well established, useful drug in the management of chronic hypertension in pregnant women.[229–232] The safety of methyldopa during pregnancy in terms of its fetal effects has been followed for longer than 7 years, and no detrimental effects have been observed in exposed offspring.[234]

Hydralazine

During the past decades, intravenous hydralazine has been the drug of choice in the management of severe preeclampsia, given intravenously by continuous infusion or intermittent boluses or by intramuscular or subcutaneous injections. However, up to 50% of patients treated with hydralazine may demonstrate tachycardia, hypotension, palpitations, headache, nausea, vomiting, anxiety, tremors, epigastric pain, and fluid retention,[228] all side effects simulating features of impending eclampsia, and 15% of patients taking high doses of hydralazine daily will develop a lupus-like syndrome after long-lasting administration.[228] More important, hydralazine might cause a too drastic decrease in BP. Such a sudden decrease in BP might adversely affect uteroplacental blood flow and thus cause fetal distress. Fetal distress has been frequently observed with hydralazine infusion. Hydralazine does not inhibit vasoconstrictor responses to noradrenalin, vasopressin, and angiotensin II in human uteroplacental arteries. The uteroplacental vasoconstriction seen with intravenous hydralazine is attributed to increased plasma concentrations of noradrenaline.[228,235,236] The major disadvantages are delayed onset of action, variable peak effect, and fetal distress. Hydralazine is certainly effective, but mainly due to its commonly appearing maternal side effects and the relatively high incidence of overshoot hypotension and subsequent fetal distress, alternate treatments are preferred.[229] Hydralazine is no longer available in many European countries.

Labetalol

Labetalol is a competitive antagonist at β_1- and β_2-adrenoreceptors and has some intrinsic activity at β_2-adrenoreceptors. In addition to its β-blocking action, labetalol has a competitive action at postsynaptic α-adrenoreceptors. It lowers high BP by blocking α_1-adrenoreceptors in peripheral vessels and thereby reducing peripheral resistance, and the heart rate is reduced because of its β-blocking effect. Labetalol has become popular for the treatment of hypertension in pregnancy and preeclampsia. It has been used both intravenously and orally for rapid BP reduction. It effectively decreases maternal BP and, according to some studies, may reduce the occurrence of proteinuria and of fetal or neonatal complications.[237–239] In normotensive pregnancies, a single dose of labetalol does not affect the fetoplacental blood flow.[240]

Diazoxide

Diazoxide, a nondiuretic benzothiadiazine derivative, is a powerful direct vasodilator. Diazoxide also produces a prompt increase in blood glucose. It produces acute BP reduction in patients with severe pregnancy-induced hypertensive disorders. Diazoxide's effects are more rapid and longer lasting than those of hydralazine. Maternal cerebral ischemia, maternal death, and fetal distress following precipitous hypotension have been reported with its use.[241,242] Most units would not use diazoxide for the management of high BP in pregnancy, except in cases of extremely elevated BPs.[228] However, recently, Hennessy and colleagues[243] directly compared the efficacy of mini-bolus diazoxide with intravenous hydralazine; 124 women with severe ante- or postpartum hypertension were randomized to either intravenous hydralazine (5-mg doses) or mini-bolus diazoxide (15-mg doses). Reduction in systolic and diastolic BP was 34 minutes for hydralazine versus 19 minutes for diazoxide ($P < .001$). The mini-bolus doses of 15 mg of diazoxide did not precipitate maternal hypotension as previously described and reduced episodes of persistent severe hypertension compared with results with hydralazine.

Dihydropyridine Derivatives

Calcium antagonists are potent direct vasodilators. Most calcium channel blockers have a rapid onset of action and are effective and safe. Common side effects include severe headache, which can mimic impending eclampsia, hypotension, flushing, and ankle edema. Theoretically, magnesium salts potentiate the hypotensive actions of nifedipine because both drugs have calcium channel functions.[244,245] Indeed, two cases of profound muscle weakness and respiratory arrest have been reportedly associated with the combined use of nifedipine and magnesium.[246,247] However, several leading experts have emphasized that this is a very rare interaction, and this interaction has not been described in any of the randomized trials, including the so-called Magpie trial, in which 29% of patients received this combination.[229,248]

Thus, the five drugs most commonly used for managing severe hypertension in pregnancy all have potentially significant side effects and/or are not always effective in the acute situation or in the management of severe hypertension. In addition, all these drugs are not tailored in any way to the pathophysiology of preeclampsia. According to the Cochrane Database,[249] there is no evidence to justify a strong preference for one of the various drugs discussed so far, although hydralazine is clearly no longer the drug of choice as first-line treatment. Magee and associates[250] reviewed outcomes in randomized, controlled trials comparing hydralazine against other antihypertensives for severe hypertension in pregnancy; 21 trials (893 women), 8 compared hydralazine with nifedipine and 5 with labetalol. Hydralazine was associated with more maternal hypotension (RR 3.29, 95% CI 1.50–7.23), more cesarean sections (RR 1.30, 95% CI 1.08–1.59), more placental abruption (RR 4.17, 95% CI 1.19–14.28), more maternal oliguria (RR 4.00, 95% CI 1.22–12.50), more adverse effects on fetal heart rate (RR 2.04, 95% CI 1.32–3.16), and more low Apgar scores at 1 minute (RR 2.70, 95% CI 1.27–5.88). Hydralazine was also associated with more maternal side effects (RR 1.50, 95% CI 1.16–1.94). The authors concluded that the results are not robust enough to guide clinical practice, but they certainly do not support the use of hydralazine as first-line choice for treatment of severe hypertension in pregnancy.[250]

USE OF CORTICOSTEROIDS TO IMPROVE PREGNANCY OUTCOME IN WOMEN WITH SEVERE PREECLAMPSIA/HELLP SYNDROME

Accelerated fetal lung maturation does not occur in preeclampsia.[220] Infants born to pregnancies complicated by hypertension syndromes treated with corticosteroids have significantly reduced risk of neonatal death, respiratory distress syndrome, and cerebrovascular hemorrhage.[251] There is insufficient evidence to support antenatal corticosteroids for those pregnancies that have reached 34 weeks' gestation.[251] A randomized trial demonstrated a small benefit of antenatal corticosteroids to mothers undergoing a term (37–39 wk' gestation) elective cesarean section.[252]

With the recognition that inflammation plays a key role in the pathophysiology of preeclampsia, it was in itself not surprising to see a series of case-control studies published since the 1990s suggesting that high-dose steroids, mostly dexamethasone, could have a beneficial impact in modulating maternal disease severity, in particular, platelet count and, to a lesser extent, liver transaminases in patients with HELLP syndrome. However, two more recent large studies have demonstrated that the use of high-dose steroids in patients with HELLP syndrome, both antenatally[253] and postpartum,[254] is not associated with a demonstrable improvement in maternal outcome. However, a smaller Dutch trial[255] ($n = 31$) in women at less than 30 weeks' gestation with HELLP syndrome comparing 50 mg of prednisolone with placebo showed contrasting results. Patients in the prednisolone group had a significantly lower risk of a recurrent HELLP exacerbation after the initial crisis had subsided than patients in the placebo group (RR 0.3, 95% CI 0.3–0.9), and platelet counts recovered faster in the prednisolone group than in the placebo group (mean 1.7 days vs. 6.2 days; $P < .01$). The authors concluded that HELLP syndrome remote from term causes a high risk for serious maternal morbidity and mortality (in the placebo group, 1 maternal death occurred as a consequence of liver rupture), but suggested that when expectant management is pursued in selected patients with a HELLP syndrome remote from term, prolonged administration of prednisolone reduces the risk of recurrent HELLP syndrome exacerbations.[255]

PLASMA VOLUME EXPANSION, FLUID BALANCE, AND URINE OUTPUT

The observation that women with severe preeclampsia may have a restricted circulating plasma volume has led to the recommendation that plasma volume should be expanded with either colloid or crystalloid solutions in an effort to improve maternal systemic and uteroplacental circulation.[256] However, intravascular volume expansion carries a risk of volume overload, which might lead to pulmonary or cerebral edema. Also, large volume expansion often requires invasive monitoring of intravascular pressure, procedures carrying risks of their own. A large trial has demonstrated that ongoing plasma volume expansion has no demonstrable maternal and/or perinatal benefits.[257] Administration of fluid at a rate greater than normal requirements should be considered only for (1) women with severe preeclampsia immediately prior to parenteral hydralazine, regional anesthesia, or immediate delivery; or (2) initial management in women with oliguria in whom there is a suspected or confirmed deficit in intravascular volume.[10,258] In established preeclampsia, it is obligatory to monitor daily fluid intake and output. In severe preeclampsia, urine output should be measured on an hourly basis with a urinary catheter. In these patients, kidney function should be assessed at least twice daily. Most patients with acute renal failure (ARF) have a marked decrease in urine flow (<600 mL/24 hr).[258] Total anuria is rare in intrinsic renal failure but, if observed, suggests cortical necrosis as a possible diagnosis, although postrenal (obstructive) failure must always be considered. The initial treatment of ARF in the preeclamptic patient will depend upon the precipitating cause. Restoration of the intravascular volume with appropriate fluids should be carefully monitored to avoid precipitating pulmonary edema. The volume status in such patients can be very difficult to assess, and this is a situation in which central pressure monitoring can be useful. The development of progressive oliguria in preeclampsia despite prudent fluid challenge (≤2000 mL of crystalloid over 2 hr) is an indication for central hemodynamic assessment via a Swan-Ganz catheter.[259] Evidence of hypovolemia in the form of depressed PCWP should be treated with colloid and/or crystalloid infusion to maintain urinary output greater than 30 mL/hr and PCWP below 12 to 16 mm Hg, depending on the colloid osmotic pressure (COP) and clinical situation. Following improvement in urinary output, further fluid management should be directed toward correcting electrolyte and serum osmolarity imbalances. Oliguria in the context of elevated PCWP must be treated only after full assessment of cardiac output and SVR and an evaluation of cardiac function. The latter can be derived by graphing the left ventricular stroke work index versus PCWP. This modified Starling curve can be used to evaluate and subsequently maximize left ventricular function. In the patient with preeclampsia and oliguria with a normal or increased PCWP, increased SVR, and decreased cardiac output, vasodilators might improve renal perfusion. However, if the SVR is normal and the cardiac output is increased, a preload reducer, such as nitroglycerin, may be beneficial.[260]

Meticulous fetal surveillance is required in the context of antepartum preeclampsia-induced oliguria, because uteroplacental blood flow might be compromised. Diuretics are sometimes used to treat the oliguric phase of ATN, but there is no evidence that this will improve the speed of recovery or the eventual outcome.[261,262] Meticulous attention to fluid balance should ensure that urine output is replaced along with insensible losses, blood losses (from delivery), and other losses (diarrhea, vomiting).

PREVENTION OF CONVULSIONS AND CONTROL OF ACUTE CONVULSIONS

The basic principles of management of eclampsia involve (1) maternal support of vital functions; (2) control of convulsions and prevention of recurrent convulsions; (3) correction of maternal hypoxemia and/or acidemia; (4) control of severe hypertension to a safe range; and (5) initiation of the process of delivery. Eclamptic convulsions constitute a life-threatening emergency. During the eclamptic seizure, measures should be taken to prevent maternal injury, such as insertion of a padded tongue blade between the teeth, and to safeguard against potential maternal morbidity after the convulsion. The most urgent parts of the therapy are to assess airway patency, to ensure maternal oxygenation, and to minimize the risk of aspiration. Most eclamptic convulsions resolve in 60 to 90 seconds. Oxygen should be administered during the convulsive episode to improve maternal oxygen concentration and to increase oxygen delivery to the fetus. Eclampsia represents a maternal crisis; a crash cesarean section in an unstable eclamptic patient may result in the birth of a healthy baby but carries tremendous risks for the mother.[226,258] Transient fetal bradycardia lasting at least 3 to 5 minutes is a common finding after an eclamptic seizure and does not necessitate immediate delivery. Resolution of maternal seizure activity is often associated with compensatory fetal tachycardia and even with transient fetal heart rate decelerations that typically resolve within 20 to 30 minutes.[263] Every attempt should be made to stabilize the mother before making a decision about delivery.[226]

Magnesium

A 1995 landmark study compared the efficacy of magnesium sulfate with other anticonvulsants in women with eclampsia. This trial compared magnesium sulfate with diazepam, phenytoin, or a lytic cocktail. This study demonstrated that magnesium sulfate is associated with a significantly lower rate of recurrent seizures and a lower rate of maternal death than that observed with other anticonvulsants.[264] Magnesium is also the drug of choice for seizure prophylaxis in women with preeclampsia. Four large randomized, controlled trials compared the use of magnesium sulfate to prevent convulsions in patients with severe preeclampsia. The overall results of the four trials demonstrate that magnesium sulfate prophylaxis compared with placebo (two trials, 10,795 women), nimodipine (one trial, 1750 women), and no treatment (one trial, 228 women) in severe preeclampsia is associated with a significantly lower rate of eclampsia (RR 0.39, 95% CI 0.28–0.55).[251,265] The largest trial to date, the Magpie trial,[248] enrolled 10,141 women with preeclampsia (largely in the developing countries). Most of the enrolled patients had severe disease, and the rate of eclampsia was significantly lower in those assigned to magnesium sulfate (0.8% vs. 1.9%; RR 0.42, 95% CI 0.29–0.60). However, among the 1560 women enrolled in the western world, the rates of eclampsia were 0.5% in the magnesium group and 0.8% in the placebo, a nonsignificant

difference (RR 0.67, 95% CI 1.19–2.37). In addition, two randomized trials compared magnesium sulfate with a placebo in women with mild preeclampsia.[266] The results of these six trials demonstrate no benefit of magnesium sulfate on perinatal outcome and/or serious maternal complications of severe preeclampsia, such as pulmonary edema, stroke, liver, hematoma, or renal failure.[265,266] Available evidence suggests that magnesium sulfate should be given during labor and immediately postpartum in a select group of women with severe preeclampsia because the benefit of magnesium sulfate in women with mild preeclampsia remains unclear. The importance of magnesium sulfate in severe preeclampsia is illustrated by the results of a recent Dutch population-wide study demonstrating that the excess of eclampsia in the Netherlands compared with other Western European countries was found to be related to the fact that patients with classic symptoms of severe preeclampsia did not receive appropriate antihypertensive therapy and magnesium.[267]

Magnesium does not cause any significant maternal-neonatal central nervous system depression when used properly. During its administration, the mother is awake and alert with intact laryngeal reflexes, which helps to protect against aspiration. Fetal magnesium levels tend to equilibrate with maternal levels after prolonged administration; however, neural muscular depression in the newborn is rarely seen with proper use of the drug. In contrast, the use of other anticonvulsants, such as narcotics, sedatives, tranquilizers, and barbiturates, can cause significant maternal-neonatal central nervous system and respiratory depression. The use of these agents may decrease the laryngeal reflexes and allow aspiration.[268,269] As any potent drug, magnesium has significant side effects with the potential for serious magnesium toxicity. Table 35–7 shows the relationship between blood levels of magnesium and symptoms and signs. Magnesium toxicity can be reversed by slow intravenous administration of 10% calcium gluconate and nasal administration of oxygen. If toxicity is not reversed, respirations must be supported until plasma magnesium levels decrease.

FETAL SURVEILLANCE (see also Chapters 10 and 11)

Although fetal surveillance is commonly recommended and performed in women with hypertensive disease in pregnancy,[9,10] there is no consensus on how this should be performed.[2,270] Frequency, intensity, and modality of fetal evaluation will depend on the individual maternal and fetal characteristics. Individual obstetric units should devise their own protocols for monitoring the fetus in pregnancies complicated by hypertension. In compiling such protocols, the following issues should be considered[9,10]:

- Accurate dating of pregnancy is important for women at high risk of preeclampsia.
- Symphysis–to–fundal height measurement is a poor screening tool for detection of IUGR.[271] Therefore, ultrasound should be performed by an experienced operator to assess fetal size, amniotic fluid volume, and umbilical artery Doppler flows in such women. Assessing growth trends by serial ultrasound is recommended if pregnancy continues.
- Umbilical artery Doppler flow is the only fetal surveillance modality that has been shown by systematic review to reduce the need for fetal interventions, improve neonatal outcome, and predict adverse perinatal outcome.[272,273] Severe early-onset IUGR should be monitored at institutions experienced in advanced fetal Doppler waveform analysis. Absent or reversed end-diastolic flow is unlikely to occur within 7 to 10 days after a normal umbilical artery Doppler waveform analysis. Umbilical artery Doppler flow studies have limited value after 36 weeks' gestation.
- Although numerous observational studies have suggested improved outcome in high risk pregnancies monitored using protocols that included biophysical profile, cardiotocography, and combinations of both,[274–276] none of these has shown significant benefit in systematic reviews.[277,278] No fetal testing can predict an acute obstetric event such as placental abruption or cord accident. In practice, many use a comprehensive approach to fetal assessment employing several monitoring modalities.
- Fetal surveillance via a day assessment unit is associated with good perinatal outcome in women with various obstetric complications, including women with well-controlled hypertension.[279]
- An appropriately grown fetus in the third trimester in women with well-controlled chronic hypertension without superimposed preeclampsia is generally associated with a good perinatal outcome. Fetal monitoring using methods other than continued surveillance of fetal growth, umbilical artery blood flow, and amniotic fluid volume in the third trimester is unlikely to be more successful in preventing perinatal mortality/morbidity.

Table 35–8 demonstrates one example of commonly used international and national protocols for fetal surveillance in women with hypertensive disease in pregnancy in whom immediate delivery is deferred. However, none of these protocols has been tested in prospective, randomized trials.[10] Because preeclampsia is an ever-changing and unpredictable disease, for those women in whom expectant management is employed, the frequency and modality of fetal surveillance should be adjusted based on the current maternal and/or fetal condition. Each obstetric unit should develop an agreed institutional approach to fetal surveillance and/or fetal medicine referral.[10]

Early-onset preeclampsia with IUGR still represents a major obstetric dilemma. How IUGR progresses is determined by when it starts and how it starts, that is, gestational age and degree of umbilical artery abnormality at onset. In patients presenting much before 30 weeks, a pattern of worsening umbilical artery Doppler established in the first 7 to 10 days reliably predicts progression to venous Doppler

TABLE 35–7

Magnesium Sulfate Blood Levels

BLOOD LEVELS (MG/DL)	SYMPTOMS AND SIGNS
4–8	Therapeutic
9–12	Nausea, warmth, flushing, somnolence, double vision, slurred speech, weakness, loss of patellar reflexes
15–17	Muscular paralysis and respiratory arrest
30–35	Cardiac arrest

TABLE 35–8

Protocol for Fetal Surveillance in Women with Hypertension in Pregnancy

HYPERTENSION	MODALITY	FREQUENCY
Chronic hypertension	Early dating ultrasound	First trimester
	Ultrasound for fetal growth/AFV/UAD	As per clinical assessment
Gestational hypertension	Ultrasound for fetal growth/AFV/UAD	At time of diagnosis and every 3–4 wk
Preeclampsia	Ultrasound for fetal growth/AFV/UAD	At time of diagnosis and every 2–3 wk
	Cardiotocography	Twice weekly
Preeclampsia with IUGR	Cardiotocography	Twice weekly
	AFV/UAD	On admission and twice weekly
	Ultrasound for fetal growth	Every 2 wk

AFV, amniotic fluid volume; IUGR, intrauterine growth restriction; UAD, umbilical artery Doppler.

From Vatten LJ, Skjaerven R: Is preeclampsia more than one disease? BJOG 2004;111:298–302.

abnormalities and very early intervention (severe early-onset placental dysfunction). In those presenting closer to 30 weeks with decreased (but still present) umbilical artery end-diastolic velocity, Doppler progression is also typically forecast within the first 2 weeks of monitoring and falls into one of two patterns. If initial Doppler abnormalities have not worsened in that first interval, they are unlikely to do so, and abnormalities remain confined to umbilical and mild cerebral changes. These fetuses do not develop venous Doppler abnormalities and are likely to deliver near term (mild placental dysfunction). If the first few weeks of monitoring show progressive elevation of umbilical artery Doppler indices, progression to abnormal venous Doppler findings and preterm delivery become more likely (progressive placental dysfunction).[280] These fetuses require antenatal testing using multiple surveillance modalities to enhance prediction of birth pH. The incorporation of venous Doppler achieves the best prediction of acidemia. Although computerized analysis enhances fetal heart rate assessment, it has limitations as a stand-alone test in IUGR. Computerized cardiotocography performs best when combined with venous Doppler or as a substitute for the traditional nonstress test in the biophysical profile score.[280]

Labor and Delivery

All women with preeclampsia should receive continuous monitoring of fetal heart rate and uterine activity with special attention to avoiding hyperstimulation and development of vaginal bleeding during labor. The presence of uterine irritability and/or recurrent variable or late decelerations may be the first sign of abruptio placentae in these women. All women with severe preeclampsia should have BP recordings at least every hour during labor, and control of BP should be continued. Maternal pain relief during labor and delivery can be provided by either systemic opioids or segmental epidural anesthesia. Epidural anesthesia is safe in women with severe preeclampsia and may assist in BP stabilization. Regional anesthesia is contraindicated in the presence of coagulopathy or severe thrombocytopenia (platelet count < 50,000 μL^{-1}).[61] A plan for vaginal delivery should

be considered in all women with severe disease, particularly those beyond 30 weeks' gestation.[1,2,61] The decision to perform cesarean delivery should be based on fetal gestational age, fetal condition, presence of labor, and cervical Bishop score. In general, the presence of severe preeclampsia is not an indication for cesarean delivery. A common policy is to recommend elective cesarean delivery for all women with severe preeclampsia below 30 weeks' gestation who are not in labor in the presence of an unfavorable Bishop score.[281] In the management of the third stage, oxytocin is allowed, whereas ergometrin is contraindicated because of the risk of provoking a hypertensive crisis and cerebral vasospasm.

Postnatal
POSTPARTUM PREECLAMPSIA

In general, preeclampsia is cured by delivery of the placenta; however, it is common for the disease to worsen during the first 48 hours after delivery. Postpartum preeclamptic women are at risk for pulmonary edema, ARF, HELLP syndrome, postpartum eclampsia, and stroke. Therefore, women with diagnosed hypertension and/or preeclampsia require very close monitoring of BP, maternal symptoms, and measurements of fluid intake and urine output as well as laboratory parameters.[1,2,19] Severe hypertension or preeclampsia may develop for the first time in the postpartum period. Hence, postpartum women should be educated about signs and symptoms of preeclampsia. Women who report persistent severe headaches, visual changes, epigastric pain with nausea or vomiting, or respiratory symptoms require immediate evaluation and potential hospitalization.[282,283]

Seizure prophylaxis and antihypertensive medication should continue after delivery, the duration being determined by the clinical and laboratory status. All commonly used antihypertensive drugs, including labetalol, methyldopa, nifedipine, and captopril, are compatible with lactation, based on their pharmacology and low detectable drug levels in breast milk.[229]

Following severe preeclampsia, women will need appropriate counseling and debriefing about their disease and management. In many countries, it is routine practice to test women with early-onset preeclampsia (<32 wk' gestation), in particular those with major placental vasculopathy for underlying disorders such as antiphospholipid syndrome and thrombophilias.

THROMBOPROPHYLAXIS

Preeclampsia is a risk factor for thrombosis, particularly in case of nephritic-range proteinuria or likely inpatient stay more than a few days.[284] When women are admitted for observation in the hospital, they will usually be relatively immobile, and graduated compression stockings should be considered, with or without prophylactic low-molecular-weight heparin. With regard to thromboprophylaxis, the postpartum preeclamptic patient needs to be recognized and treated as a high risk patient; that is, in case of cesarean section, postpartum thromboprophylaxis should be administered to all women with preeclampsia except where there is a surgical contraindication.[285,286] Units should have clear protocols to deal with timing of low-molecular-weight heparin administration in regard to insertion and withdrawal of epidural and spinal cannulae.[285,286]

SUMMARY OF MANAGEMENT OPTIONS
Preeclampsia

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Advise early prenatal care.	—/GPP	—
Control diabetes prepregnancy.	IIa/B	191
Control hypertension prepregnancy.	IIa/B	191
Provide advice on good nutrition for those at risk.	—/GPP	—
Advise weight reduction.	—/GPP	—
Supplement B vitamins.	III/B	189,190
Sexual relationship for > 8 mo (not a pragmatic management option).	IIa/B	55,56
Prenatal—Prediction of Preeclampsia		
Counsel on increased risk and vigilance in patients with chronic hypertension, renal disease, connective tissue disorder, diabetes mellitus, previous preeclampsia, positive family history, obesity.	Ia/A	186,191
Abnormal uterine Doppler flow velocity waveforms at 20 wk' gestation are associated with three- to sixfold increase in rate of preeclampsia; poor prediction from clinical and biochemical markers.	Ia/A	185,204,205
Prenatal—Prevention of Preeclampsia		
Calcium supplementation results in a modest reduction in risk and severity in patients with a low dietary calcium intake.	Ia/A	215
Low-dose aspirin reduces risk in women at high risk for preeclampsia.	Ia/A	209,214
Supplementation with vitamin E and C does not reduce the risk for preeclampsia.	Ia/A	217,218
Antihypertensives for mild to moderate hypertension prevent severe hypertension but have no effect on overall maternal and perinatal outcome.	Ia/A	228,229,231
Excessive lowering of blood pressure in women with mild disease may increase the risk of a small–for–gestational age baby.	Ia/A	232
Prenatal—Management		
Mild gestational hypertension without IUGR can be managed expectantly up to 40 wk' gestation.	IV/C	2,9,27
Diagnosis of preeclampsia at term mandates delivery.	IV/C	2,9
Severe preeclampsia at ≥ 34 wk' gestation mandates delivery.	IV/C	1,2,9,10,61
Preeclampsia remote from term (24–33 completed wk) can be managed conservatively with fetal surveillance and monitoring for disease progression.	Ib/A	221,224,225
Management of severe early-onset preeclampsia is best accomplished in a tertiary setting with adult and neonatal intensive care facilities.	—/GPP	—
Principles of Expectant Management		
• Reduce blood pressure (main aim is prevention of cerebral vascular accident).	—/GPP	—
• Prevent convulsions with MgSO$_4$	Ia/A	265,266
• Use IV fluids carefully to avoid fluid overload; there is no maternal and/or perinatal benefit associated with ongoing plasma volume expansion.	Ib/A	257

SUMMARY OF MANAGEMENT OPTIONS
Preeclampsia—cont'd

Management Options	Evidence Quality and Recommendation	References
Laboratory Studies during Expectant Management		
• Platelet count.	—/GPP	—
• AST, ALT, LDH, creatinine.		
• Clotting studies not required in preeclampsia not associated with drop in platelets; D-dimer (not INR and aPTT) useful in detecting early stages DIC.		
• A spot urine protein-to-creatinine ratio is the preferred way to screen for protein when compared with dipstick; 24-hr urine collection for protein and creatinine remains the gold standard.	Ia/A	16–18
Eclampsia Management		
Resuscitate, maintain airway, give oxygen, nurse semiprone.	—/GPP	—
Control and prevent further convulsions with MgSO$_4$; a loading dose of 4 g should be given by infusion pump over 5–10 min, followed by further infusion of 1 g/hr.	Ia/A	264
Recurrent seizures should be treated with either a further bolus of 2 g MgSO$_4$ or an increase in the infusion rate to 2 g/hr	Ia/A	264
Control blood pressure.	III/B	266,267
Check platelet count, renal function, liver enzymes, D-dimer.	—/GPP	—
Deliver when stable.	—/GPP	—
Mode of delivery based on obstetric indications.	—/GPP	—
Maintain high-dependency for 24–48 hr.	—/GPP	—
Maintain MgSO$_4$ for at least 24–48 hr, based on maternal assessment.	—/GPP	—
Fetal Assessment during Expectant Management (See also Chapters 10 and 11)		
Umbilical artery Doppler reduces need for fetal interventions, improves neonatal outcome, and predicts adverse perinatal outcome.	Ia/A	272
• Fetal heart rate monitoring (indicative of more immediate fetal health) is undertaken frequently	—/GPP	—
• US documentation of fetal growth at a minimum interval of every 2 wk.	—/GPP	—
• Growth-restricted fetuses with placental insufficiency require antenatal testing using multiple surveillance modalities to enhance prediction of birth pH.	IIa/B	280
Maternal Steroids		
Steroids for fetal lung maturation if indicated preterm delivery is anticipated.	Ia/A	252
Labor and Delivery		
Cesarean section for obstetric reasons, not for preeclampsia per se.	—/GPP	—
Epidural.	IV/C	296
Intravenous antihypertensive drugs in case of severe hypertension.	—/GPP	—
Select antihypertensive agent on basis of local expertise and drug availability.	Ia/A	250
Hydralazine is no longer first choice.	Ib/A	243
Mini-bolus diazoxide (15 mg) is at least as effective as intravenous hydralazine and blood pressure control is achieved more quickly.		

Management Options	Evidence Quality and Recommendation	References
Postnatal		
Clinicians should be aware that ≤ 44% of eclampsia occurs postpartum, especially at term, so women with signs and symptoms compatible with preeclampsia should be carefully assessed.	—/GPP	—
Continue seizure prophylaxis for 24 hr postpartum.	—/GPP	—
In patients with severe disease, close monitoring (neurologic status, renal and pulmonary function, liver enzymes, and hemostasis) and seizure prophylaxis continue for 2–4 days until disease resolves; close fluid balance with charting of input and output is essential. A catheter with an hourly urometer is advisable in the acute situation.	—/GPP	—
Steroids have no beneficial effects on recovery in case of post-partum HELLP.	Ia/A	253,254
Patients who require antihypertensive medication at discharge should remain under surveillance.	—/GPP	—
Women with persisting hypertension and/or proteinuria at 6 wk may have renal disease and require further investigation.	—/GPP	—
Even those with severe disease whose blood pressure settles are at increased risk for hypertension and other cardiovascular disorders in later life and regular review is prudent.	—/GPP	—
Women whose pregnancies have been complicated by severe disease should be offered a formal postnatal review to discuss the events of the pregnancy.	—/GPP	—
Preconceptional counseling should be offered in which the events that occurred, any risk factors, and any preventive strategies can be discussed.	—/GPP	—
Women with a history of severe early-onset preeclampsia, especially if associated with IUGR or late fetal loss, should be screened for antiphospholid syndrome and may be tested for other thrombophilias, but the implications for future pregnancies have yet to be determined.	IIa/B	33,34,120–125

ALT, alanine aminotransferase; aPTT, activated partial thromboplastin time; AST, aspartate aminotransferase; DIC, disseminated intravascular coagulation; GPP, good practice point; HELLP, hemolysis, elevated liver enzymes, and low platelets; INR, International Normalized Ratio; IUGR, intrauterine growth restriction; LDH, lactate dehydrogenase; US, ultrasound.

CHRONIC HYPERTENSION

Introduction and Maternal and Fetal Risks

Depending on the population studied and the criteria used, the incidence of chronic hypertension in pregnancy is 0.5% to 3%. Essential hypertension is responsible for 90% of cases of chronic hypertension associated with pregnancy. Causes of secondary hypertension include renal disease (glomerulonephritis, nephropathy, renovascular disease), endocrinologic disorders (diabetes with vascular involvement, thyrotoxicosis, pheochromocytoma), and collagen vascular disease (systemic lupus erythematosus, scleroderma).[287,288] Chronic hypertension in pregnancy may be subclassified into mild hypertension (diastolic BP ≥ 90 to < 110 mm Hg or systolic BP ≥ 140 to < 180 mm Hg) or severe hypertension (diastolic BP ≥ 110 mm Hg or systolic BP ≥ 180 mm Hg).[287,288] For the purpose of clinical management, chronic hypertension in pregnancy may also be divided into a low risk group (hypertension with no end-organ damage or associated significant comorbidities) or a high risk group (hypertension with end-organ damage or associated morbidities). Maternal and perinatal morbidity and mortality rates are not generally increased for patients with uncomplicated mild chronic hypertension. However, the risks to mother and fetus increase dramatically when the pregnancy is complicated by severe disease or superimposed preeclampsia. Other risk factors include maternal age older than 40 years, hypertension lasting longer than 15 years, BP greater than 160/110 mm Hg early in pregnancy, diabetes classes B through F, renal disease, cardiomyopathy, connective tissue disease, and coarctation of the aorta.[26] Maternal risks include exacerbation of hypertension, superimposed preeclampsia, congestive heart failure, intracerebral hemorrhage, ARF, placental abruption with DIC, and death as a result of any of these. Superimposed preeclampsia and abruptio placentae are the two most common complications. Superimposed preeclampsia complicates approximately 5% to 50% of pregnancies of women with chronic hypertension,

depending on whether the diagnosis of preeclampsia was made simply on the basis of exacerbation of hypertension or whether significant proteinuria was included. In patients with risk factors, the incidence of superimposed preeclampsia is 25% to 50%. The incidence of placental abruption is 0.5% to 2% in patients with mild, uncomplicated hypertension and 3% to 10% in those with severe hypertension. The incidence of superimposed preeclampsia or abruption is not affected by antihypertensives.[26,191] Fetal morbidity and mortality rates are directly related to the severity of hypertension. They are particularly high in patients with superimposed preeclampsia and abruptio placentae. Decreased uteroplacental perfusion (often iatrogenic) can lead to IUGR. Spontaneous or iathrogenic preterm birth adds the compounding complications of prematurity. The risk of mid-trimester death in utero is higher in patients with chronic hypertension, especially those who do not receive prenatal care.[26,191,288]

Management Options

Prepregnancy

Women with chronic hypertension who desire pregnancy should be encouraged to receive prepregnancy care. The cause and severity of chronic hypertension should be established, if possible. Antihypertensives with potential adverse effects on the fetus, such as angiotensin-converting enzyme (ACE) inhibitors and diuretics, should be discontinued and switched to preparations with a strong safety record in pregnancy. These changes should be under physician supervision. Adequate time must be allowed preconceptionally to gauge the patient's response to new medications to control hypertension.[287]

Prenatal

The woman with chronic hypertension should be observed frequently during pregnancy by an obstetrician and/or physician familiar with the management of hypertension in pregnancy. During the initial visits, a detailed evaluation of the etiology and severity of chronic hypertension should be made. Careful attention must be given to a history of cardiac or renal disease, diabetes, or thyroid disease and to the outcome of previous pregnancies. A detailed history, physical examination, and appropriate laboratory and cardiac testing are essential in seeking a possible cause for hypertension and to ascertain end-organ damage if present. A pragmatic baseline evaluation and laboratory studies in pregnant patients with chronic hypertension are presented in Table 35–9.[10]

Because women with chronic hypertension are at high risk of developing preeclampsia, close monitoring for its maternal and fetal manifestations is necessary. In addition to standard prenatal care, the following additional monitoring is indicated: (1) monitoring for signs of superimposed preeclampsia after 20 weeks' gestation; (2) assessment for proteinuria using a spot urine protein-to-creatinine ratio at every visit; (3) laboratory assessment (see Table 35–9) if worsening hypertension or proteinuria; and (4) assessment of fetal growth and well-being (see Table 35–8).

Admission to a hospital or day assessment unit is recommended for women with worsening hypertension or proteinuria at any stage of pregnancy. This enables assessment of

---

TABLE 35–9

Investigation of Hypertension Presenting prior to 20 Weeks' Gestation

All Patients

Establish baseline level of proteinuria; a spot urine-to-creatinine ratio is an acceptable screening method, although many clinicians still favor a 24-hr urinary protein collection to get a reliable baseline.
Microscopy of centrifuged urinary sediment for white and red blood cells (including red cell morphology) and for casts.
Midstream urine culture.
Measurement of serum electrolytes, creatinine, uric acid, and blood glucose.
Full blood examination.

Selected Patients

Electrocardiogram.
Renal ultrasound should be considered, particularly if hypertension is severe.
Fasting free plasma metanephrines or 24-hr urine collection for estimation of catecholamine excretion if there is concern regarding a possible pheochromocytoma. At least two consecutive collections are advised.

---

maternal and fetal welfare and facilitates discussion among all involved in the woman's care. When necessary, pharmacologic treatment may be commenced or revised under close supervision. Women who are at low risk (those with mild, chronic hypertension and none of the just-discussed risk factors) should be seen every 2 to 4 weeks in the first two trimesters, and then weekly. In pregnant patients with low risk chronic hypertension, Sibai and coworkers[26,191] recommend discontinuation of all antihypertensives at the first prenatal visit. Only half require subsequent medication; treatment of patients who need antihypertensives can be tailored to their individual needs. If there is no superimposed preeclampsia and fetal well-being is well documented, routine induction of labor before 40 weeks' gestation probably is not warranted.

Pregnancy in women with hypertension and additional risk factors should be managed in consultation with appropriate specialists (e.g., maternal-fetal medicine, cardiology, nephrology). Close monitoring is essential, and multiple hospitalizations may be necessary to control maternal hypertension and associated medical complications. Severe hypertension mandates an aggressive pharmacologic approach. Carefully selected antihypertensives may benefit those with mild hypertension who have additional complicating factors, such as diabetes, renal disease, or cardiac dysfunction. Intensive fetal surveillance is critical to optimize fetal outcome. Serial ultrasonography for fetal growth and weekly (or more frequent, depending on the fetal condition) antepartum fetal testing, beginning as early as 26 weeks, should be used.[26,191] The pregnancy may be continued until term, until the onset of superimposed preeclampsia, or until IUGR or other signs of fetal decompensation occur. The development of severe, superimposed preeclampsia places the patient at highest risk for maternal and perinatal complications. This development after 28 weeks is an indication for delivery. Before 28 weeks, the pregnancy may be followed conservatively in a tertiary center with daily evaluation of the maternal and fetal condition, although this approach is controversial.[26]

ANTIHYPERTENSIVE THERAPY

The continued administration or initiation of antihypertensive therapy in women with chronic hypertension in pregnancy (except for the acute treatment of severe hypertension) remains controversial. Most women manifest a physiologic fall in BP in the first half of pregnancy that may allow withdrawal or a reduction of antihypertensive medication.[26,191] Although treatment of chronic hypertension is associated with a significant reduction in severe hypertension, it has not been shown to alter the risk of superimposed preeclampsia, preterm delivery, placental abruption, or perinatal death.[26,191,287,288] There is insufficient evidence upon which to base a definite recommendation for the levels of BP at which antihypertensive drug treatment should commence.

There are no randomized trials of the treatment of severe chronic hypertension during pregnancy. However, the general consensus is that when diastolic BP reaches 110 mm Hg, it clearly requires treatment to prevent cerebrovascular accident, the largest cause of maternal death in patients with hypertension. The current Australian and New Zealand recommendation is that such treatment should definitely be started when the BP consistently reaches or exceeds 160 mm Hg systolic and/or 100 mm Hg diastolic.[10] Treatment at BPs between 140 and 160 mm Hg systolic and/or 90 and 100 mm Hg diastolic is also common practice, with good documented outcomes but certainly not based on randomized, controlled trials.[26] In patients with target organ damage, it has been recommended to keep systolic BP below 140 mm Hg and diastolic BP below 90 mm Hg.

Overzealous treatment of mild hypertension has been found to be associated with a significant increase in small–for–gestational age infants, today, a major concern because of the more recent insights in the fetal origins of adult disease. Large international trials (CHIPS) are currently in progress to finally get an answer on what BPs require treatment and, just as important, what should be the target BP to be achieved.[229,230,289]

In the third trimester of pregnancy, an increase in the requirement for antihypertensive therapy should be anticipated. The drugs used for treatment of chronic hypertension are the same as those recommended for preeclampsia and gestational hypertension. Atenolol and other highly selective β-blocker drugs are not recommended for prolonged use in pregnancy because they have been associated with IUGR.[290–292] The use of ACE inhibitors and angiotensin-receptor blockers is contraindicated in pregnancy. They have been associated with an increased risk of fetal, particularly cardiovascular, malformations in early pregnancy in one study and are known to cause adverse sequelae for the fetus in late pregnancy.[293] Diuretics, although not teratogenic, may restrict the natural plasma volume expansion of pregnancy and are not recommended for the treatment of hypertension. Management of superimposed preeclampsia should be as outlined previously for preeclampsia unless specific diagnostic issues, such as some secondary causes of hypertension, are present.

Labor and Delivery

Intrapartum management of patients with severe chronic hypertension or in patients with superimposed preeclampsia is similar to the intrapartum management of preeclamptic patients, that is, continuous fetal monitoring, appropriate analgesia, and appropriate use of antihypertensive drugs to keep the BP below 160/110 mm Hg.

Postnatal

High risk patients with chronic hypertension should be monitored closely for at least 48 hours after delivery because they are at risk for hypertensive encephalopathy, pulmonary edema, and renal failure. In many women with chronic hypertension or superimposed preeclampsia, BP is unstable for 1 to 2 weeks after delivery and may be difficult to control. It may be particularly high on days 3 to 6 after delivery, and it is often necessary to increase or commence antihypertensive medication at that time. Oral or intravenous labetalol or hydralazine, ACE inhibitors, methyldopa, or calcium channel blockers can be used to control severe hypertension. Diuretic therapy is used in patients with evidence of circulatory congestion or pulmonary edema. These women must be evaluated after the postpartum period to detect deterioration in cardiac or renal function and to adjust antihypertensive medication. Minute amounts of all antihypertensives are found in breast milk. All of the agents mentioned earlier are compatible with breast-feeding, as are the ACE inhibitors enalapril, captopril, and quinapril. However, thiazide diuretics inhibit adequate breast milk production.[229]

SUMMARY OF MANAGEMENT OPTIONS
Chronic Hypertension

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Establish the cause and severity of hypertension.	—/GPP	—
Evaluate renal function.	—/GPP	—
In those with mild to moderate hypertension, stop medication or switch to medication with few fetal side effects.	—/GPP	—
In those with severe or difficult-to-control hypertension, medication may be needed despite the potential fetal risks.	—/GPP	—
Encourage early prenatal care in an appropriate setting.	—/GPP	—

SUMMARY OF MANAGEMENT OPTIONS
Chronic Hypertension—cont'd

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Provide early and frequent prenatal care.	IV/C	26,287,288
Discontinue antihypertensive medication unless maternal diastolic pressure > 100–110 mm Hg.	Ia/A	26,231
Use oral medication in severe hypertension (methyldopa, calcium channel blockers, labetalol) and in those with mild hypertension complicated by risk factors.	Ia/A	231,229,287
Laboratory studies:	—/GPP	—
• Establish baseline level of proteinuria.		
• Baseline serum electrolytes, creatinine, urate, and glucose.		
Fetal surveillance with serial ultrasound

ANESTHETIC CONSIDERATIONS IN HYPERTENSIVE DISORDERS OF PREGNANCY

Whenever possible, an anesthetist should be informed about a woman with severe preeclampsia well in advance of labor or operative delivery to plan appropriate anesthetic management. This is associated with a reduction in both fetal and maternal morbidity.[294] Relevant issues include anesthetic risk assessment, BP control, fluid management, eclampsia prophylaxis, and planning of analgesia or anesthesia.[10,268,295–298]

Risk Assessment

Anesthetists/intensivists form an integral part of the team responsible for the critically sick preeclamptic patient. Women who develop organ failure require intensive monitoring and medical management, within either a high dependency or an intensive care setting. Antenatal and (more commonly) postpartum indications for admission of a patient with severe preeclampsia to an intensive therapy unit include pulmonary edema, intractable hypertension, anuria or renal failure, repeated convulsions, DIC, neurologic impairment requiring ventilation (e.g., intracerebral hemorrhage or infarction, cerebral edema), and critical intra-abdominal pathology (e.g., acute fatty liver; subcapsular liver hematoma).[268,295,296]

Fluid Management

Fluid management is a challenging area in preeclampsia, and there is no clear evidence regarding optimal type or volume of fluid.[296,297] Fluid therapy aims to maintain organ perfusion in the setting of vasoconstriction, endothelial dysfunction, and in some parturients, severe left ventricular diastolic dysfunction. Intravenous fluid should be administered incrementally in small volumes (e.g., crystalloid 250 mL) with monitoring of maternal hemodynamics, urine output, and fetal heart rate, because overhydration contributes to maternal mortality from pulmonary edema and adult respiratory distress syndrome.[226] Fluid loading is not mandatory prior to regional analgesia during labor when low-dose local anesthetic and opioid methods are used.[298] Prior to regional anesthesia, intravenous crystalloid loading is ineffective in preventing hypotension but colloid is effective.[299] Treatment

or prevention of hypotension with drugs such as phenylephrine or metaraminol is effective and appears safe in preeclamptic women.[300,301]

Anesthetic Technique for Vaginal Delivery

For labor and delivery, epidural analgesia is a useful adjunct to antihypertensive therapy and improves renal and uteroplacental blood flow. When relatively contraindicated (e.g., severe thrombocytopenia, coagulopathy, or sepsis), fentanyl or remifentanil patient-controlled intravenous analgesia is preferred. Although ephedrine usually does not cause rebound hypertension, occasionally vasopressors and epidural adrenaline (epinephrine) cause significant BP elevation. Other drugs that should be avoided in severe preeclampsia include ergometrin,[226] ketamine (hypertension), and the nonsteroidal anti-inflammatory drugs and cyclooxygenase-2–specific inhibitors (impaired renal function and hypertension).[10,268,300,301]

Anesthetic Technique for Cesarean Section

Unhurried preoperative preparation reduces the risk of anesthesia in women with preeclampsia.[226] Regional anesthesia is preferred to general anesthesia for cesarean section, especially because airway problems including laryngeal edema may be increased.[302–304] However, well-conducted general anesthesia is also suitable[305,306] and may be indicated in the presence of severe fetal compromise, pulmonary edema, hemodynamic instability, intraspinal hematoma risk (e.g., placental abruption, severe thrombocytopenia), or after eclampsia in which altered consciousness or neurologic deficit persists. Emergency cesarean section confers increased maternal morbidity, so early anesthetic notification by the obstetrician and in utero resuscitation provide additional time for assessment, planning, and establishment of regional anesthesia. When a well-functioning epidural catheter is in situ, general anesthesia is achieved only marginally more rapidly than conversion to epidural anesthesia.[307,308] Prophylaxis against pulmonary aspiration is recommended using clear antacid and ranitidine, with or without metoclopramide. Skilled anesthetic assistance is mandatory, as is left lateral tilt on a pelvic displacement wedge or table tilt to minimize aortocaval compression.

Attenuation of Pressor Responses at General Anesthesia for Cesarean Section

Laryngoscopy and tracheal intubation present a particularly dangerous time for the preeclamptic woman, especially if the intracranial pressure is elevated or the BP is inadequately controlled.[226] The transient but severe hypertension that usually accompanies intubation can cause myocardial ischemia, cerebral hemorrhage, or pulmonary edema, all important causes of maternal death.[226] Attenuation of this pressor response is best achieved with additional induction drugs such as remifentanil 1 μg/kg,[309,310] or $MgSO_4$ 40 mg/kg or 30 mg/kg with alfentanil 7.5 μg/kg.[311] Neuromuscular block must always be monitored closely after intravenous magnesium administration.[312]

Regional Anesthesia for Cesarean Section and Preeclampsia

All regional anesthetic techniques (spinal, epidural, or combined spinal-epidural) appear safe, provided meticulous attention is paid to fluid management, preventing aortocaval compression, and dealing with hypotension.[268,296,306] Spinal anesthesia with usual doses is now a recommended technique.[313,314] Cardiac output is well maintained and is associated with less hypotension and lower vasopressor requirements than among healthy parturients.[315] Combined spinal-epidural anesthesia appears to offer further advantages in specific cases. Low-dose aspirin therapy is not a contraindication to regional techniques that, in the absence of bleeding, are considered safe when the platelet count is greater than 75000 μL^{-1}. Platelet counts lower than 50.000 μL^{-1} are generally considered a contraindication. Within the range of 50 to 75,000 μL^{-1}, an individual assessment (considering patient risks; coagulation tests and thermoelastography or platelet function if available) and risk reduction strategies (experienced operator; single-shot spinal anesthesia or flexible-tip epidural catheter) is encouraged.[316]

LONG-TERM CONSEQUENCES OF HYPERTENSIVE DISORDERS OF PREGNANCY

Women who develop preeclampsia are at increased risk of cardiovascular complications later in life. Many of the risk factors and pathophysiologic abnormalities of preeclampsia are similar to those of coronary artery disease.[317–320] Insulin resistance, with the associated microvascular dysfunction, has been implicated as a major common factor.[317]

Preeclampsia is characterized by an increased systemic inflammatory response, whereas low-grade chronic inflammation is also a risk factor for cardiovascular disease. The mechanism for this susceptibility to inflammation could be attributable to a generalized up-regulation (genetic?) of a number of inflammatory processes or could be a specific overactivity of a particular tissue such as adipose tissue.[317,319] A recent systematic review[321] determined that the RRs for hypertension were 3.70 after 14 years follow-up, for ischemic heart disease 2.16 after 12 years, for stroke 1.81 after 10 years, and for venous thromboembolism 1.87 after 5 years. Overall mortality after preeclampsia was increased 1.5-fold after 14 years. These associations are likely to reflect a common cause for preeclampsia and cardiovascular disease, an effect of preeclampsia on vascular disease development, or both. It is reasonable to counsel patients who develop hypertension in pregnancy that they will benefit from avoiding smoking, maintaining a healthy weight, exercising regularly, and eating a healthy diet.[320,321] It is recommended that all women with previous preeclampsia or hypertension in pregnancy have an annual BP check and regular (every 5 yr or more frequently if indicated) assessment of other cardiovascular risk factors including serum lipids and blood glucose. Having a history of severe early-onset preeclampsia requiring delivery at less than 28 weeks' gestation could be a marker for underlying acquired and genetic thrombophilias. In addition to this risk for the mother, long-term follow-up studies have demonstrated that babies born growth-restricted, and in particular born preterm and growth-restricted, are more likely to develop hypertension, coronary artery disease, dyslipidemia, and diabetes (insulin resistance syndrome), and for growth-restricted female neonates, preeclampsia in adult life.[322,323]

Cardiac Disease

MARK W. TOMLINSON

INTRODUCTION: GENERAL COMMENTS

Maternal and Fetal Risks

Serious maternal cardiac disease complicating pregnancy is relatively uncommon; however, it can have a significant adverse effect on maternal and fetal outcomes despite modern cardiac care. The overall incidence of serious heart disease complicating pregnancy is approximately 1%.[1] With a decrease in maternal death as a result of the classic causes of hemorrhage, hypertension, and infection, the relative importance of cardiac disease has increased.[1] During the last few decades, the etiology of heart disease in developed countries has changed from primarily rheumatic to predominantly congenital.[1–4] Despite the potential for significant maternal morbidity, most patients with cardiac disease can expect a satisfactory outcome with careful antenatal, intrapartum, and postpartum management.[1–5] Serious complications during pregnancy and the postpartum period such as congestive heart failure, arrhythmias, and stroke are seen in 12% to 20% of patients. Mortality in some conditions can be as high as 30%. The rate of complications is related to several factors, including maternal functional status, myocardial dysfunction, significant aortic or mitral valve stenosis, and history of arrhythmias or a cardiac event.[2,4,5]

Table 36–1[6,7] shows the estimated qualitative risk of maternal complications associated with various cardiac conditions. Maternal mortality secondary to heart disease is generally uncommon today, particularly in developed countries because (1) most congenital lesions are diagnosed early, allowing appropriate surgical repair, (2) the incidence of rheumatic heart disease has significantly decreased, and (3) patients who are at greatest risk for cardiac decompensation are offered sterilization or termination.

Normal physiologic pregnancy-related changes can aggravate underlying cardiac disease, leading to the associated morbidity and mortality. Total body water increases progressively by 6 to 8 L because an additional 500 to 900 mEq of sodium is retained.[8–10] As a result, plasma volume increases steadily throughout the first two trimesters and into the early third trimester, reaching a plateau at approximately 32 weeks.[11] In a singleton pregnancy at term, plasma volume is nearly 50% greater than that seen in nonpregnant women.[12] Maternal cardiac output starts to increase at approximately 10 weeks and reaches a plateau by the early third trimester at levels 30% to 50% above nonpregnant values.[13–16] This increased output results from increases in stroke volume and heart rate. The increase in heart rate peaks in the third trimester at 10 to 15 beats/min over baseline.[15–17] These physiologic changes increase the demand on the heart, which can become critical if function is already compromised.

The pregnancy-related decrease in blood pressure may offset some of the increased work resulting from increased plasma volume. In some cases, however, the significant decrease in peripheral resistance can be deleterious; for example, it may reverse a left-to-right shunt, resulting in cyanosis. Normally, systolic and diastolic pressures fall throughout the first two trimesters, reaching a nadir between 24 and 28 weeks, before increasing to nonpregnant levels at term.[18] Systolic pressure decreases an average of 5 to 10 mm Hg, and diastolic pressure decreases 10 to 15 mm Hg.[19] Blood pressure and cardiac output may be further affected by maternal posture. Late in pregnancy, the gravid uterus may mechanically obstruct the aorta and vena cava in the supine position, leading to hypotension.[20] In addition, changes in cardiac output and blood pressure cause an initial decrease in systemic vascular resistance, followed by an increase toward nonpregnant values near term.[18] During cesarean section, fundal pressure used to facilitate delivery causes vena cava compression, resulting in decreased preload. Heart rate also decreases, possibly due to vagal stimulation. Aortic compression is usually not seen. The net effect of the changes in preload and heart rate is a decrease in cardiac output.[21] There can also be dramatic changes in venous return immediately following birth. If there is more than average blood loss, then venous return can be markedly reduced. Conversely, delivery of the placenta and the rapid contraction of the uterus can result in blood being squeezed out of the uterus and a sudden increase in venous return. This is particularly marked if the placenta is removed manually at cesarean section and oxytocics are given to make the uterus contract. Such manual removal is probably best avoided. Finally, oxytocics commonly used can have major effects on vascular tone (ergometrine producing an increase, and oxytocin producing a decrease). Although not clinically significant in normal pregnant women, the resulting changes in venous

TABLE 36–1
Risk of Maternal and Fetal Morbidity Associated with Pregnancy

Low Risk

Mitral valve prolapse without severe regurgitation
Atrial and ventricular septal defect previously repaired or without pulmonary hypertension
Corrected congenital heart disease without residual cardiac dysfunction
Patent ductus arteriosus
Pulmonary stenosis
Mild mitral or aortic valvular disease (stenosis or regurgitation) with normal left ventricular function: New York Heart Association class I or II

Moderate Risk

Marfan's syndrome with normal aorta
History of peripartum cardiomyopathy with no residual ventricular dysfunction
Previous myocardial infarction

High Risk

Any condition with New York Heart Association class III or IV
Moderate to severe systemic ventricular dysfunction
Pulmonary hypertension from any cause
Tetralogy of Fallot; uncorrected or with residual disease
Coarctation of the aorta
Mitral stenosis with atrial fibrillation
Severe aortic stenosis
Mechanical valve requiring anticoagulation
Marfan's syndrome with aortic involvement
History of peripartum cardiomyopathy with residual ventricular dysfunction

TABLE 36–2
Risk of Congenital Heart Defect in Offspring of Women with Congenital Heart Disease

CONGENITAL HEART DEFECT	NEONATAL RISK (%)
Any defect	5–6
ASD	4–10
VSD	6–10
Tetralogy of Fallot	3–5
Transposition of the great arteries	0
Aortic coarctation	4
Aortic stenosis	4–18
Pulmonary stenosis	3–4
Ebstein's anomaly	4–6

ASD, atrial septal defect; VSD, ventricular septal defect.

Management Options

Prepregnancy

Ideally in patients with significant heart disease, pregnancy is a planned event. This assumes regular and reliable use of an effective contraceptive method. Before discontinuation of contraception, preconception evaluation and counseling should take place. The patient's cardiologist should be an active participant in this process. Maternal disease status should be determined. An echocardiogram can be used not only to define the cardiac anatomy but also to describe ventricular function and estimate intracardiac pressure gradients.[27] Magnetic resonance imaging can also be useful, for example, in visualizing the descending aorta in cases of coarctation. Nuclear medicine scans, although helpful in the nonpregnant state, should be avoided during pregnancy.

A careful history is obtained to identify previous cardiac complications, including arrhythmias. The patient's functional status should also be established. The New York Heart Association (NYHA) functional classification system[28] (Table 36–3) is commonly used. Ninety percent or more of patients are categorized as having class I or II disease.[1–3,29] Outcomes are favorable in these two groups, but deterioration may occur. The reported frequency of adverse cardiac events varies from 3% to 69% depending on patient risk factors.[2,4,5] Although few patients have class III or IV disease, historically, nearly 85% of maternal deaths occur in these groups.[30]

The risk of maternal cardiac complications during pregnancy was quantified by Siu and colleagues[5] with a combination of five echocardiographic and historical factors that could be obtained and evaluated at the initial encounter. The complications studied include pulmonary edema, symptomatic arrhythmias, and stroke or transient ischemic attack of cardiac origin. The five predictive indicators were NYHA classification greater than grade II or cyanosis, left ventricular obstruction, cardiac dysfunction, previous arrhythmia, and previous cardiac complication. *Left ventricular outflow obstruction* was defined as aortic valve stenosis with a valve area less than 1.5 cm^2, mitral stenosis with a valve area of less than 2.0 cm^2, or a peak left ventricular outflow tract gradient greater than 30 mm Hg. *Myocardial dysfunction* was

return may be important in those with limited cardiac reserve.

Colloid oncotic pressure is another important variable affected by pregnancy. Both plasma and interstitial colloid oncotic pressure decrease throughout gestation, with the latter decreasing to a greater extent.[22] There is an accompanying increase in capillary hydrostatic pressure.[23] These changes lead to the normal physiologic edema of pregnancy, most marked in the lower extremities. Any further increase in hydrostatic pressure or a decrease in plasma colloid oncotic pressure will produce increased edema formation, especially in late pregnancy. After delivery, an additional decrease in plasma colloid oncotic pressure occurs, reaching a nadir between 6 and 16 hours, with a return toward intrapartum levels after 24 hours.[24,25] The marked dependent edema commonly seen in normal pregnant patients can complicate the diagnosis of cardiac decompensation.

Fetal complications in pregnancies associated with maternal cardiac disease commonly include growth restriction and preterm delivery. Despite the risk of low birth weight, overall perinatal mortality is not significantly greater than that in the general population. When a pregnant patient has congenital heart disease, the fetus is at increased risk for this disease. The increase in incidence ranges from 0% to 18%, depending on the specific lesion (Table 36–2). When the fetus is affected, approximately 50% have the same anomaly as the mother.[1,26] The risk of a cardiac lesion in the fetus is also increased when other first-degree family members have a congenital heart lesion.[26]

TABLE 36–3

New York Heart Association Cardiac Functional Classification

Class I	No limitations of physical activity; ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain.
Class II	Slight limitation of physical activity; ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.
Class III	Marked limitation of physical activity; less than ordinary activity causes fatigue, palpitation, dyspnea, or anginal pain.
Class IV	Inability to perform any physical activity without discomfort; symptoms of cardiac insufficiency or anginal syndrome may be present, even at rest; any physical activity increases discomfort.

TABLE 36–4

Classification System for Fetal Risk Associated with Medications used during Pregnancy

Category A	Controlled studies in women show no risk to the fetus in the first trimester (and no evidence of risk in later trimesters); the possibility of fetal harm appears remote.
Category B	Either animal reproduction studies show no fetal risk but there are no controlled studies in pregnant women or animal reproduction studies show an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).
Category C	Either studies in animals show adverse fetal effects (teratogenic, embryocidal, or other) and there are no controlled studies in women or studies in women and animals are not available; drugs should be given only if the potential benefit justifies the potential risk to the fetus.
Category D	There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (e.g., if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).
Category X	Studies in animals or humans show fetal abnormalities or there is evidence of fetal risk based on human experience, or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit; the drug is contraindicated in women who are or may become pregnant.

defined as an ejection fraction less than 40%, restrictive or hypertrophic cardiomyopathy, or complex congenital heart disease. A *significant history of arrhythmia* was defined as symptomatic bradyarrhythmia or tachyarrhythmia requiring therapy. If no predictive factors were present at the beginning of pregnancy, fewer than 5% of patients have a cardiac complication. When one factor was present, 30% of patients have a complication, and when two or more predictors were present, nearly 70% of patients have a complication. This information is useful in counseling patients.[2,4,5]

Medical management of the patient's cardiac condition should be optimized. During maternal drug therapy, potential fetal effects must be considered. Table 36–4 shows a fetal risk factor classification scheme that is helpful when choosing optimal medical therapy.[31] The corresponding risk factor category is listed, with medications discussed in the next sections. Coexisting conditions that may aggravate preexisting heart disease, such as anemia, arrhythmias, and hypertension, should be appropriately treated and controlled. Ideally, necessary cardiac surgery is carried out before conception.

Prenatal

Few patients are seen for prepregnancy evaluation. Therefore, most evaluation and counseling will be initiated at the first prenatal visit. Cardiac surgery, although not contraindicated, is usually not required during pregnancy.[1] If possible, it is best delayed until postpartum. When the maternal mortality rate is excessive, as in Eisenmenger's syndrome, termination of the pregnancy should be discussed.

During prenatal care, the patient should be routinely questioned and examined for signs or symptoms of cardiac failure. Vital signs and weight gain should be closely monitored. When there is an increased risk of intrauterine growth restriction (IUGR), serial ultrasound examinations every 2 to 4 weeks in the third trimester allow assessment of interval fetal growth. Antenatal testing may begin at 32 to 34 weeks unless earlier surveillance is indicated because of compromised maternal or fetal status. Anesthesiology consultation should be obtained prior to delivery. Future fertility desires and contraceptive plans should be addressed in the antepartum period. Topics should include a discussion of sterilization, depending on future fertility desires, the maternal risk due to pregnancy, and the long-term prognosis.

Labor and Delivery

Ideally, women with significant cardiac disease should be delivered in a unit with 24-hour availability of expert obstetric, cardiology, anesthetic, and midwifery/nursing care, because labor can start unpredictably at any time. However, in the most challenging cases, labor induction may be chosen to maximize availability of a skilled multidisciplinary team. The incidence of cesarean section in patients with cardiac conditions is no higher than that occurring in women without cardiac disease induced for other obstetric indications. The key to successful management is to minimize cardiovascular stress, which can be achieved effectively with the use of regional anesthesia. Cesarean section subjects the mother to more stress than a straightforward labor and delivery. Therefore, cesarean section should not be undertaken simply because the mother has cardiac disease. Moreover, induction of labor is not specifically contraindicated. In one study of women with cardiac disease, the complication rate was not higher in those who were induced than in those who were not.[32] If induction with vaginal prostaglandin is used, it is probably wise to start with a low dosage, because an acute uterine hyperstimulation requiring either tocolysis or an urgent delivery is particularly risky in a woman with significant cardiac disease. Labor should proceed with the patient in the lateral position to avoid aortocaval compression and possible hypotension. Intrapartum fluid balance should be followed closely. Continuous maternal electrocardiographic monitoring may be used, as necessary, to detect arrhythmias. Invasive hemodynamic monitoring with an arterial line should be considered in particularly high risk conditions or in patients with deteriorating cardiovascular

status, because if the parturient becomes hypotensive, external blood pressure monitoring can be very difficult. A pulmonary artery catheter (PAC) is recommended by some in particularly challenging cases, but its use has not been rigorously evaluated during pregnancy, and some question the safety and utility of the PAC in critically ill and high risk surgical patients.[33–35] Until more information is available on its safety and efficacy, a PAC should be used cautiously during pregnancy. Close fetal surveillance is needed throughout labor. Operative vaginal delivery is indicated in some patients to shorten the second stage of labor and avoid the blood pressure changes associated with pushing. Cesarean delivery can be reserved for obstetric indications.

An understanding of the principles of and indications for bacterial endocarditis antibiotic prophylaxis in pregnant patients is important. In patients with an uncomplicated labor and delivery, bacterial endocarditis is rare. In two series with a total of 906 pregnant women with cardiac disease, routine prophylactic antibiotics were not used and no cases of bacterial endocarditis were identified.[1,36] The incidence of positive blood cultures is low after uncomplicated vaginal delivery, with a reported range of 1% to 5%.[37] Bacteremia is more common with dental procedures, in which positive blood cultures are obtained in 60% to 90% of patients, depending on the procedure.[38] Recent focus has turned to bacteremia resulting from routine daily activities rather than procedure-related exposure. It has been estimated that over the course of a year, "everyday" exposure is six million times greater than that of a single tooth extraction.[37] Genitourinary procedures such as those common in obstetrics are also associated with a very low risk of endocarditis compared with typical daily exposure. The American Heart Association (AHA) suggests that the risk of adverse events related to antibiotic prophylaxis exceeds the benefit. The increased frequency of drug-resistant bacteria and the potential to add to drug resistance raise further doubts about the efficacy and cost-effectiveness of endocarditis prophylaxis. As such, the AHA[39] does not recommend antibiotic use solely for the purpose of endocarditis prophylaxis. Conversely, The Endocarditis Working Party of the British Society for Antimicrobial Chemotherapy[37] recommends antibiotic prophylaxis at cesarean section for patients at high risk for endocarditis. In any case, routine antibiotic prophylaxis for the prevention of postoperative sepsis is now well established as an appropriate measure by many prospective, randomized trials.[40] Individuals considered at high risk include those with a history of previous endocarditis, a prosthetic valve, a surgically conducted shunt or conduit, complex congenital heart disease, aortic stenosis or bicuspid aortic valve, other valve disease, and mitral valve prolapse with significant valve abnormality and regurgitation. A single intravenous dose of ampicillin 1 g plus gentamicin 1.5 mg/kg prior to the procedure has been recommended. The routine practice of prophylactic perioperative antibiotics with a first-generation cephalosporin provides coverage for some of the offending organisms and seems a reasonable compromise between the AHA and the British Society for Antimicrobial Chemotherapy recommendations.

Teicoplanin 400 mg intravenously plus gentamicin is recommended for penicillin-allergic patients. Prophylaxis is not recommended for an uncomplicated vaginal delivery (in this context, an episiotomy or repair of a vaginal tear is not considered to be a complication, unless there is an extension involving the rectal mucosa).[37] Prior to the revision of the AHA recommendations for infective endocarditis prophylaxis, Pocock and Chen[41] evaluated the intrapartum use of endocarditis prophylaxis. Only 12% of those receiving antibiotics had moderate to high risk cardiac conditions that would have potentially warranted therapy by the older recommendations. An appropriate antibiotic regime was given in only half of these cases, pointing out that even older recommendations were not being followed in clinical practice. The inappropriate and overuse of antibiotics for infective endocarditis prophylaxis highlights the broader concerns related to increasing antibiotic resistance and their effect on child development.

Postnatal

In the postpartum period, fluid balance must be monitored carefully. During the first 24 to 72 hours, significant fluid shifts occur and can lead to congestive heart failure in patients with cardiac disease. Careful attention should be paid to patients who do not have a brisk spontaneous diuresis. In these patients, progressive reduction in oxygen saturation monitored by pulse oximetry often heralds the onset of clinical pulmonary edema.

Formulating an effective contraception plan can be challenging but is essential due to the potential maternal and fetal risks associated with an unintended pregnancy. The potential side effects and complications of various contraceptive methods must be considered in relation to the unique problems associated with specific cardiac conditions. The World Health Organization[42] (WHO) provides a framework to aid in choosing an appropriate and effective contraceptive method based on known risks and contraindications. The categories are presented in Table 36–5. In general, progestin-only pills, progestin implants, and emergency contraception are category 1 and can be used in all cardiac patients. Depo-Provera can be used in most, but should be avoided in patients on warfarin. Combined hormonal contraceptive methods and the standard copper-containing intrauterine contraceptive device (IUD) present risks to some cardiac patients and should be avoided.[43] Where the concern with IUD use is related to increased risk of bleeding or infection rather than insertion complications, the levonorgestrel-releasing intrauterine contraceptive system (Mirena) is probably acceptable because its use of slow-release progestogen into the uterine cavity greatly reduces the risk of infection and heavy bleeding. The utility of these methods is reviewed for the individual conditions.

TABLE 36–5

World Health Organization Contraceptive Criteria

CATEGORY	DEFINITION
1	A condition for which there is no restriction for the use of the contraceptive method.
2	A condition where the advantages of using the method generally outweigh the theoretical or proven risks.
3	A condition where the theoretical or proven risks usually outweigh the advantages of using the method.
4	A condition which represents an unacceptable health risk if the contraceptive method is used.

SUMMARY OF MANAGEMENT OPTIONS
Cardiac Disease: General

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Obstetrician and cardiologist in collaboration.	—/GPP	—
Discuss maternal and fetal risks.	III/B	3,5,28
Discuss safe and effective contraception.	—/GPP	—
Evaluate current cardiac status.	III/B	5,28
Optimize medical and surgical management.	III/B	1,5,31
Advise against pregnancy with certain conditions.	III/B	3,5,30
Prenatal		
Assess functional class of heart disease (see Table 36–3).	III/B	3,5
Termination is an option with some conditions.	III/B	3,5
Joint management with a cardiologist.	—/GPP	—
Optimize medical management.	III/B	1,5,31
Avoid or minimize aggravating factors.	III/B	3,5
Anesthesiology consultation.	IV/C	30
Prophylactic antibiotics in some situations.	IV/C	37,39
Fetal surveillance		
• Growth and fetal surveillance (especially if left-to-right shunt).	III/B	1,3,5
• Detailed fetal cardiac ultrasonography if the patient has congenital heart disease.	III/B	1,3,5
Labor and Delivery		
Elective induction may be necessary for maternal or fetal indications.	III/B	1,3,5
Prophylactic antibiotics with certain situations.	IV/C	37,39
Avoid mental and physical stress; consider epidural.	III/B	3,5
Labor in the left lateral and upright position.	III/B	1,3,5
Monitor electrocardiogram; more invasive monitoring is needed with certain conditions.	III/B	102
Administer extra oxygen with certain conditions.	—/GPP	—
Full resuscitation facilities should be available.	—/GPP	—
Provide continuous fetal heart rate monitoring.	—/GPP	—
Assisted second stage with certain conditions.	—/GPP	—
Avoid ergotamine for the third stage; boluses of oxytocin are best avoided and it is most safely given as a slow infusion.	—/GPP	—
Postnatal		
Vigilance for cardiac failure.	III/B	1,3,5
Avoid fluid overload.	III/B	1,3,5
Continued intensive care.	—/GPP	—
Discuss safe and effective contraception.	—/GPP	—

GPP, good practice point.

CARDIAC MURMUR

Maternal and Fetal Risks

Cardiac murmurs result from turbulent blood flow that causes vibration of the cardiac structures. Systolic murmurs are very common during pregnancy, with a reported incidence exceeding 90%.[44,45] Typically, the murmur is early to midsystolic and soft (grades I–II). The left sternal border is usually the area of maximal intensity, followed by the aortic and pulmonic areas.[46] These murmurs are rarely associated with cardiac pathology and are likely secondary to the increased intravascular volume and cardiac output.

Echocardiographic studies of pregnant patients who are referred for evaluation of nonspecific systolic murmurs show normal structure and function in more than 90% of examinations. Most patients had the clinical characteristics of a benign flow murmur.[46–50] Most abnormalities were mild and were associated with a history suggesting pathology.[46,48–50] Clinically significant murmurs differ from the typical benign flow murmur. Systolic murmurs that are "loud or long" are suspicious and are more frequently associated with cardiac pathology. Late systolic, pansystolic, and diastolic murmurs are abnormal and also require further evaluation.[6,48]

Management Options

Echocardiography adds little to the clinical evaluation of nonspecific systolic murmurs, because most significant cardiac conditions seen during pregnancy are diagnosed before conception. Unsuspected mild cardiac disease may initially present during pregnancy or the puerperium. A common benign flow murmur must be differentiated from a pathologic condition. Unfortunately, the accuracy of clinical evaluation of systolic murmurs by noncardiologists is unknown.[47] A history that suggests cardiac disease or a pathologic murmur (late systolic, pansystolic, or diastolic) heard on physical examination should prompt evaluation with echocardiography. When a suspicious systolic murmur is noted, either a cardiologist's clinical examination or an echocardiogram can reliably identify significant pathology.[47] The method of choice depends on institutional resources. If a woman gives a history of repeated referrals because of an unusually loud but nonpathologic murmur, it can be helpful to give her a copy of her echocardiogram report, which she can show to future medical attendants, thus avoiding overinvestigation and the development of cardiac neurosis.

MITRAL VALVE PROLAPSE

Maternal and Fetal Risks

Mitral valve prolapse (MVP) represents a range of valvular abnormalities that allow one or both mitral valve leaflets to extend above the plane that separates the atria and ventricle. There is a wide range in the reported prevalence of MVP depending on the method of diagnosis, the diagnostic criteria, and the population studied. The condition is most common in women of reproductive age, with prevalence rates reported as high as 17%. Standardized echocar-diographic criteria and a better understanding of the shape of the mitral valve have dramatically decreased prevalence estimates.[51] The condition remains relatively common, with a prevalence of 0.5% to 3% in the general population.[52,53]

Auscultation or echocardiography may be used to diagnose MVP. A midsystolic click, with or without a midsystolic to late systolic murmur, is the clinical hallmark. With two-dimensional echocardiography, the diagnosis is made when the mitral valve is seen prolapsing into the left atrium 2 mm or more on the long-axis view.[6] Postural maneuvers are sometimes used to aid in the auscultatory diagnosis. Activities that decrease left ventricular volume increase the degree of prolapse. Hydration affects the auscultatory findings of MVP.[54] Pregnancy may have similar effects, with changes in the timing of the click and shortening or softening of the murmur. Serial echocardiograms during pregnancy showed disappearance of MVP during pregnancy in a significant number of patients.[55]

Palpitations, arrhythmias, chest pain, syncope, fatigue, and panic attacks are reported in association with MVP. Together, they make up MVP syndrome, although the existence of a distinct syndrome has been questioned. The symptoms associated with MVP syndrome are very common and are seen with near-equal frequency in patients with and without an echocardiographic diagnosis of MVP.[52,56]

Severe mitral regurgitation requiring surgery, infective endocarditis, cerebral ischemia, and sudden death are serious complications associated with MVP. The complications are uncommon in reproductive-age women because they are typically associated with severe mitral regurgitation, older age, and comorbid conditions.[57,58] In an examination of offspring of the Framingham Heart Study participants, with an average age of 54 years, the occurrence of severe complications in association with MVP was only minimally greater than that in those without the diagnosis.[52] The risk of serious complications in women younger than 45 years of age with uncomplicated MVP is estimated to be 0.2%/yr.[57]

Management Options

Prepregnancy

Prepregnancy management should document any associated mitral regurgitation by either echocardiography or evaluation by a cardiologist.

Prenatal

Patients should be observed for cardiac arrhythmias, particularly supraventricular tachycardia. Although these occur very infrequently, the patient should be counseled to avoid caffeine, alcohol, tobacco, and β-mimetic drugs. When necessary, β-blockers (most category C) may be used.[6]

Labor and Delivery and Postnatal

In addition to continued observation for arrhythmias, The Endocarditis Working Party of the British Society for Antimicrobial Chemotherapy[37] recommends endocarditis prophylaxis prior to cesarean section for high risk patients with MVP and in the presence of significant mitral regurgitation, but this has recently been questioned (see earlier).

CONGENITAL HEART DEFECTS

Atrial Septal Defect

Maternal and Fetal Risks

Ostium secundum atrial defect is one of the most common congenital heart defects seen in pregnancy, and women are more commonly affected than men. Pregnancy is generally well tolerated and uncomplicated, especially in patients with normal systolic function shown by echocardiography and NYHA functional class I or II.[59,60] Significant complications can be associated with uncorrected atrial septal defect (ASD), but these are uncommon before 40 years of age. Supraventricular arrhythmias are more frequent with advancing age and may aggravate right-sided heart failure. Paradoxical emboli from the venous to the systemic circulation can occasionally occur. Pulmonary hypertension is uncommonly associated with ASD and is typically found in older patients.[61] In fetuses born to mothers with an ASD, the risk of congenital heart disease is 4% to 10%.[7,26,60]

Management Options

PREPREGNANCY

The ASD should be evaluated for closure prior to conception and any secondary complications, such as supraventricular arrhythmias or pulmonary hypertension, should be identified. In most cases, a newly diagnosed ASD can be closed with a catheter-placed device. Pregnancy should be discouraged and effective contraception initiated when significant pulmonary hypertension is present.[61] In these patients, combination oral contraceptive pills (OCPs) and IUDs are considered class 4 (see Table 36–5) and contraindicated owing to the risk and consequences of pulmonary embolus. The concern with the IUD is related to the risk of cardiovascular instability that can occur with a vasovagal event at IUD insertion (this risk is approximately 1 in 1000), so if the intrauterine contraceptive system is considered, it should be inserted in a hospital setting with appropriate facilities for resuscitation and an anesthetist in attendance. Depo-Provera is considered a category 1 choice and can be safely used.[43] Permanent sterilization is also an option; however, surgical and anesthetic risks must be considered. The new technique of occluding the fallopian tubes with coils inserted at hysteroscopy (Essure) probably poses less of a risk than laparoscopy.

PRENATAL

Prenatal care is routine in the absence of supraventricular arrhythmias, right-sided heart failure, and pulmonary hypertension. A fetal echocardiogram should be recommended owing to the increased incidence of fetal congenital heart disease.

LABOR AND DELIVERY

Labor is generally well tolerated. Patients are monitored for arrhythmias. Blood pressure is carefully monitored, and fluid is restricted. In addition to pain control, epidural anesthesia reduces systemic vascular resistance and may reduce any left-to-right shunt.

POSTNATAL

In patients without secondary complications, postpartum management is routine. Postpartum management encourages ambulation to decrease the risk of deep venous thrombosis and paradoxical embolization.

Ventricular Septal Defect

Maternal and Fetal Risks

Ventricular septal defects (VSDs) are uncommon in adults. Small defects usually either close spontaneously or are corrected in childhood. Maternal morbidity is related to the size of the VSD and the presence of pulmonary hypertension. Small defects and those that are repaired in childhood usually present no problem during pregnancy. Some asymptomatic patients with a repaired VSD have significant, but unrecognized, pulmonary hypertension, which is manifested clinically in association with the hemodynamic stresses of pregnancy.[62,63] Paradoxical systemic emboli can also occur in patients with an uncorrected VSD. As with ASD, however, patients with good functional status and normal systolic ventricular function usually have a normal outcome.[59,60] Infants born to mothers with a VSD have a 6% to 10% risk of congenital heart disease.[7,26,60]

Management Options

PREPREGNANCY

Before pregnancy, patients with a VSD (corrected or uncorrected) should be evaluated for pulmonary hypertension. Pregnancy is discouraged in patients with pulmonary hypertension. In the absence of pulmonary hypertension, repair of uncorrected lesions should be considered. Patients should be counseled about the increased risk of congenital heart disease in their offspring.

PRENATAL

Patients should be evaluated and followed with serial echocardiography. The size of the lesion, the degree of the shunt, and the presence of pulmonary hypertension should be determined. Termination should be offered to patients with pulmonary hypertension. Owing to the increased incidence of fetal congenital heart disease, a fetal echocardiogram should be recommended.

LABOR AND DELIVERY

Hypotension should be avoided to prevent shunt reversal. Endocarditis prophylaxis is recommended by the Endocarditis Working Party of the British Society for Antimicrobial Chemotherapy[37] in patients undergoing cesarean section (but see earlier).

POSTNATAL

Volume status should be monitored during the postpartum period because of fluid shifts and the potential for congestive heart failure. Ambulation is encouraged to avoid the risk of deep venous thrombosis and paradoxical embolization. There are generally no contraceptive restrictions in the absence of pulmonary hypertension.[43]

Pulmonary Hypertension

Maternal and Fetal Risks

Pulmonary hypertension associated with pregnancy is a grave condition, and the maternal mortality rate is as high as 50%, although a recent survey suggests that improved management is reducing mortality, perhaps to as low as 25%.[64,65] Primary pulmonary hypertension is an idiopathic disease of the pulmonary vasculature that is seen primarily in women. Secondary pulmonary hypertension can result from long-standing increases in pulmonary pressure as a result of underlying cardiac disease, such as ASD or VSD, mitral stenosis, or patent ductus arteriosus (PDA).[66] Fortunately, the condition is rare, with a reported incidence of 1.6/100,000 deliveries in the United States.[67]

With primary pulmonary hypertension, the most dangerous times are labor, delivery, and the early postpartum period. Intravascular volume changes are not well tolerated because of the fixed pulmonary vascular resistance. Increases in cardiac output during labor or as a result of postpartum fluid shifts may lead to sudden right-sided heart failure. At delivery, excessive blood loss decreases preload, resulting in an inability to overcome high pulmonary vascular resistance. Both situations lead to a decrease in left ventricular preload and a dramatic decrease in left ventricular output. A direct consequence is myocardial ischemia, leading to arrhythmias, ventricular failure, and sudden death. Pulmonary thromboembolic events are usually fatal. Even small thrombi in the lungs can dramatically aggravate pulmonary hypertension.[66] There is an increased incidence of hypertensive disorders of pregnancy further complicating the condition.[67] In the fetus, chronic maternal hypoxia can lead to IUGR. Despite this, the neonatal survival rate is nearly 90%.[65]

Management Options

PREPREGNANCY

Despite improvements in maternal outcome with a comprehensive team approach,[66] maternal morbidity and mortality are significant risks. As a result, pregnancy should be discouraged and permanent sterilization should be considered.

PRENATAL

Caution should be exercised in diagnosing pulmonary hypertension during pregnancy. Cardiac catheterization is the gold standard for determining pulmonary artery pressures. In the nonpregnant patient, there is good correlation between echocardiographic-derived pressures and those obtained by cardiac catheterization. In the pregnant patient, however, echocardiographic pulmonary artery pressures tend to be overestimated, with nearly one third of those with elevated pressures found to be normal on subsequent cardiac catheterization.[68,69]

If pregnancy occurs in patients with severe pulmonary hypertension, termination should be offered because of maternal risks. If pregnancy is discovered in the second trimester and termination is chosen, dilation and evacuation in experienced hands is preferred over induction. In a continuing pregnancy, the cardiologist, critical care specialist, and obstetrician must work closely together. An obstetric anesthesiologist should be consulted early in the pregnancy.

The use of calcium channel blockers has been reported in some patients, with improvement in maternal cardiac output and successful pregnancy outcome. Nifedipine (category C) in doses of 90 to 120 mg daily was used.[70] Heparin (category C) thromboembolism prophylaxis is initiated early, with doses of 5000 to 10,000 units given subcutaneously twice daily. Patients with more severe disease, manifested by chest pain or oxygen saturation of 80% or less, are at higher risk and full heparin anticoagulation has been used. In the early third trimester, in-hospital bedrest with oxygen therapy (up to an FIO$_2$ [fractional concentration of oxygen in inspired gas] of 0.4) and frequent monitoring with pulse oximetry is advocated. Late diagnosis and late admission to the hospital were associated with an increased risk of maternal mortality.[65] Lack of improvement in arterial oxygen saturation (SaO$_2$) with oxygen suggests further increased maternal risk.[66] A recent review has suggested that optimal therapy may include the use of drugs such as prostacyclin analogues, phosphodiesterase inhibitors, sildenafil (Viagra), and inhaled nitric oxide. The use of endothelin-receptor antagonists (e.g., bosentan) has also been reported; however, this agent should be used with caution in the antepartum period because animal studies have reported teratogenicity with this agent.[64]

LABOR AND DELIVERY

Because continuing pregnancy represents such a grave risk to the mother and because 25% of babies of such mothers are growth-restricted, the majority of these women will be delivered at preterm gestations. Although spontaneous labor is preferred to prevent the increased risk of cesarean section associated with preterm induction of labor if the cervix is unfavorable, it will often be necessary to deliver the woman by cesarean section to avoid the stress of a prolonged and potentially failed induction. When indicated, however, oxytocin or E series prostaglandins can safely be used for induction, provided great care is exercised to avoid uterine hyperstimulation. Oxygen flow is increased to 5 to 6 L/min. Oxygen saturation is monitored continuously with pulse oximetry. A radial artery line is placed to allow continuous blood pressure monitoring and facilitate frequent blood gas sampling. Maintenance of stable blood pressure is important. Adequate preload is essential to maintain cardiac output. Routine use of a PAC is discouraged.[65] An alternative is to place a central venous pressure (CVP) catheter early in labor. Arguments against the use of a PAC stem from the fact that information from the right side of the heart can be obtained from the CVP line. Left-sided heart pressure may not be accurately reflected owing to elevated pulmonary artery pressures. Potential complications, such as arrhythmias, thrombosis, and pulmonary artery rupture, must be considered when deciding on PAC use. Despite these concerns, in some patients, cardiac output data obtained from a PAC is useful. The decision to use invasive hemodynamic monitoring should be made on an individual basis, after the risks and benefits are considered.

Several case reports described the use of intravenous prostacyclin or inhaled nitric oxide therapy during labor.[71–73] Both drugs cause vascular dilation and inhibit platelet aggregation, leading to improved oxygenation, decreased pulmonary vascular resistance, and a decreased risk of thromboembolism. Improvement in pulmonary

hypertension is similar between the two drugs in nonpregnant patients, and there seems to be no added benefit to a combination of the two agents. Inhaled nitric oxide avoids systemic hemodynamic changes, is easy to administer, and may cost less than other agents. Nitric oxide is typically used at a dose of 5 to 20 ppm. Elevated methemoglobin levels are a potential toxicity, but this problem has not been reported at these doses.[74]

An epidural catheter is placed early in labor and carefully activated when contractions become painful, to avoid hypotension. Intrathecal narcotics can be added to decrease the hypotensive effect of local anesthetics. During labor and delivery, the patient is placed in the left lateral position to avoid supine hypotension. Vaginal delivery, with shortening of the second stage using forceps or a vacuum to decrease the need for pushing, is desirable. Blood loss at delivery is carefully monitored. Crystalloid solution can be used to replace volume and maintain preload if blood loss is greater than normal. Older evidence suggests that cesarean delivery is associated with increased maternal morbidity and mortality and should be reserved for obstetric indications, although some studies suggest that the proportion of women being delivered by cesarean section is in fact increasing, probably due to the increasing recognition of the value of preterm delivery to avoid a third-trimester deterioration in maternal condition.[65,66] Despite the concern of increased morbidity and mortality, nearly 60% of 182 women with pulmonary hypertension were delivered by cesarean section between 2002 and 2004.[67] Although the mortality rate was not reported in that study, a more recent small case series including 15 pregnancies in 14 women with pulmonary hypertension of various etiologies evaluating anesthetic management described a cesarean rate of 69%.[75] The maternal mortality was 25% in those delivering vaginal delivery and 22% in those delivered by cesarean section.[75]

POSTNATAL

Antepartum and intrapartum management principles are continued into the postpartum period. Thromboembolism prophylaxis and oxygen therapy are continued. Excessive blood loss or right-sided heart failure as a result of fluid shifts can lead to sudden death. The patient must be monitored closely during the first 48 to 72 hours. During this time, nitric oxide is slowly weaned.[71] If prostacyclin is used, long-term therapy can continue, if necessary, through a central venous catheter.[73] Controlled diuresis is important during postpartum fluid mobilization to control preload and prevent worsening right-sided heart function.[70] Pulmonary edema may develop rapidly in patients who do not have brisk spontaneous diuresis. Permanent sterilization should be considered in patients with severe pulmonary hypertension. Depo-Provera or progesterone implants may be considered to avoid surgical and anesthetic risks. Combined hormonal contraceptives and standard IUDs should be avoided, as noted in the section on ASD.[43]

Eisenmenger's Syndrome
Maternal and Fetal Risks

Eisenmenger's syndrome is defined as pulmonary hypertension resulting from an uncorrected left-to-right shunt of a VSD, ASD, or PDA, with subsequent shunt reversal and cyanosis.

Pulmonary hypertension is defined as mean pulmonary artery pressure greater than 25 mm Hg. The increase in blood volume and decrease in systemic vascular resistance can lead to right ventricular failure, with a decrease in cardiac output and sudden death. Maternal mortality with Eisenmenger's syndrome is as high as 40% in pregnancies that continue past the first trimester.[65,76] In contrast, the 15-year survival rate is more than 75% in nonpregnant patients.[77] Postoperative fluid shifts associated with cesarean delivery pose an even greater risk, with mortality rates approaching 70%. Although maternal risk remains high, one report emphasizing a team approach, with close follow-up and careful attention to detail, achieved a more optimistic outcome.[66]

IUGR is a common fetal complication. If the maternal SaO_2 is less than 85%, babies usually die in utero before reaching a viable gestation and early miscarriage is very common. Preterm delivery is also frequent, occurring in up to 85% of pregnancies.[60,76] Despite the maternal and fetal complications, the neonatal survival rate of babies alive at birth approaches 90%.[60,65] Congenital heart defects are seen in approximately 5% of offspring.[60]

Management Options
PREPREGNANCY

Pregnancy should be discouraged and reliable contraception, preferably permanent sterilization, advised because of the extreme maternal risk associated with pregnancy. Depo-Provera or progesterone implants are nonsurgical alternatives.[43] Even first-trimester termination is associated with a maternal mortality rate of 5% to 10%.[66]

PRENATAL, LABOR AND DELIVERY, AND POSTNATAL

Echocardiography is helpful in evaluating shunting, right ventricular function, and pulmonary hypertension. Cardiac catheterization may be necessary to quantify pulmonary hypertension. Pregnancy complications and outcome are related to the degree of pulmonary hypertension. Management of pulmonary hypertension associated with Eisenmenger's syndrome follows the same principles discussed in the section on "Pulmonary Hypertension." Nitric oxide use is described in two case reports that showed improvement in pulmonary hypertension and maternal oxygenation during labor and delivery.[78,79] Unfortunately, despite continued use, progressive deterioration occurred postpartum, and neither patient survived. In one case, doses as high as 80 ppm were used, and an elevated methemoglobin level resulted.[78]

Pulmonary Stenosis
Maternal and Fetal Risks

Pulmonary stenosis is one of the more common congenital heart defects seen in adults. It is often asymptomatic even in patients with severe stenosis. Although reports on pregnancy outcome are limited, it appears that isolated pulmonary stenosis is not associated with significant adverse maternal or fetal effects.[6,7,60,80] One report does suggest, however, that there may be an increased incidence of hypertensive disorders of pregnancy and thromboembolic events.[81] In patients entering pregnancy with good functional status, maternal deterioration is uncommon. There is not an increased incidence of spontaneous preterm delivery or

IUGR. Severe stenosis does not increase the risk of adverse obstetric outcome.[60,80] The risk of congenital heart disease in the offspring is approximately 3% to 4%.[60,81]

Management Options

PREPREGNANCY AND PRENATAL

Maternal functional status and the degree of stenosis should be determined by echocardiography. Balloon valvotomy is done in patients with cardiac symptoms including exertional dyspnea, angina, or syncope when the gradient across the valve is greater than 30 mm Hg. It should also be considered in asymptomatic patients when the gradient is greater than 40 mm Hg.[6,7] Because significant problems during pregnancy are rare even with severe stenosis, balloon valvotomy should usually be delayed until after the postpartum period.[80] This will reduce the risk of thromboembolic complications associated with the sixfold increase in coagulability during pregnancy.

LABOR AND DELIVERY AND POSTNATAL

Cesarean section should be reserved for obstetric indications.[80] Patients should be monitored for signs of right heart failure during the postpartum period, although this is uncommon. There are no contraceptive restrictions.[43]

Coarctation of the Aorta

Maternal and Fetal Risks

Untreated coarctation of the aorta carries a poor prognosis and is uncommon today. As a result, pregnancy is seen almost exclusively in patients who have undergone some type of repair. When the lesions are corrected, maternal and fetal outcomes are not significantly different from those in the general obstetric population.[82] Several cardiovascular anomalies are associated with coarctation of the aorta. A bicuspid aortic valve is the most common, found in 20% to 40% of patients. VSDs, anomalies of the intercostal and subclavian arteries, and aneurysms of the circle of Willis may also be present. The benefit of screening for berry aneurysms is uncertain.[83] Hypertensive disorders of pregnancy are common and reported in more than 15% of patients.[60] Although data are limited, the physiologic changes associated with pregnancy may unmask and aggravate postrepair gradients. Aortic rupture or dissection is rare but has been reported.[82,84] Congenital heart disease is seen in approximately 4% of offspring.[60,82,84]

Management Options

PREPREGNANCY AND PRENATAL

Termination may be considered in patients with uncorrected coarctation of the aorta, especially if it is associated with other anomalies, because of the increase in morbidity and mortality seen in adults. The majority of patients will have had a previous repair and require evaluation of the repair as well as screening for associated cardiac abnormalities. The highest risk of rupture or dissection is in patients with a Dacron patch repair (a Dacron replacement of the whole root is now recognized to be safer) or an aneurysm. A fetal echocardiogram should be considered owing to the increased risk of fetal congenital cardiac anomalies.

LABOR AND DELIVERY AND POSTNATAL

Hypertension should be controlled in both the intrapartum and the postpartum periods. Epidural anesthesia is encouraged because it effectively controls pain and decreases systemic vascular resistance. Endocarditis prophylaxis is recommended by the Endocarditis Working Party of the British Society for Antimicrobial Chemotherapy prior to cesarean section in patients with coexisting aortic valvular disease (but see earlier).

Progesterone-only contraceptive methods and IUDs can safely be used for contraception. In patients with repaired coarctation, combined hormonal methods are also considered safe in the absence of an aneurysm or hypertension.[43]

Tetralogy of Fallot

Maternal and Fetal Risks

Tetralogy of Fallot is the most common cyanotic heart disease, consisting of a VSD, overriding aorta, pulmonary stenosis, and right ventricular hypertrophy. In developed countries, nearly all patients undergo surgical repair in infancy. The majority of these patients are now alive during the reproductive years and leading normal lives. Nearly all patients with corrected tetralogy of Fallot enter pregnancy with NYHA class I and tolerate pregnancy well. Maternal complications can occur, however. Pulmonary regurgitation is seen 70% to 85% of patients.[85,86] Severe pulmonary regurgitation is associated with an increased risk of arrhythmias and right heart failure. These complications also appear to be more common in patients with repair later in life.[86]

Although survival to adulthood with uncorrected tetralogy of Fallot is possible, pregnancy is rarely seen in these individuals owing to a shortened life expectancy as well as decreased fertility. When pregnancy does occur in uncorrected tetralogy of Fallot, patients are at risk of serious maternal morbidity and mortality (see Table 36–1). Preexisting pulmonary hypertension is a concern. In addition, increased cardiac output leads to increased venous return to the hypertrophic right ventricle. These changes, together with decreased systemic vascular resistance, increase the right-to-left shunt. Oxygenation decreases, hematocrit increases, and cyanosis worsens, further stressing an already compromised cardiovascular system. Risk factors that worsen the prognosis include prepregnancy hematocrit exceeding 65%, a history of congestive heart failure or syncope, cardiomegaly, right ventricular pressure exceeding 120 mm Hg or strain pattern on electrocardiogram, or oxygen saturation less than 80%.[87]

Miscarriage, preterm delivery, and perinatal mortality do not seem to be increased.[60,85,86] There may be an increased incidence of growth-restricted newborns, however.[85] Congenital heart disease affects 3% to 5% of infants of mothers with tetralogy of Fallot.[26,60]

Management Options

PREPREGNANCY

Surgery is advocated for patients with uncorrected lesions. Patients who underwent previous corrective surgery should be evaluated for residual defects, such as pulmonary stenosis

or residual VSD. If defects are found, the need for repair should be evaluated.[86]

PRENATAL

After surgical correction, patients with pulmonary regurgitation should be monitored for arrhythmias and signs of right heart failure. Patients with uncorrected tetralogy of Fallot should be offered termination. In those who continue, the pregnancy hematocrit should be followed. Supplemental oxygen may be of benefit. In all patients, a fetal echocardiogram should be preformed. In addition, serial obstetric ultrasound examinations should be done to monitor for IUGR. Antenatal testing is started during the third trimester, as indicated.

LABOR AND DELIVERY

In patients with uncorrected defects, careful fluid management and maintenance of blood pressure are the main features of intrapartum care. Central hemodynamic monitoring may be used, but there is a risk of exacerbating arrhythmias. Hypotension should be prevented to avoid shunt reversal. Epidural anesthesia can be used if the patient is adequately hydrated and it is carefully administered. To prevent decreases in venous return with bearing down, operative vaginal delivery may be used to shorten the second stage of labor. This strategy is often applied in patients with corrected tetralogy of Fallot, although it probably is not necessary.[85,86]

POSTNATAL

In patients with uncorrected tetralogy of Fallot, volume status should be monitored during the early postpartum period. A reliable contraceptive plan should be made, with permanent sterilization a good alternative. All reversible forms of contraception are considered category 1 or 2 and can be used in patients with corrected and uncomplicated tetralogy of Fallot.[43]

Transposition of the Great Arteries
Maternal and Fetal Risks

Transposition of the great arteries is a congenital heart disease consisting of discordance between the ventricles and the great arteries, in which the aorta arises from the right ventricle and the pulmonary artery originates from the left ventricle. Two types exist, depending on the concordance of the ventricles and the atria. In the first type, complete transposition, there is atrial concordance. After delivery, two parallel circulations exist. The systemic venous return enters the right atrium, proceeds to the right ventricle, and exits through the aorta, bypassing the pulmonary circulation. The pulmonary venous return enters the left atrium, continues into the left ventricle, and returns to the lungs through the pulmonary artery. Thus, no oxygenated blood reaches the systemic circulation. Without an additional congenital shunt such as a PDA or a surgical procedure to redirect blood flow more appropriately, this condition is not compatible with extrauterine life. Although several procedures are used to repair the condition, the Mustard operation, an atrial switch procedure, has been the most commonly used.[88] In this procedure, a baffle is placed between the right and left atria. Systemic venous return is redirected to the left side of the

heart and to the lungs, whereas the oxygenated pulmonary venous blood is shunted to the right ventricle and on to the systemic circulation. Surgery allowed these patients to reach adulthood and contemplate pregnancy but left them with a systemic right ventricle that often fails in the sixth decade because it is unable to cope long-term with the demands of supplying the systemic circulation. Today, the arterial switch procedure is more common, because it results in both ventricles performing their correct function. Little information regarding pregnancy is available in these patients, however, because few of them have yet reached childbearing age.[89]

The second type is congenitally corrected transposition. Both arterioventricular and atrioventricular discordance are present. The right atrium empties its systemic venous blood into the morphologic left ventricle. Oxygenated pulmonary venous blood returns to the left atrium and empties into the morphologic right ventricle. Additional cardiac anomalies are often present, including VSD, pulmonary stenosis, and valve abnormalities.[90] The major concern in both types of transposition is the ability of the morphologic right ventricle to continue to support the systemic circulation as well as the increased cardiac output occurring during gestation. Maternal mortality is uncommon but reported. The risk of significant maternal morbidity is increased in both types of transposition. Cardiovascular complications include arrhythmias, congestive heart failure, myocardial infarction (MI), and cerebrovascular accident.[3,60,88,90] There also appears to be an increased incidence of hypertensive disorders of pregnancy reported in approximately 15% of pregnancies.[60,88]

The incidence of miscarriage is high, ranging from 15% to 40%. The increased risk is primarily related to maternal cyanosis.[60,91,92] In patients with surgically ameliorated transposition, the preterm birth rate is 30% to 40%. The incidence of babies small for gestational age is 20% to 30%.[60,88] The risk of congenital heart disease in offspring of these women does not appear to be increased above that in the general population, although the number of patients evaluated was small.[26,60,88]

Management Options
PREPREGNANCY

As with all cardiac conditions in pregnancy, it is important to determine the patient's functional status. Echocardiography to evaluate the function of the systemic right ventricle is necessary. The patient should also be evaluated for arrhythmias. A cardiologist with experience in treating congenital heart disease in adults should be included in the initial evaluation and throughout pregnancy. Often, this role is filled by the patient's pediatric cardiologist because these physicians frequently follow patients into adulthood. Unfortunately, pediatric cardiologists often have a limited medical knowledge regarding pregnancy and contraception, and increasingly, a joint service between an expert in adult congenital heart disease and a high risk obstetrician is becoming available and should be recommended.

PRENATAL

Decreased activity is advised to minimize further stress on the right ventricle. Patients should have serial echocardiography to evaluate cardiac function. Symptoms of congestive heart failure should be evaluated quickly and treated with

diuretics and digoxin, as indicated. An anesthesiologist should evaluate the patient before labor.

LABOR AND DELIVERY AND POSTNATAL

Maternal cardiac monitoring is used to detect arrhythmias. Supplemental oxygen is given, as necessary. Volume overload should be avoided during labor and throughout the postpartum period. Adequate analgesia is important and can be provided with an epidural. Shortening of the second stage with forceps or a vacuum should be considered. Cesarean delivery is reserved for the usual obstetric indications.

Combined hormonal contraceptive methods can be used in patients with transposition of the great vessels (category 2), provided there are no arrhythmias or cardiac dysfunction.[43]

Ebstein's Anomaly

Maternal and Fetal Risks

Ebstein's anomaly is a relatively uncommon congenital heart defect characterized by apical displacement of the tricuspid valve leading to tricuspid regurgitation and right heart enlargement. Varying degrees of right and left ventricular dysfunction are also noted. Additional cardiac anomalies are often present, the most common being an ASD. Right-to-left shunting can occur, resulting in cyanosis. There is an increased incidence of arrhythmias, particularly Wolff-Parkinson-White Syndrome (WPW). Ablation of the accessory pathway has a lower success rate and higher recurrence rate in patients with Ebstein's anomaly than in those without structural cardiac abnromalities.[93]

Pregnancy is generally well tolerated in patients with Ebstein's anomaly; however, serious complications can occur. Arrhythmias and heart failure each occur in 3% to 4% of pregnancies.[60] The rate of preterm delivery is increased to approximately 25%.[60,94] The incidence of low birth weight is only slightly elevated and is seen primarily in women with cyanosis.[94] Congenital cardiac abnormalities are seen in 4% to 6% of offspring.[60,94]

Management Options
PREPREGNANCY

Most patients who require correction will have undergone surgery prior to adulthood. Echocardiography should be undertaken to evaluate ventricular function and the degree of tricuspid regurgitation. Those that have not had surgical correction should be evaluated for this, and if indicated, it should be done prior to pregnancy.

PRENATAL

The patient should be observed for arrhythmias. Serial maternal echocardiograms may be done to monitor cardiac function and evaluate for evidence of right heart failure. Decreased activity may be considered to decrease right heart strain. A fetal echocardiogram is indicated at 20 to 22 weeks to evaluate for fetal cardiac abnormalities. The patient should be educated and monitored for evidence of preterm labor. It may also be prudent to obtain serial ultrasounds for fetal growth with antenatal testing if growth restriction is identified.

LABOR AND DELIVERY AND POSTNATAL

Maternal cardiac monitoring should be considered to detect arrhythmias. Supplemental oxygen may be given, as necessary. Fluid balance should be monitored closely to avoid volume overload during labor and throughout the postpartum period. Adequate analgesia should be provided and can be accomplished with an epidural. Shortening of the second stage with forceps or a vacuum may be considered. Cesarean delivery is reserved for the usual obstetric indications.

Patent Ductus Arteriosus
Maternal and Fetal Risks

Surgical correction of PDA is usually accomplished in childhood. Uncorrected lesions have traditionally accounted for fewer than 5% of pregnancies complicated by congenital heart disease.[1] Maternal complications depend on the size of the ductus. Asymptomatic patients with a small PDA generally tolerate pregnancy without difficulty. Left-to-right shunting may decrease during pregnancy as a result of decreased systemic vascular resistance. A large lesion with a long-standing left-to-right shunt can lead to pulmonary hypertension.[95] In this situation, the normal decrease in systemic vascular resistance during pregnancy can cause shunt reversal, with an increase in maternal mortality.

Management Options
PREPREGNANCY

Before pregnancy, evaluation includes echocardiography to determine the size of the PDA and identify pulmonary hypertension.

PRENATAL

Antenatal management consists of echocardiography to detect pulmonary hypertension. If pulmonary hypertension develops, bedrest and supplemental oxygen should be instituted.

LABOR AND DELIVERY AND POSTNATAL

Intrapartum volume status should be monitored with care to avoid hypotension, which can result in shunt reversal. Use of a PAC may be indicated in patients with pulmonary hypertension. Careful attention to volume status should continue through the postpartum period.

RHEUMATIC HEART DISEASE: GENERAL
Maternal and Fetal Risks

Over the last several decades, a significant decline in the incidence and severity of rheumatic heart disease has occurred in developed countries. A similar pattern has been seen with rheumatic heart disease complicating pregnancy,[1] although recent data suggest that it is increasing again because of increases in immigration.[96] In a multicenter report of 562 women with heart disease managed during pregnancy, only 14% had acquired valvular lesions.[3] The changes were attributed in part to improved socioeconomic conditions. In many parts of the world, however, rheumatic heart disease remains a significant public health problem. Asia,

Africa, and South America have high prevalence rates.[97] Despite the dramatic decline in developed countries, rheumatic heart disease will continue to be seen because of immigration from high-prevalence areas.[98]

Rheumatic heart disease is a complication of rheumatic fever. Cardiac valve damage results from an immunologic injury initiated by a group A β-hemolytic streptococcal infection.[99] During pregnancy, the increased maternal blood volume and heart rate can lead to heart failure and pulmonary edema. Arrhythmias also frequently complicate pregnancy. In a series of 64 women followed in Los Angeles, congestive heart failure occurred in 38% and arrhythmias occurred in 15%. Not surprisingly, poor maternal functional class (NYHA class III or IV) was associated with worse maternal and fetal outcomes.[100] Rates of IUGR and prematurity are increased with complicated rheumatic heart disease.[100,101]

Management Options

General management principles for patients with rheumatic heart disease are aimed at preventing cardiac failure and bacterial endocarditis. Volume status is monitored, and activity should be limited. Antibiotics can be given prior to cesarean section as recommended by the Endocarditis Working Party of the British Society for Antimicrobial Chemotherapy.[37] Specific valvular lesions are discussed individually.

Mitral Stenosis

Maternal and Fetal Risks

Mitral stenosis, either alone or in combination with other lesions, is the most common valvular disorder associated with rheumatic heart disease.[1,101] In a 12-year review of 486 pregnant patients in India through 1999, 63% of lesions affected a single valve. Mitral stenosis was the abnormality in 90% of these women.[101] Although in the past, mitral stenosis was the most common rheumatic lesion associated with maternal mortality, death rarely occurs today, even in developing countries.[1,101–104] Hemodynamically, mitral stenosis is a state of fixed cardiac output caused by left atrial outflow obstruction. Pressures in the left atrium and pulmonary vasculature are increased. Long-standing severe disease may be complicated by secondary pulmonary hypertension and atrial fibrillation. In pregnancy, the increased intravascular volume can further elevate pressures and lead to pulmonary edema and arrhythmias, even in previously asymptomatic patients.[103] For this reason, any administration of intravenous fluid should be closely monitored and kept to a minimum. The risk of cardiac compromise is further aggravated by an increased maternal heart rate and decreased left ventricular filling time, which lead to a decrease in cardiac output.[102] The severity of the stenosis is the best predictor of cardiac compromise.[104,105] If maternal decompensation can be avoided, a good fetal outcome can be expected.[1,102,104]

Management Options
PREPREGNANCY

The goal of preconception care is to define the severity of cardiac compromise. Two-dimensional echocardiography and color-flow Doppler are used to determine cardiac

function and the degree of stenosis. Together, these modalities allow noninvasive evaluation and decrease the need for cardiac catheterization.[106] Severe stenosis is defined by a valve area of less than 1.0 cm.[6] Valve areas of 1.2 cm or less are associated with an increased risk of complications during pregnancy.[104] In symptomatic patients or those with severely stenotic valves, surgical correction should take place before conception. Surgical commissurotomy is the traditional treatment modality. Percutaneous mitral valve commissurotomy has emerged as an alternative in patients without calcified valves or significant regurgitation. The percutaneous method is safe and as effective as the surgical approach in appropriate patients. In addition, it is less invasive, less expensive, and the preferred therapy in many centers.[6,7,98,107,108] Satisfactory results persisted beyond 5 years in these reports, delaying and potentially avoiding the risks associated with prosthetic valves.[109]

PRENATAL

The goal of prenatal care is to avoid cardiac decompensation. Special attention should be paid to volume status. Weight gain should be closely monitored. Symptoms or physical findings associated with heart failure should be reported and evaluated promptly. Maternal tachycardia should be avoided to prevent a decrease in cardiac output. Restriction of physical activity can aid in this objective. β-Blockade may be used to control heart rate. It is frequently used empirically in mitral stenosis during pregnancy to prevent the development of tachycardia, with good maternal and fetal outcome.[6,104,110] Atrial fibrillation can be managed with digoxin (category C) or cardioversion, as necessary. If the atrial fibrillation is persistent or long-standing, these patients may also require anticoagulation to prevent atrial thrombi.

Serial echocardiography is indicated to follow cardiac function. Percutaneous mitral balloon valvulotomy may be necessary to treat patients with significant functional deterioration or refractory pulmonary edema, despite optimal medical management. Several series have reported symptomatic improvement with good maternal outcomes in women managed with balloon valvulotomy for severe mitral stenosis during pregnancy.[108,111–113] In experienced hands with abdominal shielding, fluoroscopy time and fetal radiation exposure can be minimal.[6,113] Neonatal outcomes are also reported to be better when compared with closed mitral valvotomy or valve replacement.[108,114] Follow-up of 2 to 5 years has not identified any increase in developmental delay or adverse childhood outcomes following percutaneous valvuloplasty.[111,113,115]

LABOR AND DELIVERY

During the intrapartum and postpartum periods, volume status and cardiac output are critical concerns. In patients with NYHA class III or IV disease, central hemodynamic monitoring has been used. Pulmonary pressures and cardiac output can be measured reliably. Although pulmonary capillary wedge pressure (PCWP) can warn of the potential for pulmonary edema, it does not accurately reflect left ventricular preload. The pressure gradient across the stenotic valve may necessitate a high-normal or even elevated PCWP to allow adequate left ventricular filling and maintain cardiac output. To prevent pulmonary edema after delivery as a

result of postpartum fluid shifts, PCWP should be maintained as low as possible without compromising cardiac output. Fluid restriction or careful diuresis, with attention to cardiac output, may be used to obtain desirable pressures. Decreased diastolic filling time associated with tachycardia may also decrease cardiac output. Careful intravenous administration of β-blockers (most category C) may be necessary to control heart rate and maintain cardiac output during labor.[102]

Similar considerations accompany analgesia and anesthesia during labor and delivery. Epidural analgesia is both safe and effective. Slow administration of the anesthetic agent is necessary to avoid hypotension. Control of labor pain removes a stimulus for tachycardia. The increased venous capacitance can also moderate postpartum fluid shifts. Drugs such as atropine, pancuronium, and meperidine can cause tachycardia and should be avoided.

Cesarean delivery is typically reserved for obstetric indications. If abdominal delivery is necessary, epidural is the anesthetic method of choice. Although forceps delivery is advocated to shorten the second stage of labor and reduce bearing down, it is not always required.[102] Endocarditis antibiotic prophylaxis should be given prior to cesarean section as recommended by the Working Party of the British Society for Antimicrobial Chemotherapy (but see earlier).[37]

POSTNATAL

Postpartum fluid shifts increase the risk of pulmonary edema. Clark and associates[102] noted a mean increase in PCWP of 10 mm Hg between the second stage of labor and the postpartum period in eight patients with functionally severe mitral stenosis. Because frank pulmonary edema is unlikely at a PCWP of less than 30 mm Hg, maintaining the PCWP at 14 mm Hg or lower if central hemodynamic monitoring is employed should prevent this complication.[102]

Combined hormonal contraceptive methods should be used only in patients with mild stenosis and no atrial fibrillation. Standard IUDs should be used with caution owing to a potential increased risk of endocarditis,[43] the levonorgestrel intrauterine contraceptive system is preferable because it is associated with a very low risk of infection.

Mitral Regurgitation

Maternal and Fetal Risks

Although mitral stenosis is almost exclusively caused by rheumatic heart disease, mitral regurgitation has several causes. In addition to rheumatic disease, floppy mitral valves in association with MVP, papillary muscle dysfunction, and ruptured chordae tendineae can result in mitral regurgitation.[116] In women of reproductive age, however, rheumatic heart disease is the most common cause of hemodynamically significant regurgitation. It is the dominant lesion in approximately one third of patients with rheumatic heart disease, but it is often associated with mitral stenosis.[1,105] In patients without severe mitral regurgitation or ventricular dysfunction, pregnancy is generally well tolerated. The decrease in systemic vascular resistance associated with pregnancy has a beneficial effect. Supraventricular tachycardia or atrial fibrillation may develop as a result of the increased volume, leading to atrial dilation. These arrhythmias may precipitate congestive heart failure.[105]

Management Options

PREPREGNANCY

NYHA functional status should be determined (see Table 36–3). The degree of regurgitation, atrial size, and ventricular function should be established with echocardiography. If required, digoxin (category C) therapy should be optimized. Although uncommon, if valve replacement is necessary, surgery should be performed before pregnancy. Valve replacement is indicated in asymptomatic patients with mild to moderate ventricular dysfunction and in those with atrial fibrillation, pulmonary hypertension, or symptoms such as dyspnea at rest or orthopnea.[117]

PRENATAL

In patients with NYHA class I or II disease, restriction of activity to prevent fatigue should be all that is required. In patients who have symptoms, serial echocardiography is indicated. Digoxin, diuresis, and afterload reduction should be instituted if left ventricular failure develops.

If medical therapy is unsuccessful, cardiac surgery during pregnancy can proceed, if necessary.[6] Although small case series have suggested that maternal mortality is not increased compared with nonpregnant women,[114,118] a review of the literature suggests that surgery for valvular disease during pregnancy and the early postpartum period is associated with a mortality rate of approximately 9%, roughly four times that of the nonpregnant population.[119] The fetal mortality is as high as 30%.[118,119] Factors that affected survival were gestational age at hospital admission and the degree of emergency necessitating the procedure. During cardiac bypass, fetal bradycardia and even cardiac arrest can occur as a result of maternal hypotension.[120] Fetal risks are minimized with high flow to maintain a mean maternal blood pressure greater than 70 mm Hg. Fetal heart rate can be monitored during the procedure and used as a guide to adjust flow rates. Hypothermia is also a concern because it is associated with fetal bradycardia, and therefore, hypothermia should be avoided. Perfusion temperatures greater than 30°C are generally well tolerated.[118] Uterine contractions are common, further complicating fetal heart rate abnormalities. In the larger review, however, neonatal outcome was not related to the evaluated variables associated with cardiac bypass, including duration of bypass, hypothermia versus normal temperature, and lowest temperature, provided the baby was born alive.[119]

LABOR AND DELIVERY AND POSTNATAL

Volume status should be monitored, and increases in blood pressure should be avoided to prevent worsening of regurgitant flow. When the left atrium is enlarged, cardiac monitoring may aid in the early identification of atrial fibrillation. Regional anesthesia is the method of choice for pain control during labor and delivery because of the decrease in systemic vascular resistance. Endocarditis prophylaxis may be utilized for cesarean sections.[37] Monitoring for congestive heart failure and atrial fibrillation should continue into the postpartum period.

Combined OCPs should be avoided in patients with severe regurgitation at risk for atrial fibrillation.[43]

Aortic Stenosis

Maternal and Fetal Risks

Aortic stenosis is the most common cardiac valve lesion in the United States. It can be congenital or rheumatic in origin, or it may be due to an age-related calcification of the aortic valve. All of these causes are uncommon in women of reproductive age, although congenital aortic stenosis is the most frequent etiology seen during pregnancy.[6] Aortic stenosis of rheumatic origin is typically progressive and tends to be less severe in patients of reproductive age.[121] In addition, it accounts for only 5% to 10% of cases of rheumatic heart disease in pregnancy and is usually seen in conjunction with mitral valve disease.[1]

The normal aortic valve area is 3 to 4 cm^2. The pressure gradient across the valve increases rapidly as the valve area is reduced to less than 2 cm^2, and this increase is associated with left ventricular outflow obstruction.[122] Mild to moderate congenital stenosis (valve area > 1 cm^2) is relatively well tolerated in pregnancy, and cardiac complications typically do not occur[103,105,123,124] Even patients with severe aortic stenosis generally do well. Maternal mortality is rare, although cardiac complications occur in approximately 10% of patients.[103,105,123,124] During 2-year follow-up, 36% of patients had progression of the cardiac condition that required surgery.[124] In these patients, cardiac output is fixed. Increased left ventricular pressure leads to hypertrophy and subsequent atrial enlargement. Tachyarrhythmias and atrial fibrillation may further complicate the condition. A decrease in cardiac output may result in inadequate coronary artery and cerebral perfusion, followed by sudden death.

With severe stenosis, the rate of preterm delivery and low birth weight is increased.[123] If maternal disease is congenital, the incidence of congenital heart disease in the fetus has been reported to be as high as 18%.[7]

Management Options

PREPREGNANCY

Before pregnancy, the severity of aortic stenosis should be determined by echocardiography. Severe disease should be corrected surgically before conception.[6,7]

PRENATAL

Physical activity should be limited. Patients should be observed for signs of congestive heart failure or arrhythmias. Serial fetal ultrasounds should be scheduled to detect evidence of growth restriction.

LABOR AND DELIVERY AND POSTNATAL

Fluid management is the critical component of intrapartum care. Volume overload can lead to pulmonary edema. Of greater concern, however, is hypovolemia or hypotension, with decreased venous return and cardiac output. Use of a PAC may aid in monitoring volume status in selected patients. Patients should labor and deliver in the lateral position to avoid aortocaval compression. Regional anesthesia is administered slowly and cautiously, after adequate volume loading, to avoid hypotension. A narcotic epidural can decrease the occurrence of hypotension. Blood loss should be monitored closely and replaced as necessary. If

pulmonary edema develops, overaggressive diuresis is avoided to prevent a decrease in preload. Oxygen supplementation, morphine (category B), and inotropic agents, such as dopamine (category C) or dobutamine (category C), may be needed to maintain cardiac output. Bacterial endocarditis prophylaxis is recommended for cesarean delivery.[37] Close monitoring of volume status is essential in the postpartum period.

Continued follow-up after the postpartum period is important because the condition is typically progressive. Many patients require surgical intervention within 2 years of pregnancy.[103]

Combined hormonal methods and standard IUDs need be avoided only in patients with severe stenosis. The risk of thrombosis with atrial fibrillation is a concern with the OCPs, and the potential for a vasovagal event is of concern with IUD insertion. These methods as well as progestin-only contraception can be used in patients with mild stenosis.[43]

Aortic Regurgitation

Maternal and Fetal Risks

Like aortic stenosis, aortic regurgitation is uncommon in women of childbearing age. Although it is most likely of rheumatic origin, aortic regurgitation is an infrequent rheumatic lesion. Less common etiologies include Marfan's syndrome and syphilitic aortitis. Regurgitation in both is a consequence of aortic root dilation.

With progressive aortic insufficiency, cardiac output is usually maintained by left ventricular dilation and hypertrophy as a result of increased preload and stroke volume. Because the condition is progressive, severe disease, with ventricular dilation, hypertrophy, and widened pulse pressure, typically has not yet developed in women of reproductive age and is not likely to be seen in pregnancy.[125] The decreased systemic vascular resistance and increased heart rate associated with pregnancy may improve the hemodynamics of aortic insufficiency because of decreased resistance to forward flow and decreased time for regurgitant flow during diastole. As a result, pregnancy is generally well tolerated.[126] Patients with severe regurgitation and left ventricular hypertrophy can show cardiac decompensation during the later part of pregnancy or postpartum, however.[105]

Management Options

PREPREGNANCY

Preconceptually, the extent of disease should be defined by echocardiogram. In symptomatic patients, cardiac function should be optimized with digoxin (category C) and afterload reduction, as necessary. If indicated, valve replacement should be done before pregnancy.

PRENATAL

Cardiac status should be optimized, as in the nonpregnant state, and patients should be followed for signs of congestive heart failure. If medical management is inadequate, valve replacement can be performed during pregnancy with generally good maternal outcomes but an increased risk of fetal mortality, as previously noted.[114,118]

LABOR AND DELIVERY AND POSTNATAL

Volume status should be followed during labor and delivery and into the postpartum period while the patient is observed for congestive heart failure.[6] Invasive hemodynamic monitoring is usually unnecessary unless other valvular disease is present. Pain control is best achieved with lumbar epidural anesthesia, which decreases regurgitant flow by reducing afterload.

Combined hormonal contraceptive methods can be used as the benefit generally exceeds the risk (WHO category 2).[43]

PROSTHETIC HEART VALVES

Maternal and Fetal Risks

Surgical valve replacement has allowed many patients with severe valvular heart disease to survive and lead near-normal lives. There are two broad categories of replacement valves, each with advantages and disadvantages. Mechanical valves are made of nonbiologic materials. Bioprosthetic valves are either heterografts, made of bovine or porcine valves or pericardium, or homografts, which are human aortic valves.[127] Autografts of the patient's own pulmonary valve may also be used.[128] The different characteristics of these valves make the optimal choice in women of reproductive age difficult and controversial.[6] Mechanical valves have the advantage of durability, but the risk of thrombosis requires long-term anticoagulation. DeSanto and coworkers[129] followed 267 women with mechanical mitral valves for more than 3700 patient-years. Survival, freedom from thrombotic complications, and reoperation were all high. Survival was 90% at 5 years and 72% at 25 years. Only 6% of patients experienced a thrombotic complication by 5 years after surgery, with 25% experiencing it by 25 years. Fourteen percent of patients required reoperation by 25 years of follow-up. Bioprosthetic valves do not require anticoagulation, but valve failure often occurs within 10 to 15 years.[127] Pregnancy has also been reported to increase the rate of spontaneous valve deterioration. This has not been a consistent finding, however, and may simply represent the spontaneous deterioration that occurs when these valves are implanted in a younger population.[130] In order to reduce the need for replacement, mechanical valves are recommended by some authorities for young patients.[127] Conversely, bioprosthetic valves are advocated by others to decrease the risk of thrombosis during pregnancy as well as the risk of bleeding complications due to the need for anticoagulation. Bioprosthetic valves also eliminate the significant fetal risks associated with oral anticoagulants.[131]

The Ross procedure is an alternative for young women requiring aortic valve replacement. The patient's own pulmonary valve is transplanted into the aortic valve position and an aortic or pulmonary homograft is used to replace the transplanted pulmonary valve.[6,128] The advantages of this procedure include the fact that the valve can grow with the patient and anticoagulation is not required. Disadvantages of the operation include its technically difficulty along with the fact that long-term follow-up is limited and there still is concern over the durability of the valve.[6] A small series of five women with 12 pregnancies reported no significant cardiac complications during pregnancy. There was a suggestion of an increased risk of preterm delivery, although the numbers were small. One patient required reoperation for valve complications of both the aortic and the pulmonary valves 9 years after the original operation and 5 years after the last pregnancy.[128]

The incidence of major thromboembolism in nonpregnant patients with mechanical valves averages 8%. Anticoagulation reduces this risk by 75%.[132] Valve thrombosis causes pulmonary congestion, poor perfusion, and systemic embolization. Rapid clinical deterioration often follows. Most embolization involves the cerebral vessels. Patients with atrial fibrillation or left ventricular dysfunction are at increased risk for embolic events.[129] In addition, increased rates of pregnancy loss,[133–136] prematurity, and low birth weight[135] are reported in patients with mechanical valves.

Bioprosthetic valve dysfunction is often related to rupture or tearing of a leaflet. Progressive dyspnea and congestive heart failure suggest bioprosthetic valve deterioration. Failure in these valves is more common with a mitral valve prosthesis and in patients younger than 40 years.[127] Pregnancy has been associated with an accelerated rate of valve deterioration,[134] although this finding was not confirmed by others.[137,138] In a report by Salazar and coworkers,[138] the need for bioprosthetic valve replacement was associated with the patient's age at the time of initial surgery and not with pregnancy. Bioprosthetic valve dysfunction occurred at a rate of 3.5% per patient-year in the pregnancy group compared with 3.4% per patient-year in the nonpregnant control group. Endocarditis complicates both types of prostheses equally. Reported rates vary from 3% to 6%[127] to as high as 10% to 22%.[137]

North and associates[137] reviewed their experience with valve replacement in a population of more than 230 patients 12 to 35 years of age, with nearly 1500 woman-years of follow-up. The report covered a 20-year period beginning in 1972. Of these women, 71 had a total of 132 pregnancies. Patients with bioprosthetic valves had a significantly lower incidence of thrombosis and bleeding complications as well as greater 10-year survival than those with mechanical valves. Not surprisingly, there was an increased need for replacement of the bioprosthetic valve within 10 years (Table 36–6).

In patients with mechanical valves, anticoagulation is required throughout pregnancy, and there is controversy surrounding the optimal choice of therapy. Heparin use, both low-molecular-weight (LMWH) and unfractionated (UFH) formulations (category C), have been associated with an increased incidence of valve thrombosis compared with warfarin.[136] Although the majority of cases are associated with inadequate heparin dosing or lack of adequate monitoring using anti-Factor Xa levels,[139,140] one manufacturer of LMWH recommends against its use in patients with mechanical heart valves.[139] This may, however, have more to do with reducing medicolegal liability than a true assessment of risk. Osteoporosis and fractures are also potential risks of long-term UFH therapy. LMWH has the advantage over UFH of more predictable therapeutic effect and lower risk of bleeding complications as well as lower risks of osteoporosis and thrombocytopenia. Conversely, warfarin (category D) is associated with increased fetal risk in pregnancy, both early and late, compared with heparin.[136] A specific embryopathic

TABLE 36–6
Comparison of Outcomes Associated with Mechanical and Prosthetic Valves in Young Women

OUTCOME	MECHANICAL (N = 178)	BIOPROSTHETIC (N = 73)	HOMOGRAFT (N = 72)	P
10-Yr survival (%)	70	84	96	.12
Thrombotic complications (%)	45	13	1	<.01
Bleeding complications (%)	15	4		.05
10-Yr valve replacement (%)	29	82	28	<.01

TABLE 36–7
Anticoagulation Dosing

REGIMEN	DOSING	MONITORING	THERAPEUTIC GOAL
LMWH throughout pregnancy	Begin with 1 mg/kg enoxaparin q12h	Anti-Factor Xa level 4 hr after dose	Manufacturers upper therapeutic range
UFH throughout pregnancy	Begin at 17,500–20,000 U q12h	aPTT or Anti-Factor Xa level 4–6 hr after dose	>2 × control 0.35–0.70 U/mL
LMWH or UFH through 13 wk and after 36 wk; warfarin from 14–36 wk	Heparin q12h Warfarin daily	As above for heparin INR	As above for heparin 2.5–3.5
Aspirin added to all above regimens	75–100 mg daily	None	

aPTT, activated partial thromboplastin time; LMWH, low-molecular-weight heparin; UFH, unfractionated heparin.
From Bates S, Greer I, Pabinger I, et al: Venous thromboembolism, thrombophilia, antithrombotic therapy, and pregnancy: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. Chest 2008;133:844–886.

pattern is seen when warfarin is used between weeks 6 and 9. Fetal warfarin syndrome is characterized by nasal hypoplasia and stippled epiphyses.[31] The incidence of fetal complications has been reported to be related to the warfarin dose, with a substantially increased risk noted in patients requiring more than 5 mg/day.[129,133,141] Others have reported increased fetal loss rates despite low-dose warfarin therapy.[142] Because it crosses the placenta, warfarin can also cause fetal anticoagulation and bleeding, particularly if taken within 2 weeks of labor.[143] It is associated with an increased risk of neurologic abnormalities in the baby, probably related to intracerebral bleeding.

Despite the potential fetal consequences associated with oral anticoagulation, a task force of the European Society of Cardiology[7] states that oral anticoagulation is the safest approach for the mother. UFH may be considered during the first trimester after a thorough discussion of both the maternal and the fetal risks with the patient. Warfarin is then used with a switch to UFH at 36 weeks to decrease the risk of fetal bleeding complications at delivery.

The American College of Chest Physicians[139] recommends one of three anticoagulant regimens consisting of UFH, LMWH, or warfarin with UFH or LMWH during the first trimester and at the end of pregnancy. The lack of well-designed trials does not allow identification of one approach as clearly superior to the others. The choice is individualized after a thorough discussion of the risks and benefits (Table 36–7). Low-dose aspirin (75–100 mg/day) should be added to these regimens to further decrease the risk of thrombosis.[6,139] In patients at particularly high risk of thrombotic complications, such as those with older more thrombogenic mitral valves or history of thrombosis, warfarin is recommended throughout pregnancy with heparin being used prior to delivery.[139]

Management Options
Prepregnancy
As with other cardiac lesions, NYHA functional status is determined. Baseline echocardiography is indicated. Patients with bioprosthetic valves should be informed of the symptoms of valve deterioration, although the specific relationship with pregnancy is controversial.[134,137,138] Warfarin embryopathy must be discussed with patients who have a mechanical valve. An informed decision should be made about the potential use, timing, and duration of heparin treatment.[7,139]

Prenatal
Patients with bioprosthetic valves should be followed for signs of valve deterioration. Those with mechanical valves must maintain adequate anticoagulation. In patients who continue treatment with warfarin, the International Normalized Ratio (INR) is maintained near 3.0 with a range between 2.5 and 3.5. If UFH is used, it is dosed every 12 hours with the activated partial thromboplastin time (aPTT) maintained at least twice the control value or an anti-Factor Xa level between 0.35 to 0.70 U/mL 4 to 6 hours after the dose. If LMWH is used, the anti-Factor Xa level should be maintained at the upper limits of the manufacturer's suggested range 4 hours after the dose.[139] Although rare in pregnancy, monitoring for heparin-induced thrombocytopenia should be undertaken.[144] At term, if warfarin has been used, it is discontinued and heparin initiated.[7,139]

Labor and Delivery

Clear recommendations for heparin use during labor and delivery are not available. Intravenous heparin at therapeutic doses may be given until 4 to 6 hours before delivery.[139] This approach has the advantage of preventing thrombotic complications. The benefit is small, however, because the risk of valve thrombosis during the relatively short time of sub-therapeutic anticoagulation is low.[132] If necessary, protamine can be used to reverse intravenous heparin anticoagulation at a dose of 1 mg/100 Us heparin up to a maximum dose of 50 mg. The dose is decreased as the time since heparin withdrawal increases. Another approach is to give prophylactic doses of heparin (5000–7500 U q12h) subcutaneously.

Endocarditis prophylaxis may be given prior to cesarean section.[37] Patients with bioprosthetic valves may benefit from operative vaginal delivery to shorten the second stage of labor and avoid the additional hemodynamic stresses of pushing.

Postnatal

Warfarin is initiated in the postpartum period in patients with mechanical valves. Prophylactic doses of heparin may be given while awaiting therapeutic levels of warfarin. Full anticoagulation with intravenous heparin is probably not warranted because the risk of bleeding, particularly after cesarean delivery, exceeds the risk of thrombotic complications.[132] Breast-feeding during anticoagulation with warfarin is not contraindicated, because the levels of warfarin in the breast milk are too low to be significant.[145]

Patients with bioprosthetic valves and no other complications generally can use combined hormonal contraceptive methods (WHO category 2) and IUDs. Those with mechanical valves should generally avoid combined hormonal methods, Depo-Provera, and standard IUDs.[43] The levonorgestrel-containing IUD may be acceptable.

MARFAN'S SYNDROME

Maternal and Fetal Risks

Marfan's syndrome is a connective tissue disorder resulting from a mutation in the *FBN1* gene leading to alterations in fibrillin-1, a protein found in the extracellular matrix. The characteristic findings include abnormalities in the skeletal, ocular, and cardiovascular systems. Cardiac manifestations include MVP, mitral regurgitation, and aortic root dilation. Aortic pathology is associated with increased incidence of aortic regurgitation, dissection, and rupture leading to significant morbidity and mortality.[146] In pregnant patients, morbidity and mortality rates increase when the aortic root diameter exceeds 40 mm with dissection rates reported to be 10%, compared with only about 1% if the aortic root is of normal dimensions.[147,148] However, it is most unlikely that there is a sudden increase in risk when the aortic root dimensions exceed 4 cm, and it is more likely that the risk represents a continuum, increasing with increasing evidence of progressive root dilation both before and during pregnancy. If aortic dissection occurs, mortality rates as high as 25% to 50% have been reported. Even with a normal aorta, maternal mortality has been reported. The elevated risk seen in pregnancy may be related to the increased cardiac output, placing additional stress on the relatively stiff aorta. Pregnancy-associated hypertension may further aggravate the condition.[149] Several reports suggested a better prognosis when there is minimal cardiovascular involvement. These patients had no increase in adverse maternal outcome and no accelerated dilation of the aorta compared with similar patients with Marfan's syndrome who did not become pregnant. Patients without aortic root dilation usually tolerate pregnancy well.[147,148,150] Pregnancy does not appear to be associated with an increased rate of progression of aortic root dilation in patients with a prepregnancy diameter of less than 40 mm. Pregnancy is associated with a slightly increased rate of growth in those with an initial diameter greater than 40 mm.[150]

There is an increased incidence of adverse pregnancy outcomes noted in women with Marfan's syndrome. Incompetent cervix and preterm delivery occur in 15% of pregnancies, and perinatal mortality was reported to be 7%.[151] The syndrome is inherited by autosomal dominant transmission, so there is a 50% chance that the fetus will be affected.

Management Options

Prepregnancy

Genetic counseling is an essential part of family planning in Marfan's syndrome because of the autosomal dominant inheritance. In about 80% of women (or affected men), a specific gene abnormality can be identified, allowing the possibility of prenatal diagnosis (either by preimplantation genetic diagnosis or by chorionic villus sampling in the first trimester). Echocardiographic evaluation of the aorta is performed to define maternal risk status. Pregnancy is discouraged in patients with significant aortic root dilation. If pregnancy is desired, prophylactic repair should be undertaken.[7] In nonpregnant adults, 50 mm is the critical aortic root diameter at which prophylactic repair is recommended.[146] Aortic repair is not completely protective against complications, however. Those with previous dissections are at risk for future events.[148,150] Even when the aortic root size is normal, a risk-free pregnancy cannot be guaranteed.[147,152] If cardiac involvement is minimal, however, women often choose to become pregnant. In this group of patients, initiation of β-blockade should be considered if not already utilized.[7] Although information on its use in pregnancy complicated by Marfan's syndrome is limited, studies of long-term use outside of pregnancy show that it slows the progression of aortic dilation.[146]

Prenatal

Serial echocardiography should be performed every 6 to 10 weeks throughout pregnancy to follow the aortic root size.[7,148] If not initiated preconceptually, the addition of β-blocker therapy should be considered. Little information is available to guide management in patients with progressive aortic root dilation during pregnancy. Patients should be kept at rest to minimize hemodynamic stresses. Hypertension should be avoided because of the increased risk of aortic dissection. Although it is best postponed until postpartum, prophylactic aortic root repair may be considered in extreme cases.

Prenatal diagnosis is now available in most families through linkage analysis or mutation detection.[149]

Labor and Delivery and Postnatal

Epidural anesthesia during labor should be recommended. Adequate oxygenation must be maintained, and hypertension should be avoided. Vaginal delivery is desirable, with shortening of the second stage of labor with the use of a vacuum or forceps.[7,148] Elective cesarean delivery has been recommended in patients with significant aortic dilation, but remains controversial.[7,147] Both patient and physician must remain vigilant because the risk of aortic dissection persists for 6 to 8 weeks postpartum.[148] Combined hormonal contraceptives can be used in patients without aortic dilation (WHO category 2), but should be avoided in those with dilation.[43]

DILATED CARDIOMYOPATHY

Maternal and Fetal Risks

Dilated cardiomyopathy is uncommon in women of reproductive age. Peripartum cardiomyopathy is a subset of dilated cardiomyopathy defined by onset of heart failure in the last month of pregnancy or the first 5 months postpartum, with no other etiology of heart failure identified and no history of cardiac disease. In 1997, echocardiographic evidence of left ventricular dysfunction was added to the diagnostic criteria by a National Institutes of Health and the National Heart Lung and Blood Institute work group. The dysfunction is documented by a reduced ejection fraction or decreased fractional shortening.[153] The reported frequency of the condition varies widely. The reasons for such variations are unknown. In Haiti, the incidence is as high as 1 in 300 live births,[154] whereas in the United States, it is between 1 in 3000 to 4000.[155,156] In the United States, the incidence varies by race, being more common in black women in whom the incidence is reported to be approximately 1 in 1400 births.[155,156] Despite the rarity of the condition, it is accounting for an increasing proportion of maternal mortality in the United States.[157]

The etiology of pregnancy-associated heart failure is unknown, although a number of pathologic theories exist. Evidence of varying degrees of inflammation has been found through serum markers and on endomyocardial biopsy.[158–161] The inflammation has been associated with evidence of viral infection in some cases,[158] as well as autoimmune mechanisms.[162] Hypertensive disorders and black African descent are significant risk factors.[153,155,156] A number of other risk factors have been inconsistently reported including older maternal age, multiparity, twins, and tocolytic use,[153,163] hypertensive disorders of pregnancy, and black African descent.[153] The existence of peripartum cardiomyopathy as a distinct pathologic entity is debated. To minimize confounding by exacerbation of unrecognized preexisting heart disease, the National Institutes of Health work group emphasized the importance of limiting the diagnosis to heart failure occurring within the defined 6-month window.[153] A more recent report of pregnancy-associated cardiomyopathy diagnosed more than 1 month before the end of pregnancy found no difference in risk factors, presentation, clinical course, and outcome, suggesting that there may be a continuum of the disease process during pregnancy.[163]

Regardless of the etiology, cardiomyopathy during pregnancy is associated with significant morbidity and mortality. Reported complication rates vary widely and likely reflect different patient populations and variations in diagnostic criteria. Persistent cardiac dysfunction is seen in 50% to 80% of patients.[154,164,165] A number of echocardiographic findings at initial presentation have been reported to predict persistent dysfunction. These include a decreased fractional shortening to less than 20%, a left end-diastolic dimension greater than 6 cm, a left end-systolic dimension greater than 5.5 cm, an ejection fraction less than 27%, and a left ventricular thrombus.[164–166] Maternal mortality reports vary widely with rates up to 15% in Haiti,[154] and 1% to 4% in larger population-based studies in the United States.[155,156] Survivors often require cardiac transplant.[164,167,168] The rate of recurrence in subsequent pregnancies is as high as 85%.[153] Patients with severe left ventricular dysfunction during the index pregnancy or persistent dysfunction are at increased risk of recurrent or progressive heart failure and death in subsequent pregnancies.[167,169,170] Although those with normal cardiac function 6 to 12 months postpartum fare better, they are still at risk for heart failure and a recurrent decrease in ejection fraction that may not recover after another pregnancy.[169,171] Patients whose cardiomyopathy clinically resolved had decreased contractile reserve with provocative testing.[168] This lack of reserve may cause cardiac decompensation as a result of the hemodynamic stress of a subsequent pregnancy and may contribute to the morbidity after a previous return to normal cardiac function.

Management Options

Prepregnancy

Pregnancy is strongly discouraged in patients with a history of peripartum cardiomyopathy, particularly those with residual cardiac dysfunction. In those with normal cardiac function, pregnancy is less contraindicated. The patient should be informed of the potential for worsening cardiac function during pregnancy, which may not completely resolve postpartum.[169] Combined hormonal contraceptives should be avoided in patients with residual ventricular dysfunction. Depo-Provera or IUDs can be safely used.[43] Permanent sterilization may also be considered.

Prenatal

If pregnancy occurs, echocardiography should be performed to document ventricular size and function as well as the presence of mural thrombi. Termination should be offered, especially to patients who have persistent echocardiographic abnormalities, because of the high associated maternal morbidity and mortality. If the pregnancy is continued, a multidisciplinary team, including a cardiologist, a perinatologist, an anesthesiologist, and a neonatologist, should collaborate to optimize outcome. Decreased activity and potentially even bedrest are recommended, along with salt restriction. Diuretics, digoxin (category C), and afterload reduction with hydralazine (category B) should be used, as necessary. Because of the risk of embolic phenomena, prophylactic heparin (category C) should be given.

Labor and Delivery

Patients are watched closely for signs of heart failure and pulmonary edema. Cardiac monitoring is instituted early in

labor. Fluids are restricted, and central hemodynamic monitoring may be considered if decompensation occurs. If a flow-directed PAC is necessary, care must be taken during insertion. Positioning may be difficult because of dilated chambers and decreased ejection fraction. Arrhythmias may also be precipitated during insertion. Heparin can be discontinued prior to a planned delivery or during early labor and resumed in the early postpartum period. Adequate pain control is important, and epidural anesthesia works well. Patients with significant cardiac dysfunction may need to labor in a sitting position to reduce or prevent shortness of breath.

Postnatal

Monitoring of volume status must continue through the postpartum period, with fluid restriction as necessary. Diuretics may be used as necessary, and the patient should be given an angiotensin-converting enzyme (ACE) inhibitor (category D) for afterload reduction.[153] Although uncommonly performed, endomyocardial biopsy is recommended to exclude treatable causes of cardiomyopathy. Some patients with myocarditis found on biopsy respond favorably to immunosuppressive therapy.[153] There are no contraceptive restrictions in patients whose cardiac function has completely recovered. Combined hormonal methods should not be given in the early postpartum period or to those with persistent ventricular dysfunction.[43]

CARDIAC ARRHYTHMIAS
Maternal and Fetal Risks

Cardiac arrhythmias are relatively common during pregnancy. Most are benign and include sinus bradycardia, sinus tachycardia, and atrial and ventricular premature contractions. These patients are often asymptomatic, but may have palpitations, although the correlation between symptoms and the actual arrhythmia is poor. Shotan and associates[172] evaluated symptomatic pregnant patients who were referred to a cardiac clinic and compared them with asymptomatic pregnant patients who were referred for evaluation of a cardiac murmur. The incidence of premature atrial and ventricular contractions was 50% to 60% in each group. Although the frequency of arrhythmias was higher in symptomatic patients, only 10% of symptoms occurred in conjunction with the arrhythmia. Healthy, asymptomatic patients without underlying pathology can often be managed with reassurance, observation, and rest.[173,174] Nearly all women in labor will have tachycardia and isolated premature atrial beats at some point.[175] Aside from this, however, normal labor and delivery does not seem to increase the incidence or type of arrhythmias identified when compared with nonpregnant women.[175,176]

Pregnancy may be associated with an increase in the incidence and severity of arrhythmias.[172,177,178] Supraventricular tachycardia is often seen in pregnancy. Ventricular tachycardia and multiform premature ventricular complexes are much less common but may be recognized for the first time during gestation. Atrial fibrillation is usually associated with underlying cardiac disease.[179] With any of these arrhythmias, cardiac decompensation can occur, resulting in pulmonary edema. This is particularly common with underlying

structural heart disease in which cardiac reserves may be limited. Sudden death is a concern in the presence of significant preexisting cardiac conditions. Women with a prior history of significant arrhythmias have a high incidence of recurrence during pregnancy. Atrial arrhythmias occur in approximately half of these patients, whereas ventricular arrhythmias recur in a quarter.[179]

Long QT syndrome is a genetic condition associated with a prolongation of the QT interval along with syncope and sudden cardiac death. β-Blockers are the mainstay of therapy. Women who continue therapy during pregnancy are at low risk of complications.[177,180] An increase in cardiac complications as a result of long QT syndrome has been noted during the postpartum period.[177] Some may benefit from the surgical implantation of a pacemaker.

Prematurity is increased in the presence of many arrhythmias.[179] In addition, fetal exposure to drugs used for maternal therapy is a potential concern. Symptomatic and sustained arrhythmias often require appropriate antiarrhythmic therapy. Most antiarrhythmic agents are classified as category C, except when otherwise noted. β-Blockers can be used in patients with sinus tachycardia or frequent premature atrial or ventricular contractions when symptoms persist after conservative management.[178] In patients with long QT syndrome, β-blockers are continued to reduce the incidence of cardiac events.[177] Digoxin can be used safely to control the ventricular rate in atrial fibrillation and flutter and some supraventricular tachycardias.[173,174] Adenosine has a rapid onset and very short duration of action. It is used acutely during pregnancy to treat supraventricular tachycardia and is the drug of choice.[173,178,181] Esmolol and verapamil can be used intravenously in the acute management of supraventricular tachycardia. Quinidine is used to treat some atrial and ventricular arrhythmias. Lidocaine (category B) is used acutely to control ventricular arrhythmias. Procainamide is a second-line agent because of maternal side effects, including cardiac rhythm disturbances, lupus-like syndrome, and blood dyscrasia. Amiodarone (category D) is used to treat life-threatening ventricular arrhythmias when first-line agents are unsuccessful. It is associated with neonatal hypothyroidism, hyperthyroidism, and possibly IUGR, fetal bradycardia, and neurologic abnormalities.[173,182]

Management Options
Prepregnancy

All patients with a sustained arrhythmia should undergo a baseline electrocardiogram to determine whether the rhythm abnormality originates from the atrium or the ventricle. This is followed by a search for an underlying etiology. Patients with unexplained sinus tachycardia or premature atrial or ventricular contractions are questioned about tobacco, caffeine, and illicit drug use. They are also evaluated for anemia and hyperthyroidism. If a contributing factor is identified, behavior modification is attempted, as appropriate. Medical conditions should be treated before conception. Ambulatory monitoring is considered when patients have symptoms that suggest a rhythm disturbance but no objective evidence on examination. Patients who may benefit from ablative therapy should be identified and treated before conception.[173]

Prenatal, Labor and Delivery, and Postnatal

Management during pregnancy consists of maintenance therapy to control arrhythmias. Drug levels should be monitored, as indicated, because of pregnancy-associated changes in volume of distribution and protein binding. Vagal maneuvers can be tried initially in tachyarrhythmias with first onset in pregnancy.[173] Cardioversion can be used safely during pregnancy in unstable patients or when medical therapy is unsuccessful.[173,174,183] In patients with atrial fibrillation, ventricular rate should be controlled with digoxin, a β-blocker, or a calcium channel blocker. Prophylactic anticoagulation with either aspirin or heparin (LMWH or UFH) should be added. In the stable patient, medical cardioversion with quinidine or procainamide may be tried. Electrical cardioversion should be done in those who are hemodynamically unstable.[184] Continuous cardiac monitoring may be necessary intrapartum and postpartum for symptomatic or complex arrhythmias. Occasionally, surgical implantation of automatic defibrillators can be life-saving.

MYOCARDIAL INFARCTION

Maternal and Fetal Risks

MI is still uncommon in women of reproductive age with an incidence ranging from 3 to 7 per 100,000 births in the United States; however, with the current epidemic of obesity, it is likely to become increasingly important. In the United Kingdom, the incidence of MI in pregnancy has doubled since the 1990s, and it is now one of the leading causes of maternal death (16 deaths from this cause in the triennium from 2003 to 2005).[96] Approximately 20% of cases occur during labor, with the remainder nearly equally divided between the antepartum and the postpartum periods. Maternal mortality ranges from 5% to 8% and appears to have decreased in recent years.[185–187] Mortality is approximately 20% when the MI occurs in the peripartum period. This is roughly twice the rate during the antepartum period.[186,187] Prematurity is reported to be 43% in patients with an antenatal MI. Fetal outcome is ultimately related to maternal status and outcome.[186]

Risk factors associated with MI in pregnancy include increasing age, chronic hypertension, diabetes, hypertensive disorders of pregnancy, thrombophilia, and postpartum infection. Obesity is associated with an increased incidence of several of these risk factors. Although MI was reported to be more common in black women, race was not an independent risk factor after controlling for other comorbidities.[185,186] Transfusion has also been identified as a risk factor for MI and may represent a surrogate marker for postpartum hemorrhage.[185] Karpati and coworkers[188] demonstrated elevated troponin I levels, electrocardiographic changes, and decreased cardiac contractility compatible with myocardial ischemia in half of the 55 patients they managed with severe postpartum hemorrhage.

Atherosclerosis is the most common lesion seen with MI during pregnancy and is identified in 40% of patients. Coronary artery dissection is seen in 27%, whereas 13% of patients had normal coronary arteries. A coronary artery thrombosis in the absence of atherosclerosis was seen 8% of women.[187]

Criteria for the diagnosis of MI do not change during pregnancy. The diagnosis remains a challenge, in part because the index of suspicion is often low. Physiologic changes of pregnancy may mimic the symptoms of MI and delay the diagnosis. During labor, the diagnosis is further complicated by the fact that creatinine phosphokinase and the cardiac-specific MB fraction may normally be elevated.[189] Troponin I is a specific marker for cardiac injury that does not increase during normal labor and delivery, making it a potentially useful tool in the diagnosis of MI in the pregnant woman.[190] A few case reports have described the utility of troponin I in the diagnosis of MI during pregnancy.[191,192]

Management Options

Prepregnancy

Because the underlying condition is rare, pregnancy after MI is uncommon. Unfortunately, it is even more uncommon for these patients to seek preconception counseling.[193] When possible, cardiac evaluation should be done, including stress testing and echocardiography. Even if the patient has no cardiac dysfunction, pregnancy should be planned cautiously.[193] Medication should be optimized and statins (category X) should ideally be stopped before conception. ACE inhibitors (category C) used in the second or third trimester are associated with oligohydramnios and neonatal renal failure. An alternative drug should be used beginning before conception or in early pregnancy. β-Blockers (most category C) can be used. Atenolol is a cardioselective β-blocker (category D) that has been associated with IUGR and can be used with caution. Low-dose aspirin (category C) is not associated with adverse effects. There is limited information during pregnancy for clopidogrel (category B), an antiplatelet agent. Animal studies suggest low risk. It is believed to cross the placenta and, in theory, could pose a bleeding risk to the fetus.[31] For this reason, it should thus be used with caution near delivery. Because as many as half of women with ischemic heart disease will be obese, dietary advice and support in achieving weight reduction are important.

Prenatal

Patients should rest and avoid strenuous activity. They should also be monitored for evidence of arrhythmias or congestive heart failure. If an MI occurs during pregnancy, management principles are similar to those for nonpregnant patients.[187] Most drugs used in the medical management of acute MI are category C, except where otherwise noted. Nitroglycerin, oxygen supplementation, morphine (category B), heparin, and continuous cardiac monitoring are initiated. Lidocaine (category B), dopamine, calcium channel blockers, and β-blockers can be used, as indicated. Coronary angiography can be utilized as clinically indicated during pregnancy. Percutaneous angioplasty and stent placement are being used more frequently in pregnant patients with favorable outcomes.[185,187] Coronary artery bypass surgery has also been reported in pregnancy; however, the number of cases is small and conclusions regarding outcomes are limited.[187] Pregnancy is considered a relative contraindication to thrombolytic therapy because of the theoretical increased risk of maternal and fetal bleeding; however, safe and effective use during pregnancy has been reported, as well as cases of significant maternal bleeding and abruption.

The increased incidence of coronary artery dissection also urges caution with the use of thrombolytic therapy because bleeding may worsen the dissection.[185,187]

In cases of cardiac arrest, cardiopulmonary resuscitation proceeds with some notable modifications to the procedure used in the nonpregnant patient. These include lateral displacement of the gravid uterus to prevent aortocaval compression and improve venous return. Cricoid pressure is used when ventilation is required, and early intubation is recommended owing to the increased risk of aspiration. Chest compressions are done just above the mid sterum rather than above the xiphoid. There is no change in the recommendations for defibrillation.[194] If initial attempts at resuscitation are unsuccessful, perimortem cesarean section is indicated. Although a final heroic effort, the procedure is potentially life-saving for a viable fetus, and improved effectiveness of the resuscitation may also be life-saving for the mother. Optimal maternal and neonatal outcomes are seen when delivery occurs within 5 minutes of cardiac arrest.[195] Thus, making the decision to proceed and initiating the cesarean section should occur within 4 minutes of the arrest.[194–196]

Labor and Delivery

Vaginal delivery is believed to be relatively safe in patients who have had an MI. Cesarean delivery should be reserved for the usual obstetric indications as well as those who have had a MI in close proximity to labor or are unstable. External cardiac monitoring is necessary. Supplemental oxygen should be given, and epidural anesthesia is used for pain control. Operative vaginal delivery to shorten the second stage of labor is also recommended.[187]

Postnatal

Volume status is monitored in the postpartum period, and the patient should avoid exertion. A reliable plan for contraception should be made. Combination oral contraceptives, patches, rings, or injectables are usually contraindicated (category 4). Continued use of progesterone-only methods including the mini-pill, Depo-Provera, and implants should generally be avoided because they may have adverse effects on lipid profiles (category 3). Although the risk of atherosclerosis is not increased, estrogen increases thrombotic risk, especially when other risk factors are present. If permanent sterilization is not desired, the copper-containing IUD is a reasonable alternative (category 1).[42]

HYPERTROPHIC CARDIOMYOPATHY

Maternal and Fetal Risks

Hypertrophic cardiomyopathy is an autosomal dominant condition characterized by left ventricular hypertrophy without chamber dilation and no other etiology to explain the hypertrophy. It is classically associated with left ventricular outflow obstruction, but this is not found in most patients. As a result, older names for this condition, such as idiopathic hypertrophic subaortic stenosis and hypertrophic obstructive cardiomyopathy, have been generally replaced. In the general population, the frequency of this condition is approximately 1 in 500.[197]

The presentation and prognosis are clinically variable. Most patients have a normal life expectancy without limitations; however, hypertrophic cardiomyopathy is a common cause of sudden cardiac death in young people. The annual mortality rate is estimated at 1%, substantially less than the rate reported in older series, primarily because of the identification and inclusion of patients with more benign forms of the disease.[197,198] Clinical risk factors for sudden death include a family history of sudden cardiac death, previous syncope, and documented ventricular tachycardia. Maki and colleagues[198] identified an inadequate increase in systolic blood pressure associated with exercise, defined as less than 24 mm Hg on treadmill testing, as a risk factor in patients younger than 50 years. Left ventricular wall thickness greater than 30 mm may be a risk factor in young adults.[197] Septal myectomy in nonpregnant individuals has not only improved the outflow obstruction but also resulted in significant regression of the ventricular hypertrophy.[199] Implantable cardiac defibrillators are used successfully in high risk patients and can be used in pregnant patients.[200]

Physiologic changes associated with pregnancy have variable effects on the condition. Adequate preload and systemic vascular resistance are important factors in maintaining end-diastolic volume and cardiac output. A decrease in end-diastolic volume increases outflow obstruction. The increased blood volume associated with pregnancy has a beneficial effect, whereas the decrease in systemic vascular resistance can worsen outflow obstruction. The increased heart rate can also adversely affect maternal condition as a result of decreased diastolic filling time. Despite these concerns, maternal complications are uncommon and are confined primarily to women with specific risk factors.[201,202] The autosomal inheritance pattern gives the fetus a 50% chance of having the condition.

Management Options

Prepregnancy

Genetic counseling is indicated if either parent is affected. A careful history should be taken to identify patients with historical risk factors. An echocardiogram should be done. Patients should also be seen by a cardiologist who has experience with patients who have this condition to determine the need for exercise testing and the role of Holter monitoring. High risk patients may be evaluated for septal myectomy.

Prenatal

Activity is limited to avoid tachycardia. Adequate hydration should be maintained. Although it is not necessary in all patients, β-blockade may be used in symptomatic patients.[197]

Labor and Delivery and Postnatal

Volume status is monitored to avoid dehydration and hypotension during labor. Regional anesthesia may be used, but should be administered with care after adequate volume loading, again, to prevent hypotension. If tachycardia develops and the patient becomes symptomatic, β-blocking agents (mostly category C) may be used to control the heart rate. The patient should be observed for excessive blood loss and tachycardia in the postpartum period. Volume replacement is given, as indicated.

SUMMARY OF MANAGEMENT OPTIONS
Cardiac Disease: Specific

Management Options	Evidence Quality and Recommendation	References
Cardiac Murmur		
Echocardiogram for patients with a significant history or a pathologic murmur (late systolic, pansystolic, diastolic).	III/B	6,48
Mitral Valve Prolapse		
Echocardiogram evaluation prenatally for mitral regurgitation.	IV/C	57,58
Surveillance and treatment of arrhythmias in pregnancy.	IV/C	6
Atrial Septal Defect		
Pregnancy		
Screen for arrhythmias or pulmonary hypertension; manage accordingly both before and during pregnancy (if undertaken).	III/B	59,61
Prenatal		
Routine unless the patient has arrhythmias or pulmonary hypertension.	III/B	59
Screen fetus for congenital heart defect.	IIb/B	7,26,60
Labor and Delivery		
Screen for arrhythmias, monitor blood pressure, and avoid fluid overload.	III/B	59
Postnatal		
Encourage early mobilization.	III/B	59
Screen newborn for congenital heart defect.	IIb/B	7,26,60
Ventricular Septal Defect		
Prepregnancy		
Screen for pulmonary hypertension and manage accordingly; consider repair of uncorrected lesions.	III/B	62,63
Counsel about the risk of congenital heart disease.	IIb/B	7,26,60
Prenatal		
Obtain serial echocardiograms, and manage accordingly.	III/B	62,63
Screen fetus for congenital defect.	IIb/B	7,26,60
Labor and Delivery		
Avoid hypertension; provide antibiotic prophylaxis unless the patient has an uncomplicated vaginal delivery or if the defect has been repaired.	III/B	62,63
Provide antibiotic prophylaxis prior to cesarean section.	IV/C	37
Postnatal		
Provide careful fluid balance and early ambulation.	III/B	62,63
Screen newborn for congenital heart defect.	IIb/B	7,26,60
Pulmonary Hypertension		
Prepregnancy		
Counsel against pregnancy; offer sterilization if requested.	III/B	65,66

SUMMARY OF MANAGEMENT OPTIONS
Cardiac Disease: Specific—cont'd

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Consider termination.	III/B	65,66
Joint obstetric and cardiology care and early anesthesiology consultation.	III/B	66
Thromboembolism prophylaxis.	III/B	65,66
Consider hospital admission and monitor SaO_2.	III/B	65,66
Provide fetal surveillance.	III/B	65,66
Use of calcium channel blocker has been reported.	III/B	70
Prostacyclin analogues, endothelin-receptor antagonists (e.g., bosentan), phosphodiesterase inhibitors, sildenafil (Viagra), and inhaled nitric oxide may be helpful.	III/B	64
Labor and Delivery		
Intensive care setting (degree of invasive monitoring varies); dilemma over induction (to end the pregnancy) vs. spontaneous onset of labor (because of shorter labor); oxytocin or E series prostaglandins are safe; O_2 is given at 5–6 L/min; SaO_2 is monitored continuously; monitor blood pressure and maintain fluid balance; epidural analgesic is preferable (reduce or stop anticoagulation for a few hours for delivery).	III/B	65,66
Intravenous prostacyclin or inhaled nitric oxide.	III/B	71,73
Postnatal		
Maintain intensive care monitoring; give O_2 therapy and thromboembolism prophylaxis; maintain vigilance for fluid retention and consequences; inhaled nitric oxide and intravenous prostacyclin may be continued or initiated; consider sterilization.	III/B	65,66,71–73
Eisenmenger's Complex		
As for Primary Pulmonary Hypertension.	III/B	76–79
Echocardiography may be helpful in evaluation, shunt, right ventricular function, and pulmonary hypertension.	III/B	76–79
Pulmonary Stenosis		
Prepregnancy and Prenatal		
Determine maternal functional status.	III/B	6,7
Echocardiography to determine degree of stenosis.		
Balloon valvotomy as clinically indicated.	III/B	80
Labor and Delivery and Postnatal		
Monitor volume status and for signs of right heart failure.	III/B	80
Coarctation of the Aorta		
Prepregnancy		
Screen for associated cardiac abnormalities and aortic valve disease, and manage appropriately (i.e., repair) before conception.	III/B	83
Prenatal		
Consider termination in patients with severe uncorrected disease.	III/B	84

Management Options	Evidence Quality and Recommendation	References
Labor and Delivery and Postnatal		
Avoid hypertension.	III/B	84
Provide antibiotic prophylaxis prior to cesarean section.	IV/C	37
Screen the newborn for congenital heart disease.	IIb/B	60,82,84
Tetralogy of Fallot		
Prepregnancy		
Surgical correction and evaluation of cardiac status after corrective surgery.	III/B	86
Prenatal		
Consider termination in patients with uncorrected lesions.	III/B	86
Monitor maternal Sao$_2$ and exercise tolerance; consider rest and supplemental O$_2$.	III/B	87
Fetal surveillance.	III/B	85
Fetal echocardiography to screen for congenital heart disease.	IIb/B	26,60
Labor and Delivery		
Provide careful fluid management; monitor the patient's blood pressure, Sao$_2$, and electrocardiogram; epidural use requires careful preloading, the need to shorten the second stage, and fetal monitoring; avoid fluid overload, maintain blood pressure.	III/B	85,86
Postnatal		
Maintain maternal monitoring and discuss effective contraception.	III/B	85,86
Transposition of the Great Arteries		
Prepregnancy		
Consultation with a cardiologist specializing in adults with congenital heart disease; evaluation of cardiac status with attention to the right (systemic) ventricle; monitor for arrhythmias.	III/B	60,88,90
Prenatal		
Decrease activity; monitor for heart failure and arrhythmias; perform serial echocardiography.	III/B	60,88,90
Labor and Delivery		
Provide careful fluid management; give oxygen as necessary; perform an electrocardiogram; use an epidural, shorten the second stage, and provide fetal monitoring.	III/B	60,88,90
Postnatal		
Monitor volume status.	III/B	60,88,90
Discuss effective contraception.	III/B	43
Ebstein's Anomaly		
Prepregnancy		
Echocardiography to evaluate right ventricular function and tricuspid regurgitation.	III/B	93
Surgical correction as indicated.	III/B	93

SUMMARY OF MANAGEMENT OPTIONS
Cardiac Disease: Specific—cont'd

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Serial echocardiograms; monitor for arrhythmia; decrease activity as indicated.	III/B	60
Fetal echocardiogram.	III/B	60,94
Monitor for preterm labor and intrauterine growth restriction.	III/B	94
Labor and Delivery and Postnatal		
Maternal cardiac monitoring, supplemental O_2, monitor fluid balance, epidural for pain control, vacuum or forceps to shorten the second stage.	III/B	60
Patent Ductus Arteriosus		
Prepregnancy		
Screen for pulmonary hypertension, and manage appropriately before and during pregnancy (if undertaken).	III/B	95
Prenatal		
Screen for pulmonary hypertension.	III/B	95
Labor and Delivery and Postnatal		
Monitor blood pressure and fluid balance.	III/B	95
Rheumatic Heart Disease: General		
Principles		
• Prevent heart failure.	III/B	100
• Prevent bacterial endocarditis.	IV/C	37,39
• Use a team approach, including a cardiologist and an anesthesiologist.	—/GPP	—
Mitral Stenosis		
Prepregnancy		
Assess cardiac function, optimize medical therapy, and consider surgical correction.	III/B	6,7,106–109
Prenatal		
Monitor for excess weight gain; prevent and treat tachycardia and other arrhythmias.	III/B	6,104,110
Serial echocardiography; perform percutaneous commissurotomy or surgery for symptomatic severe disease.	III/B	108,111–113
Labor and Delivery		
Intensive care setting; consider central invasive monitoring, epidural analgesia, shorten the second stage of labor.	III/B	102
Antibiotic prophylaxis; cesarean delivery.	IV/C	37
Mitral Regurgitation		
Prepregnancy		
Evaluate functional status, maternal echocardiography to evaluate cardiac function, valve replacement as indicated.	III/B	117

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Restrict activity; perform serial echocardiography; adjust medical control; consider surgery for symptomatic severe disease.	III/B	6,118,119
Perform fetal surveillance.	III/B	118,119
Labor and Delivery and Postnatal		
Avoid fluid overload and hypertension; provide maternal cardiac monitoring.	—/GPP	—
Provide endocarditis prophylaxis for cesarean deliveries.	IV/C	37
Aortic Stenosis		
Prepregnancy		
Determine severity by echocardiography.	III/B	6,7
Correct severe disease surgically before conception.	III/B	6,7
Prenatal		
Limit physical activity; maintain vigilance for heart failure and arrhythmias.	III/B	105,123,124
Fetal echocardiogram.	III/B	7
Fetal surveillance.	III/B	123
Labor and Delivery and Postnatal		
Avoid fluid overload, hypovolemia, and hypertension.	III/B	105,122–124
Some would use pulmonary artery catheter.	—/—	—
Bacterial endocarditis prophylaxis in patients undergoing cesarean section.	IV/C	37
Aortic Regurgitation		
Prepregnancy		
Echocardiography; optimize medical control (Digoxin); value replacement if indicated.	III/B	125
Prenatal		
Surveillance for cardiac failure; surgery for failed medical therapy.	III/B	114,118
Fetal surveillance.	III/B	114,118
Labor and Delivery and Postnatal		
Avoid fluid overload; invasive monitoring is usually unnecessary; epidural is beneficial; provide fetal surveillance.	III/B	125
Prosthetic Valves		
Prepregnancy		
Assess cardiac status; provide counseling about valve function and risks associated with warfarin.	III/B	7,31,134, 137–139
Prenatal		
If the patient has biosynthetic valves, monitor for deterioration; if the patient has mechanical valves, provide adequate anticoagulation; vigilance for thrombocytopenia when using heparin.	III/B	127,134,139
Labor and Delivery		
Adjust anticoagulation.	III/B	132,139
Endocarditis prophylaxis as indicated.	IV/C	37

SUMMARY OF MANAGEMENT OPTIONS
Cardiac Disease: Specific—cont'd

Management Options	Evidence Quality and Recommendation	References
Postnatal		
Readjust anticoagulation.	III/B	132
Marfan's Syndrome		
Prepregnancy		
Genetic counseling.	III/B	149
Echocardiography to assess aortic root diameter; counsel about pregnancy risks.	III/B	147,148,152
Prenatal		
Serial aortic root echocardiography; give β-blockers; avoid hypertension; encourage rest; surgery in extreme cases.	III/B	7,146,148, 149
Monitor for preterm labor.	III/B	151
Labor and Delivery and Postnatal		
Epidural is beneficial; avoid hypertension; ensure adequate oxygenation; shorten the second stage of labor; maintain vigilance for aortic root dissection for at least 8 wk postnatally.	III/B	7,147,148
Dilated Cardiomyopathy		
Prepregnancy		
Echocardiography.	III/B	169
Counsel regarding the risk of pregnancy if the patient has a history of peripartum cardiomyopathy and counsel against pregnancy if there is residual cardiac dysfunction.		
Prenatal		
Echocardiography.	III/B	164–166
Consider termination in patients with an abnormal echocardiogram; if the patient is symptomatic, provide medical therapy and anticoagulation.	III/B	164,167–169,171
Multidiscliplinary team care	—/GPP	—
Labor and Delivery		
Monitor for heart failure; avoid fluid overload; possibly use pulmonary artery catheter, vigilance for arrhythmias; adequate analgesia.	III/B	154,169
Postnatal		
Avoid fluid overload; discuss contraception.	III/B	153,154,169
Cardiac Arrhythmias		
Prepregnancy		
Investigate and treat.	III/B	173,177,178, 180,181,184
Prenatal, Labor and Delivery, and Postnatal		
Maintenance of therapy to control arrhythmia; cardioversion can be used as indicated.	III/B	173,177,178, 180,181,184

Management Options	Evidence Quality and Recommendation	References
Myocardial Infarction		
Prepregnancy		
Assess cardiac function (especially echocardiography and stress testing); counsel on the basis of results.	III/B	193
Optimize medical therapy.	III/B	31
Prenatal		
Avoid strenuous activity; provide surveillance for failure and arrhythmias; management as for a nonpregnant patient; surgery can be performed in pregnancy.	III/B	187
Percutaneous coronary artery interventions can be used as indicated.	III/B	185,187
Thrombolytic therapy may be used with caution when indicated.	III/B	185,187
Labor and Delivery		
Monitor electrocardiogram; provide supplementary oxygen; epidural is beneficial; consider cesarean section if labor occurs within 4 days of an acute myocardial infarction.	III/B	187
Postnatal		
Avoid fluid overload and exertion; discuss contraception (avoid combination oral preparations).	III/B	42
Hypertrophic Cardiomyopathy		
Prepregnancy		
Genetic counseling; evaluate cardiac status with echocardiography; implantable defibrillator may be used as indicated.	III/B	197,198,200
Prenatal		
Limit activity; give β-blockers for symptomatic patients	III/B	197
Labor and Delivery and Postnatal		
Avoid dehydration or hypotension; give β-blockers for tachycardia.	III/B	197

GPP, good practice point; Sao$_2$, arterial oxygen saturation.

Respiratory Disease

PAUL S. GIBSON and RAYMOND O. POWRIE

INTRODUCTION

A variety of physiologic adaptations to the maternal respiratory system occur in normal pregnancy. Minute ventilation increases, attributable mainly to the effect of high progesterone levels on the maternal respiratory center. Oxygen consumption rises and residual lung volume decreases, particularly in the latter half of pregnancy. Generally, these physiologic changes are well tolerated with minimal symptomatology by the pregnant woman. The interaction of these biologic changes with various pulmonary diseases is less well understood, however, despite the relatively common occurrence of some of these conditions during pregnancy. Respiratory physicians should be involved in the management of many of these disorders when they occur in pregnancy. This is particularly important in conditions such as acute severe asthma, the severity of which may be underestimated by both doctor and patient; severe pneumonia; cystic fibrosis (CF); and tuberculosis (TB), considering that the guidelines for therapy change frequently. Acute pulmonary edema is also one of the most common reasons that pregnant or postpartum women are transferred to critical care units, and appropriate understanding and management of these severely ill women is essential.

BREATHLESSNESS OF PREGNANCY

General

Pregnancy is associated with several significant changes in respiratory function. Pregnant women increase their minute ventilation by nearly 50%. This is achieved by increasing the volume of each breath rather than by increasing respiratory rate. This is an effect of progesterone, leading to a decrease in arterial carbon dioxide pressure ($PaCO_2$) to 27 to 32 mm Hg.[1] Arterial oxygen pressure (PaO_2) is increased to 95 to 105 mm Hg at sea level, as per the alveolar gas equation. A compensatory renal excretion of bicarbonate occurs in response to the chronic respiratory alkalosis, and serum bicarbonate levels normally decrease by approximately 4 mEq/L.

Pulmonary function test results, including forced expiratory volume in 1 second (FEV_1), forced vital capacity (FVC), and peak expiratory flow rates (PEFR), remain largely unchanged in pregnancy. The main change seen on pulmonary function tests (PFTs) is an approximately 20% drop in functional residual capacity (FRC; that portion of a breath that can still be exhaled after normal resting exhalation) due to a decrease in both expiratory reserve volume (ERV) and residual volume (RV).[2,3] Although the diaphragm may be elevated to 4 cm above its usual position by term, this does not have a significant effect on respiratory function because diaphragmatic excursion is not altered.[4]

Mild breathlessness is a common symptom in normal pregnancy and, therefore, does not necessarily indicate cardiorespiratory disease. Up to 70% of pregnant women will report some level of dyspnea. The most typical description of this would be "air hunger."[3,5] This symptom may appear during the late first or early second trimester, though the peak period for the onset of breathlessness is 28 to 31 weeks' gestation. Often the breathlessness occurs spontaneously at rest rather than in association with exertion. The trigger of the symptomatology has not been clearly defined, although the hormonal effect of progesterone on ventilation and the associated fall in $PaCO_2$ seem to be central features. Studies have found that the presence of dyspnea during pregnancy correlates with a relatively high baseline nonpregnant $PaCO_2$ and a low $PaCO_2$ during pregnancy.[6,7]

Management Options

It is a clinical challenge to differentiate benign breathlessness of pregnancy from more serious causes of shortness of breath in pregnancy, such as asthma, pulmonary embolism, and cardiomyopathy. Initial evaluation should be based on a careful history and physical examination. Dyspnea attributable to pregnancy physiology alone is generally episodic, insidious in onset, and not associated with any chest discomfort, cough, or sudden exacerbation. A previous history of reactive airways, the presence of cough or wheezing, or an obstructive pattern on PFT may point to asthma as a cause. Pulmonary embolism is usually characterized by the sudden onset of dyspnea or chest pain, often in association with asymmetrical leg symptoms/signs. Cardiac disease in pregnancy may present with dyspnea as an initial or predominant feature. This may reflect a preexisting cardiac condition, unmasked by the increased blood volume and cardiac work of pregnancy, or may point to a new onset of cardiac disease

such as peripartum cardiomyopathy. Findings on physical examination of tachypnea, tachycardia, an elevated jugular venous pulse, a concerning murmur, respiratory "crackles" on auscultation, or an abnormal chest x-ray or electrocardiogram (ECG) can point to a cardiac cause of dyspnea. Suspicion of a cardiac cause should lead to prompt evaluation with transthoracic echocardiography.

History and physical examination can be supplemented with investigations including: complete blood count (CBC), oxygen saturation measurement (SaO_2) with exercise, and, if necessary, a chest x-ray. The CBC can be used to identify those cases of dyspnea attributable to severe anemia. Measurement of SaO_2 (by pulse oximeter) with moderate exertion can also help alleviate a patient's anxiety about her symptoms. If the SaO_2 remains normal (>95%) on exercise, the dyspnea does not limit activity at all, and the onset was not sudden, it is unlikely but not impossible

that the patient has a pathologic cause for her dyspnea. Measurement of arterial blood gases (ABGs) will be unnecessary in the vast majority of women presenting with dyspnea in pregnancy.

When clinical evaluation leads the clinician to suspect that a patient's dyspnea is due to more than just the normal physiology of pregnancy, the clinician should be confident that all relevant diagnostic imaging procedures for investigating other causes of dyspnea can be safely performed during pregnancy. This includes chest x-rays, computed tomography (CT) scans of the chest, ventilation-perfusion scans, magnetic resonance imaging (MRI), and occasionally, pulmonary angiography.[8] Most often, if other serious causes of dyspnea do not appear to be present, management of breathlessness in pregnancy is limited to educating the patient regarding these physiologic changes and providing reassurance and follow-up.

SUMMARY OF MANAGEMENT OPTIONS
Breathlessness in Pregnancy

Management Options	Evidence Quality and Recommendation	References
Ask about wheezing, nocturnal worsening, and cough to distinguish from asthma.	IV/C	1,4,7
Ask about orthopnea and paroxysmal dyspnea and perform cardiac examination to distinguish from heart failure.	IV/C	1,4,7
Ask about sudden onset of dyspnea, presence of chest pain, personal or family history of thrombosis and look for tachypnea, tachycardia, or signs of DVT to distinguish from PE. Consider objective testing for DVT/PE if any of the above are present.	IV/C	1,4,7
Key investigations: When a diagnosis other than "physiologic" breathlessness of pregnancy is suspected, consider the following tests: • Oxygen saturation at rest and with ambulation. • Hemoglobin. • Chest radiograph. • Ventilation-perfusion scan or CT angiogram or MRI. • Echocardiography.	IV/C	8

CT, computed tomography; DVT, deep vein thrombosis; MRI, magnetic resonance imaging; PE, pulmonary embolism.

ASTHMA
General

Asthma is the most common potentially life-threatening chronic medical disorder to occur in pregnancy. The worldwide prevalence both outside and during pregnancy has been increasing. Among pregnant women, the prevalence of ever having received a diagnosis of asthma increased from 6.6% to 14.7% from 1988 to 2002.[9] According to the most recent U.S. data, about 8% of pregnant women report current active asthma during pregnancy.[9]

Available data do not describe a consistent effect of pregnancy on the frequency of asthma symptoms or the overall

severity of the disease. In one prospective study of 330 asthmatic women, asthma was unchanged in 33%, improved in 28%, and worsened in 35%.[10] A systematic review reported that 69% of women have improved methacholine-induced bronchial hyperresponsiveness during pregnancy, but that 31% have a deterioration.[11] More recent data from the northeastern United States, however, state that 88% of pregnant asthmatic women studied report one or more asthmatic symptoms during pregnancy, and that 16% of these women have symptoms almost daily.[9]

It is not clear whether the severity of asthma before pregnancy predicts its course during pregnancy,[12] but up to 75% of women who have no reported asthma symptoms in the

year before pregnancy have some symptoms during pregnancy.[9] Overall, about 6.7% of pregnant asthmatic women require emergency treatment for asthma in pregnancy, and 1.6% require hospitalization. Asthma attacks and asthma-related emergency room visits are more common in pregnant American women who are younger, unmarried, of lower family income, and of Puerto Rican or non-Hispanic black background.[9] It does appear that women tend to have similar courses with respect to their asthma in successive pregnancies.[13] Some investigators suggest that asthma tends to be less severe in the last 4 weeks of pregnancy and that if it does worsen, it tends to do so between 29 and 36 weeks.[14] Asthma exacerbations in labor are uncommon.

A common reason for asthmatic patients to deteriorate in pregnancy is the misperception that treatment for asthma is harmful to the fetus, leading to noncompliance with asthma-controlling medications. A National Institutes of Health (NIH) Consensus Conference has concluded that "under-treatment of pregnant asthmatics, particularly because of unfounded fears of adverse pharmacologic effects on the developing fetus, remains the major problem in the management of asthma during pregnancy in the United States."[15] A recent study reported that only 17% of pregnant asthmatic women took any regular controller medication during pregnancy.[9] Only half of women on a controlling medication continued it in pregnancy, and even among women with asthma symptoms in more than 10 of the preceding 12 months prior to pregnancy, use of an asthma-controlling medication during pregnancy occurred in only 42%. Another recent study of prescription claims found a decrease of 23% in inhaled corticosteroid use, of 13% in short-acting β-agonist use, and of 54% in systemic steroid use in the first trimester of pregnancy.[16] Other treatable reasons why asthma may worsen in pregnancy in individual women include pregnancy-related gastroesophageal reflux disease (GERD) and pregnancy rhinitis. These precipitating factors should be considered and treated as possible contributors in pregnant women with difficult-to-control asthma.

Maternal and Fetal Risks

There are conflicting reports concerning the relationship between asthma and maternal and fetal complications. Risks that are established are an increased risk of preterm delivery[17–22] and maternal gestational hypertension/preeclampsia.[23,24] Possible associations between maternal asthma and hyperemesis gravidarum, vaginal hemorrhage, complicated labor, neonatal mortality, and placenta previa have been noted in some studies but not in others. Intrauterine growth restriction (IUGR) and small–for–gestational age infants do not seem to be caused by maternal asthma.[18–21,25] The risk of the reported complications does appear to be greater in women with severe (steroid-dependent) or poorly controlled asthma.[19] One large study also identified a relationship between lower FEV_1 results and both preterm delivery and gestational hypertension.[26] Lastly, a few studies have suggested a small increased risk of congenital malformations in offspring of women with asthma. One recent study identified a small overall increased risk of congenital malformations (odds ratio [OR] 1.1) in offspring of asthmatic women, which was not explained by exposure to asthma medications in pregnancy.[27] Other recent reports have shown an increased

risk of gastroschisis (OR 2.06) in offspring of women who used bronchodilators in pregnancy[28] and an overall increased risk of malformations following pregnancies with an asthma exacerbation in the first trimester (OR 1.48).[29] These results require verification and, if real, the increased risk of malformations appears to be small.

It is not clear whether the relationship between asthma and these obstetric complications represents a direct effect of hypoxia and/or hypocapnia on the developing pregnancy, the effects of medication use, or a fundamental abnormality of smooth muscle in asthmatics manifest as increased contractile tone in the uterus, airways, and vasculature.[25,30] In general, asthma should not be considered a contraindication to pregnancy, although good asthma control should be emphasized as a way to minimize the incidence of many of these complications.

The risk of the child developing asthma in later life varies between 6% and 30%, depending on whether or not the mother is atopic and whether or not the father is also atopic and/or has asthma.[31] Younger maternal age at the time of delivery also appears to increase the lifetime risk of asthma in the offspring.[32]

Management Options
Prepregnancy

Preconception counseling should be included as a routine part of regular health maintenance visits in women of child-bearing age who have asthma. The counseling should be individualized with regard to the individual's disease severity and current treatment regimen. Overall, it should be communicated that pregnancy is generally well tolerated, but that compliance with asthma monitoring and maintenance treatments is essential. Patient education regarding the use of maintenance and rescue asthma medications, monitoring via PEFR use, proper use of inhalers, avoidance of asthma precipitants, and an asthma management plan (as described in the following section) are important prior to and during pregnancy. Spirometry may be desirable prepregnancy in order to serve as a baseline reference point, particularly if serial monitoring of air flows is planned as part of the asthma follow-up during pregnancy. Patients should be firmly counseled not to stop necessary medications when they find out they are pregnant.

Prenatal

Whereas asthma care should ideally be optimized prior to conception, patients often present with symptomatology during pregnancy that requires assessment and urgent management. Given the described complications of poorly controlled asthma, close monitoring of the patient's status and appropriate adjustment of treatments are essential to ensuring the best outcome for mother and child.

GENERAL PRINCIPLES

The goal of treatment for asthma in pregnancy is to provide optimal therapy to maintain asthma control, defined as minimal or no chronic symptoms, day or night; minimal or no exacerbations; no limitation of activity; maintenance of (near) normal pulmonary function; minimal use of short-acting inhaled β_2-agonists; and minimal or no adverse effects from the treatment provided. The underlying principle for

treatment of asthma during pregnancy is that with few exceptions, the same drugs and dosages that would be used outside pregnancy should be used in pregnancy for a given clinical indication.[33] Inadequate control of asthma is a greater risk to the fetus than asthma medications are. Proper control of asthma should enable a woman with asthma to maintain a normal pregnancy with little or no risk to her or her fetus. Whenever possible, treatment should be by the inhalational rather than the oral route, because this reduces maternal systemic effects[34,35] and also reduces the medication exposure of the fetus.

PREVENTION AND EDUCATION

Patient education is vital to the successful management of asthma in pregnancy because it will lead to improved compliance with monitoring and pharmacologic treatments, thereby reducing the risk of severe asthmatic exacerbations. Pregnant women with asthma should be strongly encouraged to avoid exacerbating factors, including allergens/irritants and particularly tobacco smoke. These women should also have proper inhaler use reviewed with them repeatedly. Proper use includes using a spacer to improve delivery of medication to the lungs, avoiding local side effects of inhaled steroids (such as oral thrush), and decreasing unnecessary systemic absorption of medication through the buccal mucosa.

SPECIFIC ASTHMA MEDICATIONS

Asthma medications are classified as either rescue agents or maintenance agents. *Rescue agents* are those medications used to treat acute bronchospasm and provide symptomatic relief but do not treat the underlying inflammation that causes bronchospasm. Rescue agents include all the inhaled β_2-agonists and ipratropium. The data regarding their effectiveness and the safety of rescue asthma medications in pregnancy are reviewed in Table 37–1. *Maintenance agents* are those medications that help to control airway hyperreactivity and generally treat the underlying inflammation of the airway. The inhaled steroids are the keystones of asthma maintenance. Other maintenance agents include systemic steroids, leukotriene antagonists, and cromolyn. The data regarding the effectiveness and safety of maintenance asthma medications in pregnancy are reviewed in Table 37–2.[15,36]

MONITORING AND DAILY ASTHMA MANAGEMENT WITH A STEPWISE PLAN

Women with asthma in pregnancy should be seen regularly and assessed via both history and physical examination as well some objective measure of pulmonary function (spirometry or PEFR monitoring). This objective data can be especially helpful in determining whether dyspnea is due to breathlessness of pregnancy or an asthmatic exacerbation. Serial fetal evaluations may also be indicated in the setting of significant asthma activity to monitor fetal growth and well-being.

Asthma medications are generally prescribed in a "stepwise" manner. All asthmatics should be given a written asthma management plan outlining recommended medication adjustments according to their symptoms (and PEFR if monitored), and guiding them about when to seek medical advice. Action plans are based on the best PEFR that a patient has ever obtained. Table 37–3 outlines the criteria for classification of asthma into four classes and reviews the treatment recommended during pregnancy for each degree of severity. This stepwise approach is recommended in the current guidelines by the U.S. National Asthma Education and Prevention Program[33] and the British Thoracic Society.[37] A typical action plan for a patient would tell her that if she develops symptoms more than 2 days per week or her PEFR drops below 80% of her personal best, her therapy needs "stepping up"; the patient should have instructions at home as to how to do this. The patient should be told that sustained drops in PEFR of more than 20% below her personal best warrant a call to the physician. A PEFR drop greater than 40% from her personal best warrants a trip to the emergency department (ED). When good control has been maintained for several months, the individual may consider stepping down the treatment to a regimen appropriate for the next lower level of asthma severity.

In pregnancy, GERD,[38,39] vasomotor rhinitis of pregnancy, and medication noncompliance should always also be considered as possible treatable causes of difficult-to-control asthma.

TREATMENT OF ACUTE ASTHMA EXACERBATIONS

Patients with worsening asthma, not improving on home management by the stepwise approach, will need to be seen

---

Summary of Pregnancy Data on Rescue Agents Commonly Used to Treat Asthma[15,202–209]

CLASS	AGENT	EFFECT ON EMBRYO AND FETUS
Short-acting inhaled β_2-adrenergic agonists	Albuterol, isoproterenol, pirbuterol, metaproterenol, terbutaline	Published experience with these drugs in animals and humans suggests that β-sympathomimetics do not increase the risk of congenital anomalies.[15,202,207] Albuterol is the most studied of these agents. Metaproterenol is the second most studied.
Long-acting inhaled β_2-adrenergic agonists	Salmeterol, formoterol	Animal data about intravenously administered salmeterol have not been reassuring, but this agent is still felt to probably be safe in humans when administered by inhalation.[15] Very limited human data have been published regarding salmeterol, and none regarding formoterol at this point; therefore, salmeterol may be preferred[15] and its use should be reserved for patients who have failed low-potency steroids and/or cromolyn alone.
Inhaled anticholinergic agents	Ipratropium	Reassuring animal studies but no published human data. Poorly absorbed by the bronchial mucosa so fetal exposure is likely minimal.[208] Efficacy in acute asthma attack presenting to the emergency department makes its short-term use seem justifiable, however.

TABLE 37–2

Summary of Pregnancy Data on Maintenance Medications Commonly Used to Treat Asthma[15,202,209–211]

CLASS	AGENTS	PREGNANCY DATA
Inhaled corticosteroids	<u>Low potency</u>: beclomethasone, dipropionate <u>Medium potency</u>: triamcinolone, acetonide <u>High potency</u>: fluticasone, propionate, budesonide, flunisolide, mometasone furoate	Inhaled corticosteroids are the most important pharmacologic agents in maintaining asthma control in and out of pregnancy. Only 4% of 257 patients taking inhaled glucocorticoids from the start of pregnancy had acute attacks of asthma during pregnancy, in contrast with 17% of 177 patients who were not.[210] Beclomethasone and budesonide are the most widely studied of the inhaled corticosteroids in pregnancy. The most recent data refer to budesonide, which should now be considered the preferred inhaled steroid in pregnancy.[15] Data regarding triamcinolone and fluticasone suggest no adverse pregnancy effects. Relatively little of these agents is absorbed, and human data have not suggested any teratogenic effects of these agents.[15,211-214]
Mast cell stabilizers	Disodium cromoglycate (cromolyn), sodium nedocromil	Human and animal data suggest these agents are nonteratogenic and well tolerated. These agents are virtually not absorbed through mucosal surfaces, and the swallowed portion is largely excreted in the feces. These agents are less effective than inhaled corticosteroids[15] and thus are useful in mild cases of asthma in which the decision not to use inhaled steroids has been made. Cromolyn[202,215] has been better evaluated in human pregnancy than nedocromil and should be considered the preferred agent of this class.
Leukotriene antagonists	Zafirlukast, montelukast, zileuton	Zafirlukast and montelukast both have favorable animal data, but data about their safety in human pregnancy remain limited at this point.[216] Zileuton has concerning animal data and should be avoided in pregnancy.[15] The use of these agents may be considered in pregnancy to those unusual cases in which a woman has previously had a significant improvement in asthma control with these medications before becoming pregnant, control that was not obtainable through other methods.
Sustained-release methylxanthines	Theophylline, aminophylline	Theophylline and its intravenous form aminophylline do not appear to be human teratogens.[202,207,217] The safety of aminophylline therapy in the second and third trimesters has been demonstrated in a large group of 212 gravidas in Finland.[217] The clearance of aminophylline is increased in pregnancy in a rather variable way.[217] Any patient who is taking more than 700 mg of aminophylline per day should have blood measurements made for optimal dosing. Their present role in treating asthma is generally felt to be as second- or third-line agents; they do not appear to be of benefit in an acute exacerbation.[218]
Systemic steroids	<u>Oral</u>: prednisone <u>Intravenous</u>: methylprednisolone hydrocortisone	Most data suggest that systemic steroids do not present a significant teratogenic risk in human pregnancy. Nonfluorinated systemic steroids do not cross the placenta in significant quantities because of placental metabolism[219-221] (the same is not true for betamethasone or dexamethasone). Even in higher doses, the effect of hydrocortisone or prednisone on the fetus in terms of suppression of the hypothalmic-pituitary-adrenal axis is minimal. There is a significant association with first-trimester use and oral clefts (odds ratio 6.55, 95% confidence interval 1.44–29.76).[221,222] In the setting of severe asthma or a severe exacerbation, however, the benefits of controlling a life-threatening disease make systemic steroid use (even in the first trimester) justifiable.[15]
Immunotherapy	Administration of gradually increasing quantities of an allergen extract to an allergic subject to down-regulate response	Human data from small trials suggest safety of continuing immunotherapy in pregnancy, but most physicians avoid initiation in pregnancy because of fear of provoking anaphylaxis.[223-225]

Adapted from Powrie RO: Drugs in pregnancy. Respiratory disease. Best Pract Res Clin Obstet Gynaecol 2001;15:913–936.

in an ED for evaluation. Treatment in the ED is reviewed in Table 37–4. Acute severe asthma (status asthmaticus) is a life-threatening condition that should be managed by a respiratory physician in an intensive care environment. High-dose intravenous steroids are the cornerstone of treatment for asthmatic exacerbations requiring admission to the hospital. Even in the absence of acute severe asthma, there should be a very low threshold for hospital admission of pregnant asthmatic patients because uncontrolled asthma can deteriorate very quickly.[40] General guidelines for admission to hospital include a sustained drop in PEFR to less than 60% of baseline, a PaO_2 less than 70 mm Hg at sea level, a $PaCO_2$ greater than 35 mmHg, a heart rate of greater than 120 bpm, or a respiratory rate greater than 22/min. It is important to remember that a $PaCO_2$ greater than 40 mm Hg

in a pregnant women with an asthmatic exacerbation suggests impending respiratory failure, because the normal $PaCO_2$ in pregnancy is 27 to 32 mm Hg.

Labor and Delivery

An asthma exacerbation is not generally an indication for elective delivery, but if there are other maternal or fetal problems, facilitated delivery may be considered. Asthma exacerbations commencing during labor are rare, presumably owing to the natural outpouring of endogenous steroids and epinephrine associated with the stress of delivery. Exacerbations occurring at this time should always be approached with a differential diagnosis that includes pulmonary edema (from cardiac causes or noncardiac ones such as preeclampsia, tocolysis, and sepsis), pulmonary embolism, and aspiration.

TABLE 37-3

Classification of Asthma and Stepwise Management in Pregnancy[15,202]

CATEGORY	CRITERIA	STEP THERAPY
Mild intermittent	• Symptoms up to twice a week *and/or* • Nighttime symptoms *up to* twice a month • PEFR > 80% predicted and day-to-day variability < 20%	• No daily treatment necessary • Inhaled β_2-adrenergic agonists as needed
Mild persistent	• Symptoms more than twice a week but not daily *and/or* • Nighttime symptoms *more than* twice a month • PEFR > 80% predicted *but* day-to-day variability 20%–30%	• Inhaled β_2-adrenergic agonists as needed *and* • Daily treatment with inhaled low-dose corticosteroid (preferably budesonide). • Alternatives include daily cromolyn, a leukotriene receptor antagonist, or a theophylline preparation
Moderate persistent	• Daily symptoms *and/or* • Nighttime symptoms more than once a week • PEFR 60%–80% with day-to-day variability > 30%	• Inhaled β_2-adrenergic agonists as needed *and* • Daily treatment with inhaled *low-dose* corticosteroid *and* daily treatment with salmeterol *or* • Daily treatment with inhaled *medium-dose* corticosteroid • If needed, combine treatment with daily *medium-dose* inhaled corticosteroid *and* daily salmeterol • Alternative: daily *low-medium* dose inhaled corticosteroid *and* either theophylline or a leukotriene receptor antagonist
Severe persistent	• Continual symptoms that limit activity • Frequent nighttime symptoms and acute exacerbations • PEFR < 60% predicted and day-to-day variability > 30%	• Inhaled β_2-adrenergic agonists as needed *and* • Daily treatment with inhaled high-dose corticosteroid *and* • Daily treatment with salmeterol *and, if needed* • Daily treatment with systemic corticosteroids

PEFR, peak expiratory flow rate.

TABLE 37-4

Management of the Acute Asthma Exacerbation Presenting to the Emergency Department[15,209]

1. Place patient on oxygen to keep Sao_2 > 95%.
2. Administer inhaled β_2-adrenergic agonist until improvement obtained or toxicity is noted; e.g., albuterol MDI with spacer 3 to 4 puffs *or* albuterol nebulizer every 10–20 min.
3. If exacerbation is mild-moderate (i.e., FEV_1 or PEF > 50% predicted) initiate oral corticosteroids (i,e., prednisone ~ 1 mg/kg)
4. If exacerbation is severe (i.e., FEV_1 or PEF < 50% predicted) administer either oral or systemic steroids (e.g., methylprednisolone 125 mg IV acutely and then 40–60 mg IV q6h *or* hydrocortisone 60–80 mg IV q6h. When the patient improves, she can be switched to a tapering oral regimen of prednisone).
5. Consider use of ipratropium MDI (2 puffs of 18 µg/spray q6h) or nebulizer (one 62.5-mL vial by nebulizer q6h) in first 24 hr after presentation.
6. Initiate assessment of fetal well-being if pregnancy has reached fetal viability.
7. Make individualized assessment of need for hospitalization (see text).

FEV_1, forced expiratory volume in 1 sec; MDI, metered-dose inhaler; PEF, peak expiratory flow.

Prostaglandin E_2 compounds and oxytocin can be safely used in asthmatics. 15-Methyl prostaglandin F_2 should not be used in asthmatic patients because it can cause bronchoconstriction.[41,42] Ergonovine and other ergot derivatives should also not be used in asthmatics because they too have caused severe bronchospasm in asthmatic patients, particularly in association with general anesthesia. Although morphine and meperidine may theoretically cause bronchoconstriction through histamine release, this is not generally a problem in clinical practice. Nonetheless, some experts prefer to use butorphanol or fentanyl as alternatives in pregnant asthmatics because these agents are less likely to cause histamine release. Regional anesthesia is preferable to general anesthesia because of the lower risks of pulmonary infection and atelectasis. For those women who do require a general anesthetic, bronchodilatory agents such as ketamine and halogenated anesthetics are preferred.

It is known that supraphysiologic daily doses of systemic steroids, given for as little as several weeks, may suppress the hypothalamic-pituitary-adrenal (HPA) axis for up to 1 year. This could blunt the normal physiologic outpouring of adrenal corticosteroids that occurs with stressors such as illness, surgery, and labor, though the prevalence of clinical complications seems to be low. The significance of this theoretical risk in pregnancy remains unstudied. To avoid the risk of precipitating an adrenal insufficiency crisis, however, many experts advise giving an empirical "stress dose" of systemic steroids (e.g., hydrocortisone 50–100 mg IV q8h on the day of delivery followed by 25–50 mg IV q8h on day 1 after delivery and then back to the baseline dose) to any woman in labor who has received systemic steroids in doses greater than 5 mg.day for longer than 2 to 4 weeks in the preceding year. If stress-dose steroids are not given, it is advisable to watch the patient for signs of adrenal insufficiency (anorexia, nausea, vomiting, weakness, hypotension, hyponatremia, and hyperkalemia) in the peripartum interval and postpartum.

Postnatal

Physicians should ensure that asthmatic women have their asthma medications reordered and continued postpartum. These women should also have their PEFR monitored in the days following delivery. Breast-feeding is recommended in women regardless of their asthma treatment. In fact, breast-feeding for between 1 and 6 months reduces the prevalence of atopy by about 30% to 50% in 17-year-olds who were breast-fed.[43]

SUMMARY OF MANAGEMENT OPTIONS
Asthma

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Adjust maintenance medication to optimize respiratory function.	IV/C	15,33,37
Educate patient about use of spacers and peak expiratory flow meters.	III/B	15,33,37
Educate patient to continue maintenance medications in pregnancy.	III/B	15,33,37
Provide patient with a stepwise asthma action plan.	III/B	15,33,37
Advise early referral for prenatal care.	III/B	15
Prenatal		
Use same drugs as outside pregnancy—especially steroids and β-agonists.	III/B	15,33,36
If theophylline is used, monitor blood levels, because blood volume expansion in pregnancy may mandate higher doses of the drug.	III/B	15,33,36
Monitor peak flow and adjust asthma medication as needed to control symptomatology and minimize need for "rescue" therapy.	III/B	15,33,36,37
Utilize inhalation rather than oral route.	III/B	34,35
Ensure adequate fetal oxygenation with acute exacerbation by keeping maternal oxygen saturation > 95%.	III/B	15,36
In the woman with active asthma, increase fetal growth monitoring and assessment of immediate fetal health by fetal heart rate monitoring.	III/B	15,36
Seek anesthesiology consultation in preparation for delivery if general anesthesia is anticipated.	III/B	15
Labor and Delivery		
Regional is preferable to general anesthesia.	III/B	15
Ensure adequate fetal oxygenation with acute exacerbation by keeping oxygen saturation > 95%.	III/B	15,36
Avoid prostaglandin F_2 and ergometrine	III/B	41,42
Consider parenteral "stress-dose" steroids for patients on chronic oral therapy or in those who have received more than 3 wk of systemic steroids in the past year.	III/B	15
Postnatal		
Continue maintenance drug therapy.	III/B	15,36
Encourage breast-feeding.	III/B	15,43
Physiotherapy to maintain adequate pulmonary toilet.	III/B	15,36

SARCOIDOSIS

General

Sarcoidosis is a chronic condition most commonly seen in women of reproductive age, and thus, may complicate pregnancy. The prevalence of sarcoidosis in the general population is estimated to be 10 to 20 per 100,000 population, with a lifetime risk of 0.85% among whites and three to four times more common in the black population.[44]

The lung is the organ most likely to be affected in sarcoidosis, and the majority of cases are found incidentally on routine chest x-rays. The differential diagnosis of pulmonary sarcoidosis includes malignancy, TB, HIV infection, collagen vascular disease, and occupational lung disease. Tissue biopsy is required for an accurate diagnosis in all but the most classic presentations.

Pulmonary involvement in sarcoidosis is classified by the radiographic stage of disease. Stage I is defined by the presence of bilateral hilar adenopathy, often accompanied by right paratracheal lymph node enlargement. Stage II involves bilateral hilar adenopathy along with interstitial infiltrates. Stage III disease consists of interstitial lung disease with

shrinking hilar nodes, and stage IV disease is defined by advanced pulmonary fibrosis. Most individuals (~75%) with stage I disease will have spontaneous regression in 1 to 3 years, and about two thirds of patients at stage II will undergo spontaneous resolution. Those with stages III and IV disease are likely to progress to serious lung impairment without treatment.

Sarcoidosis may also involve other organ systems including the skin (maculopapular eruptions, skin nodules, and erythema nodosum), the lymphatic system (lymphadenopathy), the eyes (iridocyclitis, chorioretinitis, and keratoconjunctivitis), and the liver. Rarely, sarcoidosis can occur in the spleen (splenomegaly); the neurologic system; the salivary glands; the bone marrow; the ear, nose, and throat; the heart; the kidneys; bones, joints, or muscle.[45,46] Sarcoidosis can also have effects on calcium homeostasis (hypercalciuria and hypercalcemia).

The cornerstone of treatment for sarcoidosis is systemic corticosteroids. In general, steroid treatment is reserved for those with significant symptoms due to pulmonary compromise or major extrapulmonary involvement. Corticosteroid therapy may also be of some benefit in milder cases of pulmonary sarcoid in which there is chest x-ray evidence of parenchymal disease (i.e., stage II or above). Whether the risks of long-term corticosteroids are worth the modest (~10%) benefit seen in asymptomatic patients remains unclear.[47,48] Chloroquine, hydroxychloroquine, methotrexate, azathioprine, pentoxifylline, thalidomide, cyclophosphamide, cyclosporine, and infliximab have all also been tried in the treatment of chronic or steroid-unresponsive sarcoidosis with variable success.[49]

Maternal Risks

Whereas sarcoidosis rarely infiltrates the female reproductive organs, involvement of the endometrium, ovary, and leiomyoma have all been reported.[50,51] In the absence of significant cardiopulmonary compromise, sarcoidosis does not appear to adversely affect fertility and does not increase the incidence of fetal or obstetric complications.[52]

Although some series have described a pregnancy-associated improvement in sarcoidosis,[53] followed by a postpartum exacerbation, the general consensus is that pregnancy does not predictably influence the natural history of sarcoidosis.[54] It has been postulated that improvement during pregnancy might be due to physiologic increases in maternal free cortisol and/or the immune modulation intrinsic to pregnancy.

Among the unfortunate patients in whom sarcoidosis has progressed to the stage of extensive pulmonary fibrosis and hypoxemia, along with cor pulmonale and pulmonary hypertension, the maternal and fetal prognosis is poor.

Fetal Risks

Beyond severe maternal disease from pulmonary or other organ involvement, leading to fetal compromise, there are no specific risks to the fetus from maternal sarcoidosis. The use of systemic steroids in pregnancy for maternal sarcoidosis poses little risk to the developing fetus. Severe maternal sarcoidosis that is unresponsive to steroids, however, might lead physicians to consider other treatments that are less

well studied in pregnancy. Untreated severe hypercalcemia in the mother could precipitate neonatal hypocalcemia and tetany, but the hypercalcemia associated with sarcoidosis is usually mild and unlikely to lead to such neonatal problems. Sarcoid granulomas have occasionally been noted in the placenta[55] but not in the fetus.

Management Options

Prepregnancy

Preconception counseling should be undertaken in women with sarcoidosis, incorporating the previous information.[53] Measurement of baseline parameters should include SaO_2 (both resting and with exercise), PFT (including a diffusing capacity for carbon monoxide [DL_{CO}], as a measure of gas exchange that is sensitive to the presence of interstitial lung disease), a chest x-ray, CBC, liver function tests, blood urea nitrogen, creatinine, and serum calcium. In the setting of moderate to severe pulmonary disease, echocardiography should be considered to evaluate for pulmonary hypertension. On the basis of these data, patients with stage I or II disease (and minor extrapulmonary manifestations) may be advised to expect a good pregnancy outcome. Women with more severe and active disease should be counseled that their pregnancy may be complicated by their disease and/or its treatment and that there is the potential for severe maternal illness to have a secondary effect on the well being of the fetus. Severe pulmonary arterial hypertension of any cause poses a very serious maternal mortality risk, and therefore, such women should be discouraged from proceeding with pregnancy (see Chapter 36).

Prenatal

Breathlessness is common in normal pregnancy but can also be seen in stages II to IV sarcoidosis. Women with sarcoidosis who develop complaints of increased dyspnea require reevaluation with SaO_2 (both resting and with exercise), chest x-ray, and PFT. Comparison with the baseline investigations (listed previously) will facilitate the interpretation of this additional testing. In some circumstances, a high-resolution CT scan may be needed to define the extent of disease. This evaluation may be undertaken with an acceptable degree of risk owing to fetal radiation exposure. Serial monitoring of maternal calcium (ionized or total calcium corrected for decreasing albumin in normal pregnancy), liver enzymes, creatinine, and CBC approximately once per trimester is also advisable. This may be helpful in identifying hypercalcemia prior to delivery as well as establishing a baseline that may help prevent the inappropriate attribution of abnormalities in creatinine or liver tests to preeclampsia later in pregnancy.

Painful joints and erythema nodosum are manifestations of sarcoidosis that may also be seen in normal pregnancies but need to be evaluated carefully, because they may be a manifestation of disease progression.

Symptomatic disease attributable to sarcoidosis should generally be treated with systemic steroids, under the supervision of a pulmonologist/internist experienced in treating this disease. As previously stated, the safety of steroids in pregnancy is well established and is discussed in the preceding section on "Asthma." Symptomatic disease unresponsive

to steroids may require treatment with other agents that are less well studied in pregnancy and will require careful consideration of both risk and potential benefits of treatment.

Patients with sarcoidosis have a risk of developing hypercalcemia, particularly in the setting of vitamin D supplementation.[56] Even in women with a normal serum calcium level, sarcoidosis-associated hypercalciuria can lead to nephrocalcinosis. Pregnant patients with sarcoidosis should, therefore, avoid both vitamin D and calcium supplementation, and the ingredients of their prenatal vitamins should be reviewed to prevent unintended supplementation.

The level of angiotensin-converting enzyme (ACE) has been advocated by some experts as an index of disease activity in sarcoidosis, but this may be invalid in pregnancy because ACE levels seem to change independently of sarcoid activity in pregnancy.[57]

Labor and Delivery

Among women with parenchymal lung disease due to sarcoidosis, regional techniques are strongly preferred to general anesthesia for cesarean delivery. Women with severe pulmonary involvement will benefit from an early epidural in labor (to reduce oxygen consumption in response to pain), and an assisted second stage of labor (forceps or vacuum suction) to reduce maternal exhaustion should be considered. Women who have been on supraphysiologic systemic steroids for more than 3 weeks in the preceding year should be considered for stress-dose steroids around the time of labor and delivery.

Postnatal

There are no specific recommendations regarding the postpartum management of the parturient with sarcoidosis.

SUMMARY OF MANAGEMENT OPTIONS
Sarcoidosis

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Reassure patient of benign nature of sarcoidosis during pregnancy (unless there is preexisting evidence of pulmonary fibrosis, hypoxemia, or pulmonary hypertension).	III/C	53,54
Obtain baseline laboratory and pulmonary function studies.	IV/C	53,54
If lung disease is significant, obtain echocardiogram for assessment of pulmonary hypertension. Discourage pregnancy in presence of severe pulmonary hypertension.	III/B	53,54
Prenatal		
Avoid multivitamins containing vitamin D.	III/B	53,54
Monitor serum calcium once per trimester (because of potential neonatal toxicities with maternal hypercalcemia).	III/B	53,54
Monitor for signs and symptoms of progressive pulmonary disease; institute steroid therapy if evidence of significant disease advancement.	III/B	53,54
Labor and Delivery		
With substantial parenchymal disease, avoid inhalation anesthesia.	IV/C	53,54
Obtain early anesthesiology consultation in patients with severe disease.	IV/C	53,54
Use parenteral "stress-dose" steroids for patients on chronic oral therapy or in those who have received more than 2–4 wk of systemic steroids in the past year.	III/B	53,54
Watch for neonatal tetany if mother has hypercalcemia.	III/B	53,54
Postnatal		
No specific recommendations.		

TUBERCULOSIS

General

Although TB made a significant resurgence in the western world in the early 1990s, the incidence of TB is once again declining in the United States. In 2004, the Centers for Disease Control and Prevention (CDC) reported a rate of new TB infections of 4.9 per 100,000 individuals.[58] There remain, however, a large number of latent (unidentified) and active cases of TB in the western world.[59,60] Most of these cases are occurring among the homeless and inner-city residents, among recent immigrants from countries with a high prevalence of TB, and among drug abusers and individuals with HIV infection.

Worldwide, TB infection remains a much more daunting problem. It is estimated that one third of the world's population has been infected with TB and that there are 8 million new cases of TB and 2 million deaths worldwide caused by TB each year.[59] Medical contact during pregnancy is an opportunity for the identification and treatment of TB among young women. Such therapy will benefit the mother, her child, and the general public.

Maternal and Fetal Risks

Although the incidence and transmission factors for TB are not altered by pregnancy, management requires additional consideration by the clinician. The main concerns are potential fetal infection and drug safety.

Maternal Risks

Pregnancy does not alter the clinical course of TB for the mother, and with modern antituberculous therapy, immunocompetent women should expect to make a complete recovery even if the TB is first diagnosed in pregnancy. It has been reported in some series that hepatotoxicity due to isoniazid (INH)—one of the key agents in antituberculous therapy—may occur with increased frequency in pregnancy.[61–63]

Fetal Risks

Risks to the fetus in the setting of maternal TB relate to (1) risk of fetal infection, (2) risk of fetal harm from antituberculous medications, and (3) fetal risks from severe maternal illness. Overall, TBs that is confined to the thorax or limited to lymphadenitis poses little risk to the fetus. Adverse fetal outcomes may be more frequent with disseminated disease.[64,65]

Mycobacterium tuberculosis rarely crosses the placenta,[65] although granulomata may be found in the placenta in the setting of primary or disseminated or miliary disease. True congenital infection is therefore extremely uncommon. This may relate to the observation that disseminated TB almost invariably involves the genital tract, which is a cause of infertility. Criteria for congenital TB include (1) confirmed diagnosis of TB in the newborn; (2) primary granulomatous complexes identifiable in the neonatal liver; and (3) in the absence of neonatal liver lesions, the diagnosis of TB in the newborn is made within a few days of birth (in order to differentiate congenital TB from neonatal/postpartum infection).[58,66] The neonate is at risk of postnatally acquired infection only if the mother is still infectious with active TB at the time of delivery. In that unusual setting, the risk of transmission to the neonate is high.[67]

Low birth weight, preterm delivery, and increased perinatal mortality rates have been reported in the setting of incomplete treatment and advanced or disseminated TB. One small study that compared pregnancy outcomes in pregnant women with extrapulmonary TB versus healthy controls found a significantly higher frequency of low–birth weight infants and infants with low Apgar scores among mothers with extrapulmonary TB.[58,67]

Given the very low risk of congenital TB infection and the generally good maternal prognosis, the main risk to the developing fetus is the issue of potential teratogenicity/toxicity of the antituberculous medications.

Management Options

Prepregnancy

Preconception counseling should address the possible effects of the antituberculous drugs on the developing fetus. Women undergoing treatment for active TB should be advised to delay pregnancy until their course of treatment course is complete. They should be counseled that in the event of an unplanned pregnancy, they should seek prompt medical attention rather than abruptly stopping their treatment. Women who have previously completed an adequate course of antituberculous therapy have no contraindication to pregnancy. Women with latent TB should be offered appropriate treatment prior to pregnancy, with a review of effective contraception if necessary in order to delay pregnancy until after the completion of the treatment.

Prenatal

Screening for TB with a tuberculin skin test (TST) is not justified for the whole general obstetric population.[68] Pregnant women from high risk populations for TB, however, should undergo a TST unless documentation of recent TST status is available. High risk populations include HIV-infected women; close contacts of persons known or suspected to have TB; immigrants or visitors from areas with a high prevalence of TB; residents and employees of high risk settings (prison, institutions) including health care workers; injection drug users; and medically underserviced, low-income populations (e.g., inner-city minority populations). TST is both safe and reasonably sensitive throughout pregnancy.[69,70]

Women who have a positive skin reaction according to standard criteria[71] and women with symptoms suggestive of active pulmonary TB (regardless of their TST results) should have a chest x-ray performed to look for evidence of active or latent pulmonary TB. If the chest x-ray is suggestive of active TB, sputum specimens must be obtained to evaluate for *Mycobacteria*.

Susceptibility testing for INH, rifampin, and ethambutol should be performed on a positive initial culture. Prior to commencing antituberculous treatment, baseline measurements of liver enzymes, bilirubin, alkaline phosphatase, serum creatinine, and platelet count should be obtained. HIV testing, if not already completed as part of prenatal care, is recommended for all pregnant patients with evidence of active or prior TB. Testing of visual acuity and red-green color discrimination should be obtained when ethambutol is to be used.

If sputum testing is positive (on acid-fast bacillus [AFB] smear, polymerase chain reaction [PCR] testing, or culture), treatment should be promptly initiated. The maternal and fetal benefits of treatment dramatically outweigh any concerns about potential drug toxicity to the fetus. Tuberculous infections in pregnancy should be managed jointly by an obstetrician and a physician experienced in the treatment of TB. Directly observed therapy is recommended because it ensures compliance. Pregnancy data about the commonly used antimycobacterial agents are reviewed in Table 37–5.[72–76] Streptomycin is the only commonly used antituberculous drug that is clearly contraindicated in pregnancy, because it has the potential to cause eighth cranial nerve damage,[77] leading to neonatal deafness. The recommendations by the World Health Organization (WHO) and the International Union Against Tuberculosis and Lung Disease (IUATLD) for uncomplicated TB in a pregnant individual include an initial 2-month course of INH, rifampin, ethambutol, and pyrazinamide. This is followed by a further 4 months of treatment with just INH and rifampin (for a total of 6 mo of treatment).[71] The current guidelines for Americans by the American Thoracic Society, in contrast, suggest that the initial treatment regimen in pregnancy should consist of INH, rifampin, and ethambutol *without* pyrazinamide. They comment that pyrazinamide is excluded "because of insufficient data to determine safety." If pyrazinamide is not included in the treatment regimen, the minimum recommended duration of treatment is 9 months.[72]

All women taking INH should also receive pyridoxine 25 to 50 mg daily to minimize the risk of neuropathy.[78] The amount of pyridoxine in multivitamins is variable but generally less than the needed amount. Vitamin K should probably also be given to the mother from 36 weeks' gestation onward in a dose of 10 mg daily to decrease the risk of

---

TABLE 37–5

Pregnancy Data Regarding Commonly Used Antimycobacterial Agents[72–76,209]

AGENT AND USUAL DOSE	ADVERSE EFFECTS IN GENERAL	PREGNANCY DATA	ADDITIONAL NOTES
Isoniazid (INH) • 5 mg/kg, up to a maximum of 300 mg daily • Dispensed in the United States as 50-, 100-, and 300-mg tablets and 50 mg/5 mL syrup	• Hepatitis • Peripheral neuropathy • Drug interaction with many agents, especially anticonvulsants • Cutaneous hypersensitivity	• FDA pregnancy classification C. • High lipid solubility; easily passes into fetal circulation. • Fair data to suggest this agent is safe in human pregnancy and any risk is outweighed by potential benefit. However, concerns about potential increase in INH hepatotoxicity in pregnancy make its routine use for prophylaxis in pregnancy in low risk cases not advisable.	• Always administer with 25–50 mg/day of pyridoxine (vitamin B_6) to decrease the risk of neurotoxicity in the mother. • Give vitamin K to mother near birth (10 mg PO daily from 36 wk on) and infant at birth to decrease risk of postpartum hemorrhage and hemorrhagic disease of the newborn. • Check transaminases monthly while on the medication.
Rifampin • 10 mg/kg, up to a maximum of 600 mg daily • Dispensed as 150- and 300-mg scored tablets in the United States	• Fever • Nausea • Hepatitis • Purpura • Flulike symptoms at high doses • Orange secretions • Increased metabolism of many agents	• FDA pregnancy classification C. • Limited data suggest no adverse fetal effects.	• Give vitamin K to mother near birth (10 mg PO daily from 36 wk on) and infant at birth to decrease risk of postpartum hemorrhage and hemorrhagic disease of the newborn. • Limited data suggest no adverse fetal effects.
Ethambutol • 15–25 mg/kg, up to a maximum of 2500 mg daily • Dispensed as 100- and 400-mg tablets in the United States	• Retrobulbar neuritis in 1% of patients • Peripheral neuropathy	• FDA pregnancy classification B. • Limited data suggest no adverse fetal effects.	• At each monthly visit, patients taking this agent should be questioned regarding possible visual disturbances, including blurred vision or scotomata; monthly testing of visual acuity and color discrimination is recommended for patients receiving the drug for longer than 2 mo.
Pyrazinamide • 15–30 mg/kg PO daily, up to a maximum of 3000 mg daily	• Thrombocytopenia • Hepatotoxicity • Interstitial nephritis • Nephrotoxicity	• FDA pregnancy classification C. • Human data extremely limited.	• Use in pregnancy supported by international recommendations but current ATS guidelines caution against use. Essential for multidrug-resistant TB and HIV-positive patients.
Streptomycin • Dose varies	• Ototoxicity	• FDA pregnancy classification D. • Reports of fetal ototoxicity preclude use.	• Avoid use in pregnancy.

ATS, American Thoracic Society; FDA, U.S. Food and Drug Administration; TB, tuberculosis.
Adapted from Powrie RO: Drugs in pregnancy. Respiratory disease. Best Pract Res Clin Obstet Gynaecol 2001;15:913–936.

hemorrhagic disease of the newborn.[79] The most common serious adverse effect of INH is a toxic hepatitis. Symptoms of hepatotoxicity (e.g., nausea, abdominal pain, hepatic tenderness) in association with hepatic transaminase elevations greater than three times the normal range or asymptomatic elevations in transaminases greater than five times the normal range should prompt discontinuation of therapy (and consideration of an alternative regimen). Pregnant women are at a higher risk of developing INH-related hepatotoxicity; therefore, testing of hepatic transaminases at initiation of treatment and at monthly intervals thereafter is advisable.[61–63]

Management of HIV-related TB is complex and requires expertise in the management of both HIV disease and TB. Because HIV-infected patients are often taking numerous medications, some of which interact with antituberculous medications, it is strongly encouraged that experts in the treatment of HIV-related TB be consulted.

Whether a positive TST, in the absence of active pulmonary TB, merits treatment with antituberculous medications during pregnancy depends on several factors: the size of the woman's TST response, her HIV status, and whether or not the woman has had recent contact with someone with an active case of TB. Indications to treat a positive TST in pregnancy, because of a high short-term risk of progression to active disease, include HIV-infected women exposed to an active case of TB; HIV-infected women with a TST result greater than 5 mm; any woman with recent active TB contact and a TST result greater than 5 mm; and women with a recent conversion from a negative to a positive TST. It remains controversial whether other pregnant women with normal immune status and a positive TST (not previously treated) should receive prophylaxis during pregnancy. A decision analysis found that antepartum treatment of a positive TST would result in fewer active TB cases, would be less expensive, and would improve life expectancy of the pregnant women affected.[80] Nonetheless, among asymptomatic immunocompetent pregnant women who are reliable to follow-up, treatment of a positive TST can generally be delayed until the postpartum period.[81,82]

The standard regimen for treatment of a positive TST is INH 5 mg/kg (up to a maximum of 300 mg) daily for 9 months. Twice-weekly doses of 15 mg/kg (up to a maximum of 900 mg) for 9 months may also be used as an alternative as part of directly observed therapy. Pyridoxine 25 to 50 mg daily should also be given, as in treatment of active TB.

Labor and Delivery

There are no specific recommendations regarding the pregnant woman with TB at the time of labor and delivery, except for appropriate infection control issues in the infectious patient. Because transmission of TB infection from mother to infant (neonatal TB) may occur postpartum, medical contact at the time of delivery may be an opportunity to evaluate the symptomatic woman for active and infectious pulmonary TB.[83]

Postnatal

In the rare circumstance of identifying a woman with active and infectious (sputum-positive) TB in late gestation or at the time of delivery, the neonate must unfortunately be separated from the mother until she is no longer infectious. In this circumstance, the neonate should also be given INH to prevent it acquiring neonatal infection. It is also reasonable to consider treating the neonate with INH-resistant bacilli Calmette-Guérin (BCG) vaccine to boost its immunity.[84]

Breast-feeding should not be discouraged for women being treated with INH, pyrazinamide, ethambutol, and/or rifampin. These agents are found in only small concentrations in breast milk and are not known to produce toxicity in the nursing newborn. These concentrations are also not significant enough to provide any protection to the nursing infant from infection with TB.[85]

SUMMARY OF MANAGEMENT OPTIONS
Tuberculosis

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Screen at-risk populations for TB with a TST prior to pregnancy.	III/B	68–70
If positive TST, treat as appropriate and delay pregnancy until after completion of antituberculous therapy.	III/B	71,72
Counsel regarding the potential teratogenesis of streptomycin, if being used.	III/B	77
Prenatal		
Perform TST on all women from high risk populations (see text).	III/B	68–72
Arrange HIV testing for all women with a positive TST.	IV/C	71,72
Administer INH prophylaxis during pregnancy to TST-positive women (without active TB) if they are HIV-positive, have a known recent TB exposure, or are new TST-converters.	IV/C	71,72

Management Options	Evidence Quality and Recommendation	References
Send sputum cultures (with antibiotic sensitivity testing) from women with active TB and start a recommended drug regimen: INH, rifampin, ethambutol ± pyrazinamide.	IV/C	71,72
Give pyridoxine 25–50 mg/day when using INH.	III/B	78
Measure hepatic transaminases monthly in pregnant women on INH.	IV/C	71,72
Labor and Delivery		
No specific recommendations except infection precautions needed with active disease.	IV/C	71,72
Postnatal		
Only separate baby from mother at birth if mother has infectious TB, and only until no longer infectious (~10 days into therapy).	IV/C	71,72
Administer INH and BCG vaccine to neonate if mother infectious at birth.	III/B	84
Encourage breast-feeding.	IV/C	85

BCG, bacillus Calmette-Guérin; INH, isoniazid; TB, tuberculosis; TST, tuberculin skin test.

KYPHOSCOLIOSIS

General

Kyphoscoliosis is usually an idiopathic disorder (>80%) involving kyphosis (anteroposterior spinal angulation) and/or scoliosis (lateral spinal curvature) that begins in childhood—and hence, often affects women of reproductive age. Affected individuals may develop functional lung impairment, the degree of which correlates well with the severity of spinal deformity. The pattern of abnormality on PFTs is restrictive, with decreased total lung capacity (TLC) and vital capacity (VC) and preserved RV. Chest wall compliance also typically decreases with age, increasing the work of breathing.

Kyphoscoliosis that is mild has a good prognosis. Conversely, in severe cases, pulmonary hypertension may develop as a result of persistent hypoxemia and result in cor pulmonale. Such individuals have a life expectancy of less than 1 year. Although various surgical and nonsurgical treatments are often undertaken in childhood, surgery has little role in adults with kyphoscoliosis. Medical therapy can include pulmonary rehabilitation, the use of supplemental oxygen, and occasionally, the use of negative- or positive-pressure ventilators.[86]

Mild degrees of kyphoscoliosis are common among pregnant women. More severe deformity resulting in respiratory impairment occurs in less than 0.1% of pregnancies. In some severe cases, it is remarkable that patients can complete a successful pregnancy despite their degree of deformity; the abdominal cavity may appear so contracted that there seems to be insufficient room for a fetus to develop normally. Nonetheless, positive outcomes are usually seen.[87]

Maternal and Fetal Risks

Among women with significant kyphoscoliosis, the maternal risks are mainly cardiac failure and cor pulmonale in the rare patient with significant pulmonary hypertension. To develop pulmonary hypertension, the condition has to be severe enough to produce hypoxemia at rest. The patient is at risk of respiratory failure if the VC is less than 1.5 L, particularly if it is less than 1 L.[88,89] The main risks to the fetus are IUGR and preterm delivery related to maternal hypoxemia.[90] Fetal hypoxic brain damage has been described in a patient with kyphoscoliosis and severe hypoxia (maternal PaO_2 < 59 mm Hg).[91]

Management Options

Prepregnancy

Preconception counseling should be undertaken, incorporating the previous information. PFTs should be obtained. If the VC is greater than 2 L, patients may be advised that they will generally tolerate pregnancy and delivery. If the VC is less than 2 L, the woman should be advised that she will be at increased risk for pulmonary complications with pregnancy. A blood gas analysis should be obtained in all women with a VC less than 2 L and if the resting PaO_2 is decreased, the fetus should be considered at risk of growth restriction. If the resting $PaCO_2$ is increased prepregnancy, the risk of maternal pulmonary complications in pregnancy is high.

In the setting of significant abnormalities on ABGs and PFTs—particularly resting hypoxia or hypercapnia—the woman should be evaluated for pulmonary hypertension. An ECG may be uninformative at evaluating for right ventricular hypertrophy in kyphoscoliosis, owing to the deformity of the chest. The pulmonary artery pressure and right heart function should therefore be assessed by echocardiography. Moderate to severe pulmonary hypertension is a relative contraindication to pregnancy (see Chapter 36). Before such a drastic recommendation is made, however, the physician may want to consider performing a direct measurement of

pulmonary vascular indices via a formal right cardiac catheterization.

Prenatal

Women with significant kyphoscoliosis require comprehensive medical care and follow-up regarding diagnosis and treatment of respiratory infections, bronchospasm, and evidence of cardiac failure. Women with hypoxia should be provided with supplementary oxygen therapy to reduce the risk of adverse fetal effects such as growth restriction. Patients identified to have significantly elevated pulmonary artery pressures and vascular resistance should be offered a termination of pregnancy, in view of the markedly increased risk of maternal mortality or severe morbidity.

These women may require hospitalization in later gestation, owing to impending respiratory compromise or for fetal concerns. Respiratory support with nasal positive-pressure ventilation has been used in some patients who have deteriorated in the third trimester.[92,93] Obstetric prenatal care relates mainly to monitoring for IUGR and preterm labor. Elective preterm delivery may be indicated for either maternal (increasing hypoxemia or frank respiratory failure) or fetal (signs of fetal hypoxia ± IUGR) indications.

Labor and Delivery

Women with severe kyphoscoliosis are often delivered by cesarean section because of concerns about concomitant pelvic deformity.[94] Regional anesthesia is much preferred to general anesthesia, and despite the severity of back deformity, a spinal or epidural puncture and catheterization is often possible in these patients—because the defect in kyphoscoliosis is typically in the upper part of the spine.

Postnatal

After delivery, optimal medical care includes early mobilization, physiotherapy, and ongoing monitoring for cardiac complications and respiratory infections.

SUMMARY OF MANAGEMENT OPTIONS
Kyphoscoliosis

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Obtain PFTs for assessment of vital capacity; obtain ABGs to assess O_2 and CO_2 levels.	III/B	88–90
If PFTs/ABGs are abnormal, assess for evidence of pulmonary hypertension; if present, advise against pregnancy.	IV/C	88–90
Counsel regarding risk for increase in pulmonary compromise as pregnancy progresses; discuss risk for fetal growth restriction and possible need for preterm delivery.	IV/C	88–90
Prenatal		
Monitor respiratory function: clinically and with periodic oxygen saturation measurement.	IV/C	88–90
Discuss pregnancy termination if pulmonary hypertension is present.	III/B	88–90
If severe cardiorespiratory compromise develops, initiate surveillance for fetal growth restriction and well-being.	III/B	88–91
Administer oxygen if maternal Sao_2 < 95%. Consider use of nasal intermittent positive-pressure ventilation if respiratory status deteriorating.	IV/C	92,93
Consider elective preterm delivery for frank respiratory failure or severe fetal compromise.	III/B	88–90
Labor and Delivery		
Supplementary oxygen if low Sao_2 values.	III/B	88–90
Consider cesarean section if associated pelvic deformities, though vaginal delivery possible in most cases; regional anesthesia for cesarean section is possible in most cases.	IV/C	88–90
Postnatal		
Chest physiotherapy, especially following general anesthesia.	—/GPP	—

ABGs, arterial blood gases; GPP, good practice point; PFTs, pulmonary function tests; Sao_2, arterial oxygen saturation.

CYSTIC FIBROSIS

General

CF is an autosomal recessive multisystem disorder characterized by recurrent pulmonary infections due to unusually thick bronchial secretions. The incidence of CF is about 1 in 2000 live births. Five percent of whites are carriers of the CF gene. Although CF remains a potentially fatal disease associated with a decreased life expectancy, the therapy of CF has undergone rapid evolution in the past few decades with a resulting significant improvement in patient survival. Many more women with CF are now surviving to reproductive age, and so we can expect to see more cases of CF in pregnancy.[95]

The symptoms and signs of CF include recurrent and persistent pulmonary infections, pancreatic exocrine insufficiency, and elevated sweat chloride levels. A functional defect in the complex chloride channel found in all exocrine tissues results in thick, viscous secretions in the lungs, pancreas, liver, intestine, and reproductive tract.[96] The resulting chronic pulmonary disease is the leading cause of morbidity and mortality in patients with CF. Pulmonary involvement is characterized by recurrent pneumonias, chronic bronchitis (with or without bronchiectasis), and an obstructive pattern on PFTs.

The tenacious respiratory secretions facilitate colonization of the airway and sinuses with pathogenic bacteria. *Staphylococcus aureus* and *Haemophilus influenzae* are common pathogens during early childhood, but over 70% of adults with CF are chronically ultimately infected with *Pseudomonas aeruginosa*, a highly pathogenic and resistant bacteria. Persistent infection with the species *Burkholderia cepacia*, notorious for inducing airway injury and exhibiting high-level antibiotic resistance,[97] is associated with an accelerated decline in pulmonary function and shortened survival among CF patients.

Acute or subacute exacerbations in CF patients are characterized by increased cough, sputum production, fever, and/or shortness of breath. Spirometry usually demonstrates a decline in airflow relative to baseline during these episodes, although chest radiographs may not show significant changes over baseline. Antibiotics are routinely prescribed when patients with CF develop an exacerbation.

Most physicians also prescribe aerosolized β-adrenergic agents to CF patients, particularly those who have clinical or spirometric evidence of reactive airways. Ipratropium bromide is also occasionally prescribed. The nebulized endonuclease DNase I is often used in CF patients with persistent productive cough, because it can decrease the viscosity of expectorated sputum by cleaving long strands of DNA into smaller segments. Patients who chronically produce purulent sputum, particularly those with concomitant bronchiectasis, benefit from chest physiotherapy and postural drainage to assist the clearance of secretions. Inhaled corticosteroids and/or daily azithromycin therapy are also sometimes used in the long-term management of this disease.

Pancreatic insufficiency is another common sequela of CF which may lead to malabsorption of fat and protein, an issue that can often be reversed with oral supplementation of pancreatic enzyme extracts. Nonetheless, many CF patients remain significantly underweight. Endocrine pancreatic insufficiency resulting in diabetes mellitus can also be seen, particularly in individuals surviving into adulthood.

Optimal medical therapy of CF lung disease can delay but does not stop disease progression, and premature death from respiratory failure still occurs in the majority of patients. As in other progressive lung diseases, lung transplantation provides an additional, albeit imperfect, management option for end-stage CF. Thirty-three percent of all double-lung transplants in adults are performed in CF patients.[98]

Maternal and Fetal Risks

Maternal Risks

Women with CF often suffer from reduced fertility, owing to both malnutrition-related amenorrhea and the production of an abnormally tenacious cervical mucus.[99] Data from the United States[100] and the United Kingdom[101] report a pregnancy rate for women with CF of 40 per 1000 per year, compared with 80 per 1000 for unaffected women. Of those who successfully conceive, 70% to 80% of pregnancies in patients with CF will result in a live birth. Among women with CF who do not have frank diabetes, glucose tolerance may be more subtly impaired, and as such, the risk of gestational diabetes appears to be increased.[102]

In contrast to early case reports of poor maternal outcome in CF patients, more recent studies have demonstrated the relative safety of pregnancy among women with CF who have good preexisting lung function.[103–108] It is reported that maternal and fetal outcomes are generally favorable if the prepregnancy FEV_1 exceeds 50% to 60% of the predicted value. If the mother has any evidence of pulmonary hypertension, however, her prognosis is much more guarded. Pulmonary hypertension from any cause confers a significant risk of right ventricular decompensation and maternal mortality in pregnancy.

Available data indicate that pregnancy does not appear to affect the rate of decline in FEV_1 or survival compared with those in nonpregnant reproductive-age women.[108,109] Following pregnancy, deaths among new mothers usually occur in those with the most severe lung disease. The absence of *B. cepacia* colonization, pancreatic insufficiency, or a prepregnancy FEV_1 below 50% of predicted were all associated with better maternal survival rates.

Women with CF who become pregnant face an additional nutritional demand as well. Those who achieve pregnancy despite being significantly underweight may become emaciated if they are unable to keep up with the significant nutritional demands of the fetoplacental unit.[110]

Fetal Risks

Well-nourished mothers with reasonably preserved lung function can expect a good pregnancy outcome. Following successful conception, 70% to 80% of pregnancies in women with CF will result in a live birth. In women with greater disability, however, IUGR and premature labor can result from chronic hypoxia and malnutrition, and maternal diabetes is associated with an increased risk of adverse pregnancy outcome in women with CF. Over half of women with severe CF lung disease deliver prematurely,[108] with acute episodes of pneumonia in pregnancy particularly associated with an increased risk of preterm delivery and

pregnancy loss. Malnutrition can also lead to fetal growth restriction.

Although most medications used for treatment of CF are safe for use in pregnancy, infection with some multidrug-resistant organisms may require use of antibiotic agents with less extensive fetal safety data.

All offspring of a mother with CF will be at least heterozygous for the condition and, in view of the high prevalence of the CF gene in the community, will have a considerable risk of being phenotypically affected.

Management Options

Prepregnancy

Preconception counseling should be undertaken in women with CF, including detailed genetic counseling. Genetic counseling is useful to explain to the parents the risk of having a child affected with CF, as determined by the partner's carrier status. Identification of the specific gene mutation in the mother will facilitate screening her partner and fetus, because most CF mutations can be identified by screening for the 20 to 30 most prevalent mutations.[109] If a mutation is identified in both mother and father, prenatal diagnosis with chorionic villus sampling or amniocentesis can be undertaken.[111] Prenatal diagnosis should be undertaken with the understanding that if the fetus is found to be affected, it may help the couple emotionally prepare for an affected child or may lead them to consider pregnancy termination.[112]

General medical care and pharmacologic treatment of CF should also be reviewed and optimized prior to conception. Given the complex nature of the disease, this is best accomplished by a multidisciplinary team led by a physician experienced in the care of CF and involving chest therapists, nutritionists, and social workers.

The nutritional status of the woman should be assessed and optimized prior to pregnancy, with a body mass index (BMI) less than 18 kg/m^2 considered a relative contraindication to pregnancy. The presence of pulmonary vascular disease should be sought, with a clear description of the substantial maternal risks communicated if significant pulmonary hypertension is found.[113,114] Pulmonary function tests, ABGs, and echocardiography (with estimation of pulmonary artery pressures) should be obtained or reviewed. Pregnancy should be strongly discouraged if the FEV$_1$ is less than 50% of predicted.[115] In the setting of severe disease, the issue that offspring may be left without a mother at a relatively young age needs to be tactfully discussed with the woman, because the 10-year mortality rate among pregnant women with CF is approximately 20%. Although heart and lung transplantation may be a future option for some patients with CF, it will not be available for the majority given the shortage of organ donors.

Prenatal

The primary goals of management for women with CF in pregnancy include optimization of her pulmonary and nutritional status. Women with severe lung impairment and/or pulmonary hypertension presenting in early pregnancy should be informed of the substantial personal risk of a pregnancy to their own health and should be offered a termination of pregnancy.

CF patients require ongoing optimal medical care throughout pregnancy. These women are usually utilizing chest physiotherapy and/or postural drainage on a daily basis, and this treatment should be continued. Exacerbations of lung involvement should be managed as they would be outside of pregnancy, recognizing that severe pulmonary exacerbations can lead to hypoxia and increase the risk of preterm delivery and fetal death. These should be a very low threshold for hospital admission in the setting of respiratory infections. The dosing of antibiotic agents may require adjustment owing to the altered pharmacokinetics of pregnancy. The use of penicillins, cephalosporins, trimethoprim/sulfamethoxazole, and/or aminoglycosides is safe in pregnancy.[116,117] Quinolone antibiotics have limited data regarding fetal safety in humans, but should be used when clinically indicated in pregnancy for the management of CF.[118,119] Bronchodilator drugs can be used safely in pregnancy. The use of supplemental oxygen is essential for maternal and fetal well-being in the setting of hypoxia.

Maternal malnutrition may lead to IUGR. Women who enter pregnancy significantly underweight may become emaciated in pregnancy owing to the additional nutritional demands of the fetoplacental unit. Whereas normal pregnancy is associated with an average weight gain of 10 to 12 kg, this can be difficult for the pregnant woman with CF. These women may need to eat 120% to 150% of their recommended daily caloric intake to maintain their body weight even when not pregnant, and to achieve adequate weight gain in pregnancy, they typically need to consume a further 300 kcal/day.[120] Even among CF women with normal prepregnancy weight, pregnancy-related dyspepsia, reflux, nausea and vomiting, and constipation may lead to a decrease in caloric intake. The additional calories needed for a healthy pregnancy may, therefore, be difficult to meet without resorting to enteral feeding. Involvement of a clinical dietician is thus advisable for monitoring and enhancement of the woman's nutritional status.

Because many women with CF will have underlying impaired glucose tolerance, screening for gestational diabetes should occur early in gestation (i.e., initially at ~18 wk' gestation, repeated at 24 to 28 weeks if initially normal). Most CF patients who are identified to have gestational diabetes will require insulin therapy. CF patients with diabetes should achieve the usual tight control of blood glucose to optimize pregnancy outcome.

If women with CF develop IUGR, decreasing maternal weight, or deteriorating respiratory function despite optimal medical treatment, facilitation of preterm delivery might be considered in individual cases—considering both maternal and fetal risks and benefits.

Labor and Delivery

A vaginal delivery is preferable for women with CF to reduce the risk of postoperative pneumonia and other maternal complications associated with an operative delivery. Use of regional anesthesia is ideal, because it will decrease maternal oxygen requirements associated with pain and avoid the need for general anesthesia should an urgent cesarean delivery be needed. In women with moderate to severe lung disease, an assisted second stage of delivery (with forceps or

vacuum suction) should be considered to avoid maternal exhaustion.

Postnatal

The vast majority of women with CF should be strongly encouraged to breast-feed their babies, because the common medications for the treatment of CF are safe to take during breast-feeding. Breast-feeding might not advisable, however, in severely ill or malnourished women. If the mother's general health is very poor, bottle feeding may permit alternate caregivers to assist in feeding and thus allow the mother to rest. The breast milk of mothers with CF has a slightly lower fat content than usual (mainly essential fatty acids) but normal electrolyte content and is adequate to nourish the child.[121–123] Infants of mothers with CF are typically screened for CF by their pediatrician.

SUMMARY OF MANAGEMENT OPTIONS
Cystic Fibrosis (Maternal)

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Document baseline respiratory function with PFTs, ABGs, echo.	III/B	103–108,110
Counsel regarding maternal risks of respiratory failure, congestive cardiac failure, IUGR, and preterm delivery if FEV_1 < 50% and/or pulmonary hypertension exists	III/B	103–108,110
Counsel regarding fetal risks of developing CF and certainty of being a carrier.	III/B	109,110
Gene test father for CF carrier status—will determine fetal CF risk and inform the potential for informative prenatal diagnosis (genes for CF identifiable in about 99% of cases).		
Assess patient weight and encourage patient to optimize nutritional status.	III/B	110
Optimize medical management of CF	III/B	110
Prenatal		
Care for patient via multidisciplinary team led by individual with expertise in CF management.	—/GPP	—
Counsel regarding fetal risks of developing CF and certainty of being a carrier—if not done prepregnancy (as above).	III/B	109,110
Optimize medical management:	III/B	110
• Chest physiotherapy.		
• Bronchodilators.		
• Treat pulmonary exacerbations as when nonpregnant.		
Increase calorific intake in pregnancy.	III/B	110,120
Monitor for IUGR and preterm delivery.	III/B	108
Labor and Delivery		
Monitor respiratory function (oxygen saturation).	III/B	110
Supplemental oxygen if hypoxic.		
Hemodynamic monitoring of women with pulmonary hypertension.		
Assisted vaginal delivery may be necessary.	III/B	110
Avoid general anesthesia for cesarean section.	III/B	110
Postnatal		
Monitor respiratory function.	III/B	110
Continue regular medications; breast-feeding is not contraindicated.	III/B	121–123

ABGs, arterial blood gases; CF, cystic fibrosis; FEV_1, forced expiratory volume in 1 sec; GPP, good practice point; IUGR, intrauterine growth restriction; PFTs, pulmonary function tests.

PNEUMONIA

General

Pneumonia and influenza are the seventh leading cause of death in the United States, and the leading cause of infectious death.[124] The incidence of pneumonia in pregnancy is between 0.8 and 2.7 cases per 1000 deliveries,[125,126] a rate similar to that in the nonpregnant population. The onset of pneumonia does not seem to occur at any particular point in gestation, with one study noting an average gestational age at diagnosis of 32 weeks.[127] Respiratory failure develops in up to 10% of pregnant women with pneumonia[128] and accounts for 12% of obstetric patients requiring intubation.[129] Overall, pneumonia accounts for 4.2% of antepartum admissions for nonobstetric causes.[130]

Risk factors for the development of pneumonia in pregnancy are maternal disease, including HIV infection, asthma, and CF; smoking; anemia; cocaine use; alcohol abuse; maternal corticosteroid administration for fetal lung maturity; and tocolytic therapy use. Overall, about 24% of women with pneumonia in pregnancy have a predisposing condition.[131]

Perhaps the most important role for physicians in the assessment and management of suspected pneumonia in pregnancy is to carefully review the differential diagnosis. Community-acquired pneumonia in the pregnant patient generally presents with typical features (abrupt onset of fever and rigors, productive cough, tachycardia, tachypnea, fever, and localized inspiratory "crackles"). Pulmonary embolism is the leading cause of maternal mortality in the United States and the United Kingdom, and it can present very similarly with dyspnea, cough, chest pain, fever, and pulmonary infiltrates. Aspiration pneumonitis and pulmonary edema related to sepsis, tocolysis, or preeclampsia can also present with a similar clinical picture.

The maternal physiologic changes to the respiratory system do not significantly alter the susceptibility to pneumonia. An exception to this principle is the pregnancy-associated reduction in cell-mediated immunity, which leaves pregnant women with an increased susceptibility to viral and fungal pneumonias. As such, pregnant women are at an increased risk of severe pneumonia and disseminated disease from atypical pathogens such as herpesvirus, influenza,[132,133] varicella,[134] and coccidioidomycosis.[135]

Maternal and Fetal Risks

Pneumonia in pregnant women may not be more common than in the general population, but it may result in greater morbidity and mortality owing to the physiologic changes of pregnancy and the needs of the fetus. Maternal prognosis from pneumonia is generally good in the antibiotic era, although severe maternal morbidity and significant mortality from primary varicella (maternal mortality ~14%)[136] and influenza pneumonia remain a major concern. Women with immunodeficiency due to HIV are at the additional risk of opportunistic infections (e.g., *Pneumocystis carinii* pneumonia, TB) and require very careful attention.

Because radiographic evidence of a pulmonary infiltrate is considered the gold standard for diagnosing pneumonia, a chest x-ray should be obtained in almost all patients.[137] Given the negligible fetal radiation exposure of a single chest x-ray with abdominal shielding (approximately equal to 1 day's background radiation), there should be no hesitation about performing chest radiology in pregnant patients suspected of having pulmonary disease. Other fetal risks in the setting of maternal pneumonia include an increased risk of miscarriage, preterm labor, prematurity, and low birth weight. Most cases of pneumonia in pregnancy are caused by organisms that do not directly affect the fetus, but occasionally, the organism causing pneumonia may present a specific risk to the fetus (e.g., varicella pneumonia and congenital varicella syndrome).[138]

Management Options

Prepregnancy

Preconception counseling is usually not relevant to bacterial pneumonia in otherwise healthy women. In HIV-infected women with low CD4 cell counts, however, continuation of *Pneumocystis* prophylaxis during pregnancy should be advised because this infection is the leading cause of AIDS-related death of pregnant women in the United States.[139] Given the increased attack rate and morbidity of influenza infection among pregnant women, the CDC and the American College of Obstetricians and Gynecologists (ACOG) have recommended that women currently pregnant or anticipating pregnancy should routinely receive influenza vaccination during the influenza season regardless of gestational age.[140] Pneumococcal vaccine is advised for women with high risk conditions—such as diabetes mellitus, asthma, chronic cardiac or pulmonary disease, or any other disease or treatment affecting immune function—either before or during pregnancy. Pneumococcal vaccine is also mandatory in women with prior splenectomy and in women with functional hyposplenism (e.g., sickle cell disease) and is recommended for women living in long-term care facilities or prisons.[141] Women without demonstrable immunity to the varicella virus should also be offered immunization with the varicella vaccine prior to pregnancy, though this live attenuated virus should not be administered during gestation.

Prenatal and Postnatal

Recommendations regarding empirical therapy for community-acquired pneumonia, per the American Thoracic Society (ATS),[142] are reviewed in Table 37–6. Per these

---

TABLE 37–6

Empirical Antibiotic Regimens for the Treatment of Community-acquired Pneumonia in Pregnancy[222,228,229]

- For uncomplicated pneumonia in patients who **do not require hospitalization**:
  Standard: azithromycin 500 mg PO on day 1 followed by 250 mg daily for 4 days
  Alternate: erythromycin 250 mg qid PO for 10–14 days
- For uncomplicated pneumonia in patients **requiring hospitalization**:
  ceftriaxone 2 g IV once daily *with* azithromycin 500 mg IV daily (or erythromycin 500 mg IV q6h). Once patient is afebrile and stable, switch to azithromycin 500 mg PO daily × 7–10 days (or erythromycin 250–500 mg PO qid × 10–14 days) with cefuroxime axetil 500 mg PO bid for 10–14 days.

guidelines, treatment varies according to the severity of illness (as reflected by whether the patient qualifies for inpatient versus outpatient care) and also reflects the increasing prevalence of drug-resistant organisms. In pregnancy, the threshold for hospitalization of borderline patients should be low, given the potential maternal and fetal risks of hypoxia from a worsening condition. Routine collection of sputum and blood cultures before initiation of antibiotic therapy is advisable, at least among hospitalized patients, even though an etiologic organism is found in only about half of cases investigated.[142,143] In the hospital, patients initially treated with intravenous antibiotics can be switched to oral agents once the patient is afebrile and improving. With appropriate antibiotic therapy, some improvement in the clinical course is expected within 72 hours. A full adequate course of therapy is 10 to 14 days, except for azithromycin, which can be given for only a shorter course because of its extended tissue half-life.

Although the ATS guidelines apply quite well to pregnant women, the treating physician should bear a few additional points in mind. If parenteral erythromycin is selected, the use of the estolate ester should be avoided owing to a relatively high incidence of subclinical, reversible hepatotoxicity when used during pregnancy.[144] Although clarithromycin and levofloxacin are often recommended for the treatment of possible drug-resistant pneumococci in the nonpregnant population, these drugs should be avoided in pregnancy. Clarithromycin appears to be teratogenic in the animal model and, therefore, should be used in only situations in which it is the drug of choice. The use of fluoroquinolones such as levofloxacin has also been discouraged owing to a described ability (ciprofloxacin and ofloxacin) to cause an irreversible arthropathy in immature experimental animals. Although subsequent human data have been generally reassuring, these agents should still be considered relatively contraindicated in pregnancy.[118,119] Tetracyclines cause staining of fetal bones and teeth and should not be used in pregnancy.

Doses of antibiotics selected should be in the upper recommended range in pregnancy[145] because of increased renal clearance. Patients may use acetaminophen as an antipyretic. Critically ill women with sepsis or refractory hypoxia may require intubation and assisted ventilation. Fairly standard ventilatory settings can be utilized, with adjustment to maintain the acid-base changes typical of pregnancy (i.e., $PaCO_2$ 28–32, normal pH).

Varicella infection in pregnancy confers a risk of transplacental infection and embryopathy, particularly in the first half of pregnancy, with an incidence of 1% to 2%. Varicella of the newborn is a life-threatening illness that may occur when a newborn is delivered within 5 days of the onset of maternal illness or after postdelivery exposure to varicella. Therefore, if exposure to varicella virus occurs in pregnancy in a woman without protective immunity, varicella zoster immune globulin (VZIG) should be administered within 96 hours in an attempt to prevent maternal infection. Because of the high prevalence and morbidity of pneumonia associated with primary varicella infection in pregnancy, parenteral acyclovir should be given to all women who develop varicella infection in pregnancy.[146–150]

SUMMARY OF MANAGEMENT OPTIONS
Pneumonia

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Vaccinate for influenza during flu season.	IV/C	140
Pneumococcal vaccination for women with splenectomy or immunodeficiency.	IV/C	141
In patients with HIV and low CD4, counsel to continue PCP prophylaxis in pregnancy.	IV/C	139
Prenatal		
Vaccinate for influenza during flu season (regardless of gestational age) if not done preconception.	IV/C	132,140
Differentiate pneumonia from other conditions, especially pulmonary embolus and ARDS.	IV/C	58
Perform chest radiographs as needed to confirm diagnosis.	III/B	137
Use standard approach with sputum and blood cultures for seriously ill women.	IV/C	58,142
Begin appropriate antimicrobial therapy based on underlying conditions and presentation:	IV/C	58
• Avoid tetracyclines in pregnancy.		
• Avoid fluoroquinolones unless specifically indicated.		
• Continue treatment for 10–14 days

PULMONARY EDEMA, ACUTE LUNG INJURY, AND ACUTE RESPIRATORY DISTRESS SYNDROME

General

The physiologic changes of pregnancy predispose pregnant women to the development of pulmonary edema (Table 35–7), and as such, this dangerous condition is not rare in pregnancy and occurs more frequently than in the nonpregnant population. The overall incidence of pulmonary edema in pregnancy is approximately 80 in 100,000 pregnancies.[151]

Pulmonary edema may be classified as cardiogenic or noncardiogenic. Cardiogenic pulmonary edema is the result of elevated pulmonary venous pressure leading to a hydrostatic pressure gradient that causes the movement of fluid into the alveoli,[152] a phenomenon referred to as *congestive heart failure*. Causes specific to pregnancy include peripartum cardiomyopathy and preeclampsia-associated myocardial dysfunction. The causes and treatment of cardiogenic pulmonary edema are discussed in Chapter 36. Noncardiogenic pulmonary edema, in contrast, is the result of fluid leaking into the alveoli across a leaky pulmonary capillary bed despite normal intravascular pressures. This may be caused by a variety of disorders in pregnancy, some pregnancy-specific and others incidental to or exacerbated by pregnancy (Table 37–8). For a diagnosis of noncardiogenic pulmonary edema to be made, the pulmonary capillary wedge pressure (PCWP) should be less than 18 mm Hg and there should be no evidence of a cardiac cause.[153]

Noncardiogenic pulmonary edema may be subclassified as acute lung injury (ALI) and the acute respiratory distress syndrome (ARDS). These two entities represent a spectrum of disease: the syndrome is defined by a scoring system based on the level of positive end-expiratory pressure (PEEP) required, the PaO_2-FIO_2 (fractional concentration of oxygen in inspired gas) ratio, the degree of static lung compliance, the degree of pulmonary infiltrates, and the clinical cause (as defined in Table 37–9).[154] Patients with less severe lung injury are defined as ALI and those more severely affected have ARDS. ARDS has an incidence in the general population of 13.5 in 100,000 per year.[155] It is considered a relatively rare but often lethal condition in pregnancy, contributing significantly to maternal mortality. Precipitants

TABLE 37–7

Normal Physiologic Changes of Pregnancy That Predispose to and May Exacerbate Pulmonary Edema[230]

20% decrease in colloid osmotic pressure
50% increase in blood volume and cardiac output
Decreased FRC in pregnancy means end-expiratory volumes closer to critical closing volumes

FRC, functional residual capacity.

TABLE 37–8

Select Causes of Noncardiogenic Pulmonary Edema in Pregnancy

Incidental to Pregnancy

Sepsis: appendicitis, bacterial pneumonia
Chemical pneumonitis
Inhalational lung injury
Venous air embolism
Cocaine and high-dose opiates in susceptible patients

Exacerbated or Facilitated by Pregnancy

Aspiration (Mendelson's syndrome)
Sepsis: pyelonephritis, viral pneumonia, listeriosis
Severe hemorrhage, especially related to systemic inflammatory response, low PCOP, and rarely leukoagglutination in the lung
Pancreatitis

Unique to Pregnancy

Tocolytic therapy
Preeclampsia/eclampsia/HELLP syndrome
Amniotic fluid embolism
Neurogenic pulmonary edema after eclamptic seizure
Sepsis: chorioamnionitis, endometritis, septic abortion

HELLP, hemolysis, elevated liver enzymes, and low platelets; PCOP, plasma colloid osmotic pressure.

TABLE 37–9

Diagnostic Criteria for Acute Lung Injury and Acute Respiratory Distress Syndrome[153,154,160,230,231]

1. Acute onset.
2. Bilateral chest radiographic infiltrates.
3. A pulmonary artery occlusion pressure <18 mm Hg or no evidence of left atrial hypertension.
4. Impaired oxygenation manifested by a Pao_2/Fio_2 of 200–300 mm Hg for ALI and ≤200 mm Hg for ARDS.

ALI, acute lung injury; ARDS, acute respiratory distress syndrome; Fio_2, fractional concentration of oxygen in inspired gas; Pao_2, arterial oxygen pressure.

of ALI/ARDS in the general population include sepsis, aspiration, pneumonia, severe trauma and burns, sudden relief of upper airway obstruction, lung and bone marrow transplants, medications (especially aspirin, cocaine, narcotics, and nitrofurantoin), leukoagglutination reactions in the lungs after a blood transfusion, venous air embolism with central venous catheter insertion, and neurocardiogenic (associated with a intracerebral bleed or seizure) causes.[153,156] Those commonly encountered in pregnancy are outlined in Table 37–9.

Although some cases of noncardiogenic pulmonary edema seen in pregnancy will meet the strict diagnostic criteria of ARDS (see Table 37–7), the majority of the pregnancy-related cases will not have the protracted course and poor prognosis typically seen with true ARDS. The mechanism in these cases relates more to transient fluid shifts across the alveolar lining due to acute inciting factors in a host predisposed because of the physiology of pregnancy (discussed later). Most of these pregnancy-related cases will improve rapidly with removal of the inciting factor and urgent medical treatment, and most will not require mechanical ventilation. Some experts suggest that these cases could better be termed *permeability pulmonary edema* rather than true ALI/ARDS. The initial clinical presentations are often indistinguishable from true ALI/ARDS, however, and many of the non–pregnancy-specific causes remain the same.[157–163]

The differentiation between cardiogenic and noncardiogenic pulmonary may be difficult clinically, in part because the clinical presentation may represent a combination of several different disorders. It is important to identify which contributor is predominant, because the optimal treatment varies considerably depending on the underlying pathophysiologic mechanisms.

Physiologic Changes in Pregnancy That Predispose Pregnant Women to Pulmonary Edema

Pregnant women have a clear predisposition to noncardiogenic pulmonary edema, which is attributable to a number of normal physiologic changes that occur in pregnancy. These changes can be viewed as "contributing" factors that increase the likelihood that a pregnant woman with a particular insult or condition will develop pulmonary edema.

These changes are discussed later and summarized in Table 37–8.

Pregnancy-associated Increase in Blood Volume and Cardiac Output

Normal pregnancy is characterized by an approximately 50% increase in blood volume and a 40% increase in cardiac output, both peaking and plateauing at 26 to 32 weeks' gestation. Fever, pain, preeclampsia, and multiple gestations can further increase cardiac work and lead to a rise in pulmonary artery occlusion pressure (PAOP) that can, despite remaining within the "normal" (<18 mm Hg) range, lead to pulmonary edema in the setting of low plasma colloid osmotic pressure (PCOP) and/or endothelial damage.

Pregnancy-associated Drop in Plasma Colloid Osmotic Pressure

The pregnancy-associated expansion of blood volume occurs via an increase in plasma free water that is greater than the expansion of blood cells and plasma proteins. This leads to a physiologic anemia and a progressive decrease in the concentration of plasma proteins including serum albumin with advancing gestation. Because the plasma protein concentration is the main determinant of PCOP, this decrease increases the propensity for fluid to move into the interstitial and alveolar spaces in pregnant women. PCOP drops further in women with preeclampsia, contributing to the increased risk of pulmonary edema seen with this entity (as discussed further later).[164,165]

Pregnancy-associated Decrease in Functional Residual Capacity

A third factor predisposing pregnant women to pulmonary edema is the elevation of the diaphragm by the gravid uterus in the latter part of gestation, decreasing the FRC in pregnant women by around 18% compared with that in nonpregnant individuals. As such, at end-expiration, the pregnant woman is closer to her *critical closing volume* (the volume at which alveoli collapse upon themselves). It is believed that this increases the likelihood that small airways and alveoli will collapse when small amounts of pulmonary edema are present and may thereby contribute to a worsening hypoxia due to pulmonary edema.

Precipitating Causes of Pulmonary Edema

Although pregnant women are predisposed to pulmonary edema due to the factors listed previously, the occurrence of pulmonary edema still generally requires an inciting event to "tip the balance" and precipitate movement of fluid into the interstitial spaces of the lung. The myriad conditions that may cause ARDS in the general population can also occur in pregnant women. Some of these conditions, such as severe viral pneumonia and aspiration, occur with increased frequency in pregnancy. Some pregnancy-specific conditions can precipitate pulmonary edema. In any pregnancy, the presence of anemia, a multifetal gestation, or the injudicious administration of intravenous fluids will further increase the risk that a particular inciting cause will result in

pulmonary edema. The common precipitants of pulmonary edema in pregnancy are outlined in Table 37–9 and discussed in the following paragraphs.

Tocolysis

A pregnancy-specific cause of noncardiogenic pulmonary edema is the use of β-adrenergic agonists (such as terbutaline) and magnesium for the treatment of preterm labor (tocolysis).[166] The incidence of pulmonary edema in this setting is 0.3 to 9.0%[154] and may be seen during the infusion of the tocolytic agent or up to 12 hours after its discontinuation. Although β-adrenergic agonists have been used extensively in the treatment of asthma in nonpregnant patients without this complication, there is a clear association in the obstetric literature between the systemic use of these agents and pulmonary edema. A recent series noted that tocolysis accounted for 25% of pregnancy-associated pulmonary edema.[151] Possible mechanisms include a β-mimetic–induced increase in cardiac work; possible catecholamine-induced myocardial dysfunction; and the frequent coadministration of excess intravenous fluids and high-dose glucocorticoids. Multiple gestation, maternal infection, and corticosteroid therapy are associated with a further increased risk of pulmonary edema in combination with tocolytic therapy.

The use of β-mimetic agents for tocolysis has been called into question because they have been found to be no more effective than nifedipine or magnesium and are associated with excess maternal morbidity.[167] We anticipate that the incidence of tocolytic-induced pulmonary edema will decrease as the sympathomimetic agents are used less frequently.

Preeclampsia

Preeclampsia is an important cause of pulmonary edema in pregnancy owing to its high prevalence. In one series, 2.9% of preeclamptic women developed pulmonary edema.[168] Maternal mortality from preeclampsia-associated pulmonary edema in this setting may be as high as 10%. About 30% of preeclampsia-associated pulmonary edema will occur antepartum, the remainder usually within the first 72 hours after delivery. The majority of women with antenatal pulmonary edema due to preeclampsia have preexisting chronic hypertension.[154] Excessive intravenous fluid administration, often in response to oliguria, is another important contributing factor in many cases. Perinatal mortality in the setting of antenatal preeclampsia-associated pulmonary edema may be as high as 50%, although this is often related to concomitant placental abruption and, therefore, more a result of the severity of the preeclampsia rather than the presence of the pulmonary edema itself.

Preeclampsia may provoke pulmonary edema by several mechanisms. One factor is the additional drop in PCOP, beyond that seen in normal pregnancy. Another is the endothelial damage, characteristic of preeclampsia, disrupting the endothelial barrier in the lungs and facilitating the leakage of fluid into the pulmonary interstitium and alveoli. In women with preexisting hypertension, diastolic dysfunction due to a thickened and noncompliant ventricle may be an important factor contributing to pulmonary edema— particularly in conjunction with a dramatic increase in afterload due to preeclampsia-associated hypertension. Lastly, preeclampsia-associated transient left ventricular systolic dysfunction may occur and contribute to pulmonary edema. The occurrence of left ventricular dysfunction in preeclampsia has been well described but is poorly understood. It is assumed that the intense vasospasm and endothelial damage that characterize preeclampsia have an impact on myocardial oxygen supply leading to impaired myocardial contractility.[168–173]

Sepsis

Infection is also a common and important mechanism leading to noncardiogenic pulmonary edema in pregnancy. Systemic bacterial infection originating from any primary site can precipitate pulmonary edema in pregnant women. Pneumonia can progress to ALI and ARDS and is an important cause of prolonged mechanical ventilation in pregnant women (see the section on "Pneumonia"). Pyelonephritis is another common cause, because pulmonary edema may complicate up to 10% of cases of pyelonephritis during pregnancy.[174,175] The main mechanism of sepsis-related pulmonary edema in pregnancy appears to be an increased sensitivity of pregnant women to bacterial endotoxin, resulting in increased capillary permeability.

Aspiration Syndromes: Mendelson's Syndrome and Bacterial Aspiration Pneumonia

Aspiration of gastric contents is among the leading nonobstetric causes of ARDS among pregnant women. Aspiration syndromes are more common in pregnancy because of increased GERD due to progesterone-mediated relaxation of the lower esophageal sphincter and reduced gastric motility and delayed emptying; and elevated intragastric pressure due to compression by the enlarging uterus. In the setting of altered mental status related to drug or medication use, seizure activity or in association with anesthesia, stomach contents can be aspirated and lead to Mendelson's syndrome and/or bacterial aspiration pneumonia.

Mendelson's syndrome may occur in association with a difficult intubation during general anesthesia or during the postanesthesia period, when the gag reflex may be depressed. It requires a high index of suspicion at times, because it may occur in association with silent GERD. Gastric secretions aspirated into the lungs lead to intense pulmonary inflammation that can rapidly progress to ALI/ARDS. Clinical manifestations may include tachypnea, hypoxia, wheezing, hypotension, and fever. Gastric contents may be noted in the pharynx or mouth during laryngoscopy. Chest x-ray changes classically show diffuse interstitial and alveolar infiltrates. Despite the rapidity and severity of the syndrome, mild cases generally resolve without antibiotics within 2 to 5 days unless bacterial superinfection intervenes.[176] Modern anesthetic management, with a preponderance of regional anesthesia for cesarean sections, has thankfully made this a far less common event than it was in the past.

Bacterial aspiration pneumonia usually has a more gradual onset than Mendelson's syndrome, presenting 48 to 72 hours after aspiration with clinical manifestations including persistent fever, purulent sputum, and leukocytosis. Chest x-ray findings tend to be localized to the areas of the lung that were dependant at the time of aspiration. The bacterial infection is generally polymicrobial, including a

preponderance of oral anaerobes, so treatment with penicillin or clindamycin is usually effective.

Massive Transfusion

Massive red cell transfusion for severe antepartum or postpartum hemorrhage can result in cardiogenic or noncardiogenic pulmonary edema. The mechanism is often multifactorial, including volume overload; reduced PCOP (from replacement of whole blood loss with packed red cells and crystalloids); endothelial damage from a systemic inflammatory response to the massive hemorrhage; and occasionally, transfusion-associated acute lung injury (TRALI), an immune-mediated reaction to human leukocyte antigens (HLA).

Amniotic Fluid Embolism (Anaphylactoid Syndrome of Pregnancy)

Amniotic fluid embolism (AFE) is a rare but catastrophic complication of pregnancy that typically presents as the abrupt onset of hypotension, dyspnea, and altered mental status proceeding to full blown disseminated intravascular coagulation (DIC) and ARDS. AFE syndrome accounts for approximately 10% of all maternal deaths in the United States and results in permanent neurologic deficits in up to 85% of survivors.[177] One U.S. study reported an incidence of 1 in 20,646 singleton pregnancies, with a mortality of 26%.[178] Risk factors for the development of AFE include multiparity, increased maternal age, maternal trauma, prolonged labor, meconium staining of the amniotic fluid, use of oxytocin, instrumental delivery, and cesarean delivery.

The AFE syndrome usually occurs in the immediate peripartum interval but has been reported to occur spontaneously antepartum. The diagnosis is clinical and should be strongly considered in any woman near term (especially in labor) who presents with sudden cardiorespiratory failure.

The mechanism of the AFE syndrome involves the entry of amniotic fluid into the maternal circulation through the endocervical veins or uterine tears. In susceptible individuals, this may precipitate a dramatic systemic reaction. Animal data suggest the initial response is acute right heart failure resulting from embolization of amniotic fluid and fetal debris (squamous cells, mucin) causing occlusion and vasospasm of the maternal pulmonary vasculature, with resulting pulmonary hypertension and systemic hypotension. This is followed by a dramatic maternal systemic reaction resulting in ARDS and DIC. Some researchers would prefer that the syndrome be called *anaphylactoid syndrome of pregnancy*, thereby emphasizing the importance of the maternal immunologic response in this syndrome.

Presentation of Pulmonary Edema in Pregnancy

The symptoms and signs of pulmonary edema in pregnancy are similar to those seen in the general medical population. Early signs and symptoms of pulmonary edema are often mild and may be mistaken for findings of normal pregnancy, given that these young women often maintain respiratory and cardiovascular stability longer than the typical medical patient with pulmonary edema.

Tachypnea is an important clinical sign that a woman's dyspnea represents a more serious condition than dyspnea of pregnancy. The lungs may be clear to auscultation early in the course when only interstitial edema has developed. Affected women will usually exhibit some degree of tachycardia along with anxiety related to dyspnea or hypoxia. As the condition progresses, diffuse "crackles," wheezing, and cough will become apparent in association with alveolar edema.

The chest x-ray in early pulmonary edema may be normal. Diffuse interstitial and alveolar infiltrates, and in some cases pleural effusions, will subsequently become manifest. In some women, the infiltrates may be patchy or even unilateral, particularly if the woman has spent prolonged periods in the lateral decubitus position. The patient can be confidently reassured that the fetal radiation exposure from a chest x-ray with abdominal shielding is negligible.

ABGs initially reveal a decrease in both PaO_2 and $PaCO_2$. As the condition progresses, the PaO_2 may decrease further and the $PaCO_2$ begin to rise, reflecting impending respiratory failure. It is essential to recall the normal ABG parameters for pregnancy, recognizing that a $PaCO_2$ of 40 mm Hg is very abnormal and indicates impending ventilatory failure. Additional laboratory investigations that should be obtained in the setting of suspected pulmonary edema include CBC, blood urea nitrogen (BUN) and creatinine, as well as "preeclampsia laboratories" (alanine aminotransferase [ALT], uric acid, lactate dehydrogenase [LDH], CBC, creatinine, and urine protein–to–creatinine ratio).

Differential Diagnosis of Pulmonary Edema in Pregnancy

The differential diagnosis of pulmonary edema in pregnancy is broad. Diagnostic possibilities include cardiac disease, including peripartum cardiomyopathy, ischemic heart disease, and valvular heart disease. Differentiation of noncardiogenic pulmonary edema from peripartum cardiomyopathy, ischemic heart disease, or occult valvular heart disease should begin with a careful history, physical examination, and ECG. When doubt remains, or to follow up on equivocal or positive cardiac findings, echocardiography should be undertaken. A prospective study of 45 pregnant women with pulmonary edema found that echocardiography identified an unsuspected cardiac abnormality in 47% of cases.[170] Pneumonia (bacterial or viral) is discussed in the "Pneumonia" section. Drug-related lung disease (nitrofurantoin hypersensitivity, cocaine-associated pulmonary edema) should also be kept in mind, and a full medication history should be obtained and a drug screen considered in some cases, recognizing that the vast majority of patients with cocaine-associated pulmonary edema will have severe hypertension.

Treatment of Pulmonary Edema in Pregnancy

Pulmonary edema in pregnancy is a medical emergency. Regardless of the etiology, the immediate goal is to maintain adequate maternal oxygenation ($PaO_2 \geq 70$ mm Hg,

$SaO_2 \geq 95\%$) to avoid potential hypoxic injury to the fetus.[179–181] The next step is to promptly identify and initiate treatment of the underlying cause(s) of the condition. Relief of symptoms to improve patient comfort should also be addressed.

Clear, reassuring communication of maternal and fetal status with the patient and her support person will decrease maternal distress. Unless respiratory failure is imminent, small doses of parenteral morphine sulfate may be given as needed to reduce maternal anxiety and decrease pulmonary congestion. Judicious titration of intravenous fluid administration and careful monitoring of fluid balance should be undertaken. Although most pregnant women with pulmonary edema will not be volume-overloaded, gentle diuresis to try to achieve the lowest PCWP that will still support normal blood pressure is advisable. Data regarding the treatment of ARDS in nonpregnant patients show that decreasing the PCWPs by 25% with diuretics and fluid restriction can improve pulmonary function and perhaps outcome.[182–184] Most patients will respond to tiny intravenous doses of furosemide (i.e., 10–20 mg). Starting with these low doses will avoid overdiuresis, which can lead to hypovolemia and hypotension and might impair placental perfusion (and precipitate fetal distress).

Remove or Treat the Underlying Cause

TOCOLYTIC-RELATED PULMONARY EDEMA

Critical to the management of pulmonary edema in pregnancy is identification and treatment or removal of the underlying cause. In the setting of established or suspected tocolytic-induced pulmonary edema, discontinuation of the tocolytic agents is mandatory. This difficult decision is made easier when one recognizes that (1) fetal well-being is dependent on maternal well-being and (2) tocolytics are of minimal proven efficacy for prolongation of gestation beyond 48 hours.

PREECLAMPSIA-RELATED PULMONARY EDEMA

When the clinical spectrum of preeclampsia evolves to include pulmonary edema, prompt maternal stabilization followed by prompt delivery is the treatment of choice. Sometimes a high index of suspicion for preeclampsia is required, if the preeclampsia is otherwise mild. Blood pressure should be brought down quickly below approximately 160/100, because the decrease in afterload and, therefore, intracardiac pressures may help decrease pulmonary edema. A small dose of furosemide may be given, with close monitoring of mother and fetus. If intravenous magnesium sulfate is felt to be required (for seizure prophylaxis in the setting of severe preeclampsia), it should be administered in the smallest volume considered safe with close following of the total fluid balance.

INFECTION-RELATED PULMONARY EDEMA

Noncardiogenic pulmonary edema due to maternal systemic infection should be promptly treated with judiciously selected broad-spectrum antibiotic(s). Empirical antibiotics should be started pending culture results. In the absence of a clear focus of infection, abdominal pain and tenderness indicative of possible appendicitis or chorioamnionitis/endometritis should be sought. Pyelonephritis should be considered in any woman with pulmonary edema associated with fever, and a urinalysis and urine culture should be obtained.

AMNIOTIC FLUID EMBOLISM/ANAPHYLACTOID SYNDROME

Suspected AFE necessitates aggressive supportive management in a critical care setting. DIC is nearly universal in the evolution of AFE and should be anticipated. Treatment should begin with aggressive volume administration with or without vasopressors to maintain adequate blood pressure. Intubation and mechanical ventilation will almost always be required. Coagulopathy and hemorrhage should be managed with aggressive blood product and factor replacement (fresh frozen plasma and cryoprecipitate as needed).

Endotracheal Intubation

The hemoglobin dissociation curve favors transfer of adequate oxygen to fetal hemoglobin as long as the maternal PaO_2 remains at 70 mm Hg or above, but if oxygenation cannot be maintained or the patient shows evidence respiratory fatigue (either clinically or on the basis of a $PaCO_2$ rising even into the normal nonpregnant range), assisted ventilation should be promptly arranged. In cases in which a normal level of consciousness is maintained, and in which a rapid reversal of the hypoxia is anticipated, a trial of spontaneous breathing with supplemental oxygen and PEEP administered through a tight-fitting mask may be considered. Noninvasive positive-pressure ventilation (NIPPV) may also be used, but concerns about its use in the setting of pregnancy-associated upper airway edema and the propensity of pregnant women to aspiration may limit its use.

Intubation is required if the patient does not improve with attempts at noninvasive assisted ventilation and/or the woman has evidence of respiratory failure ($PaO_2 < 70$ mm Hg or $PaCO_2 > 45$ mm Hg on 100% oxygen administered through a snug non-rebreather mask). Given the delays inherent in assembling the equipment for intubation, it is preferable to intubate a pregnant patient electively in controlled conditions rather than delay intubation until it is required emergently. The clinician should bear in mind that the upper airway in pregnant women is often difficult to visualize because of soft tissue swelling related to physiologic hyperemia of mucosal tissues during gestation. Because of this, the rate of failed elective intubation in pregnant patients is eight times greater than that seen in general surgical patients.

Pregnant women are at higher risk for aspiration during intubation because of reduced lower esophageal sphincter tone and delayed gastric emptying. It should also be recalled that because of reduced FRC in the latter part of pregnancy, there is less available oxygen in their lungs to maintain PaO_2 during periods of apnea. Generous preoxygenation with 100% oxygen should, therefore, always be done prior to and between attempts to intubate a pregnant woman. In light of these considerations, it is imperative that the intubation of a pregnant woman be performed by the most experienced individual available and that every effort be made to ensure that all required equipment is readily available and functioning properly before attempting intubation (Table 37–10).

TABLE 37–10

Equipment and Medications Necessary for the Intubation of a Pregnant Woman[226]

Continuous electrocardiographic monitoring
Blood pressure monitor on patient's arm
Pulse oximeter
High-flow oxygen source
Large-bore intravenous access secured in place
Intubation to be performed by most experienced individual available, with assistant at his or her side; the incidence of failed intubation in pregnancy is 1 in 200 to 1 in 300 cases, almost 10 times as high as for nonpregnant patients[226]
Mask (that fits patient securely) and manual bag-valve inflation device
Oropharyngeal suction equipment
Endotracheal tubes (with tested inflatable cuff) for oral intubation (rather than nasal intubation) with smaller endotracheal tube (6–6.5) than would be used with similar nonpregnant patient preferable owing to upper airway narrowing in pregnancy[226]
Laryngoscope with light
Stylet
Medications for sedation and (if necessary) paralysis of patient, usually thiopental 3–5 mg/kg IV for sedation, and succinylcholine 1–1.5 mg/kg, up to 150 mg IV, for paralysis
Etomidate 0.3 mg/kg IV over 60 sec may be needed in certain circumstances for muscle relaxation
Method readily available to assess that endotracheal placement is not esophageal (listener with stethoscope or CO_2 detector)
Self-inflating bulbs or syringes have been found to be unreliable in pregnant women
Chest x-ray to be done shortly after intubation to ensure endotracheal tube is properly placed 4–7 cm above the carina
Gloves, mask, goggles, and gown available to intubator
Plan in place for next step if intubation attempt fails. Use of the laryngeal mask has been described in pregnancy and should be available in this circumstance[227]

Mechanical Ventilation

In general, mechanical ventilation for the pregnant woman with pulmonary edema should be undertaken in the same manner as for the nonpregnant patient. For patients with ARDS, this generally involves the use of lower tidal volumes with lower pressures (tidal volumes ≤ 8 mL/kg predicted body weight and inspiratory plateau pressures ≤ 30 cm H_2O)[185] to avoid lung overdistention and ventilator-associated lung injury. Although this ventilation strategy has not been formally studied in pregnant women, it is recommended by the ARDS Network.[186] Although this ventilation strategy generally leads to "permissive hypercapnea" in the general medical population, the associated acid-base changes may not provide an optimal environment for the fetus. Therefore, it is recommended that the ventilatory rate be increased to maintain pH and PCO_2 in the appropriate ranges for pregnancy. The FIO_2 should ideally be kept less than 60% if possible. PEEP is also universally recommended, because it facilitates recruitment of collapsed alveoli. Excessive levels of PEEP (>10 cm H_2O) should be avoided, however, because it may reduce cardiac preload and cardiac output, thereby compromising uteroplacental blood flow. Similarly, respiratory alkalosis from overventilation should be avoided, because alkalemia can also adversely effect uterine blood flow.

Role of Pulmonary Artery Catheters in Pregnant Women with Pulmonary Edema

In most cases of pulmonary edema in pregnancy, central hemodynamic monitoring will not be necessary for diagnostic purposes. In the absence of clinical evidence of cardiac disease or preeclampsia, it can generally be assumed that the PCWP is unlikely to be greater than 18 mm Hg in a pregnant woman. Preeclampsia is an exception, because severe preeclampsia may be associated with systolic and/or diastolic cardiac dysfunction. In cases in which cardiac dysfunction is suspected, an ECG may be useful in deciding if central hemodynamic monitoring may be helpful. Such monitoring may also be useful in the setting of presumed cardiogenic pulmonary edema that does not improve quickly in response to supplemental oxygen and diuresis.

The goal of invasive monitoring in the setting of pulmonary edema in pregnancy is to safely reduce the PCWP and improve left ventricular performance. It must be remembered, however, that a PCWP that is normal outside of pregnancy may represent a level that will still lead to pulmonary congestion given the predisposing physiology of pregnancy/preeclampsia. It is most helpful, therefore, to follow trends in the PCWP during treatment than to look at absolute numbers.

Although central hemodynamic monitoring in a critical care setting may be quite helpful in difficult cases of pulmonary edema in pregnancy, it is widely accepted that beyond complex cardiac disease or sepsis, it is not generally necessary.[187–201]

Use of Vasoactive and Inotropic Medications

Use of vasoactive and/or inotropic drugs to maintain blood pressure and cardiac output may be helpful in some cases of pulmonary edema in pregnancy, particularly when sepsis or cardiac dysfunction is present. It is critical not to withhold any potentially beneficial treatment from a critically ill pregnant woman because of concerns about possible fetal effects. The paucity of human data on the effects of most of these medications on placental blood flow, however, should caution against their use to "fine-tune" maternal hemodynamic parameters.[201]

SUMMARY OF MANAGEMENT OPTIONS
Pulmonary Edema, Acute Lung Injury, and Acute Respiratory Distress Syndrome

Management Options	Evidence Quality and Recommendation	References
High or intensive care setting; nurse patient at 45-degree angle if possible.	—/GPP	—
Provide supplemental oxygen to maintain $PaO_2 > 65$ mm Hg and oxygen saturation > 95%.	III/B	179–181
If patient is maintaining blood pressure and placental perfusion is not in question, consider administration of IV furosemide (at a dose of 10 mg if patient has not received furosemide in past).	IV/C	182–184
Consider possibility of cardiogenic cause of pulmonary edema. Obtain echocardiogram in most cases to rule out cardiogenic causes.	III/B	170
Monitor fluid balance and avoid fluid overload; minimize IV fluids	III/B	182–184
Remove or treat underlying causes of pulmonary edema in pregnancy: • Discontinue tocolytics. • Evaluate for presence of preeclampsia and begin active efforts toward delivery of fetus if patient has preeclampsia. • Evaluate for presence of infection (especially pyelonephritis) and treat if present. • Protect airway if aspiration is suspected. • Check INR, aPTT, and CBC if AFE suspected.	—/GPP	—
If oxygenation cannot be maintained, consider use of intermittent positive-pressure nasal ventilation or semielective intubation.	IV/C	185,186
Consider placement of central hemodynamic monitoring line if: • Cardiac cause suspected and patient unresponsive to diuretics. • Poor urine output despite diuretic administration. • If hypotension present.	IV/C	187–192
Consider use of inotropic and vasoactive agents to maximize cardiac output in the minority of cases. Therapy should be guided in this setting by central hemodynamic monitoring.	IV/C	201

AFE, amniotic fluid embolism; aPTT, activate partial thromboplastin time; CBC, complete blood count; GPP, good practice point; INR, International Normalized Ratio; PaO_2, arterial oxygen pressure.

Anemia and White Blood Cell Disorders

JANE STRONG and JANE M. RUTHERFORD

ANEMIA: OVERVIEW

Anemia is defined as a hemoglobin value that is lower than the threshold of 2 standard deviations below the median value for a healthy matched population. The World Health Organization (WHO) defines anemia in pregnancy as a hemoglobin concentration of less than 11 g/dL.[1] The cutoff point suggested by the U.S. Centers for Disease Control and Prevention (CDC) is 10.5 g/dL in the second trimester.[2]

Marked physiologic changes in the composition of the blood occur in healthy pregnancy. Increased total blood volume[3] and hemostatic changes[4] help to combat the hazard of hemorrhage at delivery. Plasma volume increases by 50%, and red cell mass by 18% to 25%, depending on iron status. These changes cause a physiologic dilution in hemoglobin concentration that is greatest at 32 weeks' gestation. In iron-replete women, hemoglobin returns to normal by 1 week postpartum.

Worldwide, pathologic anemia is the most common medical disorder of pregnancy. Deficiency of essential hematinics usually arises from increased requirements and inadequate intake. Iron deficiency is the most common hematinic deficiency in pregnancy, followed by folate deficiency. Vitamin B_{12} deficiency rarely causes anemia in pregnancy.

In nonindustrialized countries, anemia is associated with up to 13% of maternal deaths.[5] The global prevalence of anemia is 42%, but this ranges from 5% in the United States to more than 60% in parts of Central Africa.[1]

ANEMIA: IRON DEFICIENCY

Maternal Risks

To maintain iron balance, women of reproductive age require 2 mg of iron daily. Pregnancy further stresses iron balance. The total iron requirements in normal pregnancy are approximately 1240 mg.[6] The main demands for iron arise from expansion of the red cell mass (~500–600 mg), and the fetus and placenta require approximately 300 mg. The daily iron requirement in pregnancy is approximately 4.4 mg (0.8 mg/day in the first trimester, increasing to 7.5 mg/day in the third trimester).[6,7] These requirements can be achieved only by maximizing dietary iron absorption and mobilizing iron stores.[8,9] If a woman enters pregnancy with depleted iron stores, the effects of iron deficiency develop. Vegetarians are at an additional disadvantage because heme iron (derived from meat) is more readily absorbed than nonheme iron, and heme iron also facilitates the absorption of nonheme iron in a mixed diet. Absorption of iron is less than 10%, so an average of 40 mg of dietary iron is required daily.

As iron deficiency develops, the ferritin level decreases first and then the serum iron level. A decrease in hemoglobin concentration is a late development. Iron-dependent enzymes in every cell are affected, and there is a profound effect on body functions.[10]

Tissue enzyme malfunction occurs, even in the early stages of iron deficiency. This might explain the reported association between anemia during pregnancy and preterm birth and the anecdotal evidence that blood loss at delivery is greater in women with anemia.[11,12]

In normal pregnancy, hypervolemia modifies the response to blood loss.[4] Blood volume decreases after the acute loss at delivery but remains relatively stable as long as the loss does not exceed 25% of predelivery volume. No compensatory increase in blood volume occurs, and plasma volume decreases gradually, primarily because of diuresis. Thus, hematocrit gradually increases and blood volume returns to nonpregnant values.

Fetal Risks

The fetus obtains iron from maternal transferrin, regardless of maternal iron stores. The placenta traps maternal transferrin, removes the iron, and actively transports it to the fetus, mainly in the last 4 weeks of pregnancy.[6] If maternal iron stores are depleted, the fetus obtains iron from erythrocyte breakdown or maternal intestinal absorption. Most fetal iron is found in fetal hemoglobin, but one third is stored in the fetal liver as ferritin.

When maternal iron stores are depleted, there is a decrease in fetal iron stores,[13] and this might have an important bearing on the development of anemia during the first year of life, when oral iron intake is very poor.[14–16]

Studies suggest that behavioral abnormalities occur in children with iron deficiency.[17] Iron deficiency in the absence of anemia is associated with poor performance on the Bayley

Mental Development Index.[18] Development delays in iron-deficient infants can be reversed by treatment with iron.[17] Cognitive function can also be improved with iron supplementation, as was shown in a randomized study in nonanemic, iron-deficient adolescent girls.[19]

Studies suggest that prophylaxis of iron deficiency during pregnancy might have an important role in the prevention of adult hypertension.[20,21] High blood pressure in adults appears to originate in fetal life and is associated with lower birth weight and high ratios of placenta to birth weight. Placental size at term was shown to be inversely proportional to serum ferritin concentrations at initial evaluation.[21]

Diagnosis

Hemoglobin Concentration

Although reduction in hemoglobin concentration is a relatively late development in iron deficiency, measuring hemoglobin concentration is the simplest noninvasive practical test available. Hemoglobin values of less than 10.5 g/dL in the second and third trimesters are probably abnormal and require further investigation.

Red Cell Indices

The increased drive to erythropoiesis, resulting in a higher proportion of young large red cells, appears to mask the effect of iron deficiency on mean corpuscular volume (MCV) in pregnancy, even when anemia is established. Healthy, iron-replete pregnancy is associated with a small physiologic increase in red cell size, on average 4 femtoliters (fL; 10^{-15} L), but in some women, the increase may be as high as 20 fL.[22] MCV is a poor indicator of iron deficiency that develops during pregnancy.[23] Some women enter pregnancy with established iron-deficiency anemia or with grossly depleted iron stores. These do not present diagnostic problems. Those who enter pregnancy with a precarious iron balance and a normal hemoglobin value present the most difficult diagnostic problems.

Serum Iron and Total Iron-Binding Capacity

Serum iron level and total iron-binding capacity (TIBC) provide an estimate of transferrin saturation. Reduced transferrin saturation indicates a deficient iron supply to the tissues and the development of iron deficiency. At this early stage, erythropoiesis is impaired and iron-dependent tissue enzymes are adversely affected.

In health, the serum iron of adult nonpregnant women shows considerable diurnal variation and can fluctuate from hour to hour. TIBC rises in association with iron deficiency and decreases in chronic inflammatory states. It is increased in pregnancy because of the increase in plasma volume. In nonanemic patients, TIBC is approximately one-third saturated with iron.

In pregnancy, most reports describe a decrease in both serum iron and percentage saturation of TIBC, which can be largely prevented by iron supplements. Serum iron, even in combination with TIBC, is not a reliable indicator of iron stores, because it fluctuates widely and is affected by recent ingestion of iron and other factors that are not directly involved in iron metabolism, such as infection.

Zinc Protoporphyrin

Zinc protoporphyrin increases when there is a defective iron supply to the developing red cell. Although zinc protoporphyrin may increase in patients with chronic inflammatory disease, malignancy, or infection, the increase usually is not as marked as the increase in ferritin.

Ferritin

Ferritin is a high-molecular-weight glycoprotein that is stable and is not affected by recent ingestion of iron. It appears to reflect iron stores accurately and quantitatively in the absence of inflammation, particularly in the lower range associated with iron deficiency, which is so important in pregnancy. In the development of iron deficiency, a low serum ferritin level is the first abnormal laboratory test result.

Transferrin Receptor

Serum transferrin receptor (TfR) is a relatively new method for assessing cellular iron status.[24] It is present in all cells as a transmembrane protein that binds transferrin-bound iron and transports it to the cell interior. A reduction in the iron supply increases TfR synthesis. Sensitive immunologic techniques show that TfR, like ferritin, circulates in small amounts in the plasma of all individuals, and the concentration is proportional to the total body mass of TfR. In iron-deficiency anemia, the plasma receptor is elevated threefold and the density of surface TfR in iron-deficient cells increases. Little or no change in the serum TfR concentration occurs during the early stages of storage iron depletion, but as soon as tissue iron deficiency is established, the serum TfR concentration increases in direct proportion to the degree of iron deficiency. This change, which precedes the reduction in MCV and the increase in zinc protoporphyrin, is a valuable measurement of early tissue iron deficiency. This measurement is particularly helpful in identifying iron deficiency in pregnancy.[25] It differentiates truly iron-deficient women from those who have a low serum ferritin level as a result of storage iron mobilization or those who have a low hemoglobin concentration as a result of hemodilution. It also helps to distinguish those with a normal or high serum ferritin level as a result of chronic inflammatory disease from those who have low stores that lead to genuine cellular iron deficiency. TfR accurately reflects tissue iron deficiency, both in pregnancy and in anemia of chronic disease, in which serum ferritin may be inappropriately elevated because of release from cells. In combination with serum ferritin, TfR gives a complete picture of iron status. Serum ferritin reflects iron stores (in the absence of chronic inflammatory disease), and TfR reflects tissue iron status.[24]

Marrow Iron

The most rapid and reliable method of assessing iron stores in pregnancy is to examine an appropriately stained preparation of a bone marrow sample. Without iron supplementation, there is no detectable, stainable iron in more than 80% of women at term.[26] No stainable iron (hemosiderin) may be visible once serum ferritin has decreased to less than 40 mg/L,[27,28] but other signs of iron deficiency in developing erythroblasts, particularly late normoblasts, confirm that anemia is caused by iron deficiency in the absence of stainable iron. The effects of folate deficiency, which often accompanies iron deficiency, are also apparent (discussed

later). Iron incorporation into hemoglobin is blocked if there is acute or chronic inflammation, particularly if it is caused by urinary tract infection, even if iron stores are replete. This problem is shown by examination of the marrow aspirate stained for iron and can be predicted by simultaneous assessment of serum ferritin and TfR and an indicator of chronic inflammatory disease, such as C-reactive protein.

With the development of noninvasive tests of iron status (described earlier), bone marrow examination is reserved for the differential diagnosis of severe anemia during pregnancy when the cause cannot be determined by any other means and for the investigation of other hematologic abnormalities that arise de novo during the index pregnancy.

Management Options

Prepregnancy

Iron and folate supplementation should be considered in all women of childbearing age in areas of high prevalence of iron-deficiency anemia.[29,30]

Prenatal

PROPHYLACTIC IRON SUPPLEMENTATION

Iron supplementation is used to prophylactically treat women with low iron stores or those at risk for low iron levels in pregnancy. Women with iron-deficiency anemia are a different group requiring treatment doses of iron (discussed later).

Iron supplementation in pregnancy is controversial. Despite increased iron absorption from the gastrointestinal tract,[31] physiologic iron requirements in pregnancy often are not met by diet alone. In addition, many women enter pregnancy with depleted iron stores. The goal of prophylactic iron administration is to maintain maternal iron stores during the time of increased physiologic iron demand; it may also prevent anemia in infancy.[13] According to the Cochrane Database, routine supplementation with iron or iron and folate does prevent low maternal hemoglobin at delivery, but there is very little information regarding pregnancy outcomes for mother or baby.[32,33] Unfortunately, few good-quality studies of iron and folate supplementation have been carried out in areas where iron and folate deficiency are common and anemia is a significant health problem.

Some studies have suggested that iron supplementation improves maternal iron status and increases neonatal iron reserves, preventing iron deficiency in the first year of life.[34] In pregnant women who did not receive supplementation, iron deficiency persisted many months after delivery.[35,36] Iron supplementation may prevent reduced or absent iron stores after pregnancy and reduce the risk of iron deficiency in subsequent pregnancies.[37]

Iron supplementation has few adverse effects. The dosage is generally low enough to avoid the gastrointestinal side effects seen with treatment doses. Iron supplements may interfere with the absorption of other trace elements, such as zinc.[38] Zinc depletion may be associated with fetal growth restriction.[39] A study of the effects of oral iron supplementation on zinc and magnesium levels during pregnancy concluded that decreases in the concentration of these elements were physiologic and unaffected by iron supplementation.[40]

High maternal hemoglobin concentrations are associated with poor pregnancy outcome.[41,42] This has led to concerns about iron prophylaxis. However, iron supplementation in iron-replete women does not increase the hemoglobin level.[43] In iron-replete pregnancies, the hemoglobin concentration is largely dependent on the increase in plasma volume. Ineffective plasma volume expansion increases the rate of poor pregnancy outcome.

The other concern about iron prophylaxis is that excess iron can result in the production of free radicals and oxidative damage and may be implicated in cardiovascular disease and cancer.[44,45] Concerns about iron overloading in women with hemochromatosis have been raised. Approximately 12% of western white women are heterozygous for the common mutation of the hemochromatosis gene, and 0.5% are homozygous. A study of hemochromatosis and iron stores in pregnancy suggested that heterozygosity for the hemochromatosis mutation did not affect iron storage levels in reproductive-age women. One woman in the study who had markedly reduced iron stores was homozygous for the gene.[46]

Iron supplementation can be given on a selective or routine basis. Selective administration is appropriate for women with low or depleted iron stores, usually based on ferritin levels in early pregnancy. Ferritin cutoff levels for action vary between publications. A serum ferritin level less than 50 µg/L in early pregnancy is an indication for iron supplements. Some groups further stratify the starting time of these supplements, depending on ferritin levels.[47]

This approach avoids unnecessary supplementation in women with adequate iron stores. It identifies those who are at risk for iron depletion and anemia and targets these women with prophylactic or treatment doses of iron. The need for routine iron supplementation is debatable in western countries, but supplementation is recommended in nonindustrialized countries.[48,49] Various official bodies made recommendations for routine iron supplementation. WHO recommends universal oral iron supplementation with 60 mg of elemental iron daily for 6 months in pregnancy in areas where the prevalence of iron deficiency is less than 40%. In areas where the prevalence is greater than 40%, the recommendation is to continue supplementation for 3 months postpartum.[29] The CDC recommends supplementation with 30 mg of elemental iron daily, as does the American College of Obstetricians and Gynecologists.[50,51] Some consider universal supplementation to be a practical and cost-effective approach.[52] The debate is ongoing, and the decision to choose universal or selective prophylaxis depends on the prevalence of iron deficiency in the obstetric population served, along with nutritional, economic, and social factors.

Prevention of iron deficiency also requires education about diet. Dietary iron has two forms, heme and nonheme iron. Heme iron is the most bioavailable form of iron in the diet and comes from food containing heme molecules, essentially animal meat, viscera, and blood. Nonheme iron is obtained from cereals, vegetables, milk, and eggs. Absorption of nonheme iron is enhanced by ascorbic acid, proteins, and heme and inhibited by phytates, tea, coffee, and calcium. Many countries now fortify food products with iron compounds.[53] In nonindustrialized countries, other actions to prevent iron deficiency include iron prophylaxis in nonpregnant women[29] and treatment of hookworm infestation.[54]

Prophylaxis of iron deficiency is generally provided with oral iron. Various iron salts are available in tablet or syrup form (ferrous fumarate, gluconate, sulfate, and succinate). The elemental iron content of the different salts varies slightly. Compound preparations with folic acid are available, as are modified-release preparations, which release iron into the gastrointestinal tract slowly. However, these preparations may carry iron past the first part of the duodenum, where absorption is optimal, to areas of the gut where iron absorption is poor.

The frequency of oral dosing with iron supplementation has been questioned. Intermittent weekly or twice-weekly dosing schedules are as effective as daily dosing schedules.[55–57] In nonindustrialized countries, intermittent intramuscular iron dextran injections are used to ensure compliance and maintenance of adequate iron stores.[58] Compliance is a major problem with iron supplementation and may be as low as 36%.[59] In oral intermittent iron supplementation, compliance may be an even larger issue than with daily dosing schedules.[60] Iron-rich natural mineral water may be an acceptable alternative to oral iron prophylaxis. For example, Spatone Iron-Plus contains ferrous sulfate 0.20 mg/mL, which is highly bioavailable and maintains ferritin levels more effectively than placebo.[61]

MANAGEMENT OF IRON DEFICIENCY

Iron-deficiency anemia is usually treated with oral iron preparations. The oral dose of elemental iron required to treat iron deficiency is 100 to 200 mg daily. Ferrous sulfate 200 mg three times daily is equivalent to 195 mg of elemental iron daily. Many iron preparations are available, and no scientific evidence suggests that one brand is superior. Treatment doses of iron should continue until hemoglobin normalizes and should be followed with prophylactic or maintenance doses until 3 months postpartum to ensure that iron stores are replenished. Side effects with oral iron are common. Iron salts cause gastrointestinal irritation, with dose-related nausea and epigastric discomfort. Altered bowel habits (constipation or diarrhea) and abdominal cramping are common and have a less clear dose relationship. If side effects occur, reducing the dose or taking the tablets before meals (absorption can be reduced up to 50% if the dose is taken with meals) may help. Alternative iron salts can be tried, but tolerance is often related to reducing the dose of elemental iron. The addition of laxatives should overcome problems with constipation. The response to treatment doses of elemental iron is rapid. Reticulocyte counts increase within 5 to 10 days of initiation, and hemoglobin should rise 0.8 g/dL/wk (1.0 g/dL/wk in nonpregnant women). If no clinical or hematologic response is seen after 3 to 4 weeks of oral iron therapy, diagnostic reevaluation is required. Patients who do not respond to oral iron should be evaluated for ongoing blood loss, concomitant infection, additional hematinic deficiency, noncompliance, and other causes of anemia.

Parenteral iron therapy can be administered intravenously as an infusion or injection and also intramuscularly. It has no advantage over oral therapy if oral iron is well tolerated and absorbed. The response rate to parenteral iron is similar to that with oral preparations.[62] The advantage of parenteral therapy over oral therapy is the certainty of its administration.[63] Parenteral iron is given when oral iron therapy is unsuccessful because of patient intolerance, noncompliance, or malabsorption. Parenteral forms of iron include iron dextran, iron sucrose, and ferric carboxymaltose. Iron dextran is a complex of ferric hydroxide that contains 50 mg/mL of iron and can be given intravenously. Dosage is calculated according to body weight and iron deficit. A small test dose is given, and the patient is observed for 1 hour for evidence of anaphylaxis. If the test dose is tolerated, the total dose can be administered in a 0.9% sodium chloride infusion over several hours. The product is licensed in the United Kingdom in the second and third trimesters but contraindicated in patients with a history of allergy. Anaphylactic reactions have been reported, and facilities for cardiopulmonary resuscitation must be available when these drugs are administered. Patients require close monitoring during and after administration, and treatment should be given in a hospital setting.

Iron dextran is available by deep intramuscular injections. Total dosage is calculated according to body weight and iron deficit. It is administered as a series of undiluted injections of up to 100 mg of iron each. As with the intravenous preparation, anaphylactic emergency treatment should be available.

Preparations of iron sucrose complex contain 20 mg/mL of iron and are used in pregnancy as 5- to 10-mL aliquots up to three times per week in the second and third trimesters.[64]

Ferric carboxymaltose is a new compound that is now available, although there are little human data on pregnancy effects. It does not require a test dose to be administered and can be given by bolus intravenous injection or a fast intravenous infusion.[65]

Blood transfusions are rarely indicated in pregnant women with iron-deficiency anemia. With vigilant antenatal care and appropriate iron prophylaxis and treatment, severe anemia should not be detected late in pregnancy. If a woman has severe anemia beyond 36 weeks' gestation and there is not time to achieve a reasonable hemoglobin concentration before delivery, blood transfusion should be considered.

Recombinant human erythropoietin has also been used in difficult cases. Most experience has been with Jehovah's Witnesses. It does not cross the placenta but carries a risk of hypertension and thrombosis. Its role in pregnancy is not well established. Trials have shown that in combination with intravenous iron, hemoglobin rose more quickly than with parenteral iron alone; however, parenteral iron alone should be the first-line treatment in resistant iron-deficiency anemia.[66]

Treatment of iron-deficiency anemia in pregnancy was the subject of a Cochrane review.[67] Only 17 trials met the inclusion criteria. The reviewers concluded that there was a paucity of good trials assessing the maternal and neonatal effects of iron administration in women with anemia and that large-scale, good-quality trials assessing clinical outcomes and adverse effects are required.

Labor and Delivery

There are no specific recommendations for the management of iron-deficient patients during labor. Cross-matching should be carried out for women who are anemic on admission for labor. Blood transfusion may be necessary if

significant blood loss occurs, because these women have little reserve to tolerate bleeding.

Postnatal

As the physiologic effects of pregnancy diminish, hemoglobin levels rise during the puerperium. There is no consensus on the management of severe postpartum anemia. Treatment is usually with either oral supplementation or blood transfusion. The Cochrane review of treatments for women with postpartum anemia concludes that there is some limited evidence of favorable outcomes for the treatment of postpartum anemia with erythropoietin.[68] However, most of the data focus on laboratory hematologic indices rather than clinical outcomes, and further trials are required to assess the treatment of postpartum anemia with blood transfusions and both oral and parenteral iron supplementation.[68] Any women who have clear evidence of iron-deficiency anemia should continue oral supplementation for at least 3 months.

ANEMIA: FOLATE DEFICIENCY

Folic acid, together with iron, has assumed a central role in the nutrition of pregnancy. At a cellular level, folic acid is reduced first to dihydrofolate and then to tetrahydrofolate, which is fundamental to cell growth and division.

Maternal Risks

Megaloblastic anemia in pregnancy is nearly always secondary to folate deficiency. Plasma folate levels decrease as pregnancy advances, reaching approximately half of nonpregnant values at term.[22] Explanations for the reduction in folate levels include reduced dietary folate intake because of loss of appetite,[69] increased plasma clearance of folate by the kidneys (believed to play a minor role),[70,71] transfer of folate from the mother to the fetus (~800 μg at term), and uterine hypertrophy and expanded red cell mass. As pregnancy proceeds, increased folate catabolites are excreted in maternal urine.[72]

Worldwide, folic acid deficiency may complicate one third of pregnancies. The incidence is higher in multiple pregnancies and closely spaced successive gestations.[73] Folate is readily available in most diets. Good sources include broccoli, Brussel sprouts, and spinach. Folate is often lost in the cooking process. It is heat-labile and rapidly destroyed by boiling or steaming.

Body stores of folate are found predominantly in the liver and total approximately 10 mg. Folate stores last approximately 4 to 5 months before symptomatic anemia develops. A survey of reports from the United Kingdom suggests that the incidence of folate deficiency is 0.2% to 5.0%, but more women have megaloblastic changes in their bone marrow that are not suspected based on examination of peripheral blood alone.[74] The incidence of megaloblastic anemia in other parts of the world is considerably greater and is believed to reflect the nutritional standards of the population. Current WHO recommendations advise folic acid intake of 400 μg daily with 60 mg of iron for 6 months during pregnancy and continuing for 3 months postpartum in areas of the world with poor nutrition.[29]

The maternal risk of folate deficiency appears to be megaloblastic anemia. This condition usually has an insidious onset, with gradually progressive symptoms and signs of anemia. It can be abolished with routine use of folic acid supplements during pregnancy.[75]

Fetal Risks

The risk of megaloblastic anemia is increased in the neonate of a folate-deficient mother, especially if delivery is preterm. Data also suggest an association between periconceptional folic acid deficiency and cleft lip and palate and, most important, neural tube defects.[76–82] Folate supplementation has been shown to reduce the incidence of neural tube defects.[78] It is not known how folate supplements reduce the incidence of neural tube defects.

Diagnosis

Outside of pregnancy, the hallmark of megaloblastic hemopoiesis is macrocytosis. This can be more difficult to interpret in pregnancy when there is a physiologic increase in red cell size and the possibility of masking iron-deficiency anemia. Examination of the blood film with oval macrocytes and hypersegmented neutrophil nuclei can provide useful diagnostic clues. The reticulocyte count is also low in relation to the hemoglobin. To diagnose folate deficiency, red cell folate assay is performed. Plasma folate levels fluctuate substantially from day to day, and postprandial increases are noted, limiting the use of serum folate as a diagnostic test. Red cell folate is believed to give a better indication of overall body tissue levels. However, the turnover of red blood cells is slow, and there is a delay before significant reductions in the folate concentration of red cells is evident. Patients who have a low red cell folate concentration at the beginning of pregnancy have megaloblastic anemia in the third trimester.[22] Folate deficiency in pregnancy is not always accompanied by significant hematologic changes. In the absence of changes, megaloblastic hemopoiesis is suspected when the expected response to adequate iron therapy is not achieved. Ultimately, the diagnosis of folate deficiency may depend on bone marrow examination and the finding of large erythroblasts and giant, abnormally shaped metamyelocytes. This test is usually reserved for patients with pancytopenia rather than isolated anemia.

Management Options

Prepregnancy

As with other anemias, a careful diagnostic evaluation should be undertaken, followed by prompt therapy before conception. The risks (described in earlier and later sections) should be discussed before pregnancy, and dietary advice about folate-rich foods should be given. Women who are contemplating pregnancy should be advised to take folate supplements of 400 μg daily.[29,83–85] In the United States, the Food and Drug Administration has made folic acid food fortification mandatory since 1998. All enriched flour, pasta, rice, and grain products contain 140 μg of folic acid per 100 g. Targeted fortification of food is under consideration in the United Kingdom.

Prenatal

PROPHYLAXIS

The case for giving prophylactic folate supplementation throughout pregnancy is relatively strong,[86,87] particularly in countries where nutritional and megaloblastic anemia is common. A systematic review of folic acid supplementation showed that hemoglobin levels were improved with supplementation, but there was insufficient evidence to evaluate other clinical outcomes for the mother or baby.[88] Folate should be given in combination with iron supplements. The folic acid content must be approximately 200 to 300 μg daily. The concern about routine folate supplementation is the risk to a woman with undiagnosed vitamin B_{12} deficiency. Folate treatment can worsen neuropathy in patients with vitamin B_{12} deficiency. The risk is low in pregnancy, and patients with severe vitamin B_{12} deficiency are usually infertile. Pernicious anemia is generally a disease of older people. Not one case of subacute combined degeneration of the spinal cord was reported among the thousands of women receiving folate supplements during pregnancy.[22] Folate deficiency is also an independent risk factor for thrombosis.

MANAGEMENT OF ESTABLISHED FOLATE DEFICIENCY

Severe megaloblastic anemia is uncommon in the United Kingdom and the United States, largely as a result of prophylaxis and prompt treatment. Once megaloblastic hematopoiesis is established, treatment of folic acid deficiency is more difficult, presumably as a result of megaloblastic changes in the gastrointestinal tract that impair absorption. If the diagnosis is made prenatally, initial treatment is with folic acid, 5 mg once daily, continued for several weeks postpartum.

ANTICONVULSANTS AND FOLIC ACID

Outside of pregnancy, folate deficiency can develop in patients who take anticonvulsants. Folate status is further compromised in pregnancy.[86] Interference with epilepsy control by folate supplementation may be overestimated.[89] Anticonvulsant therapy is associated with an increased incidence of congenital abnormalities,[90] prematurity, and low birth weight.[91] Hence, folate supplements should be given to all pregnant epileptic women who take anticonvulsants.

DISORDERS THAT MAY AFFECT FOLATE REQUIREMENTS

Women with hemolytic anemia, particularly hereditary hemolytic conditions, such as hemoglobinopathy and red cell membrane and enzyme disorders, require extra folate supplements from early pregnancy. The recommended supplementation is 5 to 10 mg orally daily. Anemia as a result of thalassemia trait is caused by ineffective erythropoiesis. However, the increased abortive marrow turnover results in folate depletion, and these women probably benefit from routine administration of folic acid, 5.0 mg orally daily, from early pregnancy.

Labor and Delivery

There are no specific management recommendations for folate-associated anemia during labor and delivery, as long as the patient is hemodynamically stable and blood replacement therapy is available, if needed.

Postnatal

In the 6 weeks after delivery, indices of folate metabolism return to nonpregnant values. However, if folate deficiency develops and remains untreated in pregnancy, it may be seen clinically for the first time in the puerperium. Lactation provides an added folate stress. A folate content of 5 μg/100 mL in human milk and a yield of 500 mL daily implies a loss of 25 μg of folate daily in breast milk.[92] Red cell folate levels in lactating women are significantly lower than those in infants during the first year of life.

SUMMARY OF MANAGEMENT OPTIONS

Iron and Folate Deficiency Anemia

Management Options	Evidence Quality and Recommendation	References
At Any Time		
Studies if hemoglobin < 10.5 g/dL (opinions vary; range 10.0–11.0 g/dL):	—/GPP	—
• Complete blood count.		
• Blood film.		
• Red cell indices.		
• Reticulocyte count.		
• Iron status (e.g., ferritin).		
• Red cell folate.		
• Serum vitamin B_{12}.		
• Other studies as indicated by clinical findings and laboratory results.		

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Provide dietary advice and iron therapy to ensure satisfactory hemoglobin status before pregnancy.	—/GPP	—
Institute public health measures to prevent periconceptual folate deficiency.	Ia/A	82
Use of folic acid periconceptually reduces the risk of neural tube defects.	Ia/A	78
Prenatal		
Prophylactic use of iron or folate is controversial in industrialized countries, but important for pregnant women in developing countries to maintain or increase predelivery hemoglobin levels.	Ia/A	32,33
When iron or folate is prescribed, selective use is better than routine use if women can have their hemoglobin status assessed and followed up reliably.	Ia/A	32,33
Oral iron preparations are preferred; different compounds are used to minimize side effects.	—/GPP	—
Side effects related to dose and weekly oral iron administration may be an alternative to improve compliance without losing efficacy.	Ib/A	56,57
Give parenteral iron therapy if oral iron treatment is unsuccessful because of noncompliance, poor follow-up, or poor absorption.	IIa/B	63
Consider blood transfusion in patients with severe symptomatic anemia close to delivery.	—/GPP	—
Provide folate prophylaxis with anticonvulsants.	—/GPP	—
Continue routine oral folate therapy in cases of autoimmune hemolytic anemia.	—/GPP	—
Give parenteral folate therapy if deficiency is severe.	—/GPP	—
Labor and Delivery		
Cross-match blood if anemia is severe.	—/GPP	—
Postnatal		
Continue iron therapy for patients with iron deficiency.	—/GPP	—

GPP, good practice point.

ANEMIA: VITAMIN B$_{12}$ DEFICIENCY

Muscle, red cell, and serum vitamin B$_{12}$ concentrations decrease during pregnancy.[93,94] Women who smoke tend to have lower serum vitamin B$_{12}$ levels, which may account for the positive correlation between birth weight and serum levels in women without deficiency.

Maternal and Fetal Risks

Vitamin B$_{12}$ absorption is unaltered in pregnancy,[95] but tissue uptake is increased under the influence of estrogens. Oral contraceptives also cause a decrease in serum vitamin B$_{12}$ levels. This decrease in pregnancy is related to preferential transfer of absorbed vitamin B$_{12}$ to the fetus at the expense of maintaining maternal serum concentration. The vitamin B$_{12}$-binding capacity of plasma increases in pregnancy because of the increased levels of transcobalamin II, which is derived from the liver and affects vitamin B$_{12}$ transport.

Cord blood serum vitamin B$_{12}$ levels are higher than maternal vitamin B$_{12}$ levels. Pregnancy does not greatly affect maternal vitamin B$_{12}$ stores. Adult stores are 3000 μg or more, and stores in newborns are approximately 50 μg. Minimal amounts of vitamin B$_{12}$ are required for fetal development, which may account for the few fetal problems seen in pregnancies complicated by vitamin B$_{12}$ deficiency. A deficiency syndrome is described in breast-fed neonates of mothers with significant vitamin B$_{12}$ deficiency. It is usually apparent by 6 months of age and is characterized by failure to thrive, developmental regression, and anemia.[96] Addisonian pernicious anemia is unusual during the reproductive years and is usually associated with infertility. Pregnancy is likely only if the deficiency is corrected.

Dietary deficiency of vitamin B$_{12}$ is possible in strict vegans who consume no animal products. Other disorders associated with vitamin B$_{12}$ deficiency include tropical and nontropical sprue, Crohn's disease, and surgical resection of the distal ileum.

Management Options

Prepregnancy

Women with vitamin B_{12} deficiency should have their therapy optimized and their anemia corrected before they become pregnant. This approach may be needed to restore fertility.

Prenatal

The recommended intake of vitamin B_{12} is 2.6 μg daily during pregnancy.[97] This intake is met by almost any diet that contains animal products. Strict vegans, who do not eat any animal-derived substances, may have a deficient intake of vitamin B_{12}, and this type of diet should be supplemented in pregnancy.

Difficulties can arise when interpreting vitamin B_{12} levels measured in pregnancy because many women have lower values than those quoted as the normal range outside of pregnancy.[98] This decline in vitamin B_{12} levels is not believed to represent a true deficiency.[99] Levels return to normal in the puerperium. Care must be taken in the interpretation of vitamin B_{12} levels in pregnancy. If deficiency is suspected, the etiology should be considered. Intrinsic factor antibodies may be useful if the results are positive. Therapy is instituted empirically if there is clinical concern, especially if neurologic findings are consistent with vitamin B_{12} deficiency. The earliest symptoms are numbness and paresthesia of the fingers and toes, followed by weakness, ataxia, and poor concentration. Patients may have changes in mental status. Treatment of vitamin B_{12} deficiency is generally parenteral because patients usually have absorptive problems. Cyanocobalamin or hydroxycobalamin 1 mg is given three times a week for 2 weeks, and then every 3 months. In patients who have neurologic involvement, the dosage is higher. These patients are given 1 mg on alternate days until no further improvement is noted, and then 1 mg every 2 months. Oral vitamin B_{12} can be used in patients with dietary deficiency.

Labor and Delivery and Postnatal

There are no specific measures for patients with genuine vitamin B_{12} deficiency, apart from continuing maintenance therapy.

SUMMARY OF MANAGEMENT OPTIONS
Vitamin B_{12} Deficiency

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Deficiency is rare.	—/GPP	—
Prenatal		
Continue treatment if it was instituted before conception.	—/GPP	—
Consider oral supplementation and other components for strict vegans and women with diets deficient in animal protein.	—/GPP	—
Consider checking intrinsic factor antibodies if the diet is adequate.	—/GPP	—
Labor and Delivery		
Continue treatment if already instituted.	—/GPP	—
Postnatal		
Continue treatment if already instituted; if the patient is not receiving treatment, check vitamin B_{12} levels postpartum.	—/GPP	—

HEMOGLOBINOPATHIES

Hemoglobinopathies are inherited disorders of hemoglobin. Hemoglobin is composed of heme (a combination of iron and porphyrin) and four globin chains. The type of globin chain determines many of the characteristics of the hemoglobin. Several types of globin chains are present at different times in embryonic development, in fetal life, and through to adulthood (Fig. 38–1 and Table 38–1). Abnormalities of the quantity or quality of the globin chains produced result in conditions known as hemoglobinopathies.

Hemoglobinopathies can be divided into two subgroups:
- Sickling disorders, which are qualitative abnormalities— an amino acid substitution in an α globin or β globin chain results in the synthesis of an abnormal hemoglobin. Many types of hemoglobin can sickle.
- Thalassemia syndromes are usually quantitative problems of globin chain synthesis. They result in impaired production and imbalance of globin chains. α-Thalassemia is caused by reduced α-chain production, and β-thalassemia is caused by reduced or abnormal β chain production.

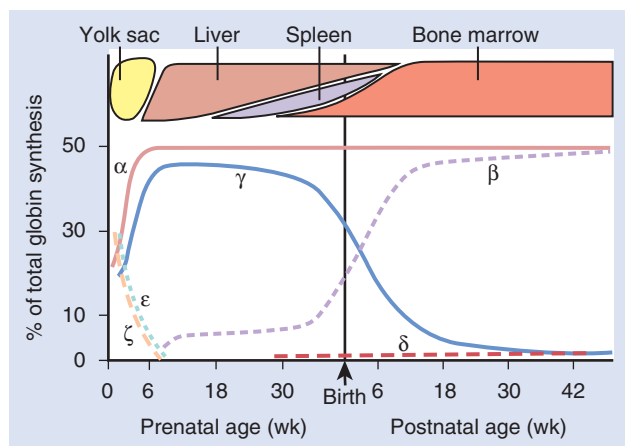
Production of different globin chains. (From Hoffbrand AV, Pettit J (eds): Genetic defects of haemoglobin. In: Essential Haematology, 3rd ed. Oxford, Blackwell, 1993, p 95.)


TABLE 38–1

Composition of Adult Hemoglobin

Structure	$\alpha_2\beta_2$	$\alpha_2\gamma_2$	$\alpha_2\delta_2$
Normal (%)	97–99	0.5–0.8	1.5–3.7

Women with major sickling and thalassemic conditions require specialized multidisciplinary team management preconception and throughout pregnancy.

Neonates with major sickling and thalassemic conditions require early identification and appropriate referral for specialized management, and this necessitates genetic screening to identify at-risk couples.

Screening for Hemoglobin Disorders[100]

Timely antenatal screening programs identify women and their partners who are carriers of these conditions and couples who are at risk for having an infant affected with a major hemoglobinopathy. This allows informed decisions regarding reproduction and prenatal diagnosis. Detection of major hemoglobinopathies leads to early identification of affected infants with improvements in care and survival.

In sickle cell disease, the first 5 years of life carries a high morbidity and mortality. Protective levels of hemoglobin F have declined by 6 months, and pneumococcal septicemia and acute splenic sequestration pose significant risks. Identification of these infants and targeted antibiotic prophylaxis, pneumococcal vaccination, and education programs have significantly improved survival. Identifying infants at risk of β-thalassemia major ensures timely further investigation and appropriate care for transfusion-dependent anemia.

In the United Kingdom, the National Health Service Sickle and Thalassemia Screening Program is a linked antenatal and neonatal program. Antenatal screening for hemoglobinopathies is universal in high-prevalence areas but selective in low-prevalence areas, depending on ethnicity and red cell indices.

The chance of being a carrier is dependent on ancestry. Tables are available that show the prevalence of traits in different countries and ethnic groups.[101]

Neonatal screening uses blood from the heelprick Guthrie card samples. All births in England are screened. Regional laboratories use high performance liquid chromatography as first-line screening for hemoglobin disorders and isoelectric focusing for confirmation of abnormalities. The Guthrie card hemoglobinopathy results are available to Child Health professionals, allowing appropriate early referrals of children requiring follow-up.

Sickle Cell Syndromes

More than 300 abnormal (variant) hemoglobins are recognized. Sickle cell disease caused by homozygosity of hemoglobin S (i.e., HbSS) is the most common sickling disorder. It is caused by a point mutation in the β globin gene on chromosome 11 that produces an amino acid change at position 6, changing valine to glutamic acid. This enhances the polymerization of hemoglobin S in the deoxygenated state and causes increased red cell rigidity and sickling. Chronic intravascular and extravascular hemolysis is a hallmark of sickle cell disease with significantly reduced red cell survival from 120 days to approximately 20 days. This results in intravascular nitric oxide depletion, endothelial activation, and vasoconstriction. Increased blood viscosity and tissue hypoxia occur as sickled cells occlude the microcirculation. Clinical consequences of sickling include

- Vaso-occlusive crises (micro- and macroinfarcts, leading to a painful crisis and organ damage).
- Anemic crises as a result of severe hemolysis, red cell aplasia, or splenic sequestration.
- Chest and girdle syndrome.
- Neurologic events.

Maternal and Fetal Risks

Sickling occurs in the homozygous condition (HbSS) or in compound heterozygous states (e.g., HbSC or HbS β-thalassemia, HbSD-Punjab, HbSE, HbSLepore, HbSO-Arab). Hemoglobin C, D-Punjab, E, and O-Arab are variant hemoglobins with mutations in the B globin gene. Hemoglobin Lepore is a variant hemoglobin that behaves like β-thalassemia.

The heterozygous state, or sickle cell trait (HbAS), is essentially a benign condition believed to have no particular antenatal sequelae. However, women with sickle cell trait are slightly more prone to renal papillary necrosis and urinary tract infection.[102] Their hemoglobin levels are similar to those of other pregnant women and should be managed similarly. Their sickle cell trait should be noted on their records, and the anesthesiologist should be informed of this condition if a general anesthetic is required. A study showed an increased incidence of preeclampsia in women with sickle cell trait.[103] Women with sickle cell trait should be identified by antenatal hemoglobinopathy screening. If the partner of a woman with sickle cell trait also carries the trait, there is a one in four chance that the offspring will be

affected by homozygous sickle cell disease. These couples require counseling and the opportunity for antenatal diagnosis.

Pediatricians must be alerted to the possibility of sickle cell disease in neonates because antipneumococcal vaccines can now be given from 2 months of age and infants with sickle cell disease require long-term prophylactic penicillin treatment and regular evaluation.

People with major sickling disorders start life relatively protected from crises for 3 to 6 months because of the ongoing production of fetal hemoglobin. When hemoglobin A production becomes predominant, chronic hemolytic anemia develops. The severity and complications of the disease vary widely between patients. Many have debilitating chronic disease and frequent crises that require hospital admission. Others appear to be free of complications but have progressive organ damage. The life expectancy of these patients is still 25 to 30 years less than that of the general population, even in the developed world, with access to medical care.[104]

There are increased risks in pregnancy for the mother with sickle cell disease and her fetus.[105] The risks are not so great as to prohibit pregnancy. Maternal mortality is increased but has significantly improved since the early 1980s. Mortality rates of 30% to 40% are reported before the 1970s but have reduced to 1% to 2% in the United States and Europe.[105]

Recognition of this at-risk group along with improvements in medical management, transfusion, and neonatal care has significantly reduced morbidity and mortality.[105] Maternal risks include exacerbated sickle cell disease phenomena,[106] such as anemia, vaso-occlusion, ischemic injury, and organ damage as a result of the physiologic stress of pregnancy. These patients have greater susceptibility to infection (chest and urinary tract), hypertensive disorders of pregnancy, and thromboembolic complications.

Risks to the fetus include increased frequency of miscarriage, intrauterine growth restriction, preterm labor, and preterm birth.[107,108] Perinatal morbidity and mortality rates vary widely in different regions of the world[109–111] but are higher than in the general population. Perinatal mortality rates of 50% to 80% are reported before the 1970s, but more recent studies report rates of 1% to 8% in the United States and Europe.[105]

Diagnosis and Management Options
PREPREGNANCY

Before an affected woman becomes pregnant, a number of issues should be addressed.

Sickle Cell Disease

The frequency and management of crises outside of pregnancy is a useful starting point and may indicate the likelihood of crises throughout pregnancy. The patient's transfusion history and red cell antibody values should be documented. Hydroxyurea should be discontinued 3 months prior to conception in both men and women who are planning to conceive because it is teratogenic in animal models. Although there is little information about its effect on the human fetus, there are case reports in which hydroxyurea

was taken throughout pregnancy with no reported adverse fetal effects.[112,113] Hydroxyurea is a disease-modifying drug that increases hemoglobin F, improves red cell hydration, and decreases the rate of polymerization of hemoglobin S. Its use decreases the frequency of crises.[114]

Contraception

Pregnancy planning is useful in women who have a chronic debilitating disease. No contraceptive choices are absolutely contraindicated on the grounds of sickle cell disease. Based on the theoretical risks of thromboembolism, sickle cell disease is listed as a relative contraindication for some combined oral contraceptives. The risks of pregnancy outweigh those of contraception.

Maternal and Fetal Complications

Past obstetric history is important, including a discussion of maternal and fetal risks associated with sickle cell disease. Patients should be told that active prenatal management significantly affects pregnancy outcome, and the importance of attending visits should be emphasized.

Multidisciplinary Team Approach

The community sickle cell service and midwifery team, along with hospital obstetric, hematology, anesthetic, and pediatric teams, plays an important role in the care of the pregnant woman and fetus.

Partner's Hemoglobinopathy Status

It is important to establish the partner's hemoglobinopathy status, ideally, before pregnancy. This information facilitates appropriate, timely, and nondirective counseling about antenatal diagnosis.

PRENATAL

These women should be seen early in pregnancy. Ideally, they should be seen by an obstetrician and hematologist with experience in this area. Partner screening should be carried out if it has not been done. A discussion about prenatal diagnosis should take place, if appropriate, and time should be taken to review the patient's obstetric history and history of sickle cell disease, including a drug history and the typical management of crises.

Laboratory evaluation should include a complete blood count, hemoglobin electrophoresis (if not previously done or available), reticulocyte count, ferritin level, folate level, urea and electrolyte levels, liver function tests, blood typing, and red cell antibody screen. The red cell antibody screen serves two purposes: (1) to identify women whose fetuses and newborns may be at risk of hemolysis because of red cell antibodies and (2) to ensure screening for the most common minor red cell antigens so that phenotypically matched blood will be available for transfusion. This is especially important because the donor population differs in ethnic origin, carries different minor cell antigens, and may sensitize this group of patients. As a result, it may be difficult to obtain suitable blood for transfusion. Blood tests should be performed to determine hepatitis A, B, and C, HIV, and rubella antibody status. Urine dipstick and culture allow identification and treatment of women with asymptomatic bacteruria. This group is more susceptible to urinary tract infections.

People with homozygous sickle cell disease may have a hemoglobin concentration of 5 to 12 g/dL, but concentrations are typically 6 to 10 g/dL. Hemoglobin S has a lower affinity for oxygen. Symptoms of anemia are decreased by the increased delivery of oxygen to the tissues. The reticulocyte count is elevated, reflecting increased red cell turnover. The bilirubin level also indicates the rate of hemolysis. Other abnormal liver function test results may indicate cholelithiasis or acute cholecystitis as a result of chronic hemolysis or chronic hepatitis.

Pregnancy outcome appears to be similar in women who undergo prophylactic transfusion compared with those who undergo selective transfusion for clinical reasons.[115] No improvement in obstetric outcome was seen in a retrospective multicenter study in the United Kingdom.[116]

There is debate about the use of blood transfusions throughout pregnancy. Prophylactic versus selective blood transfusions was the subject of a Cochrane review.[117] This review found that there was not enough evidence to reach conclusions about the use of prophylactic blood transfusions. The development of atypical red cell antibodies is a real concern.[118] Transfusion is generally given before anesthesia or as an exchange procedure in severe crises, but no data suggest that transfusions should be given prophylactically.

Red cell indices in patients with sickle cell disease alone should be normal, but low MCV and mean corpuscular hemoglobin (MCH) may indicate iron deficiency or an associated thalassemia trait. The blood film shows variable numbers of sickle cells and features of hyposplenism (Howell-Jolly bodies, target cells, and increased platelet and white cell counts). Hemoglobin electrophoresis and high-performance liquid chromatography can separate out the various hemoglobins and allow detection and characterization of variant hemoglobins. In homozygous sickle cell disease, hemoglobins S, F, and A_2 are seen. Hemoglobin S is usually the predominant hemoglobin, making up 90% to 95% of total hemoglobin. Hemoglobin A is absent. In compound heterozygous states, other hemoglobins are found, except in hemoglobin S β-thalassemia, in which the hemoglobin S level is lower than that in homozygotes.

A sickle solubility test is a quick screening test for sickling hemoglobin, but it does not elucidate the type or quantity of sickling hemoglobin. It does not distinguish between homozygous sickle cell disease and a person with sickle cell trait.

The antenatal care plan should be outlined, with a discussion of the risks for both mother and fetus and strategies to reduce these risks. The patient should be advised to avoid precipitating factors that may cause sickle crises, including education about the signs and symptoms of infection and appropriate analgesics.

Return visits should be scheduled every 2 to 3 weeks to allow early detection of maternal or fetal complications. These visits monitor the course of the pregnancy, with regular monitoring of blood pressure, and assessment of fetal growth and development at appropriate intervals. Patients with sickle cell disease also should be asked about pain and crises and should undergo laboratory assessment, including complete blood counts, reticulocyte counts, and bilirubin measurements.

COMPLICATIONS OF SICKLE CELL DISEASE

Vaso-occlusive or Painful Crisis[119,120]

Crises occur when rigid sickle cells obstruct blood vessels in the microvasculature. This obstruction leads to tissue hypoxia, infarction, and pain. It is the most common type of crisis and the reason for most hospital admissions. Factors that may precipitate or exacerbate a crisis include cold, infection, dehydration, exercise, and stress. The pain is usually bony, although it may occur in the chest or abdomen. Systemic markers include low-grade fever, tachycardia, and mild leukocytosis.

As a result of sickling in the splenic circulation, most patients become hyposplenic at a young age, increasing their susceptibility to encapsulated organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. This is the rationale for pneumococcal, *H. influenzae* B, and meningococcal vaccination and prophylactic penicillin administration.

Treatment and evaluation are as for nonpregnant women. Most pain occurs in the third trimester and the postpartum period. Underlying precipitants of pain, such as infection and toxemia, should be sought. The management hinges on good rehydration, with careful fluid balance and adequate analgesia. The pain normally requires opioid analgesia as an infusion or patient-controlled analgesia. Nonsteroidal anti-inflammatory drugs are a useful adjunct but should be avoided in the second half of pregnancy because of the risk of patent ductus arteriosus. Oxygen supplementation and intravenous antibiotics covering encapsulated organisms may be required. If intravenous antibiotics are not required, penicillin prophylaxis should be ongoing. Folic acid supplementation (5 mg daily) also should be ongoing. The patient should be kept warm. All of the relevant teams should be involved, including obstetricians, hematologists, and obstetric anesthesiologists. In women who have frequent sickling crises and heavy narcotic use, fetal growth must be monitored carefully because of the risk of intrauterine growth retardation. Pediatricians must be made aware of the risk of opiate dependence in the newborn and the need for opiate tapering. On admission, the patient should have a complete blood count, reticulocyte count, biochemistry testing, blood typing, blood cultures, arterial gases, and/or pulse oximetry. Potential sites of infection require culturing (e.g., throat swab, midstream urine, sputum, blood). Hemoglobin requires regular monitoring. Transfusion is generally given if hemoglobin is less than 5 g/dL. Review is required at regular intervals to assess the response to pain relief and look for evidence of infection, girdle or chest syndrome, splenic or hepatic sequestration, and complications of pregnancy, such as preeclampsia.

Acute Anemia

When a precipitate decrease in hemoglobin occurs, the differential diagnosis includes blood loss, bone marrow suppression secondary to infection, hyperhemolysis, and sequestration. Careful examination and basic blood tests are useful in determining the cause. A reticulocyte count will determine whether the bone marrow is responding appropriately to the anemia. If the count is low or absent, parvovirus B19 infection should be considered. This infection causes red cell aplasia, and transfusion is required. It can also cause miscarriage or hydrops, so careful fetal monitoring is required.

Prompt transfusion in splenic sequestration can be life-saving when the decrease in hemoglobin is precipitous and hazardous for the mother and fetus. Patients have acute abdominal pain, with rapid enlargement of the spleen. This situation is rare because most patients with homozygous sickle cell disease are hyposplenic. Approximately 5% have splenomegaly, but it is more common in compound heterozygote sickling states, such as HbSC and HbS β⁻ thalassemia.

Acute Chest Syndrome[121]

Acute chest syndrome is a form of acute lung injury that is distinct from pneumonia. It is believed to be caused by fat emboli from the bone marrow along with red cell sequestration. It does not resolve with antibiotics but may become secondarily infected. It usually causes clinical or radiologic evidence of consolidation, with elevated temperature, cough, and pleuritic chest pain. Hypoxemia, which may be severe, and leukocytosis are also features. Treatment is the same as for a crisis, as discussed earlier, with early recourse to top-up or exchange transfusion, depending on the baseline hemoglobin. Oxygen saturation and blood gas values must be monitored carefully, and antibiotics and bronchodilators are useful. An intensive care setting is often the best place to monitor these patients.

Neurologic Events

Neurologic events are common in patients with sickle cell disease. Thrombotic cerebrovascular accidents and seizures are the main concern. The differential diagnosis (including metabolic disturbances, toxemia, subarachnoid or intracerebral hemorrhage, ischemic stroke, cerebral venous thrombosis, meningitis, cerebral abscess, epilepsy, or tumor) must be considered, and studies may include neuroimaging, examination of the cerebrospinal fluid if fever is present, and assessment for toxemia. Sickle-related central nervous system events should be treated with exchange transfusion to reduce the sickle hemoglobin percentage to less than 30%. This value should be maintained by transfusions to keep hemoglobin levels between 10 and 11 g/dL.

LABOR AND DELIVERY

Close supervision is required during labor. The risk of sickle cell crisis in labor increases if the woman is dehydrated or has hypoxia, acidosis, or infection. Care should be taken to prevent these complications.

Labor is also a time of increased cardiac output, exacerbated by the pain of uterine contractions. Cardiac function may be reduced by chronic hypoxemia and long-standing anemia. Pain relief is important in reducing cardiac work, and epidural is particularly effective.[122] Prolonged labor should be avoided. The woman should be kept warm, well-hydrated, and oxygenated. Continuous intrapartum monitoring should take place. The timing and mode of delivery must be determined by obstetric factors. Transfusion is considered if the hemoglobin is less than 8 g/dL.[123]

Thromboprophylaxis is given to women who are immobilized or experiencing a sickle crisis at the time of delivery. Routine thromboprophylaxis for women with sickle cell disease is controversial. There are no randomized, controlled trials, and efficacy has not been conclusively shown. Patients who have cesarean delivery should have chest physiotherapy, and early mobilization is encouraged.

Cord blood can be sent to the laboratory for hemoglobinopathy screening. Those who interpret the results must be aware of the possibility of maternal contamination. Universal neonatal screening for sickle cell disorders has been introduced in England as part of the newborn blood spot test.

POSTPARTUM

The heightened risks of sickle crisis persist after delivery. Adequate oxygenation and hydration need to be ensured. Patients must be monitored for infection and crises, and thromboprophylaxis may be considered, depending on the degree of mobility and individual risk assessment. Contraception can be discussed at this time (discussed earlier).

The results of neonatal screening and follow-up arrangements with the pediatrician should be confirmed before discharge.

SUMMARY OF MANAGEMENT OPTIONS
Sickle Cell Syndromes

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Counsel against conception until disease status is optimized; assess renal and liver function.	—/GPP	—
Counsel about the risks of pregnancy.	—/GPP	—
Screen partner; if the result is positive, counsel about prenatal diagnosis.	Ia/A	100
Review medication—ensure on folic acid supplements, stop hydroxycarbamide 3 mo prior to conception.	—/GPP	—

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Early booking appointment with planned schedule of care between obstetrician and hematologist with expertise and experience in the field of hemoglobinopathies.	—/GPP	—
Hemoglobin electrophoresis screening of the entire population or high risk groups.	Ia/A	100
Screen partner; if the result is positive, consider counseling and prenatal diagnosis.	Ia/A	100
Administer folic acid 5 mg daily.	—/GPP	—
Prompt treatment of crises (adequate hydration, oxygen, screening for infection) may include exchange transfusion.	—/GPP	—
Prenatal fetal surveillance and tests for fetal well-being.	—/GPP	—
Screen for: • Urinary infection. • Hypertension or preeclampsia. • Renal and liver function. • Pathologic fetal growth and umbilical artery blood flow.	—/GPP	—
Labor and Delivery		
Ensure adequate hydration, strict fluid balance.	—/GPP	—
Avoid hypoxia, continuous pulse oximetry.	—/GPP	—
Continuous cardiotocography.	—/GPP	—
Keep warm.	—/GPP	—
Provide thromboprophylaxis.	—/GPP	—
Alert pediatricians.	—/GPP	—
Postnatal		
Use of prophylactic antibiotics is controversial; low threshold for use on clinical grounds especially after an operative delivery.	—/GPP	—
Maintain good hydration and oxygenation, especially for the first 24 hr.	—/GPP	—
Provide contraceptive counseling.	—/GPP	—
Test the neonate for hemoglobinopathies.	—/GPP	—

GPP, good practice point.

Thalassemia Syndromes

Thalassemia syndromes are usually quantitative disorders of globin chain production that affect either the α or the β globin chain.

α-Thalassemia

There are normally two pairs (i.e., four) of functional α globin genes on chromosome 16. If one or two of these genes are missing, the result is an α-thalassemia trait. The type of thalassemia trait is an important factor to consider when offering antenatal counseling and diagnosis. These traits are not detected on hemoglobin electrophoresis because no abnormal hemoglobin is made. In addition, there is neither excess nor lack of any normal hemoglobins.

Deletion of three α globin genes results in hemoglobin H (HbH) disease, a chronic hemolytic anemia, with moderate anemia, hypochromia, and marked microcytosis and normal life expectancy. Nondeletional HbH disease also exists when there is deletion of two α globin genes plus a nondeletional mutation affecting a third α globin gene. The condition can be detected by hemoglobin electrophoresis by an HbH peak on the high-performance liquid chromatography trace and the presence of HbH inclusion bodies in the red cell that appear like "golf ball" cells on supravital staining.

In α-thalassemia major, there is no α chain production and no synthesis of hemoglobin F, A, or A_2. Tetramers of fetal gamma chains (γ_4) form because no α chains are present. This condition is known as hemoglobin Barts. Patients have severe anemia, failure of oxygen delivery to tissues, cardiac failure, and abnormal organogenesis. The condition is incompatible with life and causes intrauterine hydrops. Serious obstetric complications often occur, including pre-eclampsia and delivery difficulties because of the large fetus and placenta. The nonviability of the fetus and the maternal complications make early termination advisable. Experimental fetal treatment may be available if the condition is detected early in pregnancy. There are ethical issues with this practice, and antenatal screening for α-thalassemia is directed at preventing hemoglobin Barts hydrops. To prevent this condition, women and their partners who have a cis-(2) α gene deletion (i.e., genotype – –/αα or –α_0-thalassemia trait) must be identified. These couples have a one in four chance of having a fetus with hydrops. In practice, these couples are identified on the basis of otherwise unexplained hypochromic, microcytic red cell indices (iron deficiency and β-thalassemia should be excluded). An MCH of less than 25 pg suggests the genotype – –/αα or –α/–α. Hemoglobin electrophoresis does not detect α-thalassemia traits, and definitive diagnosis requires DNA analysis to detect thalassemia-causing mutations. This diagnostic procedure is undertaken only if both the woman and her partner have indices and test results that suggest α_0-thalassemia trait or HbH disease or a combination of both within the partnership. Persons particularly at risk for α_0-thalassemia trait are those of Chinese, Southeast Asian, or Mediterranean descent.

DIAGNOSIS AND MANAGEMENT OPTIONS
Prepregnancy

Women who have α_0-thalassemia trait should be identified before pregnancy so that they can be alerted to the one in four chance of having a hydropic fetus if their partner carries the same trait. Early screening of partners is strongly encouraged. If the woman and her partner are at risk, the possibility and techniques of antenatal diagnosis can be discussed. Women with HbH disease should be encouraged to take regular folate supplementation outside of pregnancy to meet the demands of increased bone marrow turnover.

Prenatal

Prenatally, the main issues are antenatal diagnosis (if required) and maintenance of adequate hemoglobin. In women with indices that suggest α_0-thalassemia trait or HbH disease, partner carrier status should be sought early in pregnancy to determine risk, especially in affected racial groups. At-risk couples should be counseled about the risks and offered antenatal diagnosis with chorionic villus sampling or amniocentesis.

Oral iron supplements should not be prescribed on the basis of red cell indices alone (i.e., hypochromia and microcytosis). They are indicated when ferritin levels are reduced.

In HbH disease, folate supplementation (5 mg daily) is recommended, and transfusion may be needed for women with severe symptomatic anemia or early signs of fetal compromise.

Labor and Delivery and Postpartum

There are no specific management recommendations.

β-Thalassemia
MATERNAL AND FETAL RISKS

β-Thalassemia has three phenotypic presentations: the trait, intermedia, and major.

β-Thalassemia trait, or heterozygote state, is important to detect for antenatal screening purposes. It does not affect the mother's health, but causes hypochromic, microcytic red cell indices. Iron therapy must be based on hematinic measurements rather than the complete blood count.

Partner screening should be performed to determine the risk of having a child affected with a major hemoglobinopathy. If the partner carries a sickle cell trait, a β-thalassemia trait, or hemoglobin E, and the mother carries a β-thalassemia trait, there is a one in four risk of having a child with a major hemoglobinopathy. Sickle cell/β-thalassemia is a major sickling disorder, whereas hemoglobin E/β-thalassemia and homozygous β-thalassemia are transfusion-dependent states, with the associated problems of iron overload and iron chelation therapy.

Couples at risk for having a child with a major hemoglobinopathy need timely, nondirective counseling, with education about the possibility and techniques available for antenatal diagnosis.

Partners of women with β-thalassemia or hemoglobin E/β-thalassemia need antenatal screening to determine the risk of major hemoglobinopathy. If the partner has a relevant heterozygous condition, the risk of having an affected fetus increases to one in two. Although fertility is reduced in women with transfusion-dependent thalassemia, pregnancy has been reported.[124–126]

The physiologic stress of pregnancy may exacerbate symptoms of thalassemia. The transfusion regimen needs careful monitoring because blood requirements tend to increase in pregnancy. Iron chelation therapy also needs to be reviewed. Outside of pregnancy, iron chelation is usually performed with desferrioxamine mesylate (Desferal), which is given as a subcutaneous infusion over 12 hours 5 to 7 days per week. Continuing this treatment periconceptually and during pregnancy may put the fetus at risk for skeletal anomalies. This finding was noted in animal studies at doses equivalent to human dosages. The small number of reported cases in pregnant women is not sufficient to establish the safety of desferrioxamine mesylate in this setting. There are case reports of desferrioxamine mesylate use in early pregnancy,[127] but ideally, iron status is optimized prepregnancy and chelation is discontinued periconceptually, at least for the first trimester, but ideally, throughout pregnancy. A risk-benefit assessment of continuing iron chelation in pregnancy is required, and the results will depend on the degree of iron overload at the start of pregnancy. At conception, various organs may already be affected by iron overload, particularly the heart, liver, and endocrine system. These patients require careful evaluation prepregnancy and monitoring throughout gestation.

Patients with β-thalassemia major are often small in stature, and affected women have small pelvic bones. This finding might be the reason for the increased rate of cesarean delivery reported in these women.[126]

The fetus is primarily at risk if the transfusion regimen is inadequate and the mother is anemic. Fetal hypoxia may occur and has been associated with intrauterine growth restriction, pregnancy loss, and preterm labor. These complications do not occur when maternal anemia is managed well. Women with iron overload are at increased risk for maternal diabetes, which can lead to an increased risk of birth defects and prenatal and maternal complications.

DIAGNOSIS AND MANAGEMENT OPTIONS
Prepregnancy and Prenatal

β-Thalassemia trait is indicated by hypochromic, microcytic red cell indices and usually is seen with a finding of increased hemoglobin A_2 on hemoglobin electrophoresis. Complications in diagnosis can arise in patients with iron-deficiency anemia because it can falsely decrease hemoglobin A_2.

Racial groups at greatest risk include those of Mediterranean origin and some Asian populations, but it can occur in any racial group. The overall carrier rate in the United Kingdom is approximately 1 in 10,000 compared with 1 in 7 in Cyprus.

Women who are carriers of β-thalassemia trait need early education about the advisability of partner testing and the availability of antenatal diagnosis.[128,129]

In most cases, women with β-thalassemia intermedia or major are identified well before pregnancy and are receiving regular follow-up. Fertility is often reduced in women with transfusion-dependent thalassemia major owing to iron overload and central hypogonadism, but pregnancy is possible for some. Many require regular transfusion programs and iron chelation therapy. Unnecessary iron loading should be avoided. Oral and intravenous iron supplements are contraindicated. If possible, iron chelation therapy should be optimized prior to pregnancy and then discontinued during pregnancy. Iron chelation can be restarted after delivery. Desferrioxamine is safe to use if breast-feeding. Assessment of the function of organs affected by iron overload (heart, liver, and endocrine system) should be carried out regularly throughout medical follow-up. Assessment includes evaluation of cardiac status, liver function tests, thyroid and parathyroid function tests, and glucose testing.

Baseline cardiac status is important because the demands of a 30% to 50% increase in cardiac output that occurs in pregnancy can lead to cardiac decompensation with serious arrhythmias and heart failure in those with cardiac siderosis. Echocardiography assessment should be carried out, and the magnetic relaxation parameter T2* measured by magnetic reasonance imaging is useful in the quantification of cardiac iron, where available, although its predictive value for heart failure is unknown.[130]

If pregnancy was achieved spontaneously (i.e., without fertility treatment), the pituitary axis is likely to be functioning. Thyroid function and a glucose tolerance test should be carried out. Thyroid dysfunction is present in up to 75% of patients with thalassemia major, and the occurrence of treated hypothyroidism is approximately 9%. There is a high incidence of gestational diabetes among this group of women. If known to be diabetic (incidence of approximately 7% in thalassemia major), the control should be optimized prior to pregnancy.

Bone problems with osteopenia and osteoporosis often occur in transfusion-dependent thalassemics, and these can worsen during pregnancy. Vitamin D and calcium supplements are advisable if bone density is reduced, but bisphosphonates should be discontinued. Transfusion requirements tend to increase in pregnancy, and the transfusion regimen needs monitoring. The fetomaternal medicine team should monitor the health of the mother and the growth and well-being of the fetus. Partner screening should be performed.

Labor and Delivery and Postpartum

There are no specific management recommendations. As discussed earlier, issues relating to pelvis size, diabetes, and cardiac function may require assessment on an individual basis.

HEMOLYTIC ANEMIAS

Hemolytic anemias are characterized by accelerated red cell destruction, which typically results in an increased unconjugated bilirubin level, increased urobilinogen excretion, and an increased lactate dehydrogenase level. The reticulocyte count increases as the bone marrow responds. If intravascular hemolysis is present, free plasma hemoglobin and absent serum haptoglobins are characteristic findings.

Clinically, patients may have anemia, jaundice, splenomegaly, and pigment gallstones.

Hemolytic anemias are caused by something intrinsic or extrinsic to the red blood cell. Intrinsic causes of hemolysis include abnormalities in hemoglobin structure or function (i.e., hemoglobinopathies), the red cell membrane (e.g., hereditary spherocytosis), or red cell metabolism (e.g., pyruvate kinase, glucose-6-phosphate dehydrogenase [G-6-PD] deficiency). Extrinsic causes may be the result of a red cell–directed antibody (i.e., autoimmune hemolytic anemia), altered intravascular circulation (e.g., disseminated intravascular coagulation, thrombotic thrombocytopenic purpura; see Chapters 78 and 79), or infection.

Red Cell Membrane Disorders

Hereditary spherocytosis occurs in approximately 1 in 2000 individuals of Northern European descent.[131] The inheritance pattern is autosomal dominant. The red cells are spherocytic and osmotically fragile. The condition is caused by a wide range of molecular lesions resulting in defects in red cell membrane proteins. This leads to loss of red cell membrane surface, reduced red cell deformability, and accelerated red cell destruction. It is clinically and genetically heterogeneous. Diagnosis is made by a combination of non-immune hemolysis and typical blood film findings, with spherocytes and osmotic fragility testing, or flow cytometry using an eosin-5-maleimide probe. This probe is a flow cytometric test that measures the fluorescence intensity of intact red cell membrane labeled with the dye eosin-5-maleimide. This fluorescent label binds to a component of the red cell membrane known as band 3. Binding is significantly reduced in hereditary spherocytosis.[132]

Hemoglobin concentrations are usually between 9 and12 g/dL but may be lower (6–8 g/dL) in up to 10% of patients. A pregnant woman with this condition should be monitored for anemia and should receive folic acid supplementation (≤5 mg daily). Aplastic and hyperhemolytic crises may occur. Aplastic crises are usually caused by parvovirus B19, which switches off erythropoiesis and causes a dramatic decrease in hemoglobin.[133] The virus may also affect fetal erythropoiesis and development. Hyperhemolysis is characterized by increased jaundice and splenic enlargement. In severe anemia, treatment with blood transfusion may be necessary.

Splenectomy ameliorates hemolytic anemia and reduces gallstone formation, but does not alter the underlying red cell defect. After splenectomy, women should ensure that their presplenectomy vaccinations (pneumococcal, *H. influenzae* B, and meningococcal) are current preconception and should take prophylactic penicillin V. Some small case series suggest that maternal morbidity and fetal outcome may be more favorable after splenectomy.[134] Pediatricians should be made aware of infants who are born to these women because there is a 50% chance that these children will be affected with hereditary spherocytosis, which may cause neonatal jaundice. Affected infants require long-term follow-up.

Red Cell Metabolism Disorders

The mature red cell has two principal pathways of glucose metabolism, the glycolytic pathway and the hexose monophosphate shunt. The glycolytic pathway provides the red cell with adenosine triphosphate as an energy source. Other products include the reduced form of nicotinamide adenine dinucleotide to reduce methemoglobin and 2,3-diphosphoglyceric acid to regulate the oxygen affinity of hemoglobin.

Pyruvate kinase deficiency is the most common defect of the glycolytic pathway. It is inherited in an autosomal recessive fashion and is clinically and genetically heterogeneous.[135,136] Varying degrees of nonspherocytic hemolytic anemia are seen. Hemolysis can worsen during pregnancy.[136] The need for transfusion of red cells must be assessed throughout pregnancy. Folic acid supplements are important for these patients, especially during pregnancy. Patients who have had splenectomy should be current with their vaccinations and receiving prophylactic penicillin.

Metabolism of glucose through the hexose monophosphate shunt produces the reduced form of nicotinamide adenine dinucleotide phosphate to maintain the antioxidative activity of the red cell. G-6-PD deficiency is a defect in the hexose monophosphate shunt and is the most common abnormality of red cell metabolism.[137] Worldwide, it affects more than 200 million people and offers a survival advantage in the face of *Plasmodium falciparum* malaria.[138]

G-6-PD deficiency is X-linked. More than 300 genetic variants occur, and they are categorized according to the variant enzyme activity. The severity of this nonspherocytic hemolytic anemia in heterozygous women depends on the degree of lyonization, the type of defect, the level of enzyme activity, and the oxidative challenge (typically, drugs and fava beans). Heinz bodies can be seen on supravital staining of peripheral blood at times of hemolysis, and they indicate the presence of denatured hemoglobin within the red cell.

The G-6-PD A variant is an unstable enzyme, with a half-life of 13 days (normal half-life 62 days) and the enzyme activity decreases as the red cells age. This variant is found in approximately 10% to 15% of African American men. Women with this condition usually are only mildly anemic. Enzyme levels are between 10% and 60% of normal and hemolysis is intermittent and usually secondary to drugs or infection. The G-6-PD B variant (also known as G-6-PD Mediterranean) is found in up to 5% of people with Mediterranean or Asian ancestry and is clinically more severe. The unstable enzyme has a half-life measured in hours. Men and heterozygous women may have severe enzyme deficiency, but the hemolysis is usually only intermittent. The responsible agent must be removed because even the reticulocytes have low enzyme levels and are prone to hemolysis. Some variants cause congenital hemolytic anemia with persistent splenomegaly.

G-6-PD deficiency screening tests are available in most hematology laboratories. Direct quantification of G-6-PD is

available at more specialist red cell laboratories and is applicable when screening tests are positive.

In more severe variants, women must be monitored for anemia throughout pregnancy, should avoid oxidant stresses, should take folic acid, and might need transfusion. Women heterozygous for G-6-PD deficiency should avoid oxidant drugs in pregnancy and when breast-feeding because hemolysis may occur in the fetus or neonate if the drugs cross into the fetal circulation or breast milk. The pediatrician must be alerted to the risk of hemolysis and neonatal jaundice because affected patients need careful monitoring and early therapy with phototherapy or exchange transfusion with G-6-PD–screened blood if indicated by the bilirubin levels.

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia may be primary or secondary to drugs, infection, autoimmune disease (typically systemic lupus erythematosus), neoplasia, or other hematologic disorders.

Usually, the antibodies are of the immunoglobulin G class, and antibody-coated red cells are cleared by the spleen. Symptoms of autoimmune hemolytic anemia are indistinguishable from those of other causes of hemolysis. The positive direct antiglobulin test (Coombs' test) is the mainstay of diagnosis.

Treatment is usually with glucocorticoids, but some patients have undergone splenectomy or are taking other immunosuppressive agents, such as cyclophosphamide, azathioprine, and cyclosporine. Transfusion may be required in patients who do not respond to treatment, but the autoantibodies may cause difficulties with cross-matching and close liaison with the blood bank is advisable.

Women who have autoimmune hemolytic anemia should have prepregnancy counseling, and treatment should be optimized. Careful antenatal supervision to assess maternal hemoglobin and markers of hemolysis, with adjustment of steroid therapy, is required.[139] Transplacental antibody transfer may occur, and hemoglobin levels in the newborn should be evaluated. Some infants require exchange transfusion,[140] but usually no treatment is necessary.[141]

Autoimmune hemolytic anemia has been reported specifically associated with pregnancy, with remission occurring after delivery. This condition tends to recur in subsequent pregnancies. The anemia responds to steroids, and most infants are not affected.[142]

ANEMIA: BONE MARROW APLASIA

Aplastic Anemia

Aplastic anemia is a syndrome of bone marrow failure defined by pancytopenia and bone marrow hypocellularity. Normal hematopoietic tissue in the marrow is replaced by fat. Causative agents include infection, medications, and toxins, but most cases are idiopathic. Patients have pallor and fatigue as a result of anemia and bruising and bleeding as a result of thrombocytopenia. Infection is a risk because of neutropenia. Musculoskeletal abnormalities may indicate an inherited syndrome of bone marrow failure. The patient should be examined carefully for organomegaly and lymphadenopathy. These findings suggest viral infection or another underlying disease.

In patients with pancytopenia, testing should be directed by a hematologist and will include bone marrow aspirate and trephine with cytogenetic analysis and chromosome fragility tests.

Treatment of aplastic anemia is initially supportive, with blood products and growth factors. For younger patients with matched sibling donors, bone marrow transplantation is the treatment of choice. Immunosuppressive therapy with antilymphocyte globulin in combination with cyclosporin is also effective.

There are sporadic case reports of aplastic anemia in pregnancy[143–146] and reports of pregnancy occurring in women with underlying aplastic anemia.[147–152] However, overall, aplastic anemia in pregnancy is rare. The relationship between aplastic anemia and pregnancy is uncertain, but the literature suggests that there is not a strong association in most cases.[153] In a few women, however, pregnancy may play an etiologic role. There are case reports of aplastic anemia that are diagnosed for the first time in pregnancy, with spontaneous remission occurring after cessation of pregnancy.[154]

Pregnancy may exacerbate bone marrow depression and cause clinical deterioration.[155]

If severe aplastic anemia occurs in the first trimester, early termination should be considered. If spontaneous recovery does not occur after termination, bone marrow transplantation is performed as soon as possible in women who have a histocompatible sibling donor. In women with severe aplastic anemia later in pregnancy and those who refuse termination, intensive hematologic support with red cells and platelet transfusions is required until delivery. After delivery, bone marrow transplantation should be considered if spontaneous recovery does not occur. There are case reports of the use of antilymphocyte globulin in pregnancy,[154] but each case requires individual assessment and close liaison between obstetricians and hematologists.

WHITE BLOOD CELL DISORDERS

Neutrophilia

The neutrophil count increases throughout pregnancy. The increase is more marked during labor and immediately postpartum. Occasional band forms and myelocytes in the peripheral blood may be a normal finding during pregnancy. Neutrophilia may be associated with
- Bacterial infection.
- Acute or chronic inflammatory disorders.
- Tissue damage or infarction.
- Preeclampsia.
- Hemorrhage.
- Malignant disease, either hematologic (e.g., chronic myeloid leukemia) or nonhematologic.

Neutropenia

The finding of neutropenia on an automated complete blood count should be verified by examination of the peripheral blood film. Aged samples may show spurious neutropenia or neutrophil clumping. A repeat count should be obtained to ensure that the findings are reproducible. Ethnic origin affects the neutrophil count; persons of African and Caribbean descent tend to have a lower peripheral blood neutrophil count because of an increase in the marginating pool. Neutropenia may be acute or chronic and isolated or part of generalized pancytopenia. It may be caused by peripheral destruction or underlying bone marrow disease. A summary of the causes of nonmalignant neutropenia is shown in Table 38–2. The investigation of neutropenia in the pregnant woman is identical to that outside pregnancy. Drugs that

TABLE 38–2
Nonmalignant Neutropenia

TYPE	CAUSES

	Agranulocytosis
	Viral infection
	Vitamin B$_{12}$ or folate deficiency
Chronic	Race
	Immune neutropenia
	Primary
	Associated with connective tissue disorder or autoimmune disease
	Felty's syndrome
	Congenital neutropenia
	Kostmann's neutropenia
	Associated with other congenital disorders
	Chronic idiopathic neutropenia
	Cyclic neutropenia
	Aplastic anemia

may be implicated should be discontinued immediately, especially if neutropenia is severe. There are case reports of ritodrine-induced neutropenia.[156] If clinical assessment and examination of the blood film do not show the cause of neutropenia, bone marrow examination is indicated.

Maternal and Fetal Risks

In severe neutropenia, the principal maternal risk is sepsis. A patient with moderate or severe neutropenia (neutrophil count < 1.0×10^9/L) and fever should have prompt cultures of blood, urine, and sputum, if available, followed immediately by empirical treatment with broad-spectrum intravenous antibiotics, according to local policy. Antifungal therapy is considered if the fever does not resolve after 48 to 72 hours, especially when neutropenia is prolonged.

There are many case reports of pregnancy in patients with cyclic neutropenia.[157,158] This disorder is characterized by cyclic fluctuations of the neutrophil count, with a periodicity of approximately 21 days. At its nadir, neutropenia is usually severe and is often associated with clinical infection. The onset is usually in childhood, but adult-onset cyclic neutropenia is also described. Pregnancy in cyclic neutropenia is associated with preterm labor and stillbirth, possibly because of chorioamnionitis associated with the neutropenia. There are also reports of improvements in symptoms and neutrophil counts during pregnancy in patients with cyclic neutropenia, possibly because of the production of neutrophil growth factors, such as granulocyte-macrophage colony-stimulating factor, by the placenta.[159] In approximately one third of cases, cyclic neutropenia appears to be inherited in an autosomal dominant fashion; therefore, the fetus may be affected.

Management Options

Recombinant granulocyte colony-stimulating factor is successfully used to treat patients with severe chronic neutropenia of differing etiologies, including cyclic and congenital types.[160] A few pregnancies have occurred in patients treated with granulocyte colony-stimulating factor for severe chronic or cyclic neutropenia.[161] Pregnancy outcome was normal in some, but fetal abnormality, including bilateral hydronephrosis, occurred in others. Data on the safety of the use of granulocyte colony-stimulating factor during pregnancy are inconclusive. Risks and benefits should be evaluated individually.

For a patient with severe neutropenia, prophylactic antibiotics should be considered to cover invasive procedures for labor and delivery.

Some viral infections that cause neutropenia have implications for fetal development and congenital infection (e.g., rubella, parvovirus, cytomegalovirus) or hepatitis. Maternal autoimmune neutropenia may lead to transfer of antineutrophil antibodies across the placenta, resulting in fetal neutropenia.[162,163]

Malignancies of the Hematologic and Immunologic Systems

JOHN MAELOR DAVIES and LUCY H. KEAN

INTRODUCTION

Malignancy complicating pregnancy is uncommon; however, hematologic disorders account for most malignancies in women of reproductive age. Acute leukemia complicates approximately 1 in 75,000 pregnancies, and lymphoma complicates 1 in 5000 pregnancies.[1,2] Hematologic malignancies are an important consideration in pregnancy because, although they may threaten life, many are potentially curable. It is also important that the clinician has an understanding of the impact on reproduction of previously treated disease, because many women who have undergone successful treatment will later become pregnant.

The classification of tumors of the hemopoietic and lymphoid tissues is complex and subject to change. The World Health Organization classification[3] provides the major framework for categorizing these disorders. Much of the literature on these conditions in pregnancy predates the introduction of effective modern management. In some areas, data are necessarily limited, but as far as possible, the management principles discussed are evidence-based.

ACUTE LEUKEMIA

Acute leukemia results from malignant change in hemopoietic precursor cells at various stages of differentiation. Acute leukemia is traditionally subdivided into acute myeloblastic leukemia (AML) and acute lymphoblastic leukemia (ALL), depending on the major cell lineage involved. Further subdivision of AML and ALL provides additional prognostic and therapeutic information. Both AML and ALL are usually rapidly progressive and lead to bone marrow failure, with symptoms and signs of anemia, neutropenia, and thrombocytopenia. More unusually acute leukemias may present with extramedullary involvement. The myelodysplastic syndromes (MDSs) represent a heterogenous group of clonal disorders characterized by peripheral blood cytopenias and abnormal marrow morphology often with cytogenetic abnormalities. MDS may behave indolently, in which case outcome for pregnancy is excellent, whereas more aggressive forms of MDS resemble and overlap with AML in their prognosis and management.[4]

Maternal Risks

Pregnancy does not appear to affect either the development or the course of acute leukemia. Patients who have symptoms or signs with abnormalities in the complete blood count suggesting bone marrow failure or infiltration should undergo appropriate investigation. The diagnostic workup in pregnant patients with suspected acute leukemia should not differ from that in nonpregnant patients. This includes bone marrow aspiration, trephine biopsy, and examination of the cerebrospinal fluid, as appropriate. Cytogenetic and molecular diagnostic techniques are now routine and provide rapid additional prognostic information.[3] Blood chemistry including renal and hepatic function and urate should be monitored. Infection and bleeding are major risks in uncontrolled acute leukemia, particularly in some subtypes, such as acute promyelocytic leukemia. Laboratory assessment of the degree of thrombocytopenia is essential, and evidence of coagulation factor depletion and disseminated intravascular coagulation should be sought.

Supportive care, with blood and platelet transfusions and antibiotic administration, should be instituted early. However, chemotherapy offers the only prospect for long-term maternal survival. If delivery is contemplated before complete remission is achieved, then infection and bleeding pose a major risk to maternal survival. Patients may require intensive supportive care including antibiotic administration and appropriate blood, coagulation factor, and platelet replacement.

The outcome in both AML and ALL depends on a number of pretreatment prognostic factors. The prognosis is also determined by the response to treatment and the type of treatment offered. Recent population-based data from the United States show that for AML, approximately 50% of patients in the 15- to 35-year-old age group will be alive at 10 years. Similar Scandinavian data for ALL give a 60% event-free survival in patients aged 17 to 25 years. The acute leukemias are, however, a very heterogeneous group of disorders with widely varying outcomes. For example, patients with acute promyelocytic leukemia treated with modern protocols have an approximately 70% long-term survival,[3] whereas patients with Philadelphia chromosome–positive

ALL continue to present significant management problems. Despite the introduction of tyrosine kinase inhibitors, this disease remains essentially incurable with current chemotherapy regimens alone.[5] Discussion of prognosis should be highly individualized and undertaken only when all necessary information is available. Fertility is likely to be maintained in many patients with AML and ALL treated with conventional chemotherapy, and future pregnancy outcome in survivors of AML and ALL is also likely to be favorable. Counseling and contraceptive advice should include these considerations. Increasing numbers of patients have been treated with high-dose therapy including both autologous and allogeneic hemopoietic stem cell transplantation for acute leukemia. Although successful pregnancy has been reported, in most patients, these procedures significantly impair subsequent fertility.[6,7]

Fetal Risks

The main risks to the fetus are growth restriction, which occurs in both treated and untreated pregnancies, and chemotherapy-induced effects, both reversible and irreversible. Historically, fetal growth restriction and spontaneous preterm delivery occurred in approximately 40% to 50% of cases, and causation appeared to be multifactorial.[8] With modern chemotherapy and the attainment of remission in the majority of patients within 4 to 6 weeks, the fetal survival rate improves significantly.[9] Congenital leukemia is rare and essentially can be discounted. The fetal risks associated with chemotherapy depend, in part, on the timing of the treatment in terms of gestational age and also on the agents used. Although data are limited, general conclusions can be drawn about the fetal risks of chemotherapy.

First, adverse fetal events may occur at any point in gestation, although congenital malformation is more likely to occur with first-trimester exposure to chemotherapy. The literature suggests that the risk of major fetal abnormality with first-trimester exposure is 10% to 30%, depending on the degree of exposure and the agents used.[10] When a patient has known first-trimester exposure to cytotoxic agents, a careful fetal ultrasound should be performed at 18 to 22 weeks. However, not all teratogenic effects are detectable by ultrasound examination, and parents should be carefully counseled. Serial scans may improve the detection of some abnormalities, especially central nervous system (CNS), cardiac, and growth abnormalities.

Second, some chemotherapeutic agents are more likely than others to produce adverse fetal effects. For example, first-trimester use of high-dose methotrexate produces an approximately 25% risk of significant adverse fetal effects, with CNS, skeletal, and facial abnormalities being most common. Data on other agents used to treat acute leukemia are limited, and the degree of fetal risk is not known. However, successful fetal outcomes have been described following fetal exposure to many commonly used classes of cytotoxics particularly in the second and third trimesters. This includes vinca alkaloids, corticosteroids, anthracyclines, and cytarabine.[11-14] The situation is further complicated by an apparent "weakening" of predicted class effects with some agents, in that agents structurally closely linked to known human teratogens may produce less fetal abnormality than expected. All-*trans*-retinoic acid, which is used extensively to treat acute promyelocytic leukemia, is related to other retinoids that are potent human teratogens. These agents are contraindicated in women of childbearing age. There are, however, increasing case reports of the successful use of all-*trans*-retinoic acid in pregnancy, and these data emphasize that maternal versus fetal risk must be balanced at all stages in patient management.[15]

Finally, exposure to many chemotherapeutic agents is associated with the development of markers of chromosomal damage. The significance of this observation is not clear, and data on long-term effects in surviving infants exposed to chemotherapeutic agents in utero are encouraging.[16-18] However, this observation may reflect a lack of good information rather than a true lack of adverse events, with late chemotherapy-induced malignancies representing the major potential concern.[19]

Management Options

Prepregnancy

Women who undergo chemotherapy for acute leukemia should be counseled and advised against conception until remission is achieved and chemotherapy is discontinued. Oral contraceptives are not contraindicated. Methotrexate has a long "wash-out" period and can remain in tissues for periods of at least 3 months. It is, therefore, recommended that women wait at least 6 months before conceiving after receiving the drug. The risk of teratogenesis does not seem to be increased, but spontaneous miscarriage rates are higher.

For women in sustained complete remission, which is now a more common scenario, prepregnancy counseling should include a discussion of the prognosis in terms of the disease and the effect of the disease and its treatment on pregnancy. As a result of the 1994 European Registration of Congenital Anomalies (EUROCAT) study of policies for karyotyping in pregnancy, patients began to seek invasive prenatal testing because of maternal anxiety about exposure to chemotherapy or radiation therapy.[20] As discussed, although chemotherapy may cause chromosome breaks, there does not appear to be a documented increase in the risk of chromosomal or genetic problems in offspring of successfully treated patients. Importantly, previous chemotherapy exposure does not appear to increase the risk of miscarriage, growth restriction, or stillbirth.[21,22] It has not been possible to perform large studies to determine whether the incidence of childhood cancer is increased in the offspring of patients who have undergone chemotherapy. However, smaller studies suggest that there is no increased risk. Given the lack of evidence suggesting an increase in the risk of chromosomal abnormalities in the fetus, invasive prenatal diagnosis should be based on normal criteria in relation to age and screening test results. Women who have undergone pelvic radiation therapy, however, have a significantly increased risk of growth restriction in the fetus and should be counseled that increased surveillance is needed in pregnancy.

Prenatal

A pregnant woman with acute leukemia should be treated aggressively, with full supportive care and combination chemotherapy. A broad-based multidisciplinary team approach is required to manage the hematologic and obstetric aspects of care. Untreated acute leukemia is fatal to both mother

and fetus. Standard treatment should be given, when possible, with appropriate counseling about fetal risk. No robust data are available on the need for dosage modifications of chemotherapeutic drugs in pregnancy. In some cases, agents that are less likely to cause fetal abnormalities can be used (e.g., intrathecal cytarabine rather than intrathecal methotrexate for central nervous system prophylaxis in ALL). However, nonstandard regimens of unproven efficacy should not be substituted on the basis of fetal risk without full and informed discussion of maternal risks.

Counseling about the teratogenic risks of treatment should be provided, and fetal and maternal well-being should be monitored throughout pregnancy by a hemato-oncologist and an obstetrician. Regular monitoring of fetal growth is indicated for patients who have received pelvic radiotherapy in the past. Whether more intensive surveillance in all patients previously treated for hematologic malignancy is necessary is unclear. However, it would seem sensible to provide an enhanced level of fetal monitoring when this provides additional reassurance to the mother and the attending physician that the pregnancy is progressing normally.

Labor and Delivery

Delivery should be expedited for normal obstetric indications. The goal of management is to deliver a viable infant while the mother is in hematologic remission. This approach offers the best prospect for uncomplicated delivery and infant survival. There is no contraindication to the use of steroids before delivery to enhance fetal surfactant production. Early assessment of the infant should be undertaken to detect complications from in utero exposure to chemotherapy. This evaluation includes assessment of potential congenital abnormalities and hematologic testing to exclude short-term effects (e.g., neutropenia as a result of recent in utero exposure to cytotoxic agents administered to the mother). When indicated, a cord blood sample should be sent for a complete blood count.

Postnatal

If delivery is inevitable in a patient who is not in remission, vigorous supportive care should be continued peri- and postnatally. If the disease is in remission at the time of delivery, counseling and appropriate contraceptive advice should be given after delivery.

Data on the excretion of cytotoxic drugs in breast milk are variable. Methotrexate is excreted into breast milk in small amounts with a measured milk-to-plasma ratio of 0.08. However, there is a risk for tissue accumulation in the neonate, which may lead to potential problems including myelosuppression. Results of excretion studies for cisplatin are mixed. The maximum reported excretion showed that milk-to-plasma ratios may reach 1, with consequent neonatal concerns regarding breast-feeding. A small number of reports of mothers breast-feeding while taking cyclophosphamide have shown significant neonatal myelosuppression. The data on anthracycline excretion are so limited that no assessment of safety is possible. This is also the case for newer classes of drugs. The absence of good data for most cytotoxics and evidence of potential harm for some lead to the general recommendation of avoidance of breast-feeding while taking cytotoxic drugs.

CHRONIC LEUKEMIA

Chronic Myeloid Leukemia

Chronic myeloid leukemia (CML) is traditionally considered a triphasic disease (chronic phase, accelerated phase, and blast crisis) that is usually diagnosed in the chronic (early) phase. It accounts for 15% to 20% of cases of leukemia, and the median age at diagnosis is in the fifth and sixth decades. CML arises from a cytogenetic abnormality that results in production of the Philadelphia chromosome. As a result, the *BCR/ABL* fusion gene is produced that encodes for a protein with tyrosine kinase activity. CML causes systemic symptoms, such as weight loss, fatigue, and often significant splenomegaly. Laboratory findings include marked leukocytosis, and as discussed earlier, a specific marker chromosome that is detectable in blood and bone marrow. Hyperleukocytosis with ocular and other CNS effects may occur.

Management Options outside Pregnancy

The management of CML has been revolutionized by the introduction of specific tyrosine kinase inhibitors, the first of which was imatinib mesylate.[23] A recent update of one of the major comparative studies with imatinib has demonstrated an estimated event-free survival at 6-year follow-up of 83% with an overall survival of 95% when only deaths from CML are included in analysis. Tyrosine kinase inhibitors have accordingly replaced the now-historic treatment options of hydroxyurea and interferon-alfa as first-line therapy. Related or unrelated allogeneic hemopoietic stem cell transplantation, which traditionally has been used to treat this condition, is now reserved for those failing or intolerant of tyrosine kinase inhibitors.[24] The practical management of patients with CML in the imatinib era including the role of molecular monitoring and approach to imatinib resistance or intolerance has recently been reviewed.[25]

Maternal and Fetal Risks

There is no evidence that the behavior of CML is altered in pregnancy. Control of the maternal white count may be achieved in a number of ways. The risk to the fetus is probably secondary to exposure to maternal therapy, and control of the maternal white count with physical means, such as leukapheresis, should be considered. Patients on treatment with imatinib or other tyrosine kinase inhibitors should currently be counseled against becoming pregnant because good data on their use in pregnancy are insufficient.

Management Options

PREPREGNANCY

The implications and risks of pregnancy should be fully explained, and appropriate contraceptive advice should be given.

PRENATAL

Regular hematologic review is required to determine the need for active treatment. Leukapheresis may be an effective method to control the white cell count, particularly in the first trimester. This approach may be continued throughout pregnancy. Successful pregnancies are described in patients treated with hydroxyurea and interferon-alfa,[26,27] though cumulative data are insufficient to allow an estimate of the real risk of fetal abnormality. Measurement of interferon-alfa in fetuses following administration of high doses has shown that it does not appear to readily cross the placenta. This also appears to be the case for excretion into breast milk, with levels no higher than controls found following high-dose administration. Patients who become pregnant while taking imatinib should be counseled about the uncertainty regarding the risk of fetal abnormality. The degree of risk and the type of potential fetal abnormality are unknown, but this advice is based on lack of extensive evidence that imatinib is safe rather than positive evidence of high risk of harm. However, the safe option for patients in the chronic phase who become pregnant while taking imatinib is to discontinue use of the agent and to institute other methods to control the white cell count. There are, however, several case reports of successful pregnancy outcome in patients treated with imatinib at all stages of gestation.[28,29] Imatinib does not appear to cross the placenta in the third trimester, but data regarding transplacental passage at earlier gestations are not available. Therefore, careful ultrasonographic examination of the fetus should be performed in women who wish to continue the pregnancy after first-trimester exposure. Imatinib is excreted into breast milk with a milk-to-plasma ratio of 0.5 for imatinib and 0.9 for its main metabolite. This could potentially lead to levels in a term

infant of 10% of the therapeutic level. The effects of even low-dose exposure to the baby are unknown, and full discussion with the pediatric team should be considered in women who want to breast-feed.

Hematologic abnormalities that suggest disease progression, such as signs of the accelerated phase or blast crisis, should lead to management review. In the accelerated phase, expediting delivery should be considered. Maternal options include reintroduction of imatinib, use of an alternative tyrosine kinase inhibitor, and referral for hemopoietic stem cell transplantation, which is the only likely curative option. Blast crisis in pregnancy may be treated with tyrosine kinase inhibitors, if the patient is not already receiving these agents, or with combination chemotherapy, as for other forms of acute leukemia. However, the maternal outlook long-term is poor, and urgent consideration should be given to early delivery and referral of the mother, if appropriate, for hemopoietic stem cell transplantation, particularly if a second chronic phase can be obtained.[30]

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) is a disease of older populations[3] and rarely occurs in pregnancy. A "wait-and-watch" approach is often appropriate, and the patient may need treatment only if symptoms occur. When treatment is required, standard first-line therapies include corticosteroids, alkylating agents, fludarabine, and rituximab.[31] Given the usual indolent course of CLL, most pregnancies will be managed without fetal exposure to potentially teratogenic agents and with no detriment to maternal outcome.

Myeloma

Myeloma is also a disease of older age groups and is rare in pregnancy. It presents a unique set of management problems and may cause significant skeletal damage, bone marrow failure, extended risk of infection, and renal failure. Radiologic assessment of potential skeletal damage should be undertaken in a manner that limits fetal exposure to radiation. Magnetic resonance imaging (MRI) may be useful in this regard.[32] A number of chemotherapeutic agents are active in the treatment of myeloma. If treatment is required in pregnancy, then high-dose corticosteroids either alone or in combination with older agents such alkylators and anthracyclines may be preferred to newer agents such as bortezomib in which data on fetal outcome are very limited.[33] Thalidomide and its structural analogue lenalidomide, now commonly incorporated into front-line and salvage regimens, are absolutely contraindicated in pregnancy.[34] Radiotherapy has a significant role in the management of myeloma, particularly in the context of cord compression. The management of maternal spinal cord compression in pregnancy is challenging, and treatment needs to be highly individualized following full interdisciplinary discussion, which includes neurosurgical opinion.

LYMPHOMA

The lymphomas are a heterogeneous group of malignant disorders that arise in lymphoid tissue. The major histologic subdivision of lymphoma is into the following categories:

- Hodgkin's disease.
- Non-Hodgkin lymphoma.

Hodgkin's Disease

Hodgkin's disease is an uncommon lymphoid malignancy.[35] However, because of the age distribution of patients with Hodgkin's disease, it is the most common type of lymphoma seen in pregnancy. Hodgkin's disease causes nodal enlargement, classically in the neck, and diagnosis requires biopsy of the affected tissue. Further management depends on the stage of disease. Early-stage or localized Hodgkin's disease may be cured with either radiation therapy alone or a combination of chemotherapy and radiation therapy in modified dosage. More extensive stage disease requires combination chemotherapy for cure. The Ann Arbor system is still the most commonly used staging system, but staging may be refined anatomically with the Cotswolds revision.[36] In addition, information available from laboratory tests (e.g., lymphocyte count, erythrocyte sedimentation rate, serum albumin level) may be used to produce a prognostic index that may affect management. However, none of the commonly used prognostic scoring systems have been validated in pregnancy.

Maternal Risks

Hodgkin's disease in pregnancy does not appear to differ from that in nonpregnant patients, although Hodgkin's disease is less common in multiparous women. Diagnosis is made by biopsy. Further studies in the pregnant patient are associated with specific problems, particularly with regard to computed tomography (CT); however, MRI, which is considered safe in pregnancy, may be used.[37] Staging laparotomy has essentially been abandoned.[38] The outlook for cure in patients with early-stage disease treated with radiation therapy, with or without a short course of chemotherapy, is excellent.[39] The greater than 5-year disease-free survival rate in patients with advanced disease treated with combination chemotherapy is 70% to 80%.[39] After relapse, high-dose therapy may produce additional long-term survivors.[40]

Most patients who are successfully treated for Hodgkin's disease return to a normal or very near normal quality of life on cessation of treatment. Many women who receive combination chemotherapy for Hodgkin's disease remain fertile, although there is a risk of premature menopause.[41] No apparent increase in the complications of pregnancy or fetal abnormality in subsequent pregnancy is seen after combination chemotherapy for Hodgkin's disease.[42]

Fetal Risks

The risks to the fetus stem chiefly from the effects of either radiation therapy or chemotherapy. The risks to the fetus of diagnostic radiation have been reviewed.[43,44] Both CT and positron-emission tomography (PET) scanning are now routinely used in the evaluation of lymphoma including Hodgkin's disease. Exposure of pregnant women to the radiation doses used in standard abdominal and pelvic CT appears to have no substantial effect on the risk of fetal death or malformation. The risk of childhood cancer is more than doubled after fetal irradiation. Where possible, irradiation of the fetus in utero should be avoided, but staging should be sufficient to determine the correct modality of treatment. MRI is an adequate tool for staging evaluation in most circumstances and avoids exposure to ionizing radiation.[37]

The risk to the fetus of therapeutic irradiation depends on whether early-stage Hodgkin's disease involves the abdomen or pelvis. Supradiaphragmatic irradiation with heavy lead shielding of the uterus resulted in no congenital abnormalities in one series.[45] When high-dose irradiation cannot be avoided by field manipulation, infradiaphragmatic radiation therapy even with appropriate shielding carries a substantial risk of spontaneous miscarriage and fetal abnormality throughout pregnancy. Under these circumstances, chemotherapy alone rather than radiation therapy should be considered, with delivery before therapeutic irradiation. The fetal effects of combination chemotherapy used to treat Hodgkin's disease are unlikely to be substantially different from those seen in acute leukemia. The teratogenic risk is potentially greatest with first-trimester exposure. However, one series found no apparent adverse fetal effects even with first-trimester exposure to the current gold standard treatment of doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD).[46]

Management Options

PREPREGNANCY

Women with active Hodgkin's disease should be counseled about the risks of pregnancy and should take appropriate contraceptive measures. Pregnancy outcome is good in patients who have been successfully treated for Hodgkin's disease, and routine amniocentesis is not recommended.

PRENATAL

The outlook for patients treated for Hodgkin's disease is good to excellent. Diagnosis and investigation are discussed previously. Patients diagnosed in the first trimester should be counseled about the risks of continuing with the pregnancy.

In highly selected cases, early-stage supradiaphragmatic disease can be successfully treated with radiation therapy alone, with little fetal risk. Historically, early-stage intra-abdominal disease presented a management problem. The options were therapeutic abortion or early delivery, followed by local radiation therapy.

Conventional management of early-stage Hodgkin's disease now uses combined modality treatment; thus, both supradiaphragmatic and infradiaphragmatic disease may be treated with a short course of combination chemotherapy until delivery, with radiation therapy given after delivery. Management decisions are, however, complex and discussion should include the patient, hemato-oncologist, obstetrician, and radiation oncologist.

Patients with more extensive disease should be counseled about the risks of proceeding with pregnancy. Some women may wish to continue with the pregnancy and opt for combination chemotherapy on evidence of disease progression. The optimum management in this context is not

clear, but early in pregnancy, patients with symptomatic or progressive disease could reasonably receive standard chemotherapy, currently ABVD or an equivalent. Beyond the first trimester, treatment options include ABVD, corticosteroids, alone or single-agent vinblastine, which is not associated with a teratogenic risk at this point in gestation.[47] After delivery, patients may be treated with more aggressive combination chemotherapy, such as ABVD, as appropriate. There appears to be no detriment to outcome

if ABVD is used after corticosteroids or vinblastine in this situation.

POSTNATAL

Careful counseling about the prognosis for both long-term disease-free survival and preservation of fertility should be given. Patients who are undergoing active treatment for Hodgkin's disease with combination chemotherapy should be advised not to breast-feed.[48]

Non-Hodgkin Lymphomas

Non-Hodgkin lymphomas comprise a heterogeneous group of malignancies. Unlike in Hodgkin disease, extranodal presentation of non-Hodgkin lymphoma is not uncommon. The increase in the incidence of non-Hodgkin lymphomas is partly attributable to an aging population and risk factors such as HIV infection, but an unexplained real increase in

incidence has been noted. Non-Hodgkin lymphomas are uncommon in the reproductive years. The subclassification of non-Hodgkin lymphomas is complex and changing. However, in general, three types of biologic behavior are seen.[3]

Low-grade, or indolent, lymphomas that are slow-growing do not immediately threaten life and may be treated either on a wait-and-watch basis, with single-agent or

combination chemoimmunotherapy or local radiation therapy.[49] More aggressive lymphomas, such as diffuse large B cell lymphoma, have a much shorter clinical history and may cause early life-threatening complications. These are treated with combination chemoimmunotherapy.[50,51] Some lymphomas, such as lymphoblastic lymphoma or Burkitt's lymphoma behave biologically like subtypes of ALL. These are treated with aggressive combination chemotherapy, the nature of which depends on the histologic subtype.

Maternal Risks

Diagnosis is made on biopsy, and testing and staging are as for Hodgkin's disease, although advanced disease is more common in non-Hodgkin lymphomas. Treatment must be highly individualized and may, as discussed earlier, vary from a wait-and-watch policy to administration of intermediate- or high-dose combination chemotherapy.

Fetal Risks

Non-Hodgkin lymphoma does not appear to affect the outcome of pregnancy. The risks to the fetus are those of treatment. In terms of exposure to cytotoxic agents, fetal risk should not be substantially different from that seen in acute leukemia and Hodgkin's disease. The potential long-term effects on the fetus due to the recent introduction of chemoimmunotherapy into the management of many B cell lymphomas are unknown. Insufficient data are available on the effects of rituximab on pregnancy to allow formal risk stratification, and the conventional wisdom is that rituximab is contraindicated in pregnancy.[53] The introduction of an agent such as rituximab, which clearly improves outcome but has limited data in pregnancy, illustrates the dilemma that many physicians face.

Management Options

PREPREGNANCY

Women who have active non-Hodgkin lymphoma should be counseled about the outlook for the particular subtype of disease and receive appropriate contraceptive advice. Patients who are receiving active treatment for non-Hodgkin lymphoma should be advised against becoming pregnant.

PRENATAL

Management depends on the histologic subtype and extent of disease (discussed previously).

POSTNATAL

Although data are limited, patients undergoing active treatment for non-Hodgkin lymphoma should be advised against breast-feeding.

MYELOPROLIFERATIVE DISORDERS

Essential Thrombocythemia

Diagnosis, Assessment, and Risks

Essential thrombocythemia is a myeloproliferative disorder that usually occurs in older age groups. Occasional cases complicating pregnancy are reported in the literature. Causes of reactive thrombocytosis are much more common and should be carefully excluded. Common causes of reactive thrombocytosis include iron deficiency, hemorrhage, infection, and inflammatory conditions. In essential thrombocythemia, the platelet count is consistently elevated in the absence of an apparent underlying cause. Approximately 50% of patients will have evidence of the JAK 2 mutation, and this may provide the diagnosis.[54] Bone marrow biopsy may have a characteristic appearance and cytogenetic studies should be performed to exclude CML. Essential thrombocythemia may be complicated by abnormal bleeding as a result of defective platelet function or by both arterial and venous thrombosis. The incidence of these complications in younger patients is unknown, and thrombosis in particular may be less common than in older age groups. The literature on pregnancy includes small series and case reports. Spontaneous abortion, intrauterine death, and intrauterine growth restriction are possible risks, due primarily to placental infarction.[38,39] However, other small series have reported good pregnancy outcomes in asymptomatic women.[40,41]

Management Options

If the patient is asymptomatic and the platelet count is only moderately increased, in the range of 400 to 600×10^9/L, an expectant approach is reasonable.[38] If thrombosis or hemorrhage occurs, however, treatment is necessary. Because of a reluctance to use cytotoxic agents in pregnancy, plateletpheresis has been used.[38] However, each pheresis is a short-term measure, and it may be practically difficult to achieve good long-term platelet control. If plateletpheresis is used, response may be assessed over a number of days initially and the intervals between phereses extended if possible. Subsequent management decisions should balance the pheresis interval against the degree of platelet control, and alternative treatment should be introduced if necessary. Aspirin may be used to treat thrombotic complications,[39] but may aggravate an underlying platelet function defect. Aspirin may have a role in patients with essential thrombocythemia and a history of previous pregnancy failure or growth restriction, but few data are available.[40] There are anecdotal reports of the use of hydroxyurea in essential thrombocythemia in pregnancy.[39] Most experience with this agent in pregnancy is with CML, when hydroxyurea has been used for prolonged periods. However, because teratogenicity is reported in animals, first-trimester use of hydroxyurea should ideally be avoided. The safety profile is good in the second and third trimesters. Interferon-alfa has been used successfully throughout pregnancy in patients with essential thrombocythemia, without adverse effects.[42,43] More data are needed on the safety of interferon-alfa in pregnancy, but reported experience is encouraging.[42,43] It may emerge as the agent of choice if treatment of essential thrombocythemia is necessary in a pregnant woman.

Similarly, data on the safety of anagrelide, a new agent used to treat essential thrombocythemia, are limited. This agent should currently be avoided in pregnancy, and alternative methods should be used to control the platelet count, when necessary.

Because data are inconsistent, increased fetal surveillance during pregnancy is appropriate, particularly if assessment of growth and umbilical artery Doppler recordings show intrauterine growth restriction and placental dysfunction.

Platelet dysfunction may lead to an increased risk of primary and secondary postpartum hemorrhage. Secondary hemorrhage is exacerbated by the risk of retained placental fragments from an infarcted placenta. Thrombosis prophylaxis in the puerperium should include compression stockings and early mobilization. Patients with uncontrolled platelet count or a previous history of thrombosis should be treated with low-molecular-weight heparin or equivalent according to unit protocol.

Polycythemia

Polycythemia occurs when hemoglobin, hematocrit, and the red cell mass are increased above the upper limit of normal for the patient's age and sex. Polycythemia may be relative or true. Relative, or stress, polycythemia occurs when plasma volume is reduced with no increase in the red cell mass. In true polycythemia, the red cell mass is greater than 32 mL/kg for women and 36 mL/kg for men. True polycythemia may be primary or secondary. Secondary polycythemia occurs in conditions associated with either chronic hypoxia or inappropriate erythropoietin production (e.g., renal cysts or tumors). Primary proliferative polycythemia, or polycythemia vera (PV), is characterized by proliferation of erythroid precursors in the bone marrow arising as a result of a clonal stem cell defect. Understanding of the pathogenesis of PV has been revolutionized by the demonstration of the JAK 2 mutation in approximately 95% of cases. PV is usually seen in older patients, but rare cases are described in women of childbearing age.[44]

The diagnosis of polycythemia is difficult during pregnancy because physiologic changes in plasma volume may decrease hemoglobin and hematocrit.[62] Further, isotopic techniques used to determine the red cell mass are contraindicated in pregnancy. However JAK 2 testing by molecular methods may now be used to diagnose PV with features such as splenomegaly, increased white cell, and platelet counts supporting the diagnosis. However, definitive testing and diagnosis may need to be postponed until after delivery. In women who have a high hematocrit in pregnancy, secondary causes should be excluded, particularly pulmonary disease leading to chronic hypoxia. Other causes such as renal tumor are much less likely to present in this way. If erythropoietin levels are available, a low level suggests primary rather than secondary polycythemia. However, erythropoietin levels increase physiologically during pregnancy,[45] and a normal or high level is difficult to interpret.

Preeclampsia and intrauterine growth restriction can be the result of failure of normal plasma volume expansion. In these conditions, the hematocrit may be relatively increased compared with levels in normal pregnancy, but an increase above the normal range in nonpregnant women usually does not occur.

Maternal and Fetal Risks

In a series of 13 pregnancies in 8 women with PV maternal outcome was good, but fetal outcome was adversely affected. Miscarriage, intra-uterine growth restriction, preterm delivery, and stillbirth were more common than expected.[44] The risk of pre-eclampsia may also be increased. A relationship between pregnancy outcome and maternal red cell count was suggested, but the numbers in this study were too small to allow firm conclusions to be drawn. In some patients, hematocrit values decreased significantly during pregnancy.

Management Options

Venesection may be performed to maintain the hematocrit below 0.45. Myelosuppressive therapy should be avoided but may be necessary in patients with associated marked thrombocytosis. Management principles are similar to those outlined for essential thrombocythemia. Thrombosis prophylaxis in the puerperium should include compression stockings and early mobilization. Peripartum treatment with subcutaneous low-molecular-weight heparin should be considered even in the absence of a previous history of thrombosis, although there are no data specific to this patient group.

SUMMARY OF MANAGEMENT OPTIONS
Myeloproliferative Disorders

Management Options	Evidence Quality and Recommendation	References
Essential Thrombocythemia		
Prenatal		
Provide expectant approach in asymptomatic patients with moderate elevation of platelets.	III/B	56–58
If the patient is symptomatic (thrombosis or bleeding), consider plateletpheresis.	III/B	55
Give low-dose aspirin if the patient has thrombosis; no evidence supports use in all cases.	III/B	56,57
Hydroxyurea has been used, but most experience is with chronic myeloid leukemia.	III/B	56
Limited experience with interferon-alfa.	III/B	59,60
Limited experience with anagrelide thus avoid.	—/GPP	—
Obtain serial fetal growth and umbilical artery Doppler recordings.	—/GPP	—
Labor and Delivery and Postnatal		
Maintain vigilance for PPH. Consider prophylactic low-molecular-weight heparin.	—/GPP	—
Polycythemia		
Prenatal		
Maintain vigilance for hypertensive disease.	III/B	61
Obtain serial fetal growth and umbilical artery Doppler recordings.	III/B	61
Some advocate regular venesection to keep hematocrit < 0.45.	IV/C	61
Labor and Delivery and Postnatal		
Maintain vigilance for PPH. Consider prophylactic low-molecular-weight heparin.	—/GPP	—

GPP, good practice point; PPH, primary postpartum hemorrhage.

Thrombocytopenia and Bleeding Disorders

ELIZABETH HELEN HORN and LUCY H. KEAN

THROMBOCYTOPENIA

Introduction

The normal range for peripheral blood platelet count in nonpregnant individuals is generally reported as 150 to 400 × 10⁹/L. If a low platelet count is seen on an automated complete blood count, spurious thrombocytopenia should be excluded. This phenomenon may occur because of a small clot in the blood sample or because of platelet clumping caused by the addition of the anticoagulant ethylenediaminetetraacetic acid (EDTA) to the sample. A repeat count for confirmation and examination of the peripheral blood film can ascertain whether the thrombocytopenia is genuine. If the blood film shows platelet clumps, a repeat complete blood count in a sample anticoagulated with citrate may resolve the problem.

Studies of platelet counts during normal pregnancy differed in their conclusions, with some suggesting no overall effect of pregnancy on platelet count[1–3] and others showing a modest reduction in late pregnancy.[4–6] One study of platelet counts in 6715 consecutive patients delivering in a single Canadian center showed that thrombocytopenia (platelet count < 150 × 10⁹/L) occurred in 7.6% of women, and most (65.1%) had no associated pathology.[7] From a practical point of view, any pregnant woman with a platelet count of less than 100 × 10⁹/L in pregnancy should undergo further clinical and laboratory assessment. All pregnant women with a platelet count less than 150 × 10⁹/L after 20 weeks' gestation should have blood pressure and urinalysis checked. In the absence of hypertension or proteinuria, no pathology is found in most women with mild thrombocytopenia at this stage of pregnancy.[8]

Causes of Thrombocytopenia in Pregnancy

Causes of thrombocytopenia in pregnancy are summarized in Table 40–1. They can be broadly divided into the following categories:
- Platelet destruction or consumption.
- Splenic sequestration of platelets.
- Failure of platelet production in the bone marrow.

Platelet destruction or consumption is much more common than bone marrow failure in obstetric practice.

Causes with management implications in pregnancy are discussed in detail.

Investigation of Thrombocytopenia in Pregnancy

As discussed earlier, spurious thrombocytopenia should first be excluded. In assessing pregnant women with genuine thrombocytopenia, close liaison is required between the obstetrician and the hematologist. Clinical assessment and examination of the blood film are the starting points in making a diagnosis. Documentation of previous platelet counts and the timing of development of thrombocytopenia are helpful.

For patients developing thrombocytopenia after 20 weeks' gestation, particular attention should be paid to blood pressure and urinalysis for protein. Renal and liver function should be assessed and the presence of any major obstetric complications such as HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome or acute fatty liver of pregnancy should be rapidly excluded. The peripheral blood film should be examined for red cell fragmentation, the presence of which suggests HELLP syndrome or another thrombotic microangiopathy. For the remainder of those patients who have developed mild thrombocytopenia after 20 weeks' gestation and who are clinically well and without abnormalities in the peripheral blood film, gestational thrombocytopenia is the likely diagnosis.[9]

More detailed clinical and laboratory assessment are required if the platelet count is less than 70 × 10⁹/L, if the blood film is abnormal, if thrombocytopenia occurs before 20 weeks' gestation, or if there is a previous history of thrombocytopenia or bleeding. In such patients who have a normal blood film, autoimmune thrombocytopenia (AITP) is the most likely diagnosis and is a diagnosis of exclusion[9]

In the history, the presence of current or previous bleeding problems should be noted. The clinical severity of any hemorrhagic problems should be assessed. Other medical or obstetric problems, a drug and alcohol history, and a recent transfusion history should be noted. For example, a history of recurrent miscarriage may suggest antiphospholipid syndrome. Risk factors for HIV and hepatitis B or C virus

Causes of Thrombocytopenia in Pregnancy

Platelet Consumption or Destruction
Gestational thrombocytopenia
Autoimmune thrombocytopenia
   Primary
   Secondary
Antiphospholipid syndrome
Systemic lupus erythematosus and connective tissue disorders
Drug-induced
HIV-associated
Other viral infection (e.g., Epstein-Barr virus)
Lymphoproliferative disorder
Nonimmune
Disseminated intravascular coagulation
Preeclampsia or HELLP syndrome
Thrombotic thrombocytopenia purpura or hemolytic uremic syndrome
Acute fatty liver of pregnancy
Large vascular malformations
Heparin-induced thrombocytopenia (rare in pregnancy)
Splenic Sequestration
Splenomegaly
Portal hypertension
Liver disease
Portal or hepatic vein thrombosis
Myeloproliferative disorders
Lymphoproliferative disorders
Storage disease (e.g., Gaucher's disease)
Infection (e.g., tropical splenomegaly or malaria)
Failure of Platelet Production
Bone marrow suppression
Drug-induced
Aplastic anemia
Paroxysmal nocturnal hemoglobinuria
Infection (e.g., parvovirus B19)
Bone marrow infiltration
Hematologic malignancy
Nonhematologic malignancy
Severe vitamin B_{12} or folate deficiency

HELLP, hemolysis, elevated liver enzymes, and low platelets.

(HCV) should be assessed. Enquiry should be made regarding a family history of hemorrhagic problems.

On examination, important features include petechiae and signs of mucosal bleeding. The clinician should look for clinical features that suggest underlying autoimmune disease or chronic liver disease and should exclude splenomegaly.

Careful examination of the blood film is mandatory because it may give important clues to the diagnosis. For example, red cell fragmentation narrows the differential diagnosis to thrombotic microangiopathies (discussed later) (Table 40–2). Hypersegmented neutrophils and oval macrocytes suggest folate deficiency, and other red and white cell abnormalities may suggest underlying bone marrow disease. In gestational thrombocytopenia and AITP, the blood film

is normal except for the apparent reduction in platelet count. Renal and liver function should be routinely checked.

After initial assessment, further tests may be indicated, including antinuclear factor, specific tests for lupus anticoagulant and anticardiolipin antibodies, or tests for the diagnosis and typing of von Willebrand's disease (vWD). The lactate dehydrogenase level is usually elevated in microangiopathic hemolysis. The results of coagulation screening tests and D-dimer may be abnormal in thrombocytopenia associated with consumptive coagulopathy. The serum urate level may be increased in preeclampsia, HELLP syndrome, or acute fatty liver of pregnancy. Bone marrow examination is necessary only when features suggest underlying bone marrow disease. However, bone marrow examination should be carried out in AITP if the patient fails to respond to first-line therapy.[8]

Platelet antibody testing is of little value both diagnostically and prognostically in suspected cases of AITP.[8,10–12] In cases of suspected thrombotic thrombocytopenic purpura (TTP), some specialized laboratories carry out assays of ADAMTS 13 activity. ADAMTS 13 (discussed later) is a plasma von Willebrand's factor (vWf)–cleaving protease whose activity is reduced in most cases of primary idiopathic TTP.[13]

Gestational Thrombocytopenia

Gestational thrombocytopenia, or incidental thrombocytopenia of pregnancy, accounts for approximately 70% of cases of maternal thrombocytopenia at delivery.[7,14] The cause is unknown. There is evidence of a degree of physiologic platelet activation in vivo during pregnancy; platelet life span is reduced, and the site of platelet activation is believed to be the placental circulation.[15,16] These mechanisms and hemodilution may contribute to gestational thrombocytopenia.[9]

Gestational thrombocytopenia usually develops in the third trimester and is usually mild to moderate. Results of other studies are normal. The platelet count is usually greater than 80×10^9/L, but counts of 40 to 50×10^9/L can occasionally occur due to gestational thrombocytopenia.[7,17,18] The platelet count rapidly returns to normal after delivery, usually within 7 days.[7,17] Gestational thrombocytopenia is a diagnosis of exclusion. Antenatally, it can be difficult to distinguish from mild AITP. The diagnosis is suggested by a late decrease in platelet count in a patient with no history of previous thrombocytopenia outside of pregnancy. One group of investigators attempted to define predictors of AITP versus gestational thrombocytopenia in pregnancy. They reported that the detection of thrombocytopenia before 28 weeks' gestation and a platelet count less than 50 $\times 10^9$/L were independently predictive of AITP.[19] Certainty often rests on observations of platelet counts in the puerperium.

Maternal and Fetal Risks

Gestational thrombocytopenia has no pathologic significance for the mother or fetus.[7,8,14,17,18,20] If AITP cannot be excluded, a potential concern is the transfer of antiplatelet antibodies across the placenta, leading to fetal and neonatal thrombocytopenia. However, neonatal thrombocytopenia is uncommon in women in whom thrombocytopenia is

TABLE 40–2

Variation in the Features and Management of Thrombotic Microangiopathic Hemolytic Anemia

DIAGNOSIS	TTP	POSTPARTUM HEMOLYTIC UREMIC SYNDROME	HELLP SYNDROME	PREECLAMPSIA OR ECLAMPSIA

incidentally detected in pregnancy and in whom there is no history of AITP. The incidence of neonatal thrombocytopenia in these patients is approximately 4%,[18,21] which is not statistically different from the incidence of thrombocytopenia in infants of nonthrombocytopenic mothers. Further, no infants in these studies had cord platelet counts less than 50 $\times 10^9$/L, and none had clinical hemostatic impairment.[18,21]

Management Options

PREPREGNANCY AND PRENATAL

If a woman with previous gestational thrombocytopenia seeks prepregnancy counseling, the most important issue is the exclusion of alternative diagnoses. This is also the case when thrombocytopenia is detected incidentally in the antenatal period. The maternal platelet count should be monitored at a frequency determined by the platelet count, rate of decline, and expected date of delivery.[8] No treatment is necessary for gestational thrombocytopenia. Invasive approaches to fetal monitoring, such as fetal blood sampling to determine the fetal platelet count, are not indicated because the risks are not justifiable (discussed later).[8,20]

LABOR AND DELIVERY

Because the fetus is not at risk for hemorrhage, the mode of delivery is determined by obstetric considerations, and invasive fetal blood sampling to determine the fetal platelet count is not indicated. Although there is no evidence that gestational thrombocytopenia is associated with a risk of maternal bleeding, most anesthetists would not contemplate the use of regional analgesia if the platelet count was below 80 $\times 10^9$/L.[8] If AITP has not been excluded, management options for labor and delivery are the same as those for AITP.[8]

POSTNATAL

If it is difficult to distinguish between gestational thrombocytopenia and AITP, management of the infant should be the same as in maternal AITP (discussed later). Maternal platelet counts should also be followed postnatally. A rapid return to normal confirms the diagnosis of gestational thrombocytopenia, whereas continued thrombocytopenia after pregnancy should prompt reassessment of the patient.

Autoimmune Thrombocytopenia

AITP is relatively common in women of childbearing age. AITP occurs in approximately 0.14% of pregnant women at delivery and accounts for 3% of cases of thrombocytopenia at that time.[17] AITP is the most common cause of thrombocytopenia in the first trimester of pregnancy.[9]

AITP is caused by autoantibodies, which are usually directed against platelet surface glycoproteins, particularly glycoprotein IIb/IIIa and glycoprotein Ib/IX.[22,23] These antibodies adhere to the platelet membrane, causing platelet destruction through Fc receptors in the reticuloendothelial system. The major site of platelet destruction is usually the spleen. AITP may cause purpura and self-limiting mucosal bleeding. This pattern of acute AITP, often after a viral infection, is most commonly seen in children. Conversely, AITP in adults is usually chronic. The symptoms are variable and often insidious. Although fluctuations in the platelet count may occur, the condition is not self-limiting, and continuing thrombocytopenia is the usual course. Chronic AITP may be asymptomatic and may be found by routine testing, such as the testing that is performed during pregnancy.

AITP may be primary or idiopathic or may be secondary to another disorder (see Table 40–1). In primary AITP, if the thrombocytopenia is severe, the clinical examination may show purpura, bruising, or signs of mucosal bleeding, but findings are otherwise normal. Other than a reduced platelet count, findings on the blood film are normal, and the bone marrow is normal, with normal or increased numbers of megakaryocytes. As noted previously, bone marrow examination is no longer routinely recommended in AITP. In primary or idiopathic AITP, all other test results

are normal. Secondary causes of AITP may be associated with antinuclear antibodies or increased levels of antiphospholipid antibodies. HIV and HCV testing should be offered in all cases.

Neither assays of platelet-associated immunoglobulin G (IgG) nor assays of glycoprotein-specific antibodies are reliable as diagnostic tools in suspected AITP.[23] Further, no assay of platelet antibodies has predictive value for maternal or fetal outcome.[8,10–12]

Maternal Risks

The risk of maternal bleeding has generally been thought to relate to the severity of thrombocytopenia. In AITP, clinical bleeding is often less severe for a given platelet count than in conditions in which thrombocytopenia is caused by an underlying bone marrow disorder.

Women with severe thrombocytopenia (platelet count $< 20 \times 10^9/L$) are at risk for spontaneous bleeding antenatally as well as at delivery, and they generally require treatment. Women with platelet counts less than $50 \times 10^9/L$ may be at risk for increased bleeding at delivery[8,24,25]; therefore, treatment may be required in late pregnancy to ensure a safe platelet count for delivery in asymptomatic women. Both British[8] and American[24] guidelines suggest that a platelet count greater than $50 \times 10^9/L$ is safe for a vaginal delivery. British guidelines suggest aiming for a platelet count above $80 \times 10^9/L$ for cesarean section,[8] whereas American guidelines considered a platelet count greater than $50 \times 10^9/L$ was suitable for all modes of delivery.[24] A platelet count of greater than $80 \times 10^9/L$ is recommended for epidural anesthesia by the British Committee for Standards in Haematology (BCSH).[8] These figures are generally accepted by clinicians but are somewhat arbitrary.

A retrospective series of 119 pregnancies in 92 women with AITP reported a 21% incidence of bleeding in pregnancy. Bleeding was uncommon at delivery and was not correlated with the platelet count, even although 15% of women had a platelet count less than $50 \times 10^9/L$.[26] Another observational series showed that bleeding at delivery was increased in women with platelet counts less than $50 \times 10^9/L$ who underwent cesarean section but not vaginal delivery.[25,27] There is no evidence that bleeding time is helpful in predicting hemorrhagic problems in AITP.

Fetal Risks

In mothers with AITP, IgG antiplatelet antibodies may cross the placenta and cause fetal thrombocytopenia, resulting in fetal or neonatal bleeding. Maternal findings, such as platelet count and platelet-associated IgG level, are of no value in predicting fetal thrombocytopenia.[11,28,29] It has been suggested that the only clear predictor of neonatal thrombocytopenia in pregnant women with thrombocytopenia is a history of AITP, and even then, the incidence of neonatal bleeding is low (<2%).[18] Limited data suggest that in women with AITP, the outcome of a previous pregnancy with respect to neonatal thrombocytopenia is a reasonable guide to the likely outcome of a current pregnancy, if there have been no significant changes in the course or management of AITP in the mother.[10,30]

In the early 1990s, large prospective studies helped to clarify that in maternal AITP, the risk to the fetus and neonate of bleeding as a result of thrombocytopenia is

extremely low. In these and subsequent studies, the overall incidence of fetal or neonatal thrombocytopenia was 10% to 30%, but severe thrombocytopenia was less common and intracranial hemorrhage was rare.[10,14,18,29] The largest study,[14] which was conducted over 7 years and included more than 15,000 mothers and infants, showed that among 46 mothers with AITP, 4 (8.7%) neonates had cord platelet counts of 20 to $50 \times 10^9/L$. No infant whose mother had AITP had a platelet count of less than $20 \times 10^9/L$, and none had an adverse outcome. In 3 of the 4 cases, delivery was vaginal.[14] In this study, all of the neonates with clinically severe bleeding had alloimmune thrombocytopenia (see Chapter 15). Another study showed that 18 of 88 neonates (20%) born to women with AITP before the index pregnancy had platelet counts of less than $50 \times 10^9/L$. Five had clinically important bleeding, and 2 of these had intracranial hemorrhage.[18] Other studies confirm an approximate 20% incidence of neonatal thrombocytopenia in infants of mothers with AITP,[26,27] and that major neonatal bleeding, including intracranial hemorrhage is uncommon.

Another salient point is the time course of thrombocytopenia and bleeding complications in the fetus and neonate in a pregnancy affected by AITP. Bleeding in utero in maternal AITP is rare.[31] Other studies concluded that after birth, the platelet count continues to decrease in affected neonates, reaching a nadir 2 to 5 days after delivery.[11]

Management Options

PREPREGNANCY

In general, pregnancy does not affect the clinical course of AITP; however, there is anecdotal evidence of worsening of AITP during pregnancy, with improvement after delivery.[32]

In women known to have AITP before pregnancy, therapy should be optimized before pregnancy is planned. The advent of several new treatments for AITP has opened up more management options, but management for most patients continues to be with well-established treatments. Most treatment in AITP is aimed at reducing immune destruction of platelets. Steroids or intravenous immunoglobulin (IVIG) is the usual initial treatment, but neither is curative.[33,34] Splenectomy is the most commonly used second-line treatment in patients who continue to have clinical symptoms following treatment with steroids. Sixty-six percent of patients have a complete remission following splenectomy,[34] which is durable in the majority. A proportion of others have a very useful partial response.[33] In patients with chronic AITP, decisions about splenectomy are best made before the patient becomes pregnant.

More recently, anti-D immunoglobulin has been used as first- or second-line treatment (as an alternative to IVIG) in patients who are RhD-positive. Its efficacy is limited to patients who have not been splenectomized.[33] The mechanism of action is thought to be via preferential removal of antibody-coated red cells via the reticuloendothelial system. Patients who respond to anti-D may be given maintenance treatment, which may be limited by anemia. Treatment with anti-D may postpone the need for splenectomy, but this treatment is unlikely to lead to long-term remission.[34]

A small number of women of childbearing age have refractory AITP. A wide range of treatments have been used in

refractory AITP, most of which act as immunosuppressants.[33,34] These include azathioprine, cyclosporine, mycophenolate mofetil, danazol, cyclophosphamide, vinca alkaloids, and more recently, an anti-CD20 monoclonal antibody (rituximab).[35,36]

There are no randomized, controlled trials of any of these agents in refractory AITP. The evidence for their use comes from case series. Many patients with refractory AITP have been treated with the anti-CD20 monoclonal antibody, and it is generally well tolerated. Case series data suggest rates of response of 40% to 50%.[35,36] Sustained responses have been reported, and treatment may be successfully repeated if relapse occurs in previous responders.[37,38] Adverse effects include anaphylactoid reactions, serum sickness, infections and rarely, progressive multifocal leucoencephalopathy.[36,39] There has been debate about whether this treatment may be used as second-line therapy as an alternative to splenectomy.[38] It is not yet recommended that this should be routine practice, but second-line use of anti-CD20 antibodies is acceptable in patients who decline splenectomy or who are unfit for surgery. A further important advance in the treatment of AITP has been made. Thrombopoietin receptor agonists have been shown in randomized, controlled trials to be effective in increasing the platelet count in patients with refractory AITP.[40] One of these agents (eltrombopag) has been granted a limited license for treatment of AITP by the U.S. Food and Drug Administration (FDA). The platelet count falls when the drug is stopped. The future use of these agents is, therefore, likely to be confined to situations in which the platelet count needs to be temporarily increased (e.g., for surgery) or for symptomatic patients refractory to other treatments.

Many third-line agents used for the treatment of AITP should be avoided in pregnancy, and women of childbearing age requiring such treatment should generally be advised to use effective contraception. Until recently, azathioprine was the most commonly used third-line agent for women with AITP who wished to become pregnant. There is considerable experience of the safe use of azathioprine in pregnancy in clinical settings other than AITP.[41,42] In more recent years, many clinicians prefer to attempt to induce a response in AITP with the anti-CD20 monoclonal antibody rituximab, given as a course of four treatments at weekly intervals.[34,36] There are reports of successful outcome of pregnancy following antenatal administration of this treatment.[43,44] It would be preferable, however, to use this agent in advance of pregnancy, to advise contraception at the time of use, and also to allow time to assess the response. There are as yet no safety data for thrombopoietin (TPO) agonists in pregnancy; these agents should, therefore, be avoided in women planning pregnancy.

In summary, the aim of prepregnancy management of symptomatic AITP is to achieve a sustained improvement in platelet count in order to reduce hemorrhagic risk, using the least-toxic therapies.

The potential hazards of AITP and its treatment in pregnancy must be individually assessed, and patients should be counseled carefully. Prepregnancy counseling should cover the risk of bleeding for the mother and fetus and the risks of various treatment options in pregnancy. For very few women with severe refractory AITP, pregnancy may be hazardous and should be avoided.

PRENATAL

In the prenatal period, the aims of management are
* To treat maternal symptoms of hemorrhage at any stage of pregnancy.
* To achieve a safe platelet count for delivery.

There is no evidence that any available modalities of treatment administered to the mother affect the platelet count in the fetus or neonate.[25] The frequency of monitoring of platelet counts should be based on the initial count and the rate of any decline. Closer surveillance is required in the last trimester to ensure a safe count for delivery. Treatment is generally required in symptomatic patients if the maternal platelet count is less than 20×10^9/L.[8,25] Treatment is also often given in late pregnancy, in the absence of symptoms, to raise the platelet count to 50×10^9/L or more for delivery.[8,24,25]

Principal options for the treatment of AITP in pregnancy include corticosteroids and high-dose IVIG. Conventionally, steroids are used by many as the first-line treatment. When steroid therapy is chosen, prednisolone is usually given initially at a dose of 1 mg/kg daily (based on nonpregnant body weight). A response is obtained in most patients, allowing the dose to be tapered gradually to achieve the minimum dose at which a safe platelet count is achieved. Potential disadvantages of steroid therapy during pregnancy are the precipitation or exacerbation of hypertension, excessive weight gain, gestational diabetes, osteoporosis, and psychiatric disorders.[8,24,25] These considerations are particularly relevant when prolonged therapy is required and when high doses are needed to control symptoms. From the fetal point of view, corticosteroids are not teratogenic. Fetal adrenal suppression is unlikely because prednisolone is extensively metabolized in the placenta.[45]

Concerns about potential adverse maternal effects of steroids have led some to use IVIG as first-line therapy in pregnancy.[17,24,25] Others reserve this treatment for patients who do not respond to steroids and for those in whom the maintenance dose of steroids is unacceptably high. IVIG is usually given in doses of 1 g/kg daily for 1 or 2 days.

This regimen increases the platelet count in most cases, but the response to immunoglobulin is temporary in adult AITP. On average, responses are seen by the fifth day of infusion, with a peak response occurring approximately 4 to 5 days after the end of the infusion.[46] Responses tend to be sustained for only 2 to 4 weeks,[24] but the duration of response is extremely variable.[46] When IVIG is used to increase the platelet count before delivery, treatment is initiated approximately 7 to 10 days before delivery is planned. In mothers who need treatment for symptomatic AITP, courses of IVIG may be repeated at intervals to prevent symptoms and ensure a safe platelet count for delivery. One study outside the context of pregnancy showed that approximately one third of patients who require repeated infusions eventually stop responding to immunoglobulin.[47]

IVIG is a pooled blood product. IVIG preparations that have been virally inactivated have an excellent safety record, but the risk of transfusion-transmitted infection cannot be completely excluded.[8,48]

Other adverse effects include allergic reactions, and occasional cases of anaphylaxis have occurred in IgA-deficient patients. Aseptic meningitis is well documented, and there are a few reports of thrombotic complications, mainly in

elderly patients.[48] Renal failure may be precipitated by IVIG preparations with a high sucrose content.[49] IVIG is well tolerated in most patients. Other adverse effects tend to be mild.[48]

The placenta contains Fc receptors; therefore, immunoglobulins can cross the placenta. This finding led to hopes that maternal treatment with high-dose IVIG would improve the fetal platelet count.[50,51] There are no controlled studies, but fetal and neonatal thrombocytopenia have been reported following maternal use of IVIG.[48] Evidence does not show a substantial effect of IVIG on fetal platelet counts in maternal AITP, in contrast to fetal alloimmune thrombocytopenia, in which treatment with IVIG is now the first-line management for maintenance of fetal platelet counts.

Patients with severe hemorrhage associated with profound thrombocytopenia require aggressive management. Although platelet transfusion has little efficacy prophylactically in AITP, platelets should be administered in large doses to patients with life-threatening bleeding.[8] Options for further management in severely hemorrhagic patients include intravenous methylprednisolone and IVIG.[8,24] IVIG was shown in one study to be more effective than methylprednisolone in leading to a rapid increase in platelet count in recently diagnosed AITP.[52]

If a pregnant woman with AITP does not respond to standard treatment with steroids and IVIG, decisions about further therapy must be considered. Factors such as gestation and hemorrhagic symptoms should be taken into account. If the woman is not hemorrhagic, an observant approach is the best option. Platelet transfusion may be required at delivery, even if the patient is asymptomatic prenatally. If the patient is hemorrhagic antenatally, several options are available, but supporting evidence is anecdotal. Splenectomy may be carried out in pregnancy, preferably in the second trimester.[53] Splenectomy is commonly performed laparoscopically in nonpregnant patients. In pregnancy, the laparoscopic approach is also preferable and is technically feasible up to 20 weeks.[54] The enlarging uterus, however, may cause difficulties with laparoscopic splenectomy after 20 weeks' gestation. Conventional splenectomy in the third trimester may precipitate premature labor, but in some cases, when the fetus is mature, splenectomy may be combined with cesarean delivery in late pregnancy.[53] Approximately two thirds of patients have a useful response to splenectomy. Prophylaxis against infections with organisms such as pneumococci, *Haemophilus*, and *Neisseria meningitidis* is necessary. When splenectomy is performed during pregnancy, penicillin V prophylaxis should be given in the prenatal period, and vaccination against these organisms should be performed postnatally.

Many of the other therapies discussed in the "Prepregnancy" section ealier are contraindicated in pregnancy. Azathioprine is probably the treatment with most experience in pregnancy. Use in renal transplant recipients suggests that teratogenicity is rare in humans, but intrauterine growth restriction may occur.[41,42]

Anecdotal reports exist of successful use of anti-D[55] and of rituximab in pregnancy.[43,44,56,57] Anti-D was associated with a positive direct antiglobulin test in some neonates, none of whom was anemic or jaundiced.[55] Rituximab crossed the placenta and was associated with a temporary reduction in numbers of B cells in the neonate, but no clinical consequences apparently resulted.[43] Until further studies are available, use of these agents in pregnancy should be restricted to refractory cases in which alternatives are unsuitable or have failed.

Collaboration with an obstetric anesthetist in the third trimester is necessary for all women with platelet counts low enough to affect management of delivery. Regional analgesia is usually ruled out for women with a platelet count below 80×10^9/L.[8,24,25] Alternatives to regional analgesia, such as patient-controlled analgesia, can be offered when epidural analgesia is considered unsafe.

LABOR AND DELIVERY

From the maternal point of view, when possible, vaginal delivery is preferred in mothers affected by AITP.[8,25] If the maternal platelet count remains low at the time of delivery, despite optimal antenatal treatment, and hemorrhagic complications result, platelet transfusion may be required to treat maternal bleeding. Platelets should be available for women who have a platelet count less than 50×10^9/L at delivery, but platelet transfusion given for purely prophylactic reasons is unnecessary and ineffective. For women who have experienced hemorrhage around the time of delivery, the administration of IVIG should be considered with the aim of rapidly improving the platelet count over the next few days to minimize risk of primary postpartum hemorrhage (PPH).

Epidural anesthesia should be avoided if the platelet count is less than 80×10^9/L,[8] although there is little concrete supporting evidence.

Thrombocytopenic women are at risk of bleeding from surgical incisions. Judicious administration of platelets during operative procedures is reasonable in women with severe thrombocytopenia.[24] As discussed earlier, large, well-conducted studies show that the risk to the fetus and neonate of bleeding as a result of thrombocytopenia is low in maternal AITP.[14,18] No maternal findings are of value in predicting fetal thrombocytopenia. There is no role for measuring fetal platelet count in late pregnancy or during labor. Fetal scalp sampling is often inaccurate and can cause significant scalp bleeding or hematoma formation in thrombocytopenic fetuses. Intrauterine fetal blood sampling cannot be justified as a routine practice in maternal AITP because the associated risks outweigh the risk of serious fetal hemorrhage.[8,10]

In AITP, it was previously assumed that cesarean section may protect the fetus from bleeding as a result of head trauma. However, no difference was seen between vaginal delivery and cesarean section in bleeding complications in 474 infants born to mothers with AITP.[58] Because the nadir of the platelet count often occurs several days after delivery, peripartum events may not have a major effect on neonatal bleeding complications.[59]

The low incidence of neonatal bleeding in modern studies and the data on the mode of delivery and time course of thrombocytopenia support a conservative approach to the management of the fetus in pregnancies complicated by AITP, both antenatally and during labor and delivery. Traumatic delivery, delivery by Ventouse extraction, and the use of midcavity rotational forceps should be avoided. Decisions about cesarean section should be made on obstetric grounds, without determining the fetal platelet count. Most authors recommend avoiding the use of fetal scalp electrodes and scalp blood sampling to determine acid-base status.[8]

POSTNATAL

Mothers with thrombocytopenia are unlikely to bleed from the uterine cavity after the third stage of labor, provided that there are no retained products of conception. However, bleeding may occur from surgical wounds, episiotomies, or perineal tears. Prompt suturing and close observation of these sites are required. Immediately after delivery, a cord blood sample should be taken. If the infant is thrombocytopenic but not hemorrhagic, a complete blood count should be repeated over the next few days because the platelet count often continues to decrease, reaching a nadir between days 2 and 5.[8] If the infant has signs of skin or mucosal bleeding or has severe thrombocytopenia (platelet count $< 20 \times 10^9$/L, or $< 50 \times 10^9$/L in a premature sick neonate), cranial ultrasound should be considered and treatment instituted. IVIG 1 g/kg is the preferred treatment in neonates[8,10] and increases the platelet count in most infants affected by maternal AITP. Platelet transfusion is rarely necessary, but is indicated if bleeding is life-threatening (e.g., intracranial hemorrhage). Products that are known to be cytomegalovirus-negative should be used.[60] Preterm infants with very low birth weight (<1.5 kg) are at greater risk for transfusion-transmitted cytomegalovirus infection than are healthy term infants.

AITP should not exclude women from consideration for peripartum thrombosis prophylaxis. Risk assessment should be carried out and consideration given to constitutional and acquired thrombotic risk factors as well as the risk of bleeding. Prophylactic doses of low-molecular-weight heparin (LMWH) are generally safe if the platelet count is greater than 50×10^9/L.[8] Graduated compression stockings may be used for women who require specific thrombosis prophylaxis if the platelet count is less than 50×10^9/L. Nonsteroidal anti-inflammatory drugs should be avoided for maternal postpartum analgesia.

SUMMARY OF MANAGEMENT OPTIONS
Autoimmune Thrombocytopenia

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Optimize management and consider splenectomy.	—/GPP	—
Discuss risks in pregnancy if the patient is refractory to treatment.	—/GPP	—
Prenatal		
Monitor platelet count (frequency determined by initial values).	IV/C	8,24,25
Treat if symptoms occur or platelet count $<20 \times 10^9$/L at any stage in pregnancy.	IV/C	8,24,25
Treat if $<50 \times 10^9$/L in late pregnancy even if the patient is asymptomatic:	IV/C	8,24,25
• Treatment option 1: Prednisolone. Debate whether to use as first-line therapy vs. IVIG.	IV/C (Ib for nonpregnant adults)	8,24,25 34*
• Treatment option 2: High-dose IVIG.	IV/C (Ib for nonpregnant adults)	8,24,25 34*
• Treatment option 3: Splenectomy may be performed in refractory cases in the second trimester or occasionally in the third trimester at the time of cesarean section.	IV/C (III for nonpregnant adults)	54
• Treatment option 4: Rituximab or anti-D. For severe cases unresponsive to steroids/IVIG as an alternative to splenectomy.	IV/C (III for nonpregnant adults)	34–38*, 43,44,55
• Treatment option 5: Azathioprine (slow onset of action) may be used in nonresponsive cases. It is safe in pregnancy but beware of IUGR.	IV/C (III for nonpregnant adults)	34*,41,42
Inform anesthetists and pediatricians of impending delivery.	—/GPP	—

SUMMARY OF MANAGEMENT OPTIONS
Autoimmune Thrombocytopenia—cont'd

Management Options	Evidence Quality and Recommendation	References
Labor and Delivery		
Platelets should be available if count $<50 \times 10^9/L$, but use only if the patient is bleeding.	IV/C	8,24
Avoid epidural if platelet count $<80 \times 10^9/L$.	IV/C	8
Avoid traumatic delivery, fetal scalp electrodes, and fetal blood sampling.	IV/C	8,10
Cesarean delivery has no benefit over vaginal delivery.	IV/C	8,25
Postnatal		
Because of the risk of bleeding, repair perineal trauma promptly.	—/GPP	—
Obtain a cord blood platelet count.	IV/C	8,24,25
Obtain a platelet count daily for a few days if count is initially low (nadir = days 2–5).	IV/C	8,24,25
If neonatal count $<20 \times 10^9/L$ or symptoms occur, perform ultrasound scan of brain and treat with IVIG.	IV/C	8,24,25
Administer platelets if bleeding is life-threatening.	IV/C	8,24,25

* Refers to evidence in nonpregnant adults.
GPP, good practice point; IUGR, intrauterine growth restriction; IVIG, intravenous immune globulin.

Special Considerations in Secondary Autoimmune Thrombocytopenia: Risks and Management Options

Antiphospholipid Syndrome (See Chapter 43)

Primary antiphospholipid syndrome (APL) includes the reproducible presence of antiphospholipid antibodies (either lupus anticoagulant or anticardiolipin antibody) and one of the following clinical features: venous thrombosis, arterial thrombosis, and fetal loss (recurrent if <10 weeks' gestation).[61]

Thrombocytopenia is not a diagnosis-defining criterion for antiphospholipid syndrome.[61] However, antiphospholipid antibodies are frequently found in patients with AITP,[62] and 20% to 40% of patients with primary antiphospholipid syndrome are thrombocytopenic.[63] In these cases, thrombocytopenia is autoimmune.[63] Antiphospholipid antibodies are probably not the cause of the immune platelet destruction. In some cases, platelet consumption mediated by antiphospholipid antibody–induced platelet activation may contribute.[62]

Outside the context of pregnancy, responses to the treatment of immune thrombocytopenia are similar in patients with and without antiphospholipid antibodies.[64] There is debate about whether the incidental finding of positive antiphospholipid antibodies in a patient with thrombocytopenia leads to an increased risk of thrombosis.[65,66] A panel of experts in antiphospholipid syndrome have suggested that patients with AITP and antiphospholipid antibodies require closer follow-up, because they may be at risk of future thrombotic events, and that these patients should be regarded as having "associated thrombocytopenia."[61]

Management options during pregnancy are similar to those for primary AITP. However, if the patient meets criteria for a diagnosis of primary antiphospholipid syndrome, there are other implications for pregnancy. In addition to recurrent spontaneous abortion, women with antiphospholipid syndrome are at risk for other complications, such as intrauterine fetal death, intrauterine fetal growth restriction, preeclampsia, and maternal thrombosis.[67–70] The mechanism of fetal loss is complex. Thrombosis in the placental vasculature is a contributory factor, but there is also evidence of inadequate trophoblastic invasion, induced by antiphospholipid antibodies.[71,72]

A combination of low-dose aspirin and prophylactic heparin is helpful in preventing recurrent spontaneous abortions in antiphospholipid syndrome.[73] Moderate thrombocytopenia should not alter decisions about antiplatelet or antithrombotic therapy in antiphospholipid syndrome.[63] In

patients who have more marked thrombocytopenia, decisions should be made on an individual basis, taking account of the risks and potential benefits of various management options.

Close maternal supervision and fetal monitoring are required antenatally. Antenatal and postnatal thromboprophylaxis is indicated in women with antiphospholipid syndrome and a history of thrombosis.[74,75] As discussed previously, thrombocytopenia should not necessarily preclude this, and the balance of risks should be assessed individually (see Chapter 43).

Systemic Lupus Erythematosus (See Chapter 43)

Immune platelet destruction may occur in systemic lupus erythematosus (SLE) because of antiplatelet antibodies or immune complexes. Thrombocytopenia is not usually severe, but if treatment is required, patients may respond to immunosuppression used for other manifestations of SLE. Otherwise, management is governed by the principles outlined for primary AITP. Thrombocytopenia has been shown to be associated with an increased likelihood of end-organ damage in SLE.[76] Women with SLE are also at risk for preeclampsia, which may be complicated by thrombocytopenia. Other management issues are discussed in Chapter 43.

HIV-Associated Thrombocytopenia (See Chapter 28)

Thrombocytopenia may be associated with HIV infection. A survey of HIV-positive pregnant women showed that 3.2% were thrombocytopenic, and in most cases, thrombocytopenia was believed to be directly related to HIV infection. Slightly fewer than half of the thrombocytopenic women in this series had platelet counts less than 50×10^9/L, and 20% had hemorrhagic complications. Of 28 infants, only 1 had thrombocytopenia.[77]

Thrombocytopenia associated with HIV is multifactorial. In advanced disease, drugs and infection may lead to marrow dysfunction that results in thrombocytopenia. However, thrombocytopenia is relatively common in otherwise-asymptomatic HIV-positive individuals. Immune platelet destruction by antiplatelet antibodies or immune complexes and the formation of antibodies that cross-react with the HIV virus and platelets are likely mechanisms of thrombocytopenia in these patients.[62,78] Thrombotic thrombocytopenic purpura (TTP; discussed later) may also be associated with HIV.[79]

Suppression of viral replication by antiretroviral therapy increases the platelet count in HIV-positive patients with thrombocytopenia. Combinations of antiretroviral drugs are much more effective at suppressing HIV viral load than is monotherapy, and treatment is usually unaltered in pregnancy.[80] All patients with HIV-associated thrombocytopenia should receive treatment with highly active antiretroviral therapy (HAART).[62,81]

Careful evaluation of trends in platelet counts that correspond to changes in therapy and viral load is helpful in assessing thrombocytopenia in HIV-infected patients. Blood film examination (for red cell fragmentation associated with TTP and other cytopenias that may be associated with disease, infection, or therapy) and bone marrow examination

to assess whether thrombocytopenia is caused by peripheral consumption may be useful in selected cases, especially if the platelet count does not improve with HAART.

When immune destruction is believed to be a significant component of thrombocytopenia, and the thrombocytopenia does not respond to HAART, IVIG may be required to treat hemorrhagic symptoms or to increase the platelet count before delivery in thrombocytopenic HIV-positive women.[77] Corticosteroids are also effective in HIV-associated immune thrombocytopenia, but prednisolone is associated with oral candidiasis and reactivation of herpes simplex.[78] Many physicians avoid the use of steroids because of the risk of further immunosuppression and infection. Issues related to the management of labor and delivery in HIV-positive women are covered in Chapter 28.

Thrombocytopenia Associated with Hepatitis C Infection

HCV infection has been reported in 10% to 30% of patients diagnosed clinically as AITP.[62,82] HCV testing should be considered in all patients with apparent AITP, and testing is definitely indicated in those with risk factors for HCV. Immune mechanisms may contribute to the etiology. Thrombocytopenia may respond to steroids in such patients, but steroids have been associated with an increase in transaminases and viral load.[62] Treatment should primarily be directed at the HCV. The thrombocytopenia is likely to respond to anti-HCV treatment. In women of childbearing age, this should be carried out prior to pregnancy and women should be advised to use contraception. IVIG or anti-D may also be helpful if thrombocytopenia remains problematic.[62] Recognition is important because of these differences in management. Furthermore, the knowledge that a woman is HCV polymerase chain reaction (PCR)–positive may influence management options around the time of delivery (see Chapter 27).

Drug-Induced Thrombocytopenia

Drugs may cause thrombocytopenia through immune destruction or through suppression of platelet production in the bone marrow. Both are uncommon in pregnancy, but drug-induced causes should be considered and excluded.

One type of drug-induced thrombocytopenia merits further discussion. Heparin-induced thrombocytopenia (HIT) occurs in 1% to 5% of patients receiving unfractionated heparin (UFH). HIT is caused by an antibody directed against the heparin-platelet factor 4 complex, which can induce platelet activation and aggregation in vivo.[83] The mechanism of thrombocytopenia, therefore, differs from classic immune destruction in the reticuloendothelial system. HIT also differs from many other drug-induced thrombocytopenias because the platelet activation induced in HIT is associated with thrombosis and not with bleeding. Thrombosis in HIT may be venous or arterial and may be life-threatening.[83]

The incidence of HIT in patients treated with LMWH is considerably lower than that in patients treated with UFH.[84] Cross-reactivity of antibodies is common, and low-molecular-weight agents are not suitable once HIT has occurred.[85] HIT has been reported in pregnancy,[86,87] although it is considerably less common in pregnant than in nonpregnant

individuals.[88] Fetal thrombocytopenia does not occur because heparin does not cross the placenta.

Heparin should be withdrawn immediately on clinical suspicion of HIT. Laboratory tests are available to confirm the diagnosis. The heparinoid danaparoid may be used as an alternative anticoagulant when HIT is diagnosed.[89] Danaparoid has been used successfully to treat HIT in pregnancy.[87] Hirudin is an alternative in nonpregnant patients, but experience is limited in pregnancy and its use is not recommended unless there is no suitable alternative.[90,91] Ancrod has been used in HIT,[90] but great caution should be used in pregnancy. Platelet transfusion should be avoided in patients with HIT.

Routine monitoring of platelet counts in pregnant women on prophylactic LMWH is no longer required because of the very low incidence of HIT in this situation,[92,93] but regular monitoring of the platelet count is still required in pregnant women receiving UFH.[92,93] BCSH guidelines advise that the platelet count should be monitored in women receiving treatment doses of LMWH, on the grounds that most studies on the incidence of HIT with use of LMWH have included very few pregnant patients on treatment doses.[92] The Royal College of Obstetricians and Gynaecologists venous thromboembolism guidelines recommend that monitoring is not necessary unless a woman has received UFH.[93] Recognition of HIT also remains important, and clinicians should consider HIT as a possible diagnosis in any patient who develops thrombocytopenia, skin reactions around injection sites, or new thrombosis in the first 21 days of therapy with heparin.[92]

Thrombocytopenia with Microangiopathy

Several syndromes are associated with thrombocytopenia as a result of platelet activation, red cell fragmentation, and a variable degree of hemolysis (microangiopathic hemolytic anemia). Some syndromes are unique to obstetric practice. The differential diagnosis is particularly pertinent for obstetricians and is important because management options differ.[94]

The differential diagnosis is summarized in Table 40–2.

DISSEMINATED INTRAVASCULAR COAGULATION RISKS AND MANAGEMENT OPTIONS (See later under "Acquired Coagulation Disorders" and Chapter 77)

Platelet consumption and consequent thrombocytopenia occur as part of the process of disseminated intravascular coagulation (DIC). DIC, particularly if chronic, may also occasionally be associated with microangiopathic features on the blood film. DIC is discussed briefly in the section on "Acquired Coagulation Disorders."

PREECLAMPSIA AND HELLP SYNDROME
(See Chapters 35 and 78)

Risks and Management Options

Preeclampsia is a multisystem disorder unique to pregnancy. Its pathophysiologic basis lies in widespread damage to the vascular endothelium.[7] The platelet count decreases as a result of platelet activation.[15] A decrease in the platelet count often precedes clinical signs of disease,[95] but

thrombocytopenia is rarely severe, and although there may be evidence of consumptive coagulopathy, severe DIC is unusual.[96] The extent and rate of the decrease in the platelet count indicate the severity of preeclampsia,[97] and together with other aspects of clinical and laboratory assessment, these findings may be used to guide the timing of delivery. HELLP syndrome is thought to be a variant of preeclampsia characterized by microangiopathic hemolysis, elevated liver enzyme levels, and a low platelet count.[98] Work on gene expression in the placenta has shown that there are substantial differences in gene transcripts between placentas from women with preeclampsia and HELLP, suggesting that these may be separate disease entities.[99] Hypertension may be minimal. HELLP syndrome carries a particularly bad prognosis for pregnancy outcome if delivery is postponed, so recognition is important. Platelet transfusion is infrequently required in preeclampsia or HELLP[100] but may be needed if bleeding occurs or if thrombocytopenia is severe and cesarean delivery is planned.[101] In both preeclampsia and HELLP, delivery of the fetus and placenta is the only effective treatment, and delivery results in resolution of hematologic and other features of the condition. Regional analgesia is an option if the maternal platelet count is greater than 80×10^9/L and the results of coagulation screening tests are normal. If severe thrombocytopenia, hemolysis, or organ dysfunction persist after delivery, plasma exchange may be considered,[102] but the diagnosis should also be reviewed. A role for postnatal treatment with steroids in HELLP syndrome has been postulated because initial reports suggested a more rapid resolution in platelet counts.[103] However, this initial enthusiasm has not been confirmed in randomized trials, which have shown no benefit.[104]

THROMBOTIC THROMBOCYTOPENIC PURPURA
(See Chapters 41 and 78)

TTP is a rare disorder associated with platelet activation that leads to thrombocytopenia and the formation of platelet thrombi in the microcirculation. The clinical features of TTP consist of a classic pentad of thrombocytopenia, microangiopathic hemolysis, renal impairment, neurologic features, and fever.[105] Many patients do not have all of the features. Results of coagulation screening tests are normal, and D-dimer levels are normal or minimally elevated.[105] TTP may be primary with no clear precipitating factors, secondary to infection (including HIV), drugs, underlying malignancy, or occur after transplant procedures. The pathophysiology of primary idiopathic TTP and secondary TTP are different.[13] TTP is more common in women and can occur in association with pregnancy. A large review of the literature reported that 13% of female patients with TTP were pregnant.[106] The pathophysiology of pregnancy-associated TTP is similar to that of primary idiopathic TTP.[13,106] Chronic relapsing TTP may be congenital.[107]

Severe deficiency of a vWf-cleaving metalloproteinase was recognized in patients with both congenital and primary idiopathic TTP.[108,109] This metalloproteinase is a member of the ADAMTS family (ADAMTS 13)[110] and can cleave ultralarge vWf multimers. The presence of ultralarge vWF multimers, not normally present in plasma, is the likely mechanism promoting formation of platelet microthrombi.[111]

ADAMTS 13 deficiency may be heritable, leading to congenital TTP, or may be caused by an inhibitory autoantibody, leading to primary idiopathic TTP.[13,107,109] Most cases of TTP occurring in pregnancy are due to autoimmune severe ADAMTS 13 deficiency, but congenital TTP may present for the first time or relapse during pregnancy.[106] Severe ADAMTS 13 deficiency is not seen in most cases of secondary TTP.[13,112] Levels of ADAMTS 13 decrease in the second and third trimesters of pregnancy, but do not reach the very low levels seen in severe ADAMTS 13 deficiency associated with TTP.[106,113] Variable reductions in ADAMTS 13 are also seen in hepatic failure and sepsis-induced DIC.[13] Preeclampsia and HELLP syndrome are not associated with ADAMTS 13 deficiency.

The diagnostic role of ADAMTS 13 deficiency in microangiopathic syndromes has been debated, and assays to measure ADAMTS 13 levels are available only in laboratories with a research interest in ADAMTS 13. The diagnosis of TTP does not require the demonstration of ADAMTS 13 deficiency,[107] but these assays may be helpful in cases of diagnostic difficulty, particularly in differentiating other microangiopathies in pregnancy.[114] Plasma exchange therapy (see later) should not be delayed until results of these assays are available.

Studies vary in the reported timing of TTP associated with pregnancy, with some reporting the most common occurrence in the second trimester[114,115] and others report the most common occurrence in late pregnancy or the postpartum period.[106] Preeclampsia/HELLP syndrome usually occurs after 20 weeks in pregnancy, and hemolytic-uremic syndrome (HUS) mainly occurs postnatally.[116]

Maternal and Fetal Risks

Untreated TTP is almost uniformly fatal for the mother and fetus. However, treatment with plasma exchange with fresh frozen plasma (FFP) markedly improves the outlook.[116,117] When treated with plasma exchange, the outlook for patients with TTP in pregnancy is similar to that in nonpregnant individuals.[118]

High recurrence rates have previously been reported in subsequent pregnancies, although a large cohort study showed a lower rate of recurrence in subsequent pregnancy if the TTP had originally presented in pregnancy compared with other cases of primary TTP.[119] TTP in pregnancy may be associated with superimposed preeclampsia.[114]

Fetal risks include intrauterine growth restriction and intrauterine fetal death,[114] but comparison of modern and historical data predating widespread use of plasma exchange suggests that fetal risks may be reduced if the condition is quickly recognized and treated with plasma exchange.[114]

Management Options

Plasma exchange with FFP has been shown in randomized, controlled trials to be an extremely effective treatment for idiopathic TTP (including those associated with pregnancy) and is superior to plasma infusion.[116,117] In the United Kingdom, it has been recommended that the replacement fluid of choice for plasma exchange is FFP that has been subjected to pathogen reduction procedures (e.g., solvent detergent–treated) and sourced from donors outside of the United Kingdom.[120] Plasma exchange should be instituted as soon as possible after the diagnosis of TTP (within 24 hr). Daily plasma exchange should continue until at least 48 hours after complete remission is obtained.[116] Exchange is often tapered (e.g., to alternate-day treatments). In pregnancy, repeated maintenance plasma exchange cycles or plasma infusion therapy is often used until delivery, although data to support this approach are lacking. It is possible that measurement of ADAMTS 13 levels could help to guide ongoing therapy in pregnancy after an initial complete response has been obtained.[121,122]

Cryosupernatant was advocated as superior to standard FFP as an exchange replacement fluid,[123] but a subsequent randomized trial did not confirm this.[124] In practice, the use of cryosupernatant is usually reserved for patients with a poor response to exchange with FFP. Furthermore, any advantage is unlikely to apply to solvent detergent–treated FFP as both cryosupernatant and solvent detergent–treated FFP are lacking in very large von Willebrand multimers.[116] There is a rationale for use of immunosuppressive therapy in those patients with inhibitors of ADAMTS 13. Steroids are often given concomitantly with plasma exchange in TTP, but there is no firm evidence of their benefit.[107] Guidelines in the United Kingdom recommended the use of adjuvant steroids in idiopathic TTP.[116] Additional immunosuppression with the anti-CD20 monoclonal antibody, rituximab has been used with success in primary TTP that has relapsed following standard treatment.[36,107] Rituximab has been used for TTP in pregnancy,[121] but experience is limited.

The use of low-dose aspirin has been advocated when the platelet count increases to more than $50 \times 10^9/L$.[116] In pregnancy, LMWH has been administered, in part to reduce the risk of placental failure syndromes.

Platelet transfusion is contraindicated and may lead to rapid worsening of the condition.[125] Red cell transfusion should be given as required, and folic acid is administered as requirements are increased in hemolytic states.

Unlike in preeclampsia/HELLP syndrome, delivery does not necessarily cause rapid resolution, but delivery should be considered in pregnant women with TTP who are unresponsive to standard therapy.[116]

The correct management of subsequent pregnancies in women with previous TTP is unclear. High rates of recurrence have been reported by some investigators. An aggressive approach with the use of prophylactic plasma exchange together with aspirin and LMWH has been reported in one observational case series with an excellent outcome.[121] The authors advocated the measurement of ADAMTS 13 in early pregnancy in women with a previous history of TTP as a guide to selecting patients for prophylactic plasma exchange therapy.[121]

HEMOLYTIC-UREMIC SYNDROME (See Chapter 78)

HUS is characterized by microangiopathic hemolytic anemia, renal impairment, and a variable degree of thrombocytopenia. In most childhood cases and some adult cases, HUS occurs after infection with Shiga toxin–producing organisms such as some types of *Escherichia coli*. In adults, many cases are atypical and are difficult to distinguish from TTP. Fifty percent of cases of atypical HUS are associated with abnormalities of complement regulatory proteins (e.g., mutations in Factor H or CD46).[126]

Pregnancy-associated HUS usually occurs postpartum with acute renal failure.[115,116] Subsequent chronic renal failure is common.

Initial management of atypical HUS including those cases associated with pregnancy should be with plasma exchange, although this is less well proved than in TTP.

The rationale is, first, the difficulty in distinguishing such cases from TTP, and second, anecdotal data suggesting some benefit of plasma therapy in those patients with defects of complement regulatory pathways.[127] Otherwise, management is supportive and includes renal dialysis and red cell transfusion.

SUMMARY OF MANAGEMENT OPTIONS
Secondary Autoimmune Thrombocytopenia

Management Options	Evidence Quality and Recommendation	References
Antiphospholipid Syndrome and Systemic Lupus Erythematosus (See also Chapter 43)		
Manage thrombocytopenia as for autoimmune idiopathic thrombocytopenic purpura.	III/B	62,63,64
Thromboprophylaxis	IV/C	61,66
HIV Thrombocytopenia (See also Chapter 28)		
Platelet count may be improved by the use of HAART, IVIG, or steroids	III/B (nonpregnant adults)	62*
For cesarean section, consider platelet cover, as with autoimmune idiopathic thrombocytopenic purpura, if platelet count is low.	—/GPP	—

Disseminated intravascular coagulation.	See below and Chapter 78	
Preeclampsia or HELLP syndrome.	See Chapters 35 and 79	
Thrombotic thrombocytopenic purpura (see also Chapters 41 and 78)		
• Plasma exchange with fresh frozen plasma is the first-line treatment.	Ib/A	117*
• Steroids may have a role.	III/B	116*
• Consider aspirin when platelet count > 50 ×10^9/L.	IV/C	116*
• Avoid platelet transfusion.	IV/C	116*
Hemolytic Uremic Syndrome (See also Chapter 79)		
Supportive care.	IV/C	115,116
Renal dialysis.	IV/C	115,116
Red cell transfusion.	IV/C	115,116
Plasma exchange has a role in selected cases.	IV/C	127

* Refers to evidence in nonpregnant adults.
GPP, good practice point; HAART, highly active antiretroviral therapy; HELLP, hemolysis, elevated liver enzymes, and low platelets; IVIG, intravenous immune globulin.

COAGULATION DISORDERS

Heritable Coagulation Disorders

Von Willebrand Disease

The primary function of vWf, which is a large, multimeric protein, is to promote platelet adhesion to the subendothelium. It also binds to and stabilizes plasma Factor VIII. vWD is a common bleeding disorder that arises as a result of heritable mutations that result in quantitative or qualitative defects in vWf.

vWD is divided into several types and subtypes.[128] Identification of the type of vWD has implications for management. Type 1 vWD is due to quantitative deficiency of vWF, and type 2 vWD results from qualitative defects in vWf. Some patients have little or no vWf in terms of measurable antigen and function, and these patients have associated marked reductions in Factor VIII activity (type 3 vWD).

Most types of vWD are inherited in an autosomal dominant fashion, but the pattern of inheritance in type 3 disease is autosomal recessive.

Patients with type 1 or 2 vWD usually have a mild to moderate bleeding disorder characterized by skin and mucosal bleeding and bleeding after surgery or trauma. Patients with type 3 disease have a severe bleeding diathesis and may have deep joint and intramuscular bleeding resembling the pattern seen in hemophilia, in addition to skin and mucosal bleeding.

Coagulation screening tests in patients with vWD may show a prolonged activated partial thromboplastin time (aPTT). More definitive diagnostic tests depend on the finding of reduced plasma vWf activity measured by ristocetin cofactor activity (vWf:RCo) or collagen-binding assay (vWf:CB), accompanied by variable reductions (depending on the type) in vWf antigen and Factor VIII (FVIII:C).[129,130]

Several further tests that aid in classification include analysis of ristocetin-induced platelet aggregation, vWf multimer analysis, and assay of Factor VIII binding to vWf.[129,130] Stress, inflammation, physical exercise, recent surgery, and pregnancy increase plasma vWf and Factor VIII levels, and diagnosis may be difficult in these circumstances. A subtype of type 2 vWD, type 2BvWD, is associated with thrombocytopenia.[129,130]

Molecular genetic analysis may be useful as an aid to diagnosis in type 2 or 3 vWD. Knowledge of the mutation may also aid genetic counseling and allow the option of prenatal diagnosis to be offered to women at risk of having a child with severe type 3 vWD.[131]

MATERNAL RISKS

Levels of vWf and Factor VIII tend to increase during pregnancy. This increase results in improvement in the bleeding tendency in most patients with type 1 vWD.[132] In type 2 vWD, vWf antigen and Factor VIII levels may increase, but this increase is not accompanied by clinical improvement.[133,134] The platelet count may decrease further in patients with type 2B vWD during pregnancy, causing diagnostic problems.[135,136] In type 3 vWD, no improvement occurs in either laboratory parameters or clinical severity.[137]

The risk of bleeding in patients with vWD is usually greatest postpartum.[134,137,138] Levels of Factor VIII and vWf may decrease rapidly after delivery.[139] One series showed an 18.5% incidence of PPH and a 20% incidence of secondary PPH in vWD.[140] In type 1 vWD, Factor VIII levels are a good predictor of the risk of bleeding at delivery (minimal if the Factor VIII level > 0.5 IU/mL).[141] Invasive procedures during the first trimester (e.g., chorionic villus sampling [CVS]) may also carry a risk of bleeding in all types of vWD because vWf and Factor VIII levels do not start to increase until late in the first trimester.[142]

FETAL RISKS

There is very little literature on fetal risk in vWD. Two case series suggest a possible increased rate of spontaneous miscarriage,[143,144] but others disagree.[138,140] A survey of risk factors for antenatal fetal intracranial hemorrhage listed maternal vWD as a predisposing factor.[145] General experience, however, is that fetal or neonatal hemorrhage is rarely encountered in infants with vWD. This observation is supported by a retrospective case series that showed no neonatal hemorrhagic complications after pregnancies affected by maternal vWD.[140] Newborns with type 2 and particularly type 3 vWD may be at increased risk of bleeding including intracranial bleeding following trauma during delivery.[146] Identification of infants affected with type 3 vWD before birth is difficult other than in families in which there are consanguineous relationships.

MANAGEMENT OPTIONS

Prepregnancy

One important aspect of pregnancy management in patients with vWD is its recognition. Patients with vWD may have menorrhagia. Recognition and treatment of vWD may allow avoidance of hysterectomy and a more conservative approach to management.[143,147]

In women diagnosed with vWD, counseling should be given about its inheritance, which is autosomal dominant in most cases. Vaccination against hepatitis A and B should be carried out before pregnancy. The type of vWD should be characterized to plan optimal management of pregnancy and delivery.[142]

In patients with type 1 vWD, it is often useful to carry out a trial of therapy with intravenous desmopressin (DDAVP) to determine the patient's response.[142] This agent may help to prevent or control mild to moderate bleeding. A synthetic analogue of vasopressin, DDAVP increases Factor VIII and vWf levels in plasma.[148] Its major advantage is the avoidance of exposure to pooled blood products.

If menorrhagia has been problematic, iron-deficiency anemia should be corrected before pregnancy. For women with vWD who stopped using a combined oral contraceptive to become pregnant, alternative therapies to control menorrhagia may be required (e.g., tranexamic acid)[142] if pregnancy can be excluded at the time of use.

For women at risk of having a child with severe type 3 vWD (most of whom are asymptomatic carriers, recognized in families with consanguineous relationships), the option of prenatal diagnosis should be discussed at prepregnancy counseling. The causative mutation in the family should be identified, where possible, before pregnancy.[131]

Prenatal

Close liaison between the obstetrician and the hematologist is necessary. Factor VIII, vWf antigen, and vWf activity levels should be monitored.[142,146] U.K. guidelines recommend monitoring at booking, 28 weeks', and 34 weeks' gestation and prior to invasive procedures.[146] Management plans should be determined individually, depending on the patient's hemostatic response to pregnancy. As discussed earlier, in patients with type 1 vWD, hemostatic values are more likely to normalize as pregnancy progresses. If hemostatic parameters have not improved, treatment may be required to cover invasive procedures (particularly in the first trimester) or episodes of antenatal bleeding.

Options for the treatment or prevention of bleeding in vWD include DDAVP (in responsive patients, mainly those with vWD type 1) and Factor VIII concentrates that contain sufficient quantities of vWf.[99,142,149] The use of DDAVP has been controversial in pregnancy. Theoretical concerns have existed about possible oxytocic effects and maternal

vasoconstriction. However, there are now several published reports of successful use of DDAVP in pregnancy without adverse effects.[148,150–152] Hyponatremia can occur, particularly after repeated dosing or if copious intravenous fluids are given concomitantly.[149] DDAVP should be avoided in women with preeclampsia.[146]

DDAVP is contraindicated in type 2B vWD because it may worsen thrombocytopenia.[148] Patients with type 2A vWD have a variable response to DDAVP, and patients with type 3 vWD are unresponsive.[149]

When DDAVP is considered unsuitable, patients are treated with a Factor VIII concentrate that contains sufficient vWf. Recombinant factor VIII concentrates do not contain vWf; therefore, suitable products are plasma-derived Factor VIII concentrates that have undergone viral inactivation.[148,149] A high-purity, plasma-derived vWf concentrate is also available, but it must be administered initially with Factor VIII.[153]

Public health considerations for management of invasive procedures are covered in the section on "Labor and Delivery."

Labor and Delivery

For all women with vWD, delivery plans should be agreed among the obstetrician, the hematologist, the obstetric anesthetist, and the patient in advance of labor. This is best done with knowledge of the laboratory vW profile in the third trimester.

For women with type 3 vWD, type 2 vWD, and women with more severe forms of type 1 vWD whose hemostatic profile has not corrected in pregnancy, it is preferable for delivery to take place in a major obstetric unit that has close geographic and professional links with a hemophilia center and where appropriate laboratory facilities for monitoring exist.[146] This is also the case if the fetus is at risk for severe vWD. For patients whose von Willebrand's profile has normalized in pregnancy, no specific hemostatic support is required. For patients whose vWf activity has not normalized, hemostatic supportive therapy is necessary to cover either vaginal delivery or cesarean section. Treatment is indicated to raise vWF activity and Factor VIII levels above 0.5 IU/mL.[142,146,148] Patients with type 1 vWD may receive DDAVP if they are responsive and there are no current contraindications; patients with type 2 or 3 vWD will usually require a suitable coagulation factor concentrate. vWF activity and Factor VIII levels should be maintained at greater than 0.5 IU/mL for 3 days following vaginal delivery and for at least 5 days following cesarean section.[146]

Ventouse delivery, rotational forceps, fetal blood sampling, and scalp electrodes should be avoided if the fetus is at risk for type 2 or 3 vWD or more severe forms of type 1 vWD.[146] The third stage of labor should be managed to ensure adequate uterine contractions. Effort should be made to ensure the placenta is complete. Careful and prompt repair of episiotomies or perineal tears should be undertaken. A low threshold for antibiotics should be adopted if the uterine cavity is opened or explored.

Risks of regional analgesia should be considered on an individual basis.[154] Close collaboration between the hematologist and the anesthetist is required. In type 1 vWD when vWf activity and Factor VIII levels have spontaneously corrected, epidural anesthesia is likely to be safe for the majority. Alternatives should be used for patients with type 2 or

3 vWD and in type 1 vWD where vWf activity has remained low.[146] Bleeding in such cases does not always correlate with laboratory parameters after corrective treatment and so caution should be exerted even after treatment has been given. Patient-controlled analgesia with short-acting opioids can be useful when regional analgesia is contraindicated.

For patients previously treated in the United Kingdom, the patient's "at-risk status" for public health purposes with respect to new-variant Creutzfeldt-Jakob disease (nvCJD) should be documented prior to labor and delivery. All recipients of pooled plasma products manufactured from U.K. plasma between 1980 and 2001 are considered "at risk of nvCJD for public health purposes."[155] This is particularly relevant if instrumental or operative delivery is required. The reproductive tissues and the placenta are considered low risk for contamination with prion proteins,[156] but advice should be sought from an expert in infection control in cases deemed "at risk."

Postnatal

All patients should be observed closely for PPH. Uncorrected hemostatic defects should be treated after delivery. In suitable responsive patients, DDAVP is the treatment of choice to prevent and treat mild to moderate postpartum bleeding.[157] Factor VIII and vWf:RCo levels should be checked a few days after delivery because they may fall rapidly after delivery.[139] FVIII:C and vWf:RCo levels should be maintained in the normal range for at least 3 days following vaginal delivery and 5 to 7 days after cesarean section.[137,146,148,157]

It is difficult and unnecessary to diagnose type 1 vWD in the neonate. If type 2 or 3 vWD is suspected, a cord blood sample should be sent for assay of Factor VIII and vWF activity. Affected infants who have clinical signs of significant bleeding should be treated with a coagulation factor concentrate that contains vWf, and infants with severe vWD may require treatment if delivery has been traumatic.[149] Intramuscular injections should be avoided for both mother and newborn. Vitamin K may be given orally.

Nonsteroidal anti-inflammatory drugs should be avoided for maternal analgesia. Tranexamic acid may be used as an adjunct in the management of postpartum bleeding.[146] Women taking tranexamic acid may breast-feed. Individual decisions should be made about thromboprophylaxis in order to balance the thrombotic with the hemorrhagic risk. Mechanical methods are the first-line approach in patients with bleeding disorders.

Carriers of Hemophilia A and B

Hemophilia A (deficiency of Factor VIII) is the most common severe heritable bleeding disorder, with a prevalence of approximately 1 in 5000 in the population. Hemophilia B (deficiency of Factor IX) is approximately five times less prevalent. The conditions are inherited in an X-linked fashion and are clinically identical. Affected males have a bleeding disorder that correlates in severity with the reduction in the level of Factor VIII or IX. Severely affected males have spontaneous bleeding into muscles and joints; mildly affected patients may bleed only after surgery or trauma.

Females in families with a history of hemophilia may be obligate, potential, or sporadic carriers, depending on the details of the pedigree.[158] An obligate carrier is a woman

whose father has hemophilia, a woman who has a family history of hemophilia and who has given birth to a hemophiliac son, or a woman who has more than one child with hemophilia. A potential carrier of hemophilia is a woman who has a maternal relative with the disorder. A woman with one affected child and no family history may be a sporadic carrier.[158] Carriers of hemophilia usually have Factor VIII or IX levels that are approximately 50% of normal, because of lyonization. Abnormal bleeding does not occur at this level of Factor VIII activity. Some carriers have lower Factor VIII or IX levels, and these individuals have a bleeding disorder that varies according to the coagulation factor level.[159]

MATERNAL RISKS

As discussed earlier, Factor VIII levels tend to increase during pregnancy.[160] This increase usually, but not invariably, occurs in carriers of hemophilia A. The risk of bleeding in carriers of hemophilia A is greatest in the postpartum period because Factor VIII levels may decrease rapidly after delivery.[134,137,161] Invasive procedures during the first trimester, such as CVS, also carry a risk of bleeding. No substantial increase in Factor VIII occurs at this early stage in pregnancy.[137] The risk of antepartum hemorrhage is not increased.[161]

There is usually no substantial increase in Factor IX levels during pregnancy.[137,161,162] Consequently, compared with carriers of hemophilia A, carriers of hemophilia B who have low Factor IX levels are more likely to require treatment to prevent bleeding complications during delivery.

The possible need for treatment with coagulation factor concentrate should be pointed out when counseling women who are carriers of hemophilia. The risks of pregnancy and the safety and potential risks of available treatments should be discussed. This is best carried out by medical and nursing staff with expertise in the management of bleeding disorders.

FETAL RISKS

If the mother is a definite carrier of hemophilia A or B, a male fetus has a 50% chance of being affected. The family history predicts the severity of the hemophilia for the affected fetus.[162] Spontaneous fetal or neonatal bleeding is unusual, even in severe hemophilia, but there are well-documented cases after traumatic delivery.[161,163]

The most serious risk is that of intracranial hemorrhage. Cephalohematoma may also lead to serious bleeding. One retrospective series reported a combined incidence of 3.58% for intracranial hemorrhage and cephalohematoma in newborns with hemophilia A and B.[164,165] Other reported areas of bleeding in hemophilic neonates are at puncture sites, the umbilical stump, and during circumcision.[165]

If the parents seek prenatal diagnosis of hemophilia, counseling should cover the fetal risks associated with CVS. This procedure carries a 1% to 2% risk of miscarriage.[166]

MANAGEMENT OPTIONS
Prepregnancy

All women who are potential, obligate, or sporadic carriers of hemophilia require prepregnancy counseling, including genetic counseling. Arrangements for genetic counseling vary from one area to another, but there is general agreement that a genetic counselor and a physician who is responsible for the management of patients with hemophilia should be involved.[167] It should be established that there is truly a history of hemophilia in the family (not, e.g., another bleeding disorder). The pedigree should be established and the possibility of hemophilia carriership confirmed or refuted. Counseling of obligate and potential carriers should include a discussion of the nature and management of hemophilia.[167]

Carrier identification studies with molecular genetic techniques should be offered to all potential carriers of hemophilia A and B. Written informed consent is recommended before blood samples are collected for molecular analysis.[167] Advances in molecular genetics have made accurate diagnosis of carriership possible in most cases.[167–170] Molecular genetic studies should be carried out in laboratories experienced in molecular analysis of the Factor VIII and IX genes.[169,170] Hemophilia A and B are genetically heterogeneous. The starting point is identification of the mutation responsible for hemophilia in an affected male member of the family (direct mutation detection).[169–171] Potential carriers may be screened for this mutation. The availability of a molecular marker in the family is necessary if prenatal diagnosis is required later.

Approximately 20% of cases of hemophilia A (45% of severe hemophilia A) are caused by an inversion in intron 22 of the Factor VIII gene.[169,171,172] An inversion in intron 1 is the molecular basis of 1% to 2% of cases of severe hemophilia A.[169] If an affected male is not available and there is a family history of severe hemophilia A, a potential carrier should be screened for these common molecular defects. Direct mutation detection is difficult if there is no available affected male but may be attempted in specialized laboratories.

Linkage analysis is now rarely used, but may occasionally be useful if the mutation responsible for hemophilia cannot be identified.[169,171] Intragenic polymorphic markers should be used.[169] Blood from an affected male family member is required, and more extensive family testing is needed for successful linkage analysis. Linkage analysis will be unsuccessful if the potential carrier is homozygous (un-informative) for common intragenic polymorphisms.[171] In families in which there is a single affected male (sporadic hemophilia), female family members may be excluded from carriership by linkage analysis, but carriership cannot be positively diagnosed by this method.[169]

Coagulation studies should also be carried out to identify carriers with low Factor VIII or IX levels. Normal levels of Factor VIII or IX do not exclude carriership. Women with low levels of Factor VIII or IX should be offered vaccination against hepatitis A and B. The immunity status should be checked if the patient has been vaccinated. Women who have low levels of Factor VIII may have a useful hemostatic response to DDAVP.[173] To establish whether this response is occurring, a trial of intravenous DDAVP can be attempted, with measurement of the response in Factor VIII levels over the next 24 hours. DDAVP is not useful for women with low Factor IX levels.[174]

Once carriership has been established, careful planning of pregnancies should be encouraged. Partners of hemophilia carriers should be encouraged to attend prepregnancy counseling sessions.[158,162] Couples should be informed that

hemophilia "breeds true" in families. In other words, its severity is predictable by the family history.[162] Approximately 25% of patients with hemophilia A will develop an inhibitor to Factor VIII in their lifetime.[175] Inhibitors are less common in hemophilia B. The development of an inhibitor renders usual treatment with Factor VIII concentrate ineffective or less effective and is a serious complication. There is a genetic component to the risk of inhibitor development.[175,176] Some molecular genetic defects are associated with an increased risk of inhibitor formation (e.g., large deletions).[176] This should be addressed during counseling. Couples should be counseled in a nondirective manner about all reproductive options, including the availability of prenatal diagnosis. They should be encouraged to consider the matter in advance of pregnancy,[158,167] although circumstances may change and final decisions must be made given the circumstances in each pregnancy. Prepregnancy counseling may need to be repeated in subsequent pregnancies. Discussion of the techniques and risks associated with prenatal diagnosis is appropriate during preconception counseling sessions.[158] Carriers should be encouraged to seek care early in pregnancy, especially if prenatal diagnosis is being considered or has not been excluded.

Preimplantation genetic diagnosis may be made available by referral to specialized centers for carriers of hemophilia who, after counseling, do not wish to contemplate bringing up a hemophilic child, but would not consider termination.[146] Preimplantation diagnosis is possible only with in vitro fertilization and is available only in a few specialized centers. In the United Kingdom, each new test requires a license from the Human Fertilisation and Embryology Authority. Couples contemplating this procedure require complex counseling with the involvement of an expert in in vitro fertilization and the opportunity to discuss possible pitfalls with the relevant specialist center in advance of the procedure.

Prenatal

Identification and counseling of carriers should be carried out before pregnancy, but may be necessary in early pregnancy if a woman with a family history of hemophilia does not seek care until pregnancy is diagnosed. General practitioners, midwives, and obstetricians should refer these patients for specialized counseling as early as possible.[167]

Pregnancies in patients who are carriers of congenital bleeding disorders should be managed in a hospital with hemophilia expertise.[137,146,161] Close liaison between the obstetrician and the hemophilia team is necessary. Factor VIII or IX levels should be monitored regularly throughout pregnancy. U.K. guidelines recommend measurement of coagulation factor levels at booking, at 28 weeks, and at 34 weeks.[146] Knowledge of coagulation factor levels toward the end of the third trimester (34–36 wk) is necessary to plan management of delivery.[161,162]

If prenatal diagnosis is requested and a suitable molecular marker exists, testing is usually carried out by CVS at 11 to 14 weeks. Amniocentesis from 15 weeks onward is an alternative. CVS is generally considered the method of choice for prenatal diagnosis because it offers early diagnosis.[146] Fetal blood sampling by cordocentesis is now rarely carried out because of hazards. Risks associated with these procedures should be fully discussed with the patient. CVS and amniocentesis carry a 1% risk of miscarriage. Fetal bleeding sufficient to result in death is a recognized risk of cordocentesis.[146]

The use of prenatal diagnosis is decreasing in developed countries. As hemophilia care improves, more couples are willing to contemplate bringing up a child with hemophilia.[162]

If prenatal diagnosis is requested, treatment may be necessary to increase maternal Factor VIII or IX levels if they are less than 0.5 IU/mL. Laboratory measurement of coagulation factor levels should be used to monitor treatment. DDAVP may be used for women with reduced Factor VIII levels for patients demonstrated to be responsive.[148,150,161,162] DDAVP is ineffective in increasing Factor IX levels. Readers are referred to the section on "von Willebrand's Disease" for further discussion on the use of DDAVP in pregnancy. If coagulation factor concentrates are used, a recombinant Factor VIII or IX concentrate should be chosen.[174] Many patients are previously untreated, and even a minimal risk of transmission of infection from plasma-derived products is unacceptable. Further, parvovirus B19, which can cause fetal hydrops, may be transmitted by plasma-derived concentrate, and no method of viral inactivation seems to be effective in eradicating this virus.[177] Women previously treated with plasma-derived factor concentrates manufactured from U.K. plasma between 1980 and 2001 are considered "at risk of nvCJD for public health purposes."[155] When invasive procedures are required in such cases, advice should be taken from an expert in infection control. Reproductive tissues have been considered low risk for transmission of prions by the Health Protection Agency in the United Kingdom.[156]

Fetal sex should be determined in all pregnancies in which the fetus is at risk for hemophilia.[146] Ultrasonography at 20 weeks has been the standard approach.[137,161,162] This information is necessary for the obstetrician and hematologist to plan delivery, even if the parents do not wish to know the sex of the infant. Research into fetal sexing earlier in pregnancy has given rise to two techniques that have been successfully applied in small numbers of pregnancies. The first is detection of free fetal DNA in maternal plasma. This depends on quantitative PCR for Y chromosomal DNA sequence.[178,179] A second technique is that of gender determination by ultrasound at 11 to 14 weeks' gestation.[178] These techniques are, at present, limited to centers with research expertise, and it has been recommended that if used, both techniques should be used to check that the results are in agreement. Fetal sexing by free fetal DNA in the late first trimester has now, however, been shown to have a high rate of accuracy.[180,181] In cases in which fetal sex can be determined by these methods in the first trimester, this may aid decisions regarding CVS for some women.

A delivery plan taking account of the patient's coagulation factor level, the sex of the fetus, and obstetric considerations should be made in the third trimester of pregnancy. This should be agreed among the obstetrician, the hemophilia specialist, the obstetric anesthetist, and the patient. The use of third-trimester amniocentesis to aid delivery planning if the fetus is male has been advocated by some obstetricians (T Overton, personal communication). The rationale is that definite molecular diagnosis may exclude a fetus from having hemophilia and open up more options for management of delivery. There is a small risk of premature labor,[182] which

in turn, may increase risk of bleeding for a hemophilic infant (because the coagulation system is less mature). Risks must, therefore, be balanced carefully if this is considered, but this approach may be useful in individual cases. If the fetus is male and hemophilia has not been excluded or if *baseline* maternal coagulation factor levels have been low, delivery should be planned in a center where hemophilia expertise, including laboratory monitoring, is readily available.[146]

Labor and Delivery

If maternal Factor VIII or IX levels remain low at 34 to 36 weeks in hemophilia carriers, treatment to correct maternal hemostasis is necessary for delivery.[137,161,162] Factor VIII or IX levels should be maintained at greater than 0.5 IU/mL for all modes of delivery.[146] Considerations similar to those discussed earlier govern the choice of treatment. Recombinant Factor VIII or IX or DDAVP (for carriers of hemophilia A only) should be used.[174] Full laboratory monitoring of hemostatic replacement therapy is necessary. Epidural anesthesia may be used if coagulation defects have been corrected.[161]

As discussed previously, the maternal "at-risk" status for nvCJD should be noted and infection control advice sought when appropriate.[155]

If the fetus is a known hemophiliac, is male and of unknown hemophilia status, or is of unknown sex, care should be taken to avoid traumatic vaginal delivery.[161–163,165] When possible, obstetric problems should be identified before the expected date of delivery, and the mode of delivery should be planned. Routine cesarean delivery is unnecessary,[162,163,165] but cesarean delivery should be carried out if obstetric complications are anticipated.

Fetal scalp sampling and scalp electrodes should not be used if the fetus may have hemophilia.[146,161,162] Similarly, in such cases, ventouse delivery is absolutely contraindicated because major cephalohematoma and intracranial bleeding have been documented after this procedure.[146,162,163,165] Mid-cavity rotational forceps delivery should be avoided, but simple lift-out forceps delivery may be preferable to a difficult cesarean section if the fetal head is low in the pelvis.[162]

Active management of the third stage of labor is recommended.[146] Maternal perineal trauma should be minimized, with suturing performed promptly after delivery.

Postnatal

Most bleeding problems in carriers of hemophilia occur postpartum. There is a 22% risk of primary post partum bleeding and an 11% risk of secondary PPH.[161]

As discussed earlier, replacement therapy should be given immediately after delivery to mothers with an uncorrected hemostatic defect. Coagulation factor levels should be rechecked urgently if postpartum bleeding occurs. Options at this stage include DDAVP for mothers who are carriers of hemophilia A and recombinant coagulation factor concentrates for carriers of hemophilia A or B. Supportive therapy to maintain hemostasis should be continued for 3 to 4 days after vaginal delivery and for 5 to 7 days after cesarean section.[137,146] All hemostatic parameters must be normal before epidural catheters are removed. Nonsteroidal anti-inflammatory analgesics should be avoided. All mothers who are carriers, regardless of whether they need peripartum hemostatic support, should be observed for signs of PPH.

Coagulation factor levels should be checked daily after delivery because they may decrease quickly.[146,162]

Women who are carriers of hemophilia should not be excluded from considerations regarding thromboprophylaxis. In general, mechanical methods should be the method of first choice but risks and benefits should be assessed individually. Women with risk factors for thrombosis may merit prophylaxis with LMWH if coagulation factor levels have been corrected. Close clinical monitoring for signs of bleeding and laboratory monitoring to ensure adequate coagulation factor levels is advisable under such circumstances.

In the infant, intramuscular injections (including vitamin K) should be avoided until hemophilia has been excluded.[162] Vitamin K may be given orally.[165] Cord blood should be obtained for appropriate factor assays.[162,165] Except for very mild cases, hemophilia A can be diagnosed easily in the neonatal period. Difficulties may arise with mild or moderate hemophilia B because of the physiologic reduction in Factor IX levels that occurs in the newborn.[165,183] However, severe hemophilia B is usually easily identified.

There has been debate about the routine administration of coagulation factor concentrates to neonates with hemophilia.[184] There is some evidence that the administration of factor concentrate in very early life might increase the risk of inhibitor development.[185] Factor concentrate should not, therefore, be administered routinely. Treatment with recombinant factor concentrate should be considered if there has been trauma at delivery or if the neonate has significant hemorrhagic signs.[146,184] Prompt coagulation factor support is clearly needed if there is clinical evidence of intracranial hemorrhage or significant bleeding from other sites.[165] Cranial ultrasound or computed tomography scanning should be carried out in infants with hemophilia if delivery has been traumatic or if there is clinical suspicion of intracranial bleeding.[146,165]

The hemophilia team should be involved from the outset in counseling parents of infants with newly diagnosed congenital bleeding disorders. A clear follow-up plan should be discussed with the parents at discharge.[165] The community midwife and family physician should be informed if the infant is hemophilic.

Other Heritable Bleeding Disorders

Some women have rare deficiencies of coagulation factors or congenital platelet function disorders.[186] Detailed description is beyond the scope of this chapter. As with all bleeding disorders, close liaison between the obstetrician and the hematologist is required. The principles of management revolve around assessment of the risk of bleeding for the mother and infant. The risks of hemostatic supportive therapy must be taken into account. Many (but not all) disorders are inherited in a recessive manner; therefore, the risk of fetal or neonatal bleeding is often negligible unless there is a consanguineous partnership. For rarer congenital coagulation factor deficiencies, clinical bleeding does not always correlate with coagulation factor levels. This is particularly the case for Factor XI deficiency.[186] Women with deficiency of fibrinogen or Factor XIII may have recurrent fetal loss.[187,188] Placental abruption is reported in congenital afibrinogenemia.[187] Appropriate replacement therapy can help to maintain pregnancy.[187,188]

SUMMARY OF MANAGEMENT OPTIONS
Coagulation Disorders—Inherited

Management Options	Evidence Quality and Recommendation	References
Von Willebrand's Disease		
Prepregnancy		
Establish type of von Willebrand's disease.	IV/C	149
Provide genetic counseling (usually dominant except type 3).	IV/C	131,146
Give hepatitis A and B immunization.	IIa/B	174*
For type 1 von Willebrand's disease, perform a DDAVP trial to establish efficacy (contraindicated in type 2B von Willebrand's disease).	IV (for trial)/C III (for efficacy)/B	149 173*
Prenatal		
Combined or interdisciplinary team approach (obstetric and hemophilia team).	IV/C	146
Monitor vWf:Ag, vWf:RCo, FVIII:C, platelet count (in many cases, parameters improve).	IV/C	146
Treatment is unlikely to be required unless invasive procedures are performed or an episode of antenatal bleeding.	IV/C	146
Labor and Delivery		
Deliver in center with readily available expert hematologic support if severe type 1, 2 or 3.	IV/C	146
Maternal hemostatic support is needed if FVIII:C <0.5 IU/mL or if vWf:RCo significantly reduced.	IV/C	146
DDAVP may be used in responsive patient (except in type 2B von Willebrand's disease), or a plasma-derived concentrate containing vWf may be used.	IV/C	146,149
Aim for atraumatic delivery (vaginal delivery if uncomplicated delivery is anticipated, but avoid fetal scalp electrodes and fetal scalp sampling if risk of severe type 1, 2 or 3).	IV/C	146
Active management of the third stage.	IV/C	146
Prompt repair of perineal trauma.	—/GPP	—
Postnatal		
Vigilance for postpartum hemorrhage.	IV/C	140,146
Cord samples are not indicated unless type 2 or 3 von Willebrand's disease is suspected in the newborn.	IV/C	146
Avoid neonatal intramuscular injections until status is known.	IV/C	146
Recheck maternal FVIII:C, vWf:Ag, and vWf:RCo for a few days after delivery. If parameters fall or if the patient is bleeding, give hemostatic supportive therapy. Maintain support based on laboratory parameters for 3–5 days.	IV/C	140,146
Carriers of Hemophilia A or B		
Prepregnancy		
Provide genetic evaluation and counseling.	IV/C	146,167
Establish mutation, if possible; if not, define whether linkage analysis is of use.	IV/C	167,169,170
If maternal Factor VIII or IX is reduced, obtain baseline virology (including hepatitis B and C, HIV, and immunity vs. hepatitis A and parvovirus).	—/GPP	—

Management Options	Evidence Quality and Recommendation	References
Give hepatitis A and B immunization if the patient is not immune.	IIa/B	174*
For carriers of hemophilia A with low Factor VIII levels, perform a trial of DDAVP to establish efficacy.	III (for efficacy of DDAVP)/B	173*
Prenatal		
Provide combined or interdisciplinary team approach (obstetric and hemophilia team).	IV/C	146
Offer prenatal diagnosis (chorionic villus sampling) at 11–14 wk (cover with factor concentrate if level of Factor VIII or IX < 0.5 IU/mL); use recombinant products, or DDAVP.	IV/C	146
Obtain maternal serial clotting factor levels.	IV/C	146
Fetal sexing either by free fetal DNA with confirmation by ultrasonography at 16–20 wk if invasive prenatal diagnosis is not requested or by ultrasound alone.	IV/C	146,180
Labor and Delivery		
Consider factor concentrate cover for labor and delivery if Factor VIII or IX level <0.5 IU/mL	IV/C	146
For hemophilia A carriers, consider DDAVP alone if the patient is known to be responsive, if normal vaginal delivery is anticipated, and if the coagulation defect is mild.	IV/C	146
If high risk fetus, aim for atraumatic unassisted (no ventouse or forceps) delivery (vaginal delivery if uncomplicated delivery is anticipated, but avoid fetal scalp electrodes and fetal scalp sampling).	IV/C	146
Postnatal		
Obtain cord blood for neonatal evaluation if risk of hemophilia A or B.	IV/C	146,165
Avoid neonatal intramuscular injections until status is known.	IV/C	146,165
Give vitamin K orally if neonate has hemophilia or if hemophilia not excluded.	IV/C	146,165
Consider cranial ultrasound/CT if neonate has severe hemophilia and traumatic delivery.	IV/C	146,165
A clear follow-up plan is needed for the parents and child.	IV/C	146
Vigilance for postpartum hemorrhage.	—/GPP	—
Provide maternal hemostatic support for 3 days if vaginal delivery and for 5 days if cesarean delivery.	IV/C	146

Acquired Coagulation Disorders

Disseminated Intravascular Coagulation (See Chapter 77)

DIC occurs in a wide variety of obstetric complications. It is triggered by vascular endothelial damage, release of procoagulant substances as a result of tissue damage or liquor entering the circulation, or cytokine-mediated up-regulation of tissue factor expression on monocytes and endothelial cells.[189,190] These triggers lead to the generation of thrombin, cause defects in inhibitors of coagulation, and suppress fibrinolysis. These hemostatic changes result in deposition of fibrin in the microcirculation and consumption of coagulation factors and platelets, leading to a bleeding tendency.

In obstetrics, DIC often develops acutely, for example, in placental abruption, and results in rapid defibrination with hemostatic failure. Very long clotting times and marked thrombocytopenia usually occur. At the other end of the

spectrum, chronic DIC may cause minimal or no abnormality on standard coagulation screening tests.

No single test is diagnostic of DIC; the diagnosis depends on a combination of clinical findings and laboratory test results.[190,191]

Thrombocytopenia or a decreasing platelet count is a sensitive indicator.[191] In most cases of DIC, whether acute or chronic, the plasma D-dimer level is elevated.[191] In interpreting the results of coagulation screening tests in suspected DIC in pregnant women, it is prudent to note that normal baseline values are altered by physiologic changes. The plasma fibrinogen level is elevated and Factor VIII levels increase in pregnancy, leading to an acceleration of aPTT.[160,192] Fibrinogen levels and aPTT in the normal nonpregnant range in late pregnancy should be regarded suspiciously. Fibrinogen should be assayed by the Clauss method.

The use of a scoring system for diagnosis of DIC has been advocated.[193] This has been evaluated in a wide range of critical care patients but not specifically in obstetric patients.

Because rapid changes in parameters may occur in DIC, repeat testing and ongoing monitoring until resolution are always necessary.[191]

MATERNAL RISKS

Maternal risks arise as a result of the underlying disorder, but there are also risks of bleeding and small vessel occlusion as a direct result of DIC.

FETAL RISKS

Fetal risks in DIC are associated with the underlying cause.

MANAGEMENT OPTIONS

Management of DIC includes treatment of the underlying cause and appropriate resuscitative measures to maintain tissue perfusion. Hemostatic replacement therapy is indicated if there is significant hemorrhage or if invasive procedures are required.[191] When clinically indicated, replacement therapy with FFP, platelet transfusions, and in some cases, a source of fibrinogen (such as cryoprecipitate or fibrinogen concentrate) is based on the results of laboratory tests and clinical findings.[120] Prothrombin time and aPTT provide a guide for FFP usage, and the fibrinogen level can be used to guide the use of both FFP and cryoprecipitate.[191] The goal is to increase the fibrinogen level to 1 g/L. Platelet transfusion is required if bleeding occurs in a patient with a platelet count less than 50×10^9/L.[191] However, the goal is not simply to correct laboratory defects, and clinical features are paramount in guiding treatment.[189] Treatment of the underlying cause is the most important consideration.[189,191]

The use of heparin is controversial, and it should be reserved for cases in which microvascular occlusion rather than hemorrhage is the predominant clinical problem. The cautious use of heparin may also have a place alongside replacement therapy in the management of amniotic fluid embolism. The rationale is that the underlying cause cannot be removed, and because of the rate of consumption, it is difficult to keep pace with replacement therapy unless thrombin generation is inhibited concomitantly.[189,190]

For patients who are not bleeding with DIC, prophylactic doses of UFH or LMWH are recommended for prevention of venous thromboembolism.[191]

Concentrates of the anticoagulant protein activated protein C have been used in patients with severe sepsis including those with DIC caused by severe sepsis. Reduction in mortality and improvement in hemostatic parameters have been observed in patients with severe sepsis.[194–196]

Activated protein C increases the risk of major bleeding and should be avoided in patients at particular risk of bleeding or if platelets are less 30×10^9/L.[191]

Massive Blood Loss (See Chapters 58 and 78)

Causes of massive obstetric hemorrhage are discussed elsewhere (see Chapters 58 and 78). Massive bleeding in obstetric practice (e.g., as a result of placental abruption) is often accompanied by DIC. Bleeding as a result of placenta previa may be massive but is not necessarily associated with DIC. Resuscitative measures and red cell transfusion are the first considerations. However, dilutional effects on coagulation factors and platelets occur, and bank blood does not provide platelets and labile clotting factors.

MANAGEMENT OPTIONS

The underlying cause should be treated. Resuscitative measures and red cell transfusion are paramount concerns. Blood should be warmed when rapid transfusion is required because cold injury can exacerbate end-organ damage and DIC.[197]

Coagulation defects should be corrected with FFP, and thrombocytopenia is treated with platelet transfusion. Treatment should be guided by the findings on complete blood count, coagulation screening tests, and fibrinogen measurements. Reasonable aims are to keep the platelet count above 50×10^9/L[197] and to keep the fibrinogen level above 1.0 g/L[197] and the hemoglobin above 80 g/L (or 8 g/dL). A trigger platelet count of 75×10^9/L has been recommended in British transfusion guidelines to ensure that the platelet count is always kept above 50×10^9/L.[197] In some cases, cryoprecipitate or fibrinogen concentrate may be required as a source of fibrinogen if the fibrinogen remains below 1 g/L despite transfusion of FFP.[197]

In intractable major hemorrhage, recombinant Factor VIIa may be used to stem bleeding when all other measures have failed. This treatment, which was originally developed for the management of bleeding in hemophilic patients with inhibitors, has been used successfully in a variety of clinical situations associated with major bleeding and is becoming viewed as a "universal" hemostatic agent.[198] Recombinant Factor VIIa is not licensed for control of massive bleeding in such circumstances. DIC is not a contraindication to the use of recombinant Factor VIIa if massive bleeding is occurring. However, caution should be exercised in patients with major DIC because there are occasional reports of thrombosis and DIC after the use of recombinant Factor VIIa.[199] Recombinant Factor VIIa should not be viewed as a replacement for conventional approaches to control bleeding. It is important to correct acidosis and hypothermia and to optimize the platelet count as far as possible in order to maximize the chance of efficacy of recombinant Factor VIIa.[200]

There are several reports of the successful use of recombinant Factor VIIa to control massive hemorrhage in obstetric patients.[201–203]

There are no clinical trials in obstetric practice of the use of Factor VIIa in massive hemorrhage. Nevertheless, a recent European consensus statement included massive PPH as a suitable clinical condition in which to consider use of Factor VIIa (grade E recommendation).[200] Use in this situation may avoid the need for hysterectomy.[203]

Liver Disease (See Chapter 47)

MATERNAL RISKS AND MANAGEMENT OPTIONS

Patients with liver disease, especially if it is advanced, often have significant hemostatic impairment. Several mechanisms contribute to this impairment, including thrombocytopenia as a result of splenic enlargement or alcohol use, impaired production of coagulation factors in the liver, impaired polymerization of fibrin, platelet dysfunction, and hyperfibrinolysis.[204] In pregnant women with liver disease, a complete blood count should be obtained and coagulation parameters monitored. Coagulation screening tests and measurement of fibrinogen levels are indicated. In some cases, screening for DIC or coagulation factor assays is helpful. The risk of bleeding is greatest during and after surgery or invasive procedures. Hemostatic supportive therapy may be required in these situations or if bleeding occurs during labor or delivery. Standard therapy is with FFP and platelets. Efficacy may be limited in patients with liver disease, and large volumes of FFP may be required. In cases of severe bleeding in liver disease that are unresponsive to conventional component therapy, the use of modern prothrombin complex concentrates (PCCs) may be considered. In the past, liver disease has been considered a relative contraindication to the use of PCCs. However, modern PCCs contain less activated coagulation factors and a better balance of procoagulant and anticoagulant proteins.[205] Successful use of such concentrates in patients with liver disease has been reported.[206]

Acquired Inhibitors of Coagulation (Acquired Factor VIII Inhibitor)

MATERNAL RISKS

Rarely, pregnancy is associated with the development of an antibody that inhibits Factor VIII activity. Most reported cases occur postpartum.[207–209] This antibody may lead to postpartum hemorrhage or postsurgical bleeding. Bleeding may be severe and life-threatening; therefore, recognition is important. The pattern of spontaneous bleeding differs in acquired hemophilia compared with that in heritable Factor VIII deficiency. Classically, in acquired hemophilia, subcutaneous bleeding and bleeding from mucous membranes occur. Inhibitors that develop early in the postpartum period are associated with PPH, whereas skin and soft tissue bleeding is a more common presenting manifestation if inhibitors develop later in the postpartum period.[209] The severity of bleeding correlates less well with the Factor VIII level than in males with heritable Factor VIII deficiency.[210]

The timing of the development of these postpartum inhibitors is highly variable. One series reported identification of acquired hemophilia between 3 and 150 days postpartum.[207] Postpartum Factor VIII inhibitors may disappear spontaneously, but the usual pattern is persistent for months or even years.[207,208] The more common pattern seems to be that inhibitors do not recur in subsequent pregnancies.[207]

In the laboratory, a Factor VIII inhibitor is associated with a prolonged aPTT, with normal prothrombin time and fibrinogen levels. The addition of normal plasma in vitro does not correct the aPTT. Specialized tests are necessary to confirm the presence of a Factor VIII inhibitor, and it is important to differentiate a Factor VIII inhibitor from a lupus inhibitor because the clinical implications are profoundly different.[211,212]

FETAL RISKS

Most inhibitors occur postpartum, so there are generally no fetal risks. However, inhibitors that arise antenatally have been reported. These antibodies may cross the placenta and persist for up to 3 months in the neonate. Bleeding complications have not usually occurred, but intracranial hemorrhage has been reported.[208] The management of these pregnancies should be based on the assumption that the fetus potentially is phenotypically hemophilic, regardless of the sex. Delivery plans and immediate neonatal management are as described earlier. The management of a neonate with bleeding complications as a result of a maternal Factor VIII inhibitor requires the expert input of a pediatric hemophilia specialist. Conventional Factor VIII concentrates are likely to be ineffective.

MANAGEMENT OPTIONS

Patients with acquired hemophilia should be managed in a hospital where hemophilia expertise exists.

Conventional Factor VIII concentrates may be ineffective in controlling bleeding. Various coagulation factor concentrates are available for immediate control of bleeding in patients with Factor VIII inhibitors. Detailed discussion is outside the scope of this chapter. In a young woman with bleeding as a result of acquired hemophilia, options include recombinant Factor VIIa[212,213] or larger doses of a recombinant Factor VIII concentrate, if a useful Factor VIII recovery and half-life can be achieved.

It is important to attempt to eradicate the inhibitor because the risk of severe bleeding otherwise persists.[214] Steroids and immunosuppressive therapy have been used.[212,214] Successful use of the anti-CD20 monoclonal antibody rituximab has been reported.[212,214,215]

Combination therapy with steroids and immunosuppressive therapy may be more efficacious in reducing the time to disappearance of inhibitors,[207] but cyclophosphamide should be avoided if possible in women of childbearing age.[214] It has been suggested that postpartum Factor VIII inhibitors may take longer to eradicate than similar autoantibodies occurring in different clinical circumstances.[216] Women should be advised to use effective contraception until the inhibitor has been eradicated. Prepregnancy counseling should be offered prior to the next pregnancy. Although most inhibitors do not recur in subsequent pregnancies, recurrence has been reported and women should be informed about this possibility.[209,216]

SUMMARY OF MANAGEMENT OPTIONS
Acquired Coagulation Disorders

Management Options	Evidence Quality and Recommendation	References
Disseminated Intravascular Coagulation (See also Chapter 77)		
Provide interdisciplinary approach (obstetric and hematology).	IV/C	191*
Treat the cause.	IV/C	191*
Serial monitoring is important because rapid changes may occur.	III/B	191*
Replace fresh frozen plasma, cryoprecipitate, and platelets on the basis of clinical condition and laboratory results.	IV/C	191*
Consider heparin in DIC due to amniotic fluid embolism.	IV/C	189,190
Consider thromboprophylaxis with LMWH or UFH if patient is not bleeding.	Ib/A	191*
Concentrates of activated protein C are useful in DIC due to severe sepsis.	Ib (nonpregnant)/A	194,195*
Massive Hemorrhage (See also Chapters 58 and 77)		
Treat the cause.	IV/C	197*
Resuscitation with volume replacement to maintain tissue perfusion.	Ib/A	197*
Replace red cells, fresh frozen plasma, cryoprecipitate, and platelets on the basis of laboratory results and clinical condition	IV/C	197*
Consider recombinant Factor VIIa if massive bleeding continues despite correction of surgical hemostasis and adequate conventional product replacement; most experience is outside pregnancy, although it is increasing in pregnancy.	IV/C	200
Acquired Factor VIII Inhibitor		
Provide interdisciplinary approach with involvement of experts in hemophilia.	IV/C	214*
Recombinant Factor VIIa if severe acute bleeding is nonresponsive to other therapy.	IIb/B	214*
Provide immunosuppressive therapy (see text).	IIb/B	214*

* Refers to evidence in nonpregnant adults.
DIC, disseminated intravascular coagulation; LMWH, low-molecular-weight heparin; UFH, unfractionated heparin.

Clotting Disorders

CHRISTINA S. HAN, MICHAEL J. PAIDAS, and
CHARLES J. LOCKWOOD

INTRODUCTION

Disorders of coagulation can lead to significant maternal and fetal compromise during pregnancy and the puerperium. In 2006, the World Health Organization reported the contrasting disorders of embolism and hemorrhage as the second and third leading causes of maternal mortality in the developed world, contributing to 14.9% and 13.4% of maternal deaths, respectively. Hypertensive disorders, the leading cause, accounted for 16.1% of deaths.[1]

Maintenance of an intact vascular compartment in the face of vessel damage requires meticulous coordination of platelet function, coagulation products, fibrinolytic factors, and the vascular endothelium. Physiologic changes during pregnancy and the puerperium pose a significant challenge to the hemostatic system, evolving from a hypocoagulable state that allows for uterine perfusion to a hypercoagulable state that prevents maternal hemorrhage.

HEMOSTATIC SYSTEM

Coagulation is mediated by a cascade of extracellular clotting factors and cellular components that seal breached endothelium with fibrin-platelet plugs. This procoagulant activity is dampened by endogenous anticoagulants and fibrinolysis.

Platelet Plug Formation

Damage to the endothelial surface exposes collagen in the subendothelial layer to the coagulation factors trafficking within the bloodstream. One factor that is both produced constitutively within the endothelium and freely flowing in the plasma is von Willebrand's factor (vWF), a large multimeric glycoprotein (GP) that binds to the uncovered subendothelial collagen. The A1 domain of vWF binds to the GP1b/IX/V receptor on platelets, recruiting platelets to sites of endothelial disruption.[2] Platelets can also adhere directly to subendothelial collagen via their GP1a/IIa ($\alpha_2\beta_1$ integrin) and GP VI receptors.

Recruited platelets are activated by collagen following binding to the GP VI receptor, which triggers calcium flux and activates protein kinase C. Activated protein kinase C, in turn, triggers platelet secretory activity and activates various signaling pathways. Activated platelets degranulate to release various compounds that biochemically enhance the plug formation.[3] These compounds include thromboxane A2 (TXA_2), dense granules of adenosine diphosphate (ADP), serotonin, vWF, vitronectin, fibronectin, thrombospondin, partially activated Factor V, fibrinogen, β-thromboglobulin, and platelet-derived growth factors. Activation causes the platelet GPIIb/IIIa receptor ($\alpha_{IIb}\beta_3$ integrin) to undergo a conformational change that promotes binding to fibrinogen molecules, which serves as a glue to bind other platelets, causing platelet aggregation.[4] Multiple disorders of the coagulation cascade can occur at this level and result in bleeding diatheses (Table 41–1).

Fibrin Plug Formation

The platelet plug is further enhanced by fibrin formation, thereby creating a synergistic partnership that allows for controlled propagation of the coagulation cascade. The initiation of clotting is triggered by exposure of tissue factor (TF), present on the membranes of subendothelial cells (e.g., fibroblasts, vascular smooth muscle cells, and parenchymal cells), to circulating Factor VII. Factor VII autoactivates upon binding to TF to trigger a greater than 100-fold increase in catalytic activity.[5] The TF/VIIa complex then activates Factors IX and X. Activated Factor Xa binds to its co-factor Va to convert prothrombin (Factor II) to thrombin (Factor IIa). Of note, the co-factor Va is generated from Factor V by either Factor Xa or thrombin. Partially activated Factor Va can also be directly delivered to the damaged site by the platelet α-granule.[6]

Locally generated Factor IXa diffuses to adjacent activated platelet membranes and binds to Factor VIIIa. Factor VIII is activated by thrombin and released from its vWF carrier molecule to form active Factor VIIIa. The Factor IXa/VIIIa complex is able to alternatively generate Factor Xa to further drive production of thrombin. In addition, thrombin on activated platelet surfaces activates Factor XI to XIa, which alternatively activates Factor IX. These redundant pathways all lead to thrombin generation, which converts fibrinogen to fibrin. The final hemostatic plug is formed when fibrin monomers self-polymerize and are cross-linked by thrombin-activated Factor XIIIa (Fig. 41–1). The most well-known bleeding diathesis involving fibrin plug formation is hemophilia, or Factor VIII deficiency (see Table 41–1).

Endogenous Anticoagulants

A system of mechanical and biochemical barriers evolved to confine the extent of coagulation activity. The adherence and activation of platelets diminish over time as a firm network of platelets settles into the breach, concealing the subendothelial collagen. This mechanical blockade of platelet aggregation and platelet-associated clotting is complemented by the action of endogenous anticoagulants, such as tissue factor pathway inhibitor (TFPI), activated protein C (APC), protein Z–dependent protease inhibitor (ZPI), and antithrombin (AT). TFPI rapidly deactivates circulating Xa,

which may have diffused away from the TF/VIIa prothrombinase complex. APC, with its co-factor protein S (PS), inactivates Factors VIIIa and Va. ZPI inhibits Factor XIa, and with its co-factor protein Z (PZ), also efficiently inhibits Factor Xa. Lastly, AT, the most potent inhibitor of both Factor Xa and thrombin, binds to endothelial surface heparanoids to enable a greater than 1000-fold inactivation of thrombin.[7] Disorders involving endogenous anticoagulants result in thrombophilias (see Table 41–1).

Fibrinolysis

Restoration of the vasculature to its normal state is enabled by fibrinolysis. Fibrinolysis occurs when plasmin degrades cross-linked fibrin polymers to form fibrin degradation products (FDPs).[8] Plasmin is derived from plasminogen via proteolysis by tissue-type plasminogen activator (tPA) and is embedded within the fibrin clot.

As with all systems of checks and balances in the hemostatic system, fibrinolysis is further regulated by a series of inhibitors, including α_2-plasmin inhibitor, plasminogen activator inhibitor-1 (PAI-1), and thrombin-activatable fibrinolysis inhibitor (TAFI). PAI-1 is an inhibitor of tPA and released by platelets and endothelial cells in response to thrombin binding to protease-activated receptors.[9] PAI-1 bound to vitronectin and heparin inhibits thrombin and Factor Xa activity.[10] Overexpression of PAI-1 results in hypercoagulability (see Table 41–1).

EFFECTS OF PREGNANCY ON HEMOSTASIS

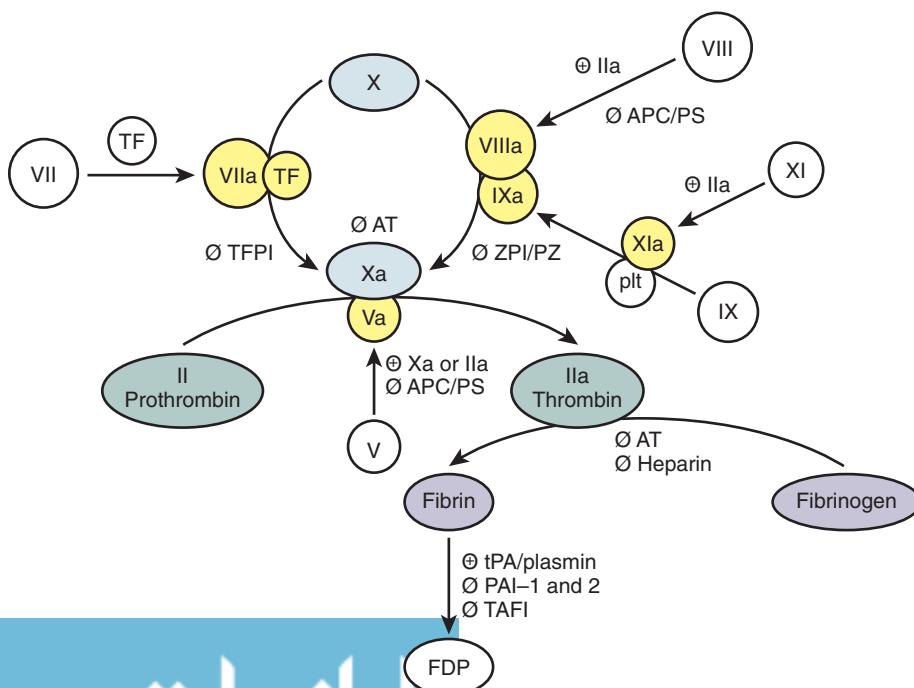
Virchow's classic triad of stasis, vascular trauma, and hypercoagulability all occur naturally in pregnancy. Estrogen augments G-protein receptor coupling and drives endothelium-derived nitric oxide production, resulting in vessel dilation and increasing deep vascular capacitance. Venous stasis is further exacerbated by positional obstruction of the lower


FIGURE 41–1
Hemostatic, thrombotic, and fibrinolytic pathways. Ø, inhibitory effect; ⊕, stimulatory effect.
(From Gabbe SG, Niebyl JR, Simpson JL, et al [eds]: Obstetrics: Normal and Problem Pregnancies, 5th ed. Philadelphia, Churchill Livingstone, 2007.)

extremity vasculature by the enlarging uterus.[11,12] Endothelial damage frequently occurs peripartum, especially when associated with cesarean delivery, hypertension, tobacco use, and infections.

The hypercoagulable state results from changes in the coagulation cascade including

- Increases by 20% to 1000% in fibrinogen, vWF, Factors II, VII, VIII, IX, and X levels.[13]
- Decreases by 60% to 70% in level of PS. Levels nadir at delivery due to hormonally induced increases in levels of the PS carrier protein, complement 4B-binding protein.[14–17]
- Progressive increases in resistance to APC.[18]
- Increases in the levels of antifibrinolytic PAI-1 and PAI-2.[19,20]
- Progressive platelet activation.

HYPERCOAGULABLE DISORDERS

Acquired Thrombophilia

Antiphospholipid antibody syndrome (APAS) is an autoimmune disorder of coagulation that predisposes to clot formation. Anionic phospholipids, such as cardiolipin and phosphatidylserine, are major components of the inner layer of cell membranes, which are exteriorized following endothelial cell perturbations. Proteins binding negatively charged phospholipids such as β_2-glycoprotein-I (β_2GPI) alter their tertiary shape and become neoantigens that are then targeted by the immune system. More than half of the patients with antiphospholipid antibodies have secondary APAS, which is defined by the presence of an underlying disorder, such as systemic lupus erythematosus (SLE).

The multiple pathways by which antiphospholipid antibodies induce a thrombophilia include

- Direct inhibition of the anticoagulant effects of anionic phospholipids-binding proteins such as β_2GPI and annexin V.[21,22]
- Inhibition of thrombomodulin, APC, and AT activity.
- Induction of tissue factor, PAI-1, and vWF expression in endothelial cells.
- Augmentation of platelet activation.
- Induction of complement activation.[23]

Diagnosis

The diagnostic criteria for APAS have evolved through debate in the expert community. The original Sapporo classification from 1999[24] was revised during a recent international consensus conference in 2006.[25] The requirement for one clinical criterion and one laboratory criterion has allowed for uniformity in diagnosis.

CLINICAL CRITERIA

The diagnosis of APAS requires one clinical criterion, which may be either related to an adverse pregnancy outcome (APO) or a nonobstetric thrombotic event.

Obstetric Outcomes

1. History of *three* unexplained consecutive spontaneous abortions at 10 weeks' or less gestational age (GA), or
2. History of unexplained fetal death of 10 weeks' or later GA (morphologically and karyotypically normal), or

3. History of preterm delivery at less than 34 weeks' GA, as a sequelae of preeclampsia or uteroplacental dysfunction, including the following:
   - Non-reassuring fetal testing indicative of fetal hypoxemia (e.g., abnormal Doppler flow velocimetry waveform).
   - Oligohydramnios (amniotic fluid index ≤5 cm).
   - Intrauterine growth restriction (IUGR) below the 10th percentile.
   - Placental abruption.

Nonobstetric Outcomes

Thrombosis in any tissue, diagnosed by objective, validated criteria, such as diagnostic imaging or histopathologic diagnosis.

1. Arterial thrombosis including cerebrovascular accidents, transient ischemic attacks, myocardial infarction, amaurosis fugax.
2. Venous thromboembolism (VTE) including deep venous thrombosis (DVT), pulmonary emboli (PE), or small vessel thrombosis.

LABORATORY CRITERIA

Positive testing for antiphospholipid antibodies is required on two occasions, at least 12 weeks apart, and no more than 5 years prior to clinical manifestations. Any of the three following tests can be utilized to fulfill the criteria:

1. **Anticardiolipin antibody** (ACA) immunoglobulin G (IgG) or IgM isotype, present in medium or high titers (i.e., >40 GPL or MPL, or >99th percentile), or
2. **Anti-β_2GPI antibody** IgG or IgM isotype (>99th percentile), or
3. Presence of **lupus anticoagulant** (LA) in plasma. It is important to recognize that LA is a misnomer that arises from its in vitro ability to prolong phospholipid-dependent coagulation tests, despite its in vivo thrombogenic properties. One common test used is the dilute Russell viper venom time (dRVVT), which utilizes the coagulant properties of the snake venom to activate Factor X and promote thrombin production. The presence of LA will prolong the clotting time.

Maternal and Fetal Risks
THROMBOSIS

Thrombotic outcomes vary depending on the qualifying criteria used to verify the diagnosis of APAS. The presence of ACAs alone entails a lower risk than positive LA, which signifies the presence of downstream effects of these antibodies on prothrombin activation. In a meta-analysis of more than 7000 patients, LA yields an odds ratio (OR) for arterial thrombosis of 8.6 to 10.8 and 4.1 to 16.2 for venous thrombosis.[26] The presence of ACA yields an OR for arterial thrombosis of 1 to 18 and a lower OR for venous thrombosis of 1 to 2.5.

In patients with APAS secondary to SLE, the risk of VTE has been similarly computed from a meta-analysis of 18 studies. ACA carrier status is associated with ORs of 2.50 (95% confidence interval [CI] 1.51–4.14) for acute VTE and 3.91 (95% CI 1.14–13.38) for recurrent VTE, whereas LA-positive status again carries higher ORs of 6.32 (95% CI

3.71–10.78) for VTE and 11.6 (95% CI 3.65–36.91) for recurrent VTE.[27]

ADVERSE PREGNANCY OUTCOMES

The diagnostic criteria for APAS include pregnancy complications that occur from conception through the third trimester. Here, we review the effects of APAS on subsequent pregnancies in a similar, chronologic fashion.

Despite its inclusion as a diagnostic criterion, there is much debate regarding the association of APAS with recurrent pregnancy loss (RPL) prior to 10 weeks' GA. The effect of APAS on pregnancy loss is clearer after the establishment of embryonic cardiac activity. More than 50% of pregnancy losses in patients with APAS occur after 10 weeks' GA.[28] Fetal heart activity was seen prior to fetal death in 86% of women with APAS, compared with only 43% of women without APAS ($P < .01$).[29] Furthermore, there was no significant association between APAS and clinical pregnancy rates (OR 0.99; 95% CI 0.64–1.53) or live birth (OR 1.07; 95% CI 0.66–1.75) in a meta-analysis of seven studies of women undergoing in vitro fertilization (IVF).[30] Finally, treatment of APAS patients does not appear to improve IVF outcomes.[31]

The data on fetal loss after the first trimester are more convincing. In a meta-analysis of 25 studies, LA was associated with late fetal loss with a pooled OR of 7.79 (95% CI 2.30–26.45), whereas moderate to high titers of LA yielded an OR of 4.68 (95% CI 2.96–7.40).[32]

In the second and third trimesters, APAS may manifest as IUGR and/or preeclampsia. The reported frequency of IUGR in APAS ranges from 11.7% to 31%.[33,34] A systematic review of APAS and preeclampsia revealed an OR of 2.73 (95% CI 1.65–4.51) for ACL, and 1.45 (95% CI 0.70–4.61) for LA. The association appears stronger for early-onset, recurrent severe preeclampsia compared with mild, near-term preeclampsia.[35]

The concern for thrombosis in APAS patients is heightened in the setting of pregnancy, given its inherent hypercoagulable state. In one report, more than half of the thrombotic episodes in patients with APS occurred in relation to pregnancy or the use of the combined oral contraceptive pill.[36] Some studies report a significant proportion of patients still have thrombotic episodes, even with medical and mechanical thromboprophylaxis.[34]

A rare but life-threatening variant of APAS with thrombosis is the catastrophic antiphospholipid syndrome (CAPS), characterized by multiple thromboses that lead to multiorgan failure. CAPS can be triggered by infection, trauma, surgery, anticoagulation withdrawal, or flares of underlying autoimmune processes. In a registry-based case series, 43% of CAPS in pregnancy occurred during the puerperium and 46% resulted in maternal mortality.[37]

APAS may affect a pregnancy beyond parturition secondary to the transplacental passage of antibodies. Neonatal antiphospholipid syndrome is a rare clinical condition that can cause neonatal thrombocytopenia, livedo reticularis, effusions, and thrombosis. Only a few cases have been described in the literature.[38]

Management Options

Management of APAS in pregnancy is directed at prevention of maternal and fetal adverse outcomes. Chapter 43 contains a detailed description of the treatment options for APAS.

Inheritable Thrombophilia

Background

Inherited thrombophilias predispose pregnant patients to various morbidities, including VTE, fetal loss, and placental abruption.[39–41] The following mutations are most common: APC resistance (most commonly caused by the Factor V Leiden [FVL] mutation), prothrombin G20210A mutation heterozygosity, hyperhomocysteinemia (most commonly associated with homozygosity for the methylenetetrahydrofolate reductase [MTHFR] mutation), and PAI gene 4G/4G polymorphism homozygosity. Rarer causes of inherited thrombophilias include AT deficiency, PS deficiency, protein C (PC) deficiency, and PZ deficiency (Table 41–2).

Factor V Leiden and Activated Protein C Resistance

MUTATION

FVL refers to a guanine to adenine point mutation at nucleotide 1691 on chromosome 1q23, resulting in the replacement of arginine by glutamine at position 506. The mutated Factor V is resistant to APC cleavage at position 506 and, therefore, retains its procoagulant activities while concealing the anticoagulant function.[42] The mutation is inherited in an autosomal dominant fashion.[43] Screening is done by assessing APC resistance, followed by genotyping for the FVL mutation if APC resistance is found.

FREQUENCY OF MUTATION

Homozygosity is present in 5% to 9% of the European population, 3% of African Americans, and 2.1% of Native American, but is virtually absent in African blacks and Asian populations. FVL is the most common heritable thrombophilia, accounting for 40% to 50% of cases of VTE in pregnancy.[44,45]

MATERNAL AND FETAL RISKS
Thrombotic Effects of Mutation

FVL heterozygosity confers a 5- to 10-fold increased risk of VTE, whereas homozygosity confers a greater than 25-fold increased risk of VTE.[46] Although FVL is present in 40% of pregnant patients with VTE, the estimated risk of VTE among heterozygous pregnant women without a personal or family history of thrombosis is only 1.5%, given the overall incidence of thrombosis in pregnancy (1 in 1400) and the high incidence of the mutation in the European-derived population.[41] The risk may be as high as 17% among pregnant women with a personal or strong family VTE history.[47] However, the applicability of such studies remains unclear because there were no differences in adverse outcomes between FVL carriers and noncarriers in a multicenter, prospective observational study of 134 FVL mutation carriers among 4885 gravidas.[48] Universal screening for FVL is not recommended at this time.

Fetal Loss

Several studies report strong associations between FVL and second- and/or third-trimester fetal loss, but not with early first-trimester losses.

TABLE 41–2

Inherited Thrombophilias and Their Association with Venous Thromboembolism in Pregnancy

TYPE	PREVALENCE IN EUROPEAN POPULATION (%)	PREVALENCE IN PATIENTS WITH VTE IN PREGNANCY	RR/OR OF VTE IN PREGNANCY (95% CI)	PROBABILITY OF VTE IN PREGNANCY WITH HISTORY (%)*	PROBABILITY OF VTE IN PREGNANCY WITHOUT HISTORY (%)*	REFERENCES
High Risk						41,47,69,97, 103,181–188
FVL homozygous	0.07	<1	25.4 (8.8–66)	>10	1.5	
PGM homozygous	0.02	<1	N/A	>10	2.8	
AT III deficiency	0.02–1.1	1–8	119	11–40	3.0–7.2	
FVL/PGM compound heterozygous	0.17	<1	84 (19–369)	4.7 (COMBINED RISK)		
Low Risk						
FVL heterozygous	5.3	44	6.9 (3.3–15.2)	>10	0.26	
PGM heterozygous	2.9	17	9.5 (2.1–66.7)	>10	0.37–0.5	
PC deficiency	0.2–0.3	<14	13.0 (1.1–123)		0.8–1.7	
PS deficiency	0.03–0.13	12.4			<1–6.6	
Hyperhomocysteinemia	<5		6.1 (1.3–28.4)			

* History of personal history of VTE or first degree relative with history of VTE.

AT III, antithrombin III; CI, confidence interval; FVL, Factor V Leiden; N/A, not available; OR, odds ratio; PC, protein C; PGM, prothrombin G mutation; PS, protein S; RR, risk ratio; VTE, venous thromboembolism.

- Roque and coworkers[49] evaluated 491 patients in a retrospective cohort study with a history of various APO and concluded that FVL carrier status was paradoxically protective against losses at less than 10 weeks with an OR of 0.23 (95% CI 0.07–0.77), but significantly associated with losses at greater than 14 weeks with an OR of 3.71 (95% CI 1.68–8.23).
- This protective effect of FVL on early pregnancy is also seen within the IVF population, where implantation rates were substantially higher among FVL carriers than among noncarriers (90% vs. 49%; P = .02).[50]
- In a meta-analysis of 31 studies in 2003, FVL was associated with early (<13 wk) pregnancy loss with an OR of 2.01 (95% CI 1.13–3.58), but was more strongly associated with late (>19 wk) fetal loss with an OR of 3.26 (95% CI 1.82–5.83).[51]
- In another meta-analysis of 54 case-control or cohort studies in 2004, pooled OR for association with first-trimester fetal loss with FVL was heterogeneous (P = .06) and no dose-response curve could be found. For second- and third-trimester fetal loss, there was a consistent and graded increase in risk, with isolated third-trimester fetal loss having an OR of 2.4 (95% CI 1.1–5.2), and recurrent second- and/or third-trimester fetal loss having an increased OR of 10.7 (95% CI 4.0–28.5).[52]
- In a French study, using a nested case-control group of 4396 pairs from a large cohort of 32,700 patients, multivariate analysis revealed an association between FVL and pregnancy loss after 10 weeks with an OR of 3.46 (95% CI 2.53–4.72), but not for losses occurring between 3 and 9 weeks.[53]
- A large European retrospective cohort involving 1524 pregnancies from 571 women with thrombophilia, compared with 1019 pregnancies from 395 controls, found a trend toward stillbirth for patients with FVL (OR 2.0; 95% CI 0.5–7.7), but no association with spontaneous abortion (OR 0.9; 95% CI 0.5–1.5).[54]

Preeclampsia

The link between FVL and preeclampsia is even more controversial. Overall, there is not sufficient evidence to conclude that FVL is associated with an increased occurrence of preeclampsia, though there is inadequate power to rule out an association between this thrombophilia and severe, early-onset preeclampsia.

- A prospective observational study in 1999 noted a link between FVL and severe preeclampsia in 110 women with APO (OR 5.3; 95% CI 1.8–15.6).[55] However, multiple subsequent case-control studies have failed to find a link between FVL and moderate to severe preeclampsia.[56–58]
- Dudding and Attia's meta-analysis[52] estimated a 2.9-fold (95% CI 2.0–4.3) increased risk of severe preeclampsia among FVL carriers.
- Lin and August[59] conducted a meta-analysis including 31 studies with 7522 patients. FVL associated with any preeclampsia had an OR of 1.81 (95% CI 1.14–2.87) and with severe preeclampsia with an OR of 2.24 (95% CI 1.28–3.94).
- Kosmas and colleagues[60] observed that studies performed before 2000 reported a modest association between FVL and preeclampsia (OR 3.16; 95% CI 2.04–4.92), whereas those published after 2000 did not (OR 0.97; 95% CI 0.61–1.54). A reporting bias appears to be present after the discovery of the mutation in the early 1990s, which may have since dissipated.
- A more recent meta-analysis in 2008 again revealed a significant but weak association with preeclampsia (pooled OR 1.49; 95% CI 1.13-1.96).[61]
- In 2009, the Montreal Preeclampsia Study[62] reviewed 113 preeclamptic patients from a cohort of 5162 patients, compared with 443 control subjects. This case-control study did not find an increased risk of preeclampsia, including early-onset or severe preeclampsia, in association with maternal FVL mutation.

- A risk of recurrent preeclampsia was found in 59% of patients with FVL mutation versus 25.9% of patients without thrombophilia in an Italian prospective cohort study published in 2009 involving 172 patients with a prior history of preeclampsia.[63]

Abruption

There may be an association between FVL and placental abruption.

- Kupferminc and associates[55] reported a modest association between FVL and abruption with an OR of 4.9 (95% CI 1.4–17.4).
- Procházka and coworkers[64] conducted a retrospective case-control study among 102 women with placental abruption and 2371 controls. The increase in FVL carriers among affected patients compared with controls, with an OR of 1.5 (95% CI 0.9–2.7), did not reach significance. However, in 2007, the same group[65] retrospectively reviewed 180 women with placental abruption and 196 controls, and this time noted a significantly increased carrier rate for FVL compared with controls, with an OR of 3.0 (95% CI 1.4–6.7).
- Alfirevic and colleagues[66] conducted a systematic review and reported a strong association between placental abruption and homozygosity for FVL, with an OR of 16.9 (95% CI 2.0–141.9). A milder, but statistically significant, association was also seen for FVL heterozygosity, with an OR of 6.7 (95% CI 2.0–21.6).
- The prospective, observational, nested carrier-control analysis from the National Institute of Child Health and Human Development (NICHHD) in 2005[48] revealed no difference between FVL carriers and noncarriers in development of abruption, but the study was underpowered for this observation.

Intrauterine Growth Restriction

There is no consistent evidence for an association between FVL and IUGR.

- Martinelli and associates[67] noted an association between FVL and IUGR, with an OR of 6.9 (95% CI 1.4–33.5).
- However, multiple large case-control and cohort studies have reported no statistically significant association between FVL and IUGR less than the 10th and less than the 5th percentiles.[55,58,68]
- A systematic review by Howley and coworkers[69] analyzed 10 case-control studies and 5 cohort studies. The case-control studies showed a significant association between FVL and IUGR, with a pooled OR of 2.7 (95% CI 1.3–5.5), whereas the cohort studies (2 prospective and 3 retrospective) showed no association (summative relative risk [RR] 0.99; 95% CI 0.5–1.9). This discrepancy highlights differences in studies based on design may account for many of the conflicts in the field. As a rule, the better the study, the weaker the association.
- The recent meta-analysis in 2008 by Dudding and colleagues[61] failed to identify an association with IUGR, yielding a pooled OR of 1.15 (95% CI 0.95–1.39).

Conclusions Based on Current Literature

Because it is the most common inheritable thrombophilia, there has been debate regarding the effect of FVL on various APOs. There is a positive association between FVL and fetal loss after 10 weeks, with a particularly strong association after 22 weeks. There is also probably an association with abruption. There is no association between FVL and early first-trimester embryonic loss, preeclampsia, or IUGR. Given its prevalence, we do not recommend routine FVL testing as a part of work-up for APO without a history of maternal VTE.

Prothrombin Gene Mutation
MUTATION

The G20210A polymorphism for prothrombin is a point mutation causing a guanine to adenine switch at nucleotide position 20210 in the 3′-untranslated region of the gene at chromosome 11p11-q12.[70] The switch results in increased translation and circulating levels of prothrombin. Other prothrombin gene mutations (PGMs) have been described (e.g., C20209T and A19911G), but literature is sparse regarding their effects.

FREQUENCY OF MUTATION

PGM is less prevalent than FVL and is present in only 2% to 3% of the European population, with the preponderance in southern Europeans.[41] The mutation is exceedingly rare in the black or Asian populations.[71]

MATERNAL AND FETAL RISKS
Thrombotic Effects of Mutation

PGM accounts for 13% to 17% of women with an initial VTE. However, because of the overall low incidence of VTE in pregnancy, the actual risk of clotting in a PGM mutation carrier is 0.5%. Homozygous patients without a personal or strong family history of a VTE have a 2.8% risk for VTE in pregnancy, whereas a positive history confers around a 20% risk in pregnancy. Compound heterozygosity for FVL and PGM results in a 4.6% risk of VTE, even in the absence of a strong family history.[41,72]

Fetal Loss

Analogous to FVL, the association between PGM and pregnancy loss may increase with increasing GA.

- One case-control study reported the presence of the PGM in 9% of recurrent miscarriage patients versus 2% of controls, yielding an OR of 4.7 (95% CI 0.9–23).[73] Finan and associates[74] also noted an association between PGM and recurrent abortion, OR of 5.05 (95% CI 1.14–23.2).
- Other studies failed to identify a link. Carp and coworkers[75] could detect no statistically significant association between PGM and pregnancy loss in a case-control study. Jivraj and colleagues[76] reached similar conclusions in a European white cohort.
- A 2003 meta-analysis of PGM reported an increased risk of recurrent first-trimester loss (OR 2.3; 95% CI 1.1–4.8), fetal loss prior to 28 weeks (OR 2.6; 95% CI 1.0–6.3), and late nonrecurrent fetal loss (OR 2.3; 95% CI 1.1–4.9).[51]
- A 2004 meta-analysis of seven studies evaluating the link between PGM and RPL, defined as 2 or more pregnancy losses in the first or second trimester, found a combined OR of 2.0 (95% CI 1.0–4.0).[77]

- Silver and coworkers, representing the NICHD MFM Unit network, performed a secondary analysis of the FVL study,[78] in patients who were also tested for the PGM polymorphism. They found no association between PGM and any APO in low-risk women without a history of VTE.

Preeclampsia

Multiple studies have failed to establish a link between PGM and either preeclampsia or severe preeclampsia.

- A small case-control study revealed a 5.2% carrier rate for PGM in women with preeclampsia, compared with 4.1% ($P = .76$) in controls.[58]
- A meta-analysis including 31 studies with 7522 patients by Lin and August[59] observed a pooled OR for PGM and all preeclampsia was 1.37 (95% CI 0.72–2.57) and 1.98 (95% CI 0.94–4.17) for severe preeclampsia.
- Morrison and associates[79] compared 404 women with preeclampsia to gestational hypertensive and healthy controls and found no association between preeclampsia and PGM. Livingston and coworkers[80] performed a prospective cross-sectional study and found no differences of PGM carrier rate between patients with severe preeclampsia and controls (0% vs. 1.1%, $P = .92$). Similarly, in a 2007 case-control study by Larciprete and colleagues,[81] there was no association between PGM and preeclampsia.
- The Montreal Preeclampsia Study[62] reviewed 113 preeclamptic patients from a cohort of 5162 patients, compared with 443 control subjects in 2009. This case-control study did not find an increased risk of preeclampsia, including early-onset or severe preeclampsia, in association with maternal PGM.

Abruption

There is likely no association between PGM and abruption.

- The case-control study of Kupferminc and associates[55] observed an association between PGM and abruption (OR 8.9; 95% CI 1.8–43.6).
- Procházka and associates noted in the 2003 retrospective case-control study[64] an association between PGM and abruption, OR of 8.9 (95% CI 1.8–43.6).
- The systematic review by Alfirevic and colleagues in 2002[66] also suggests a link between PGM heterozygosity and placental abruption, with an OR of 28.9 (95% CI 3.5–236.7).

Intrauterine Growth Restriction

There is also likely no association between PGM and IUGR.

- Kupferminc and associates[55] found an association between PGM and IUGR (<5th percentile), OR 4.6 (95% CI 1–20). Martinelli and colleagues[66] also noted an association, OR 5.9 (95% CI 1.2–29.4).
- In contrast, the large case-control study of Infante-Rivard and coworkers[68] could identify no link between heterozygotes for PGM and IUGR (OR 0.92; 95% CI 0.36–2.35). Franchi and colleagues[82] and Verspych and associates[83] concluded similarly.
- Facco and coworkers reported in a 2009 meta-analysis[84] that the association between PGM and IUGR was not significant (OR 1.52; 95% CI 0.98–2.35).

Conclusion Based on Current Literature

Uncertainty exists regarding the putative role of PGM in the genesis of APO. We do not recommend PGM testing as a routine part of work-up for APO without a history of maternal VTE.

Hyperhomocysteinemia

MUTATION

Homozygosity for mutations in the MTHFR gene on chromosome 1p36.3, such as C677T and A1298C polymorphisms, is the most common cause of hyperhomocysteinemia. C677T is a thermolabile variant that causes mild enzymatic dysfunction and mild hyperhomocysteinemia in folate-deficient patients. The A1298C mutation alone does not cause hyperhomocysteinemia, but compound heterzogysity of A1298C/C677T may induce a biochemical profile similar to C677T homozygosity.[85]

FREQUENCY OF MUTATION

Homozygosity for the MTHFR C677T and A1298C polymorphisms is present in 10% to 16% and 4% to 6% of all Europeans, respectively.[86] Allele frequency is 7% in sub-Saharan African and 34% in Japanese populations. Little data are available for other populations.[84] Clinical sequelae are rare in the United States because of folate fortification of grains, which has resulted in decreased national homocysteine levels, which are then further decreased by physiologic changes of pregnancy. It is not appropriate to screen by testing for the presence of an MTHFR mutation, which is the second step after first identifying hyperhomocysteinemia. Screening for this disorder in pregnancy should use a cutoff of greater than 12 μmol/L.

MATERNAL AND FETAL RISKS

Thrombotic Effects of Mutation

Hyperhomocysteinemia is a risk factor for VTE with an OR of 2.5 (95% CI 1.8–3.5).[87] Isolated MTHFR mutations without hyperhomocysteinemia do not convey an increased risk for VTE in either nonpregnant[88] or pregnant women.[89] This finding was confirmed in 2008 in a large population-based study of 66,140 individuals from Norway in whom there was no association between VTE and isolated MTHFR mutation in women.

Fetal Loss

As with thrombotic risk, elevated fasting homocysteinemia is associated with RPL rather than isolated MTHFR mutation.

- A meta-analysis by Nelen and colleagues in 2000[90] calculated pooled risk estimates for fetal loss at less than 16 weeks of 2.7 (95% CI 1.4–5.2) for hyperhomocysteinemia and 1.4 (95% CI 1.0–2.0) for isolated MTHFR mutation.
- In a review of 14,492 pregnancy outcomes, the Hordaland Homocysteine Study[91,92] concluded there was an association of elevated homocysteine with stillbirth (OR 2.03; 95% CI 0.98–4.21), though this did not reach statistical significance.

Preeclampsia

There is no clear association between hyperhomocystein-emia or isolated MTHFR mutation and preeclampsia.

- In a case-control study of various polymorphisms of MTHFR, there was no association identified between MTHFR mutation and preeclampsia.[93] The Hordaland Homocysteine Study[91,92] reached a similar conclusion (OR 1.32; 95% CI 0.98–1.77).
- Induced hyperhomocysteinemia is not sufficient to induce a preeclamptic state in the mouse.[94]

Abruption

There is an association between hyperhomocysteinemia and placental abruption, but not with isolated MTHFR mutation.

- In a 2007 case-control study from the New Jersey-Placental Abruption group,[95] neither homozygosity for C677CT (OR 0.60; 95% CI 0.33–1.18) nor A1298C (OR 2.28; 95% CI 0.82–6.35) was associated with placental abruption.
- The Hordaland Study[91,92] observed a clear association between abruption and homocysteine greater than 15 μmol/L (OR 3.13; 95% CI 1.63–6.03); a weaker but significant association was observed between C677T homozygosity and abruption (OR 1.6, 95% CI 1.4–4.8).
- A meta-analysis confirmed the previous finding, with hyperhomocysteinemia yielding a stronger pooled OR for abruption of 5.3 (95% CI 1.8–15.9) than MTHFR mutation homozygosity (OR 2.3; 95% CI 1.1–4.9).[96]

Intrauterine Growth Restriction

A weak association may be present between hyperhomocysteinemia and IUGR, but this may reflect publication bias.

- The Hordaland Study[91,92] showed an association between elevated homocysteine and very low birth weight (OR 2.01; 95% CI 1.23–3.27).
- In a 2009 meta-analysis of case-control studies, Facco and coworkers[84] reported that the association between MTHFR mutation and IUGR was not significant (OR 1.01, 95% CI 0.88–1.17), but was significant for the case-control studies (OR 1.35, 95% CI 1.04–1.75). A funnel-plot analysis of the case-control studies suggests publication bias.

Conclusion Based on Current Literature

Studies strongly suggest that hyperhomocysteinemia, not isolated MTHFR mutations, is linked to VTE and APO. There is a positive association between hyperhomocysteinemia and abruption. There may be a weak association with IUGR and fetal loss. There is no association between hyperhomocysteinemia and preeclampsia. Additional risks include fetal neural tube defects, with C677T heterozygosity yielding an OR of 1.52 (95% CI 1.16–2.00) and homozygosity yielding an OR of 2.56 (95% CI 1.75–3.74).[97]

Protein C Deficiency
MUTATION

Deficiencies of PC result from over 160 distinct autosomal dominant mutations, producing a highly variable phenotype. Two primary types are recognized: (1) type I, with reduced antigen and activity levels and (2) type II, with normal levels but reduced activity. Most laboratories use activity levels below 50% to 60% as abnormal.

FREQUENCY OF MUTATION

PC deficiencies occur with a frequency of 0.2% to 0.5% in the general population.[98]

MATERNAL AND FETAL RISKS
Thrombotic Effects of Mutation

PC deficiency carries a less than 2% to 8% risk of VTE during the antepartum period, a 10% to 20% risk in the puerperium, and accounts for 10% to 25% of all VTEs in pregnancy.[99] RR for VTE is reported as 6.5 to 12.5.[69]

Fetal Loss

There is no clear association between PC deficiency and miscarriage, but there may be an association with stillbirth.

- In a 1996 study, loss rates were 28% for PC deficiency, compared with the control group, which had a loss rate of 11%.[54]
- Preston and associates[54] reported the risk of miscarriage does not appear increased with PC deficiency (OR 1.4; 95% CI 0.9–2.2), and although the risk of stillbirth seemed modestly increased, it did not reach statistical significance (adjusted OR 2.3; 95% CI 0.6–8.3).
- In contrast, Alfirevic and colleagues[66] found no association of PC deficiency with stillbirth in a meta-analysis. Saade and McLintock[101] also failed to find an association between PC deficiency and late fetal loss, with adjusted an OR of 1.22 (95% CI 0.09–15).

Preeclampsia

A limited number of studies note a strong association between PC deficiency and preeclampsia.

- Roque and coworkers[49] reported a strong association between PC deficiency and preeclampsia in a retrospective cohort study (OR 6.85; 95% CI 1.09–43.2). A meta-analysis also concluded there was a strong association (OR 21.5; 95% CI 1.1–414.4).[65]

Abruption

There is a paucity of literature on the potential relationship between PC deficiency and abruption.

- Roque and coworkers[49] observed a strong association between PC deficiency and abruption (OR 13.9; 95% CI 2.21–86.9).

Intrauterine Growth Restriction

There are no reports on the association of PC deficiency with IUGR.

Conclusion Based on Current Literature

There is a positive association between PC deficiency and preeclampsia, and perhaps a weaker association with IUGR (very limited data). There is no clear association between PC deficiency and early miscarriage. There are insufficient data to evaluate the relationship between PC deficiency and abruption or IUGR. It is worth noting that neonatal purpura fulminans may occur with PC deficiency.[102,103]

Protein S Deficiency

MUTATION

Over 130 mutations have been linked to PS deficiency.[69] Two major phenotypes of PS deficiency exist: (1) type I, with low total and free PS antigen levels, and (2) type IIb, with low free PS levels due to enhanced binding to the complement 4B–binding protein. Type IIb phenotype is frequently caused by a serine to proline mutation (PS Heerlen), which is also associated with either FVL or PC mutation in about half the patients, suggesting a synergistic effect.[104]

PS activity assay is associated with substantial inter-assay and intra-assay variability, due in part to frequently changing physiologic levels of complement 4B–binding protein.[105] Paidas and coworkers[106] noted far lower levels in normal pregnancy, suggesting the cutoffs for free PS levels in the second and third trimester of 38.9% ± 10.3% and 31.2% ± 7.4%, respectively.

FREQUENCY OF MUTATION

The prevalence of true PS deficiency is low (0.03%–0.13%).[69,104]

MATERNAL AND FETAL RISKS

Thrombotic Effects of Mutation

The degree of thrombogenicity is modest (OR 2.4; CI 0.8–7.9). Among those with a strong family history, the risk of VTE in pregnancy is 6.6%.[98]

Fetal Loss

There appears to be an association between PS deficiency and fetal loss.

- One meta-analysis observed an association between PS deficiency and recurrent late fetal loss (OR 14.7; 95% CI 1.0–2181), as well as nonrecurrent fetal losses at greater than 22 weeks (OR 7.4; 95% CI 1.3–43).[51]
- A second meta-analysis suggested an even stronger link between PS deficiency and stillbirth (OR 16.2; 95% CI 5.0–52.3).[65]
- Saade and McLintock[101] also noted an association between PS deficiency and late fetal loss, with an adjusted OR of 41 (95% CI 4.8–359).
- In a 2006 systematic review, PS deficiency was associated with late pregnancy loss with an OR of 20.1 (95% CI 3.7–109).[107]

Other Adverse Pregnancy Outcomes

Alfirevic and colleagues[66] concluded after a meta-analysis that there was a link between PS deficiency and preeclampsia-eclampsia (OR 12.7; 95% CI 4–39.7) and IUGR (OR 10.2; 95% CI 1.1–91.0), but not between PS deficiency and abruption.

Conclusion Based on Current Literature

There is a positive association between PS deficiency and fetal loss. There may well be an association with preeclampsia and IUGR, but the data are too limited. There is no association was between PS deficiency and abruption. Note, neonatal purpura fulminans may occur with PS deficiency.

Antithrombin Deficiency

MUTATION

AT deficiency is an autosomal dominant condition. Over 250 mutations of the AT gene contribute to a highly variable phenotype, with three main variants.[69,108] Type I involves reductions in both antigen and activity; type II has normal antigen levels but decreased activity; and type III is a very rare homozygous deficiency associated with little or no activity. Acquired AT deficiency may result from decreased production (hepatic dysfunction), consumptive coagulopathy (disseminated intravascular coagulation [DIC]), or increased excretion (nephrotic syndrome). The laboratory cutoff of 50% function is used.

FREQUENCY OF MUTATION

AT deficiency is the rarest of the heritable thrombophilias, with prevalence from 0.02% to 1.1%.[108]

MATERNAL AND FETAL RISKS

Thrombotic Effects of Mutation

AT deficiency confers the highest thrombogenic risk of the heritable thrombophilias, with a 25-fold increase in the non-pregnant state.[108] However, only 1% to 8% of VTE is due to AT deficiency owing to its low prevalence.[69] Thromboembolism during the antepartum period occurs at a range of 12% to 60%, and in the puerperium of 11% to 33%.[109] Risk can be further stratified based on personal or family history of thromboembolic events, with VTE developing in 3% to 7% without a history and up to 40% with a history.[71]

Obstetric Effects of Mutation

In a large retrospective cohort study, AT deficiency was associated with an increased risk of stillbirth at greater than 28 weeks (OR 5.2; 95% CI 1.5–18.1), but a far more modest association with miscarriage at less than 28 weeks (1.7; 95% CI 1.0–2.8).[54] Given its very low prevalence, there are little data linking it to other APOs. Roque and coworkers[49] observed an increased risk of IUGR (OR 12.93; 95% CI 2.72–61.45) and abruption (OR 60.01; 95% CI 12.02–300.46).

Conclusion Based on Current Literature

There is a positive association was found between AT deficiency and stillbirth after 28 weeks' GA. Possible associations exist with early stillbirth, IUGR, and abruption.

Protein Z Deficiency

MUTATION

Two nonsense mutations in the coding region of the PZ gene account for most cases of PZ deficiency. Normal PZ levels in the second trimester are 2.0 ± 0.5 μg/mL, and in the third trimester, levels are 1.9 ± 0.5 μg/mL, with a statistically significant decrease in patients with adverse outcomes.[105]

FREQUENCY OF MUTATION

Unknown.

MATERNAL AND FETAL RISKS
Thrombotic Effects of Mutation

In one study, PZ deficiency was identified in 4.4% of patients with VTE, compared with 0.8% of controls (OR 5.7; 95% CI 1.25–26.0).[110] In another study, PZ deficiency (activity < 5th percentile) was associated with strokes, but not VTE.[111] Other studies have shown that PZ deficiency influences the prothrombotic phenotype in patients with the FVL mutation.[112]

Obstetric Effects of Mutation

PZ deficiency has been linked to late fetal loss (10–16 wk′ gestation) in one study (OR 6.7; 95% CI 3.1–14.8),[132] but not others.[113,114] In the presence of other thrombophilic mutations in patients with prior fetal loss, PZ deficiency may confer resistance to heparin therapy.[111]

Plasminogen Activator Inhibitor-1 Overexpression
MUTATION

Two polymorphisms, A844G and –675 4G/5G, are described in the promoter region of the PAI-1 gene on chromosome 7q21.3-22.[115] In patients homozygous for the 4G/4G allele, the presence of four instead of five consecutive guanine nucleotides in the PAI-1 promoter produces a site that is too small to allow repressors to bind. As a result, circulating PAI-1 levels are modestly increased.[116] Conversely, the A844G polymorphism affects a consensus sequence binding site for the regulatory protein Ets, thereby enhancing PAI-1 transcription. Whereas laboratory testing for the PAI-1 antigen is reliable via immunoassay, PAI-1 activity assay is best performed in a reference laboratory because variable results for PAI-1 activity are common.

FREQUENCY OF MUTATION

The prevalence of the 4G/4G genotype in the general population is high, ranging from 23.5% to 32.3%.[117,118]

MATERNAL AND FETAL RISKS
Thrombotic Effects of Mutation

Most studies have not found an association between the –675 4G/5G polymorphism and VTE.[119–121] However, the 4G/4G genotype, in conjunction with FVL or PS deficiency, has been linked to an increased risk for VTE, suggesting an additive role despite lack of independent thrombogenic activity.[122] No relationship has been identified between the A844G and VTE.[118]

Fetal Loss

There was no association between isolated homozygosity for 4G/4G and recurrent abortion in several small studies.[123,124] Glueck and colleagues[125] conducted a case-control study and observed that compared with patients with 5G/5G or 4G/5G, patients homozygous for 4G/4G had more second- and third-trimester fetal deaths (9% vs. 2%; *P* = .004). However, a larger multicenter study did not find a relationship between fetal loss and 4G/4G, though it had less than 30% power to detect a difference.[126]

Preeclampsia

Yamada and associates[127] described a modest association between 4G/4G homozygosity and severe preeclampsia (OR 1.62; 95% CI 1.02–2.57).

Intrauterine Growth Restriction

Glueck and colleagues's case-control study[125] noted that homozygous 4G/4G allele had higher rates of IUGR (4% vs. 0.4%; *P* = .012). However, caution must be exercised in the interpretation because 30% of patients homozygous for the 4G/4G mutation also had coexisting thrombophilias. In addition, affected patients generally exhibit elevated PAI-1 levels only in the presence of metabolic syndrome, which is itself a major risk factor for preeclampsia.

Conclusion Based on the Literature

The significance of derangements in PAI-1 activity, antigen, or the presence of the 4G/4G mutation remains uncertain with respect to VTE and APOs owing to limited data. Based upon available evidence, screening for PAI-1 activity, antigen, and the genetic 4G/5G mutation should be strongly discouraged in the investigation of APOs.

Management Options for Inheritable Thrombophilias
SCREENING

Patients with a personal history of VTE, a strong family history of VTE, or a history of APO may be candidates for evaluation of inheritable thrombophilias. Screening of an unselected population is not recommended.[128]

DIAGNOSIS

Laboratory testing for thrombophilia should ideally be done in the nonpregnant patient who is not receiving hormonal or anticoagulation therapy and is remote (>6 mo) from a history of VTE.[129] Testing can include APC resistance (with FVL polymerase chain reaction [PCR] for confirmation), PGM G20210A PCR, fasting homocysteine levels, AT activity, PC activity, PS activity (with consideration for normally reduced PS levels in pregnancy), and PAI-1 protein assay. Genotyping for PAI-1 4G/4G mutation and MTHFR mutation are not recommended.

TREATMENT
Prevention of Adverse Pregnancy Outcomes

Several small observational studies suggest a benefit of anticoagulation to prevent APOs in patients with various thrombophilias.[130,131] Gris and coworkers[132] randomized 160 patients with FVL, prothrombin 20210A, or PS deficiency and a history of one unexplained loss after 10 weeks to either low-dose aspirin or enoxaparin (40 mg subcutaneously daily). They observed a significant increase in live-born rates in the enoxaparin group (86.2% vs. 28.8%; OR 15.15; 95% CI 7–34). However, given the lack of consistent evidence of an association between maternal thrombophilia and recurrent early first-trimester loss (<10 wk), anticoagulant therapy does not at present appear justified.[49] Definitive recommendations await further clinical trials of anticoagulation in this population. Vitamin B$_{12}$ and folic

acid should be supplemented if hyperhomocysteinemia is diagnosed.

Prevention of Venous Thromboembolism

Women with high risk (more thrombogenic) thrombophilias (AT deficiency, FVL homozygosity, and PGM homozygosity and FVL/PGM compound heterozygosity) should be treated with full therapeutic anticoagulation during pregnancy, and for at least 6 weeks postpartum, regardless of the history. Pregnant women who have low risk (less thrombogenic) thrombophilias (FVL heterozygosity, PGM heterozygosity, PC or PS deficiency, hyperhomocysteinemia [unresponsive to folate therapy]) do not need antepartum anticoagulation if there is no personal history of VTE or affected first-degree relative.[133] However, they should receive postpartum prophylaxis if they require a cesarean delivery because most fatal pulmonary emboli occur during this period.[134] Some experts also recommend postpartum prophylaxis in the setting of vaginal delivery, and especially if the patient has an affected first-degree relative or another thrombotic risk factor (e.g., obesity or immobilization).

Prevention of Recurrent Venous Thromboembolism

Women with VTE during a current pregnancy should receive therapeutic anticoagulation for at least 4 months during the pregnancy, followed by prophylactic therapy for at least 6 weeks postpartum. Women with a history of VTE associated with nonrecurrent risk factors (e.g., surgery, orthopedic immobilization), but without acquired or inherited thrombophilia, appear to be at very low risk for a repeat event. Although anticoagulation during the antepartum period appears unnecessary in these patients, prophylaxis should be used during the higher risk postpartum period.[135]

SUMMARY OF MANAGEMENT OPTIONS
Inherited Thrombophilias

Management Options	Evidence Quality and Recommendation	References
Screening		
Screening should be considered in patients with personal history of VTE or a strong family history of VTE.	III/B	169
Population screening is not recommended.	III/B	128
Screening for inheritable thrombophilia is not recommended in patients with history of APOs.	III/B	128
Laboratory testing should include APC resistance (with FVL PCR for confirmation), PGM G20210A PCR, fasting homocysteine levels, AT activity, PC activity, PS activity, and PAI-1 protein assay.	IV/C	129
Prenatal		
Unclear benefit of treatment for a history of APO with anticoagulation.	IIa/B	172,189
Provide therapeutic heparin or low-molecular-weight heparin with VTE during pregnancy.	IV/C	134
Provide prophylactic or therapeutic heparin or low-molecular-weight heparin for a history of VTE, depending on the level of risk and recurrent features.	IV/C	133
Provide folate and vitamin B12 supplementation for hyperhomocysteinemia.	III/B	133
Intrapartum		
Reduce or stop heparin for labor and delivery; restart after 6 hr.	III/B	173
Postnatal		
Switching to warfarin postpartum is an option.	III/B	174

Essential Thrombocythemia

Essential thrombocythemia is a nonreactive chronic myelo-proliferative disorder with sustained elevation of the platelet count.[136] A slight female preponderance is reported, with a overall prevalence of 2.38 patients per 100,000.[137] Proposed etiologies include increased sensitivity to cytokines and decreased inhibition of platelet inhibitory factors.

Diagnosis

Typical criteria used in the diagnosis of essential thrombocythemia include platelet count greater than 600,000/μL, megakaryocyte hyperplasia, splenomegaly, and hemorrhagic or thrombotic complications. Weight loss, sweating, low-grade fever, and pruritus may occur in up to 20% of patients. Although 40% to 50% of patients have splenomegaly and 20% have hepatomegaly, most are undetectable by physical examination and seen only on ultrasound or computed tomography. Typically, prothrombin time and activated partial thromboplastin time (aPTT) are unaffected. One fourth of patients have elevated uric acid and vitamin B_{12} levels. Levels of potassium, phosphorus, and acid phosphatase may be falsely elevated. Elevated levels of acute-phase reactant C-reactive protein, fibrinogen, and interleukin-6 suggest secondary thrombocytosis.[138]

Maternal and Fetal Risks

THROMBOSIS

Essential thrombocythemia may cause arterial or venous occlusive disease. Microvascular disease may involve transient ischemic attacks, migraine, visual dysfunction, digital ischemia, and erythromelalgia.[139,140] Arterial thrombosis may include occlusion of the lower extremity, pulmonary, coronary, or renal arteries. Venous thrombosis of the splenic, hepatic, or pelvic veins may occur.[73,141]

HEMORRHAGE

Hemorrhagic complications are seen in patients with very high platelet counts (>1,000,000/μL) and may include bruising of the skin and bleeding of the mucous membranes or digestive tract. This paradoxical effect occurs via a functional deficiency of von Willebrand's multimers.[142,143]

LEUKEMIA

The evolution of essential thrombocythemia into leukemia is rare, but the incidence may be increased by some chemotherapeutic agents.[144]

ADVERSE PREGNANCY OUTCOMES

Essential thrombocythemia in pregnancy is associated with a 50% risk of obstetric complications, including recurrent abortion, premature delivery, IUGR, and placental abruption. The proposed mechanism of pathogenesis is placental infarction.

Management Options

Some authors recommend treatment during pregnancy with aspirin or subcutaneous heparin.[145,146] Current recommendations for treatment have yet to be defined, as illustrated by a Mayo Clinic study that showed no therapeutic benefit of treatment in 18 women (34 pregnancies) with essential thrombocythemia.[147] In this study, 45% of pregnancies ended in spontaneous abortion, with no specific factors predisposing to miscarriage. Because outcomes were similar in treated versus untreated patients, anticoagulation is not recommended in asymptomatic low risk patients.

Interferon-alfa (pregnancy category C) is a cytoreductive agent that antagonizes platelet-derived growth factor and is associated with a dose-dependent reduction in platelet count. A 90% reduction in the platelet count (<600,000/μL) has been obtained after 3 months of therapy, with an average dose of 3 million IU daily. It has been used in some pregnant patients without apparent harm[148,149] and has been used successfully in those candidates who are at increased risk for thrombosis.[150]

Two pregnancy category D medications used efficaciously outside of pregnancy are hydroxyurea and busulfan.[151] Lastly, anagrelide (pregnancy category C) is a newer imidazoquinolin that causes the suppression of megakaryocytes and thus decreases platelet counts without affecting other hematopoietic cell lines. Significant complications include palpitations, tachycardia, cardiac arrhythmias, and congestive heart failure. Little is known about its use in pregnancy.[148]

SUMMARY OF MANAGEMENT OPTIONS
Essential Thrombocythemia

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Provide interdisciplinary approach.	III/B	176
Use expectant approach in symptomatic patients with only moderate elevation of platelets.	III/B	176
In symptomatic patients (thrombosis or bleeding), consider plasmapheresis in first instance.	III/B	176
Provide low-dose aspirin and heparin if thrombosis occurs; evidence does not support use in all cases.	III/B	176

Management Options	Evidence Quality and Recommendation	References
Hydroxyurea has been used, but most experience is with chronic myelogenous leukemia.	III/B	151
Limited experience with interferon-alfa.	III/B	148,150
No experience with anagrelide; avoid.	III/B	149
Obtain serial fetal growth and umbilical artery Doppler velocimetry.	III/B	147,150
Labor and Delivery		
Maintain vigilance for postpartum hemorrhage.	III/B	142,143

Thrombotic Thrombocytopenic Purpura–Hemolytic-Uremic Syndrome

The classic pentad of thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP-HUS) consists of thrombocytopenia (<30,000/μL), microangiopathic hemolytic anemia (MAHA), fever, and neurologic and renal abnormalities, but the complete complement of findings is seen in only a minority of patients. TTP-HUS may be triggered by pregnancy, pathogenic bacterial diarrhea, autoimmune processes, drugs, HIV, malignancy, or malignant hypertension.

Most patients with TTP-HUS are women (69%), and a significant number are pregnant (25%).[152] Puerperium is the most likely period for TTP-HUS to develop. The clinical picture is often ambiguous in pregnancy, and differential diagnoses may include lupus flare, severe preeclampsia, and HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome.

Damage to the microvascular endothelial cells, leading to release of usually large von Willebrand's multimers, is the current hypothesis to explain the pathogenesis of TTP-HUS.[153,154] Typically, these large multimers are cleaved to a normal size by a plasma protease specific to vWF.[155] Accumulation of these multimers is associated with the promotion of platelet aggregation,[156] but is not specific for TTP-HUS.[157]

ADAMST13 Deficiency

Patients with TTP-HUS may have an inherited or acquired deficiency of the vWF-cleaving protease, named a disintegrin and metalloproteinase with thrombospondin type 1 (ADAMST13). Deficiencies of ADAMST13 lead to disseminated formation of platelet-rich thrombi in the microcirculation, mechanical hemolytic anemia, consumptive thrombocytopenia, and multivisceral ischemia.[158] Severe ADAMST13 deficiency is associated with TTP-HUS relapses in 37%, compared with 6% of those without severe ADAMST13 deficiency. During remission, persistently undetectable levels of ADAMST13 in patients with severe ADAMST13 deficiency have been associated with a 38% risk of relapse, compared with a 5% risk with detectable levels.

False positives, with less pronounced reductions in ADAMST13 levels, can be seen in patients with DIC, isoimmune thrombocytic purpura, severe sepsis, SLE, cirrhosis,

and heparin-induced thrombocytopenia, and even in patients without disease. In pregnancy, these protease levels decline with advancing gestation. Thus, an asymptomatic pregnant patient with decreased baseline levels of cleaving protease may not manifest with TTP-HUS until late gestation.[159]

Diagnosis and Maternal and Fetal Risks

Classically, the diagnosis of TTP-HUS was made only if the patient had the classic pentad of signs and symptoms as described previously. Because of the ability of plasma exchange to improve the survival rate from less than 10% to approximately 80%, the diagnostic criteria have been eased.[160,161] Thrombocytopenia coupled with MAHA without an alternative diagnosis is sufficient to define TTP-HUS and possibly begin plasma exchange. Abdominal pain is another common symptom, including pain, nausea, diarrhea, and vomiting. In contrast, seizures, fever with chills, and extensive purpura suggest an alternative diagnosis.[162] Recently, a characteristic placental feature, called the "snowman sign" has been described in placentas of patients with TTP, referring to alternating zones of vascular dilation and constriction.[163]

Preeclampsia/HELLP syndrome may make the diagnosis of TTP-HUS difficult because both conditions are associated with thrombocytopenia, MAHA, and neurologic symptoms (visual changes or seizures). In preeclampsia/HELLP syndrome, thrombocytopenia typically reaches a nadir soon after delivery, and spontaneously recovers. Hemolytic anemia is much less common in patients with preeclampsia (2%).[164] Patients with HELLP syndrome may have hemolytic anemia that is significantly slower to recover than thrombocytopenia.[165] The changes in mental status that are typical in TTP-HUS are rarely seen in patients with preeclampsia or HELLP syndrome. In these patients, neurologic symptoms usually include blurred vision, headache, visual scotomata, and rarely, eclamptic seizures. Although proteinuria is a diagnostic hallmark of preeclampsia, renal failure is rare in preeclampsia unless the process is complicated by severe hypertension, DIC, hypotension, or sepsis.[166]

Management Options

Plasma exchange is an empirical and effective treatment for TTP-HUS. Mental status changes may be the first to resolve, with slower recovery of more severe neurologic symptoms,

thrombocytopenia, MAHA, and renal failure. Days or months of treatment may be required to achieve a lasting remission. Increasing the frequency of plasma exchange may be required in patients who show a poor response. Plasma exchange is usually tapered to reduce the risk of relapse. Complications include those related to central venous catheter placement and the administration of large volumes of plasma.

If plasma exchange is not available, the inferior therapies of plasma infusion and platelet transfusion have been advocated.[167] Although controversial, occasional supplemental treatment with glucocorticoids, vincristine, splenectomy, intravenous immune globulin, immunosuppressive agents, and antiplatelet drugs has been anecdotally recommended.[168]

Observation may be appropriate in a clinically stable patient who is remote from term and has an uncertain diagnosis. Deterioration of clinical status should prompt treatment with plasma exchange or delivery. If the patient's symptoms do not resolve after delivery, the clinician must consider the diagnosis of TTP-HUS, especially if symptoms persist beyond the third postpartum day. TTP-HUS may recur in subsequent pregnancies; however, at least 50% have an uncomplicated pregnancy.[169]

SUMMARY OF MANAGEMENT OPTIONS
Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

Management Options	Evidence Quality and Recommendation	References
Plasmapheresis is the treatment of choice.	IV/C	167
Fresh frozen plasma and platelet transfusions are secondary approaches.	IV/C	167
Use high-dose steroids.	III/B	154
Provide appropriate supportive therapy for renal failure and neurologic features.	III/B	161,164
Use critical care setting and interdisciplinary approach.	III/B	160

Thromboembolic Disease

ROY G. FARQUHARSON and MICHAEL GREAVES

INTRODUCTION

Venous thromboembolism (VTE) is one of the most common causes of maternal death. For example, 33 women died during pregnancy or soon after delivery in the United Kingdom between 2003 and 2005,[1] which equates to a rate of 1.56 deaths per 100,000 pregnancies. Despite publicity and the propagation of practice standards, pulmonary embolism remains the leading direct cause of maternal mortality, and the total number is disappointingly similar to that reported in previous 3-year periods with the exception of 1994 to 1996 when the total peaked at 46 deaths. There is room for encouragement, at least in the United Kingdom, after news that the number of fatal VTE events after cesarean delivery continues to decline from the reported peak of 15 to 7 following the introduction of the Royal College of Obstetricians and Gynaecologists (RCOG) guidelines on thromboprophylaxis in 1995.[2] Even early pregnancy is a significant risk period for VTE; 10 cases (30%) occurred before 12 weeks' gestation. Fatal VTE may occur before the first prenatal visit. As such, it would not be possible to prevent all fatalities caused by pulmonary embolism in pregnancy even if the risk of VTE could be predicted accurately.

An accurate measure of the total incidence of pregnancy-related VTE in the United Kingdom is difficult to determine because there is no national registry. The Swedish national register suggests an overall incidence of 1.3 events per 1000 deliveries[3] for all types of VTE, including deep vein thrombosis (DVT) and fatal and nonfatal pulmonary embolism. This rate corresponds closely to the prevalence reported in a large, unselected cohort of pregnant women in Glasgow, Scotland.[4]

MATERNAL RISKS

Pregnancy significantly increases the risk of VTE. Many substantial changes in the coagulation and vascular systems occur during pregnancy, and these changes support the accepted orthodoxy that pregnancy is a state of hypercoagulability. There is a progressive increase in the plasma concentration of several coagulation factors, including Factor VIII, and some reduction in the coagulation inhibitor protein S. As a result, there is increased thrombin generation such that the consumption of antithrombin in normal pregnancy

is similar to that seen in nonpregnant subjects with septic shock.[5] In addition, systemic fibrinolysis suppressed and there is altered venous flow in the lower limbs. Table 42–1 summarizes additional features in pregnancy that contribute to VTE, based on individual case analysis.[1]

Inherited thrombophilia, for example, due to factor V Leiden or deficiency of a physiologic coagulation inhibitor, increases the risk of VTE throughout life, and this risk is increased further in pregnancy and during the puerperium (Table 42–2). Screening for thrombophilia has been suggested as part of the first prenatal visit. Yet this approach identifies relatively few women who will go on to develop VTE,[6] and there is a very real risk of exposing large numbers of healthy women to anticoagulant prophylaxis without benefit. Further, screening for the most common heritable thrombophilia, heterozygosity for Factor V Leiden is not cost-effective for the prevention of pregnancy-related VTE.[7] Indeed, the clinical value of testing for heritable thrombophilia is questioned in most clinical situations.[8] Most commonly, inherited thrombophilia represents a nonfatal, late-onset clinical disorder of low penetrance. Testing may lead to inappropriate anxiety and false reassurance. It should be undertaken by specialists, and pretest counseling is mandatory. Non–evidence-based interventions determined by the results of testing must be avoided.[9] We recommend women be assessed for thrombosis risk primarily in relation to clinical risk factors. If an asymptomatic woman has a strong family history of unprovoked or pregnancy-related VTE, testing for heritable thrombophilia can be considered.

The consequences of VTE are clinically important. Untreated pulmonary embolism has a significant mortality. Although recovery from a nonfatal pulmonary embolism may seem to be complete, pulmonary hypertension develops in a proportion of cases. DVT results in damage to venous valves and incompetence. Postphlebitic syndrome is a long-term consequence. Fortunately, symptoms are usually mild, with residual swelling and some skin pigmentation. However, severe postphlebitic syndrome, with skin ulceration, is associated with significant impairment of quality of life.

FETAL RISKS

Most fetal risk is secondary to the maternal consequences of VTE and therapeutic interventions. For example, hypoxia

Risk Factors Identified from Individual Case Analysis of 33 Maternal Deaths from Venous Thromboembolism (2003–2005)

RISK FACTOR	NUMBER OF CASES	COMMENT
Older age	31	The rate of death is doubled in women older than 30 yr.
Obesity	16	Body mass index >30. All patients affected in the third trimester were overweight. Higher doses of low-molecular-weight heparin may be necessary for the treatment of VTE in the obese.
Immobility	1	Prolonged bedrest.
Family history of VTE	2	Strong history of VTE. All deaths occurred in the antenatal period.
Cesarean delivery	7	The number of events decreased dramatically from the previous report after the 1995 Royal College of Obstetricians and Gynaecologists guideline.
History of VTE	2	Both patients were obese.
Air travel	2	Both cases occurred before 24 wk' gestation.

VTE, venous thromboembolism.
From Lewis G (ed): The Confidential Enquiry into Maternal and Child Health (CEMACH). Saving Mother's Lives: Reviewing Maternal Deaths to Make Motherhood Safer—2003–2005. The Seventh Report on Confidential Enquiries into Maternal Deaths in the UK. London, CEMACH, 2007.

TABLE 42–2

Prevalence of Inherited Thrombophilia with the Relative Risk of Venous Thromboembolic Disease

	PREVALENCE (NORTHERN EUROPE) (%)	ESTIMATED LIFELONG RELATIVE RISK OF VTE
Homozygous factor V Leiden	0.1	×80
Heterozygous factor V Leiden	4	×5
Heterozygous prothrombin G20210A	2	×4
Protein C deficiency	0.2	×12
Protein S deficiency	?	?
Antithrombin deficiency	0.02	×30

Note: All values are estimates. Prevalence varies between populations. VTE risk varies between molecular subtypes, for example, in antithrombin deficiency. Reliable data for protein S deficiency and homozygous prothrombin G20210A are not available. Combinations of thrombophilias generally lead to higher risk of VTE.
VTE, venous thromboembolism.

and circulatory failure are consequences of major pulmonary embolism with a high likelihood of an adverse effect on placental and fetal homeostasis. Furthermore, VTE occurring close to term may affect the management of delivery.

Although heparin does not cross the placenta, it may lead to or worsen maternal hemorrhage, with all of its consequences for both mother and fetus. Warfarin and other coumarins do cross the placenta, are teratogenic, and impair fetal hemostasis. Warfarin is seldom used in pregnancy, perhaps the most common indication being a maternal mechanical heart valve.

Whether inherited thrombophilias are associated with poor pregnancy outcomes, including miscarriage and fetal death, remains the subject of investigation.[10] Current data suggest a weak association with pregnancy failure. The role of these, and acquired thrombophilias,[11] is discussed in the chapters on clotting disorders and autoimmune disease in pregnancy (see Chapters 41 and 43).

THROMBOEMBOLISM IN PREGNANCY

General

The key elements of the management of VTE in pregnancy include a high index of clinical suspicion for the diagnosis, objective confirmation by imaging, and the administration of heparin for the rest of the pregnancy followed by heparin or warfarin for at least 6 weeks postpartum, for a minimum of 3 months total.

Clinical Diagnosis

The typical clinical features of DVT in pregnancy differ somewhat from those in the nonpregnant patient in relation to lateralization and extent. In up to 90% of cases, thrombosis affects the left leg, and in most patients, the proximal veins are affected. In contrast to the nonpregnant state, DVT confined to the calf veins is uncommon during pregnancy, although it may occur in the postpartum period.

The differential diagnosis of a painful, swollen lower limb in pregnancy is narrow. Alternative causes, such as ruptured Baker's cyst and hematoma, are rare in this age group, and cellulitis is uncommon and generally easily distinguished from VTE by the history and clinical signs. Superficial thrombophlebitis results in more localized pain, swelling, erythema, and tenderness and may progress to DVT. Although symptoms of DVT may be subtle and mistaken for common benign changes in pregnancy, such as lower extremity edema or muscle cramping, DVT is almost always unilateral. In addition to swelling, there may be pain on compression of the calf or on deep palpation in the femoral triangle. Dorsiflexion of the foot sometimes causes pain (Homan's sign), but this feature is neither reliable nor discriminatory. In the experience of the authors, in an occasional case, the more usual symptoms and signs of lower limb DVT in pregnancy are preceded by severe low back pain. DVT affecting other sites during pregnancy may occur, such as the upper limb or splanchnic veins, but is exceedingly rare compared with lower limb thrombosis.

The clinical features of pulmonary embolism are no different from those in the nonpregnant patient, but may be masked by the perception of dyspnea which is commonly associated with pregnancy. Delayed diagnosis is common because both patient and physician fail to appreciate the significance of the symptoms. In most cases, the common features are those of pulmonary infarction, with pleuritic chest pain of acute or subacute onset, with or without dyspnea. There may be hemoptysis and low-grade fever. The differential diagnosis includes chest infection with

pleurisy and pneumothorax, but as a rule, pulmonary infarction should be considered most likely until it has been excluded or an alternative diagnosis identified. In some women, there may be increasing dyspnea only, presenting a diagnostic challenge. A larger embolus may cause severe dyspnea, often of sudden onset, with evidence of arterial oxygen desaturation. There may be visibly increased jugular venous pressure and other evidence of right heart strain. In massive pulmonary embolism, there is hypotension, usually with severe dyspnea, cyanosis, and collapse, or sudden death. There may be no chest pain, or central chest pain as a result of myocardial ischemia from increased right ventricular work in the face of low arterial oxygen tension. Clinical and electrocardiographic evidence of increased right heart pressure and right ventricular strain are evident. In the absence of a high index of suspicion, much valuable time may be lost running through the differential of less dangerous disorders.

Clinical risk factors to consider in addition to pregnancy include family history, high parity, age older than 30 years, obesity, recent immobilization, and operative delivery.[4] About two thirds of patients have an obvious risk factor.

Confirmation of the Diagnosis

A diagnosis of VTE in pregnancy requires full anticoagulant therapy for several months, with its attendant risks of iatrogenic injury and its effect on the management of delivery. A diagnosis of VTE also affects the management of future pregnancies, contraceptive choices, and the use of hormone replacement therapy as well as the perceived level of risk of VTE in first-degree relatives. Objective confirmation is essential because of these considerations and the inaccuracy of clinical diagnosis.

In lower limb DVT, compression ultrasonography is preferred because it is noninvasive and sensitive to thrombi in the proximal veins. The typical criteria for diagnosis are lack of vessel compressibility, absence of blood flow, and vessel dilation or visualization of the thrombus. The principal limitation is reduced sensitivity for thrombi confined to the distal calf veins, although such a distribution of thrombus is rare in pregnancy and thrombi that remain localized to calf veins have a low risk of embolization. Other sources of diagnostic error relate to diminished flow in a patent femoral or iliac vein because of extrinsic compression from the gravid uterus (may occur as early as 18 weeks' gestation), and persistent flow in the face of a nonocclusive thrombus in the iliac vein. For these reasons, many practitioners prefer an imaging test initially whereby the actual clot in the proximal system is demonstrated. When the diagnosis is in doubt, repeat ultrasound examination after a few days or an alternative imaging modality is needed. X-Ray contrast venography with shielding of the uterus is a rarely required option. It is invasive, causes some discomfort, and inevitably involves radiation exposure, but the diagnostic sensitivity is high. An alternative and attractive technique is magnetic resonance imaging (MRI), which may be sensitive to the presence of DVT.[12] However, its role remains uncertain and contraindications to use of some contrast media require consideration.

When there is suspicion of a venous thrombosis restricted to a minor calf vein, one strategy is to withhold anticoagulant therapy after a first ultrasound examination and to repeat the study in 3 to 5 days to exclude progression to the popliteal vein. Anticoagulant therapy is introduced only if progression is seen. This approach is based on observations of nonpregnant subjects that progression occurs in only some cases and that pulmonary embolism is uncommon when the DVT is restricted to an intramuscular calf vein and may not be applicable to the pregnancy situation.

When pulmonary embolism is suspected based on the clinical features, imaging is essential to confirm the diagnosis or establish an alternative one. Although electrocardiography is usually performed as part of the bedside assessment, it is insensitive and insufficiently specific. Arterial blood gas analysis is used to indicate the degree of hypoxia, but may be normal in pulmonary infarction. In several studies of young patients with pulmonary embolus, the average arterial oxygen level exceeded 90 mm Hg. Ultrasonography examination of the lower extremities is sometimes recommended in suspected pulmonary embolism in pregnancy because it is accessible, is noninvasive, and carries no risk from radiation exposure. However, a negative finding on ultrasound study of the legs does not exclude pulmonary embolism because the clot may have embolized in its entirety or there is an alternative source of thrombus (e.g., pelvic veins). A chest x-ray should be obtained with lead apron shielding of the fetus. The most common finding on chest x-ray is a "normal" result. Although not diagnostic in isolation, the chest x-ray may reveal an alternative cause of the symptoms such as pneumothorax or pneumonia. A chest x-ray is also required for interpretation of the results of a ventilation-perfusion scan should one be performed. The unavoidable radiation exposure has been judged acceptable in pregnancy and can be minimized by performing the perfusion scan first, and then proceeding to the ventilation scan only if perfusion is abnormal. The principal limitation of this technique is a lack of specificity. Although a normal scan excludes pulmonary embolism with an acceptable sensitivity, and a scan showing unmatched perfusion defects at the segmental level or greater can be considered diagnostic, many scans are interpreted as intermediate probability. At present, a computed tomography (CT) scan of the chest is thought to have the greatest sensitivity for pulmonary embolus among noninvasive tests. CT angiography may be a preferred approach, although technical limitations in pregnancy have been identified.[13] Radiation scatter to the abdomen is sufficiently low to be considered safe for use in pregnancy. MRI techniques are also being developed for use in diagnosis of pulmonary embolism.

There has been increasing interest in the use of D-dimer assay alongside a clinical algorithm to assess patients with suspected DVT. D-Dimer is a product of the plasmin digestion of cross-linked fibrin. An increased concentration in plasma is a marker for thrombus formation. Although this test is sensitive, it is not specific for VTE and is insufficient to confirm the diagnosis. Further, diagnostic algorithms that use a D-dimer assay were validated only in previously healthy, nonpregnant, nonhospitalized subjects.[14] Products of fibrin digestion increase in concentration in plasma from approximately 10 weeks' gestation in healthy pregnancy and increase further and abruptly immediately postpartum. Therefore, the use of D-dimer in the diagnosis of VTE in pregnancy would require the establishment of

Prevention and Treatment

Interventions to prevent and treat VTE include pharmacologic and mechanical measures (Table 42–3). Among the pharmacologic agents, heparins and warfarin are the principal drugs; they are effective in the prevention of VTE in a range of settings as well as in treatment. Aspirin has been promoted for the prevention of postoperative VTE, but its efficacy is debated. There may be some evidence for its efficacy in lower limb orthopedic surgery,[15,16] but the use of aspirin for thromboprophylaxis in pregnancy is not evidence-based. Novel oral anticoagulants are under development, including direct inhibitors of thrombin and Factor Xa, which are active by the oral route. Although promising, their role is not established, and there are no data on their use in pregnancy. In the context of VTE in general, use of thrombolytic drugs such as streptokinase and recombinant tissue plasminogen activator is generally restricted to the emergency management of massive pulmonary embolism or limb salvage in rare cases of massive lower limb DVT with a threat of venous gangrene. The bleeding risk from their use is substantial, although it may be reduced by a catheter-directed approach to drug delivery. Although there are reports of their use in life-threatening pulmonary embolism, thrombolytic therapy is associated with pregnancy loss (miscarriage or fetal death) and maternal bleeding and is relatively contraindicated during pregnancy. Similarly, thrombolytics may induce massive uterine hemorrhage during the puerperium. Under these circumstances, massive pulmonary embolism has been treated with heparin anticoagulation and emergency embolectomy. Despite the previously discussed concerns regarding thrombolytic drugs, one review of anecdotal reports of thrombolytic therapy in pregnancy implied the risks to the mother and fetus may be lower than suggested.[17]

Heparins

Unfractionated heparin (UFH) is manufactured from mammalian intestine or lung. It consists of a heterogeneous mixture of highly sulfated polysaccharide chains with a molecular weight ranging from 5000 to 35,000 daltons. Its anticoagulant action is principally the result of binding through a specific pentasaccharide sequence to antithrombin III, with a resultant profound acceleration in the rate of inhibition of coagulation enzymes, particularly thrombin and Factor Xa. Available formulations must be administered by either a subcutaneous or an intravenous route.

Although UFH is an effective antithrombotic agent, laboratory monitoring of the anticoagulant effect is necessary when it is used to treat established thrombosis. The activated partial thromboplastin time (aPTT) is typically used, but there is marked variation in reagent sensitivity to heparin, and laboratory standardization of heparin dosage control has not been achieved.

Low-molecular-weight heparins (LMWHs) are manufactured from UFH. With an average molecular weight of approximately 5000 daltons, they include a high concentration of molecules with fewer than 18 saccharides. These molecules cannot bind to antithrombin III and thrombin simultaneously, a feature necessary for thrombin inhibition. However, the anti-Xa effect is preserved because there is no requirement for direct binding to Factor Xa for the acceleration of inhibition by the heparin–antithrombin III complex. Consequently, the anti-Xa activity of LMWH is greater than that of UFH, relative to the antithrombin activity. The aPTT is relatively insensitive to LMWH; assay of anti-Xa activity is the method of choice. Like UFH, parenteral administration of LMWH is necessary, but the bioavailability from subcutaneous tissues is greater and the plasma half-life is longer than that of UFH, permitting effective anticoagulation by once- or twice-daily subcutaneous administration without laboratory monitoring in nonpregnant subjects. These attributes of LMWH have led to the replacement of UFH for many clinical indications. This development is supported by clinical trials in nonpregnant subjects that show at least equivalence to UFH in safety and efficacy in the prevention and treatment of VTE. Indeed, DVT can be treated safely with LMWH in the community setting,[18] although data on pregnant patients are limited. Although the available LMWH preparations differ somewhat in their composition and metabolism, there is little to suggest clinically important differences in clinical efficacy in routine use.

The efficacy, ease of administration, and possible greater safety of LMWH suggest that these agents are preferable to UFH in pregnancy. However, the pharmacokinetics of LMWH are altered in pregnancy. This fact is important because the dosing of LMWH has been extrapolated from data in nonpregnant subjects and increased renal clearance during pregnancy has not been considered. Some early observational studies of LMWH in pregnancy had design flaws, including nonstandardized gestation intervals, a nonhomogenous case mix, and small numbers of patients with few serial observation points.[19] One systematic review reported 40 citations of LMWH involving 728 pregnant and postpartum women. However, only 2 articles were categorized at the highest level with regard to the quality of evidence,[20] and 19 of the articles were considered to be of limited quality. Variations in dosage regimens were marked

and ranged from 2500 to 22,000 units daily, which included fixed dosages, increasing dosages as pregnancy progressed, dosages based on body weight, and dosages titrated according to anti-Xa levels. The wide variation in dosage regimens highlights the uncertainty about the pharmacokinetics in pregnancy. Some useful data have emerged. In a longitudinal study of LMWH prophylaxis during pregnancy, the mean peak anti-Xa level occurred later, at 4 hours, compared with 2 hours in the nonpregnant state.[19] Mean peak values were significantly different at the 2-hour time point at 12 and 36 weeks' gestation compared with the nonpregnant state (Fig. 42–1).[21] A previous study in a smaller cohort with nonstandardized gestation intervals supports this trend.[22] Compared with the nonpregnant state, the area under the anti-Xa curve (AUC) is lower in pregnancy, with the nadir occurring at 36 weeks' gestation (Fig. 42–2).[21] The AUC reflects anti-Xa activity and, therefore, reduced plasma activity with advancing gestation. Renal excretion is the principal route of clearance of LMWH. In contrast, UFH is also cleared in part by
the reticuloendothelial system. Pregnancy-related physiologic adaptations in renal function probably account for the lower AUC of anti-Xa in pregnancy. This observation is supported by higher AUC values in 12 healthy, nonpregnant volunteers given LMWH.[23] Conversely, the biologic half-life of LMWH is increased in renal failure.[24] These issues highlight the unresolved question as to whether dosing regimens based on trials in nonpregnant individuals can be used in pregnancy. Hunt and coworkers[25] recommended dose escalation after 20 weeks' gestation to overcome these altered heparin pharmacokinetics in pregnancy. We suggest that rather than guessing, measurement of the peak anti-Xa level each trimester may give some reassurance that the target degree of anticoagulation has been achieved.

The principal side effect of heparin is bleeding. Spontaneous hemorrhage is uncommon, even when treatment doses are administered, but increased bleeding from surgical incisions is inevitable. Nevertheless, LMWH has proved to be highly effective and safe, with generally acceptable levels of increased bleeding when used as prophylaxis against postoperative VTE.

Heparin-induced thrombocytopenia with paradoxical thrombosis is an uncommon but potentially lethal side effect of heparin exposure (UFH and LMWH). It is caused by a heparin-induced antibody leading to platelet activation and consumption in a new thrombus. Typically, the platelet count begins to decrease 5 to 10 days after first exposure to heparin, even at a low dose, and in many cases, new or worsening thrombosis is noted. It is imperative to discontinue heparin immediately and to substitute an alternative anticoagulant, because the induced prothrombotic state persists for some time. This complication is around 10-fold more likely with UFH than with LMWH,[26] and fortunately, it appears extremely uncommon with LMWH in prophylactic doses during pregnancy.

Clinically significant osteoporosis is a rare consequence of pregnancy and also of long-term (>3 mo) exposure to heparin. It is less likely to occur with LMWH than with UFH. The potential for osteoporosis has been addressed by several prospective studies that concluded the physiologic effect of pregnancy-induced bone loss is probably greater than that seen with long-term heparin use (Table 42–4).[27–30]

Bone remodeling is uncoupled during pregnancy, with a marked increase in early bone resorption subsequently followed by late bone formation[27] and alteration of bone architecture.[31] Though osteoporotic fracture in pregnancy is an alarming condition, it is rare and sporadic.

Fondaparinux is a synthetic pentasaccharide Factor Xa inhibitor.[32] Like UFH and LMWH, it must be administered parenterally, but it has no antithrombin activity. It is used for prophylaxis and treatment of VTE and to prevent infarct in cardiac ischemia. There are reports of its successful use in the management of VTE in pregnancy.[33]

Coumarins

Coumarins are vitamin K antagonists. They are active orally and inhibit the synthesis of the vitamin K–dependent procoagulants (prothrombin, Factors VII, IX, and X) as well as the anticoagulant proteins C and S. Ingestion of coumarins produces a dose-dependent prolongation of clotting times, especially the prothrombin time, and an anticoagulant effect in vivo. Warfarin is the most commonly used coumarin in clinical practice. There is considerable interindividual variation in the dose-response to warfarin owing in great part to genetic heterogeneity in the genes encoding the cytochromes responsible for coumarin metabolism and those coding for the target enzyme influencing coagulation factor synthesis.[34] The dose-response is also influenced by diet and drug interactions. Close laboratory monitoring is critical. The adoption of the International Normalized Ratio (INR) system to express prothrombin time ensured uniformity between laboratories. Prospective trials established that the appropriate target INR in a variety of clinical situations is 2.5, range 2.0 to 3.0. Although the risk of bleeding increases markedly with INR greater than 3.0, there is a significant risk even in the target therapeutic range (~25% of bleeds occur when the INR < 3.0), which increases markedly should the INR climb above 5.0. In an unselected series, the prevalence of life-threatening bleeding in subjects treated with warfarin was approximately 1 to 2 events per 100 treatment-years.[35] The greatest risk is to subjects with peripheral or cerebrovascular disease and older patients. It may be lower in women of childbearing age. There have been case reports of intra-abdominal hemorrhage from the site of ovulation, leading to the suggestion that women taking warfarin should use contraceptive methods that suppress ovulation. Bleeding complications are most likely to occur during the first weeks of warfarin therapy. The identification of the genetic influences on individual sensitivity to coumarin has led to the possibility of a pharmacogenomic approach to dosage prediction,[34] but this has not been adopted widely in most countries to date.

Warfarin is a teratogen causing both an embryopathy and a fetopathy (see Chapter 34). Up to 30% of fetuses exposed between 6 and 10 weeks' gestation have been estimated to be affected to some degree, although recent data suggested congenital anomalies in a smaller number of exposed pregnancies—around 6%. The developing skeleton is the principal target, with abnormalities ranging from subclinical stippling of the epiphyses on x-ray, to nasal deformity, and to severe phocomelia. Heparin is a safer alternative, and warfarin is never used to manage VTE during the first trimester. Further, it is rarely the anticoagulant of choice to treat or prevent VTE at any stage of gestation because of

reports of intracranial abnormalities and developmental problems attributed to fetal hemorrhage. Commonly, heparin anticoagulation during pregnancy is switched to warfarin postpartum because of the ease of administration.

Mechanical Measures

Well-fitted graduated compression hosiery is widely used to prevent VTE. Although there are few studies of pregnant women, there is evidence of efficacy perioperatively in non-pregnant patients. There is also evidence that symptoms of postphlebitic syndrome are less likely to develop if compression stockings of appropriate class are worn regularly for 2 years after an episode of lower limb DVT.[36] Whether below-the-knee stockings are as effective as full-length hosiery is the subject of debate, although there are some data supporting this practice in the postoperative state,[37] and compliance tends to be better with below-the-knee stockings.

Mechanical devices that stimulate calf muscle contraction or compress the calf intermittently have been used to prevent DVT perioperatively, and may be useful in women who are not candidates for pharmacologic thromboprophylaxis because of a high risk of bleeding.

Filter devices that can be placed in the inferior vena cava either temporarily or permanently have been used in subjects with lower limb proximal DVT considered high risk for pulmonary embolism. The frequency of their use varies among nations. Risks include inferior vena cava thrombosis, vessel perforation, and migration of the filter. They are mostly used in patients in whom either anticoagulant therapy is contraindicated (e.g., those with a recent cerebral hemorrhage) or when a pulmonary embolism has occurred despite therapeutic levels of anticoagulation. Successful use has been reported,[17] but pregnancy poses additional challenges including the need to use radiologic screening to ensure safe placement and the possibility that vena caval compression by the gravid uterus will hinder placement. These devices may be helpful when VTE presents at term, for example.

Management Options: Established Venous Thromboembolism in Pregnancy

Treatment protocols with heparin have been based largely on those used in nonpregnant patients and seem safe and effective. Heparin should be initiated when there is strong clinical suspicion of DVT and continued after the diagnosis is confirmed. Because of the advantages of LMWH, (low injection volume, occasional vs. frequent testing), most clinicians consider LMWH the anticoagulant of choice. LMWH is administered by subcutaneous injection at the recommended dose for the particular product based on early pregnancy body weight. Once-daily administration may be preferred for convenience and is reasonable as long as therapeutic levels can be maintained. Coagulation times, such as aPTT, are not appropriate for this purpose because the aPTT may remain short, even in patients who are given therapeutic doses of LMWH. The anti-Xa assay gives an indication of the pharmacologic response but is a poor predictor of antithrombotic efficacy and provides limited information on bleeding risk in nonpregnant subjects.[38] A peak (4 hr after injection) plasma anti-Xa concentration of around 0.5 to 1.0 anti-Xa international units appears to be acceptable for a 12-hourly regimen, with slightly higher peak levels sought

for a 24-hourly regimen. More intensive monitoring by anti-Xa assay has been recommended when the dose-response is likely to be less predictable, for example, in the very over- or underweight patient and when renal function is impaired. UFH may be preferred in renal failure.

If preferred, treatment with UFH can be initiated by intravenous bolus, followed by continuous intravenous infusion, with adjustment to maintain the aPTT ratio to control of 1.5 to 2.5. This value is often difficult to achieve, especially in late pregnancy, because the starting aPTT is short owing to the physiologic increased concentration of several clotting factors, including Factor VIII. There are few indications for use of UFH rather than LMWH in the context of VTE. It may, however, be justified if there is concern that rapid reversal of the anticoagulant effect may be unpredictably and urgently required, in renal failure, and in the initial management of unstable pulmonary embolism.

Whether UFH or LMWH is administered in treatment doses, the platelet count should be monitored from day 5 until around day 20. A progressive, unexplained decrease in the platelet count suggests heparin-induced thrombocytopenia. In the event of this rare complication, heparin should be discontinued. The condition is caused by the development of platelet-activating antibody, and there is a high risk of further thrombosis if the heparin is continued. Warfarin does not appear to be effective for the prevention of thrombosis in this situation. Lepirudin, a direct inhibitor of thrombin, is the alternative anticoagulant of choice in non-pregnant patients with heparin-induced thrombocytopenia, and there are occasional reports of its use in pregnancy.[39] Another alternative is the heparin-like danaparoid, but cross-reactivity may be a problem and there have been problems with availability. It has been used in pregnancy.[40] Fondaparinux can be considered as an alternative. As in all cases of thrombosis in pregnancy, optimal treatment should be determined individually, with consideration for the relative lack of pregnancy-specific evidence on which to base decisions.

The initial management of most cases of pulmonary embolism is comparable with that of DVT. The exception is life-threatening massive pulmonary embolism, in which the relative risks of surgical embolectomy and thrombolytic therapy must be considered urgently.

There are a few additional management issues to consider in VTE. Elevating the affected limb helps relieve symptoms in DVT, and analgesia is frequently necessary because of the considerable swelling and discomfort caused by either proximal venous occlusion or the pain associated with pulmonary infarction. Confinement to bed is not mandatory. Fitted (vs. one size fits all) graduation compression stockings should be used as soon as resolution of swelling allows them to be worn without discomfort.

Full-dose heparin treatment should be maintained to delivery. The patient should be advised to withhold the next due dose of heparin once labor has begun or the morning of a planned induction. There has been some concern about the safety of spinal or epidural anesthesia in laboring women who are receiving anticoagulants.[41] In general, insertion and withdrawal of a spinal catheter should be avoided within 12 hours of a subcutaneous dose of LMWH, and preferably for 24 hours after a treatment dose. Whether the risk is increased after this period is unclear, but the potential risk must be balanced against the needs for analgesia and anesthesia during labor.

If no abnormal bleeding occurs during delivery, heparin can be reintroduced 12 to 24 hours postpartum. Alternatively, warfarin may be initiated along with heparin (until the INR is in the therapeutic range, when heparin can be discontinued) and continued postpartum. Anticoagulation is typically continued 6 to 12 weeks postpartum or a total of 3 months from the initial diagnosis of VTE, whichever is longer. Although warfarin is secreted in breast milk, the breast-fed neonate of a treated mother is not adversely affected. However, warfarin is best avoided when the mother is expressing milk to feed to a severely premature neonate.

SUMMARY OF MANAGEMENT OPTIONS
Established Thromboembolism in Pregnancy

Management Options	Evidence Quality and Recommendation	References
Clinical Diagnosis	III/B	14
DVT: Can be difficult; sometimes different clinical presentation to nonpregnant state.		
PE: Similar presentation to nonpregnant state.		
Key: "High index of suspicion."		
Confirmation of Diagnosis	III/B	14
DVT: Compression ultrasound, venogram.		
PE: Perfusion scan, CT angiogram (ECG insensitive and nonspecific; chest x-ray excludes other pathology; Pao$_2$ indicates degree of hypoxia).		
D-Dimer is not specific for VTE.		

SUMMARY OF MANAGEMENT OPTIONS
Established Thromboembolism in Pregnancy—cont'd

Management Options	Evidence Quality and Recommendation	References
Initial Management	Ia/Ib/A	18
Heparin: Give UFH IV bolus loading dose then continuous IV, e.g., 1000–2000 U/hr or LMWH in therapeutic doses. LMWH is preferred.	III/B	44
Monitor aPTT (with UFH) or peak anti-Xa level (with LMWH); monitor serial platelet counts.		
Additional measures: Analgesia; elevation and compression stockings with DVT; with severe PE, consider surgical embolectomy and intensive care (see Chapter 78).		
Maintenance	Ia/A	19
Heparin: Give UFH (e.g., 10,000 units SC twice daily) or therapeutic dose LMWH. LMWH is preferred.	III/B	44
Monitor aPTT (1.5–2.5 times control) (UFH) or peak anti-Xa (LMWH); monitor platelet counts.		
Intrapartum	IIa/B	44
Temporarily discontinue heparin therapy with onset of labor.		
The timing of heparin administration should be considered in relation to catheter placement for regional analgesia, and catheter withdrawal.		
Reinitiate treatment with UFH or LMWH approximately 12 hr after delivery if no active bleeding occurs.		
Postpartum	IIa/B	43
Continue LMWH, UFH, or warfarin (with monitoring) for 6 wk or at least 3 mo after an acute event.		
Graduated elastic compression stockings should be worn for 2 yr.	Ia/A	37
Breast-feeding is not contraindicated.		

aPTT, activated partial thromboplastin time; CT, computed tomography; DVT, deep vein thrombosis; ECG, electrocardiogram; LMWH, low-molecular-weight heparin; Pao$_2$, arterial oxygen pressure; PE, pulmonary embolism; UFH, unfractionated heparin; VTE, venous thromboembolism.

Management Options: Thromboprophylaxis in Pregnancy

Thromboprophylaxis should be offered selectively. All pregnant women should undergo clinical assessment for risk of VTE. Population screening for hereditary thrombophilias is not performed as a routine and should be based on the clinical circumstances and the family history. When a heritable thrombophilia is detected in an asymptomatic subject as part of a family study, this information can be used for an informed risk assessment. Acquired factors are at least as important as genetic predisposition in assessing thrombotic risk. A personal history of VTE is an important consideration for thromboprophylaxis in pregnancy. In addition, patient age, parity, and weight can be considered. Limited mobility and some chronic medical conditions such as systemic lupus erythematosus may be relevant. The risk of venous thrombosis is greatest in the puerperium and higher yet in women who have had cesarean delivery, especially as an emergency procedure, or in preeclampsia.

The risk of VTE in women with a personal history of thrombosis may be lower than previously considered. In a persuasive prospective study of 125 women who had a history of venous thrombosis and in whom antenatal thromboprophylaxis was withheld, the overall rate of recurrence in a subsequent pregnancy was only 2.4%. No recurrence was reported in the subgroup of women who had a temporary risk factor at the time of the first event.[42] This study also suggested that the recurrence rate may be higher in heritable thrombophilia, but was too small to allow firm conclusions to be drawn. The risk of pregnancy-associated first occurrence of VTE in women with heritable thrombophilia may be overstated. Although data from a large cohort study suggest a substantial risk, possibly as high as 1 in 3 in some kindreds with antithrombin deficiency, the risk is much lower, perhaps around 1 in 100 in asymptomatic

TABLE 42–5

Sample Recommendations for Thromboprophylaxis in Pregnancy

RISK CATEGORY	MANAGEMENT
Low	
Women who have no personal history of venous thrombosis, but a positive family history and who are heterozygous for protein S deficiency, heterozygous for factor V Leiden, or heterozygous for prothrombin G20210A. Women with a history of venous thrombosis in association with a temporary risk factor that is no longer present.	In general, pharmacologic thromboprophylaxis is not required antenatally in the absence of additional risk factors, but anticoagulant prophylaxis may be considered after delivery. In reaching a decision, the early pregnancy or antenatal risk assessment at booking should clearly identify the presence of additional risk factors such as advanced maternal age (>35 yr), high BMI (>30 kg/m^2) and smoking. For example, the presence of three risk factors should trigger expert assessment.
Intermediate	
Women who have a personal history of apparently spontaneous VTE and who have a thrombophilic mutation who are no longer receiving anticoagulant prophylaxis. Women who have no personal history of venous thrombosis, but a positive family history of venous thrombosis and who are heterozygous for protein C deficiency, are homozygous for factor V Leiden or the prothrombin G20210A mutation, or have combinations of defects.	Postpartum thromboprophylaxis with heparin or warfarin should be given. Expert review of risk factor assessment is strongly recommended. Antenatal thromboprophylaxis with LMWH or UFH should be considered.
High	
Women who are receiving long-term anticoagulant therapy for VTE. Women who have type I antithrombin deficiency or a type II reactive site antithrombin defect (regardless of whether they have had a thrombotic episode).	Prophylaxis should be strongly considered throughout pregnancy and postpartum. Adjusted doses of LMWH or UFH, higher than those usually used to prevent venous thrombosis, can be considered.

Note: Clinical assessment of risk factors is paramount. The individual patient history and clinical assessment must be considered in each case, especially the presence of combinations of heritable and acquired risk factors, as well as patient preference.
BMI, body mass index; LMWH, low-molecular-weight heparin; UFH, unfractionated heparin; VTE, venous thromboembolism.
From Walker ID, Greaves M, Preston FE: Investigation and management of inherited thrombophilia. Br J Haematol 2001;114:512–528.

subjects with protein C deficiency, and perhaps lower still in asymptomatic women heterozygous for Factor V Leiden.[4] Based on these observations, an attempt to stratify risk has been made with recommendations for thromboprophylaxis of graded intensity depending on these factors.[9] The RCOG in the United Kingdom has recommended an algorithm, based on an assessment of personal and family history, heritable thrombophilia, and acquired risk factors.[44] Table 42–5 is modified from the recommendations of the British Committee for Standards in Haematology.[9] National bodies in other countries have recommended guidelines also. The aim should be to achieve a balance between efficient prevention of VTE and avoidance of exposure of a large number of healthy women to unnecessary pharmacologic thromboprophylaxis throughout their pregnancies. It has to be accepted that it will not be possible to prevent all VTE.

The ideal stage of pregnancy to introduce LMWH prophylaxis is debated. Some clinicians introduce treatment in the second trimester to minimize the duration of exposure. In doing so, it should be remembered that VTE, including fatal pulmonary embolism, may occur during the first trimester.

The use of compression stockings antenatally and postpartum is a reasonable precaution in any woman deemed to be at increased risk of VTE. In general, for the reasons discussed earlier, LMWH is preferable to UFH for pharmacologic thromboprophylaxis. The use of preloaded syringes is convenient and increases safety. Most women can safely self-medicate after instruction. Heparin-induced thrombocytopenia is vanishingly rare in healthy pregnant women receiving LMWH, and the monitoring of the platelet count

is not mandatory in women using prophylactic doses only. Warfarin can be used for postpartum prophylaxis with a target INR of 2.5. Updated thromboprophylaxis recommendations have been published by the RCOG,[43] and in addition, acute management recommendations for thromboembolic disease in pregnancy and the puerperium were published in 2007.[44]

Autoimmune Diseases

JEFF M. DENNEY, TROY FLINT PORTER, and D. WARE BRANCH

INTRODUCTION

The immune system's remarkable ability to protect the body from invasion by foreign pathogens stems from its capacity to distinguish biologic "self" from "nonself." An aberration in this normally well-regulated process leads to a state of so-called *autoimmunity*, in which immune effector cells are directed against "self" tissues. Persistent immunologic activation results in an *autoimmune disease*, characterized by a typical pattern of clinical signs and symptoms of disease and confirmed by the serologic presence of immune effector cells, usually autoantibodies. For many autoimmune conditions, serologically detected autoantibodies play an active role in tissue damage. In others, their presence may serve only to confirm the existence of an autoimmune process.

The pathophysiologic mechanisms that lead to autoimmune diseases have been studied extensively. The earliest theory held that autoimmunity resulted from a failure in the normal deletion of lymphocytes that recognized self-antigens. More recently, investigators have suggested that autoimmunity results from a failure of the normal regulation of the immune system (which contains many immune cells that recognize self-antigens but are normally suppressed). Regardless of what fundamental immunologic disturbance allows autoimmunity, it appears that a combination of environmental, genetic, and host factors must be present for the full expression of an autoimmune disease.

Autoimmune diseases have a predilection for reproductive-age women and are frequently encountered during pregnancy. Indeed, more than 70% of patients with autoimmune disease are women of reproductive age.[1] Studies in both animal models and humans support the role that sex hormones play in the development of autoimmunity; estrogens accelerate disease and androgens are protective.[2-6] It should come as no surprise that pregnancy-associated fluctuations in sex hormones may influence disease severity. Interestingly, the effect of pregnancy depends on whether the autoimmune disease is innate (cellular) or adaptive (humoral) in nature. Diseases with strong cellular pathophysiology, such as rheumatoid arthritis (RA) and multiple sclerosis, are associated with remission during pregnancy, whereas diseases characterized by autoantibody production, such as systemic lupus erythematosus (SLE) and Graves' disease, tend toward increased severity in pregnancy. Still others are unique to pregnancy or have unique features associated with pregnancy. Thus, the obstetrician should be familiar with the more common autoimmune diseases, how they influence and are influenced by pregnancy, and what special medical risks may be in store for mother or the conceptus.

SYSTEMIC LUPUS ERYTHEMATOSUS

General

SLE is an idiopathic chronic inflammatory disease that affects skin, joints, kidneys, lungs, serous membranes, nervous system, liver, and other organs of the body. Like other autoimmune diseases, its course is characterized by periods of remission and relapse. The most common complaint among patients with SLE is extreme fatigue (Table 43–1). Fever, weight loss, myalgia, and arthralgia are also particularly common symptoms.

The prevalence of SLE is 5 to 100 per 100,000 individuals, depending on the population studied. The disease is at least 5, and probably closer to 10 times, more common among adult women than adult men.[1] The lifetime risk of developing SLE for a white woman is 1 in 700,[7] with an overall incidence of 1 in 2000 in the United States. The incidence varies among populations and is approximately two to four times higher in African Americans and Hispanic Americans.[7] A genetic predisposition to SLE is likely, given that approximately 10% of patients with SLE also have an affected relative[8]; concordance between twins is reportedly greater than 50%.[9] Several alterations in the human leukocyte antigen (HLA) system have been linked to the development of SLE, and homozygous carriers of mutations responsible for complement deficiency disorders also appear to be predisposed to development of the disease.

Diagnosis

Serologic Markers

The diagnosis of SLE, suspected by the clinical presentation, is confirmed by demonstrating the presence of circulating autoantibodies. Patients are initially screened for nonspecific antibodies directed against nuclear antigens. Cumbersome biologic assays of antibodies directed against nucleoprotein

TABLE 43–1

Approximate Frequency of Clinical Symptoms in SLE

SYMPTOMS	PATIENTS (%)
Fatigue	80–100
Fever	80–100

Lymphadenopathy	50
Central nervous system	
Seizures	15–20
Psychosis	<25

(nucleohistone) commonly referred to as the *LE phenomenon*, have been replaced by immunofluorescent assays for non-specific antinuclear antibodies (ANAs). Findings are interpreted according to antibody titer and, to some degree, on the pattern of antibody binding. The *homogeneous* pattern is found most commonly in patients with SLE (65%), though its specificity is low. A peripheral pattern is the most specific for SLE, even if it is not very sensitive. The speckled and nucleolar patterns are more specific for other autoimmune diseases.

Immunofluorescent assays that identify specific nuclear antigen-antibody reactions are better for confirming the diagnosis of SLE, monitoring disease activity, and guiding immunotherapy. Particularly useful are anti–double-stranded DNA (anti-dsDNA) antibodies, present in 80% to 90% of patients with newly diagnosed SLE, elevations of which precede symptomatic flare in 80% of SLE patients followed prospectively.[10,11] In pregnancy, anti-dsDNA antibodies correlate with flare and preterm delivery.[11,12]

Antibodies to single-stranded DNA (anti-ssDNA) are also found in a large number of untreated SLE patients, but are less specific for SLE than is anti-dsDNA. Patients with SLE may also have antibodies to RNA-protein conjugates, often referred to as *soluble* or *extractable antigens*, because they can be separated from tissue extracts. These antigens include the Sm antigen, nuclear ribonucleoprotein (nRNP), the Ro/SS-A antigen, and the La/SS-B antigen. The Sm and nRNP antigens are nuclear in origin, and the presence of anti-Sm, found in about 30% to 40% of patients with SLE, is highly specific for the disease. Anti-Ro/SS-A and anti-La/SS-B, found in the sera of both SLE patients and patients

with Sjögren's syndrome, are of particular importance to obstetricians because they are associated with neonatal lupus.

In addition, rises in the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels correlated with disease activity.[13] When serum levels of complement C1q are noted to be persistently low, patients are at higher probability for having not only SLE but also SLE-associated proliferative glomerulonephritis.[14] Notably, not all patients with measurable serologic markers have active disease. Moreover, the presence of serologic markers of lupus neither confirms active disease nor reliably predicts exacerbation.[15]

Diagnostic Criteria

In 1971, the American Rheumatism Association devised criteria for SLE as a framework for comparing studies of patients with SLE. These were revised in 1982[16] and again in 1997[17] (Table 43–2). To be classified as having SLE, an individual must have at least 4 of 11 clinical and laboratory criteria at one time or serially. These criteria are very sensitive and specific for SLE, but were never intended to form the sine qua non for the diagnosis of SLE. Many patients have fewer than four clinical or laboratory features of SLE and do not meet strict diagnostic criteria. Exclusion of patients with an autoimmune diathesis from the diagnosis of SLE by the dogmatic use of strict diagnostic criteria can result in patients being confused and frustrated. Although these patients should not be considered to have SLE, they are often referred to as having lupus-like disease. Such individuals may benefit from therapies for SLE and often require special care during pregnancy. A subset of these patients will ultimately develop the clinical syndrome.

Lupus Nephritis

Clinically obvious renal disease is a relatively common complication of SLE, eventually occurring in as many as two thirds of patients with SLE.[18,19] Lupus nephropathy probably results from anti-DNA antibodies and glomerular immune complex deposition leading to complement activation and inflammatory tissue damage in the kidney.[20] The most common presentation is proteinuria, which occurs at some time in up to 75% of patients. About 40% of patients will have hematuria or pyuria, and about a third will have urinary casts. Note that the presence of hematuria, pyuria, and cellular casts in the urine sediment are important distinctions of lupus nephritis as opposed to preeclampsia.

Renal biopsy is necessary to confirm the diagnosis of lupus nephropathy. Because laboratory and clinical manifestations are poor prognosticators for the progression of disease, obtaining biopsy to determine renal histology is key to understanding the prognosis and providing direction for appropriate treatment.[21] Renal biopsy findings are used to group lupus nephropathy into four basic histologic and clinical categories. Of these, *diffuse proliferative glomerulonephritis* (DPGN) is the most common (40%) and most severe, with 10-year survival around 60%. Patients with DPGN typically present with hypertension, moderate to heavy proteinuria and nephrotic syndrome, hematuria, pyuria, casts, hypocomplementemia, and circulating immune complexes. *Focal proliferative glomerulonephritis* is usually associated

TABLE 43–2

Revised American College of Rheumatology Classification Criteria for Systemic Lupus Erythematosus*

CRITERION	DEFINITION
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring possible in older lesions
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	a. Pleuritis—convincing history of pleuritic pain or rubbing heard by a physician, or evidence of pleural effusion b. Pericarditis—documented by ECG or rub or evidence of effusion
7. Renal	a. Persistent proteinuria >0.5 g/day or >3+ if quantitation not performed b. Cellular casts—red cell, hemoglobin, granular, tubular, or mixed
8. Neurologic	a. Seizures—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance) b. Psychosis—in the absence of drugs or metabolic derangements
9. Hematologic	a. Hemolytic anemia—with reticulocytosis b. Leukopenia—<4,000/μL on two or more occasions c. Lymphopenia—<1500/μL on two or more occasions d. Thrombocytopenia—<100,000/μL in absence of drugs
10. Immunologic	a. Anti-DNA—antibody to native DNA in abnormal titer b. Anti-Sm—presence of antibody to Sm nuclear antigen c. Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis for 6 mo
11. ANA	An abnormal ANA titer by immunofluorescence or an equivalent assay at any time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome

* SLE can be said to be present if four or more of the criteria are present simultaneously or serially.
ANA, antinuclear antibody; ECG, electrocardiogram; Ig, immunoglobulin; SLE, systemic lupus erythematosus.

---

with mild hypertension and proteinuria; serious renal insufficiency is uncommon. *Membranous glomerulonephritis* typically presents with moderate to heavy proteinuria but lacks the active urinary sediment and does not cause renal insufficiency. *Mesangial glomerulonephritis* appears to be the least clinically severe lesion and carries the best long-term prognosis.[21]

Notably, both type and severity of disease dictate the protocol for optimal treatment.[22] The first line of therapy in patients with active lupus nephropathy has traditionally been glucocorticoids, usually given as oral prednisone, 40 to 50 mg/day, for several weeks to several months. Thereafter, the dose is tapered while carefully watching the patient for evidence of signs and symptoms of worsening disease. Avoiding conception while on immunosuppressants or glucocorticoids minimizes risk of adverse fetal effects, but the maternal disease may dictate at least a judicious continuation of glucocorticoid therapy of the lowest effective dose.[23] Severe proliferative lesions, such as seen in moderate to severe DPGN, have been shown to respond best to cytotoxic agents. Cyclophosphamide, in a divided monthly dose of 0.5 to 1.0 g/m^2, is now generally used.

Lupus Cerebritis

Ten percent to 35% of patients with SLE develop neurologic and psychiatric manifestations of their disease, also referred to as *lupus cerebritis*.[24–26] Patients most often present with new-onset cognitive dysfunction, seizures, although peripheral neuropathy, headaches, chorea, stroke syndrome (i.e., either transient ischemic attack or ischemic brain infarction), mood disorders, transverse myelitis, and psychosis also are reported. The severity of lupus cerebritis may also be influenced by other problems commonly encountered in patients with SLE, including metabolic abnormalities, infection, and chronic steroid use. Prospective studies suggest that a high percentage—50% to 78%—of neurologic episodes are caused largely by secondary factors: hypertension, corticosteroid toxicity, uremia, and other metabolic complications of other organ system failure.[27,28] An evaluation for lupus cerebritis should include an assessment for the presence of infection, including lumber puncture if necessary, radiologic imaging, and electroencephalogram. Patients with lupus cerebritis who present with chorea, transverse myelitis, or stroke should be tested for antiphospholipid antibodies (aPLs). There is a higher risk for stroke with presence of aPLs in SLE, especially when more than one type is present. These antibodies also correlate with increased incidence of small high-intensity white matter lesions on magnetic resonance imaging (MRI).[29]

Empirical therapy for lupus cerebritis typically includes glucocorticoids (e.g., prednisone 0.5–1.0 mg/kg/day) as a first-line therapy, with cyclophosphamide (0.5–1.0 g/m^2) monthly for 6 months and intravenous immune globulin (IVIG) reserved for refractory cases.[30]

Risks of Systemic Lupus Erythematosus and Pregnancy

The Risk of SLE Exacerbation (Flare)

Whether pregnancy is associated with a higher rate of SLE exacerbation is debated. Early studies on the subject were hampered by poor study design, not to mention the difficulty of differentiating between normal manifestations of pregnancy and the signs and symptoms typically associated with SLE. At the same time, common complications of pregnancy such as preeclampsia may mimic exacerbations of SLE.

Between the early 1950s and the early 1970s, the findings of several small retrospective series suggested that women with SLE were placing themselves at substantial risk for severe morbidity and even mortality during pregnancy.[31] Many also reported relatively high rates of pregnancy wastage among women with SLE.[32] These concerns led many practitioners to the opinion that SLE patients should not become pregnant. However, these early studies were plagued by several problems, and their conclusions should not be the basis of clinical decision-making today. All were retrospective and relatively small and, because of the lack of generally agreed-upon criteria for the classification of SLE, were predisposed to include a disproportionate number of more severe cases. In addition, without standardized diagnostic criteria for SLE exacerbation, early investigators may have incorrectly diagnosed preeclampsia and other obstetric complications as SLE exacerbations.

Studies undertaken since 1980 have done much to clarify the relationship of pregnancy to the rate and nature of SLE exacerbations. Overall, the rate of flare during pregnancy or the postpartum period varies between 15% and 60% of women.[33–45] Several prospective studies deserve special consideration. Lockshin and colleagues[33] matched nonpregnant SLE patients with 28 SLE patients undertaking 33 pregnancies and used a previously published scoring system to define SLE exacerbations. There was no difference in the flare score between the cases and the controls, and a similar number in both groups required a change in their medication. The same investigators have now followed 80 consecutive pregnancies in women with SLE and conclude that exacerbations occur in less than 25% of cases and that most are mild in nature. If only signs or symptoms specific for SLE are included, exacerbations occurred in only 13% of cases.

Mintz and coworkers[35] prospectively studied 92 pregnancies in women with SLE and used a similar group of nonpregnant SLE patients on oral contraceptives derived from a previous study as controls. Exacerbations were defined by criteria different from those used by Lockshin and colleagues. As a matter of policy, all pregnant women were started on 10 mg prednisone daily, even if there was no evidence of SLE activity. The rate of SLE flares per month at risk was similar in both groups. As in Lockshin and colleagues's studies, most of the exacerbations tended to be easily controlled with low to moderate doses of glucocorticoids, but 7 patients (8%) had severe exacerbations requiring more aggressive therapies. Interestingly, the majority (54%) of the exacerbations occurred in the first trimester.

Using criteria for SLE flare that differed from either of the other two studies, Petri and associates[36] found SLE flares (flares/person-years) to be more common among pregnant

women than among controls. Fortunately, over three quarters of the flares were mild to moderate in nature.

Urowitz and colleagues[37] reported their experience comparing 79 pregnancies in patients with active SLE with a matched control group of 59 nonpregnant women with active SLE. They also compared these women with 216 women with inactive disease. Using a previously defined SLE exacerbation score, they found no significant differences in disease activity between the three groups. Only inactive patients at the onset of pregnancy showed a significant reduction in SLE activity (41%).

Ruiz-Irastorza and coworkers[38] analyzed the course of SLE in 78 pregnancies in 68 patients and a matched control group of 50 nonpregnant women. Sixty-five percent of the patients experienced an exacerbation of SLE during pregnancy, for a flare rate of 0.082/patient-month. In the control group, 42% of the patients experienced a flare, with a flare rate of 0.039/patient-month, representing a statistically significant difference.

Georgiou and associates[39] prospectively evaluated the frequency of SLE exacerbation during 59 pregnancies in 47 women with SLE and 59 nonpregnant women matched for parameters other than disease activity and duration. Using accepted clinical criteria, they reported SLE exacerbation in 8 (13.5%) pregnant patients compared with 13 (22%) nonpregnant women. More than half of the exacerbations in the pregnant group occurred during the first trimester. As in the previous studies, all exacerbations were mild and easily treated with glucocorticoids.

It follows that whether or not pregnancy predisposes to SLE exacerbation is unsettled. At most, the predisposition to SLE flare during pregnancy is modest. Importantly, in a majority of studies of pregnant women with SLE, flares have been mild to moderate in nature and easily treated with glucocorticoids.[33–45] However, a prospective study of consecutively enrolled pregnant lupus patients in one center found the rate of flare was highest among women who discontinued their prepregnancy hydroxychloroquine compared with those who continued it.[46] The authors concluded that the continuation of prepregnancy hydroxychloroquine during pregnancy promotes the maintenance of "quiet lupus activity."

Preexisting disease activity undoubtedly plays a large role in risk of SLE flare during pregnancy. Derksen and colleagues[42] reported that SLE exacerbation occurred in fewer than 20% of women with sustained remission prior to pregnancy. More recently, Cortez-Hernandez and coworkers[44] studied 60 women with 103 pregnancies and found that SLE exacerbations during pregnancy were more likely in women who discontinued maintenance therapy before pregnancy and/or had a history of more than three severe flares prior to pregnancy. The findings of several other studies support the notion that women with active disease should postpone pregnancy until sustained remission can be achieved.[39,43,45]

Better prognoses are attained for both mother and fetus when the disease and any associated renal dysfunction has been quiescent for 6 months prior to conception. Thus, judicious family planning and contraceptive use are paramount to best outcomes. The mother and fetus face higher risks of adverse outcome with SLE in the presence of comorbidities such as pulmonary hypertension, restrictive lung disease, chronic renal failure, heart failure, history of

preeclampsia, history of cerebrovascular accident, and lupus flare within a 6-month period preceding pregnancy.[47]

The Risk of Lupus Nephritis Exacerbation

Women with lupus nephropathy face several challenges during pregnancy.[48–50] Some evidence suggests that pregnancy may worsen renal function. In turn, underlying renal disease presages increased risks of maternal and fetal complications. Those with chronic renal disease are likely to have worsening proteinuria during gestation as renal perfusion increases. In turn, this inevitably poses the question of whether the increased proteinuria represents an exacerbation of underlying renal disease, preeclampsia, or both.

Whether renal flares are more common in pregnancy in all women with SLE remains controversial. Two studies reported high frequencies of renal flares (43%–46%) during pregnancy,[51,52] whereas others have reported lower figures (9%–28%).[35,38,53,54] Three studies describe the patients' status during pregnancy in terms of whether the SLE was active or in remission prior to conception.[55–57] In all three, the rate of SLE exacerbation was lower among pregnancies in which the patient was in remission prior to conception.

Studies of pregnancy outcome in women with past or current SLE nephritis are scarce. This may be explained, in part, by (1) the reduced fertility associated with long-term cyclophosphamide or impaired renal function, or both, and (2) the classic assumption that pregnancy should be discouraged in women with a history of lupus nephritis. The earliest reports suggested that lupus nephropathy was a major contributor to serious maternal morbidity or death.[31,32,58] However, larger, more recent series suggest that the outlook for pregnancy in women with lupus nephropathy is usually favorable if the disease is well-controlled and renal function is preserved.[59] Oviasu and associates[60] reviewed eight studies (151 pregnancies) published between 1973 and 1991 on the effect of completed pregnancy on maternal renal function in established lupus nephritis and reported that transient deterioration of renal function occurred in only 17% of pregnancies and permanent deterioration occurred in 8%.

Even better outcomes were reported in three studies published in the 1990s.[60–62] Of 143 patients with lupus nephropathy, only 1 developed irreversible loss of renal function after pregnancy. Importantly, the majority of women in these studies had normal renal function, mild proteinuria, and well-controlled hypertension *before* conception. Petri and colleagues at the Hopkins Lupus Pregnancy Center reported that only women who began pregnancy with nephrotic syndrome went on to renal failure after delivery.[52] Hayslett and Lynn[55] and Bobrie and coworkers[57] also found that the rate of renal deterioration was somewhat lower among pregnancies in which the patient was in remission prior to conception. Most recently, Moroni and associates[63] reported that renal flare occurred in 5% (1/20) of pregnancies in women with inactive lupus nephropathy prior to conception compared with 39% (12/31) in women with active lupus nephropathy prior to conception ($P < .01$). The sole predictors for renal flare were a plasma creatinine greater than 1.2 mg/dL or proteinuria of 500 mg or greater in the 24-hour collection. Permanent deterioration occurred in 2 women with active lupus nephropathy prior to conception, 1 of whom eventually died.

Based on the published data summarized in Table 43–3, approximately one third of women with lupus nephropathy experience SLE exacerbation during pregnancy and 21%

PTC, prior to conception.

experience some form of renal deterioration. The median rate for permanent deterioration is 7%. Women with inactive lupus nephropathy prior to conception rarely suffer permanent deterioration during pregnancy.

Medical prudence would strongly suggest that pregnancy is contraindicated in patients with active lupus nephropathy (especially DPGN), nephrotic syndrome, and severe hypertension. Pregnancy should be attempted only if immunosuppressive therapy is effective in reducing disease activity and antihypertensive therapy reduces blood pressure to acceptable levels. Ideally, pregnancy is undertaken without exposure to immunosuppressants or steroids. Hence, azathioprine should be used with caution, and glucocorticoids should be used at the lowest effective dose.[64,65] Moderate renal failure (creatinine 1.5–2.0 mg/dL) is a relative contraindication to pregnancy, and advanced renal failure (creatinine >2.0 mg/dL) should be considered an absolute contraindication to pregnancy.

Problems of Detection of Systemic Lupus Erythematosus Exacerbation (Flare) in Pregnancy

Thorough and frequent clinical assessment remains essential for the timely and accurate detection of SLE exacerbation. However, detection of flare during pregnancy is hampered by the fact that many of the typical signs and symptoms associated with flare are considered normal manifestations of pregnancy.[66–68] In addition, common complications of pregnancy such as preeclampsia may be mistaken for SLE exacerbation. Nevertheless, criteria for measuring SLE flare during pregnancy have been tested and have been found valid.[69] Fever, weight loss, myalgia, and arthralgia are very common.[70] As in all patients with SLE, the most common presenting symptom of flare during pregnancy is extreme fatigue (see Table 43–1). In addition, skin lesions occur in greater than 90% and arthritis/arthralgias in greater than 80% of SLE exacerbations during pregnancy.[39,52]

Serologic evaluation of SLE disease activity may be beneficial in confirming flare in confusing cases. Most specific are elevations in anti-dsDNA titers that precede lupus flare in more than 80% of patients.[10,11] In pregnancy, elevated anti-dsDNA titers have also been shown to correlate with the need for preterm delivery.[12] In combination with anticardiolipin antibodies, elevated levels of anti-dsDNA are associated with an increased risk of fetal loss.

Early reports suggested that serial serologic evaluation of complement components and activation products were beneficial in predicting SLE flare during pregnancy. In two studies, Devoe and colleagues[68,71] found that SLE exacerbation was signaled by a decline of C3 and C4 into the subnormal range. Buyon and coworkers[72] found that SLE exacerbation was associated with an absence of the usual increase in C3 and C4 levels during normal pregnancies. However, the practical utility of serial determinations of complement components or their activation products during pregnancy remains unproved. Lockshin and associates[73] reported that low-grade activation of the classic pathway may be attributed to pregnancy alone. Wong and colleagues[51] prospectively studied 19 continuing SLE pregnancies and found that neither ANA, C3, nor C4 levels predicted which patients were going to have a flare. Nossent and Swaak[74] observed that fewer than half of the pregnancies

with decreased serum C3 levels were associated with a clinical SLE flare. Finally, although some have found that hypocomplementemia has been reported to correlate with poor pregnancy outcomes,[75–77] there is also evidence that hypocomplementemia may occur in pregnant patients without SLE and no adverse pregnancy outcomes.[78]

Laboratory confirmation of SLE flare is probably most helpful in women with active lupus nephropathy in whom proteinuria, hypertension, and evidence of multiorgan dysfunction may easily be confused with preeclampsia. Distinguishing between the preeclampsia and the SLE flares is not always possible, and the two conditions may occur concurrently. Nonetheless, both clinical findings and serum markers may be utilized in an effort to differentiate the two.[79] Table 43–4 outlines features that may prove helpful in distinguishing between the two conditions. Preeclampsia is more likely in women with prior history of preeclampsia, diabetes mellitus, aPLs, increased levels of complement, or decreased levels of antithrombin III.[80–82] On the contrary, SLE flares tend to be associated with increased anti-DNA antibody titers, active urine sediment (red and white cells and cellular casts), proteinuria, and hypocomplementemia.[83,84] Complement concentrations are not always helpful because activation may also occur in women with preeclampsia.[85] In the most severe and confusing cases, the correct diagnosis is possible only by renal biopsy. Ultimately, concerns about maternal and fetal well-being often prompt delivery, rendering the distinction between SLE flare and preeclampsia clinically moot.

SLE, systemic lupus erythematosus.

Risks of Immunosuppressive Agents in Pregnancy
GLUCOCORTICOIDS

The group of drugs most commonly given to pregnant women with SLE is the glucocorticoid preparations, both as maintenance therapy and in "bursts" to treat suspected SLE flares. The doses used in pregnancy are the same as those used in nonpregnant patients. Pregnancy per se is not an indication to reduce the dose of glucocorticoids, though a carefully monitored reduction in dosage may be reasonable in appropriately selected women whose disease appears to be in remission.

Some groups have recommended prophylactic glucocorticoid therapy during pregnancy,[35,45,54] but there are no controlled studies to show this practice to be prudent or necessary in the face of inactive SLE. Moreover, good maternal and fetal outcomes are achieved without prophylactic treatment of women with stable disease.[42] In contrast, glucocorticoid treatment of women with active disease and/or elevated anti-dsDNA titers has been shown to result in fewer relapses and better pregnancy outcomes.[11,39]

Although glucocorticoids have a low potential for teratogenesis, they are not without risk during pregnancy. Patients requiring chronic maintenance therapy are best treated with prednisolone or methylprednisolone because of their conversion to relatively inactive forms by the abundance of 11-β-ol dehydrogenase found in the human placenta. Glucocorticoids with fluorine at the 9-α position (dexamethasone, betamethasone) are considerably less well metabolized by the placenta, and chronic use during pregnancy should be avoided. Both have been associated with untoward fetal effects. Maternal side effects of chronic glucocorticoid therapy are the same as in nonpregnant patients and include weight gain, striae, acne, hirsutism, immunosuppression, osteonecrosis, and gastrointestinal ulceration. During pregnancy, chronic glucocorticoid therapy has also been associated with an increased risk of preeclampsia,[86–88] uteroplacental insufficiency, and intrauterine growth restriction (IUGR),[89] and glucose intolerance.[87,88] Women undergoing chronic treatment with glucocorticoids should be screened for gestational diabetes at 22 to 24 weeks', 28 to 30 weeks', and 32 to 34 weeks' gestation.

ANTIMALARIALS

An accumulating body of evidence suggests that antimalarial drugs, such as hydroxychloroquine, may be used safely for the treatment of SLE during pregnancy.[90–94] In the past, many patients and their physicians have discontinued antimalarials during pregnancy because of concerns about teratogenicity, including ototoxicity[95] and eye damage.[96] The latter was of particular concern because of the affinity of antimalarials for melanin-containing tissues found in the eye. However, hydroxychloroquine has been used in women considered at risk for malaria for years without any reported adverse fetal effects. This experience has been confirmed in large series showing hydroxychloroquine to be relatively safe during pregnancy.[90–94] Furthermore, these agents may be more beneficial than glucocorticoids for women who need maintenance therapy during pregnancy. In a randomized controlled trial, women who continued hydroxychloroquine during pregnancy experienced a significant reduction in SLE disease activity compared with women who changed

to glucocorticoid therapy.[97] The findings of a case-control trial, which compared the effects of in utero exposure to hydroxychloroquine, were very reassuring.[94] There were no differences between 122 infants with in utero exposure to hydroxychloroquine and 70 control infants in the number and type of defects identified at birth or in the proportion of infants with visual, hearing, growth, or developmental abnormalities at follow-up (median 24 mo).

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

The most common types of analgesics used in the treatment of SLE outside of pregnancy are nonsteroidal anti-inflammatory drugs (NSAIDs). Unfortunately, they readily cross the placenta and block prostaglandin synthesis in a wide variety of fetal tissues. Maternal ingestion of normal adult doses of aspirin in the week before delivery has been associated with intracranial hemorrhage in preterm neonates.[98] Although short-term tocolytic therapy with indomethacin appears to be safe,[99,100] chronic use has been associated with a number of untoward fetal effects; when used after 32 weeks' gestation, chronic indomethacin therapy may result in constriction or closure of the fetal ductus arteriosus.[101] Long-term use of all NSAIDs has been associated with decreased fetal urine output and oligohydramnios as well as neonatal renal insufficiency.[102] Given these risks, chronic use of adult dosages of aspirin and other NSAIDs should be avoided during pregnancy, especially after the first trimester. Acetaminophen and narcotic-containing preparations are acceptable alternatives if analgesia is needed during pregnancy.

CYTOTOXIC AND IMMUNOSUPPRESSIVE AGENTS

Cytotoxic agents, including azathioprine, methotrexate, and cyclophosphamide, are used to treat only the most severely affected patients with SLE. Limited data suggest that azathioprine, a derivative of 6-mercaptopurine, is not a teratogen in humans, though it has been associated with IUGR[103,104] and evidence of impaired neonatal immunity.[105] Women who require azathioprine to control SLE disease activity should not necessarily be discouraged from becoming pregnant, though potential fetal risks should be carefully weighed against the benefits of the medication.

Cyclophosphamide has been reported to be teratogenic in both animal[106] and human studies[107,108] and should be avoided during the first trimester. Thereafter, cyclophosphamide should be used only in unusual circumstances such as in women with severe, progressive proliferative glomerulonephritis.[109] Methotrexate is known to kill chorionic villi and cause fetal death, and its use should be scrupulously avoided. Cyclosporine, high-dose IVIG, mycophenolate mofetil, and thalidomide have been studied in the treatment of nonpregnant patients with SLE.[109] Cyclosporine is a U.S. Food and Drug Administration (FDA) pregnancy category C agent that should be used in pregnancy only when the benefits clearly outweigh concerns about possible fetal-neonatal effects. Mycophenolate mofetil (CellCept) is associated with an increased risk of first-trimester pregnancy loss and an increased risk of congenital malformations, especially external ear and other facial abnormalities including cleft lip and palate, and anomalies of the distal limbs, heart, esophagus, and kidney. IVIG has been used during pregnancy without reports of adverse fetal effects. Obviously, thalidomide is strictly contraindicated during pregnancy because of

Suggested Methods for Tapering Prednisone

1. Consolidate to a single morning dose of prednisone. Reduce the daily dose by 10%/wk, as tolerated. When a dose of 20–30 mg/day is reached, reduce by 2.5-mg increments/wk. If the patient remains asymptomatic at a dose of 15 mg/day, reduce the dose by 1-mg increments/wk to a dose of 5–10 mg/day.
2. Consolidate to a single morning dose of prednisone. Taper to 50–60 mg/day by reducing the dose 10%/wk. Thereafter, eliminate the alternate-day dose by tapering it 10%/wk, as tolerated. Thereafter, taper the remaining every-other-day dose by 10%/wk, as tolerated.

its known potent teratogenicity. Complete immunoablative therapy followed by bone marrow stem cell transplantation has also been studied in patients with the most severe, unresponsive SLE.[109]

Treatment of Systemic Lupus Erythematosus Exacerbations in Pregnancy

Mild to moderate symptomatic exacerbations of SLE without central nervous system (CNS) or renal involvement may be treated with initiation of glucocorticoids or an increase in the dose of glucocorticoids. Relatively small doses of prednisone (e.g., 15–30 mg/day) will result in improvement in most cases. For severe exacerbations without CNS or renal involvement, doses of 1.0 to 1.5 mg/kg/day of prednisone in divided doses should be used, and a good clinical response can be expected in 5 to 10 days. Thereafter, glucocorticoids may be tapered by several different approaches (Table 43–5).

Severe exacerbations, especially those involving the CNS or kidneys, are treated more aggressively. In recent years, an intravenous pulse glucocorticoid approach has become popular. The initial regimen involves a daily intravenous dose of methylprednisolone at 10 to 30 mg/kg (~500–1000 mg) for 3 to 6 days. Thereafter, the patient is treated with 1.0 to 1.5 mg/kg/day of prednisone in divided doses and rapidly tapered over the course of 1 month. One can expect that 75% of patients will respond favorably to this approach.[110] This regimen may be repeated every 1 to 3 months in severe cases as an alternative to cytotoxic drugs.

In nonpregnant patients, both azathioprine and cyclophosphamide may be used in severe SLE exacerbations to control disease, reduce irreversible tissue damage, and reduce glucocorticoid doses.[111–113] In particular, severe proliferative lupus nephritis may be treated more effectively with cyclophosphamide, usually in combination with glucocorticoids.[113] The drug may be given either orally or intravenously, but the most effective cyclophosphamide regimen is uncertain. Cyclophosphamide appears to be useful in the treatment of severe cerebral lupus as well.

Plasmapheresis and IVIG have been used to treat severe cases of SLE flare unresponsive to standard treatments. Plasmapheresis should be considered in life-threatening disease that is unresponsive to other treatments. A cytotoxic agent should also be administered soon after plasmapheresis is initiated (days 5–10 of therapy) if the patient is no longer pregnant. IVIG has been used for salvage treatment of recalcitrant SLE flare with neuropsychiatric or renal involvement.[114]

Obstetric Complications in Women with Systemic Lupus Erythematosus

GESTATIONAL HYPERTENSION AND PREECLAMPSIA

The exact incidence of pregnancy-related hypertension associated with SLE is difficult to estimate owing to inconsistencies in the definition and classification of these disorders as well as the inclusion of patients with lupus nephropathy in the various studies. Nevertheless, it appears that between 20% and 30% of women with SLE develop either gestational hypertension or preeclampsia (gestational hypertension with proteinuria) sometime during pregnancy.[86,115–117] Women with lupus nephropathy are undoubtedly most vulnerable given the known association between preeclampsia and underlying renal disease of any origin.[118] In one prospective series, preeclampsia occurred in 7 of 19 (37%) women with lupus nephritis, compared with 15 of 106 (14%) without.[86] Other important predisposing factors include chronic hypertension, antiphospholipid syndrome (APS), and chronic steroid use.[60,117,119,120]

PREGNANCY LOSS

Women with SLE are probably more likely to have an unsuccessful pregnancy than women in the general obstetric population. The exact physiologic mechanisms responsible for pregnancy loss in women with SLE and other immunologic diseases remain uncertain, though a clear relationship between pregnancy failure and histologic evidence of inflammation has been well documented. Recent experimental observations suggest that altered complement regulation causes and may perpetuate pregnancy loss.

In most retrospective studies, the rate of pregnancy loss appears to be higher in women with SLE than in the general obstetric population, ranging between 8% and 41%, with a median of 22%.[31,34,55,66,117,121–126] In one case-control trial comparing obstetric outcomes between 481 pregnancies in 203 lupus patients, 566 pregnancies in 177 healthy relatives, and 356 pregnancies in 166 healthy unrelated women, investigators found that pregnancy loss occurred significantly more often in women with SLE (21%) than in either their healthy relatives (8%) or the unrelated healthy controls (14%).[127] In the group of women with SLE and prior pregnancy, those whose diagnosis was made with SLE onset *after* their first pregnancy had a higher rate of loss once the diagnosis was made (27% vs. 19%). The pregnancy loss rates observed in most prospective trials of lupus pregnancies have been better than those found in retrospective trials, possibly because of careful monitoring of SLE activity and routine antenatal surveillance. Still, from the data summarized in Table 43–6, between 11% and 34% of women with SLE experienced pregnancy loss, with a median of 24%. In the well-detailed prospective trials, fetal deaths in the second or third trimester accounted for between 10% and 40% of the total number of losses.[39,43] Though not clearly linked to better management, Clark and coworkers[127] suggested that the incidence of pregnancy loss with SLE has declined over the past several decades from a mean of 43%

PTC, prior to conception.

in the 1960s to 17% from 2000 to 2003. The latter figure coincidentally approximates reported pregnancy loss rate of the general American population. In contrast, a 2008 report of a multiethnic, North American cohort with SLE cited an incidence of stillbirths and fetal losses to be 45%.[128] Control of disease activity appears to have a salutary effect on the rate of pregnancy loss,[41] with one early study reporting live births in 64% of women with active disease within 6 months of conception, compared with 88% in women with quiescent disease.[48] In a more recent prospective study of pregnancy in SLE patients, pregnancy loss occurred in 75% of women with active disease compared with 14% of women with inactive disease.[39] Not surprisingly, pregnancy loss is more likely if SLE is diagnosed during the index pregnancy.[56,67,124]

Preexisting renal disease increases the rate of pregnancy loss in women with SLE. Table 43–7 summarizes obstetric outcomes in 411 pregnancies in 261 women with a

diagnosis of lupus nephropathy prior to conception. Excluding therapeutic abortions, the median rates of miscarriage, fetal and neonatal death, and live birth were 13%, 7%, and 75%, respectively, figures not remarkably different from those for all patients with SLE shown in Table 43–6. Pregnancy loss rates in individual studies vary widely, probably because of variations in the degree of renal impairment of included patients as well as definitions of pregnancy loss.

The degree of renal impairment no doubt influences the likelihood of pregnancy loss in women with lupus nephropathy. In a study of lupus nephropathy in pregnancy that included only women with inactive disease and normal renal function (serum creatinine <0.8 mg/dL), the overall fetal survival rate was greater than 90%, after exclusion of embryonic losses (losses <10 weeks' gestation).[126] These results contrast markedly to those of another study in which the rate of fetal loss was 50% in pregnant women with lupus nephropathy and moderate to severe renal insufficiency (serum creatinine ≥1.5 mg/dL).[55] In a study comparing obstetric outcomes according to the degree of renal impairment in women with lupus nephropathy, spontaneous abortion occurred in 26% of women with minimally impaired renal function (serum creatinine <1 mg/dL, creatinine clearance >80 mL/min, and proteinuria <1 g/day) and 36% in women with mild impairment (creatinine clearance 50–80 mL/min and proteinuria 1–3 g/day).[66]

Among SLE patients, fetal deaths are associated with the presence of aPLs (see the sections on "Antiphospholipid Syndrome"). In several studies, the presence of aPLs has been the single most sensitive predictor of fetal death.[129] The positive predictive value of aPLs for fetal death is over 50%.[86] For women with SLE and a prior fetal death, the predictive value is over 85%.[130] In a prospective trial, the presence of any aPL was the single strongest predictor of subsequent pregnancy loss, even in women with active disease and underlying renal impairment.[131]

PRETERM BIRTH

Preterm birth has been reported in as few as 3% and as many as 73% of pregnancies complicated by SLE.[35,51,55,56,66,67,125,129,132–134] Not surprisingly, the presence of aPLs, chronic hypertension, and disease activity have all been reported to increase the likelihood of preterm birth in women with SLE.[39,131] Only a handful of studies have compared preterm birth rates in women with SLE with those in healthy controls. In one retrospective case-control study, preterm birth occurred more commonly in a group of women with SLE than in a group of matched controls (12% vs. 4%).[135] This was not the case in a more recent prospective trial, in which the rates of preterm birth in women with SLE and healthy controls were statistically similar (8% vs. 15%).[39] Interestingly, preterm birth was more common among women with active SLE than among those with inactive disease (12.5% vs. 4%).

A substantial proportion of preterm birth associated with SLE is undoubtedly a result of iatrogenic delivery for obstetric and medical indications rather than idiopathic preterm labor. From the few studies that provide sufficient detail, between 28% and 66% of preterm deliveries are indicated because of preeclampsia and another 12% to 33% because of suspected or confirmed fetal compromise.[125,130–132,135] An association between SLE and preterm premature rupture of membranes (PPROM) has also been reported, occurring in 39% of pregnancies delivered at 24 to 36 weeks' gestation.[134]

INTRAUTERINE FETAL GROWTH RESTRICTION

Uteroplacental insufficiency resulting in IUGR or small–for–gestational age neonates has been reported in between 12% and 40% of pregnancies complicated by SLE.[38,41,43,62,116,131] Mintz and coworkers[35] reported higher rates of IUGR in pregnancies complicated by SLE than in pregnancies in normal controls (23% vs. 4%). However, the higher rate of IUGR associated with SLE may have been due to all the women with SLE receiving prophylactic glucocorticoid therapy during pregnancy. In a more recent prospective trial during which glucocorticoids were given only for symptomatic SLE flare, Georgiou and associates[39] reported no significant differences in the rate of IUGR between SLE pregnancies and healthy controls. Factors that have been associated with a higher rate of IUGR in SLE pregnancies include renal insufficiency and/or hypertension.[89,117,131]

NEONATAL LUPUS ERYTHEMATOSUS

Neonatal lupus erythematosus is a rare condition of the fetus and neonate, occurring in 1 in 20,000 of all live births and in fewer than 5% of all women with SLE.[136] Dermatologic manifestations are the most common manifestation of neonatal lupus and are described as "erythematous," "scaling annular," or "elliptical" plaques occurring on the face or scalp, analogous to the subacute cutaneous lesions in adults.[137] Lesions appear in the first weeks of life, probably induced by exposure of the skin to ultraviolet light, and may last for up to 6 months. Hypopigmentation may persist for up to 2 years. A small percentage of affected infants will go on to have other autoimmune diseases later in life.[136] Hematologic neonatal lupus is rare and may be manifest as autoimmune hemolytic anemia, leukopenia, thrombocytopenia, and hepatosplenomegaly.

Cardiac neonatal lupus lesions include congenital complete heart block (CCHB) and the less frequently reported endocardial fibroelastosis. CCHB is due to disruption of the cardiac conduction system, especially in the area of the atrioventricular node. The diagnosis of CCHB is typically made around between 18 to 24 weeks[138] when a fixed bradycardia, in the range of 60 to 80 beats/min, is detected during a routine prenatal visit. The associated mortality approaches 20%, making it a very concerning diagnosis.[139] Sonographic markers in affected fetuses that negatively correlate with survival include ascites, increasing cardiothoracic circumference ratio, and hydrops. In cases of CCHB, fetal echocardiography reveals complete atrioventricular dissociation with a structurally normal heart.[140] Confirmation of neonatal lupus is based on the presence of autoantibodies in maternal circulation. Endomyocardial damage is irreversible; in the most severely affected cases, cardiac failure leads to hydrops fetalis and fetal death. In less severely affected neonates, pacemaker placement is frequently necessary to ensure survival. In the largest series of prenatally diagnosed CCHB, the 3-year survival was only 79%; the majority of deaths occurred before 90 days of life.[138] Cutaneous manifestations of neonatal lupus have also been reported in infants with CCHB.[137]

Not all women who give birth to babies with neonatal lupus have been previously diagnosed with an autoimmune disorder.[137,138,141] However, in one study, 7 of 13 previously asymptomatic mothers who delivered infants with dermatologic neonatal lupus were later diagnosed with one of several autoimmune disorders.[137] Surprisingly, asymptomatic women who deliver infants with CCHB were less likely to develop an autoimmune disorder than those who delivered infants with dermatologic manifestations.[141]

A model of passively acquired autoimmunity, neonatal lupus manifestations are presumed to arise from the transplacental passage of autoantibodies directed against Ro/SS-A ribonucleoprotein antigens.[138,142–145] Anti-Ro/SS-A antibodies are found in 75% to 95% of mothers who deliver babies with neonatal lupus.[138,146,147] A smaller percentage have anti-La/SS-B, and some have both.[147] More than 80% of mothers of infants with CCHB have autoantibodies to the 52-kDa Ro/SS-A protein.[148,149] The finer specificity of this autoantibody has been identified as epitope expressed by amino acids 200-239 of the Ro/SS-A 52-kDa protein.[150] Using sera from a large research registry, other investigators have shown that reactivity to this peptide (aa200-239) is a dominant but not uniform anti-Ro/SS-A 52 response in women whose children have CCHB.[151]

The proposed mechanism of CCHB is that the relevant autoantibodies cross the placenta and damage the myometrium or conduction system of the fetal heart. However, the SS-A antigen containing the SS-A 52 protein is intracellular, and authorities acknowledge that the maternal autoantibody is requisite but not sufficient to cause CCHB. Other factors, including genetic contributions and the fine specificity of the autoantibodies, are likely important. One group has shown that the p200-specific anti-SSA antibodies from humans bind to cultured cardiomyosites, affect cellular calcium homeostasis, and lead to cellular apoptosis.[150] They have further demonstrated that the pups of rats immunized against the p200 amino acid stretch of SS-A 52 develop heart block. The authors suggest that the autoantibodies do not bind to intracellular SS-A, but to a cross-reactive cell surface antigen.

Among all mothers with SLE, the risk of neonatal lupus is less than 5%.[136] Of mothers with SLE who are serologically positive for anti-Ro/SS-A antibodies, 15% will have infants affected with dermatologic neonatal lupus; the proportion that delivers infants with CCHB is much smaller. The latter condition is more prevalent in infants born to women with high anti-Ro/SS-A and anti-La/SS-B titers.[152] Also, once a women with SLE and anti-Ro/SS-A antibodies delivers one infant with CCHB, her risk for recurrence approaches 20%, some three- or fourfold higher than women with anti-Ro/SS-A or anti-La/SS-B antibodies who have never had an affected child.[138,153] Recurrence of dermatologic neonatal lupus is approximately 25%.[153,154]

In women with anti-Ro/SS-A and/or anti-La/SS-B antibodies, the presence of anti-La/SS-B anti-idiotypic antibodies in maternal serum confers lower risk; these anti-idiotypic antibodies may protect the fetus by binding and, in effect, blocking the activity of harmful maternal autoantibodies. Women with neonates with congenital heart block tend not to express these anti-idiotypic antibodies. As such, testing for such "anti-idiotypic" responses has been suggested as being useful for predicting outcomes.[155]

Management Options

Prepregnancy

Women with SLE who are contemplating pregnancy should be counseled before conception about potential obstetric problems, including pregnancy loss, preterm birth, gestational hypertension/preeclampsia, and IUGR. They should also be informed of the risk of SLE flare as well as special concerns related to APS and neonatal lupus. Preconceptional laboratory evaluation should include an assessment for anemia and thrombocytopenia, underlying renal disease (urinalysis, serum creatinine, and 24-hr urine for creatinine clearance and total protein) and aPLs. It is also common practice to obtain anti-Ro/SS-A and anti-La/SS-B antibodies on all patients with SLE, but the cost-effectiveness of these is questionable given the low prevalence of the condition and the lack of proven intervention.

Women with active SLE should be discouraged from embarking on pregnancy until remission can be attained. Cytotoxic drugs and NSAIDs should be stopped before pregnancy. However, maintenance therapy with hydroxychloroquine or glucocorticoids need not be discontinued.

Prenatal

The obstetric management of the patient with SLE is guided by the potential risks to the mother and fetus. Once pregnancy is confirmed in a woman with SLE, the following examinations and tests are recommended: physical examination complete with blood pressure, complete blood count, urinalysis, urine protein–to–urine creatinine ratio, glomerular filtration rate, and aPL antibodies (if not recently performed). Some experts routinely test for anti-Ro/SS-A and anti-La/SS-B antibodies, anti-dsDNA antibodies, and complement (C3 and C4), though the need for these in unselected, and especially in asymptomatic, cases is questionable. Periodic reassessment of platelet count or complete blood count is recommended by some.[156]

As mentioned, prenatal visits should occur every 1 to 2 weeks in the first and second trimesters and every week thereafter. A primary goal of the antenatal visits after 20 weeks' gestation is the detection of hypertension and/or proteinuria. Because of the risk of uteroplacental insufficiency, fetal ultrasonography should be performed every 4 to 6 weeks starting at 18 to 20 weeks' gestation. In the usual case, fetal surveillance (daily fetal movement counts and once- or twice-weekly nonstress tests and amniotic fluid volume measurements) should be instituted at 30 to 32 weeks' gestation. More frequent ultrasonography and fetal testing is indicated in patients with SLE flare, hypertension, proteinuria, clinical evidence of IUGR, or APS. In the patients with APS, fetal surveillance as early as 24 to 25 weeks' gestation may be justified.[157]

In fetuses at risk for CCHB, some experts have used weekly fetal PR interval determinations from 16 to 26 weeks, performed using gated pulsed Doppler techniques, in an effort to detect early evidence of evolving heart block.[158] In the PRIDE (PR Interval and Dexamethasone Evaluation) study,[158] this approach detected a prolonged PR interval (>150 msec) in only a few of nearly 100 fetuses at risk and failed to reliably diagnose impending CCHB. A somewhat similar European study detected a much higher rate of prolonged PR intervals, defined as greater than 135 msec, in an at-risk population.[159] In both studies, though, transiently

prolonged PR intervals of uncertain clinical significance were seen, and in neither study was it definitively shown that detection of a prolonged PR interval altered fetal-neonatal outcomes with regard to CCHB. Thus, in a strict sense, PR interval monitoring in fetuses at risk for CCHB remains investigational. Nonetheless, most experts would recommend that at-risk fetuses be monitored frequently from approximately 16 to 26 weeks.

The treatment of fetuses with CCHB is somewhat uncertain. A 2002 report of consecutive cases from a single institution suggested that a combination of dexamethasone, along with a β-mimetic when the fetal heart rate is less than 55 beats/min, results in improved overall survival.[160] These investigators found 1-year neonatal survival rates of in excess of 80% using their management regimen. Less salubrious results come from the recently published PRIDE study.[158] The PRIDE investigators enrolled 40 pregnant women with anti-Ro/SS-A antibodies and a fetus with heart block from 33 centers. Thirty of the mothers elected to take dexamethasone, whereas 10 did not. None of the 22 fetuses with complete (third-degree) heart block recovered any conduction in association with dexamethasone treatment. Of the 6 fetuses with second-degree heart block who were treated with dexamethasone, 3 progressed to third-degree block, whereas 2 stabilized at second-degree and only 1 reverted to normal sinus rhythm. Two fetuses found to have first-degree heart block reverted to normal sinus rhythm with dexamethasone treatment.

Outcomes were fairly similar in the nondexamethasone group, in which 9 of the 10 fetuses presented with third-degree heart block. Though case selection likely played a role, there were no fetal-neonatal deaths in the nondexamethasone group, whereas there were 6 (20%) in the dexamethasone group. The preterm birth rate was higher in the dexamethasone group.

The case of CCHB associated with fetal hydrops may pose a special circumstance. A retrospective analysis of collected cases found that dexamethasone use was associated with improvement in the hydrops, though not the heart block.[161] Based on available evidence, although much of it less than convincing, most experts still recommend a trial of dexamethasone if first- or second-degree heart block is found or in selected cases of CCHB with hydrops (Table 43–8).

Another therapy that has become of interest in the prevention of CCHB is that of IVIG. IVIG has the potential to lower the transplacental passage of autoantibodies against Ro/SS-A-La/SS-B that are responsible for the pathogenesis of CCHB.[162] Favorable outcomes have been reported in case reports.[163] The PITCH (Preventative IVIG Therapy for Congenital Heart Block) study is currently under way to answer the question of whether maternal administration in the context of positive Ro/SS-A and/or La/SS-B titers, maternal rheumatic disease either symptomatic or not, and a previously affected child with CCHB or neonatal lupus.[164] Though the results of two prospective studies (one European and the PITCH study) are as yet unpublished, neither found a decrease in the frequency of CCHB in high risk populations when mothers were treated with periodic infusions of IVIG. These important results strongly suggest that IVIG is not indicated for the prevention of CCHB. Thus, insufficient evidence exists to recommend IVIG therapy except under an approved experimental protocol.

TABLE 43–8

Management Approaches for Anti-Ro/SSA Antibody Associated Risk of Complete Congenital Heart Block or Evidence of Cardiac Conduction Abnormalities

CLINICAL SITUATION	MANAGEMENT
Maternal anti-SSA antibodies; no history of fetus with CCHB	Expectant management. Evaluation of the fetus by serial echosonography is recommended by some experts.
Maternal anti-SSA antibodies; prior fetus with CCHB	Expectant management. Evaluation of the fetus by serial echosonography is recommended by some experts.
Fetal first-degree heart block (prolonged mechanical PR interval)	Repeat echocardiographic assessment within 24 hr. If first-degree heart block persists, treat with maternally administered DEX), 4 mg daily. If first-degree heart block persists or resolves, continue DEX until 24–26 wk, then taper. If there is progression to third-degree heart block, taper DEX to discontinuation.
Fetal second-degree heart block or alternating second-/third-degree heart block	Treat with maternally-administered DEX, 4 mg daily. If second-degree heart block persists or resolves, continue DEX until 24–26 wk, then taper. If there is progression to third-degree heart block, taper DEX to discontinuation.
Fetal third-degree heart block	Expectant management, with monitoring for fetal hydrops. If fetal heart rate <55 beats/min, treat with maternally administered oral terbutaline (2.5–7.5 mg q4–6h) sufficient to result in mild maternal tachycardia.
Fetal third-degree heart block with evidence of myocarditis or fetal hydrops	Treat with maternally administered DEX, 4 mg daily, at least until improvement in fetal sonographic findings.

CCHB, complete congenital heart block; DEX, dexamethasone.

Fetuses with heart rates less than 55 beats/min are more likely to have hydropic changes and demise.[165–168] Because of this, some clinical investigators have used maternally administered β-sympathomimetic agents in a effort to increase the fetal heart rate,[169–171] and reports suggest that the use of these agents may favorably alter signs of cardiac insufficiency and result in higher fetal-neonatal survival rates.[169–171] Jaeggi and associates in 2004[160] analyzed 37 cases of fetal CCHB since 1990. The investigators stratified their data by their institution's initiation of β-sympathomimetic stimulation for fetal heart rates of less than 55 beats/min in 1997 when reports of worse outcomes for this finding surfaced. Significant improvement in neonatal morbidity and 1-year survival rates (80%–95%; $P < .01$) were noted with the addition of β-stimulation to dexamethasone therapy for CCHB when the fetal heart rate was les than 55 beats/min.

Labor and Delivery

The management of the gravida with SLE during labor and delivery represents a continuation of her antenatal care.[172] Exacerbations of SLE can occur during labor and may require the acute administration of steroids. Regardless, stress doses

of glucocorticoids should be given during labor or at the time of cesarean delivery to all patients who have been treated with chronic steroids within the previous year. This compensates for the anticipated endogenous adrenal insufficiency in these patients. Intravenous hydrocortisone, given in three doses of 100 mg every 8 hours, is an acceptable regimen. Complications such as preeclampsia and IUGR should be dealt with based on obstetric concerns; their management is not specifically altered by the presence of SLE. Neonatology support may be needed at delivery for problems associated with CCHB and other manifestations of neonatal lupus.

Postnatal

The true predisposition for SLE exacerbation following delivery is uncertain. Regardless, care should be taken to examine for these flares in the symptomatic parturient. If gestational hypertension complicates the intrapartum process, it should be anticipated that the patient will clear these acute effects in a manner similar to otherwise normal women with this condition. Maintenance medications should be restarted immediately after delivery, at similar doses as during the pregnancy. Further dose adjustments can be handled in the outpatient setting.

SUMMARY OF MANAGEMENT OPTIONS
Systemic Lupus Erythematosus

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Establish good control of SLE; adjust maintenance medications.	—/GPP	—
Discontinue azathioprine and cyclophosphamide if possible and only under careful supervision; avoid methotrexate.	IIb/B	98,101,103,105, 106,109,110
It is not necessary to discontinue hydroxychloroquine.	IIa/B	88–92
Laboratory assessment for anemia, thrombocytopenia, renal disease, antiphospholipid antibodies (antiphospholipid).	—/GPP	—
Counsel patient regarding risks (exacerbations, preeclampsia, fetal/neonatal).	—/GPP	—
Prenatal		
Provide multidisciplinary care.	—/GPP	—
Encourage early prenatal care.	—/GPP	—
Obtain a dating scan.	—/GPP	—
Obtain frequent antenatal checks: every 2 wk in the first and second trimesters, weekly in third trimester.	—/GPP	—
Maintain vigilance for SLE flare, preeclampsia, IUGR.	—/GPP	—
For SLE patients with renal involvement, perform baseline 24-hr urine collections for creatinine clearance and total protein; repeat as clinically indicated.	—/GPP	—
Drugs		
• Antimalarials.	IIa/B	88–92
• Glucocorticoids.	IIb/B	103
• Azathioprine if steroids are ineffective.	III/B	101
• Cyclophosphamide as third choice.	III/B	103,110
• Avoid full-dose NSAIDs and methotrexate.	III/B	98,105,106,109
Serial biometry (q3–4wk) to assess fetal growth and amniotic fluid from 18-wk anatomic survey to delivery.	—/GPP	—
Begin fetal surveillance at 30–32 wk' gestation (earlier in patients with worsening disease, evidence of fetal compromise, or a history of poor pregnancy outcome).	III/B	157
Consider low-dose aspirin, especially if history of early-onset severe preeclampsia.	Ib/A	57,58

SUMMARY OF MANAGEMENT OPTIONS
Systemic Lupus Erythematosus—cont'd

Management Options	Evidence Quality and Recommendation	References
Labor and Delivery		
Deliver at term; avoid postdates.	—/GPP	—
Continuous fetal heart rate monitoring.	—/GPP	—
Intravenous glucocorticosteroids for delivery in patients who have received maintenance or steroid bursts during pregnancy.	IIb/B	80
Postnatal		
Monitor for SLE exacerbation.	—/GPP	—
Restart maintenance therapy.	—/GPP	—
Check neonate for SLE manifestations.	—/GPP	—

GPP, good practice point; IUGR, intrauterine growth restriction; NSAIDs, nonsteroidal anti-inflammatory drugs; SLE, systemic lupus erythematosus.

ANTIPHOSPHOLIPID SYNDROME

General

APS was first identified as a syndrome of thrombosis or fetal loss in association with circulating lupus anticoagulant (LA) or anticardiolipin antibodies in the mid-1980s.[173,174] Preliminary classification criteria for the syndrome were derived by expert consensus in 1998 and included recurrent preembryonic and embryonic pregnancy loss, fetal death, and severe preeclampsia or placental insufficiency requiring delivery prior to 34 weeks' gestation.[175] This classification was revised in 2004, and both the thrombotic and the obstetric clinical criteria were preserved.[176]

Antiphospholipid Antibodies

Current evidence suggests that the primary clinically relevant epitope for aPLs is on β_2-glycoprotein I. This glycoprotein is a ubiquitous, multifunctional plasma protein with affinity for negatively charged phospholipids and regulatory roles in coagulation, fibrinolysis, and other physiologic systems.[177] Specifically, it appears that autoantibodies that bind a cryptic epitope in domain I of β_2-glycoprotein I correlate best with thrombosis, a primary clinical feature of APS.[178–181] These relevant aPLs can be detected in several different assay systems, including clotting assays that detect LA and enzyme-linked immunosorbent assays (ELISA) for anticardiolipin and anti-β_2-glycoprotein I antibodies (Table 43–9). Importantly, the common feature is a dependency for binding on the presence of β_2-glycoprotein I. aPLs, though, are a heterogeneous, and β_2-glycoprotein I–independent "antiphospholipid" antibodies can be detected in immunoassays. These antibodies appear to play little or no role in APS.

The revised consensus criteria for the diagnosis of definite APS accept one or more of three aPLs as diagnostic. These include LA, anticardiolipin, and anti-β_2-glycoprotein I antibodies. Most experts hold that LA, which is detected via coagulation assays in plasma, is more specific but less

TABLE 43–9
Detection of Antiphospholipid Antibodies

Lupus anticoagulant	1. Screening with two phospholipid-dependent, in vitro clotting assays using patient's platelet-poor plasma. The assays most commonly used in the United States are the aPTT (which tests the intrinsic coagulation pathway) and the dRVVT (which tests the final common pathway).
	2. If either of the above is prolonged, the test is repeated with a mix (usually 1:1) of patient and normal platelet-poor plasma. If mixing studies do not "correct" the prolonged clotting time(s), lupus anticoagulant is suspected.
	3. Lupus anticoagulant is confirmed by demonstrating marked shortening or correction of the prolonged clotting time after addition of excess phospholipid. This is most commonly done using the platelet neutralization procedure or hexagonal phase phospholipid neutralization.
	4. If the confirmatory test is negative or equivocal, additional tests may be done to investigate other possible coagulopathies or specific factor inhibitors.
Anticardiolipin antibodies	ELISA for IgG and IgM antibodies. The assay used should employ available international calibrators, and results should be reported in GPL and MPL units.
Anti-β_2-glycoprotein I antibodies	ELISA for IgG and IgM antibodies. The assay used should employ available international calibrators, and results should be reported in standard units.

aPTT, activated partial thromboplastin time; dRVVT, dilute Russell's viper venom time; ELISA, enzyme-linked immunosorbent assay; GPL, reference reagent for IgG; Ig, immunoglobulin; MPL, reference reagent for IgM.

sensitive than the other two tests.[180] Both anticardiolipin and anti-β_2-glycoprotein I are detected in serum by ELISA. Many patients with APS have all three antibodies detected. However, many also do not, indicating that the three antibodies are not identical. Moreover, LA and anticardiolipin antibodies may be separated in the laboratory.[181] Thus, aPLs are perhaps best viewed as related but distinctly different immunoglobulins.

LA is detected in platelet-poor plasma and is so named because it paradoxically prolongs phospholipid-dependent, in vitro clotting tests such as the activated partial thromboplastin time (aPTT). The presence of LA is detected through a series of tests (see Table 43–9). Screening typically is performed using a sensitive aPTT and the dilute Russell's viper venom time (dRVVT). Prolongation of these tests may be due to plasma factor deficiencies, anticoagulant medications, or factor-specific inhibitors. Thus, if either of the screening tests suggests the presence of LA, subsequent tests are done to exclude other causes of prolonged clotting times and to establish that the prolonged clotting times is caused by a phospholipid-sensitive inhibitor-LA. The latter step usually involves either the platelet or the hexagonal phase phospholipid neutralization procedure. LA is reported as either present or absent. Transient positive tests may occur; the diagnosis of APS requires repeatedly positive aPL tests at least 12 weeks apart.

Anticardiolipin antibodies are most commonly detected using ELISA (see Table 43–9). Experts recommend that immunoglobulin G (IgG) and IgM isotypes be sought. It is widely held that IgG anticardiolipin antibodies are most strongly associated with clinical features of APS.[182] The clinical relevance of IgA anticardiolipin antibodies is poorly characterized and the diagnosis of APS should not be made on the basis of isolated IgA anticardiolipin antibodies. Historically, standardization of anticardiolipin antibody assays has been difficult, resulting in poor concordance between laboratories.[183] More recently, though, interlaboratory agreement, in terms of semiquantitative results, is seemingly improved.[184]

Standard, reference reagents for anticardiolipin antibodies are available, and results are typically reported in arbitrary units, designated "GPL" for IgG and "MPL" for IgM. Because the accuracy and reliability of quantitative anticardiolipin antibody results are somewhat limited, consensus guidelines have emphasized the use of semiquantitative results (e.g., negative, low, medium, or high). Thus, a laboratory might report that a patient's serum is positive at 42 GPL units, a result that is better interpreted as a "medium" positive.

As with anticardiolipin antibodies, anti-β_2-glycoprotein I antibodies are most commonly detected using enzyme-linked immunosorbent assays (see Table 43–9). However, in the case of assays for anti-β_2-glycoprotein I antibodies, high-affinity, hydrophilic, negatively charged immunoassay plates are required.[185] As with anticardiolipin antibodies, experts recommend that IgG and IgM isotypes anti-β_2-glycoprotein I be sought and hold that the IgG isotype is most strongly associated with APS.

Anti-β_2-glycoprotein I antibodies are reported most commonly in standard units known as "SGU" or "SMU" for IgG and IgM, respectively. Optimal interpretation of results is in semiquantitative terms (e.g., negative, low, medium, or high).

Other "Antiphospholipid" Antibodies

The revised criteria for the diagnosis of definite APS include only three aPLs—LA, anticardiolipin, and anti-β_2-glycoprotein I.[176] Some laboratories offer testing for other so-called aPLs, often in a panel of tests. Results from such assays do little to improve the diagnosis of APS and are not recommended.[186]

aPLs represent a special consideration in APS. Some investigators have found the presence of these antibodies to be clinically relevant,[187–189] whereas others have not.[190,191] There is, however, no clear consensus as to how antiprothrombin antibody assays should be performed,[192] and some investigators have found substantial levels of aPLs in the normal population.[179] Thus, aPLs are not recommended for the diagnosis of APS.[176]

The Pathogenesis of Antiphospholipid Syndrome

Whether aPLs per se are the cause of adverse obstetric outcomes remains the subject of some debate. Investigators working with murine models have found that passive transfer of aPLs results in clinical manifestations of APS, including fetal loss and thrombocytopenia.[193,194] One group has used a murine pinch-induced venous thrombosis model to demonstrate that human polyclonal and murine monoclonal aPLs are associated with larger and more persistent thrombi than in mice treated with control antibodies.[195]

In humans, APS-related pregnancy complications are probably related to abnormal placental function. Some authorities have focused on abnormalities in the decidual spiral arteries as the immediate cause of fetal loss in APS pregnancies. Some investigators have found narrowing of the spiral arterioles, intimal thickening, acute athetosis, and fibrinoid necrosis.[196–198] In addition, placental histopathology demonstrates extensive necrosis, infarction, and thrombosis.[196] These abnormalities might result from thrombosis during the development of normal maternoplacental circulation via interference with trophoblastic annexin V[198] or by impairing trophoblastic hormone production or invasion.[199]

aPLs appear to activate endothelial cells, indicated by increased expression of adhesion molecules, secretion of cytokines, and production of arachidonic acid metabolites.[200] The findings that some anticardiolipin antibodies cross-react with oxidized low-density lipoprotein[201] and that human anticardiolipin antibodies bind to oxidized, but not reduced, cardiolipin[202] imply that aPLs may participate in oxidant-mediated injury of the vascular endothelium. However, aPLs do bind perturbed cells, such as activated platelets[203] or apoptotic cells,[204] which typically lose normal membrane symmetry and express anionic phospholipids on their surface.

Some work points to the complement system as having a major role in APS-related pregnancy loss, showing that C3 activation is required for fetal loss in a murine model.[205] Inactivation and inhibition of the complement cascade prevents fetal loss and growth restriction that is associated with addition of aPLs.[206] Tumor necrosis factor-α (TNF-α), a pro-inflammatory cytokine associated with complement activation, has likewise been implicated in the signaling

Revised Sapporo Criteria for the Diagnosis of Definite Antiphospholipid Syndrome

APS is present if at least one of the clinical criteria and one of the laboratory criteria that follow are met.*

Clinical Criteria

1. Vascular thrombosis[†]
   One or more clinical episodes[‡] of arterial, venous, or small vessel thrombosis,[§] in any tissue or organ. Thrombosis must be confirmed by objective validated criteria (i.e., unequivocal findings of appropriate imaging studies or histopathology). For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.

2. Pregnancy morbidity
   a. One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th wk of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus, or
   b. One or more premature births of a morphologically normal neonate before the 34th wk of gestation because of (i) eclampsia or severe preeclampsia defined according to standard definitions (ACOG) or (ii) recognized features of placental insufficiency,[¶] or
   c. Three or more unexplained consecutive spontaneous abortions before the 10th wk of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded.

In studies of populations of patients who have more than one type of pregnancy morbidity, investigators are strongly encouraged to stratify groups of subjects according to a, b, or c above.

Laboratory Criteria

1. LAC present in plasma, on two or more occasions at least 12 wk apart, detected according to the guidelines of the International Society on Thrombosis and Haemostasis (Scientific Subcommittee on LAs/phospholipid-dependent antibodies).
2. aCL antibody of IgG and/or IgM isotype in serum or plasma, present in medium or high titer (i.e., >40 GPL or MPL, or >99th percentile), on two or more occasions, at least 12 wk apart, measured by a standardized ELISA.
3. Anti-β_2-glycoprotein-I antibody of IgG and/or IgM isotype in serum or plasma (in titer >99th percentile), present on two or more occasions, at least 12 wk apart, measured by a standardized ELISA, according to recommended procedures.

* Classification of APS should be avoided if <12 wk or >5 yr separate the positive aPL test and the clinical manifestation.
† Coexisting inherited or acquired factors for thrombosis are not reasons for excluding patients from APS trials. However, two subgroups of APS patients should be recognized, according to (a) the presence and (b) the absence of additional risk factors for thrombosis. Indicative (but not exhaustive) such cases include age (>55 in men and >65 in women), and the presence of any of the established risk factors for cardiovascular disease (hypertension, diabetes mellitus, elevated LDL or low HDL cholesterol, cigarette smoking, family history of premature cardiovascular disease, body mass index ≥ 30 kg/m^2, microalbuminuria, estimated GFR <60 mL min^{-1}), inherited thrombophilias, oral contraceptives, nephrotic syndrome, malignancy, immobilization, and surgery. Thus, patients who fulfill criteria should be stratified according to contributing causes of thrombosis.
‡ A thrombotic episode in the past could be considered as a clinical criterion, provided that thrombosis is proved by appropriate diagnostic means and that no alternative diagnosis or cause of thrombosis is found.
§ Superficial venous thrombosis is not included in the clinical criteria.
¶ Generally accepted features of placental insufficiency include (i) abnormal or non-reassuring fetal surveillance test(s), e.g., a nonreactive nonstress test, suggestive of fetal hypoxemia, (ii) abnormal Doppler flow velocimetry waveform analysis suggestive of fetal hypoxemia, e.g., absent end-diastolic flow in the umbilical artery, (iii) oligohydramnios, e.g., an amniotic fluid index ≤5 cm, or (iv) a postnatal birth weight <10th percentile for the gestational age.
Investigators are strongly advised to classify APS patients in studies into one of the following categories: I, more than one laboratory criteria present (any combination); IIa, LAC present alone; IIb, aCL antibody present alone; IIc, anti-β_2-glycoprotein-I antibody present alone.
aCL, anticardiolipin; ACOG, American College of Obstetricians and Gynecologists; APS, antiphospholipid antibody syndrome; ELISA, enzyme-linked immunosorbent assay; GPL, reference reagent for IgG; HDL, high-density lipoprotein; Ig, immunoglobulin; LAC, lupus anticoagulant; LDL, low-density lipoprotein.
Modified from Miyakis S, Lockshin MD, Atsumi T, et al: International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS). J Thromb Haemost 2006;4:295–306.

pathways by T cells that are essential to the pathogenesis of aPL; that is, pregnant TNF-α knock-out murine models do not experience miscarriage when injected with aPLs.[207]

Diagnostic Evaluation of Antiphospholipid Syndrome

Diagnostic Criteria

The 2006 revision of the 1999 International Consensus Statement provides simplified criteria for the diagnosis of APS; such criteria are often referred to as the *Sapporo criteria* (Table 43–10).[176]

For obstetricians, the pertinent differences between the original and the revised criteria are

- The inclusion of anti-β_2-glycoprotein I IgG and IgM antibodies as diagnostic of APS. LA and anticardiolipin antibodies were retained as pertinent aPLs.
- Recognition that the threshold used to distinguish medium levels of anticardiolipin and anti-β_2-glycoprotein I antibodies from low levels has no standard; thus, a positive test for either of these antibodies should be greater than 40 GPL or MPL units or greater than the 99th percentile.
- Repeat testing for an initially positive test for aPLs, which is required for the diagnosis of the syndrome, should be performed 12 weeks or later after the initial clinical manifestation and positive test(s).
- The distinction between "primary" and "secondary" should be abandoned because of the lack of differences in clinical consequences between the two categories.

Essentially, patients with bona fide APS must manifest at least one clinical criterion (vascular thrombosis or pregnancy morbidity) and at least one of three laboratory criteria (positive LA or medium to high titers of β_2-glycoprotein I–dependent IgG or IgM isotype anticardiolipin antibodies or anti-β_2-glycoprotein I antibodies), confirmed on two separate occasions, at least 12 weeks apart. Thrombosis may be either arterial or venous and must be confirmed by an imaging or Doppler study or by histopathology. Pregnancy morbidity is divided into three categories: (1) otherwise unexplained fetal death (10 wk′ gestation), (2) preterm birth (34 wk′ gestation) for severe preeclampsia or placental insufficiency, or (3) otherwise unexplained recurrent

preembryonic or embryonic pregnancy loss. Autoimmune thrombocytopenia and amaurosis fugax are often associated with APS but are not considered sufficient diagnostic criteria. APS may exist as an isolated immunologic derangement (primary APS) or in combination with other autoimmune diseases (secondary APS), most commonly SLE.

The assays for anticardiolipin antibodies and anti-β_2-glycoprotein I antibodies are more sensitive tests for detection of APS; the assay for LA is more specific. Low titers of anticardiolipin antibodies and anti-β_2-glycoprotein I antibodies are present in up to 5% of normal individuals and should not be used to make the diagnosis of APS. Women with low levels of IgG anticardiolipin antibodies have been found to have no greater risk for aPL-related events than women who tested negative.[208,209] Medium to high titers of the antibodies are more specific for the diagnosis of APS, as is the specificity of the IgG isotype compared with the IgM isotype. The presence of isolated IgM or IgA aPL levels also is of questionable clinical significance. Women with isolated IgM anticardiolipin antibodies are no more likely to suffer aPL-related morbidity than women who tested negative for all aPLs.[146] Finally, repeatedly positive tests, as required to meet revised Sapporo criteria, are uncommon and thus are more indicative of APS.[208] As a final note, the 2006 International Consensus Statement Criteria[176] were developed primarily for research purposes to ensure more uniform patient characterization as well as disease subcategorization in APS studies. Not unlike the situation with autoimmune conditions such as SLE, some patients will present with one or more clinical or laboratory features suggestive but not diagnostic of APS. In such cases, the decision to proceed with therapies generally reserved for patients with APS should be based on experienced clinical judgment.

Risks of Antiphospholipid Syndrome and Pregnancy

Thrombotic Complications of Antiphospholipid Syndrome in Pregnancy

Venous thrombotic events (VTE) that have been associated with aPLs include that of deep venous thrombosis (DVT) and pulmonary embolus (PE). Transient ischemic attacks (TIA) and cerebral vascular accidents (CVA) are the most common arterial events associated with APS. Numerous retrospective studies confirm a link between aPLs and venous or arterial thrombosis.[173,210] A meta-analysis of studies in the general population found an association of both arterial and venous thromboses in patients with LA antibodies (odds ratio [OR] 8.6–10.8; OR 4.1–16.2, respectively).[211] Approximately 70% of thrombotic events occur in the venous system, although arterial thromboses and CVAs are also common.[211] Transient CNS manifestations of ischemia also are common in APS patients.[212] aPLs are present in approximately 2% of individuals with unexplained thrombosis[213] and are the only identifiable predisposing factor in 4% to 28% of cases of stroke in otherwise healthy patients younger than age 50.[214–217] In the only prospective study of untreated APS patients (who also had SLE), 50% of those with LA had a thrombotic episode during the study period; the annual risk of venous thrombosis and arterial thrombosis was 13.7% and 6.7%, respectively.[218] The lifetime risk of thromboembolism in women with APS is unknown. However, over half occur in relation to pregnancy or the use of combination oral contraceptives.[219] In the two largest series of prospectively followed APS pregnancies, the rates of thrombosis and stroke were 5% and 12%, respectively.[130,220]

Obstetric Complications of Antiphospholipid Syndrome in Pregnancy

GESTATIONAL HYPERTENSION/PREECLAMPSIA

The median rate of gestational hypertension/preeclampsia in pregnancies complicated by APS is 32%, with a range up to 50%.[220,221] Preeclampsia may develop as early as 15 to 17 weeks' gestation.[222] The rate of gestational hypertension/preeclampsia does not appear to be markedly diminished by treatment with either glucocorticoids and low-dose aspirin or heparin and low-dose aspirin.[220,223] In contrast to the high rate of preeclampsia observed in some case series of women previously diagnosed with APS, aPLs are not found in a statistically significant proportion of a general obstetric population presenting with preeclampsia[224,225] or in women at moderate risk to develop preeclampsia because of conditions such as underlying chronic hypertension or preeclampsia in a prior pregnancy.[226] However, two groups of investigators have reported that women with early-onset, severe preeclampsia are more likely to test positive for aPLs compared than are healthy controls.[222,227] Based on these findings, testing for aPLs should be considered only in early-onset, severe preeclampsia.

INTRAUTERINE GROWTH RESTRICTION AND PRETERM BIRTH

Several investigators have found relatively high rates of IUGR in association with aPLs.[139,220,222,228] Even with currently used treatment protocols, the rate of IUGR approaches 30%.[130,220] Pregnancies complicated by APS are also more likely to exhibit non-reassuring fetal heart rate patterns during antenatal tests of fetal well-being and intrapartum monitoring.[129,220] Not surprisingly, the rate of preterm birth in these series ranges from 32% to 65%.[129,220,224]

PREGNANCY LOSS

In the original description of APS, the sole obstetric criterion for diagnosis was fetal loss (>10 menstrual wk' gestation).[173] At least 40% of pregnancy losses reported by women with lupus anticoagulant or medium to high positive IgG anticardiolipin antibodies occur in the fetal period[220,229–232]; this rate is not affected by the administration of prednisone.[233] More recently, APS-related pregnancy loss has been extended to include women with early recurrent pregnancy loss, recurrent pregnancy loss including those occurring in the preembryonic (<6 menstrual wk' gestation) and embryonic periods (6–9 menstrual wk gestation).[175] In serologic evaluation of women with recurrent pregnancy loss, 10% to 20% have detectable aPLs.[232–237]

Fetal death and early recurrent pregnancy loss might be considered two points along the same continuum of APS-related pregnancy loss. However, women with APS identified because of a prior fetal death and/or thromboembolism seem to have more serious complications in subsequent

pregnancies than those with early recurrent pregnancy loss.[232] Prospective treatment trials of APS during pregnancy have been composed mainly of women with early recurrent pregnancy loss and no other APS-related medical problems.[234–236,238–240] Accordingly, the rates of obstetric complications were relatively low, with fetal death, preeclampsia, and preterm birth occurring in 4.5% (0%–15%), 10.5% (0%–15%), and 10.5% (5%–40%), respectively. Only 1 of 300 women suffered a thrombotic event, and no neonatal deaths due to complications of prematurity were reported. Thus, women with early recurrent pregnancy loss probably represent a different patient population than those with second- and third-trimester events.[241]

Postpartum and Catastrophic Antiphospholipid Syndrome

Catastrophic APS is a rare but devastating syndrome characterized by multiple simultaneous vascular occlusions throughout the body, often resulting in death.[242] The diagnosis should be suspected if at least three organ systems are affected and confirmed if there is histopathologic evidence of acute thrombotic microangiopathy affecting small vessels. Renal involvement occurs in 78% of patients.[242,243] Most have hypertension; 25% eventually require dialysis. Other common manifestations described by Asherson and colleagues[242] include adult respiratory distress syndrome (66%), cerebral microthrombi and microinfarctions (56%), myocardial microthrombi (50%), dermatologic abnormalities (50%), and disseminated intravascular coagulation (25%). Death from multiorgan failure occurs in 50% of patients.[242] The pathophysiology of catastrophic APS is poorly understood. However, the onset may be presaged by several factors, including infection, surgical procedures, discontinuation of anticoagulant therapy, and the use of drugs such as oral contraceptives.[242–244]

Early and aggressive treatment of catastrophic APS appears prudent.[242] Patients should be transferred to an intensive care unit where supportive care can be provided. Hypertension should be aggressively treated with appropriate antihypertensive medication. Although no treatment has been shown to be superior to another, a combination of anticoagulants (usually heparin) and steroids plus either plasmapheresis or IVIG has been successful in some patients.[242,243,245] Streptokinase and urokinase have also been used to treat acute vascular thrombosis.[242] Women suspected of catastrophic APS during pregnancy should probably be delivered.[242]

Management Options
General Considerations
TREATMENT FOR ANTIPHOSPHOLIPID SYNDROME DURING PREGNANCY

The goals of treatment for APS during pregnancy are
- To improve fetal-neonatal outcome by reducing the risk of pregnancy loss, preeclampsia, placental insufficiency, and preterm birth.
- To reduce or eliminate the maternal thrombotic risk and to appropriately manage the potential impact of gestational hypertensive disease on the mother.

TABLE 43–11

Suggested Subcutaneous Heparin Regimens for the Treatment of Antiphospholipid Syndrome in Pregnancy (See Text for Postpartum Thromboprophylaxis Recommendations)

Antiphospholipid Syndrome without Prior Thrombosis
- Recurrent early (preembryonic or embryonic) miscarriage
  Unfractionated heparin
    5000–7500 U subcutaneously q12h
  Low-molecular-weight heparin
    Enoxaparin, 40 mg, or dalteparin, 5000 U, subcutaneously once daily, or
    Enoxaparin, 30 mg, or dalteparin, 5000 U, subcutaneously q12h
- Fetal death (>10 wk' gestation) or prior early delivery (<34 wk' gestation) due to severe preeclampsia or placental insufficiency
  Unfractionated heparin
    7500–10,000 U SC q12h in the first trimester; 10,000 U SVC q12h in the second and third trimesters, or
    q8–12h adjusted to maintain the midinterval aPTT* 1.5 times the control mean
  Low-molecular-weight heparin
    Enoxaparin, 30 mg, or dalteparin, 5000 U, SC q12h

Antiphospholipid Syndrome with Thrombosis
- Unfractionated heparin
  q8–12h adjusted to maintain the midinterval aPTT* or heparin level (anti-Xa activity)* in the therapeutic range
- Low-molecular-weight heparin
  Weight adjusted, e.g., enoxaparin 1 mg or dalteparin 200 U/kg, subcutaneously q12h with monitoring of anti-Xa activity*

* Women without a lupus anticoagulant in whom the aPTT is normal can be monitored using the aPTT. Women with lupus anticoagulant should be monitored using anti-Xa activity.
aPTT, activated partial thromboplastin time.

ANTIPHOSPHOLIPID SYNDROME WITHOUT PRIOR THROMBOSIS

APS patients *without* a prior thrombotic event may be categorized into one of two groups for the purpose of treatment: (1) those with recurrent early (preembryonic or embryonic) miscarriage and no other features of APS and (2) those with one or more prior fetal deaths (>10 wk' gestation) or prior early delivery (<34 wk' gestation) due to severe preeclampsia or placental insufficiency. A third group of patients is composed of those with a history of thrombosis, irrespective of pregnancy history. Table 43–11 summarizes treatments during pregnancy and in the postpartum period for these patients.

RECURRENT EARLY (PREEMBRYONIC OR EMBRYONIC) MISCARRIAGE

Three randomized trials have addressed APS patients with predominantly recurrent early miscarriage. In two trials, unfractionated heparin (UFH) plus low-dose aspirin was compared with low-dose aspirin alone, and in both of these, the proportion of successful pregnancies was significantly improved using heparin.[234,235] A third trial, which proved negative, involved the use of low-molecular-weight heparin (LMWH).[246] A 2005 Cochrane systematic review[247] concluded that women with recurrent miscarriage and APS should be treated with a combination of heparin 5000 U subcutaneously twice-daily and low-dose aspirin. The

preponderance of data indicates that good pregnancy outcomes are achieved with heparin initiated in the early first trimester when a live embryo is discernable by ultrasound. Most experts recommend anticoagulant treatment in the postpartum period,[248] though the duration of treatment is debated.

FETAL DEATH (>10 WEEKS' GESTATION) OR PRIOR EARLY DELIVERY (<34 WEEKS' GESTATION) DUE TO SEVERE PREECLAMPSIA OR PLACENTAL INSUFFICIENCY

The optimal treatment for women in this category is not defined by randomized trials. Case series suggest that these women are at risk for thrombosis.[249] Some experts recommend intermediate-dose heparin[248] (see Table 43–11). Others recommend either prophylactic or intermediate-dose UFH or prophylactic LMWH combined with low-dose aspirin. The preponderance of data indicates that good pregnancy outcomes are achieved with heparin initiated in the early first trimester when a live embryo is discernable by ultrasound. Experts recommend a minimum of 6 weeks of postpartum thromboprophylaxis in women with obstetric APS.[248,250] After delivery, this can be safely accomplished with warfarin.

ANTIPHOSPHOLIPID SYNDROME WITH THROMBOSIS

For women with APS who have a thrombotic event, experts recommend full heparin or LMWH anticoagulation[248,250] (see Table 43–11). Patients enrolled in most published series also received low-dose aspirin, but the benefit of adding aspirin is uncertain. Patients should be switched from warfarin to heparin anticoagulation at no later than 6 weeks' gestation. Anticoagulation should be continued for a minimum of 6 weeks postpartum to minimize the risk of maternal thromboembolism.[250] After delivery, this can be safely accomplished with warfarin.

OTHER THERAPIES IN PREGNANCY

Other therapies have been suggested for treatment of pregnancy women with APS including corticosteroids and IVIG. Several case series have reported a 60% to 70% rate of successful pregnancies in women with APS treated with prednisone and low-dose aspirin.[251,252] However, a meta-analysis of therapeutic trials showed no reduction in pregnancy loss in women treated with prednisone and low-dose aspirin.[247] Direct comparison of studies is difficult because subjects had different clinical and laboratory findings and dosing regimens, and many studies were of case series, nonrandomized and poorly controlled.

Treatment with IVIG has been evaluated in the treatment of APS. Randomized trials have demonstrated that either the addition of IVIG to heparin or IVIG alone offers no better outcomes than heparin and low-dose aspirin or prednisone and low-dose aspirin.[253–255] A subsequent Cochrane analysis concluded that IVIG was associated with an increased risk of pregnancy loss or premature birth compared with heparin and low-dose aspirin.[247] Thus, IVIG is not recommended in the treatment of APS in pregnancy.

Prepregnancy

Women with APS will preferably seek preconception counseling. At that time, the presence of clinically significant levels of aPL should be confirmed and potential maternal

and obstetric complications discussed, including thrombosis, pregnancy loss, preterm delivery, gestational hypertension/preeclampsia, and uteroplacental insufficiency. APS patients, like patients with SLE, should be assessed for evidence of anemia, thrombocytopenia, and underlying renal disease (urinalysis, serum creatinine, 24-hr urine for creatinine clearance, and total protein).

The various anticoagulation prophylaxis regimens should be discussed, along with their risks and limitations. Patients should also be informed about the risks of heparin-induced osteoporosis and heparin-induced thrombocytopenia (HIT), and recommendations for appropriate protective measures should be provided. Some authorities recommend instituting daily low-dose aspirin (81 mg) prior to conception.

Prenatal

Women with APS who suspect they are pregnant should be evaluated immediately. An early transvaginal ultrasound is useful to confirm an intrauterine pregnancy as well as provide accurate dating of the pregnancy. One of the anticoagulation prophylaxis regimens discussed previously (see Table 43–11) should be instituted, and appropriate precautions against heparin-induced osteoporosis and HIT should be taken. Calcium supplementation is encouraged, as well as the performance of daily weight-bearing exercise.

Prenatal visits should occur every 2 to 4 weeks until 20 to 24 weeks' gestation and every 1 to 2 weeks thereafter. Patient visits should be specifically designed to monitor for the development of preeclampsia and thrombosis and to monitor fetal well-being. Because of the risk of IUGR and oligohydramnios secondary to uteroplacental insufficiency, serial ultrasound examinations should be performed every 3 to 4 weeks after 17 to 18 weeks' gestation. Antenatal surveillance (daily fetal movement counts and at least once-weekly nonstress tests with amniotic fluid volume measurements) should be initiated at 30 to 32 weeks' gestation (or earlier if uteroplacental insufficiency is suspected). More frequent ultrasound examinations and more frequent or earlier fetal testing may be indicated in selected cases.

Labor and Delivery

Labor and delivery in women with APS should be managed in the same way as in any patient who is considered at high risk for preeclampsia and uteroplacental insufficiency. Most authorities recommend continuous electronic fetal monitoring throughout labor, given the increased risk of non-reassuring fetal heart rate tracings noted in women with APS.

The most common management dilemma in women with APS probably involves the need to alter anticoagulation regimens in a way that minimizes the risk of bleeding at the time of delivery without placing the patient at a prohibitively high risk of thromboembolism. Treatment approaches vary, and there is no evidence that one method is better than another. Patients receiving prophylactic anticoagulation with heparin can be instructed to withhold their injections at the onset of labor. Alternatively, injections can be discontinued 12 hours before a planned induction. The most common practice in women with APS on full-dose anticoagulation (UFH or LMWH) is to hold the last injection 24 hours prior to a planned induction of labor or cesarean delivery. As an alternative for women deemed at extremely high risk for thromboembolism, including those with an

event within 2 weeks of delivery, intravenous heparin can be started in labor and discontinued 2 to 4 hours prior to anticipated delivery. Intravenous heparin can be resumed 4 to 6 hours after vaginal delivery and 12 hours after cesarean.

Spontaneous labor is problematic for women who are fully anticoagulated, particularly those receiving LMWH preparations. Anti-Factor Xa levels might be helpful but have been found to underestimate the risk of bleeding in some patients. Protamine sulfate may be necessary in the event of surgical intervention. For those on adjusted-dose UFH, careful monitoring of the aPTT (or heparin level) is required. If the aPTT is prolonged near delivery, protamine sulfate may be necessary to reduce the risk of bleeding.

Many anesthesiologists are particularly concerned that anticoagulation in any form increases the risk of spinal hematoma formation in women receiving regional anesthesia in labor or for cesarean delivery. The American Society of Regional Anesthesia (ASRA) recommends that neuraxial blockade should be withheld until 24 hours after the last injection in women on full anticoagulation with LMWH.[256] The same recommendation has been made for women receiving adjusted-dose anticoagulation with UFH. For women receiving low-dose thromboprophylaxis (low-dose twice-daily UFH or once-daily LMWH), ASRA has recommended that needle placement be delayed until 10 to 12 hours after the last dose.[256]

Postpartum

Anticoagulant coverage of the postpartum period in women with APS and prior thrombosis is critical.[257] We prefer initiating warfarin thromboprophylaxis as soon as possible after delivery, with doses adjusted to achieve an International Normalized Ratio of 2.0 to 3.0. There is no consensus regarding the postpartum management of APS patients without prior thrombosis. The recommendation in the United States is to treat with anticoagulant therapy for 6 weeks after delivery. The need for postpartum anticoagulation in women with APS diagnosed solely on the basis of recurrent preembryonic or embryonic losses is uncertain. Both heparin and warfarin are safe for breast-feeding mothers.[257] Finally, oral contraceptives containing estrogen are contraindicated.

SUMMARY OF MANAGEMENT OPTIONS
Antiphospholipid Syndrome

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Counsel regarding risks of thromboembolism, pregnancy loss, pregnancy complications.	—/GPP	—
Check for		
• Anemia.	III/B	129

RHEUMATOID ARTHRITIS

General

RA is a debilitating disease, the hallmark feature of which is chronic symmetrical inflammatory arthritis of the synovial joints. RA is more common than SLE, with an incidence of from 2.5 to 7 per 10,000 per year and a prevalence of approximately 1% in the adult U.S. population. Although found in virtually all populations, it is more common in some populations (Native American) and less common in others (Native African). Although it is often said to peak in the 40s or 50s, RA can appear at any age of life (including in children), and the prevalence increases with age into the 60s or 70s in both females and males. As with many autoimmune conditions, RA is more common in women than men, with a ratio of 2 : 1 to 3 : 1 women to men.[258]

Pathogenesis of Rheumatoid Arthritis

Histologic features of RA are described as symmetrical inflammatory synovitis marked by cellular hyperplasia, accumulation of inflammatory leukocytes, and angiogenesis with membrane thickening, edema, and fibrin deposition as common early findings. Inflammatory damage at the synovium eventually leads to typical joint erosion involving a locally invasive synovial tissue called *pannus*.

The characteristic autoantibody in patients with RA is rheumatoid factor (RF), an autoantibody made by oligoclonal activated B cells in the peripheral circulation and synovium of RA patients. This group of autoantibodies, which reacts with antigens on the Fc portion of IgG, is composed of a heterogeneous group of antibodies containing light and heavy chains distributed among all the variable region subgroups. It is unknown whether RF autoantibodies are simply markers for RA or whether they are directly responsible for tissue damage. There is some evidence that RF autoantibodies form IgG aggregates in synovial fluid, resulting in complement activation and local inflammation and eventual joint erosion.

Concordance for RA is found in approximately 15% of monozygotic twins and 5% of dizygotic twins. It is estimated that heritable factors account for approximately 60% of the predisposition to RA.[259] The HLA region (HLA class II gene locus DRB1, encoding HLA-DR), is of primary importance in RA susceptibility. Variant forms of DRB1 have been identified in association with RA, including DRB1*0401, *0404, *0405, *0101, *1402, and *1001. These alleles encode for similar amino acid sequences (*shared epitopes*) that are suspected of bestowing susceptibility to RA. Others suspect HLA complex genes are located on chromosomes 1p and 1q, 9, 12p, 16cen, and 18q.[260,261]

Juvenile rheumatoid arthritis (JRA) is a somewhat different, but related, arthritis. It is probably a heterogeneous group of diseases. By definition, JRA has its onset in individuals younger than 16 years; males and females are equally represented. One prominent subgroup is composed of individuals with Still's disease. This condition is initially systemic in nature and includes fever, skin rash, serositis, and lymphadenopathy. Arthritis occurs late in the course of disease and tends not to be as destructive or chronic as classic RA. Nearly three quarters of children with JRA have spontaneous, permanent remission by the time they reach adulthood.

Diagnostic Evaluation of Rheumatoid Arthritis

Clinical Presentation

The symptoms of RA develop insidiously over several months; the clinical course is variable. Less commonly, disease onset is acute and somewhat rapid.[262] Twice as many patients present during winter months than summer months, and trauma (including surgery) is a frequent precursor. Morning stiffness, pain, and swelling of peripheral joints are the most common initial features. The disease tends to involve primarily the joints of the wrists, knees, shoulders, and metacarpophalangeal joints in an erosive arthritis that

typically follows a slowly progressive course marked by exacerbations and remissions. Eventually, joint deformities may occur; these are especially obvious at the metacarpophalangeal joint and proximal and distal interphalangeal joints of the hands.[262] Fatigue, weakness, weight loss, and malaise are also common.

Rheumatoid nodules, present in 20% to 30% of affected patients, are made up of a local proliferation of small vessels, histiocytes, fibroblasts, and other cells and are usually located in the subcutaneous tissues of the extensor surfaces of the forearm. Uncommonly, extra-articular tissues may also be affected, including the lung (pleuritis, pleural effusions, interstitial fibrosis, pulmonary nodules, pneumonitis, and airway disease) and heart (pericarditis, effusion, myocarditis, endocardial inflammation, conduction defects, and arteritis leading to myocardial infarction).

Diagnostic Criteria

The classification criteria published by the American College of Rheumatology are shown in Table 43–12. Physical examination should reveal evidence of joint inflammation, including joint tenderness, synovial thickening, joint effusion, erythema, and decreased range of motion. Symmetrical involvement should be noted. Radiographic evidence of RA includes joint space narrowing and erosion; although too expensive for routine use, MRI may detect synovial hypertrophy, edema, and early erosive changes.

Laboratory Criteria

More than 70% of patients with clinical features of RA are also seropositive for RF. In addition, some of those who are initially seronegative will eventually convert, leaving only 10% of RA patients without a positive RF. Approximately 5% of the general population also test positive for RF, as do many patients with other autoimmune conditions (e.g., SLE, scleroderma, and mixed connective tissue disease), viral infections, parasitic infections, chronic bacterial infections, and after irradiation or chemotherapy.

Rheumatoid Arthritis in Pregnancy

The relationship between RA and pregnancy is fascinating even if the basic scientific understanding of the relationship remains elusive. The observation that in many patients, RA dramatically improves during pregnancy eventually led Philip Hench[263] to discover cortisone. Numerous studies (Table 43–13) show that at least 50% of patients with RA demonstrate improvement in their disease in at least 50% of their pregnancies.[263–269]

For a majority of patients, the improvement in RA starts in the first trimester, heralded by a reduction in joint stiffness and pain.[265,266] The peak improvement in symptoms

---

TABLE 43–12

Classification Criteria for the Diagnosis of Rheumatoid Arthritis

CRITERIA*	DEFINITION
Morning stiffness	Morning stiffness in and around the joints, lasting at least 1 hr before maximal improvement
Arthritis of ≥ three joint areas	At least three joint areas simultaneously have had soft tissue swelling or fluid (not bony overgrowth alone) observed by a physician. The 14 possible areas are right or left proximal interphalangeal, metacarpophalangeal, wrist, elbow, knee, ankle, and metatarsophalangeal joints
Arthritis of hand joints	At least one area swollen (as defined above) in a wrist, metacarpophalangeal, or proximal interphalangeal joint
Symmetrical arthritis	Simultaneous involvement of the same joint areas (as defined above) on both sides of the body (bilateral involvement of proximal interphalangeals, metacarpophalangeals, and metatarsophalangeals is acceptable without absolute symmetry)
Rheumatoid nodules	Subcutaneous nodules, over bony prominences or extensor surfaces, or in juxta-articular regions, observed by a physician
Serum rheumatoid	Demonstration of abnormal amounts of serum rheumatoid factor by any method for which the result has been positive in <5% of normal control subjects
Radiographic changes	Radiographic changes typical of rheumatoid arthritis on posteroanterior hand and wrist radiographs, which must include erosions or unequivocal bony decalcification localized in or most marked adjacent to the involved joints (osteoarthritis changes alone do not qualify)

* For classification purposes, a patient shall be said to have rheumatoid arthritis if he or she has satisfied at least four of these seven criteria. Criteria 1 through 4 must have been present for at least 6 wk. Patients with two clinical diagnoses are not excluded. Designation as classic, definite, or probable rheumatoid arthritis is *not* to be made.

RA, rheumatoid arthritis.

generally occurs in the second or third trimester. Other aspects of the disease may also improve during pregnancy, with studies indicating that the subcutaneous nodules associated with RA may disappear during pregnancy.[267] Even with the overall improvement in symptoms, the clinical course of RA during pregnancy is characterized by short-term fluctuations in symptoms, as in the nonpregnant state.[268] Most patients who experience an improvement in RA during pregnancy will have a similar improvement in subsequent pregnancies.[269] In addition, Hazes and coworkers[270] reported a protective effect of pregnancy in development of RA. However, this is not a given, and some patients will have relatively less improvement in a second or third pregnancy. There are no laboratory or clinical features that predict improvement of RA in pregnancy.

A quarter of RA patients have no improvement in their disease during pregnancy, and in a small number of cases, the disease may actually worsen. Unfortunately, nearly three quarters of patients whose disease has improved during pregnancy will suffer a relapse in the first several postnatal months.[265–267] The level of disease during the first postnatal year generally returns to that of a year before conception, but might be worse.[269]

In contrast to SLE, there are no data to suggest that RA in remission is likely to have a better course during pregnancy than active RA. The long-term prognosis for RA patients undertaking pregnancy appears to be similar to those who avoid pregnancy. Oka and Vainio[269] compared 100 consecutive pregnant RA patients with age- and disease-matched controls and found no significant differences between the groups in terms of the severity of their disease. There are few studies of JRA, but Ostensen in 1991[271] found that only 1 case in 20 had a worsening or reactivation of their disease associated with pregnancy.

The mechanism(s) by which pregnancy favorably affects RA has yet to be fully elucidated. Plasma cortisol, which rises during pregnancy to peak at term, was initially thought to be important to the amelioration of RA.[263] However, there is no correlation between cortisol concentrations and disease state.[272] Some studies suggest that estrogens or estrogens and progestagens favorably affect arthritis,[273] but there are conflicting studies,[274] and a double-blind crossover trial found that estrogen did not benefit RA.[275] Sex hormones may interfere with immunoregulation and interactions with the cytokine system.[276] Promising data suggest that certain proteins circulating in higher concentrations during pregnancy or unique to pregnancy are associated with improvement of RA. These include pregnancy-associated α_2-glycoprotein[277] and gamma globulins eluted from the placenta.[278] Other investigators feel that the placenta may modify RA by clearing immune complexes[279] or that modification of immune globulins during pregnancy alters their inflammatory activity.[280] Nelson and associates[281] suggested that amelioration of disease was associated with a disparity in HLA class II antigens between mother and fetus. In fact, these investigators have correlated improvement of RA symptoms of pregnant women with increased HLA mismatch; this mismatch may be mediated by the induction of suppressor mechanisms. Hence, the more "foreign" the fetal HLA type is to the maternal immune system, the more likely the maternal disease is to undergo remission during gestation.[281]

Risks of Rheumatoid Arthritis in Pregnancy
Obstetric Complications and Rheumatoid Arthritis

About 15% to 25% of pregnancies in women with RA end in miscarriage,[282,283] a figure that may or may not be slightly higher than in normal women. One controlled study found that women with RA have a significantly higher frequency of miscarriage than normal women, even before the onset of their disease (25% vs. 17% before disease; 27% vs. 17% after disease).[282] Another controlled study did not find that women with RA have a higher proportion of miscarriage prior to the onset of disease.[268] Interestingly, this same study found that the frequency of fetal death was higher in patients who later develop RA than in nonaffected relatives. There are scant data available, but women with RA do not appear to be at significant risk for preterm birth, preeclampsia, or IUGR.

Management Options
Prepregnancy

The prepregnancy management of RA is similar to that of any of the other autoimmune disorders. This includes stabilization of the underlying disease process, reducing maintenance medications to minimize early fetal risks, and avoidance of known teratogenic agents.

Prenatal

As with SLE, a physician should see a woman with RA every 2 to 4 weeks throughout the pregnancy, especially if the patient is having trouble with her disease. Rest is an important part of the management of RA, and the patient should be counseled to plan adequately for this. Physical therapy can be helpful in patients whose disease does not improve with pregnancy.

It is best to use acetaminophen for simple analgesia. If possible, the patient should avoid NSAIDs and aspirin (see discussion in the "Systemic Lupus Erythematosus" section). Glucocorticoids should be considered for patients whose RA does not improve during pregnancy.[272] Relatively low doses of prednisone are usually adequate for RA during pregnancy and are not often necessary for maintenance therapy. Intra-articular steroids can also be used if necessary in pregnancy. If NSAIDs prove necessary, the minimum dose necessary to control inflammation should be used.[284] Methotrexate is absolutely contraindicated during the first trimester and relatively contraindicated thereafter. The anti-TNF-α agents are of unknown safety in pregnancy and probably should be avoided. Leflunomide (Arava),[285] a pyrimidine synthesis inhibitor, is teratogenic in animals, and is contraindicated not only in pregnant women but also in those of reproductive age who are contemplating pregnancy. In fact, women of reproductive age who wish to become pregnant should not only stop the therapy but also have verification of plasma levels less than 0.02 mg/L.[285]

Labor and Delivery

Because RA has little, if any, adverse effect on pregnancy outcome, there are no special prenatal obstetric concerns. In a rare case, severe deforming RA can pose a problem to the mechanics of vaginal delivery; such cases are obvious and require individualized care.

Postnatal

Postpartum management of the RA parturient is similar to that of patients with other autoimmune disorders (see the section on "Systemic Lupus Erythematosus"). Roughly 90% of women flare within the first 3 months postpartum; this risk may be somewhat more pronounced after a first pregnancy.[286] Lactation has been reported to have a protective effect on the development of RA and decreased mortality of RA, with a direct correlation with total time of lactation.[287]

SUMMARY OF MANAGEMENT OPTIONS
Rheumatoid Arthritis

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Counsel regarding risk of exacerbation during pregnancy, risk of medication exposure.	III/B	208–212
Establish good control of RA and adjust maintenance medications.	—/GPP	—
If possible, discontinue cytotoxic medications before conception. This should be done only under careful supervision. Avoid methotrexate.	III/B	208–212
Reduce dosage to lowest levels achieving therapeutic effect.	—/GPP	—
Avoid known teratogens (e.g., leflunomide, methotrexate).	—/GPP	—
Prenatal		
Review regularly (joint obstetrician and physician surveillance).	—/GPP	—
Rest (general and local).	—/GPP	—
Physiotherapy/physical therapy recommended in some patients.	—/GPP	—
Drugs	III/B	208–212
• Avoid full-dose aspirin and NSAIDs if possible (or use minimum doses to control inflammation).		
• Prescribe steroids for worsening disease (RCT not in pregnancy).		
• Avoid methotrexate		
• D-Penicillamine contraindicated		
Use glucocorticoids judiciously for exacerbations of disease. Use lowest dosage possible.	III/B	208–212
Avoid teratogenic medications (consider Embrel as a substitute if indicated).	III/B	208–212
Schedule prenatal visits every 2–4 wk throughout pregnancy.	—/GPP	—
Labor and Delivery		
Individualize care according to physical abilities.	—/GPP	—
Postpartum		
Monitor for RA exacerbations.	—/GPP	—
Consult with rheumatology subspecialist.	—/GPP	—

GPP, good practice point; NSAIDs, nonsteroidal anti-inflammatory drugs; RA, rheumatoid arthritis; RCT, randomized controlled trial.

SYSTEMIC SCLEROSIS

General

The term *scleroderma* is derived from words referring to *hardening* ("scleros") and *skin* ("derma"), the hallmark feature of this disease. *Systemic sclerosis* (SSc) refers to internal organ involvement, characterized histologically by a marked increase in collagen, mostly in the dermis, with hyalinization and often obliteration of small blood vessels.[288] Early in the disease process, the dermis contains mononuclear cell infiltrates and sometimes calcium due to the deposition of calcium hydroxyapatite. Pathologic changes also include thinning of the epidermis and loss of normal dermal appendages. Most patients with SSc report Raynaud's phenomenon, and vascular features are evident in biopsies from SSc patients. Small arteries and arterioles exhibit characteristic endothelial cell proliferation and intimal thickening as well as

increased amounts of fibrinogen and fibrin, with lumina often occluded by fibrosis. Remaining vessels become dilated, visible through the skin as telangiectasias.

Internal organs have similar histologic changes. Fibromucoid intimal thickening in the kidney results in narrowing and thinning of the lumen. Cortical glomerular involvement is usually focal and includes endothelial cell proliferation and thickening of the basement membrane. In the lung, the most common finding is interstitial fibrosis with increased numbers of fibroblasts, capillary congestion, and thickening and occlusion of alveolar walls and arteriolar intima. Densely hyalinized fibrosis is found in the gastrointestinal tract and random focal fibrosis in the myocardium.

The disease is uncommon, occurring in no more than 10 to 15 individuals per million per year.[288] The ratio of females to males is 10:1 in the 15- to 44-year-old age group. The mean age of onset is in the early 40s, when many affected women may potentially become pregnant.[289,290]

Pathogenesis of Systemic Sclerosis

The pathophysiologic changes of SSc include vascular abnormalities, immunologic abnormalities, and disordered collagen synthesis. The initial event most likely occurs in small blood vessels with early proliferation of intimal layer endothelial cells that produce cytokines, growth factors, adhesion proteins, vasoactive proteins, coagulation factors, and extracellular matrix.[291] Aberrant production of factors such as von Willebrand's factor also occurs. A hallmark feature of SSc is clearly increased fibroblast activity with an accelerated rate of fibroblast collagen synthesis.

An association between an increase of HLA-DR11 (whites) and HLA-DR15 (Asians) in patients with diffuse SSc has been described. Associations have also been described with the SSc-associated autoantibodies topoisomerase I and anti-centromere antibody, although results have varied in different ethnic and racial groups.[292]

A number of different non-HLA genes have most recently been identified in association with SSc. Genes encoding for extracellular matrix proteins have been identified, notably COL1A1 and COL1A2, genes encoding type I collagen. Other interesting studies have identified a candidate gene near the fibrillin 1 gene on chromosome 15q in studies of a Native American population with a particularly high prevalence of SSc. Polymorphisms in transforming growth factor-β1, 2, and 3 genes have also been identified in association with SSc, as have polymorphisms in TNF-α, TNF-β, CXCR2, tissue inhibitor of metalloproteinase-1, and interleukin-4 receptor-α.[292]

Diagnostic Evaluation of Systemic Sclerosis

Clinically, the expression of SSc varies considerably; the morbidity depends on the extent of skin or internal organ involvement. Raynaud's phenomenon is common, especially in patients with CREST syndrome (calcinosis of involved skin, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias), a more limited form of scleroderma. Patients who eventually develop diffuse disease involving the internal organs are more likely to present with arthritis, finger and hand swelling, and skin thickening. The skin thickening, which usually starts on the fingers and hands, eventually involves the neck and face. In severe, progressive disease, much of the skin may be involved and marked deformities of the hands and fingers may occur. Raynaud's phenomenon and internal organ damage are attributed to fibrosis of arterioles and small arteries. In these circumstances, the normal vasoconstrictor response to various stimuli, including cold, causes near-complete obliteration of the vessel. As a result, digital ischemia may occur. A similar vasculopathy is probably responsible for internal organ involvement. Lower esophageal dysfunction is most common. Other portions of the gastrointestinal tract may be involved, producing malabsorption, diarrhea, and/or constipation.[288]

A variety of pulmonary lesions may occur, with the most common being progressive interstitial fibrosis. Pulmonary hypertension, a problem of special interest to the obstetrician, may also occur in long-standing disease. Nearly half of the patients with well-established SSc have evidence of myocardial involvement. Arrhythmias are probably the most common sign encountered. Renal disease occurs to some extent in many patients and is a major cause of mortality among patients with SSc. Severely involved cases may present with proteinuria and renal insufficiency, hypertension, or both. Sudden onset of severe hypertension and progressive renal insufficiency with microangiopathic hemolysis is known as *scleroderma renal crisis*. These crises usually occur in cold weather, suggesting that the pathophysiology is similar to that of Raynaud's phenomenon.[288]

ANAs are present in most patients with SSc, but anti-DNA antibodies are not. About half of patients have serum cryoglobulins. Antibodies to centromere detected by indirect immunofluorescence are common among patients with limited scleroderma (CREST syndrome), but not among those with diffuse disease. Up to 40% of patients have antibody to an extractable nuclear antigen designated Scl. The biologic significance of these autoantibodies is unclear.

Risks of Systemic Sclerosis in Pregnancy
Complications of Systemic Sclerosis in Pregnancy

Pregnancy in women with SSc is uncommon, with fewer than 200 reports in the published literature. Early reports suggested that fertility was impaired in women with SSc, although this has not been confirmed in more recent studies.[289,293] Rather, women in the SSc group were older and either had waited to have children or had not desired pregnancy.[289] The effect that pregnancy might have on the course of SSc depends to some extent on the degree of preexisting disease involvement. Published data regarding the risks of pregnancy in women with SSc are scarce, and the findings of case reports and small series that suggest pregnancy should be avoided in women with SSc should be regarded with caution. Historically, the largest and most complete studies suggested that overall maternal outcomes are more salubrious, with worsening of disease in pregnancy in no more than 20% of cases.[289,293,294] Very recent data from an estimated 11.2 million deliveries in the Nationwide Inpatient Sample of the Healthcare Care and Utilization Project included 504 women diagnosed with systemic sclerosis; these women exhibited increased rates of hypertensive disorders like preeclampsia (OR 3.71, 95% confidence interval

[CI] 2.25–6.15), IUGR (OR 3.74, 95% CI 1.51–9.28), and increased length of hospital stay. Such results led Chakravarty and colleagues[295] to recommend extensive preconceptional counseling to women diagnosed with SSc about their risks incurred by conception and subsequent pregnancy. Postpartum, approximately one third of women with SSc have exacerbations of Raynaud's phenomenon, arthritis, and skin thickening.[294]

Pregnancy is probably safest in SSc patients without obvious renal, cardiac, or pulmonary disease. Although data are scant, women with SSc with moderate to severe cardiac or pulmonary involvement likely face increased risks of substantial morbidity or mortality and should not undertake pregnancy. In addition, SSc patients with moderate to severe renal disease and hypertension probably face a substantial risk for preeclampsia and perhaps mortality due to renal crisis. Pregnancy should be discouraged in these women as well. Finally, there may be an increased risk of renal crisis in patients with early diffuse SSc[294]; therefore, some authorities suggest that these patients delay pregnancy.

Obstetric Complications in Women with Systemic Sclerosis
PREGANCY LOSS

Fetal outcomes in SSc pregnancies are mixed, with half or more ending in term live births and another quarter ending in liveborn premature infants.[293,296–302] Preterm birth is particularly prominent in women with early, diffuse disease. Women with late, diffuse SSc may be at increased risk for miscarriage, reported at 65% in one case series. There has been some suggestion that a predisposition to pregnancy loss predates the onset of SSc in some women. Of 154 patients who eventually developed SSc and 115 matched controls, a significantly greater number of women with SSc had a history of miscarriage (29% vs. 17%).[302] However, only 3 met the definition for recurrent miscarriage (three or more consecutive losses). The large case-control trial failed to find any association between a history of pregnancy loss and the subsequent development of SSc.[294]

GESTATIONAL HYPERTENSION, PREECLAMPSIA, AND INTRAUTERINE GROWTH RESTRICITON

Given the microvascular nature of the condition and the relative frequency of renal involvement in SSc, one might speculate that preeclampsia and IUGR would occur significantly more often in SSc pregnancies. This is supported by high rates of preeclampsia in case reports but not by case series. In one case series, 10% of pregnancies were complicated by IUGR.[293] Neonatal involvement with skin sclerosis possibly attributable to SSc has been reported in a few cases. The risks of this condition, as well as its relationship to SSc itself, remain unclear. Among the 29 pregnancies accumulated in case reports, there were 2 miscarriages (7%), 2 fetal deaths (7%), and 1 neonatal death attributable to prematurity. Two other infants died because of multiple anomalies. Among the 103 pregnancies in the small series,[297–300] there were 24 miscarriages (23%), 3 fetal deaths (3%), and 2 neonatal deaths due to prematurity. Thus, noncontrolled reports suggest that 72% to 83% of pregnancies among women with SSc are successful (excluding perinatal deaths

due to anomalies). In the case-control study by Giordano and coworkers,[301] 80 SSc patients had 299 pregnancies. Of these, 50 ended in miscarriage (17%), significantly higher than the rate of miscarriage in the matched controls (10%). There was no difference in the miscarriage rate between patients with diffuse versus those with limited SSc. The retrospective study of Steen[294] included 86 pregnancies after the onset of SSc. Of these, 15% ended in miscarriage and 2% ended in mid-trimester fetal deaths. These percentages were not significantly different from those in RA controls or neighborhood controls. The later prospective study by this same group[303] found that 18% of 67 SSc pregnancies ended in miscarriage, compared with 158 control pregnancies. Taken together, the available data suggest that the rate of miscarriages and fetal deaths in patients with SSc might be slightly increased compared with controls.

Management Options
Prepregnancy

Currently, most experts agree that the typical women with mild to moderately severe SSc has a high likelihood for favorable pregnancy outcomes with appropriate preconceptional planning, antepartum management, and close monitoring.[304] However, patients with early diffuse SSc, severe visceral involvement, significant cardiopulmonary involvement (ejection fraction <30%), pulmonary hypertension, severe restrictive lung disease (forced vital capacity <50%), or severe renal insufficiency have significantly increased risk of adverse pregnancy outcomes and, thus, should be counseled against getting pregnant.[303] Patients who have a history of renal crisis but, at present, have disease that has been stable for years may be counseled that their disease does not represent contraindication to future pregnancy.[305] A trial off of angiotensin-converting enzyme (ACE) inhibitors to determine whether blood pressure may be controlled with nonteratogenic antihypertensive medications has been suggested. Naturally, patients who fail the trial should be placed back on the ACE inhibitor.[303] Likewise, women who experience scleroderma renal crisis should be treated aggressively with ACE inhibitors.[303,304]

Prenatal

SSc patients considering pregnancy and any patient with SSc who presents for medical care already pregnant should have her clinical situation thoroughly investigated. Special attention should be given to the evaluation of possible renal or cardiopulmonary involvement. It is prudent to recommend pregnancy termination in patients with diffuse SSc and cardiopulmonary involvement or moderate to severe renal involvement.

Even in the nonpregnant state, there is no satisfactory therapy for SSc. Patients with limited disease are usually managed with vasodilators and anti-inflammatory agents. As discussed previously, NSAIDs should be avoided if at all possible during pregnancy. Oral vasodilators for the prevention and treatment of Raynaud's phenomenon may be continued, although substantial data to prove fetal safety are not available. Patients with diffuse SSc may be taking glucocorticoids (see discussion in the section on "Systemic Lupus Erythematosus"). Nacci and associates[306] recently reported amelioration of joint and skin involvement in SSc during

pregnancy. Other immunosuppressive or cytotoxic agents should be avoided. Although sometimes used as therapy in SSc, cyclophosphamide should be avoided in pregnancy because this agent is associated with a 16% to 22% risk of congenital anomalies following exposure during the first trimester.[284] ACE inhibitors appear to be particularly efficacious in treating SSc-related hypertension and renal crises. These drugs have been associated with fetal/neonatal renal insufficiency in a small number of cases. However, in SSc-related hypertension, the benefits of these medications probably outweigh the risks of discontinuing them.[307]

Patients with continuing pregnancies should be seen by a physician every 1 to 2 weeks in the first half of pregnancy and once weekly thereafter. Although serial laboratory testing is not necessary, laboratory assessment of unusual or suspicious symptoms or signs may be helpful. The possible risk of IUGR and fetal death requires serial examination of the fetus by sonography. Fetal surveillance should be instituted by 30 to 32 weeks' gestation, or sooner if the clinical situation demands.

In the event of relapse, risks associated with essential therapies are high in the gravid female. However,

low-dosage prednisone has been safely administered without increased risk for development of maternal renal crisis or fetal oral cleft.[308,309]

Labor and Delivery

In patients with mild to moderate disease, few additional precautions are needed during the labor and delivery process. Again, signs of preeclampsia should be sought, because this complication may be more likely with scleroderma. Wound healing may be a problem in patients with advanced disease or those on steroids. Therefore, operative interventions require meticulous attention to this issue. In patients with significant pulmonary, cardiac, or renal impairment, intensive care management may be needed.[303–305]

Postnatal

Postpartum care represents a continuation of the intrapartum management plan. Most often, reinstitution of maintenance medication is all that is required. Complications of scleroderma, as previously outlined, require individualization of care.

SUMMARY OF MANAGEMENT OPTIONS
Systemic Sclerosis

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Counsel regarding risk of exacerbation during pregnancy, risk of medication exposure.	IIa/B	231
Establish good control of SSc and adjust maintenance medications.	III/B	232
If possible, discontinue cytotoxic medications before conception. This should be done only under careful supervision.	—/GPP	—
Assess cardiopulmonary and renal function (advise against conception if significantly compromised).	III/B	232
Prenatal		
Provide joint obstetrician and physician surveillance.	III/B	232
Prenatal visits should occur every 2–4 wk until 20–24 wk' gestation and every 1–2 wk thereafter.	III/B IV/C	232 228
Monitor cardiopulmonary and renal function (consider termination of pregnancy if severe compromise).	IV/C	228
Drugs		
• Anti-inflammatory for moderate joint problems.	—/GPP	—
• Vasodilators for pulmonary problems.	—/GPP	—
• Steroids for worsening disease.	—/GPP	—
Maintain vigilance for preeclampsia.	IV/C	228
Use of ACE inhibitors is a dilemma if hypertension is present; avoid if possible.	III/B	232
Check fetal growth (q3-4wk after 18 wk) and health.	IIa/B	231
Fetal surveillance should be initiated at 30–32 wk' gestation or earlier if uteroplacental insufficiency is suspected.	—/GPP	—

MYASTHENIA GRAVIS

General

Myasthenia gravis (MG) is an autoimmune disorder affecting neuromuscular transmission, resulting in variable weakness and fatigability of skeletal muscle. Increasing weakness with repetitive use of the muscle(s) is the characteristic feature. Occurring in only 2 to 10 per 100,000 individuals, MG affects twice as many women as men, with an onset usually in the second or third decade in women.[310,311] The immediate cause of the disease is probably an autoimmune attack on the acetylcholine receptor (AChR) complex of the neuromuscular junction. Serum autoantibodies against acetylcholine receptors (anti-AChR) are found in the serum of 85% of patients with MG.[312,313] The disease can be transferred passively to laboratory animals by the injection of IgG from affected individuals.[314] Accordingly, 10% to 20% of infants born to women with MG show signs of neonatal MG, thought to be caused by the transplacental passive transfer of antibodies from mother to child.[315,316]

Ocular muscle weakness resulting in diplopia or eyelid ptosis is the usual presenting problem. Some patients have difficulty with chewing or talking. In a large majority of patients, MG progresses from ocular to generalized skeletal muscle involvement over a 1- to 2-year period. Any trunk or limb muscle may be involved, but the neck flexors, deltoids, and wrist extensors are notable. Death results from severe respiratory muscle fatigue. Muscle weakness varies throughout the day but is usually worse toward the end of the day. The long-term course of disease is likewise variable and is characterized by periodic fluctuations in severity. For unclear reasons, MG tends to be worsened by emotional distress, systemic illness, and increased temperature (fever, hot weather).[311]

Pathogenesis of Myasthenia Gravis

It is apparent that the pathophysiology of disease is not simply the blockade of AChR by antibody. The muscle endplate, wherein the AChR resides, is misshapen and bears a reduced number of AChRs.[317] This is presumed to be due to autoimmune damage, perhaps mediated through complement destruction. The net result is a diminished depolarization response to a normal amount of released acetylcholine at the postsynaptic membrane.

Recent data suggest that a subset of individuals afflicted with MG are seronegative for anti-AChR antibodies. Rather, these individuals test positive for antibodies against the muscle-specific kinase (anti-MuSK–positive).[318] Animal models demonstrate the injection of IgG from anti-MuSK triggers muscle weakness by impairment of the neuromuscular junction, inducing MG.[314]

Abnormalities of the thymus are found in most patients with MG. In total, 75% have lymph follicle hyperplasia and 10% to 15% have lymphoblastic or epithelial thymic tumors. Thymectomy results in remission in 35% and improvement in 50% of patients.[319] These observations suggest that MG may be due to (1) an autoimmune attack on the antigens common to the thymus and motor endplate or (2) abnormal clone(s) of immune cells in the thymus.

Moreover, ectopic germinal centers are found with MG. Meraouna and colleagues[320] used gene chip analysis to identify 88 genes that were both associated with thymic dysregulation and normalized by glucocorticoids. They determined a B-cell chemoattractant (CXCL13) to be overproduced by MG patients and served as a main target of corticotherapy in ex vivo experiments, suggesting that new therapies targeting this chemoattractant might be of interest in the treatment of MG. Autoantibodies to other muscle proteins are suspected. Sera from MG patients induces muscle cell disarray of actin microfilaments, inclusion bodies, intracellular vesicles, and complement-independent induction of cellular death atypical of classic apoptosis. Continuing ex vivo and animal model experimentation is needed to further our knowledge of how this disease manifests through seemingly multiple pathways.[321]

Treatment of Myasthenia Gravis

MG is treatable but not curable. The use of anticholinesterase drugs is reportedly safe during pregnancy. Pyridostigmine, an analogue of neostigmine, is the most commonly used anticholinesterase medication. These medications

impede degradation of acetylcholine and bring about improvement in muscle function. Some patients with MG may respond only to immunosuppressive therapy with corticosteroids, azathioprine, and cyclosporine.[319] Remission is often accomplished with high-dose corticosteroids followed by slow tapering to maintain the remission state.[322] In the occasional patient with refractory MG, IVIG and plasmapheresis have been used with some success[310,322,323]; IVIG 2 g/kg appears to be highly effective for MG as measured by The Quantitative Myasthenia Gravis (QMG) Score for Disease Severity.[323]

Diagnostic Evaluation of Myasthenia Gravis

The diagnosis of MG rests on the clinical presentation, physical examination, and confirmatory diagnostic procedures. Repetitive use of the muscle under study results in apparent exhaustion. The muscle vigor can be dramatically restored with short-acting anticholinesterase drugs, such as edrophonium, in doses of 210 mg given by intravenous injection.[322] More sophisticated tests are now available, including single-fiber electromyography and repetitive nerve stimulation studies.

Risks of Myasthenia Gravis in Pregnancy

Complications of Myasthenia Gravis in Pregnancy

Several pregnancy-related physiologic changes may have detrimental effects on MG. Nausea, vomiting, altered gastrointestinal absorption, expanded plasma volume, and increased renal clearance require adjustment of anticholinesterase throughout pregnancy. Elevation of the maternal diaphragm by the gravid uterus causes hypoventilation of the lower portions of the lungs, which exacerbates respiratory compromise in some women with MG. Increased physical exertion in the second and third trimesters and the emotional stress of pregnancy itself may also result in MG exacerbation.[324]

The course of MG during pregnancy is highly variable. Both infection and shorter history of disease increase risk for puerperal flares.[324] Cartlidge[325] recommends postponement of pregnancy in women recently diagnosed with MG because this period represents the time of greatest risk. In an extensive review, approximately 40% of women with MG had exacerbation of their disease during pregnancy; approximately 30% had no change, and 30% had postpartum exacerbations that were frequently sudden and serious in nature.[326] Moreover, of the approximately 30% of MG patients whose disease remained unchanged during pregnancy, several had significant postpartum exacerbations. In a review that included both patients who were in remission prior to pregnancy and patients who were taking therapy, exacerbations occurred in 10 of 54 pregnancies (19%), improvement in 12 (22%), and no change in 32 (59%).[324] Plauche[326] found an overall maternal mortality of 4% (9 of 225 reported cases). The majority of these (7 of 9) were due to refractory MG.

Obstetric Complications in Myasthenia Gravis

The rates of miscarriage and fetal death in pregnancies complicated by MG do not appear to be significantly different from those of the normal population.[310,327] However, early series suggested preterm birth in up to two thirds of patients with MG,[327–330] and anticholinesterase drugs are thought to

have an oxytocic action.[310,331] Historically, reports have suggested differences in the prevalence of preterm birth and low birth weight in 54 MG patients compared with the general population.[310] More recently, Hoff and coworkers[331] found that neonatal survival, birth weight, and gestational age at delivery in women with MG were no different than controls.

Mothers with MG are no more likely than controls to require oxytocics in labor. According to the Medical Birth Registry of Norway from 1967 to 2000, cesarean section rates and PPROM were higher in gravidas with MG. Since 1981, assisted vaginal delivery with either forceps or vacuum has been no different from controls.[331] The transplacental passage of anti-AChR antibodies can lead to fetal or neonatal MG. Only about 10% to 15% of infants born to mothers with MG show signs of MG.[332] The relative infrequency of fetal involvement was due to α-fetoprotein, which has been shown to inhibit the binding of anti-AChR to AchR.[333,334] Most infants with neonatal MG have high concentrations of anti-AChR in their circulation.

The diagnosis of neonatal MG is made by observation of poor sucking, feeble cry, and respiratory difficulties that respond to edrophonium. Neonatal MG is transient, usually abating over a period of 1 to 4 weeks. The symptoms usually develop within the first several days of life, but are often absent initially, perhaps because of the presence of α-fetoprotein.[334] When properly recognized, the disease is easily managed with supportive care and anticholinesterase drugs. There does not appear to be any correlation between the risk of neonatal MG and the severity of maternal MG manifestation[331] or the level of maternal anti-AChR antibodies.[335,336] However, there does appear to be a relationship between neonatal levels and the severity of neonatal MG.[315] Arthrogryposis multiplex congenita (AMC), a nonprogressive congenital contraction disorder thought to result from poor fetal movement, has rarely been reported in infants born to women with MG.[332,337,338] There is some evidence that plasmapheresis and immunosuppressive therapy may reduce the recurrence of AMC in MG patients with a prior neonatal death presumably due to AMC.[339]

Management Options

Prepregnancy

Adjustment of medication to establish quiescence/control of the disease process is vital before pregnancy. Patients should be appropriately educated regarding the need for close supervision, the expected increase in fatigue, and the potential for respiratory compromise (especially late in pregnancy). The fetal risks of preterm delivery, the potential for associated anomalies, and the transient nature of neonatal MG should be discussed.[340]

Prenatal

Treatment is frequently necessary before, during, and after pregnancy to ensure maternal and fetal well-being. Pregnancy-related changes in drug absorption, increased renal clearance, and expanded plasma volume may require alterations in medication in order to maintain adequate drug levels. The first line of therapy is quaternary ammonium compounds with anticholinesterase activity. Although neostigmine (Prostigmin) was the first such drug to be used, its short half-life was a major drawback. Pyridostigmine

(Mestinon), which has a longer half-life, is the most popular long-acting medication currently used for maintenance therapy of MG. There is now a sustained-release form of the drug (Mestinon Timespan, 180 mg), but its popularity is limited by concerns about irregular absorption and drug preparation. Oral pyridostigmine is typically given in doses of 240 to 1500 mg/day in divided doses at 3- to 8-hour intervals. When used, the sustained-release preparation is typically given as a single bedtime dose of 180 to 540 mg. If the patient requires more drug, as is often the case with advancing pregnancy, it is best to first shorten the interval between doses. If this fails to control symptoms, the dose of pyridostigmine should be increased by increments of 15 to 30 mg. Such maneuvers usually lead to adequate control of MG during pregnancy. The most common side effects of these medications are due to the accumulation of acetylcholine (muscarinic effects). These include gastrointestinal symptoms (nausea, vomiting, cramping, diarrhea) and increased oral and bronchial secretions. Overdose of anticholinesterase drugs results in the rare so-called cholinergic crisis, which paradoxically includes muscle weakness and respiratory failure.[340]

Glucocorticoids are effective in most patients with MG. Most authorities prefer high doses (prednisone 60–80 mg/day) to start; the dose is tapered over many months after improvement is noted. The disease may transiently worsen soon after the steroids are started; for this reason, patients should be hospitalized for steroid therapy. Unfortunately, remission appears to be maintained only if the patient continues on steroids, and withdrawal of steroids may cause myasthenic exacerbations. For these reasons, pregnant MG patients should maintain glucocorticoid therapy through pregnancy and the postpartum period. Some authors believe that glucocorticoid-induced remission is a particularly good time for pregnancy in patients with MG.[338]

Plasmapheresis has been used with success in severe MG. Most patients were also taking glucocorticoids. There is one case report of using plasmapheresis to successfully treat MG in pregnancy.[339] It may be that maternal plasmapheresis might be the treatment of choice in MG pregnancies in which the fetus has markedly reduced or absent fetal movement predisposing it to AMC.

Thymectomy may result in improvement in many patients with MG by mechanisms that are unknown. However, resorting to thymectomy during pregnancy would seem imprudent because of frequent long delays before improvement and perioperative maternal and fetal concerns. Notably, neonatal myasthenia is less common in neonates born to women who have undergone thymectomy.[336,341] Patients with MG should be seen relatively frequently throughout pregnancy, every 2 weeks in the first and second trimesters, and every week in the third trimester. Undue emotional and physical stress are to be avoided, because they may result in exacerbation of MG. The patient and physician should be alert to the possibility of preterm labor and appropriate preventive steps instituted. Although care must be individualized, limiting exercise and work is probably in order for many patients. Infections may also result in exacerbation of MG. Respiratory and urinary tract infections must be identified and treated promptly.

Fetal involvement with MG is suspected by poor fetal movement and hydramnios. This is not treatable in utero.

Differentiating poor fetal movement due to MG from that due to fetal hypoxemia may be difficult, but normal fetal heart rate tests, especially a negative contraction stress test and a normal biophysical profile score, are reassuring.

Labor and Delivery

The management of labor and delivery in patients with MG requires limitation of emotional and physical stress and the appropriate use of parenteral anticholinesterase drugs. Neostigmine can be given subcutaneously, intramuscularly, or intravenously. As a rough guide, 60 mg oral pyridostigmine is equivalent to 0.5 mg intravenous neostigmine and 1.5 mg subcutaneous neostigmine. The usual dose of parenteral neostigmine is 0.5 to 2.5 mg. Maximal effects on skeletal muscle may occur 2 to 30 minutes after intramuscular injection; the effects last for about 2.5 hours. Pyridostigmine can be given intramuscularly or very slowly intravenously. The usual dose is 2 mg (~1/30 of the usual oral dose) every 2 to 3 hours. The course of the first stage of labor in patients with MG is not altered because MG does not affect smooth muscle.[316] The second stage of labor could be affected by the weakened material expulsive efforts, although the average duration of labor in MG patients is normal.

It is important to recognize that certain medications that may be used in the management of obstetric concerns are contraindicated in patients with MG. These are listed in Table 43–14. Magnesium sulfate is absolutely contraindicated because it further interferes with the neuromuscular blockade of MG. Preterm labor can probably be treated with β-sympathomimetics,[331] but the associated hypokalemia should be carefully avoided. A small number of patients with MG have an associated cardiomyopathy, which could increase the risks of β-sympathomimetics.

Because the patient with MG is particularly sensitive to neuromuscular drugs, analgesic and anesthetic considerations are important before the onset of labor. All patients with MG should be seen in consultation with an anesthesiologist early in the course of pregnancy. Epidural anesthesia is probably best because it limits the need for analgesia, may help prevent anxiety and fatigue, and is excellent for forceps procedures. Amide-type local anesthesia agents are used.[337] Some authors recommend general endotracheal anesthesia for cesarean section in patients with respiratory involvement. Myasthenic crises requiring ventilatory support may be precipitated by the stress of labor and delivery,

---

Barbiturates	Ether
Lithium salts	Penicillamine
Trichlorethylene	

an inadvertent change in medication, or surgery. Rarely, cholinergic crises may result from overdosage with anticholinesterase drugs. These patients have prominent muscarinic symptoms in addition to respiratory weakness. In all patients with MG, labor and delivery management should include the immediate availability of personnel and equipment for ventilatory support and airway maintenance. Postoperative care may be best accomplished in an intensive care setting.[340]

Postnatal

It would be difficult to find a patient, following delivery, who is not fatigued and weakened. Differentiating this normal state of affairs from exacerbation of MG may be difficult without objective testing. Drug dosages may need to be rapidly adjusted, in particular downward, as the effects of the volume expansion of pregnancy clear.

SUMMARY OF MANAGEMENT OPTIONS
Myasthenia Gravis

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Counsel regarding risk of exacerbation during pregnancy, risk of medication exposure	III/B	241
Review therapy; establish good control of SLE; adjust maintenance medications.	III/B	250–256
If possible, discontinue cytotoxic medications before conception. This should be done only under careful supervision.	III/B	250–256
Consider thymectomy in symptomatic women who are refractory to therapy.	III/B	250–256
Prenatal		
Provide joint obstetrician and physician surveillance.	III/B	251
Continue Preexisting Drugs	III/B	241
• Anticholinesterase.		
• Steroids.		
• Azathioprine.		
Consider plasmapheresis and IVIG in refractory cases.	III/B	241
Provide fetal surveillance, especially activity (biophysical profile score).	—/GPP	—
Initiate fetal surveillance at 30–32 wk' gestation.	—/GPP	—
Avoid/minimize physical/emotional stress.	III/B	250–256
Labor and Delivery		
Minimize stress.	III/B	250–256
Continue anticholinesterase drugs (parenteral).	III/B	250–256
Administer intravenous glucocorticosteroids for delivery in patients who have received maintenance or steroid bursts during pregnancy.	—/GPP	—
Regional analgesia is preferable to narcotics for pain relief and general anesthesia.	III/B	250–256
Use experienced anesthetists if general anesthesia (advisable to consult in prenatal period).	III/B	250–256
Assisted second stage is more likely.	III/B	250–256
Avoid magnesium sulfate in patients with preeclampsia (and other contraindicated drugs).	IV/C	255
Postnatal		
Provide special care and surveillance of newborn; may need short-term anticholinesterases.	III/B	241,260
Review dosage of drugs	III/B	241

ROBERT FRASER and TOM FARRELL

INTRODUCTION

Diabetes complicating pregnancy is becoming more common worldwide, but the last 5 years have produced several major advances in the management of the diabetic syndromes from well-designed randomized, controlled trials addressing improvement in outcome. The majority of complications seen in fetal development, growth, and labor and delivery can be ascribed in the broadest context to relative maternal hyperglycemia, and it follows that optimal maternal diabetic control at all stages from pregnancy planning to the postnatal period is critical to the various outcomes. It is important to note, however, that many of the medical complications of diabetes can affect the success or otherwise of pregnancy but also that the pregnancy itself may contribute to a deterioration in the long-term health of the mother. There are short-term risks to the mother as well particularly from hypoglycemia because of the combination of medical and patient attempts to maintain a low blood glucose in preparation for a pregnancy and during the pregnancy. Women with complications such as proliferative retinopathy and large vessel arteriopathy may experience acute deteriorations in their health. Important further considerations include the safety of some drugs used to minimize progression of diabetic complications, such as nephropathy, for use during pregnancy. Obesity is common among women who have type 2 diabetes or gestational diabetes mellitus (GDM). The medical and surgical complications of obesity can be superimposed onto the existing complications associated with hyperglycemia of diabetes in pregnancy.

CLASSIFICATION OF DIABETES

Preexisting Diabetes

This comprises cases of type 1 (insulin-dependent) and type 2 (non–insulin-dependent diabetes). These conditions can have been present for a variable length of time before the onset of a pregnancy, and in particular, type 1 diabetes can have been present from early childhood. Although there is considerable individual variation, as a general guide, the long-term complications of the diabetic state and indeed many of the complications seen in pregnancy become more common when the diabetes has been present for more than

10 years. Type 2 diabetes used to be relatively less common than type 1 in pregnancy, but the ratio is changing because of the increasing proportion of type 2 diabetes now being recognized in women of childbearing age, particularly where childbearing is more common in the late fourth and fifth decades. Taking these two conditions together, approximately 1 pregnancy in 250 will be complicated by preexisting diabetes. A small number of these cases that are starting to become more widely recognized are of monogenic diabetes, also called MODY (mature-onset diabetes of youth), a series of single gene defects that are inherited dominantly and may lead to diabetes complicating pregnancy through several generations of a family.

Gestational Diabetes Mellitus

Although the relative risk of preexisting diabetes remains less than 1% in most populations worldwide, there is a dramatic difference in the number of cases seen with GDM, which is defined as "any degree of glucose intolerance with onset or first recognition during pregnancy."[1] This definition includes women whose glucose tolerance will return to normal after pregnancy and those who will persist with glucose intolerance and type 2 diabetes. The latter group contains individuals who had unrecognized type 2 disease prior to pregnancy. In United Kingdom practice universal screening, where applied, reveals between 3% and 5% of women have biochemically diagnosed GDM. It is felt that the incidence of the condition is increasing in association with increasing obesity in the population at large and the increase in age-specific maximum fertility. In obstetric management terms, GDM probably has most of the risks of preexisting diabetes with regard to the second half of pregnancy but because the majority of women with GDM are normoglycemic at the time of conception, the excess risk of congenital malformation is not seen. It is, however, becoming increasingly recognized that a proportion of women diagnosed as having GDM on provocative screening during pregnancy are in fact previously unrecognized cases of type 2 diabetes,[2] and there is a suggestion from various national and international audits that this proportion, which might be as high as 20%, is increasing. In some populations in which obesity is particularly common or in which the population is dominated by ethnic groups at high risk for

diabetes, GDM complicating pregnancy may be seen in up to 40% of women.

Apart from recognizing the adverse effects of GDM on the outcome of pregnancy, it is also of value to make this diagnosis because, after the delivery, interventions such as pharmacologic drugs, dietary modification, and lifestyle modification may reduce the risk of subsequent pregnancies being complicated by diabetes. It may also improve the long-term health of the woman potentially by reducing her risk of developing chronic type 2 diabetes.

PREEXISTING DIABETES

Maternal Risks

The recent national enquiry in the United Kingdom performed by CEMACH (Confidential Enquiry into Maternal and Child Health)[3,4] in women with preexisting diabetes identified the risks for the mother in an intensively studied subset. Recurrent hypoglycemia occurred in 51% of women, and in 20% of women, there was at least one episode of hypoglycemia requiring "third-party assistance," meaning another person was required to assist in the reversal of insulin-induced hypoglycemia and implying a more serious condition. Most severe hypoglycemic episodes occur between 8 and 16 weeks' gestation, probably associated with nausea and anorexia at this stage of pregnancy. Twenty-three percent of women entered pregnancy with some degree of retinopathy and a further 9% were recognized as having retinopathy for the first time during the pregnancy. Pregnancy is associated with an independent risk of progression of retinopathy. Twelve percent of pregnancies of women with preexisting diabetes were complicated by nephropathy. Preeclampsia is more common by a factor of two to four times in women with preexisting diabetes than in women free of diabetes. In a large case series from the United States, there was a stepwise increase in preeclampsia frequency with the duration and complication rate in preexisting diabetes, from 10.8% in those with the disease for less than 10 years to 22.0% in those with a longer duration but no vascular complications to 36.2% in those with proliferative retinopathy, nephropathy, or both.[5]

Fetal and Neonatal Risks

Congenital Abnormality

Congenital anomalies are now the leading single cause of perinatal death among infants of diabetic mothers, accounting for 40% to 50% of all perinatal deaths.[6–8] The nature of the congenital abnormalities are blastogenetic in origin,[9] and as a result, the insult responsible for the congenital malformations must impact on the developing organ systems before the seventh week of pregnancy.[10,11] Maternal hyperglycemia is considered to be the primary factor responsible for increased congenital abnormalities in pregnancy in diabetes. The proportion of pregnancies complicated by congenital malformation in which the periconceptional hemoglobin A$_{1c}$ (HbA$_{1c}$) is less than 7% is not significantly greater than the rate seen in the nondiabetic population however. Above this percentage, there is a progressive rise with rates of congenital malformation exceeding 8% where the HbA$_{1c}$ level is above 10%[12,13] (Fig. 44–1).
Shields and coworkers[14] in a cohort of women with preexisting diabetes found no cardiac abnormalities in women with an early pregnancy HbA$_{1c}$ level under 6.1%. Similarly, Wong and colleagues[15] demonstrated that no congenital abnormalities were found in a cohort of women when the HbA$_{1c}$ was under 9%.

There do not appear to be specific abnormalities associated with increasing levels of maternal hyperglycemia during embryogenesis. Abnormalities of all organ systems are seen. What is apparent is that the degree of maternal hyperglycemia appears to have a greater influence on the number of organ systems that are adversely affected rather than on which organ system is specifically involved. This is reflected in increased risk of multiple congenital abnormalities with increasing levels of maternal hyperglycemia.[16]

The usually quoted frequency of major congenital abnormalities in pregnancy in diabetes is 6% to 10%.[15–18] More recent data from the CEMACH enquiry found the prevalence of major congenital anomalies to be 46 per 1000 births in women with diabetes (48/1000 births for type 1 diabetes, 43/1000 births for type 2 diabetes), more than twice the population rate.[19] The increase in congenital abnormality rates was mainly due to a 4.2-fold increase in neural tube defects (NTDs) and a 3.4-fold increase in congenital heart disease. Although the spectrum of type of congenital anomalies is varied, it does appear that both neural tube and cardiovascular defects predominate.

There is little difference between preexisting type 1 and type 2 diabetes with regards to both the rate and nature of congenital abnormalities seen.[2,19,20] Women with GDM, conversely, are a heterogeneous group of women containing women with previously undiagnosed preexisting diabetes and glucose intolerance of pregnancy (see earlier).

Farrell and associates[2] reported on major anomalies in a New Zealand population of women with type 1, type 2, and GDM. The incidence of major abnormalities was 5.9% in women with type 1 diabetes, 4.4% with type 2 diabetes, and 1.4% in women with GDM. Women with GDM were then

reclassified once the results of the postnatal glucose tolerance test were known. The congenital abnormality rate for those women later reclassified as having unrecognized type 2 diabetes was 4.6%, whereas in the remaining women with GDM, the rate had fallen to 0.9%.

Martinez Frias and coworkers[21] found GDM was associated with an increased of risk of congenital abnormalities (odds ratio [OR] 2.8) in obese women. A strong association between GDM and major congenital anomalies was confirmed when the initial fasting glucose at diagnosis was greater than 6.7 mmol/L. There is an association between maternal obesity and relatively high fasting glucose levels.[22]

Pathologic Fetal Growth

Disordered fetal growth is well recognized as a problem in pregnancy complicated by all types of maternal diabetes, with intrauterine growth retardation being common in those with long-standing diabetes with macrovascular disease, but much more common in all the diabetic syndromes is fetal overgrowth (macrosomia) associated with excess glucose transfer across the placenta and secondary fetal hyperinsulinemia. In the newborn period, complications including hypoglycemia, respiratory distress syndrome (RDS), hyperbilirubinemia, hypocalcemia, and polycythemia may occur. Feeding difficulty associated with delayed gastric emptying secondary to raised serum amylin levels is more common in overgrown newborns.[23]

Fetal Well-being

Despite good glycemic control in pregnancy, there is a persisting increased risk of stillbirth in pregnancy complicated by maternal diabetes in the United Kingdom.[3] This increased risk of stillbirth has led to a generally accepted policy of induction of labor at around 38 weeks to avoid late fetal loss, which has invariably contributed to the higher cesarean section rate experienced by women with diabetes.

The cause of late stillbirth is likely to be multifactorial. Fetal hypoxia and acidosis have been implicated, as has hypokalemia leading to fetal cardiac dysrhythmias, as well as placental dysfunction. The increased risk of late stillbirth was shown many years ago to correlate with poor glycemic control during late pregnancy.[24] Histologic examination of the placenta from women with diabetes demonstrates characteristic changes often described as "immature villi."

Blood glucose levels appear to be the metabolic driver responsible for these placental changes that result in milder degrees of uteroplacental compromise being less well tolerated than in pregnancy in women free of diabetes. Identifying the fetus at risk of late intrauterine death remains a challenge.

Stillbirth, perinatal death, and neonatal mortality rates per 1000 births compared with the general population were 26.8, 31.8, and 9.3 versus 5.7, 8.5, and 3.6, respectively, in the U.K. national dataset.

There is agreement in the literature about the late pregnancy risks of women with frank GDM with a fasting plasma glucose above 6.9 mmol/L or a 2-hour plasma glucose above 11.0 mmol/L. Collected series confirm that the adverse outcomes of late pregnancy in such women left untreated are as common as in women with preexisting diabetes and poor control in late pregnancy. There has been, however, lack of agreement over the clinical significance of mild GDM (sometimes called impaired glucose tolerance [IGT]) that comprises a group of women with fasting plasma glucose levels below 7 mmol/L but 2-hour levels above 7.8 mmol/L but below 11.1 mmol/L. This group corresponds to some extent with those diagnosed as GDM by having two abnormal values on a 3-hour glucose tolerance test using the American Diabetes Association (ADA) criteria for diagnosis (Table 44–1). The recent publication of two double-blind studies, the Australian Carbohydrate Intolerance Study in Pregnant Women (ACHOIS) study[25] and the Maternal-Fetal Medicine Units Network (M-FMUN)[26] study, appears to have addressed this question in that both studies demonstrated that significant reductions in pregnancy complications such as preeclampsia and adverse perinatal outcomes were achieved by referral to a joint diabetes antenatal clinic after randomization compared with untreated groups (Table 44–2). The untreated women were blinded, as were their medical attendants, to the presence of GDM and, therefore, attended the routine antenatal clinics. With the evidence from these two studies, most authorities would accept that the diagnosis is worth making because treatment is likely to be effective, and therefore, some form of screening approach is appropriate.

The classical Pedersen hypothesis was that excessive glucose transfer across the placenta stimulated excessive fetal insulin production and that this relative fetal

hyperinsulinemia in the second half of pregnancy was the driver to hypertrophy of the insulin-sensitive tissues in the fetus leading to the common diagnosis of fetal macrosomia.[27] The Pedersen hypothesis was elaborated by Freinkel and Metzger[28] with the recognition that other nutrient substrates, particularly certain amino acids, were also fetal insulin secretagogues and probably contributed to the development of fetal hyperinsulinemia. In normal pregnancy, glucose becomes a fetal insulin secretagogue only around 26 weeks' gestation. In maternal diabetes with maternal hyperglycemia however, early maturation of the mechanism by which glucose causes secretion of fetal insulin is obtained, and in approximately half of cases of fetal macrosomia, the pattern of excessive growth can be recognized on late midtrimester ultrasound scanning. In the remainder of cases in which macrosomia is developing, it is recognized only in the third trimester.

Figure 44–2 shows the relative incidence of fetal hyperinsulinemia from studies performed in our unit and reveals that despite modern target-oriented hypoglycemic therapy in women with both GDM and preexisting diabetes, a significant number of fetuses are hyperinsulinemic.[29]

Fetal insulin secretion rates play a major role in fetal growth.[27] Increases in fetal plasma insulin levels are directly correlated with increased maternal glucose levels because of the process of facilitated diffusion of glucose across the placenta. This increase in fetal insulin leads to accelerated growth of insulin-sensitive tissues in the fetus such as bone, muscle, and adipose tissue.[30] As a result, macrosomia associated with maternal diabetes results in larger shoulder diameters, increased skinfold thicknesses, and lower head–to–abdominal circumference ratios[31] than "constitutional" macrosomia seen in pregnancies free of maternal diabetes. The increase in biacromial distance may explain why the incidence of shoulder dystocia reported by birth weight in the CEMACH Enquiry rose from 0.9% in infants of birth weight below 2.5 kg to 4.7% between 2.5 and 3.9 kg, 23.0% between 4.0 and 4.5 kg, and 42.9% over 4.5 kg.[3]

The reported incidence of macrosomia in pregnancies in diabetes ranges between 8% and 43%.[32] This variation may simply reflect differing populations, different targets for
FIGURE 44–2

maternal glucose control in pregnancy, or the influence of other factors predisposing to fetal macrosomia such as maternal weight, weight gain during pregnancy, parity, and genetic factors.[33]

Traditionally, fetal macrosomia was considered to be driven by maternal glucose control in the third trimester with the 1-hour postprandial blood glucose level strongly associated with fetal birth weight.[34] There is now evidence to suggest that diabetic control in the first and early second trimesters is also important in the development of a macrosomic infant.[35–37] Increased maternal glucose levels in early pregnancy may result in the fetal pancreas being "reprogrammed" in terms of insulin secretion and additionally

result in hyperplasia of fetal adipose cells that become hypertrophied in response to third-trimester glucose transfer to contribute to fetal macrosomia.

Neonatal Complications

From a combination of spontaneous and elective delivery, the preterm birth rate in preexisting diabetes is 4.9% at less than 32 weeks' gestation and 32% between 32 and 36 completed weeks.[3] RDS is more common at all gestational ages in infants of women with diabetes.[38] Other causes of respiratory distress such as transient tachypnea of the newborn (TTN) are also more common. Intrapartum difficulties with delivery, particularly shoulder dystocia, are responsible for neonatal complications such as bony injuries, particularly fractures to the humerus or clavicle, and brachial plexus trauma resulting typically in Erb's palsy. This was reported in 0.45% of births in the CEMACH audit.[3] This complication is more common in fetal macrosomia driven by fetal hyperinsulinism. Neonatal hypoglycemia resulting from autonomous insulin secretion and delayed gastric emptying induced by high levels of amylin is more likely in these overgrown infants.[23] Chronic intrauterine hypoxia is thought to be the mechanism underlying excessive erythropoietin production and polycythemia, which leads to increased blood viscosity and secondarily to hyperbilirubinemia in the newborn. Hypocalcemia is also more common in the newborn of the diabetic mother and enters into the differential diagnosis with hypoglycemia of the infant with symptoms such as jitteryness and convulsions.

Management Options

Prepregnancy

All women of reproductive age with preexisting diabetes should be advised about the potential benefits of prepregnancy planning at their regular contacts with medical services in which their diabetes is reviewed. Women with diabetes should also be aware of the options with regard to effective contraception in an attempt to reduce the number of unplanned pregnancies, particularly when adequate preparation for pregnancy with regard to diabetes control has not been undertaken.

From adolescence onward, women with diabetes and, if possible, their partners should be offered education on the role of diet, body weight, and exercise as well as the importance of planning any pregnancy. They should be made aware that the risks of pregnancy are associated with both the quality of diabetes control and the presence and duration of any complications of their diabetes. The value of measurement of glycated HbA_{1c} in preparation for pregnancy is well established from observational studies if not from any randomized, controlled trials.[39,40] The nomenclature for laboratory-based measurements of HbA_{1c} is about to change, as detailed in Table 44–3.[41] A reasonable target for HbA_{1c} in prepregnancy counseling is to aim for 6%, and when such a target has been chosen, outside pregnancy, in randomized, controlled trials of intensified insulin treatment, it has been associated with successful achievement of levels of approximately 7% to 7.4% compared with mean levels of HbA_{1c} of 9% when conventional insulin regimes are followed. In women participating in the Diabetes Control and Complications Trial who became pregnant, there were 8 congenital

malformations among 86 women randomized to conventional treatment but only 1 in 94 in those randomized to intensive insulin treatment.[42]

An improvement in HbA_{1c} levels can also be achieved by switching to short-acting modern analogue insulins and by enrolling the prepregnant subject into education programs that teach enhanced carbohydrate counting. Examples include the Dose Adjustment for Normal Eating (DAFNE)[43] for women with type 1 diabetes. Similar structured education programs exist for type 2 diabetes, such as Diabetes Education and Self-Management for Ongoing and Newly Diagnosed (DESMOND).[44] Switching someone who has established diabetes with which they are able to cope and lead a normal lifestyle into an enhanced program of tight diabetic control is not without its risks from the point of view of hypoglycemia.[45,46] There are important social considerations if hypoglycemia becomes more common including the threat of loss of the driving license and problems with maintaining employment and normal lifestyle if hypoglycemic episodes become frequent. At the time of submitting women to enhanced prepregnancy glycemic control regimes, education should be provided on recognition and management of hypoglycemia for both the patient and her partner. Third-party administered glucose supplements such as buccal glucose gel and intramuscular glucagon must be made available. These regimes are intensive and demanding, and once an acceptable target range for HbA_{1c} has been achieved, contraception can be safely discontinued. The situation should be closely monitored, and an early resort to referral to the infertility service should be considered, perhaps as early as 6 months after trying has failed to achieve a pregnancy. When women, despite their best efforts, do not achieve an optimal percentage of HbA_{1c}, more detailed investigation into the pattern of diabetes control such as that obtained by continuous glucose monitoring (CGMS) should be considered. When conventional insulin regimes do not appear to be effective, some women

would benefit from continuous subcutaneous insulin infusion (CSII) using an insulin pump.

As a counseling guide, women with HbA_{1c} above 10% might reasonably be recommended to continue contraception and avoid pregnancy until there has been a significant improvement. Data from a recent large case series suggest that the relative risk for perinatal mortality is also correlated with levels of periconceptional HbA_{1c}.[12] It is important during prepregnancy counseling to discuss the still relatively high rate of congenital malformations that can complicate pregnancy in women with diabetes even if they achieve HbA_{1c} targets (see Fig. 44–1).[13] In practice, however, the uptake of prepregnancy counseling remains poor in proportionate terms, and many pregnancies are unplanned or occur with a relatively high HbA_{1c} value.

Attitudes to antenatal diagnosis and termination of pregnancy should be explored. Women who have obesity with preexisting diabetes, commonly type 2 diabetes, should have expert dietetic advice in the prepregnancy period. In gross obesity, it may be considered that preconceptional bariatric surgery has a place for a small number of women. As a guide, to reduce the superimposed complications of obesity on type 2 diabetes in pregnancy, a target body mass index (BMI) of 27 might be considered, although there will be large individual variation of what can be achieved by dietary advice, lifestyle modification, and perhaps, the use of biguanide drugs such as Metformin rather than sulfonylureas or insulin. Both of the latter can be associated with increased fat deposition.[47]

In prepregnancy counseling, the current drug regime should also be reviewed. Some hypoglycemic drugs have not been evaluated for safety in pregnancy, including some of the newer long-acting insulin analogues. Antihypertensives, particularly angiotensin-converting enzyme (ACE) inhibitors[48] and angiotensin II receptor antagonists,[49] should be discontinued prior to pregnancy or as soon as pregnancy is recognized. The former are teratogenic and the latter can cause fetal anuria, though this risk to the fetal kidney does not appear to be related to first-trimester drug exposure. Medication with statins would generally be discontinued, although there is no consistent evidence of a teratogenic effect,[50] but stopping them during pregnancy should have no detrimental effect on long-term therapy of hyperlipidemia.

All women with preexisting diabetes should have been subject to regular digital imaging of the retina, preferably with mydriasis using tropicamide or with dilated retinoscopy when digital photography is not available. Women with any degree of previously unrecognized retinopathy should have a referral to an ophthalmic surgeon prior to discontinuing contraception. It should also be pointed out to them that rapid optimization of glycemic control can be associated with a deterioration in retinopathy. One cohort study of 171 pregnant diabetic women reported a more rapid rate of progression of retinopathy with an OR of 1.8 (95% confidence interval [CI] 1.1–2.8) compared with 298 nonpregnant women with type 1 diabetes over a comparable period of time independent of HbA_{1c}, blood pressure, number of previous pregnancies, and duration of diabetes.[51] Continued monitoring of the retina during any pregnancy and during periods of enhanced prepregnancy diabetic control is essential. Those at greatest risk appear to be those entering pregnancy with established retinopathy, but in one cohort study in 154 women, there was progression in 23% of women with no retinopathy in the first trimester, 41% with nonproliferative retinopathy deteriorated, and 63% of those with established proliferative disease experienced progression.[52]

When pregnancy occurs without any prepregnancy counseling, then an urgent assessment of all the previous factors should be undertaken as soon as possible at the antenatal clinic.

Prenatal
GESTATIONAL DIABETES: DIAGNOSIS, AND SCREENING

The diagnosis of GDM is based on World Health Organization (WHO) criteria with a 75-g oral glucose load with fasting and 2-hour glucose levels[53] or the ADA criteria using a 100-g load[1] (see Table 44–1). Many national bodies, including National Institute for Clinical Excellence (NICE),[54] have recommended screening for GDM in pregnancy either in the whole population or in identified high risk groups. A new diagnostic criterion, also included in Table 44–1, is based on fasting, 1-hour, or 2-hour levels has been suggested by a consensus group reviewing the Hyperglycaemia and Adverse Pregnancy Outcomes (HAPO) study.[55]

As a rough guide to the various approaches to screening (which are summarized in Appendix B of the NICE guideline *Diabetes in Pregnancy*[56]), screening can be selective or universal. Individual units may choose their own approach, but one consideration is the likely prevalence of GDM in any particular country or, indeed, individual obstetric unit within any country. Where the disorder has an expected prevalence of less than 3%, screening based on historic risk factors might be considered an acceptable approach, but where prevalence is expected to be above 3%, provocative testing by either one- or two-step glucose loading with a 50-g glucose challenge test (GCT) or diagnostic screening with a 75-g oral glucose tolerance test (OGTT) might be considered. Rationalization could be applied by offering universal screening, but with the exclusion of women recognized as being at "low risk" on the grounds of age and/or ethnicity. The ADA defines these women as age younger than 25 years, normal BMI, and not from a high-prevalence ethnic minority group.[1]

When a selective approach to screening is to be applied, then the recommended screening historic risk factors are as follows[54]:
- BMI of 30 or above.
- Previous macrosomic infant.
- Previous pregnancy complicated by GDM.
- Family history of diabetes in first-degree relatives.
- Ethnic origin with known high prevalence of diabetes including subcontinental Asia, black Caribbean, and Arabic, particularly of Middle Eastern origin.

It is acknowledged that a selective screening approach will miss a proportion of women with GDM, perhaps up to 30%.

When a case of GDM is recognized by a screening program, the woman should be referred to a joint antenatal/diabetes clinic where she can be instructed in self-monitoring of blood glucose levels. Having made the diagnosis of GDM, usually in the last trimester, and enrolled the

patients into a program of self-monitoring and diet with or without hypoglycemic agents, the antenatal care and targets for glycemic control should be the same as those described in the next section for women with preexisting diabetes.

GLYCEMIC TARGETS

The evidence suggests that therapeutic approaches that succeed in reducing the rate of fetal hyperinsulinemia will also be associated with improved obstetric outcomes and a reduction in the typical neonatal morbidity of the macrosomic newborn. Two small, but well-conducted, randomized, controlled trials, one in women with type 1 diabetes[57] and one in women with GDM,[58] confirm that postprandial, compared with preprandial, glucose monitoring with a target in both studies of a 1-hour blood glucose level lower than 7.8 mmol/L is associated with important reductions in birth weight and in typical neonatal morbidity (Table 44–4).

A likely cause of fetal hyperinsulinemia despite apparently well-controlled maternal glycemia based on the previous target is that in many women with type 1 diabetes experience high postprandial peaks of glucose or high fasting levels of glucose on some days but not others.[59] This phenomenon has been well described in observational studies using continuous glucose monitoring systems (CGMS), and a new randomized, controlled trial by Murphy and colleagues[60] from the United Kingdom randomizing women to intermittent use of adjunctive CGMS or conventional intermittent self-monitoring also reveals a major stepwise improvement in reduced birth weight and perinatal morbidity. A small randomized, controlled trial of the use of CGMS in GDM reported an increase in the use of hypoglycemic therapy (31% vs. 8%) in the self-monitored group. There were no differences in pregnancy outcomes; however, the study was underpowered to assess these.[61] CGMS technology is expected to become more widely available for use in pregnancy with the hope of improving pregnancy outcomes

and in particular in those with ultrasound evidence of incipient macrosomia.

Conventionally, intermittent sampling is used in all types of diabetes, and it is recommended that the target for glucose levels after an overnight fast should be maintained between 3.3 and 5.9 mmol/L of glucose and the 1-hour postprandial glucose level should be maintained at less than 7.8 mmol/L, except in cases in which this regime provokes frequent severe maternal hypoglycemia.[57,58]

HYPOGLYCEMIA

Both hypoglycemia and hyperglycemia can complicate diabetes control in pregnancy, particularly in women with type 1 diabetes. The greatest frequency of hypoglycemia occurs between weeks 8 and 16, corresponding with the time at which most women who are susceptible will experience nausea and vomiting and anorexia. Although some authors have suggested this is a likely etiologic factor,[62] others have reported no difference in the self-reported incidence of nausea and/or vomiting in the previous week between those with and those without episodes of severe hypoglycemia.[63] A further complicating factor that women should be made aware of in prepregnancy counseling or in early pregnancy is that their usual subjective experience of hypoglycemia awareness may be obtunded in pregnancy and this is an independent risk factor for requiring third-party assistance because of hypoglycemic coma in the first half of pregnancy.[63] Vulnerable women should be instructed in the more frequent use of self-monitoring of blood glucose sampling and to particularly increase the frequency of sampling before planned activities such as driving. Obviously, they will be familiar with the requirement to carry readily available calories with them, but also their partners and close relatives, friends, or work colleagues might be advised about the use of preparations such as buccal glucose gel and indeed intramuscular glucagon, as stated in the "Prepregnancy" section earlier.

HYPERGLYCEMIA

Hyperglycemia with the risk of diabetic ketoacidosis (DKA) in type 1 diabetes is fortunately less common in pregnant than in nonpregnant women. It is potentially a very serious problem because untreated mild or moderate DKA can be associated with intrauterine fetal death. Women with type 1 diabetes in pregnancy should be offered or advised to use a blood glucose monitoring system that can also measure ketones and to test themselves when they become unexpectedly hyperglycemic or otherwise feel unwell. Early admission to the hospital is appropriate when DKA is suspected, and rapid correction of the acid-base balance is essential if fetal viability is to be preserved. Accident and emergency units, acute medical admission units, and/or obstetric units should have written protocols for the management of DKA in pregnancy, and if the diagnosis is confirmed, it is recommended that treatment is offered on a suitable high-dependency unit. An assumption of incipient or actual DKA should be made if an urgent serum bicarbonate level on admission is less than 20 mmol/L or if an arterial blood gas analysis confirms maternal acidosis (Table 44–5).

Iatrogenic DKA and on some occasions fetal death have been provoked in the past by treatment of suspected preterm labor with β-sympathomimetic drugs and/or maternal steroids, both of which have insulin counterregulatory actions (see the section on "Preterm Labor," later). In addition to the urgent treatment of DKA, underlying causes such as maternal urinary infection or respiratory infection should be sought and treated as appropriate. The recognition of fetal distress in association with DKA in late pregnancy will generally provoke urgent delivery, but here close cooperation with an experienced obstetric anesthetist is essential because there are maternal risks of induction of anesthesia in someone who may have a deteriorating pattern of metabolic acidosis.

DIETARY MANAGEMENT

In modern obstetric practice, diabetes management is offered by a multidisciplinary team, usually working in a joint antenatal clinic. Women with all types of diabetes will generally benefit from either a prepregnancy or an early pregnancy review of their "normal" diet. Where available, women who have not had the benefit of attending DAFNE[43] or similar courses when not pregnant (see earlier) should be offered a place in such a course as early as possible during the pregnancy. The importance of adopting appropriate dietary patterns should be emphasized so that the doses of insulin or oral hypoglycemic drugs can be minimized. For many women with GDM, oral hypoglycemic or insulin therapy may be avoided altogether with no increase in adverse perinatal outcomes. In women with GDM, observational studies have shown an inverse relationship between birth weight and proportion of dietary energy obtained from carbohydrate.[64] Low–glycemic index (GI) carbohydrate sources are associated with enhanced maternal sensitivity to endogenous insulin,[65] a mechanism that should contribute to several benefits such as reduced likelihood of requiring hypoglycemic therapy, lower rates of fetal macrosomia, and lower maternal net body weight gains after the completion of the pregnancy. One recent randomized, controlled trial of low GI versus a conventional high dietary fiber diet resulted in insulin being required in 29% of low GI but 59% of high dietary fiber. There were no differences in obstetric or fetal outcomes.[66] Prepregnancy dietary advice is adaptable to use in pregnancy with all types of diabetes.

The first approach to glycemic control should be dietary advice based on Diabetes UK[67] or ADA[1] criteria (Table 44–6). These recommend a diet relatively high in carbohydrate sources of known low GI, lean proteins including oily fish, and a balance of polyunsaturated and monounsaturated fats. Women with a high BMI might be advised to restrict calorie intake with expert dietetic advice and consider suitable enhanced mild or moderate exercise during the pregnancy.

INSULIN THERAPY

If insulin therapy is required or has been chosen in type 2 or GDM, intermittent bolus doses of insulin to cover each main meal will usually be prescribed with the pregnant woman given telephone access to a diabetes specialist nurse or diabetes specialist midwife for advice on dose adjustment. More severe type 2 diabetes and type 1 diabetes are generally treated by a combination of long-acting basal insulins with three or four times daily short-acting insulins. Modern short-acting analogue insulins are known to be safe for use

---

TABLE 44–5

Recognition and Management of Diabetic Ketoacidosis in Pregnancy

Clinical Suspicion

- All pregnant women with Type 1 diabetes should be provided with Optimum Xceed Meter (or equivalent) and B-ketone test strips.
- If feeling unwell for any reason, or any vomiting, or blood sugars above target having been within normal range before test blood for ketones: if <0.6 mmol/L, repeat in 2 hrs if symptoms persist or if blood sugar rising despite normal insulin doses; if ≥0.6 mmol/L, arrange self-referral/urgent professional review.

Biochemical Confirmation

- Urgent FBC/U & E venous bicarbonate, or arterial blood gases.

Urgent Management

- Venous bicarbonate:
    If <20 mmol/L, commence DKA regime.
    If <16 mmol/L, commence DKA regime and seek urgent assistance from diabetes physician.
- DKA regime:
    Admit HDU: Commence IV normal saline and administer 1000 mL in first hr. Give second 1000 mL over 2 hr.
    K⁺ replacement in normal saline, based on serum potassium measurement:
       >5.5 mmol/L no KCl supplement, repeat U & E in 2 hr.
       4–5.5 mmol/L 20 mmol KCl/1000 mL saline.
       <4.0 mmol/L 40 mmol KCl/1000 mL saline.
- Insulin
    50 U Actrapid in 49.5 mL normal saline by pump/syringe driver
    6 U/hr; if blood glucose not falling after 2 hr, increase to 12 U/hr.
- Fetal monitoring
    CTG if fetal viability established.
- Maternal investigations
    Throat swab
    MSU
    Vaginal swab   } for C & S in microbiology
    Blood culture

C & S, culture and sensitivity; CTG, cardiotocogram; DKA, diabetic ketoacidosis; FBC, full blood count; HDU, high-dependency unit; MSU, midstream urine; U & E, urea and electrolytes.

TABLE 44-6

Dietary Advice for Pregnant Women with Diabetes

COMPOSITION OF THE DIET	NUTRITIONAL ADVICE FOR PEOPLE WITH DIABETES
Protein	Not > 1 g/kg body weight
Total fat	<35% of energy intake.
Saturated + transunsaturated fat	<10% of energy intake.
ω-6 polyunsaturated fat	<10% of energy intake
ω-3 polyunsaturated fat	Eat fish, especially oily fish, once or twice weekly. Fish oil supplements not recommended.
cis-monounsaturated fat	10%–20% } 60%–70% of energy intake
Total carbohydrate	45%–60%
Sucrose	≤10% of daily energy.
Fiber	No quantitative recommendation. *Soluble fiber*—has beneficial effects on glycemic and lipid metabolism. *"Insoluble" fiber*—has no direct effects on glycemic and lipid metabolism, but its high satiety content may benefit those trying to lose weight and is advantageous to gastrointestinal health.
Vitamins and antioxidants	Encourage foods naturally rich in vitamins and antioxidants.
Salt	≤6 g sodium chloride/day.

Modified from Nutrition Subcommittee of the Diabetes Care Advisory Committee of Diabetes UK: The implementation of nutritional advice for people with diabetes. Diabet Med 2003;20:786–807.

in pregnancy and probably have advantages in their speed of action helping to reduce postprandial peaks.[68,69] There is some theoretical risk associated with the use of longer-acting insulin analogues, but small observational studies have reported no adverse outcomes.[70] Larger-scale randomized, controlled trials addressed to the safety and effectiveness of these drugs are currently in progress. Many women entering pregnancy on a combination of short- and long-acting analogue insulins will wish to continue using these drugs. If they do so, they should be aware of the uncertainty of the risks of the long-acting analogue preparations, pending the performance and publication of suitable randomized, controlled trials. If commencing long-acting insulins for the first time in pregnancy or in women who are not taking long-acting analogue insulins, the more traditional human isophane (NPH) insulin should be prescribed.

Some women are using continuous subcutaneous insulin infusion (CSII), the "insulin pump," when they enter pregnancy and there is no reason to discontinue these devices. A systematic review of randomized, controlled trials comparing CSII with intensified conventional insulin regimens has revealed no advantage or disadvantage to either regime.[71] It is also likely that a small number of women who find that their control, in terms of both hypoglycemia and/or hyperglycemia, has been disturbed by the adjustments they need to make for pregnancy will benefit from either a short-term or a long-term switch to CSII. In the future, it is likely that women who have difficulty with glycemic control will be helped by feedback devices combining CGMS with automatic insulin infusion by a CSII regime.

ORAL HYPOGLYCEMIC DRUGS

The conventional recommendation for women with type 2 diabetes has been to discontinue oral hypoglycemic drugs when planning a pregnancy or as early as possible in any unplanned pregnancy because of concerns about teratogenesis. However, systematic reviews and meta-analyses have failed to demonstrate any increase in structural congenital malformations associated with use of these drugs in pregnancy and suggest that when a woman with type 2 diabetes has satisfactory control maintained on an oral hypoglycemic agent, she should continue it during pregnancy unless she chooses to switch to insulin.[72,73]

The other concern about the continuation of oral hypoglycemics during pregnancy is the greater likelihood of poor glucose control compared with insulin. One retrospective cohort study from South Africa reported a higher perinatal mortality rate in women on oral hypoglycemics compared with those switched to insulin during the pregnancy.[74] In GDM, new-generation short-acting sulfonylureas were the subject of one large-scale randomized trial by Langer and associates.[75] Four hundred four women with GDM were randomized between 11 and 33 weeks' gestation to receive glibenclamide (glyburide) or insulin with a primary endpoint of maternal glycemic control with targets of 5.3 mmol/L fasting and 6.7 mmol/L 2 hours postprandial. Four percent of women in the glibenclamide group could not maintain these levels of control without supplementary insulin. The dose of glibenclamide was started at 2.5 mg daily in the morning and then increased on a weekly basis by 2.5 or 5 mg/day up to a maximum of 20 mg. No significant differences emerged between the groups: the rate of birth weight above the 90th percentile was 12% on glibenclamide and 13% on insulin. Neonatal respiratory distress was seen in 8% versus 6%, neonatal hypoglycemia 9% versus 6%, and cord serum insulin concentrations were identical, suggesting a similar quality of maternal glycemic control. No glibenclamide was detected in the in cord serum, suggesting that this short-acting sulfonylurea does not cross the placenta in significant amounts.

A more recent study randomizing women similarly to insulin or metformin for the treatment of GDM has been reported by Rowan and coworkers.[76] There were 363 women randomized to metformin and 370 randomized to insulin. In

that study, the dosage of metformin was started at 500 mg once or twice daily and increased every first or second week toward glycemic targets up to a maximum daily dose of 2500 mg. Seven women randomized to metformin had to discontinue the drug because of gastrointestinal side effects. The outcomes of the pregnancy for mothers and infants were not significantly different, apart from an excess of preterm birth, 12% versus 7.6% in the metformin group. There was, however, only 1 birth before 32 weeks' gestation in each group, and 9 infants in each group required transient treatment with continuous positive airway pressure. Forty percent of women in this study required supplementary insulin, however.

Perhaps more important in terms of long-term maternal prognosis, particularly in this group of women who are often obese, there was a net increase in weight loss from enrollment to the postpartum visit of 8.1 kg in the metformin group versus 6.9 kg in the insulin group.

In conclusion, modern short-acting sulfonylurea drugs and metformin are likely to have an increasing place in the management of GDM. Metformin may become the drug of choice for those entering pregnancy who are overweight or obese.

RETINAL ASSESSMENT

During pregnancy, digital retinal imaging should be performed with mydriasis at or as soon as practicable after the first antenatal clinic appointment. The Diabetic Retinopathy Study Research Group[77] reported that the presence of any of the following high risk characteristics at any stage of life is associated with a 2-year risk of developing severe visual loss:

- Presence of vitreous or preretinal hemorrhage.
- Presence of new vessels.
- Location of new vessels on or near the optic disk.
- Severity of new vessels.

In randomized studies, photocoagulation in the presence of these abnormalities reduced the risk of severe visual loss by 50% or more. Background or mild nonproliferative retinopathy should be followed by a further digital retinal imaging at 16 to 20 weeks. With a normal retina in early pregnancy, the second assessment can be deferred to 28 weeks' gestation.[78]

There is a particular concern about the risk of visual loss if diabetic macular edema is detected, and in nonpregnant randomized, controlled studies, photocoagulation is associated with a reduced risk of visual loss from 24% to 12% at 3-year follow-up. No such study has been reported in pregnancy, but it seems likely that the ophthalmologist would wish to consider urgent treatment of macular edema, should it be detected.

DIABETIC NEPHROPATHY

Renal function should be assessed not only prepregnancy but also as early as possible during pregnancy. Diabetic nephropathy is classified as

- Stage 1: microalbuminuria (albumin-to-creatinine ratio ≥3.5 mg/mmol).
- Stage 2: macroalbuminuria (albumin-to-creatinine ratio ≥ 30 mg/mmol) or urinary albumin concentration of 200 mg/L or more.
- Stage 3: end-stage renal disease.

Early consultation with a nephrologist is indicated if the serum creatinine is above 120 μmol/L or urinary protein excretion exceeds 2g/day.

A systematic review of progression and development of nephropathy showed that for most women, pregnancy was not associated with either an increased incidence or a deterioration in mild nephropathy, but some women with moderate or advanced nephropathy may progress to end-stage renal disease during the pregnancy.[79] When nephropathy is present throughout pregnancy, intrauterine growth retardation, chronic hypertension, preeclampsia, and preterm birth are all more common and appropriate maternal and fetal surveillance should be undertaken during the pregnancy. Pharmacologic treatment of nephropathy with ACE inhibitors is generally contraindicated in pregnancy (see earlier) but should be recommended after the completion of the pregnancy.

SCREENING FOR CONGENITAL MALFORMATIONS

The NICE Antenatal Guideline[54] currently recommends that all women should be offered first-trimester screening for Down syndrome. The combined nuchal translucency test (nuchal translucency, free β-human chorionic gonadotrophin [β-hCG], and pregnancy-associated plasma protein A [PAPP-A] is the test of choice). Levels of free β-hCG and PAPP-A have been found to be unaffected by diabetes in pregnancy.[80] As a result, the detection rate and screen-positive rates remain 80% and 5% for the combined nuchal translucency test for pregnancy with diabetes.

Increased nuchal translucency thickness (>3.5 mm) is associated with an increased risk of cardiac anomalies in chromosomally normal fetuses. A first-trimester nuchal translucency thickness of greater than 4.5 mm has been reported to be associated with a 15-fold increased risk of congenital cardiac disease. These findings may prove selective fetal echocardiography for women with diabetes and increased nuchal translucency thickness to be a more cost-effective approach.

Diabetes in pregnancy is associated with an increased risk of NTDs.[3] There is an association between maternal serum α-fetoprotein (AFP) and NTD, however, the weighted-corrected median multiple-of the mean value is lower in pregnancies affected with preexisting diabetes than in pregnancy not complicated by diabetes.[81] In practice, many consider that there is no benefit from maternal AFP screening in women with diabetes if routine 20-week anomaly screening is in place.[17,82]

Ultrasound screening for fetal anomaly should be routinely offered between 18 and 21 weeks' gestation.[56] A comprehensive ultrasound examination is of paramount importance given the increased risk of congenital anomaly. A cohort study compared 130 women with diabetes (85 type 1 diabetes, 45 type 2 diabetes) with 12,169 low risk pregnant women over the same period.[15] All women had a routine ultrasound scan at 16 to 24 weeks' gestation. Ten major anomalies (7.7%) were present in fetuses of women with diabetes compared with 1.4% in nondiabetic women. Ultrasound antenatal detection of the fetal abnormality was significantly lower in women with diabetes compared with the low risk group (42% vs. 86%). An increased BMI was responsible for 35% of the ultrasound scans performed in women with diabetes being considered suboptimal. Of the 7 major

congenital anomalies missed by antenatal ultrasound, 3 were abnormalities of the cardiovascular system. This does raise the question of whether routine fetal echocardiography is warranted in the diabetic population. Most of the common cardiac defects seen in diabetic pregnancy are of conotruncal or septal origin.[83–85] As such, a standard four-chamber view including the two ventricular outflow tracks should detect the majority of cardiac abnormalities. Smith and colleagues[86] reported a detection rate of major congenital cardiac abnormalities of 82% using the four-chamber view and outflow track ultrasound views. They concluded there was no benefit in universal fetal echocardiography in women with diabetes if a comprehensive anatomic ultrasound survey, which included four-chamber and outflow tracks, was reported as normal.

A cost-effectiveness analysis of fetal echocardiography screening of pregnant diabetic women demonstrated an increased detection rate of cardiac abnormalities using fetal echocardiography compared with standard comprehensive ultrasound. Selective fetal echocardiography after an abnormal detailed comprehensive anatomic survey was more cost-effective than a policy of universal fetal echocardiography screening of women with diabetes of pregnancy. Fetal echocardiography should be restricted to those women with diabetes who had increased nuchal translucency in the first trimester or either have a cardiac anomaly suspected at routine fetal anatomic survey ultrasound scan or when cardiac views are restricted by increased body fat and confirmation of normal cardiac structure cannot be made.

MONITORING FETAL GROWTH AND WELL-BEING
(See Also Chapters 10 and 11)

Excessive birth weight is defined as either large for gestational age (LGA) or fetal macrosomia. Large for gestational age relates to a birth weight equal to or greater than the 90th percentile for gestational age. A macrosomic fetus is, however, variously defined as a birth weight greater than either 4 kg or 4.5 kg regardless of gestational age. This is recognized clinically by a disproportionate increase in abdominal circumference on ultrasound (see later). Excessive fetal growth is associated with increased maternal and infant morbidity. Shoulder dystocia rates and subsequent brachial plexus injuries are increased as are fetal asphyxia, operative deliveries, and the incidence of postpartum hemorrhage.

Ultrasound prediction of fetal weight in pregnancy in diabetes is inaccurate and sometimes technically difficult. Accuracy of fetal weight estimation decreases with increasing birth weight, a fact compounded in women with both obesity and diabetes.[87,88] A comparison was made between a single biometric measurement, abdominal circumference greater than 36 cm, and fetal weight estimation using multiple standard ultrasound biometry measurements in predicting birth weight greater than 4 kg (estimated fetal weight [EFW]).[89] There was no difference in accuracy between EFW and abdominal circumference in the prediction of macrosomia at birth likelihood ration (LR) 5.7 (95% CI 4.3–7.6) and LR 6.9 (95% CI 5.2–9.0), respectively. This demonstrates that both a single abdominal circumference measurement and an EFW are only moderately predictive of birth weight.

Examination of neonates of women with diabetes clearly shows that these infants have different anthropometric features than macrosomic babies of nondiabetic women. The phenotypic features are a result of excess growth in the insulin-sensitive tissues such as liver, bone, and abdominal and subcutaneous fat. Perhaps because of the distortion of normal body composition parameters, prediction of fetal weight by ultrasound in pregnancies in diabetes underestimates fetal weight by more than 15% of true birth weight in a quarter of cases compared with only 5.4% in nondiabetic women.[87] The measured parameters in standard formulas for EFW are less accurate in pregnancy in diabetes often underestimating but sometimes overestimating true fetal weight.[87,90]

Fetal subcutaneous fat layers, three-dimensional upper arm volumes, fetal liver volumes, and cheek-to-cheek measurements have all been compared with standard ultrasound biometry in the prediction of macrosomia in diabetes and have, in small studies, been found to be perform well when compared with abdominal circumference or EFW.

It is important to note that infants of mothers with diabetes have an accelerated growth pattern unless coexisting vasculopathy complicates the pregnancy.[91] Management of such a pregnancy would deviate from standard protocols for diabetic pregnancy and involve fetal heart rate monitoring, umbilical and middle cerebral Doppler velocimetry, and biophysical profile (BPP) testing owing to the increased fetal risk.

The NICE Guideline on Diabetes in Pregnancy[56] recommends that fetal growth is assessed on a 4-weekly basis from 28 to 36 weeks' gestation. This would seem a reasonable proposal; however, one would advise that interpretation of any ultrasound scan in a women with diabetes is carefully made. Evidence of disproportion between the measurements may indicate truncal adiposity. The EFW is likely to be underestimated, and the presence of a macrosomic fetus and polyhydramnios may reflect a hyperinsulinemic fetus with the greatest risk of late stillbirth.

Pregnancy in diabetes complicated by vascular disease appears to confer the greatest risk of uteroplacental insufficiency and subsequent fetal intrauterine growth restriction (IUGR) and its sequelae. Antenatal surveillance of fetal well-being in this group of women is likely to have a favorable effect on perinatal outcome, and management of such pregnancies would follow strategies similar to those for fetal IUGR in nondiabetic pregnancies. Those women with pre-existing diabetes, no vascular complications, and good maternal glycemic control rarely have fetal compromise and are, therefore, unlikely to benefit from a policy of universal antenatal surveillance using fetal well-being protocols.

Antenatal fetal surveillance of high risk pregnancy is usually performed using a combination of fetal heart rate monitoring, BPP testing, and umbilical artery Doppler velocimetry. Each method has been independently found to be predictive of fetal compromise in high risk pregnancy groups. However, whether the tests are equally predictive in pregnancies with diabetes is questionable.

Umbilical artery Doppler velocimetry is an indirect measure of placental flow resistance. An abnormal umbilical Doppler result is usually associated with chronic placental insufficiency typically associated with preeclampsia and IUGR. The use of umbilical artery Doppler velocimetry in high risk pregnancies has demonstrated a significant reduction in cesarean section for fetal distress and resulted in a nonsignificant trend in reducing perinatal mortality in high

risk women.[92] An abnormal umbilical artery Doppler does appear to predict fetal compromise in pregnancy complicated by diabetes if there is coexisting diabetic vasculopathy, hypertension, or IUGR.[93] The absence of these comorbidities does significantly reduce the effectiveness of umbilical artery Doppler in predicting adverse fetal outcome in these women.

The BPP is an ultrasound assessment of fetal well-being that incorporates fetal movements, fetal tone, fetal breathing movements, and liquor volume. It is a time-consuming test but does have a role in the antenatal assessment of high risk pregnancy. The role of the BPP test in antenatal surveillance of pregnancy complicated by diabetes is controversial because the test has been shown to be a poor predictor of adverse pregnancy outcome.[94] A normal test result, however, is usually thought to be reassuring of fetal well-being.[95]

A rise in maternal glucose levels is known to stimulate fetal breathing movements, contributing to a positive score for one of the components of the BPP. In addition, maternal diabetes is often associated with increased amniotic fluid, again a positive score in the BPP. It is, therefore, easy to see why the role of the BPP is controversial because two of the five tests of fetal well-being are influenced positively simply by having diabetes in pregnancy.

Brasero and associates[96] compared the ability of the BPP, the cardiotocogram (CTG), and the assessment of umbilical artery Doppler in pregnancies complicated by diabetes to predict adverse outcome. Adverse outcome was categorized as cesarean section for fetal distress, hypocalcemia, hypoglycemia, hyperbilirubinemia, fetal respiratory distress, and/or preterm delivery under 37 weeks. The relative risk was 1.7 for both the BPP and the fetal heart rate pattern. Umbilical artery Doppler velocimetry had a relative risk of 2.6 in predicting one of the composite outcomes. As is often a problem with such studies, perinatal mortality is low, there were no stillbirths in this series, and therefore, the ability to predict perinatal mortality remains unknown.

Given the paucity of good randomized, controlled studies on assessment of fetal well-being in pregnancies with diabetes, a pragmatic approach to monitoring these fetuses must be taken. The presence of either diabetic vasculopathy, hypertensive disease, or the identification of a growth-restricted fetus should trigger comprehensive fetal surveillance, the frequency of which will be determined by the severity of the underlying comorbidity. In those women with well-controlled diabetes and no additional obstetric risk factors, the value of antenatal fetal well-being testing is questionable because it will not improve the already good outcome in these pregnancies. If delivery beyond 38 weeks is anticipated, however, then despite the absence of good-quality evidence, weekly tests including CTG, umbilical artery Doppler, and possibly BPPs would seem appropriate.

ANTENATAL CARE SCHEDULES IN MATERNAL DIABETES

The pattern of antenatal care offered to women with diabetes in pregnancy should incorporate appointment times and investigations that would be applicable to all pregnant women as stipulated by the recent NICE Diabetes in Pregnancy Guideline.[56] The relevant flowcharts are shown in Table 44–7. The number of additional antenatal units

TABLE 44–7

Specific Antenatal Care for Women with Diabetes

APPOINTMENT	CARE FOR WOMEN WITH DIABETES DURING PREGNANCY*
First appointment (joint diabetes and antenatal clinic)	Offer information, advice, and support in relation to optimizing glycemic control. Take a clinical history to establish the extent of diabetes-related complications. Review medications for diabetes and its complications. Offer retinal and/or renal assessment if these have not been undertaken in the previous 12 mo.
7–9 wk	Confirm viability of pregnancy and gestational age.
Booking appointment (ideally by 10 wk)	Discuss information, education, and advice about how diabetes will affect the pregnancy, birth, and early parenting (such as breast-feeding and initial care of the baby).
16 wk	Offer retinal assessment at 16–20 wk to women with preexisting diabetes who showed signs of diabetic retinopathy at the first antenatal appointment.
20 wk	Offer four-chamber view of the fetal heart and outflow tracts plus scans that would be offered at 18–20 wk as part of routine antenatal care.
28 wk	Offer ultrasound monitoring of fetal growth and amniotic fluid volume. Offer retinal assessment to women with preexisting diabetes who showed no diabetic retinopathy at their first antenatal clinic visit.
32 wk	Offer ultrasound monitoring of fetal growth and amniotic fluid volume.
36 wk	Offer ultrasound monitoring of fetal growth and amniotic fluid volume. Offer information and advice about: • Timing, mode and management of birth. • Analgesia and anesthesia. • Changes to hypoglycemic therapy during and after birth. • Management of the baby after birth. • Initiation of breast-feeding and the effect of breast-feeding on glycemic control. • Contraception and follow-up.
38 wk	Offer induction of labor, or cesarean section if indicated, and start regular tests of fetal well-being for women with diabetes who are awaiting spontaneous labor.
39 wk	Offer tests of fetal well-being.
40 wk	Offer tests of fetal well-being.
41 wk	Offer tests of fetal well-being.

* Women with diabetes should also receive routine care according to the schedule of appointments in reference 54, including appointments at 25 wk (for nulliparous women) and 34 wk, but with the exception of the appointment for nulliparous women at 31 wk.

From National Collaborating Centre for Women's and Children's Health: Diabetes in Pregnancy. London, RCOG Press, 2008.

required would be based on whether the diabetes was pre-existing or gestational.

For preexisting diabetes, it would be anticipated that the woman would attend for preconception advice and counseling. Information would be imparted on the type of care she would receive within the joint care diabetes clinic and would be given education and advice in relation to achieving optimal glycemic control. If the woman has not attended for preconception advice, this information should be given at the first hospital visit. Clinical history and investigations would establish the extent of diabetes-related complications such as neuropathy and vascular disease. Retinal assessment would be recommended at this time if this has not been performed in the preceding 12 months. Additional retinal assessment would be required between 16 and 20 weeks if diabetic retinopathy had been present at the time of the booking assessment. In the absence of prepregnancy or booking retinopathy, further assessment is indicated at 28 weeks' gestation.

At 20 weeks' gestation, ultrasound anatomic examination of the fetus should be performed and include a four-chamber view of the heart and outflow tracks. Thereafter, serial assessment of fetal growth and amniotic volume should take place at 28, 32, and 36 weeks' gestation. Following the 36-week ultrasound scan, information and advice with regard to timing and mode of delivery and management of labor and birth should be discussed. At 38 weeks' gestation, delivery, whether by induction of labor or cesarean section if indicated, should be offered to all women with diabetes in pregnancy (see below). If the decision is made to await spontaneous labor, weekly assessment of fetal well-being should be performed. Those women who have been diagnosed with GDM as a result of routine antenatal screening should also be offered serial fetal growth and amniotic fluid volume assessment at 28, 32, and 36 weeks.

PRETERM LABOR MANAGEMENT AND OUTCOMES

The etiology and management of preterm labor is discussed in detail in Chapter 61. There is an increased risk of spontaneous preterm birth in diabetes, however, that may be inversely proportional to the quality of maternal diabetic control and the corresponding frequency of polyhydramnios. There is some evidence in women free of diabetes that the preterm birth rate goes up with mean HbA_{1c}.[97] If tocolytic agents are being considered for use in women with diabetes, β-minetics should be avoided because they have an acute hyperglycemic effect and can provoke DKA in type 1 diabetes. When preterm delivery is anticipated, antenatal steroids, usually in the form of betamethasone injections, 12 mg intramuscularly, repeated after 24 hours, can be administered. Glucocorticoids cause insulin resistance and hyperglycemia, and the inadequately supervised use of these drugs has been associated in some cases with hyperglycemia and even DKA. To avoid this in women with type 1 diabetes, one group recommended that daily insulin doses should be increased by enhancement of their existing regimes as follows[98]:

Day 1 Insulin dose increased by 25%.
Day 2 Insulin dose increased by 40%.

Day 3 Insulin dose increased by 40%.
Day 4 Insulin dose increased by 20%.
Day 5 Insulin dose increased by 10%.
Day 6 Return to previous insulin doses.
Alternative approaches to managing the steroid induced relative hyperglycemia include

- Titration of intermittent subcutaneous short-acting insulin on a sliding scale based on 4-hourly glucose values.
- Titration of an intravenous insulin infusion on a sliding scale based on 4-hourly glucose values. This may be of value particularly in those who may not be eating normally because of abdominal pain or uterine contractions and when delivery may be imminent.

Elective or spontaneous preterm birth of an infant of a mother with diabetes should wherever possible be in a unit with neonatal intensive care facilities. There should be joint consultation with neonatal pediatricians because of the potential neonatal complications.

Labor and Delivery
TIMING AND MODE OF DELIVERY

In pregnancy complicated by diabetes, timing of delivery presents a challenge. Elective delivery by induction of labor or cesarean section after 37 completed weeks has the potential advantage of reducing the risk of shoulder dystocia secondary to macrosomia and the risk of mature stillbirth. Twenty-seven percent of nonmalformed stillbirths in women with preexisting diabetes in the CEMACH data[3] occurred after 37 completed weeks, when it might be assumed that had the baby been born alive, it would have been a healthy survivor. Against the apparent advantages of early elective delivery are the relatively high cesarean section rates that are often associated with a diagnosis of failed induction of labor and the relatively high incidence of respiratory difficulty, including RDS, in the newborn because of pulmonary immaturity that is often associated with fetal hyperinsulinemia.

Only one randomized, controlled trial of expectant management has been performed in 200 women the majority of whom had insulin-treated GDM.[99] They were randomized to active management, which consisted of induction of labor in the 38th week of gestation, or expectant management, which consisted of weekly physical examination, twice-weekly CTG, and weekly ultrasound estimates of amniotic fluid volume. The expectant group had a doubling of the rate of spontaneous labor (44% vs. 22%), but they also had a doubling of babies born above the 90th percentile for gestational age (23% vs. 10%). The expected endpoint of a reduction in cesarean section rate was not obtained (31% vs. 25%). There were three cases of mild shoulder dystocia, all of which occurred in the expectantly managed group.[99]

One further randomized, controlled trial was undertaken in 273 women with an ultrasound estimate of fetal macrosomia (4.0–4.5 kg), but this was performed in nondiabetic women.[100] The rates of mode of birth were almost identical in the induced and the expectant groups, the mean birth weights were 4.06 versus 4.13 kg, and there were 5 cases of shoulder dystocia in the induced group and 6 in

the expectant group.[100] The relevance of this study to management of women with diabetes may be questioned because of the increased risk of shoulder dystocia associated with the disproportionate growth seen in macrosomia in the hyperinsulinemic fetus of the mother with diabetes. Many authorities would opt for elective cesarean section when an ultrasound EFW exceeds 4.5 kg, not least because current methods of EFW are likely to overestimate the weight of the hypertrophic fetus (see "Prenatal Care" section, earlier). It is the case, however, that this policy has not been subject to any randomized, controlled trial. A small number of case series and cohort studies would suggest that vaginal birth after cesarean section is often successful in the absence of antenatally diagnosed fetal macrosomia.

ANALGESIA AND ANESTHESIA (See Also Chapter 70)

There are limited data on the risks and benefits of various methods of analgesia and anesthesia available for labor and delivery, but all commonly used modalities appear to be suitable for women with diabetes. Obesity in type 2 diabetes and GDM may introduce its own complications for both the anesthetist and the obstetrician, and joint consultation with the anesthetist in the antenatal period for women with a high BMI above 35 might be considered worthwhile.

GLYCEMIC CONTROL IN LABOR OR FOR CESAREAN SECTION

On the day of labor and/or delivery for most women, their usual approach to glycemic control will have to be replaced to allow flexibility in calorie intake for the demands of labor, to maintain nil by mouth for those going for elective, or potentially for emergency, cesarean section, and finally to maintain glycemia in a range that minimizes neonatal hypoglycemia.

A reasonable approach is to aim to maintain the plasma glucose level in the physiologic range (between 4 and 7 mmol/L), and in particular in women with type 1 diabetes, an adequate insulin regime must accompany oral or intravenous feeding. Common practice would be to secure the maintenance of blood glucose within the physiologic range in spontaneous or induced labor or on the day of elective cesarean section by a balanced regime of intravenous dextrose and insulin such as the one in Table 44–8.[101] There should be a flexible approach to the way euglycemia is achieved in labor, however, and some women will choose to continue CSII throughout labor if they have been used to this technique for insulin replacement; others will be able to maintain their glycemic targets with intermittent subcutaneous injections of short-acting insulin. These latter two approaches may have some advantages for the woman in terms of mobility and the adoption of more comfortable positions in labor. As a general guide, women who have not required insulin during the pregnancy for type 2 or GDM and those women whose insulin dose has totaled less than 20 U/day will often maintain their blood glucose levels

---

within the physiologic range without resorting to an intravenous dextrose and insulin regimen.

MODE OF DELIVERY

For women in whom the intravenous dextrose insulin regimen is indicated, this can be commenced as soon as the diagnosis of labor is confirmed. For those women in whom induction of labor is planned, a satisfactory regimen on the morning of induction after any treatment required for cervical favorability the previous evening is to allow a light breakfast accompanied by the normal dose of short-acting insulin but to omit any morning dose of intermediate- or long-acting insulin. The intravenous dextrose and insulin regime can be commenced after induced labor has been established.

For those women who are to have an elective cesarean section in type 1 diabetes, it is recommended that the intravenous dextrose and insulin regimen be commenced in the morning of surgery and maintained until the postoperative woman is able to eat and drink normally. At this time, insulin can be recommenced based on either the prepregnancy doses of insulin or the woman's self-direction if she has been trained on a DAFNE course or similar regimen.

For those with type 2 or GDM having elective cesarean section, preoperative blood glucose may be checked and, if it is within the physiologic range, most women will be able to have the surgical procedure without the need for intravenous dextrose or insulin, although obviously it is sensible to retain this as an option and in particular to consider it for women whose return to normal eating and drinking postsurgery is delayed for any reason.

NEONATAL HYPOGLYCEMIA AND MATERNAL GLYCEMIA IN LABOR

The newborn infant of the mother with diabetes complicating pregnancy is at risk of potentially harmful hypoglycemia in the newborn period as a result of three mechanisms, only one of which is modifiable. The two unmodifiable ones are, first, that the newborn who had hyperinsulinemia established in fetal life may in the first 24 or 48 hours of neonatal existence have persisting autonomous increased secretion of insulin unmatched by oral calorie intake. Second, it has now been established that because amylin is cosecreted with insulin and is a potent cause of delay in gastric emptying, the hyperinsulinemic newborn may be unable to maintain its blood glucose despite an apparently adequate calorie intake (often with an increased glucose component).[23] For these reasons, a significant minority of newborn infants will require transfer to a neonatal care unit for intravenous dextrose feeding to bypass the gastrointestinal tract. The third mechanism for neonatal hyperglycemia is in the fetus who is not necessarily severely hyperinsulinemic but who has β cells sensitive to transplacental glucose infusion, and relative maternal hyperglycemia in labor can provoke transient neonatal hypoglycemia that may be severe. Several observational studies have been published typically showing that neonatal hypoglycemia is seen in about 30% to 50% of the infants of mothers whose blood glucose was 7 mmol/L or more in the hours prior to delivery compared with rates between 0% and 20% in those in which maternal blood glucose was maintained between 4 and 7 mmol/L in the hours prior to birth.[102] In addition to this, two uncontrolled prospective studies suggest that fetal distress in labor and perinatal asphyxia are more common with a mean blood glucose in labor above 7 mmol/L.[103,104]

Postnatal

MATERNAL POSTNATAL CARE IN RELATION TO TYPE OF DIABETES

Following delivery, insulin requirements fall immediately in both women with preexisting and those with GDM. Women with insulin-treated preexisting diabetes should reduce their insulin immediately after birth to near prepregnancy levels and monitor their blood glucose levels carefully to establish the appropriate dose. The immediate postnatal period is a time of increased risk of hypoglycemia, especially when breast-feeding, and women with insulin-treated preexisting diabetes should be advised to have a meal or snack available before or during feeds. Those women with preexisting type 2 diabetes should resume or continue with their oral hypoglycemic medication. However, if breast-feeding, only metformin and glibenclamide should be considered suitable.

In those women with GDM, a small subgroup will have persisting hyperglycemia postnatally and be subsequently diagnosed to have type 2 diabetes. In a New Zealand population, 13% of women with GDM was subsequently found to have type 2 diabetes on postnatal glucose tolerance testing.[2] Following delivery in women with GDM, insulin

therapy and oral hypoglycemic agents should be discontinued and blood glucose monitoring extended into the immediate postnatal period. Those with persisting hyperglycemia and newly diagnosed diabetes would then be identified and referred to the diabetes team for consideration of subsequent management. For the majority of women whose blood glucose levels are normal, monitoring can discontinue and a fasting plasma glucose measurement offered at a 6-week postnatal check.

All women with diabetes in pregnancy should, prior to discharge, be reminded of the importance of contraception and the need for preconception care when planning future pregnancies.

Women who develop GDM have a lifetime risk of developing type 2 diabetes of approximately 40%.[105] All women should, therefore, be advised of the symptoms of hyperglycemia and offered lifestyle advice that includes weight control, diet, and exercise in order to reduce this risk of developing type 2 diabetes. It is important that an annual fasting glucose test is performed to enable prompt detection of diabetes and early management to reduce longer-term associated morbidity.

Those with GDM should be informed of the risks of GDM in future pregnancies and should be offered a fasting plasma glucose or OGTT to exclude diabetes when planning future pregnancies.

NEONATAL CARE OF THE INFANT OF THE MOTHER WITH DIABETES

The more common neonatal complications are RDS and neonatal hypoglycemia, necessitating careful supervision of the infant of the mother with diabetes. Other complications, particularly in the macroscomic hyperinsulinemic infant, include cardiomyopathy, hypocalcemia, hypomagnesemia, polycythemia, hyperbilirubinemia, and hyperviscosity. Women with diabetes should not be delivered in obstetric units where there are no facilities for neonatal intensive care. Although routine admission to the neonatal unit is not required, these mothers and babies must be admitted to a transitional care unit or similar facility in which monitoring of the newborn is of high quality.

Breast-feeding should be encouraged in women with diabetes, and there is no indication that the quality of milk is significantly different in women with diabetes than in those who do not have this disorder. Because early feeding may be indicated to prevent neonatal hypoglycemia, women with diabetes may consider banking colostrum in the antenatal period, but in many cases, formula feeding may be required to manage hypoglycemia in the short term in the newborn period to avoid the need for neonatal unit admission and intravenous dextrose. Neonatal hypoglycemia should be tested for either in the laboratory, or in a laboratory-certified bedside method that is accurate in the severe hypoglycemia range. Testing should be commenced at approximately 3 hours of age and a level below 2.0 mmol/L should lead to the encouragement of early oral feeding or tube feeding. Intravenous dextrose should be withheld in the absence of clinical signs of hypoglycemia, or a falling level 1 hour after a recording of 2.0 mmol/L or less to 1.4 mmol/L or less.

SUMMARY OF MANAGEMENT OPTIONS
Diabetes

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Advise all women with diabetes in the reproductive years about the benefits of prepregnancy planning.	III/B	45,46
Screen for complications of diabetes and review therapeutic options.	IV/C	77
Target prepregnancy HbA$_{1C}$ level at 6.1% to reduce rate of structural malformation.	Ib/A	13,42
Refer for DAFNE or alternative structured education programs.	Ib/A	43,44
Commence folic acid supplements.	IV/C	4,56
Switch to short-acting insulin analogues/consider CSII to improve prepregnancy glycemic control.	Ib/A	68
Continue contraception if HbA$_{1C}$ >10%.	III/B	42
Recognize risks of complications of hypoglycemia from intensified regime and provide appropriate emergency treatments.	III/B	45
Continue oral hypoglycemic regimes with short-acting sulfonylureas/metformin if judged effective.	III/B	72,73
Discontinue potentially teratogenic drugs used for complications of diabetes.	III/B	48,49
Prenatal		
Screen for GDM universally or according to expected prevalence within geographic areas or by ethnic and age groups.	Ia/A	25,26
Enroll cases of GDM in joint diabetes/antenatal clinic, commence fetal growth monitoring.	Ia/A	25,26
Treat GDM unresponsive to diet by glycemic criteria with insulin or glibenclamide.	Ib/A	58,75
Refer women with preexisting diabetes to calorie counting/DAFNE course as early as possible in pregnancy—if not previously attended.	Ib/A	43
Advise target-orientated therapy, based on fasting and 1-hr postprandial levels.	Ib/A	57,58
Use CGMS intermittently if available.	Ib/A	60
Advise about management of hypoglycemia and supply hypostop/glucagon for those at risk.	GPP	—
Advise women how to suspect early DKA and how to self-monitor for ketonemia or ketonuria.	GPP	—
Arrange admission of any pregnant woman suspected of DKA to high dependency unit, and maintain unit protocol for management.	GPP	—
Offer antenatal care through a multidisciplinary clinic.	GPP	—
Arrange dilated retinal photography as soon as referred with pregnancy and preexisting diabetes. Arrange follow-up retinal scans based on initial findings.	—/GPP	—
Measure albuminuria and refer to nephrology if serum creatinine > 120 µmol/L.	III/B	79
Offer first-trimester screening for Down syndrome if requested.	GPP	
Arrange anatomy scan at 18–21 wk.	GPP	
Include cardiac outflow tracts in anatomy scan.	III/B	86
Refer for fetal echocardiography selectively.	III/B	86
Scan for fetal growth and amniotic fluid index at 4-wk intervals from 26 wk' gestation.	GPP	

Management Options	Evidence Quality and Recommendation	References
Review and intensify hypoglycemic (insulin) regime if incipient macrosomia.	GPP	
Initiate tests of fetal well-being if IUGR is diagnosed.	GPP	
Offer induction of labor/elective CS if indicated after 37 completed wk' gestation.	Ib/A	99
Monitor fetal well-being weekly in women who wish to continue their pregnancy beyond 38 wk.	Ib/A	99
Avoid β-sympathomimetics in preterm labor	GPP	
Establish in-house protocols for insulin dose increases when administering maternal steroids.	GPP	
Elective preterm birth in maternal diabetes should be in a unit with neonatal ICU facilities.	GPP	
Labor and Delivery		
Maintain plasma glucose levels between 4.0 and 7.0 mmol/L in labor and during elective or emergency CS.	III/B	102
Monitor newborn infant for evidence of respiratory distress and/or clinical or biochemical hypoglycemia.	GPP	
Postnatal		
Return women with preexisting diabetes to their prepregnancy insulin/hypoglycemic therapy.	GPP	
Discontinue hypoglycemic therapy in women with GDM, and monitor blood glucose levels for evidence of newly diagnosed type 2 diabetes.	GPP	
Offer contraceptive advice.	GPP	
Check fasting plasma glucose at 6 wk postdelivery and annually to exclude a new diagnosis of type 2 diabetes.	III/B	105

CS, cesarean section; CSII, continuous subcutaneous insulin infusion; CGMS, continuous glucose monitoring system; DAFNE, dose adjustment for normal eating; DKA, diabetic ketoacidosis; GDM, gestational diabetes mellitus; GPP, good practice point; HbA$_{1c}$, hemoglobin A$_{1c}$; IUGR, intrauterine growth restriction.

Thyroid Disease

ANNA P. KENYON and CATHERINE NELSON-PIERCY

Thyroid disease is the second most common cause of endocrine dysfunction in women of childbearing age (diabetes is the first). It can often be challenging to diagnose and manage because many of the symptoms of the disease are common symptoms in pregnancy. Physiologic changes in the serum levels of pituitary and thyroid hormones may hamper diagnosis, and a clear understanding of these changes is needed when managing those women with suspected or known thyroid disease.

The thyroid gland is a bilobed gland composed of spherical follicles. A follicle comprises a colloid center surrounded by a single layer of follicle cells. Intimately involved with follicle cells are parafollicular C cells, lymphatic drainage channels, and capillary networks.

Iodide ions are actively transported from the blood into the apical surface of follicle cells and, via the action of thyroid peroxidase (TPO), are oxidized to iodine. The thyroid regulates the amount of iodide it actively traps and is able to withstand fluctuations in dietary supply. In the lumen, (colloid) iodide is incorporated into the tyrosine residues of thyroglobulin (also made in the follicle cells) to produce inactive monoiodotyrosine and diiodotyrosine. This process is termed the *organification* of iodide. Combinations of these products result in formation of the active thyroid compounds thyroxine (T_4) and triiodothyronine (T_3), which are released into the capillary network at the apical surface of follicle cells after reentering from the colloid at their basal surface (endocytosis).

Production is controlled by the hypothalamus-pituitary-thyroid axis. Thyroid-releasing hormone (TRH) is released from the hypothalamus, and thyroid-stimulating hormone (TSH) from the anterior pituitary. TSH is a glycoprotein with α- and β-subunits. Many anterior pituitary hormones share the α-subunits, but the β-subunit is unique. TSH has many actions, one of which is to increase release of T_4 and T_3 via increased iodide transport into follicular cells, organification and release of thyroglobulin into the follicular lumen, and endocytosis of colloid.

More T_4 than T_3 is produced by the thyroid gland, but T_4 is converted in some peripheral tissues (liver, kidney, and muscle) to the more potent T_3.

In the plasma, more than 99% of all T_3 and T_4 is carrier protein–bound to thyroid-binding globulin (TBG), albumen, and transthyretin (previously known as thyroid-binding pre-albumen). TBG has the highest affinity for T_3 and T_4, so although it is present in the lowest concentration, 75% of all thyroid hormones are bound to it. Only the free hormones (free T_4 and free T_3) are biologically active (0.04% of total T_4 and 0.5% total T_3). Pregnancy results in a rise in TBG (and transthyretin) via the effects of estrogen favoring increased synthesis but also decreased clearance. The elevation is present at 2 weeks' gestation and peaks at 20 weeks' gestation.[1] Because only the free hormone is biologically active, only free hormone measurements should be used in pregnancy.

Pregnancy is a state of relative iodine deficiency secondary to an increase in renal loss (increased glomerular filtration rate in the early first trimester) and transfer of iodine to the developing fetus. In order to compensate, the thyroid gland increases its uptake of iodine from the blood, and if this is lacking, cellular hyperplasia and goiter will result. It is suggested that, although a physiologic goiter may be seen on ultrasound examination by a change in gland size of up to 10% to 20%, this is not clinically detectable. If apparent clinically, it suggests iodine deficiency or pathology.[1]

Fetal thyroid disorders are discussed in Chapter 21.

THYROID-STIMULATING HORMONE CHANGES IN PREGNANCY

Human chorionic gonadotrophin (hCG) and TSH share a common α-subunit and their β-subunits share some similarities, as do their receptors. The rise in hCG of early pregnancy is thought to "spill over" and stimulate the TSH receptor, causing a suppression of TSH (and a rise in T_4). The longitudinal study by De Geyter and coworkers[2] of 18 women attending for infertility investigations preconception suggested that in very early pregnancy, TSH was present in rising concentrations peaking at week 6 with levels declining thereafter. In contrast, serum hCG levels increased progressively to weeks 9 to 12[2,3] with stable levels thereafter[2]; however, free T_4 and T_3 remained unchanged during the whole sampling period.[2]

A large American study of 9562 women attending antenatal screening for aneuploidy with paired samples in the first and second trimesters confirmed TSH levels to be lower and to show greater variability in the first trimester than in the second. The median first-trimester TSH (1.05 mIU/L) was lower than in the second trimester (1.23 mIU/L) and the

98th percentile was higher (4.15 mIU/L vs. 3.77 mIU/L). The variance (spread) of TSH values was greater at 10 to 13 weeks than at 15 to 18 weeks at both the lower and the upper extremes of the distribution. Of those with TSH above the 98th percentile in the first trimester, 68% had second-trimester values over the 95th percentile,[3] suggesting that in some, the relative rise was sustained. In 2004, Haddow and colleagues[4] studied 1126 pregnant women and confirmed lower median TSH in the first trimester (1.00 mIU/L vs. 1.29 mIU/L) but a higher 98th percentile (5.20 mIU/L vs. 4.18 mIU/L). A Scandinavian longitudinal study of 52 normal pregnancies confirmed that in weeks 7 to 17, the lower limit of normal (2.5th percentile; and 95% confidence interval [CI]) for TSH was 0.09 (0.00–0.26) rising to 0.78 (0.52–1.04) and the upper limit (97.5th percentile; and 95th CI) was 3.39 (3.02–3.76).[5]

A recent longitudinal study of a U.K. general antenatal population (307 women) demonstrated that for TSH, the range is broader and higher than outside pregnancy. In addition, the median expected value rises throughout pregnancy.[6] Thus, it seems that after an initial rise in TSH, concentrations fall to a nadir at week 12 and thereafter rise with advancing gestation; however, the normal range in the first trimester remains wide (Table 45–1).

THYROXINE LEVELS IN PREGNANCY

The elevated concentrations of hCG of early pregnancy "spill over" and stimulate the TSH receptor resulting in a rise in T_4 in early pregnancy. This may have the advantage of providing the fetus with T_4 before it becomes autonomous. The rise in TBG necessitates a small rise in production of T_4 (1%–3%) and T_3 until a plateau level is reached when hCG levels are maximal. In addition, there is enhanced peripheral conversion of free T_4 to free T_3, and it has been suggested that this increased efficiency may be in preparation for the exertions of labor and delivery.[7] Lambert-Messerlian and associates[8] confirmed that free T_4 concentrations are higher in the first trimester than in the second at all percentiles ($P < .001$). In contrast to TSH, however, the within-person correlation of T_4 between trimesters is weak. The previously cited study in the U.K. general antenatal population (307 women) reported that compared with levels outside pregnancy, free T_4 has a narrower and lower range and falls throughout pregnancy and free T_3 has a broader and higher range, falling through most of gestation to a nadir at 30 weeks and 5 days; then the upper end of the range increases and the lower end of the range reduces to term.[6] Thus, T_4 concentrations appear to be highest in the first trimester (but still lower than nonpregnant values) and fall with rising gestational age.

Table 45–1 shows normal values for thyroid function tests throughout pregnancy. Whereas the literature is useful in identifying trends, the reference ranges cited are not easily translated into meaningful values to guide clinical practice. Older free hormone[6] or TSH assays may be less accurate and values may vary between laboratories.[3] The studies use differing sample sizes, populations of different ethnicities and fertility and study women from geographically discrete areas with different iodine intakes. The studies may restrict investigation to one trimester, use different gestational age

---

TABLE 45–1

Reference Ranges for Thyroid Function Tests in Pregnancy (See also Appendix of Normal Values)

		TSH (MU/L)	THYROXINE (PMOL/L UNLESS OTHERWISE STATED)	TRIIODOTHYRONINE (PMOL/L)
Nonpregnant	Guys & St. Thomas' NHS Foundation Trust, United Kingdom, 2009	0.27–4.2	12–22	3.1–6.8
First trimester	Cotzias[6]	0–5.5	10–16	3–7
	Shan[9]	0.09–4.38	11.41–23.76	
	Marwaha[10]	0.6–5	12–19.45	1.92–5.86
	Larsson[5]	0.09–3.39		
	Lambert-Messerlian[8]	0.12–2.68	0.87–1.38 ng/dL	
Second trimester	Cotzias[6]	0.5–3.5	9–15.5	3–5.5
	Marwaha[10]	0.435–5.78	9.48–19.58	3.2–5.7
	Larsson[5]	0.37–3.88		
	Lambert-Messerlian[8]	0.35–2.77	0.72–1.26 ng/dl	
Third trimester	Cotzias[6]	0.5–4	8–14.5	2.5–5.5
	Marwaha[10]	0.74–5.7	11.3–17.71	3.3–5.18
	Larsson[5]	0.23–2.83		

Key:
Cotzias[6]: Cross-sectional analysis of 307 women. Median trimester thyroid hormone intervals rounded to nearest 0.5.
Shan[9]: 4800 women, cross-sectional study. Samples drawn at 4, 8, 12, 16, and 20 wk. Antibody-positive women excluded. Only those <12 wk shown here. 5th and 95th percentiles.
Marwaha[10]: 331 Indian women. Singleton pregnancies. Antibody-positive women excluded. Cross-sectional study. 107, 137, and 87 women recruited in first, second, and third trimester, respectively. 5th and 95th percentiles.
Larsson[5]: 52 normal pregnancies. Longitudinal study. Samples drawn at 12 and 20 wk and at 4-weekly intervals thereafter. "Upper" and "lower" limit of the calculated reference range.
Lambert-Messerlian[8]: 8531 and 8415 singleton antibody-negative women in first and second trimesters, respectively. 5th and 95th percentiles. Paired first- and second-trimester samples.
NHS, National Health System; TSH, thyroid-stimulating hormone.

ranges, and use different statistical methods to define "normal" ranges.[4–6,9,10] This can make clinical decisions regarding dosage adjustments in pregnancy problematic. Target ranges are not clear.

HYPOTHYROIDISM

General

Hypothyroidism affects 1% of pregnant women, and as with hyperthyroidism, many of the symptoms are encountered in normal pregnancy. Discriminatory symptoms are cold intolerance, slow pulse rate, and delayed relaxation of deep tendon reflexes, particularly those of the ankle.

The most common cause of hypothyroidism is autoimmune in origin associated with TPO autoantibodies leading to destruction of the gland, lymphoid infiltration, and eventual atrophy and fibrosis. This is termed *atrophic (autoimmune) hypothyroidism*. In some cases, antibodies blocking the TSH receptor have been implicated. Hashimoto's thyroiditis is a different form of autoimmune thyroiditis also with TPO (microsomal) autoantibodies, often in high titers. However, in this condition, there are atrophic changes with regeneration resulting in goiter formation. Where the origin is autoimmune, there are associations with other autoimmune disease (e.g., pernicious anemia, insulin-dependent [type 1] diabetes mellitus, and vitiligo).

Hypothyroidism may be iatrogenic following lithium, amiodarone, or antithyroid medication. Alternatively, it may be transient, occurring as part of the disease course in subacute de Quervain's thyroiditis or postpartum thyroiditis.

Any woman on T_4 for iatrogenic hypothyroidism should have a careful history taken to determine the original cause of her disease. This is particularly true in those women on T_4 following thyroidectomy or radioiodine therapy in which the original indication for the surgery may have been hyperthyroidism. Thyrotoxic symptoms in such women should not be attributed to treatment excess until a flare of residual disease has been excluded.[11]

Diagnosis

Hypothyroidism may be diagnosed in those with a reduced free T_4 concentration in association with an elevated TSH, which outside pregnancy, is a sensitive indicator of the degree of thyroid hormone deficiency. However, pregnancy represents a challenge for establishing reliable reference ranges and cutoffs.[8] Identifying TPO autoantibodies can confirm the diagnosis, but these are nonspecific, being present in 20% to 30% of the normal population.[12]

Maternal and Fetal Risks

The most serious consequence of hypothyroidism is myxedema coma. This is extremely rare in pregnancy, but it represents a true medical emergency with a 20% mortality rate. The clinical picture of myxedema coma includes hypothermia, bradycardia, decreased deep tendon reflexes, and altered consciousness. Hyponatremia, hypoglycemia, hypoxia, and hypercapnia may also be present. Once the diagnosis is made, therapy should begin immediately with supportive care and thyroid hormone replacement.

Improvement in symptoms usually occurs after 12 to 24 hours of therapy.[13]

One study addressing outcome in hypothyroidism demonstrated that gestational hypertension, (eclampsia, preeclampsia, and pregnancy-induced hypertension) occurred more commonly in the overt and subclinical hypothyroid patients than in the general population, with rates of 22%, 15%, and 7.6%, respectively. In addition, 36% of the overt and 25% of the subclinical hypothyroid subjects who remained hypothyroid at delivery developed gestational hypertension. Low birth weight in both overt and subclinical hypothyroid patients was secondary to premature delivery for gestational hypertension. Older studies have suggested a link with congenital malformations, but more recently, no such association has been reported.[14]

Little T_4 crosses the placenta after the first trimester, and the placenta is relatively impermeable to TSH and T_3. The fetal thyroid gland begins to form at 5 weeks' gestation and has some function at 10 weeks but is only autonomous at 12 weeks when T_4, T_3, and TSH can all be measured in fetal serum.[15] Levels continue to rise until 35 to 37 weeks' gestation when they reach adult levels. The gland, however, is relatively immature with high TSH levels relative to the amount of T_4 produced.

T_4 is important in early development of the fetal brain. Haddow and coworkers[16] have suggested impaired neuropsychiatric development in the offspring of hypothyroid mothers. Pop and colleagues[17] demonstrated that children of women who had hypothyroxinemia (free T_4 levels below the 10th percentile and TSH levels within the reference range) during the first trimester of pregnancy are at risk of having a baby with delay in both mental and motor development at 1 and 2 years, with the effect being most pronounced in those whose levels remained low throughout gestation. Those children born to mothers in whom T_4 was maintained between the 50th and the 90th percentile during early pregnancy showed normal neurodevelopment.[17] A study examining IQ scores in offspring born to mothers who were hypothyroid in early pregnancy who were subsequently treated failed to show any adverse effect on mental development when compared with their siblings born when the same mothers' were euthyroid.[18] Haddow and coworkers[16] studied 25216 women and found 62 had TSH above the 98th percentile in conjunction with a low T_4 at the time of screening for prenatal diagnosis in the second trimester. These women were then matched to 124 control women. The children born to mothers with high TSH performed less well on IQ tests. Forty-eight of the women were not treated and these had the lowest scores.[16] The fetus is thus reliant on maternal T_4 prior to 12 weeks' gestation, and correction of maternal hypothyroxinemia in the first 12 weeks of pregnancy might, therefore, be expected to improve neurodevelopmental outcome.[16]

Cretinism (deaf mutism, spastic motor disorder, and hypothyroidism) is a distinct and severe form of brain damage caused by severe maternal iodine deficiency.

Neonatal or fetal hypothyroidism secondary to transplacental transfer of maternal autoantibodies is extremely rare (1 in 180,000 neonates or ~2% of babies with congenital hypothyroidism)[19] if it occurs at all.[20]

Congenital absence of the thyroid gland is also exceptionally rare, and in these cases, the fetus is reliant on transfer

of maternal T_3 and T_4 across the placenta[21] throughout gestation.

All infants are screened for hypothyroidism via the blood spot Guthrie card collected via a heelprick on day 6 of life. Those with an abnormality are recalled for further testing (0.2%–0.3% of the general population).

The fetus is not thought to be at risk of hyperthyroidism from maternal T_4 therapy because placental transfer is so poor.

Management Options

Prepregnancy

In hypothyroidism, the frequency of menstrual irregularities has been variously reported as between 56% and 80% of patients. Oligomenorrhea, amenorrhea, polymenorrhea, and menorrhagia have all been reported. Most are likely to be attributed to anovulatory cycles. However, a recent study reported far fewer menstrual irregularities; 23.4% among 171 hypothyroid patients studied (three times more frequent than in 124 controls).[22] The most common manifestation in this group was oligomenorrhea (42.5%) followed by menorrhagia in 30%. Reduced libido may be an associated feature.

Ovulation and conception can occur in mild hypothyroidism.[23] It is likely, however, that severe hypothyroidism is associated with failure of ovulation, and therefore, tests of thyroid function are appropriate in the investigation of an infertile couple. The guidelines issued by the National Collaborating Center for Women's Health in 2004 suggest that testing should be done only when the woman reports menstrual irregularities or other symptoms consistent with thyroid disease.

Given the association of hypothyroidism and other autoimmune diseases, performing thyroid function tests in women with insulin-dependent (type 1) diabetes mellitus prior to pregnancy may be a useful screening tool.

Patients with hypothyroidism should be counseled to delay pregnancy until maintenance T_4 levels have been achieved. Reassurances should be given for the safety of T_4 during pregnancy. It is useful to perform a baseline TSH and free T_4 measurement in those contemplating a pregnancy in the near future or as early as possible postconception. Recent guidelines produced by the Endocrine Society[24] have advised that in those known to be hypothyroid prior to pregnancy, adjustment of the preconception T_4 dose to reach TSH less than 2.5 µIU/L before pregnancy is advisable.

Prenatal

A new diagnosis of hypothyroidism in pregnancy is uncommon, given its association with infertility. A more common problem is someone who is inadequately replaced embarking on a pregnancy or in those labeled with hypothyroidism following an episode of postpartum thyroiditis that resolved but the diagnosis was never reviewed.

Those who enter pregnancy euthyroid can expect a good outcome. Hypothyroidism requires treatment with T_4. If there is no coexisting heart disease, an initial dose of 100 µg of T_4 is usually required. In women who are stable on treatment, checking thyroid function in each trimester will suffice. However, if dosage changes are implemented,

thyroid function tests (TSH and free T_4) should be measured after 4 to 6 weeks. More frequent testing (every 2 wk) may be needed in those with very poor control in early pregnancy. When making dosage adjustment, the free T_4 should be used rather than TSH, which can take time to fall. However, poor compliance may also result in a raised TSH with a normal free T_4. Several investigators have variously advocated increasing doses of T_4 with advancing gestation.[25–27] Alexander and associates[3] prospectively studied 20 women who were hypothyroid and planning a pregnancy. Samples were taken preconception, every 2 weeks during the first trimester, and then monthly thereafter. The T_4 dose was increased in order to keep the TSH concentration at prepregnancy values or increased if TSH was greater than 5 mIU/L The serum TSH level increased during the first 10 weeks of gestation, prompting an increase in the levothyroxine dose in 85% of the group. A mean increase in dose by 47% was required in these women to keep TSH at prepregnancy concentrations. The increased doses were required during the first 16 to 20 weeks. In the hypothyroid women studied, the peak in TSH at 8 to 10 weeks was accompanied by a downward trend in free T_4, as is observed in normal subjects. The authors concluded that women on treatment for hypothyroidism should be advised to increase their current dose of levothyroxine by taking two extra daily doses during each week (i.e., to increase the dose by 29%) beginning the week pregnancy is confirmed and to continue doing so until they are able to undergo thyroid function testing; thus, additional T_4 is provided during this time of increased demand.[3] The small Abalovich and coworkers' study[28] suggested that in hypothyroid women attending their clinic, 69.5% required a dose increase to achieve a target of TSH 0.5 to 2.0 mIU/L (but considered a TSH to be adequate if < 4 mIU/L), and of their population, 69% needed a reduction in dose postnatally. Suggested mechanisms for this increased requirement were of an elevated extrathyroidal pool of T_4, the need to saturate large quantities of TBG, increased degradation of T_4, reduced absorption of T_4, and increased transfer of T_4 from mother to fetus.[29] However, Girling[7] and Chopra and Baber[30] suggest that there is no need to adjust doses of T_4 replacement provided replacement was adequate before the pregnancy. The Chopra and Baber study[30] also stresses the point that taking T_4 at the same time as iron supplements may reduce its absorption and, therefore, its effectiveness. It is not currently routine UK practice to routinely increase thyroxine dose on diagnosing pregnancy though some guidelines do advocate this.[31] Instead dosage adjustments may be made when necessary with reference to thyroid function tests early in pregnancy. A reasonable approach is to measure thyroid function tests as soon as pregnancy is confirmed, and adjust the dose if necessary, aiming for a free T_4 at the upper end of the normal range and TSH in the lower half of the normal range. Thyroid function tests should then be repeated once each trimester, or every 4 to 6 weeks if there has been a dose adjustment.

Labor and Delivery

In the patient who is adequately controlled, no specific measures are needed for labor or delivery. However, when a large goiter causes respiratory compromise, anesthetic and/or surgical advice may be required.

Postnatal

The presence of TPO autoantibodies is significantly associated with not only postpartum thyroiditis (see later) but also postpartum depression.[32]

Clinically Euthyroid—Subclinical Hypothyroidism

Subclinical hypothyroidism (SCH) describes those patients with a high TSH and normal thyroxine concentration with no specific symptoms or signs of thyroid dysfunction. Outside pregnancy, there is not considered to be an absolute threshold between hypothyroidism and euthyroidism, but it is suggested that a normal TSH is likely to be below 5 to 6 mU/L.[33] SCH affects 5% of the general population[2] and is more common in women, particularly those who have antithyroid antibodies.[33] There is an association with hypothyroidism, but outside pregnancy in those with TSH lower than 10 mU/L without thyroid antibodies, the conversion rate is less than 3%/yr.[33] In 1999, Haddow and coworkers[16] reported that when noted in pregnant women (unrecognized TSH > the 99.7th percentile), 58% (26/45) progressed to a clinical diagnosis of hypothyroidism in 5 years. Diagnosing SCH in pregnancy is usually an incidental finding, and screening for the condition has not been recommended. The prevalence with which SCH is observed will vary depending on the reference range (and gestation) used for diagnosis and whether antibody-positive women are included or not. Lambert-Messerlian and associates[8] noted 0.16% (16/9562) of women had a TSH greater than 10 mIU/L, and Allan and colleagues[34] systematically screened an antenatal population (9403 unselected women) in the second trimester and reported a TSH greater than 6 mU/L in 2.2%. Casey and associates[35] noted that among 25,756 women with singleton pregnancies of whom 67% were enrolled at 20 weeks' gestation, SCH (TSH > 97.5th percentile for gestational age) was noted in 2.3%. Marwaha and coworkers[10] reported SCH in 14.2% (78/541) of normal pregnant women across all gestations. The higher prevalence may be explained by their definition of SCH (TSH > 4.2 μIU/L) and the inclusion of antibody-positive women. However, the authors did determine pregnancy-specific ranges for thyroid function (see Table 45–1) but did not reevaluate the SCH population. The importance of pregnancy-specific ranges was highlighted in a Chinese cross-sectional study of 480 women at less than 20 weeks (excluding those with antithyroid antibodies) when up to 4% of women were reclassified with SCH using pregnancy-specific ranges who would have been "normal" if nonpregnant reference ranges were used.[9] On screening 10,990 pregnant women, Cleary-Goldman and colleagues[36] noted SCH (TSH > 97.5th percentile and normal free T$_4$ of 2.5 in the 97.5th percentile) in 2.2% of women in the first and 2.2% of women in the second trimester. SCH in pregnancy is appearing increasingly in the literature because of a suggested association with adverse obstetric outcome. Indeed much of the drive for determining a "normal" range for thyroid function in pregnancy has been fueled by emerging evidence of adverse obstetric outcome in those with SCH or poorly controlled thyroid function. Allan and colleagues[34] reported a significantly higher rate of fetal death (3.8%) in those women with TSH greater than 6 mU/L (2.2%) compared with those with TSH lower than 6 mU/L

(0.9%) (odds ratio [OR] 4.4, 95% CI 1.9–9.5). The other complications of pregnancy occurred at rates similar to the rest of the population, and gestational ages and delivery and birth weights were similar.[34] Casey and associates[35] noted that placental abruption and preterm birth (<34 wk) were both observed more frequently in the SCH group than in the controls (relative risk [RR] 3.0, 95% CI 1.1–8.2, and RR 1.8, 95% CI 1.1–2.9, respectively). Stagnaro-Green and associates[37] compared 124 women delivering at less than 37 weeks to 124 controls. Elevated TSH (≥3 mIU/L as measured at "entry to care," ~16 wk' gestation) was associated with an increased risk of very preterm (<32 wk) delivery (adjusted odds ratio [AOR] 3.13, 95% CI 1.02–9.63) after control for the mother's history of prior preterm delivery and parity. However, in the Cleary-Goldman and colleagues study,[36] SCH in either the first or the second trimester was not associated with an adverse obstetric outcome.

In order to justify seeking a diagnosis of SCH and then managing women with SCH in pregnancy in light of this evidence, one would need to be convinced of evidence that intervention improved outcome. Data from randomized controlled trials are lacking. However, Negro and coworkers[38] randomized 115 TPO antibody (TPO-Ab)–positive women to receive T$_4$ or no treatment and compared outcomes with those of the antibody-negative women. The given dose of T$_4$ was maintained throughout gestation. Women were recruited at their first prenatal visit (~10 wk) and blood was sampled again at 20 and 30 weeks and 3 days after delivery. TSH concentrations were initially higher in the antibody-positive women and remained high in those not receiving treatment. Those antibody-positive women not on treatment had a higher percentage (13.8%) of pregnancy loss than those on treatment (3.5%, P < .05, RR 1.72, 95% CI 1.13–2.25) or antibody-negative women (2.4%, P < .01, RR 4.95, CI 2.59–9.48). Preterm deliveries also occurred more frequently (22.4%) in the group not on treatment than in those on treatment (7%, P < .05, RR 1.66, 95% CI 1.18–2.34) or antibody negative women (8.2%, P < .01, RR 12.18, CI 7.93–18.7). Other complications of pregnancy (hypertension, preeclampsia, placental abruption) did not vary between the groups. Because the pregnancy losses all occurred early, the authors concluded that T$_4$ supplementation should occur early.[38] After parturition, half of the patients studied had a free T$_4$ lower than the normal range.[38] A further study, though not randomized and looking at both SCH and overt hypothyroidism, by Ablovich and coworkers[28] retrospectively examined hypothyroid women delivering their unit. Thirty-five of 150 women were diagnosed with SCH (TSH 12.87 ± 8.43 mIU/L, T$_4$ 6.93 ± 1.88 μg/dL) as defined at conception and were given T$_4$ to achieve TSH between 0.5 and 2.0 mIU/L. Blood was then tested each trimester. Those with overt hypothyroidism were similarly managed. In those who were euthyroid at conception, the miscarriage rate was 4%, and in those hypothyroid at conception, it was 31.5%. Gestations at delivery were similar. In those with SCH who were inadequately treated, the miscarriage rate was 71.4%. There were no miscarriages in the adequately treated group (P < .006). The term delivery rate was 21.4% in the inadequately treated SCH group (20.8% total for the hypothyroid group) and 90.5% in those on adequate treatment (P < .006).[28] It has been suggested that those with a reduced functional thyroid reserve

(hypothyroid, raised TSH, thyroid antibodies) cannot compensate for the increased hormone requirement of early pregnancy (described earlier) caused by higher thyroid-binding globulin, increased volume distribution of thyroid hormones, and increased placental transport and degradation.[38] Negro and coworkers[38] suggested a potential benefit of treatment. On examining the effects of treatment on TSH profiles in early pregnancy, they found that T_4 does not appear to completely correct these values. De Geyter and coworkers[2] recruited 16 women attending for infertility investigation preconception. Eight were defined as SCH (TSH > 4.5 mU/L) and 8 were euthyroid controls. Blood was sampled weekly. Those with SCH were all given 50 μg T_4 until 12 weeks' pregnancy. TSH levels remained higher in the SCH group than in the controls, and for both groups, TSH was present in rising concentrations peaking at week 6. Thereafter, levels declined. Serum hCG levels increased progressively to week 9 with stable levels thereafter. Free T_4 and T_3 remained unchanged during the whole sampling period. Of note is that a proportion of these pregnancies received exogenous gonadotrophins[2] when elevations in TSH are of greater magnitude and occur earlier.[3]

Several authors suggest that SCH may have a better prognosis than overt hypothyroidism because of normal concentrations of T_4, but a worse outcome when compared with the general antenatal population,[28] and thus represent a continuum of reducing thyroid reserve.

Screening of the general population at booking for raised TSH has not yet been recommended.[39] One study has suggested that screening using TSH or TSH and antibody positivity are both cost-effective strategies.[39] Outside pregnancy, treatment of SCH is advised only insofar as it is better to treat SCH before overt hypothyroidism develops.[33] The Endocrine Society Clinical Practice Guideline[24] advocated that in patients previously known to be antibody-positive or in those who have been screened with TSH (e.g., as part of subfertility investigations), in those with a previous history of miscarriage or preterm delivery, aggressive case finding using TSH should be carried out. However, what concentration of TSH to use for diagnosis, what dose of T_4 to commence, what target TSH to aim for, and what is the important gestation to diagnose and commence treatment to improve outcome has not been agreed on.

Clinically Euthyroid—Thyroid Antibody–Positive

Higher TSH levels are consistently seen in those who are TPO-Ab or TBG antibody–positive, and a high prevalence of SCH is noted in these women.[24] A prospective study by Glinoer and coworkers[40] was undertaken in 87 healthy pregnant women with thyroid antibodies (TPO or TG) and normal thyroid function (T_3 and T_4 within normal reference ranges adjusted for gestational time and TSH 0.20–4 mU/L) at initial presentation. Antibody-positive women had a basal TSH value significantly higher, though normal, in the first trimester (1.6 vs. 0.9 mU/L, P < .001) than controls, as previously reported elsewhere. At delivery, 40% of the cases had serum TSH levels above 3 mU/L, and 16% had serum TSH levels above 4 mU/L. Furthermore, free T_4 concentrations were in the range of hypothyroid values in 42% of the women.[40] Among the 87 women in the Glinoer and

coworkers study,[40] 7% (75 women) miscarried compared with 3.3% in 606 pregnant women, and the rate of premature delivery doubled (16% vs. 8%). A higher rate of miscarriage was confirmed by Stagnaro-Green and colleagues[41] who reported that among 552 women screened in the first trimester, 17% of antibody-positive women miscarried compared with 8.4% of antibody-negative women.[24] Cleary-Goldman and colleagues[36] screened 10,990 women and found 15% were antibody (TPO and TG) positive in the first and second trimesters. All had higher TSH concentrations than antibody-negative women and, when antibodies were positive in both the first and the second trimesters, preterm premature rupture of membranes (PPROM) was significantly increased compared with antibody-negative women. No other associations were reported.[36] It has been suggested that TPO-Ab and TG-Ab are found more commonly in those women with recurrent (≥3) miscarriages,[42] the risk of which may be associated with antibody titer and avidity.[26,42,43] These studies tested women because of their history of recurrent miscarriage (and were, therefore, at risk of miscarrying again anyway) rather than any clinical or biochemical features of hypothyroidism. Cleary-Goldman and colleagues[36] discuss whether their observed association of antibody-positivity and PROM might just be a marker of an inflammatory process placing women at risk of PPROM. Of note is that thyroid antibody-positivity is seen more frequently with advancing age (also a risk factor for miscarriage) and is a risk factor for subfertility.[38]

Glinoer and coworkers[40] systematically screened 234 women attending for assisted reproductive technology (ART) for TPO antibodies (TPO-Ab), serum TSH, and free T_4 before the first ART cycle. Women with overt thyroid dysfunction were excluded. Fourteen percent of the cohort had positive TPO-Ab. Concentrations of TSH (1.6 [0.02–4.1] mU/L) and T_4 (12.2 [9.1–18] ng/L) were comparable with those of the 86% of women without antibodies (TSH, 1.3 [0.05–3.6] mU/L) and free T_4 (11.7 [9.5–16.5] ng/L). In the antibody-positive group, the pregnancy rate was 53% versus 43% in the antibody-negative group, with an OR of 0.67 (95% CI 0.32–1.41, P = not significant); however, within the group that was pregnant, the miscarriage rate was 53% and 23%, respectively, with an OR of 3.77 (95% CI 1.29–11.05, P = .016). The age of the women was also an independent risk factor for miscarriage (OR 1.08, 95% CI 1.03–1.15, P = .005).[44] Several other papers have reported increased rates of miscarriages among antibody-positive women.[45] It has thus been suggested that antibody positivity reflects or is a cause of reduced or imminent reduction in thyroid reserve (discussed earlier). What is not clear is whether this increased risk of adverse pregnancy outcome (e.g. miscarriage) is a manifestation of an altered humoral response to pregnancy, or whether the thyroid autoantibodies themselves are implicated in the pathophysiology. It has been suggested that those who are known to be antibody positive but euthyroid should have their TSH monitored serially[24] because they are at risk of developing hypothyroidism. In those who are antibody-positive and have SCH, whether treatment with T_4 may improve outcome, as suggested by the Negro study,[38] needs to be subjected to further randomized, controlled trials. There is currently insufficient evidence to support T_4 treatment for pregnant women who are antibody-positive with normal thyroid function.[24]

SUMMARY OF MANAGEMENT OPTIONS
Hypothyroidism

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Consider diagnosis in those with subfertility/menstrual disorders.	IIa/B	23
Optimize medical therapy; delay pregnancy until good control.	IIa/B	16,17
Prenatal		
Obtain baseline thyroid function tests as soon as possible.	—/GPP	—
Use pregnancy-specific reference ranges when interpreting thyroid function tests.	III/B	3,5,6,9,10
Obtain thyroid function tests every 3 mo. More frequently if dosage adjustments are made.	—/GPP	—
Routine increases in thyroxine doses are not required. Make dosage adjustments based on results of thyroid function tests.	III/B	4,30
Avoid taking iron supplements at the same time as oral thyroxine therapy.	III/B	30
Check compliance in those with vomiting.	—/GPP	—
Clinically Euthyroid with Subclinical Hypothyroidism		
Early thyroxine treatment appears to reduce the miscarriage rate.	Ib/A	38
Clinically Euthyroid and Thyroid Antibody–Positive		
Monitor TSH levels and give thyroxine only if patient becomes hypothyroid.	III/B	24
Labor and Delivery		
Large maternal goiter may cause anesthetic complications.	—/GPP	—
Postnatal		
Observe for signs of postpartum thyroiditis.	—/GPP	—
Screen for postpartum depression.	III/B	32

GPP, good practice point; TSH, thyroid-stimulating hormone.

HYPERTHYROIDISM

General

Hyperthyroidism affects 0.2% of pregnant women,[46,47] and 95% of these will have a diagnosis of Graves' disease, an autoimmune disorder associated with circulating immunoglobulin G (IgG) antibodies to the thyroid TSH receptor, which stimulate thyroid hormone production.

Possible causes of hyperthyroidism are

- Graves' disease.
- Toxic multinodular goiter.
- Toxic nodule/adenoma.
- Subacute thyroiditis.
- Acute thyroiditis (De Quervain's [viral] or postpartum).
- Iodine treatment.
- Amiodarone therapy.
- Lithium therapy.
- Hyperfunctioning ovarian teratoma (Struma ovarii)
- TSH-producing adenoma.
- hCG-producing tumor.
- Thyroid carcinoma.

Diagnosis

Thyrotoxicosis usually presents in the late first or early second trimester. Symptoms are as for thyrotoxicosis outside pregnancy, but these may be unhelpful and commonly reported by many euthyroid pregnant women (e.g., palmar erythema, emotional lability, vomiting, goiter. and heat intolerance). Discriminatory symptoms may be weight loss, tremor, lid lag, lid retraction. and a persistent tachycardia greater than 100 beats/min.

Diagnosing hyperthyroidism in early pregnancy may be difficult.

Careful consideration of normal ranges must be made when contemplating a diagnosis of hyperthyroidism in early pregnancy. This is especially so in the context of hyperemesis gravidarum, in which hCG secretion may be exaggerated, or in trophoblastic disease, in which it is grossly elevated. Two thirds of women with hyperemesis will have abnormal thyroid function tests in the absence of thyroid disease with 30% having undetectable TSH, 60% suppressed TSH, and 59% an elevated free T_4.[48]

Symptoms that persist beyond 10 to 20 weeks' gestation that antedate the pregnancy and the presence of thyroid-stimulating antibodies suggest true hyperthyroidism. The diagnosis of hyperthyroidism is confirmed by an elevated free T_4 and/or free T_3 with suppressed TSH levels.

Carbimazole, methimazole (a metabolite of carbimazole), and propylthiouracil are all used to treat hyperthyroidism in and out of pregnancy. All are of the thionamide class and act by competitively inhibiting the peroxidase-catalyzed reactions necessary for iodine organification. They also block the coupling of iodotyrosine, especially diiodothyronine formation. Their onset of action is delayed until the preformed hormones are depleted, a process that can take 3 to 4 weeks.

Maternal and Fetal Risks

Important maternal side effects of thionamides are agranulocytosis and hepatitis that is idiosyncratic with propylthiouracil but dose-related with carbimazole. Monitoring of liver function tests may be necessary. It is essential that in those women with sore throat or a fever, a white blood cell count be performed to exclude agranulocytosis. A neutropenia should prompt discontinuation of therapy, and thionamides should not be given again. A drug rash or urticaria is reported in 1% to 5% and would necessitate a switch to an alternative preparation. Additional symptoms sometimes reported are nausea, vomiting, and diarrhea.

The two most serious maternal complications of untreated hyperthyroidism are heart failure and thyroid storm, a medical emergency associated with a maternal mortality rate of 25% even with appropriate management.[49] Heart failure is the more common of the two serious maternal complications. It is caused by the long-term myocardial effects of T_4 and is intensified by other pregnancy conditions such as preeclampsia, infection, or anemia.[50]

When diagnosed in pregnancy, thyrotoxicosis is associated with adverse outcomes including miscarriage, growth restriction, preterm labor, placental abruption, pregnancy-induced hypertension, preeclampsia, infection, and increased perinatal mortality. One study has suggested an increased risk of chromosomal abnormalities.[51] The relative risk for low birth weight is reported as 0.74 in one euthyroid (controlled hyperthyroidism) population, 2.36 in the same population with uncontrolled hyperthyroidism in the first half of pregnancy, and 9.24 in those hyperthyroid throughout pregnancy.[52] The same study showed an OR for developing preeclampsia of 4.74 in those with uncontrolled hyperthyroidism at term.[52] This study suggests that treatment improves outcome and is supported by another study[16] showing stillbirth in 24% of those untreated hyperthyroid pregnancies, falling to 5% to 7% in those on treatment. The incidence of prematurity was 53%, falling to 9% to 11% with treatment.

There is a risk of fetal and/or neonatal thyrotoxicosis due to the passive transplacental passage of immunoglobulins associated with Graves' disease. Such antibodies are able to exert an effect on the fetal thyroid at 20 weeks' gestation.[53] Infants born to mothers with high titers of antibodies or poorly controlled disease[46,53] are particularly at risk. Studies report varying prevalences between 1% and 17%,[53,54] with

fewer cases being diagnosed in utero than in the neonatal period.

Fetal thyrotoxicosis may be suspected in a fetus with a persistent tachycardia (>160 beats/min), a goiter, or growth restriction,[53] and as such, may be diagnosed with antenatal ultrasound screening.[55,56]

Fetal thyrotoxicosis may result in preterm delivery[53] and the development of fetal craniosynostosis, exophthalmos, heart failure (hydrops fetalis), hepatosplenomegaly, thrombocytopenia, exophthalmos, goiter (with neck obstruction and polyhydramnios), and growth restriction. Additional neonatal features include jaundice, poor feeding, poor weight gain, and irritability.[53] The mortality of the condition may be as high as 25%.[47]

Thyrotoxicosis presenting in the neonatal period is usually transient, lasting only 2 to 3 months after delivery. Presentation may be delayed up to 2 weeks postnatally if the mother was on medication at the time of delivery. The effects of maternal antithyroid medication are eventually cleared from the neonates' circulation but the thyroid-stimulating antibodies are cleared at a slower rate.

In order to predict fetal thyrotoxicosis, maternal TSH receptor autoantibodies should be tested in early pregnancy; to predict neonatal disease, they should be tested again in late pregnancy.[57] One suggested protocol is to test in the first trimester and again at 6 months' gestation.[26] If high titers of antibodies are detected in early pregnancy or if levels have not fallen with advancing gestation, fetal thyrotoxicosis should be anticipated and obstetric ultrasound scans may be recommended to assess fetal growth, heart rate, and the presence of goiter. If antibodies are detected in late pregnancy, then cord blood and neonatal (days 3–4 and 7–10)[47,58] thyroid function tests (TSH and free T_4) should be performed.[57] It is important to recognize the risk of neonatal/fetal thyrotoxicosis in women who appear at first glance to have hypothyroidism because they are on T_4 replacement for previous thyroidectomy or radioiodine treatment but, in fact, may have high titers of TSH receptor autoantibodies.

Treatment for fetal thyrotoxicosis is possible in utero by giving the mother increased doses of antithyroid medication. Any subsequent maternal hypothyroidism can be treated with T_4, which will not cross the placenta in significant amounts. Percutaneous fetal blood sampling to measure thyroid function (for which normal ranges exist) is technically possible and may play a role in management.[15]

Fetal effects of maternal antithyroid medication have been reported, particularly the association of carbimazole or methimazole with aplasia cutis.[59] This condition results in patches of absent skin at birth, 70% to 85% of which occur on the scalp. However, the condition is rare. The natural incidence of the condition is 0.03%,[60] but in this study in a population of 49,000 babies, none of the mothers[58] on antithyroid medication had affected babies, and in 643 women with Graves' disease, there were no cases.[29]

High doses of antithyroid medication may cause fetal hypothyroidism but only rarely goiter. In one study, 43 women treated with thionamides until delivery were compared with 27 women in whom treatment was discontinued in the pregnancy. Free T_4 levels were slightly lower in fetuses compared with mothers in the first group and higher in the second group in which some maternal and cord T_4 levels were in the thyrotoxic range at delivery.[61] This suggests that

if maternal disease is controlled too tightly, some infants may become hypothyroid. Neonatal hypothyroidism usually spontaneously resolves by day 5 of life[62] and is said to occur in 10% to 20% of patients treated with thionamides.[63]

Management Options

Prepregnancy

Menstrual abnormalities are less common now than in previous series. The most common manifestations are hypomenorrhea and oligomenorrhea. However, most thyrotoxic women are thought to remain ovulatory.[23]

Therapy for hyperthyroidism is best begun prior to pregnancy. This will allow for the use of radioactive iodine studies for diagnosis, higher initial doses of pharmacologic agents without fetal concern, and surgery when needed for unresponsive cases. Those having had radioiodine are advised not to conceive until 4 months after their last treatment.[64] Some would argue for establishing a euthyroid state 3 months prior to conception. Counseling should be supportive and reassuring, because treated thyrotoxicosis has a low risk of adverse obstetric outcome. Women should be counseled against discontinuing medication either prepregnancy or antenatally.

Prenatal

The aim of treatment is to maintain the euthyroid clinical state and maintain a level of free T_4 at the upper limit of normal (with reference to pregnancy-specific ranges). This allows the lowest possible dose of medication and minimizes the risks of fetal hypothyroidism. Women should be seen and have thyroid function tests monthly in newly diagnosed cases, but less frequent testing is required in those with stable disease.

In Graves' disease, there is often a temporary worsening of control in early pregnancy due to rising hCG levels and perhaps reduced absorption of medication secondary to vomiting. There is then an improvement with women often requiring less medication because the relative immune suppression of pregnancy results in a fall in antibody levels. Thirty percent can stop all medication in the last weeks of pregnancy.[65]

Block and replace regimes sometimes used outside pregnancy are not suitable for pregnant women. Antithyroid medications cross the placenta freely, whereas T_4 does not. Such a regime would, therefore, place the fetus at risk of hypothyroidism. Fetal abnormalities are seen more commonly in the offspring of women receiving T_4 and carbimazole (9.5%) than in those on carbimazole alone (4.1%).[29,55] Such regimens may be of some use in the treatment of fetal thyrotoxicosis.

Therapeutic modalities for hyperthyroidism can be divided into five categories:

- Thionamides (propylthiouracil, carbimazole, methimazole).
- β-Blockers.
- Iodides.
- Radioactive iodine.
- Surgery.

Propylthiouracil, methimazole, and carbimazole are the mainstays of treatment for hyperthyroidism in pregnancy. Carbimazole is a pro-drug as it converts to methimazole after absorption. Propylthiouracil is more highly protein bound than the other two agents and thus crosses the placenta less readily. A disadvantage with propylthiouracil is that more frequent dosing is often necessary than with carbimazole. Newly diagnosed cases should be aggressively treated initially with high doses for 4 to 6 weeks, which can then gradually be reduced by up to a quarter.

In the United States, propylthiouracil had been considered the drug of choice in pregnancy for the treatment of hyperthyroidism until recently. This related to concerns regarding possible teratogenic effects of methimazole. However, reports of severe propylthiouracil-related liver failure in adults, including during pregnancy, have raised concerns about its routine use.[68] The incidence of this adverse occurrence is approximately 1 in 10,000 adults. Teratogenic concerns of prenatally administered methimazole include choanal atresia and aplasia cutis (approximate risk 0.03%). The American Thyroid Association and the U.S. Food and Drug Administration now suggest that propylthiouracil use be limited to the first trimester only, and that patients be switched to methimazole in the second trimester.[66] Methimazole is approximately 20–30 times as potent as propylthiouracil. Therefore a propylthiouracil dose of 300 mg would be roughly equivalent to 10–15 mg of methimazole. Thyroid function testing should be performed within a few weeks of switching drugs to confirm maintenance of a euthyroid state. Propylthiouracil is still recommended in preference to methimazole in the setting of life-threatening thyrotoxicosis to take advantage of its ability to inhibit peripheral conversion of T4 to T3. In the United Kingdom it is common practice to continue a patient already on carbimazole throughout the pregnancy.

In those with troublesome autonomic (sympathetic) symptoms of palpitations, tachycardia, and tremor, propranolol may be used for up to a month until longer-term treatment with thionamides becomes effective. Longer treatment courses should be avoided because of the risk of growth restriction.[67] β-Blockers have the additional beneficial action of reducing peripheral conversion of T_4 into T_3.

Iodide treatment is an older mode of therapy and essentially now limited to preoperative use. Otherwise, this therapy results in a high incidence of fetal goiter and hypothyroidism when used long-term and does not result in adequate control of thyrotoxicosis.[68]

The fetal thyroid concentrates iodine at a significantly higher rate than the maternal thyroid. Therefore, the use of radioactive iodine (131-I) or any radioactive tracers such as iodine-131 or technetium-99, although widely used outside pregnancy for treatment of Graves' disease and in high doses for carcinoma, are absolutely contraindicated in pregnancy, because they ablate the fetal thyroid gland causing fetal and neonatal hypothyroidism.[3] There is some additional concern about possible effects on the parental gonads, and it is usually advised that pregnancy be delayed following treatment. Radioactive iodine also frequently results in maternal hypothyroidism.[16,29]

Surgery is reserved for patients who do not respond to medication, who develop intolerance to the medication, or those with compressive symptoms from a large goiter. Thyroid surgery is associated with a high incidence of hypothyroidism postoperatively. Other postoperative complications include hypoparathyroidism (1%–2%) causing hypocalcemia, and recurrent laryngeal nerve palsy

(1%–2%). Surgical and anesthetic morbidity and mortality are also increased in pregnancy. The reported pregnancy loss associated with general anesthesia and surgery of all types in the first trimester is approximately 8%, and decreases to 6.5% in the second trimester. Prior to surgery, patients should be prepared medically with 7 to 10 days of iodide to decrease gland vascularity and prevent thyroid storm. Overall, surgery is reserved for failures of the standard medical management and/or in those women with a significant goiter causing stridor, respiratory distress, dysphagia, or carcinoma.

Labor and Delivery

In women with adequately treated thyrotoxicosis, labor and delivery are not associated with increased risks. However, labor and delivery are events that may precipitate thyroid storm in pregnant women with poorly controlled or untreated thyrotoxicosis. The patient may present with extreme symptoms of hyperthyroidism particularly cardiovascular symptoms (palpitations, tachycardia, and atrial fibrillation with rapid ventricular response), and if severe, high-output cardiac failure. Blood pressure is usually normal, though there may be an increased pulse pressure. With prolonged duration of symptoms, shock may ensue.[69]

Fever is invariably present, is progressive, begins a few hours after a stressful event, and may exceed 40°C. Mental status is commonly altered, ranging from restlessness and confusion to psychosis, seizures, and coma. Severe diarrhea, nausea, vomiting, and nonspecific abdominal pain may also be present.[70] If the patient has a large goiter, exophthalmos, or a known history of hyperthyroidism, the diagnosis of thyroid storm is usually not difficult to establish. However, without the obvious findings or history, it may be difficult to make the diagnosis because biochemical tests may not differ from those with thyrotoxicosis without thyroid storm.

Treatment should not be delayed if the condition is suspected.

The aims of treatment in thyroid storm are (1) to decrease thyroid hormone production, (2) to decrease the effect of circulating hormone, (3) to provide supportive therapy, and (4) to treat the underlying cause. Methimazole/carbimazole may be used, although propylthiouracil (300–400 mg q8h orally, nasogastrically, or rectally) is preferred because it decreases peripheral conversion of T_4 to T_3 as well as decreasing thyroid hormone production. Potassium iodide (2–5 drops orally) or sodium iodide (0.5–1.0 g intravenously) every 8 hours should be commenced approximately 1 to 2 hours after the initiation of therapy with thionamides. This is done in an attempt to block preformed thyroid hormone release from the colloid space.

Supportive therapy involves maintenance of blood volume, glycemic control, temperature control, and restoring electrolyte balance. Propranolol (40–80 mg orally or 1 mg/min intravenously) should be given to reduce adrenergic overactivity.

Postnatal

To exclude hyperthyroidism secondary to passive antibody transfer and hypothyroidism secondary to transfer of antithyroid medications, perform thyroid function tests on umbilical cord blood and in the neonate in women who are breast-feeding. For propylthiouracil, only 0.07% of the maternal dose is excreted in breast milk, with a slightly higher dose (0.5%) excreted for carbimazole and for methimazole (10%).[55] Breast-feeding is, however, generally thought to be safe in those on less than 150 mg/day of propylthiouracil and less than 15 mg/day carbimazole.[55,71]

Graves' disease can flare postnatally as maternal antibody levels rise postpartum. In those having stopped medication, it is often necessary to re introduce it at 2 to 3 months postpartum. It is important to distinguish such changes from a true postpartum thyroiditis.

SUMMARY OF MANAGEMENT OPTIONS
Hyperthyroidism

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Establish the diagnosis of hyperthyroidism (elevated free T_4 and/or free T_3 with suppressed TSH levels) prior to pregnancy so that a complete diagnostic workup (including radioiodine studies) can be performed and therapy instituted.	—/GPP	—
Avoid conception until 4 mo after radioiodine therapy. Advise euthyroid state for 3 mo prior to conception.	IV/C	64
Prenatal		
Use pregnancy-specific reference ranges when interpreting thyroid function test results.	III/B	3,5,6,9,10
Caution interpreting thyroid function tests in early pregnancy: TSH levels fall as result of rising hCG.	IIa/B	48
If autoimmune etiology, disease may improve as pregnancy advances and antibody levels fall.	—/GPP	—

Management Options	Evidence Quality and Recommendation	References
Continue therapy; keep T$_4$ at upper limit of normal.	—/GPP	—
Test thyroid function every 3 mo, more frequently if dose adjustments are made.	—/GPP	—
Screen for agranulocytosis and hepatitis in those on thionamides.	—/GPP	—
Measure TSH receptor antibody titer early pregnancy (1 mo); if high, there is a risk of fetal thyrotoxicosis.	III/B	26,57
Perform fetal USS for fetal growth, tachycardia, or goiter.	III/B	47,58
Measure TSH receptor antibody titer in late pregnancy (6 mo); if high, there is a risk of neonatal thyrotoxicosis.	III/B	26,57
Labor and Delivery		
May precipitate thyroid storm.	—/GPP	—
Large maternal goiter may cause anesthetic complications.	—/GPP	—
Postnatal		
Observe for worsening symptoms in postpartum period, especially in those whose medications were reduced. If medications were stopped, these may need to be reintroduced at 2–3 mo postpartum.	—/GPP	—
If high TSH receptor antibody titer in late pregnancy, screen for neonatal thyrotoxicosis by testing infant on days 3–4 and 7–10 of life.	III/B	26,57
Observe neonate for signs of hypothyroidism if born to mothers on high doses of antithyroid medication. Test cord blood and neonatal blood if breast-feeding.	III/B	47,57,58
Perform complete diagnostic evaluation.	—/GPP	—

THYROID NODULES AND THYROID CANCER

General

Thyroid nodules or solitary toxic nodules or adenomas are found in 2% of pregnant women[72] and usually present with hyperthyroidism. An important consideration is that, although rare overall,[50] 90% of thyroid cancers present as thyroid nodules. Carcinomas derived from thyroid epithelium may be papillary, follicular (differentiated), or undifferentiated. They are only rarely active hormonally, but 90% secrete thyroglobulin, which is used outside pregnancy as a tumor marker. It has been suggested that there is an increased incidence of malignancy in pregnancy (40%).[55] Indeed, an association between enlargement of the thyroid gland in pregnancy[73] or a recent pregnancy (within 5 yr) has been linked with the development of thyroid cancer.[74,75] However, because these malignancies are most commonly seen in women of childbearing age, any additional risk in pregnancy may be difficult to determine. Only those nodules thought to be malignant need further investigation or treatment, which is usually by surgery with or without radioiodine. Following such treatment, T$_4$ may be used to suppress production of TSH and so prevent any stimulation of residual thyroid tissue or tumor. One study has suggested a target TSH of 0.5 to 5.0 µU/mL^3 in those with previous thyroid cancer.

Diagnosis

Outside pregnancy, radioiodine is used to distinguish "cold" (more likely to be malignant) from "hot" (functioning) nodules. However, such studies are avoided in pregnancy. Ultrasound, therefore, forms the main investigative tool. Fine-needle aspiration should be reserved for rapidly enlarging nodules, cystic nodules larger than 4 cm or solid nodules larger than 2 cm.[55] Cystic nodules are usually benign (multinodular goiter or solitary toxic adenoma). Those with retrosternal extension or tracheal deviation and respiratory compromise may necessitate further imaging. Biopsy results are usually of four types: insufficient sample (in < 5%), biopsy in these women should be repeated; definitely benign (75%), these women should be reassured; definitely malignant (5%), these women should undergo surgery; and indeterminate (20%), this is usually because follicular cells have been seen and often require surgery. Prognoses are similar for those cases diagnosed in or out of pregnancy.[72]

Management Options

Prepregnancy

Thyroid nodules should be investigated and treated prior to embarking on a pregnancy. Pregnancy should be delayed for 1 year after thyroid cancer has been treated with high-dose

radioactive iodine because congenital abnormalities have been reported.[64]

Prenatal

Because of the risk of malignancy, investigation should proceed as outlined previously and not be delayed because of pregnancy. Antithyroid drugs should be used as described earlier to treat any hyperthyroidism, but nodules do not usually remit after such treatment. Only if a nodule is found at greater than 20 weeks' gestation should aspiration wait until the postnatal period. Those in which biopsy confirms malignancy should undergo surgery in pregnancy unless only a few weeks from term. In those in which the histology is not clear, benign, low-grade malignant, or slowly growing lesions, surgery may be deferred until after delivery. Surgery is safest when carried out in the second trimester and, with the previous exceptions, should not be delayed because of pregnancy.[76,77] Radioactive iodine should not be used in pregnancy. Suppressive doses of T_4 should be safe in pregnancy, taking care to avoid maternal thyrotoxicosis

Labor and Delivery

When a large goiter with retrosternal extension is present, careful consideration must be given to possible respiratory compromise and complications of intubation in the event of a general anesthetic. Retrosternal extension should be suspected in those with respiratory symptoms, dysphagia, and rarely with vocal cord paralysis, Horner's syndrome, and vascular or lymphatic compromise.

Postnatal

Radioactive iodine may be administered after delivery but not while breast-feeding. Contact with the baby may also need to be temporarily limited to reduce exposure risk.[78]

SUMMARY OF MANAGEMENT OPTIONS
Thyroid Nodules and Cancer

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Delay pregnancy for 1 yr after thyroid cancer has been treated with high-dose radioactive iodine	IV/C	35
Prenatal		
Nodule identified at > 20 wk should be biopsied after delivery.	—/GPP	—
If biopsy confirms malignancy, proceed to surgery.	III/B	76,77
Surgery is safest after second trimester.	III/B	76,77
If biopsy shows intermediate pathology, delay surgery until after delivery.	III/B	76,77
Labor and Delivery		
Watch for anesthetic complications in those with large goiter/retrosternal extension.	—/GPP	—
Postnatal		
Radioactive iodine may be used, but not while breast-feeding, and contact with the infant may need to be temporarily limited.	IV/C	78

GPP, good practice point.

POSTPARTUM THYROIDITIS

General

Postpartum thyroiditis is thought to occur in 5% to 10% of pregnancies,[79] and the frequency with which it is diagnosed largely depends on the extent to which it is sought. Women may not report symptoms, instead attributing them to normal postpartum physiology. The condition occurs 3 to 4 months postpartum but has been reported up to 6 months after delivery.[80] It is an autoimmune disorder, and thyroid antibody–positive women in the first trimester have a 33% to 50% chance of developing thyroiditis in the postpartum period.[79] The disease is seen more commonly (threefold higher) in those with insulin-dependant (type 1) diabetes mellitus,[81] with a family history of the disease, or with TPO-Ab (present in 75% of affected individuals).

Differential diagnosis of hyperthyroidism in the postpartum period includes

- Postpartum painless thyroiditis.
- Postpartum Graves' disease.
- Postpartum Hashimoto's thyroiditis.
- Postpartum toxic multinodular goiter.

The most common is postpartum painless thyroiditis, which is characterized by an initial destructive phase in the first 2

months, with release of preformed thyroid hormone, resulting in hyperthyroidism. This is followed about 3 months later by hypothyroidism as stores of preformed thyroid hormone are depleted and the gland itself is destroyed. However, any combination of clinical states is possible at any time. Most resolve spontaneously.

Diagnosis

Radioiodine uptake studies can be used in those women who choose not to breast-feed. Low uptake is seen in postpartum painless thyroiditis in which T_4 release is all preformed, as distinct from Graves' disease in which new T_4 is generated. In women who are breast-feeding, repeat thyroid function tests 1 month later may reveal a transition from hyperthyroid to hypothyroid, so confirming the diagnosis.

Management Options

Most cases resolve spontaneously. However, a study of 86 women showed only 51% of those not treated were biochemically euthyroid at 9 months, and the authors advocate early institution of permanent T_4 replacement in women with postpartum thyroid dysfunction, elevated TSH, and positive thyroid antibodies.[82] Later hypothyroidism (in 23%–39%) may occur in those who recover, particularly when antibodies are found. For this reason, some would advocate yearly thyroid function tests. T_4 may be discontinued in some. Close observation in the puerperium of any future pregnancies should be undertaken because the risk of recurrence is high.

Pituitary and Adrenal Disease

MARK B. LANDON

PITUITARY DISEASE

Normal Changes in Pregnancy

The anterior lobe of the pituitary gland may enlarge significantly during pregnancy as a result of lactotroph proliferation. Magnetic resonance imaging (MRI) scans confirm that the gland more than doubles in size by the end of gestation.[1] Accordingly, prolactin levels increase approximately 10-fold in preparation for lactation.[2]

Pregnancy also affects the levels of other pituitary hormones. Gonadotropin concentrations decrease and show a diminished response to gonadotropin-releasing hormone. The response of growth hormone (GH) to insulin or arginine stimulation is similarly blunted. Pituitary GH levels decline and are accompanied by a progressive increase in the placental variant of GH. Plasma levels of adrenocorticotropic hormone (ACTH) increase throughout pregnancy, but absolute levels remain lower in the pregnant than in the nonpregnant state.[3] Curiously, the increase in ACTH levels occurs despite an increase in free and bound cortisol. The placenta produces ACTH, which may explain this phenomenon. The diurnal variation of cortisol, although blunted, is maintained during pregnancy. Thyrotropin levels are unaffected by pregnancy. Free levels of thyroxine and triiodothyronine are unchanged, whereas total levels increase as a result of estrogen-induced synthesis of thyroxine-binding globulin.

Posterior pituitary function is also altered during normal pregnancy. A significant preterm increase in oxytocin is observed, whereas plasma levels of vasopressin remain similar to those obtained in the nonpregnant state. However, plasma osmolality decreases 5 to 10 mOsm/kg in pregnant women, indicating a decreased threshold for vasopressin secretion in pregnancy. During gestation, patients also experience thirst at a lower plasma osmolality.[4]

Prolactin-Producing Adenomas

Maternal and Fetal Risks

Widely available radioimmunoassays for serum prolactin and improved techniques for radiologic diagnosis have led to the detection of an increasing number of prolactin-secreting pituitary adenomas in women. Prolactin-producing tumors represent the most common pituitary neoplasm encountered during pregnancy. Spontaneous ovulation is uncommon in patients with a pituitary tumor. Therefore, most patients with this disorder have amenorrhea-galactorrhea or anovulatory cycles and infertility. With ovulation induction and suppression of prolactin synthesis by dopaminergic agents, such as bromocriptine, pregnancy can often be achieved in patients with prolactinomas.

Much of the normal pituitary gland enlargement that occurs in pregnancy is secondary to hyperplasia of the anterior pituitary lactotrophic cells, which are stimulated by estrogen. Although this stimulus may cause enlargement of adenomas during pregnancy,[5] most patients with a microadenoma, a pituitary tumor of less than 1 cm, have an uneventful pregnancy.[6–8] In the few patients who have symptoms, regression usually occurs after delivery.

Management Options

PREPREGNANCY

Most women with prolactin-secreting adenomas require ovulation induction to conceive. Nonpregnant patients who have amenorrhea-galactorrhea and hyperprolactinemia (prolactin level > 20 ng/mL) should be evaluated for pituitary adenoma. Although serum prolactin levels are correlated with pituitary adenomas, when a patient with hyperprolactinemia is considering pregnancy, a thorough radiologic examination is warranted. MRI has replaced both computed axial tomography and coned-down sella turcica radiographs as the procedure of choice to evaluate the size of the pituitary gland.

Once a pituitary tumor is diagnosed, it may be prudent to reevaluate the gland for growth after several months before attempting ovulation induction. Bromocriptine therapy is often all that is required for patients with microadenomas. Macroadenomas, which are tumors that measure 1 cm or more, should be treated definitively with surgery. These patients are more likely to have symptoms during pregnancy when treated with medical therapy alone.[5,8] Continued bromocriptine therapy after surgery is indicated if symptomatic residual tumor enlargement occurs.

PRENATAL

Evaluation for possible prolactin-secreting tumors is difficult during pregnancy because of the physiologic increase in serum prolactin that occurs in normal gestation. At term,

Maternal serum prolactin concentration in patients with microadenoma (*shaded bars*, n = 237) and control subjects (*open bars*, n = 215) in the nonpregnant state (NP) and during each trimester.

(From Divers W, Yen SSC: Prolactin producing microadenomas in pregnancy. Obstet Gynecol 1983;62:425.)

Time from the beginning of pregnancy to the onset of symptoms (headache or visual disturbances) in 91 pregnancies in women with previously untreated pituitary tumors.

(From Maygar DM, Marshall JR: Pituitary tumors and pregnancy. Am J Obstet Gynecol 1978;132:739.)
serum prolactin levels may reach values that are 20 times normal. Further, prolactin levels do not always increase during pregnancy in women with prolactinomas, nor do they always increase with pregnancy-induced tumor enlargement (Fig. 46–1).[9] Enlargement usually produces a headache as the first clinical feature, before visual disturbance. Therefore, radiologic diagnosis is necessary for the pregnant patient who has severe headaches or a visual field defect.

Management of the pregnant patient with a previously diagnosed prolactinoma requires careful attention by a team of physicians, including an obstetrician, an endocrinologist, and an ophthalmologist. Women with asymptomatic microadenomas may discontinue bromocriptine and receive routine obstetric care with prompt evaluation for any symptoms of tumor expansion. In contrast, women with asymptomatic macroadenomas should be evaluated with visual field testing at least every 3 months. Women with symptomatic macroadenomas should be seen monthly. Prompt self-referral in patients with headache or visual symptoms should be encouraged. Visual field testing should be performed monthly in women with macroadenomas. Headaches may reflect tumor enlargement and impingement on the diaphragmatic sella or adjacent dura. Visual disturbances are caused by compression of the optic nerve. If the optic chiasm is compressed by superior extension, bitemporal hemianopsia may develop. Although the limitations of serum prolactin levels have been discussed, marked elevations outside the normal range for pregnancy at a given gestational age may signal rapid tumor enlargement.

Gemzell and Wang[5] reviewed the course of 85 women during 91 pregnancies affected by previously untreated microadenomas. Only 5% had complications. Four of the 5 patients with headache and visual disturbances showed resolution after delivery. One patient who had a visual field defect noted early in pregnancy subsequently underwent transsphenoidal hypophysectomy after cesarean delivery for a triplet gestation at 36 weeks. Similarly, Albrecht and Betz[10] reported a low rate of complications in women with untreated
TABLE 46–1

Effect of Pregnancy on Prolactinomas

Microadenoma	No	246	4
Macroadenoma	No	45	7
Macroadenoma	Yes	46	2

microadenomas during gestation. Of 352 patients, 8 (2.3%) had visual disturbances and 17 (4.8%) had headaches.

Maygar and Marshall[6] reported that symptoms are more common in the first trimester than in the second or third, with a median time at onset of 10 weeks' gestation. However, the likelihood of visual symptoms did not differ among trimesters (Fig. 46–2). In this series, symptoms requiring therapy occurred in more than 20% of the 91 patients with untreated tumors, but in only 1% of women with previously treated adenomas.

Molitch[8] reviewed 16 series that included 246 cases of prolactin-secreting pituitary microadenomas in pregnancy. Only 4 of the 246 women (1.6%) had symptoms of tumor enlargement, and 11 (4.5%) had asymptomatic enlargement on radiologic examination (Table 46–1). In no case was surgical intervention necessary. Molitch[8] also reviewed 45 patients with macroadenomas, 7 of whom (15.5%) had symptomatic tumor enlargement. Four of these women required surgery during pregnancy. Cabergoline, a dopamine agonist, has been used to treat refractory cases of tumor enlargement during pregnancy.[11] Although data on cabergoline are less extensive, preliminary evidence does not suggest an increase in adverse perinatal outcomes.[12] The risk of symptoms is probably related to the size of the tumor at

the onset of pregnancy. Further data are needed to define which group of patients with a microadenoma should be treated with bromocriptine for a prolonged period before conception.

Treatment of complications during pregnancy is influenced by both gestational age and the severity of symptoms. If the fetus is mature, induction of labor or cesarean delivery should be accomplished. Cesarean section is generally performed for obstetric indications. Earlier in gestation, therapy should not be delayed if radiologic evidence suggests tumor enlargement. Medical treatment with bromocriptine or cabergoline is successful in most symptomatic patients and has become the preferred primary approach during pregnancy.[9] Bromocriptine has an established safety profile in early pregnancy, as evidenced by its use to induce ovulation in large groups of women with hyperprolactinemia without an increased incidence of congenital malformations.[13,14] Other treatment modalities used during pregnancy include transsphenoidal surgery,[6–8] and in one case, hydrocortisone therapy.[14] Complications of transsphenoidal surgery include infection, hypopituitarism, hemorrhage, and transient diabetes insipidus. The risk of these complications is probably not increased during pregnancy. However, the risk of preterm delivery is increased in those women requiring surgical intervention.[6]

LABOR AND DELIVERY

Intrapartum care of the patient with a prolactin-producing adenoma does not differ from that of the general obstetric population. Some undiagnosed patients may have sudden visual impairment, and prolactinoma must be differentiated from more common conditions, such as preeclampsia and migraine, which may cause the same symptoms.

POSTNATAL

After delivery, radiologic assessment of tumor size and a serum prolactin assay should be performed at the first postpartum visit. Breast-feeding is not contraindicated in patients with a prolactin-secreting microadenoma.[7] Because serum prolactin levels may remain elevated during breast-feeding, caution must be used in interpreting these results. However, serum prolactin levels do not appear to be significantly higher than prepregnancy levels in women with microadenomas who choose to breast-feed.[15] Counseling patients about future pregnancies requires establishing that progression of tumor growth has not occurred. Some suggest continuing bromocriptine therapy for 12 months before conception to reduce the risk of tumor enlargement during gestation.[12] Gemzell and Wang[5] concluded that in 16 patients with untreated pituitary adenomas, symptoms did not seem to occur with increasing frequency in subsequent pregnancies.

• Cabergoline for resistant cases (less experience).	III/B	11,12
• Limited experience with hydrocortisone.	IV/C	14
• Surgery in extreme cases that do not respond to medical measures.	III/B	7,8
Postnatal		
Can breast-feed.	III/B	7,15
Monitor symptoms, the prolactin level (may be difficult to interpret in breastfeeding mothers), and tumor size by imaging.	III/B	15

Acromegaly

Maternal and Fetal Risks

Acromegaly is caused by excessive secretion of GH, most often because of an acidophilic or chromophobic pituitary adenoma. Most patients have tumors greater than 1 cm in size. Although amenorrhea is common in women with acromegaly, pregnancy occasionally occurs.[16] Pregnancy may be accompanied by tumor expansion that necessitates medical treatment and surgical resection.[17] Patients with acromegaly are at increased risk for diabetes, hypertension, and cardiomyopathy.

Management Options

Documenting elevation of GH levels during pregnancy may be difficult because of placental expression of a GH variant.[18] Few laboratories offer specific radioimmunoassays to differentiate GH from the placental variant. Lack of suppression of GH levels below 2 mg/mL during a glucose tolerance test can help to establish the diagnosis. Measurement of the level of somatomedin C, which mediates the effects of GH, is more useful in establishing the diagnosis of acromegaly in nonpregnant women. However, levels of this insulin-like growth factor may increase in normal pregnancy. Definitive surgical treatment or radiation therapy is often undertaken before conception. Tumor expansion necessitating hyperphysectomy during pregnancy can be expected to occur in 10% of untreated cases.[19] Dopaminergic agents may paradoxically decrease GH levels in patients with acromegaly. Case reports confirm the lack of tumor expansion during pregnancy in women receiving bromocriptine therapy.[20] More recently, octreotide (Sandostatin) was used to reduce GH levels in women with acromegaly who were pregnant or were attempting pregnancy.[21] Maternal-fetal transfer of octreotide has been shown to occur without side effects. However, few cases have been reported, and the potential benefits of octreotide treatment should be weighed carefully against the potential risks.[21,22]

Diabetes Insipidus

Maternal and Fetal Risks

Diabetes insipidus is rare, with fewer than 100 cases complicating pregnancy reported in the literature. The disease results from inadequate or absent antidiuretic hormone (vasopressin) production by the posterior pituitary gland. The etiology of diabetes insipidus is often unknown, although in most cases, it follows pituitary surgery or destruction of the normal pituitary architecture by tumor. It is a primary idiopathic disorder in up to 50% of cases. Many cases are likely autoimmune, with lymphocytic infiltration of the posterior pituitary gland. Massive polyuria, caused by failure of the renal tubular concentrating mechanism, and dilute urine, with a specific gravity less than 1.005, are characteristic of diabetes insipidus. To combat dehydration and the intense thirst produced by this syndrome, affected individuals consume large quantities of fluid. The diagnosis of diabetes insipidus relies on the finding of continued polyuria and relative urinary hyposmolarity when water is restricted. Administration of intramuscular vasopressin causes water retention and an appropriate increase in urine osmolality. This response is not seen in patients with nephrogenic diabetes insipidus, in which free water clearance is increased because of insensitivity of the renal tubules to antidiuretic hormone. In patients with primary polydipsia or psychogenic diabetes insipidus, urine osmolality increases in response to vasopressin or desmopressin (DDAVP).

However, the increase is not as marked as in individuals with central diabetes insipidus. Other conditions that cause polyuria, such as diabetes mellitus, hyperparathyroidism with hypercalcemia, and chronic renal tubular disease, must be considered in the differential diagnosis. However, these conditions usually can be distinguished from central diabetes insipidus by appropriate laboratory testing.

Hime and Richardson[23] reviewed 67 cases of diabetes insipidus complicating pregnancy and noted that 58% of patients showed deterioration during gestation, whereas 20% of patients showed improvement. To explain this phenomenon, it has been suggested that the increased glomerular filtration rate seen in pregnancy may increase the requirement for antidiuretic hormone.[24] Mild disease may worsen during pregnancy because antidiuretic hormone clearance is increased by increased placental vasopressinase activity.[25] Impaired liver function, including fatty liver of pregnancy, is seen with arginine vasopressin (AVP)–resistant but DDAVP-responsive diabetes insipidus during pregnancy, suggesting that several factors may explain the observed worsening of this condition.

Transient diabetes insipidus of pregnancy has been reported during the last trimester in women with presumed limited vasopressin secretion capacity.[26] Transient diabetes insipidus is associated with acute fatty liver and HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome as well as twin gestation. Increased placental vasopressinase activity, along with insufficient liver degradation in HELLP syndrome and acute fatty liver, may unmask this condition. Finally, diabetes insipidus can accompany Sheehan's syndrome.

Management Options

Synthetic vasopressin, in the form of l-deamino-8-D-arginine vasopressin (DDAVP), is the treatment of choice. This drug is given intranasally in doses of approximately 0.1 to 0.25 mg twice daily. Plasma electrolytes and fluid status should be monitored carefully with initiation of therapy. A stable dose is usually easy to achieve. Oxytocic activity is rarely observed. The successful use of DDAVP in pregnancy and the puerperium suggests that this drug is safe for both mother and fetus as well as during lactation.[27]

Spontaneous labor and lactation seem to occur in most patients with diabetes insipidus. Although older reports suggest an increased incidence of dysfunctional labor in affected patients, oxytocin release appears to be independent of vasopressin secretion.[28]

Pituitary Insufficiency

Maternal and Fetal Risks

Approximately 70 years ago, Sheehan[29] described postpartum ischemic necrosis of the anterior pituitary. This form of hypopituitarism is usually observed in patients with severe postpartum hemorrhage and hypotensive shock. Because pituitary necrosis is uncommon in patients with other conditions associated with hypovolemic shock, the hyperplastic pituitary gland of pregnancy may be more susceptible to hypoperfusion. It has been suggested that small sella size may be a risk factor.[30] Lymphocytic hypophysitis, an autoimmune form of hypopituitarism, is also more common in pregnant women and during the puerperium. It should be considered when hypopituitarism is suspected in patients without preceding postpartum hemorrhage. Slow clinical progression suggests that factors other than ischemia may be involved in the pathogenesis of pituitary insufficiency

after pregnancy. Tissue necrosis may release sequestered antigens, triggering autoimmunity of the pituitary and delayed hypopituitarism in Sheehan's syndrome.[31] Destruction of the gland as a result of tumor invasion, surgery, or radiation therapy may accompany pregnancy, although fertility is often compromised. Antepartum pituitary infarction is a rare complication of insulin-dependent diabetes mellitus.[32] In these cases, insulin requirements may decrease dramatically.

Patients with Sheehan's syndrome may have varying degrees of hypopituitarism, and specific assays of tropic hormones as well as stimulation and suppression tests may be necessary to establish the diagnosis. During pregnancy, because of normal physiologic changes, adjustments must be made in interpreting both hormone levels and responses to various stimuli. An average delay of 7 years is observed between onset and diagnosis. Hypovolemic shock from postpartum hemorrhage is a precipitating event in up to 79% of cases.[32] There is no apparent correlation between the degree of hemorrhage and the occurrence of Sheehan's syndrome. The characteristic clinical picture begins with failure to lactate. However, this does not occur in all cases. Some patients have late-onset disease and progress to loss of maxillary and pubic hair, oligomenorrhea, or amenorrhea with senile vaginal atrophic changes as well as signs and symptoms of hypothyroidism. Patients with these findings are usually infertile, although the frequency of pregnancy is difficult to ascertain. In a review of 19 patients with Sheehan's syndrome documented by endocrinology studies or postmortem examination, 39 pregnancies occurred after the onset of hypopituitarism.[32] Eleven of these women required hormonal therapy to establish a pregnancy, and replacement therapy was used during 15 (38%) of the 39 pregnancies. The treated group had a live birth rate of 87%, compared with 54% in untreated patients, suggesting that early diagnosis and proper therapy improve outcome.

Because pregnancy may occur in women with Sheehan's syndrome,[33] this diagnosis should be considered in all patients with a history of postpartum hemorrhage. Measuring gonadotropin levels is of little value because levels decrease with normal pregnancy. However, the finding of a low or low-normal level of thyroid-stimulating hormone in conjunction with a low serum thyroxine level is consistent with secondary hypothyroidism. Similarly, low cortisol levels that do not increase with stress and decreased ACTH levels support the diagnosis.

Management Options

The treatment of pituitary insufficiency involves replacement of hormones that are necessary to maintain normal metabolism and respond to stress. Thyroid hormone may be provided as L-thyroxine in doses of 0.1 to 0.2 mg daily. Target free thyroxine levels should be in the mid-normal range. Corticosteroids are essential for patients who have adrenal insufficiency. Maintenance dosage is cortisone acetate 25 mg every morning and 12.5 mg every evening or prednisone 5 mg every morning and 2.5 mg every evening. Mineralocorticoid replacement is rarely necessary because adrenal production of aldosterone is not solely dependent on ACTH stimulation. The dose of glucocorticoids should be increased during the stress of labor and delivery.

ADRENAL DISEASE

Normal Changes in Pregnancy

A two- to threefold increase in cortisol levels is observed by the end of normal pregnancy.[34] Most of this increase is caused by an estrogen-induced increase in cortisol-binding globulin levels; however, biologically active free cortisol levels are also elevated.[35] An increase in free, or unbound, cortisol is apparent by the end of the first trimester. The urinary free cortisol concentration is also elevated during gestation.

Increased cortisol-binding globulin levels prolong the half-life of cortisol in plasma, and cortisol production is also increased. Urinary 17-hydroxycorticosteroid levels are actually lower in pregnancy because excretion of cortisol tetrahedron metabolites is decreased.[36] ACTH levels increase

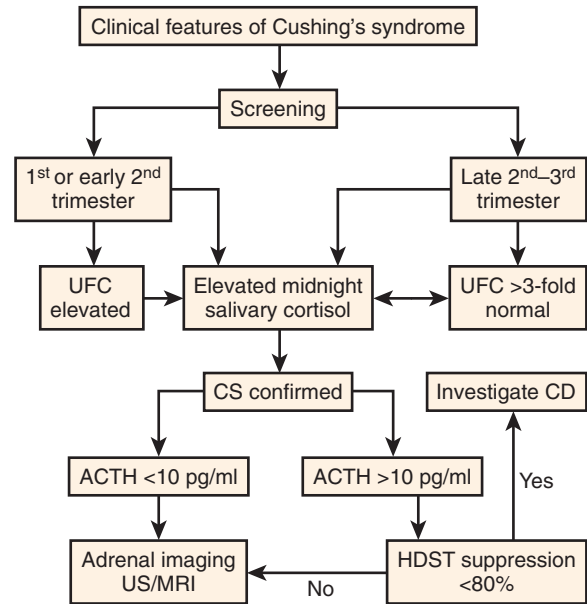
throughout pregnancy, but absolute levels remain lower in the pregnant than in the nonpregnant state.[37] Both ACTH and cortisol surge during labor. Unlike cortisol, ACTH does not cross the placenta. ACTH is manufactured by the placenta, as is corticotropin-releasing hormone. The relationship between these placental hormones and maternal adrenal function is unknown. Aldosterone secretion, which is controlled by the renin-angiotensin system, increases in early pregnancy. Finally, the production of dehydroepiandrosterone in the adrenal cortex is elevated in normal pregnancy. This hormone is aromatized to estradiol and estrone by the placenta.

Cushing's Syndrome

Maternal and Fetal Risks

Cushing's syndrome, which is characterized by excess glucocorticoid production, arises from ACTH-dependent or -independent inappropriate hypersecretion of ACTH by a pituitary adenoma (Cushing's disease) or from ectopic production of ACTH.[38] Cushing's syndrome as a result of primary adrenal disease, usually an adrenal adenoma, is more common during pregnancy than in the nonpregnant state. It accounts for approximately 50% of Cushing's syndrome cases during pregnancy.[39] Patients with pituitary disease and secondary adrenal hyperplasia are more likely to have excess androgen secretion, which can inhibit pituitary gonadotropin release. Amenorrhea is common in this setting. In contrast, adrenal adenomas are more likely to be pure cortisol producers and less likely to impair fertility.[34] Other causes of Cushing's syndrome include neoplastic ectopic ACTH production, nodular adrenal hyperplasia, and excessive doses of exogenous corticosteroids.

Because women with Cushing's syndrome are usually infertile, de novo cases are rare in pregnancy. Most cases occur in patients who were previously or partially treated. The clinical features may be difficult to distinguish from many signs and symptoms that accompany normal pregnancy. Weakness, weight gain, edema, striae, hypertension, and impaired glucose tolerance may be observed, both during gestation and in Cushing's syndrome. Early onset of hypertension, with easy bruising and proximal myopathy, strongly suggests the diagnosis and requires further evaluation.

Laboratory diagnosis includes elevated serum cortisol levels without diurnal variation and failure to suppress cortisol secretion with the administration of dexamethasone. Assays for ACTH are of variable accuracy and may confuse the diagnosis. However, an elevated early-morning ACTH value in the presence of high urinary levels of free cortisol suggests ACTH-dependent Cushing's syndrome. During gestation, total and free cortisol levels normally increase. Therefore, laboratory results must be compared with established norms for pregnancy. Diurnal variation in cortisol production is maintained in normal pregnancy, although free plasma cortisol levels at term may be two to three times higher than those in nonpregnant women. Further, even in normal pregnant patients, cortisol secretion may not be suppressed with low doses of dexamethasone (1 mg).[37] The preferred screening test for Cushing's syndrome is a 24-hour urine free cortisol measurement. A mean eightfold increase


in urinary free cortisol accompanies cases of Cushing syndrome during pregnancy.[38] It has been suggested that if urinary collection shows levels elevated threefold and midnight salivary cortisol is also present, then Cushing's syndrome is diagnosed and the cause of excess cortisol production must be determined[40] (Fig. 46–3). A high-dose dexamethasone test may be helpful in distinguishing the site of excess cortisol production. Most patients with adrenocortical hyperplasia show greater than 50% reduction in plasma and urinary corticosteroid levels with an 8-mg dose (2 mg q6h for 2 days). If suppression is unsuccessful, an adrenal tumor, an autonomous adrenal nodule, or ectopic ACTH production must be considered. After testing, pituitary or adrenal gland imaging should be undertaken. MRI is the optimal imaging modality during pregnancy because no radiation is used.

Several reports suggest that Cushing's syndrome may be exacerbated by pregnancy, with improvement of symptoms after delivery.[34,38,39] In most cases, Cushing's syndrome is associated with an adrenal adenoma.[38] Keegan and colleagues[41] speculated that placental ACTH may stimulate a latent adrenal tumor, with adrenal cortisol secretion decreasing after parturition. The idea that pregnancy may stimulate the development of Cushing's syndrome is supported by the fact that in virtually all reports of Cushing's syndrome in pregnancy, the diagnosis was not established until pregnancy occurred.[34] Several cases of recurrent Cushing's syndrome during pregnancy have been described. These may represent hyperresponsiveness of adrenocortical cells to a non-ACTH or non–corticotropin-releasing hormone substance that is produced during pregnancy.[42]

Pregnancy outcome in Cushing's syndrome is marked by a high rate of preterm delivery (43%) and stillbirth (6%) when elective termination is not performed.[38] Maternal

TABLE 46–2

Cushing's Syndrome and Perinatal Complications in 65 Pregnancies

COMPLICATION	%
Miscarriage	3.1

hyperglycemia may be a contributing factor to the intrauterine deaths observed (Table 46–2). Hypertension has been reported in 68% of cases, and preeclampsia in 9%.[31,38]

Koerten and coworkers[43] reviewed 33 cases of Cushing's syndrome in pregnancy and concluded that maternal complications are more common with adrenal adenomas than with hyperplasia. In this review, every patient with an adenoma had hypertension if the pregnancy progressed beyond the first trimester. Seven of 16 (47%) patients had pulmonary edema, and 1 died. In contrast, only 1 of the 12 patients with adrenal hyperplasia had hypertensive disease. The overall prematurity rate (delivery after 20 weeks' gestation) was 20 of 33 cases (61%); stillbirth occurred in 4 cases.

Management Options

Management of the pregnant patient with cortisol excess includes identifying the source of hormone production and instituting proper therapy. Surgery is recommended for disease diagnosed during the first trimester.[38] Patients with pituitary disease are most often treated surgically if a tumor can be well defined. Surgical removal of adrenal adenomas can be accomplished through a posterior incision. Bevan and associates[44] examined maternal and fetal outcomes based on the timing of surgery. Fetal loss occurred in 1 of 11 (9%) patients treated during gestation versus 8 of 26 (31%) in whom definitive therapy was delayed. In Buescher and colleagues's review[34] of 105 cases in which 32 women underwent therapy to relieve hypercortisolism, treatment reduced the perinatal mortality rate from 15% to 6.3%. Again, because the incidence of adrenal adenoma and carcinoma appears to be increased in pregnant patients with Cushing's syndrome, prompt evaluation with MRI is warranted, particularly if high levels of dexamethasone do not suppress excess cortisol production. Surgery is indicated if an adrenal tumor is discovered. Treatment may be delayed in the third trimester if an expedited delivery is planned.

Primary Aldosteronism

Maternal and Fetal Risks

Few cases of primary aldosteronism during pregnancy have been reported.[40] The diagnosis is suggested in a patient with hypertension, hypokalemia, and metabolic alkalosis. Adrenal adenoma is the most common etiology, present in nearly 75% of cases. Glucocorticoid-remediable aldosteronism is a hereditary form of primary aldosterone excess that causes hypokalemia and hypertension in childhood. This diagnosis is established before pregnancy and is amenable to medical treatment. The clinical course of these pregnancies has been described, including a high rate of preeclampsia in patients with underlying chronic hypertension.[45] Because aldosterone secretion is increased during pregnancy, the diagnosis of new-onset hyperaldosteronism can be difficult to establish. However, elevated aldosterone levels accompanied by suppressed renin levels support the diagnosis of primary

hyperaldosteronism. High levels of urinary potassium with serum hypokalemia also help to establish the diagnosis. Failure to replace serum potassium may also suppress aldosterone secretion, obscuring the diagnosis.[45] Inappropriately high aldosterone levels are present after suppression testing. The potassium level should be normalized before the administration of suppression tests, such as 9-α-fludrocortisone. Amelioration of hypertension and hypokalemia during gestation is attributed to high levels of progesterone, which may block the action of aldosterone. Even so, patients often have severe hypertension and superimposed preeclampsia.

Management Options

The management of patients without toxemia complicating primary aldosteronism is controversial.[46] Although early case reports suggested prompt surgical excision of underlying adrenal adenomas, Lotgerring and associates[47] described successful medical therapy from midgestation with spironolactone, an aldosterone antagonist, and other antihypertensive medications. This therapy should be used cautiously because spironolactone is an antiandrogen that may cause feminization of a male fetus. Laparoscopic adrenalectomy has been used to treat primary hyperaldosteronism during pregnancy.[48]

• Open surgery.	IV/C	46

Adrenal Insufficiency

Maternal and Fetal Risks

Adrenal insufficiency is usually primary (Addison's disease) and caused by autoimmune destruction. Granulomatous diseases, such as tuberculosis, bilateral adrenalectomy, fungal infection, and AIDS, are other rare etiologies. Pituitary failure or adrenal suppression as a result of steroid replacement may also lead to adrenal insufficiency. In these cases, mineralocorticoid production is preserved. Adrenal crisis, an acute, life-threatening condition, may accompany stressful conditions, such as labor, the puerperium, or surgery. Unfortunately, the diagnosis of hypoadrenalism is often difficult, particularly in patients who have enough adrenal reserve to sustain normal daily activity. Postpartum adrenal crisis may lead to the diagnosis of adrenal insufficiency for the first time.[49]

The clinical presentation of Addison's disease during gestation is similar to that in the nonpregnant state. Fatigue, weakness, anorexia, nausea, hypotension, nonspecific abdominal pain, hypoglycemia, and increased skin pigmentation are hallmarks of this endocrinopathy. Mineralocorticoid deficiency leads to renal sodium loss, with resultant depletion of intravascular volume. A small cardiac silhouette on chest radiography is often associated with reduced cardiac output and eventual circulatory collapse. Hypoglycemia, which is common in early pregnancy, may be exacerbated by glucocorticoid deficiency.

Management Options

The diagnosis of adrenal insufficiency is based on specific laboratory findings. Plasma cortisol levels are decreased. However, because the level of cortisol-binding globulin is elevated in pregnancy, even low-normal cortisol values may reflect adrenal insufficiency.

Stimulation of the adrenal gland by synthetic ACTH may help to establish a diagnosis.[50] After intravenous administration of 0.25 mg cosyntropin (Cortrosyn), the plasma cortisol level should be increased at least twofold over baseline values. Failure to respond to this stimulus suggests primary adrenal insufficiency. This test may be used in pregnancy because little ACTH crosses the placenta. A longer ACTH stimulation test is used if the short test does not confirm the diagnosis. Measurement of serum ACTH may also help to distinguish primary adrenal insufficiency from hypopituitarism. Low baseline serum cortisol levels, coupled with ACTH levels greater than 250 pg/mL, confirm the diagnosis of primary adrenal insufficiency.

Pregnancy usually proceeds normally in treated patients. Maintenance replacement of adrenocortical hormones is provided by cortisone acetate 25 mg orally each morning and 12.5 mg in the evening. As an alternative, prednisone may be substituted at doses of 5 mg and 2.5 mg, respectively. Mineralocorticoid deficiency is treated with fludrocortisone acetate (Florinef) 0.05 to 0.1 mg daily. Stress doses of glucocorticoids should be administered during labor and

delivery. With doses of glucocorticoids exceeding 300 mg in 24 hours, supplemental mineralocorticoid therapy is unnecessary. The use of a mineralocorticoid requires careful observation for symptoms of fluid overload. Patients with edema, excess weight gain, and electrolyte imbalance require dose adjustment.

Adrenal crisis is a rare, life-threatening condition that requires immediate medical attention. Treatment in an intensive care setting is recommended. Women with undiagnosed Addison's disease may have a crisis during the puerperium. Symptoms include nausea, vomiting, and profound epigastric pain accompanied by hypothermia and hypotension. After blood samples are obtained for diagnostic purposes, treatment initially consists of glucocorticoid and fluid replacement. Intravenous hydrocortisone is given at a dose of 100 mg, followed by repeat doses every 6 hours for up to several days. Mineralocorticoid replacement is indicated in cases of refractory hypotension or hyperkalemia.

Patients with adrenal insufficiency should wear an identifying bracelet. Emergency medical kits are available to help these patients when they travel. Women with Addison's disease require an increase in steroid replacement during periods of infection or stress and during labor and delivery. Cortisol is administered at a dose of 100 mg intravenously every 8 hours for the first 24 hours. The dose of steroids is reduced by 50% the next day.

Pheochromocytoma
Maternal and Fetal Risks

Pheochromocytoma is a rare, catecholamine-producing tumor that is uncommon in pregnancy. Approximately 200 cases have been reported in the literature.[40] The tumors arise from the chromaffin cells of the adrenal medulla or sympathetic nervous tissue, including remnants of the organs of Zuckerkandl, neural crest tissue that lies along the abdominal aorta. In pregnancy, as in the nonpregnant state, the tumor is located in the adrenal gland in 90% of cases.[51] The incidence of malignancy, which can be diagnosed only when metastases are present, is approximately 10%. In patients with a family history of pheochromocytoma, multiple endocrine neoplasia syndrome (MEN types IIa and IIb) should be suspected. Pheochromocytoma is more common in patients with neurofibromatosis. Schenker and colleagues[51,52] reported mortality rates of 55% with postpartum diagnosis versus 11% with diagnosis during pregnancy. Fetal loss rates can exceed 50%.

In pregnancy, pheochromocytoma may cause a hypertensive crisis, with cerebral hemorrhage or severe congestive heart failure. Pheochromocytoma is easily confused with other medical diseases. The signs and symptoms may mimic those of severe pregnancy-induced hypertension (Table 46–3). Hypertension, headache, abdominal pain, and blurring of vision are common to both entities. Although not uniformly present, paroxysmal hypertension (particularly <20 wk' gestation), orthostasis, and absence of significant proteinuria and edema may be helpful in the differential diagnosis. Severe thyrotoxicosis may also resemble this

---

TABLE 46–3
Symptoms and Signs in 89 Cases of Pheochromocytoma in Pregnancy

SYMPTOM OR SIGN	%

disease. However, significant diastolic hypertension is rarely seen with hyperthyroidism. Aggravation of hypertension with administration of β-blockers suggests pheochromocytoma. An unexplained hypertensive response to anesthesia or circulatory collapse after delivery should also prompt consideration of this diagnosis.

Management Options

PREPREGNANCY

If this condition is suspected, a complete diagnostic evaluation is indicated before pregnancy is attempted. Definitive therapy should be undertaken (discussed later).

PRENATAL

The diagnosis depends on laboratory measurement of catecholamines and their metabolites in a 24-hour urine collection. Elevated metanephrine excretion appears to be the most sensitive and specific finding, although isolated elevated vanillylmandelic acid excretion may be present.[50] Because episodic secretion of catecholamines occurs with some tumors, plasma assay of epinephrine or norepinephrine may be helpful during symptomatic episodes.[52] Levels of catecholamines are unaffected by normal pregnancy. Levels may be elevated after eclamptic seizures. Extra-adrenal tumors have characteristic elevations of norepinephrine, but not epinephrine.

Pharmacologic testing may establish the diagnosis in the nonpregnant patient. The phentolamine (Regitine) test is based on the observation that marked α-adrenergic blockade causes a decrease in blood pressure in many patients with pheochromocytoma. This test is not advised during pregnancy because it is associated with maternal and fetal deaths.[52] Nonetheless, it is extremely importance that the

diagnosis be established. Approximately 90% of maternal deaths as a result of pheochromocytoma occur in patients who are undiagnosed before delivery.[53] When symptoms suggest pheochromocytoma and laboratory findings support the diagnosis, the tumor should be localized with radiologic techniques. MRI is the procedure of choice in pregnancy. In the nonpregnant state, selective venous catheterization of the adrenals may be performed. The tumor is bilateral in approximately 10% of cases, including those that occur during gestation.

Before surgery, the patient's condition should be stabilized with oral doses of phenoxybenzamine and α-adrenergic receptor blockers.[54] Careful evaluation of fluid status with central monitoring is essential when using these preparations. β-Blockade with propranolol or similar selective agents is reserved for the treatment of tachyarrhythmias and should not be instituted before α-blockade because hypertensive crisis may ensue. Labetalol is not recommended because it is a combined adrenergic-blocking agent. Hypertensive crisis requires intravenous phentolamine administration in an intensive care setting.

Schenker and Granat[52] recommend prompt surgical removal of pheochromocytomas detected before 24 weeks' gestation. Laparoscopic removal has been achieved during pregnancy.[55] When the diagnosis is made during the early third trimester, maternal stabilization with medical therapy has been successful, allowing further fetal maturation.

LABOR AND DELIVERY AND POSTNATAL

Cesarean delivery is preferred because it minimizes the potential catecholamine surges associated with labor and vaginal delivery. Adrenal exploration is performed at the time of cesarean delivery. Careful follow-up is needed because tumors may recur and are potentially malignant.

CATHERINE WILLIAMSON and JOANNA GIRLING

INTRODUCTION

Anatomy and Physiology of the Liver

An understanding of the physiologic changes of normal pregnancy is vital if pathologic conditions are to be correctly defined. False-positive and false-negative interpretations can result if the normal changes due to pregnancy are not fully appreciated.

The liver moves superiorly and posteriorly in pregnancy, such that a palpable liver edge is likely to be pathologic. Absolute blood flow to the liver is unchanged, although the proportion of cardiac output perfusing the liver falls from 35% to 25%. Venous pressure increases in the esophagus due to increased circulating volume, increased portal pressure, and increased pressure from the gravid uterus, thereby diverting a greater proportion of venous return from the inferior vena cava via the azygos system. This results in transient esophageal varices in up to 60% of healthy pregnant women.[1,2] Spider nevi, palmar erythema, and edema are common findings in normal pregnancy, reflecting, in part, peripheral vasodilation. They should not be assumed to be due to chronic liver disease unless they clearly antedate the pregnancy.

The liver has several important functions, including protein synthesis, metabolism, excretion, and inactivation of a number of substances. Changes in each of these should be considered in relation to both the effect of normal pregnancy and the potential overlap with the changes of liver disease outside pregnancy:

- Protein synthesis increases in pregnancy, with rises in coagulation Factors VII, VIII, and X and fibrinogen: The last of which has usually doubled by the end of pregnancy, so an apparently normal result may reflect a significant abnormality in, for example, disseminated intravascular coagulopathy (DIC).[3] This increase is probably the main cause of the increase in erythrocyte sedimentation rate that occurs in pregnancy; the 95th percentile for the second trimester in a nonanemic woman being 70 mm/hr.[4] In acute liver failure, prolongation of the prothrombin time (PT) may be the first sign of coagulopathy, because prothrombin has the shortest half-life of those coagulation factors manufactured in the liver. Production of albumin is not changed during uncomplicated pregnancy, and hemodilution results in a fall in concentration, so that levels of 28 g/L are commonly seen. These do not reflect failure of hepatic synthesis, as might be the case outside pregnancy. The concentration of many hormone-binding proteins is increased, largely due to reduced metabolism rather than increased hepatic synthesis. For example, the higher concentration of estrogen stimulates greater sialylation of the carbohydrate moieties of thyroxine-binding globulin, which extends its half-life from 15 minutes to 3 days[5] and so greatly increases the total throxine (T_4).

- Amino acids undergo oxidative deamination in the liver to produce ammonia, which is converted to urea in the Krebs cycle. Failure of this process in severe liver disease can contribute to hepatic encephalopathy. It may also be associated with low urea concentrations, which must not be confused with the fall in urea that occurs as a consequence of the increased glomerular filtration rate of normal pregnancy.[6]

- Hypercholesterolemia occurs in some forms of chronic liver disease owing to impaired excretion. Hypertriglyceridemia can occur in chronic alcohol abuse. In normal pregnancy, their concentrations increase by 50% and 300%, respectively,[7] and take several months to return to normal after delivery.

- The liver is responsible for postprandial glucose storage and subsequent release during fasting. Hypoglycemia may occur, despite these large glucose reserves, in patients with massive liver necrosis, for example, in acute fatty liver of pregnancy (AFLP), and is an important cause of liver coma. Serial measurements of blood glucose and, subsequently, intravenous infusion of 50% dextrose are important in preventing hypoglycemic coma in patients with severe liver failure.

Anatomy and Physiology of the Gastrointestinal Tract

The gastrointestinal tract also undergoes extensive physiologic changes in pregnancy. These changes contribute to the common findings of nausea and vomiting, gastroesophageal reflux, constipation, and hemorrhoids, although the exact basis for these changes is not clearly understood. Nausea and

TABLE 47–1

Liver Function Tests in Normal Pregnancy

TEST	NONPREGNANT	FIRST TRIMESTER	SECOND TRIMESTER	THIRD TRIMESTER
AST u/L	7–40	10–28	11–29	11–30
ALT u/L	0–40	6–32	6–32	6–32

Alk phos u/L	30–130	32–100	43–135	130–418

Alk phos, alkaline phosphatase; ALT, alanine aminotransaminase; AST, aspartate aminotransaminase; Bili, bilirubin; GGT, γ-glutamyl transferase.
From Girling JC, Dow E, Smith JH: Liver function tests in preeclampsia: Importance of comparison with a reference range derived for normal pregnancy. Br J Obstet Gynaecol 1997;104:246–250.

vomiting seem to be due to the combined actions of estrogen and progesterone, although this is not certain; human chorionic gonadotrophin may also make a contribution (see the section on "Hyperemesis Gravidarum"). Gastroesophageal reflux occurs in up to 80% of pregnancies[8] and is thought to be due to a combination of reduced lower esophageal sphincter pressure, raised intragastric pressure, reduced pyloric sphincter competence with backwash of alkaline bile, and failure of clearance of acid gastric contents. Constipation is traditionally attributed to progesterone-driven smooth muscle relaxation and increasing transit times allowing more fluid to be absorbed. However, in pregnancy, only small bowel transit times have been reported[9]; colonic times have not been studied directly. Iron supplements, dietary changes, and altered exercise levels may also contribute, as may mechanical problems in the lower gastrointestinal tract, especially the anal sphincter.[10]

Liver Function Tests

So-called liver function tests (LFTs) are really nonspecific tests of liver cell damage: In essence, they reflect the extent of hepatocyte damage, although if damage is extensive and sustained, values may plummet. In pregnancy, significant changes occur in the commonly measured tests of liver function, which must be borne in mind when interpreting blood results. Aspartate transaminase (AST), alanine transaminase (ALT), γ-glutamyl transferase (GGT), and total bilirubin each fall during pregnancy, the upper limit of normal being about 25% lower than outside pregnancy. This is mainly as a result of hemodilution[11] (Table 47–1). Alkaline phosphatase rises steadily through pregnancy, reaching a peak in the third trimester up to 300% above the nonpregnant range, owing to the production of a heat stable placental isoenzyme: If there is a clinical indication to differentiate the hepatic from the placental form, the sample can be heat-treated to 60°C for 10 minutes and then reanalyzed, the fall representing the liver isoenzyme.

In the postnatal period, alkaline phosphatase falls steadily, reaching nonpregnant values by day 13 in most women. The transaminases may rise considerably, especially during the first 5 days of the puerperium, and can exceed both the pregnant and the nonpregnant reference ranges[12] (Table 47–2). This is because they are not specific to liver, occurring also in breast, smooth and striated muscle, and red blood cells. The exercise of labor, the trauma of delivery, and breast-feeding may all contribute to this phenomenon.

TABLE 47–2

Liver Function Tests following Delivery in Normal Pregnancy

TEST	POSTPARTUM PEAK (DAYS)	MEAN RISE (%)	RANGE RISE (%)
AST	2–5	88	0–500
ALT	5	147	0–1140
GGT	5–10	62	0–450
Alk phos	Predelivery	–	–

Alk phos, alkaline phosphatase; ALT, alanine aminotransaminase; AST, aspartate aminotransaminase; GGT, γ-glutamyl transferase.

It is essential to bear this in mind when managing liver disease in the puerperium.

The Fetus and Maternal Liver Disease

In many cases, the fetus is only affected by the maternal liver condition if the pregnant woman is systemically unwell, for example, febrile, dehydrated, hypoglycemic, or profoundly malnourished. Specific issues relating to transmission of infection, the genetic input of the fetus to the maternal condition (e.g., AFLP), the role of the placenta (e.g., preeclampsia and HELLP [hemolysis, elevated platelets, and low platelets] syndrome), and fetal "poisoning" (e.g., obstetric cholestasis [OC]) are covered in the relevant sections. It does not seem that fetal exposure to raised bilirubin, even if prolonged, or toxic metabolites of maternal liver failure influence development.[13] Unconjugated bilirubin crosses the placenta bidirectionally, and this is the main route of fetal clearance. There is not a simple link between maternal and fetal levels of bilirubin.

JAUNDICE

Jaundice may be coincidental to the pregnancy or due to a condition that is specific to the pregnancy. Worldwide, the most common cause of jaundice in pregnancy is viral hepatitis, usually hepatitis A. In some parts of the world, hepatitis B, C, or E is most prevalent. Hepatitis secondary to infection with cytomegalovirus (CMV), Epstein-Barr virus (EBV), toxoplasmosis, or herpes simplex should also be considered as causes of jaundice in pregnancy, not least because of the

FIGURE 47–1

The potential points for pathologic processes resulting in jaundice.
other important implications that these infections have for the fetus. Other common causes of jaundice not related to the pregnancy are the complications of gallstones, drug reactions (in the United Kingdom co-amoxiclav is the most common prescription-related cause of cholestatic jaundice), and drug abuse, including alcohol.

The pregnancy-specific causes of jaundice are AFLP, HELLP syndrome, OC, and hyperemesis gravidarum. Only in the first of these, which is also the rarest, is jaundice a common feature.

Physiology

When faced with the challenge of a jaundiced pregnant patient, it is easier to reach a diagnosis if a simple logical pathway is followed. Initially, the jaundice should be classified according to its type. Then, its cause can usually be determined. An understanding of the physiology of bilirubin handling makes this much easier.

Following the destruction of a red blood cell, the released hemoglobin is broken down into globin and heme; other heme-containing proteins, such as myoglobin, cytochromes, and catalase, contribute up to 15% of the total heme. The heme is broken down to biliverdin, which is reduced to form bilirubin, usually amounting to 250 to 300 mg daily: This is not changed by pregnancy. This bilirubin is unconjugated and water-insoluble and usually carried to the liver bound to albumin. In this state, it is unable to pass through the kidney or the blood-brain barrier. However, unbound unconjugated bilirubin is lipid-soluble and can cross the blood-brain barrier. This is most likely in neonates with immature conjugating mechanisms or in the presence of either profound hypoalbuminemia or displacement of bilirubin from albumin by, for example, fatty acids, salicylates, or sulfonamides.

At the hepatocyte membrane, unconjugated bilirubin is actively taken up and conjugated to two molecules of glucuronide, by the action of uridine diphosphoglucurosyl (UDP) transferase. This conjugated bilirubin is water-soluble and usually remains in the liver. Hepatocyte (or canalicular) damage allows it to enter the blood, and the part that remains unbound passes into urine and causes the dark urine of cholestatic jaundice; it is always abnormal to find bilirubinuria. The protein-bound conjugated bilirubin contributes to the yellow discoloration of skin and mucus membranes and the hyperbilirubinemia of liver disease.

From the hepatocyte, bilirubin is actively taken up by the bile canaliculus. It is these energy-dependent steps that are most likely to be impaired by either liver damage or increased pressure in the biliary tract. From the canaliculus, conjugated bilirubin drains into the extrahepatic bile ducts, the common bile duct, and finally, the small intestine. The conjugated bilirubin is too large to be absorbed from this location. It passes to the terminal ileum where bacterial action hydrolyzes it to free bilirubin, which is then reduced to urobilinogen. Some of this undergoes further bacterial action in the stool, changing it to stercobilinogen, which contributes to the dark color of feces—reduced entry of bilirubin into the gut accounts for the pale stool of cholestatic jaundice. The rest of the urobilinogen is absorbed and returns to the liver via the enterohepatic circulation; from there it is reexcreted into the bile. This urobilinogen is water-soluble, and in normal circumstances, a small amount passes into the urine. Urinary urobilinogen is increased either if there is an increased load of bilirubin, in which case, the hepatic capacity to reexcrete the urobilinogen may be overwhelmed, or if hepatic damage impairs reexcretion.

Classification and Risks

In Figure 47–1, the potential points for pathologic processes resulting in jaundice are highlighted. Three pathologic processes lead to jaundice:

- Hemolysis
- Congenital hyperbilirubinemia
  - Unconjugated
  - Conjugated
- Cholestasis
  - Intrahepatic
  - Extrahepatic

Hemolytic Jaundice

Hemolytic jaundice occurs when there is excess breakdown of red blood cells and is characterized by increased unconjugated bilirubinemia. There are no abnormalities in AST, ALT, or GGT unless liver disease is present as well. Investigations are centered on causes of hemolytic anemia, including hereditary spherocytosis or elliptocytosis, thalassemia, sickle cell disease, glucose-6-phosphate dehydrogenase, blood group incompatibility, or drug reaction. In HELLP syndrome, the main cause of jaundice may be hemolysis.

Congenital Hyperbilirubinemia

In this group of disorders. raised bilirubin is the only biochemical abnormality. It occurs when there is either defective conjugation or abnormal handling of bilirubin. The most common condition in this category is Gilbert's syndrome. This benign, familial cause of unconjugated hyperbilirubinemia affects up to 7% of the general population. Most patients have a reduced level of UDP transferase, to around 30% of normal. A number of gene mutations have been described, although phenotypic expression of carriers varies widely, with some individuals being asymptomatic and others experiencing intermittent jaundice. Fasting, intercurrent illness, and pregnancy have been reported to increase the level of unconjugated bilirubinemia, with up to half of pregnant women developing worsening of jaundice.[14] Apart from the raised bilirubin, the other LFTs are normal, and there are no stigmata of chronic liver disease. The reticulocyte count is not raised, thus excluding hemolysis.

Crigler-Najjar syndrome is a very rare and much more serious cause of unconjugated hyperbilirubinemia, which is due to either absence of (autosomal recessive) or marked reduction of (autosomal dominant) UDP transferase. This usually presents at birth, with jaundice and sometimes kernicterus.

Conjugated hyperbilirubinemia is due to defective handling of bilirubin within the liver. Dubin-Johnson syndrome is autosomal recessive and results from a mutation in the *MRP2* (multidrug-resistance protein 2) gene, which is responsible for transporting a wide range of compounds out of the hepatocyte across the canalicular border, including bilirubin and bile salts. It is benign, with a good prognosis, with most affected individuals experiencing only mild and fluctuating jaundice. Rotor's syndrome is a similar condition,

which is often autosomal dominant. In both conditions, bilirubinuria is present.

Benign recurrent intrahepatic cholestasis (BRIC) and progressive familial intrahepatic cholestasis (PFIC) are rare causes of conjugated congenital hyperbilirubinemia, which in pregnancy may account for a small proportion of cases of OC (see the following sections).

Cholestatic Jaundice

The broad term *cholestasis* refers to failure to excrete bile from the hepatocyte, the canaliculus (intrahepatic), or the common bile duct (extrahepatic) owing to acquired damage or obstruction. Consequently, some or all of the substances usually excreted by this route, including bilirubin, bile salts, cholesterol, and phospholipids, accumulate in the blood. Alkaline phosphatase levels may rise, due to either increased synthesis at the sinusoidal surface of the hepatocyte or reentry from the sinusoids into the systemic circulation in response to raised intraductal pressure. Cholestasis may occur without jaundice if excretion of bilirubin is maintained or only part of the liver is affected. Jaundice occurs when the failure of excretion of bilirubin results in its accumulation in the circulation.

Intrahepatic cholestatic jaundice is due to any of a wide range of abnormalities at a cellular level and has a diverse number of clinical causes. Within this category fall viral hepatitis, drug reactions, alcohol abuse, cirrhosis of any cause, OC, AFLP, and hyperemesis gravidarum. Extrahepatic cholestasis is due to obstruction to the flow of bile at any point beyond the canaliculus; causes include gallstones, biliary stricture, pancreatitis, and malignancy.

In both forms of cholestatic jaundice, there may be pale stool, dark urine, and conjugated bilirubinemia. They must be clearly differentiated from each other by careful history, examination, and investigation because they require different management strategies.

In practical terms, an important step in assessing a patient with jaundice is to establish the type of jaundice (see the section on "Classification" and Table 47–3). This is very simply and quickly done by asking the laboratory to report the bilirubin as both the total amount and divided into conjugated and unconjugated forms (also referred to as "direct" and "indirect" bilirubin). Commercial urine dipsticks should be used to test for bilirubinuria (which is always abnormal) and urinary urobilinogen. Table 47–3 can then be used to establish the most likely type of jaundice.

TABLE 47–3

Serum and Urine Findings in a Jaundiced Patient, Allowing Characterization of the Cause of the Jaundice

| CAUSE OF JAUNDICE | SERUM BILIRUBIN | | URINE BILIRUBIN | | RETICULOCYTE COUNT | ALT |

Management Options

Prepregnancy

Some causes of jaundice have long-term implications for maternal health and should be discussed prior to pregnancy.

Prenatal

It is important to determine the type of jaundice and its cause. Management depends on the cause and involves interdisciplinary approaches with health professionals from other specialties according to differential diagnosis.

Labor and Delivery

Planned early delivery may be required as "treatment" for some pregnancy-specific causes of jaundice, but is not inevitable. An epidural should not be sited if a coagulopathy or profound thrombocytopenia is present.

Postnatal

Resolution of jaundice should be confirmed. Care should be taken with the use of the oral contraceptive pill. Implications for future pregnancy depend on the cause and should be discussed with the patient.

OBSTETRIC CHOLESTASIS

General

OC affects 0.7% of pregnancies in whites in the United Kingdom and approximately double this proportion of women of South Asian origin.[15,16] It is associated with maternal hepatic impairment and with fetal morbidity and mortality. OC has a complex etiology, with genetic, environmental, and endocrinologic factors playing a role.[17–22]

Women who develop OC are thought to have an increased sensitivity to the cholestatic effect of raised serum estrogens in pregnancy. The condition occurs most commonly in the third trimester when estrogen levels are highest and some women with a previous history of OC develop similar symptoms when taking the oral contraceptive pill[23] or when challenged with exogenous estrogens.[24] It has also been suggested that progesterone may play a role in the etiology of the condition because 34 of 50 women (68%) in a French prospective series of OC cases had been treated with oral micronized natural progesterone for risk of premature delivery.[25]

Diagnosis

The classic maternal symptom of OC is generalized pruritus without a rash. Dark urine, pale stool, or jaundice may also be present, but these are uncommon. If pruritus is associated with abnormal liver transaminases or raised bile acids, OC should be considered. A U.K. study demonstrated that pruritus without hepatic impairment occurs in approximately 50% of pregnancies.[26] Among women with pruritus, 3% had OC (using a diagnosis of pruritus plus raised serum

FIGURE 47–2
Dermatologic features observed in obstetric cholestasis cases: Dermatitis artefacta.

transaminases or bile acids), and in this group, the itch was more commonly described as "all over," "on the legs," or "on the palms and soles."

Measurement of bile acids is the most useful test for the diagnosis of OC. In unaffected pregnancies, the levels of serum bile acids change little.[27] The extent of the rise in OC pregnancies is variable and can be marked. A Swedish study of approximately 700 OC pregnancies showed that fetal complications of spontaneous preterm delivery, meconium-stained liquor, and fetal asphyxia occur more commonly in pregnancies in which the fasting serum bile acids are greater than 40 μmol/L[28]; several smaller studies have supported this finding.[29–32] Serum transaminases (ALT and AST) also rise in the majority of cases, but the extent of the rise may not be marked (i.e., two- to threefold). The relative value of serum bile acids, ALT, and AST for the diagnosis of OC is a matter of debate because it is not yet certain which is the best prognostic indicator.[31] In a subgroup of women, the rise in serum bile acids and transaminases can occur up to 15 weeks after the onset of pruritus, so it is advisable to repeat the tests in women with persistent symptoms of OC even if the initial results are normal.[33]

Raised bilirubin can occur in OC, but it is not commonly seen and should not be used alone to make the diagnosis. Alkaline phosphatase rises in the third trimester of normal pregnancies, mainly as a consequence of the placental iso-enzyme, and is therefore not of value in the diagnosis of OC. GGT is elevated in approximately 33% of cases.[27]

Women with pruritus and abnormal LFTs should have viral hepatitis (hepatitis A, B, C, CMV, and EBV) and autoimmune hepatitis (antimitochondrial and anti–smooth muscle antibodies) excluded. An ultrasound scan of the liver and biliary tree should be performed to exclude other causes of biliary obstruction. In a study of 227 U.K. cases of OC, gallstones were present in 13%; of these cases, 70% had a history of symptoms of cholelithiasis prior to pregnancy.[34] Asymptomatic gallstones are unlikely to cause OC and are more likely to be present because mutations in at least one gene predispose affected women to both OC and gallstones.[35]

The diagnosis of OC should be one of exclusion and be finally confirmed by resolution of symptoms and biochemical abnormalities postpartum. Antenatally, once the diagnosis of OC has been made, the LFTs, including a PT, should be checked once per week: This will allow monitoring of the decline of serum bile acids or transaminases. It should be borne in mind that some women with other pregnancy disorders (e.g., preeclampsia or AFLP) may present with initial symptoms of pruritus.

It is particularly important to establish whether a woman with OC has hepatitis C, because pregnancies in seropositive women are more likely to be complicated by spontaneous prematurity.[36] In addition, women with hepatitis C infection have a higher prevalence of OC.[36] An additional argument for screening for hepatitis C in women with OC is that treatment with interferon and ribavirin postnatally can be curative.

Maternal and Fetal Risks

Maternal Risks

Pruritus can be a very distressing symptom, and some women may have such marked dermatitis artefacta that they develop permanent scars (see Fig. 47–2). The pruritus and hepatic impairment resolve rapidly after delivery in the majority of cases. If symptoms or biochemical abnormalities persist more than 3 months postpartum, women should be referred to a hepatologist.

There was a 90% risk of recurrence of OC in U.K. cases. Twenty-seven percent of women complained of either cyclical or oral contraceptive-induced pruritus when they were not pregnant.[34] Therefore, women with OC should be advised to avoid estrogen-containing contraceptives. If no alternatives are suitable, the oral contraceptive pill should be introduced only with serial monitoring of LFTs, surveillance for pruritus, and discontinuation if changes develop.

Fetal Risks

OC has been reported to be associated with increased rates of spontaneous prematurity, fetal distress (defined as meconium-stained amniotic fluid or cardiotocography [CTG] abnormalities), and intrauterine death (IUD). However, the rates of these complications vary depending upon the diagnostic criteria used. An increasing number of studies indicate that the level of the serum bile acids is related to the fetal complication rate.[28–30,32] Table 47–4 summarizes the frequency of these complications in each of the studies that have been performed in all successive cases within specific hospitals/regions in which the diagnosis was made using serum bile acids. There is considerable debate about whether the rates of IUD can be decreased with a policy of delivery by 38 weeks' gestation. Some studies revealed that OC-related IUDs cluster at later gestations,[22] and therefore, this policy is relatively prevalent in the United Kingdom. However, there have been no prospective studies to establish whether the policy of early delivery is effective at improving fetal and neonatal outcomes or safety. Some data from in vitro animal studies suggest that ursodeoxycholic acid (UDCA) treatment is safe and may also be protective.[37] Furthermore, UDCA treatment reduced pruritus and maternal serum transaminases, bilirubin, and bile acids in women with serum bile acids greater than 40 μmol/L in a randomized, controlled trial,[38] and the improvement in biochemical abnormalities may further reduce fetal risk.

Iatrogenic prematurity is also more common in OC pregnancies,[34] and it is important not to underestimate the fetal risks of elective delivery at 37 weeks' gestation. A study of neonatal respiratory morbidity following elective cesarean section for all indications reported a higher incidence of respiratory distress syndrome and transient tachypnea of the newborn in those who were delivered during the week 37 + 0 to 37 + 6 compared with 38 + 0 to 38 + 6, and a similar difference was seen when this was compared with deliveries in the following week of gestation.[39]

Management Options

Once the diagnosis of OC has been made, we recommend consideration of delivery between 37 and 38 weeks' gestation in women with raised serum bile acids because this may reduce the risk of IUD. Fetal surveillance can be performed with regular CTG, although there is no evidence that this predicts which pregnancies are at risk of fetal distress or IUD. We recommend that vitamin K, 10 mg orally, should be taken daily to reduce the risk of

TABLE 47–4

hemorrhage. UDCA has been shown to improve maternal symptoms and biochemical abnormalities in OC, but there are currently no clinical data on whether it improves fetal outcomes or on safety.

Vitamin K

The active vitamin-K–dependent clotting factors (II, VII, IX, and X) are formed from precursors in the liver, and patients with liver disease are at risk of hemorrhage due to deficiency of these clotting factors. In OC, impaired intestinal absorption secondary to steatorrhea is the most likely cause of vitamin K deficiency, although hepatic impairment may also contribute in some cases. It is possible that the increased prevalence of postpartum hemorrhage in OC is related to vitamin K deficiency, although it is feasible that prematurity, induction of labor, instrumental delivery, or other factors are more relevant.

Ursodeoxycholic Acid

There have been more studies of UDCA than any other drug for the treatment of OC. In the Cochrane Database of Systematic Reviews,[40] three trials totaling 56 women are identified in which UDCA is compared with placebo: In two, there is no difference in relief of symptoms; in one trial, greater reduction in bile salts and liver enzymes was noted with UDCA.[40] When the results of 10 studies with a total of 85 affected women who have been treated with UDCA are combined, 74 (87%) showed clinical or biochemical improvement or both.[41] A more recent study that randomized women with OC to treatment with UDCA, dexamethasone, or placebo only demonstrated benefit in symptoms and biochemical abnormalities in women who received UDCA.[38] In addition, UDCA has been shown to reduce the levels of bile acids in the cord blood and amniotic fluid at the time of delivery.[42] UDCA is commonly started at a dose of 500 mg twice a day, but doses of up to 2000 mg/day were given in several studies, and some women will respond only to higher doses. All babies born to mothers given UDCA were delivered safely, and no problems attributable to treatment have been reported, although there has been no follow-up of these babies.

Dexamethasone

One Finnish case series demonstrated improvement in clinical symptoms and biochemical abnormalities in 10 women with OC who were treated with oral dexamethasone, 12 mg daily, for 7 days, with a gradual reduction in dose over the subsequent 3 days.[43] However, subsequent case reports and case series have not supported this finding.[38,44,45] There have been no long-term studies of the subsequent effects on the child of antenatal exposure to high doses of dexamethasone in the 7- to 10-day regimen used in obstetric cholestasis. However, there are concerns about the potential fetal risks of high doses of antenatal corticosteroids on growth and neuronal development.[46,47]

Other Drugs That Can Be Used to Treat Obstetric Cholestasis

Several other drugs have been used to treat OC, including cholestyramine, S-adenosylmethionine, and guar gum (reviewed in Williamson[41]). Although all resulted in clinical improvement in some studies, none of these agents consistently resulted in a biochemical improvement and no studies were powered to show improvement in fetal outcome.[48]

Aqueous cream with menthol often relieves the pruritus for a short time, and some women find this helps them to fall to sleep.

Amniocentesis and Amnioscopy

Meconium staining of the amniotic fluid is reported in almost all cases of IUD that complicate OC in the current literature. Amniocentesis for the presence of meconium has been proposed as the best way to predict the at-risk fetus.[49] No IUDs were reported in a series of 206 women in whom amnioscopy and amniocentesis were used to test for meconium before 37 weeks' gestation as part of a management protocol for OC.[50] However, such an approach may be considered too intrusive to be used routinely by most obstetricians.

SUMMARY OF MANAGEMENT OPTIONS
Obstetric Cholestasis

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
If previous history of OC, advise of recurrence risk of 90%.	III/B	22,34
Obtain biliary tract ultrasonography to exclude other pathology.	III/B	3
Prenatal		
Confirm the diagnosis with serum bile acid, ALT, or AST measurement.	IIa/B	27–31,33
Monitor serum bile acids in women with a proven diagnosis of OC.	III/B	28–30,32
Exclude viral infection, including hepatitis C, autoimmune hepatitis, and other causes of biliary obstruction.	III/B	34–36
Treat maternal symptoms initially with simple topical measures (e.g., aqueous cream with menthol).	IV/C	22
Consider UDCA 500 mg bid for women with severe symptoms.	Ib/A	38,41
Consider oral vitamin K to reduce risk of PPH.	IV/C	22
Dexamethasone (problem of possible fetal adverse neurologic effects of repeated doses).	IIb/B	41,44,45
Cholestyramine, guar gum.	IV/C	41
Monitor fetal well-being, though it does not predict at-risk fetus.	III/B	16,22
Labor and Delivery		
Consider elective delivery at 37–38 wk.	III/B	16,22
Maintain vigilance for postpartum hemorrhage.	IV/C	22
Postnatal		
Monitor biochemical resolution; generally long-term maternal health and baby health are good.	—/GPP	—
Vitamin K supplement for baby	—/GPP	—
Use oral contraceptives only with close clinical and biochemical monitoring: 27% of cases have cyclical or oral contraceptive-induced pruritus.	III/B	34
Consider referral to hepatologist if symptoms and biochemical abnormalities persist.	—/GPP	—

ALT, alanine aminotransaminase; AST, aspartate aminotransaminase; GPP, good practice point; OC, obstetric cholestasis; UDCA, ursodeoxycholic acid.

ACUTE FATTY LIVER OF PREGNANCY

AFLP is a rare but dangerous disorder. The clinical symptoms and signs are not specific, and because the definition is one of exclusion (rather than inclusion), the diagnosis can be difficult to reach. However, failure to do so may jeopardize the life of the pregnant woman or her fetus.

General

Definition

AFLP may be defined as acute liver failure with reduced hepatic metabolic capacity in the absence of other causes. Histologically, there is panlobular microvesicular steatosis, with sparing of periportal areas and intrahepatic cholestasis: These appearances, which are not unique to AFLP, can be difficult to detect with conventional fixing and staining techniques. The very nature of the illness means that a liver biopsy is often not appropriate. In reviewing the literature, it is clear that subjective diagnoses are often used, and this, in conjunction with the rarity of the condition, makes evidence-based care of women with AFLP challenging. The Swansea criteria (see later) represent a set of standard diagnostic criteria that have recently been validated and, therefore, add some consistency to the diagnosis.[50]

Incidence

The incidence of AFLP has previously been reported to be between 1 in 7000 (diagnosis on clinical criteria alone in 27 of 28 cases)[51] and 1 in 13,000 pregnancies (10 cases, all biopsy-proven).[52] More recently, United Kingdom Obstetric Surveillance System (UKOSS) has reported an incidence of 5 in 100,000 maternities, based on 57 women with AFLP reported during an 18-month period of surveillance of all consultant-led maternity units in the United Kingdom in 2005 and 2006.[53] Approximately three quarters of cases are

reported in the third trimester, although it is described as early as 20 weeks, and one quarter in the puerperium. Twin pregnancy is associated with a 14-fold increase in the risk of developing AFLP (odds ratio [OR] 14.3, 95% confidence interval [CI] 6.4–28.6). AFLP is also more likely in older women and primiparous women.

Diagnosis

The symptoms and signs of AFLP are vague and nonspecific, such that making an early diagnosis is challenging. It is likely that many women experience a prodromal phase in which there is only a gradual deterioration in their condition and when jaundice may not be apparent. In one study, this lasted on average for 9 days (range 1–21 days)[51] prior to the rapid and sometimes catastrophic decline that can occur with AFLP; in the UKOSS study[53] over 80% women experienced a prodromal period. There should be a low threshold for performing LFTs on pregnant women who present in the third trimester with potential prodromal symptoms including new-onset nausea, vomiting, epigastric or right upper quadrant pain, malaise, or polyuria or polydipsia (diabetes insipidus).

The presence of more than 5 Swansea criteria (see later) represents a validated method for supporting the clinical diagnosis of AFLP. Use of these criteria will allow consistency in both clinical management and future research. In the UKOSS study, 55 of the 57 women with AFLP had more than 5 of the 14 criteria present; all 4 women referred to UKOSS, who were deemed on clinical grounds not to have AFLP, had fewer than 5 criteria.

- Vomiting.
- Abdominal pain.
- Polydipsia and polyuria.
- Encephalopathy.
- Elevated transaminases (>42 IU/L; often 3 to 10 times the upper limit of normal; be aware that falling or low levels may be due to very extensive liver damage).
- Elevated bilirubin (>14 μmol/L).
- Hypoglycemia (<4 mmol/L).
- Elevated urate (>340 μmol/L).
- Renal impairment (creatinine > 150 μmol/L).
- Elevated ammonia (>47 μmol/L).
- Leucocytosis (>11 × 10^9/L; often 20–30 × 10^9/L).
- Coagulopathy (PT > 14 sec, activated partial thromboplastin time [aPTT] > 34 sec).
- Ascites or bright liver on ultrasound scan.
- Microvesicular steatosis on liver biopsy.

One of the keys to the diagnosis of AFLP is the rapidity with which LFT can deteriorate in the aggressive phase of the disease. This typically is combined with features of hepatic synthetic failure, including hypoglycemia, deranged clotting, and confusion secondary to hepatic encephalopathy. Other pregnancy-specific liver conditions do not impair liver function in this way. Other causes of fulminating liver failure must be excluded: Paracetamol (acetaminophen) overdose and acute viral hepatitis are the most common causes; rarer causes include Wilson's disease, poisoning with carbon tetrachloride, and drug reactions (e.g., to halothane or isoniazid).

Imaging of the liver has not been successful in accurately detecting fatty infiltration nor, if it is present, in determining its cause. Techniques that have been used include ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI). Apart from ultrasound, it is unlikely that imaging will be either portable or easily accessible to the delivery suite. Abdominal CT is better avoided when possible prior to delivery because of radiation exposure to the fetus, and many pregnant women will be too large to fit inside a standard MRI machine even if they are well enough to be moved there. False-positive and false-negative diagnoses are equally common with all modalities.[54] In the recent UKOSS study,[53] 80% of women had an ultrasound scan, of which only one quarter showed the classic features of bright liver or ascites. If the diagnosis remains in doubt and, in particular, if there is not a rapid improvement after delivery, the place for imaging the liver should be reconsidered.

Liver biopsy is another possibly helpful diagnostic tool. Bearing in mind the histopathologic caveats outlined earlier and the potential complexities of performing a biopsy in the presence of deranged clotting, the need for a tissue diagnosis should be carefully assessed on an individual basis.

Maternal and Fetal Risks

Women experiencing AFLP have increased maternal and fetal mortality and morbidity. However, it is likely that the outcome for mother and baby has improved in recent years. In the 1960s, 16 cases of AFLP associated with the use of tetracycline were reported, with a 70% maternal mortality.[55] Among 33 pregnancies with biopsy-proven AFLP reported in the 1980s, maternal mortality was 21% and fetal mortality was 27%.[56] Castro and associates in the 1990s[51] reported 28 clinically diagnosed cases with no maternal mortality and a 7% neonatal mortality. The UKOSS report,[53] which is the most robust and recent series of cases, gives maternal mortality of 2% (1 death in 57 cases) and 10% fetal mortality. There is an ongoing need for all obstetricians, anesthetists, and midwives to be aware of AFLP, not just those working in large tertiary referral centers.

Etiology

The cause of AFLP is uncertain, but is likely to be multifactorial, with a genetic component in a number of cases. In some women, AFLP may occur because of an autosomal recessive abnormality in fetal long-chain fatty acid beta oxidation. This is an interesting concept, because it demonstrates that the fetus may determine maternal complications of pregnancy. In addition, for these families, the risk of recurrence is significant and in the order of 15% to 20%.

Long-chain hydroxyacyl coenzyme A dehydrogenase (LCHAD) deficiency is a recently described disorder of mitochondrial fatty acid oxidation that is usually asymptomatic in heterozygous carriers. Affected (homozygous) individuals often die in early childhood or sooner from complications of hypoglycemia, cardiomyopathy, or fatty liver failure. Those who live longer develop chorioretinopathy, rhabdomyolysis, and peripheral neuropathy, although these can be ameliorated by a high-carbohydrate and low-fat diet, in which the fat component is medium-chain triglycerides. Several mutations of the α-subunit of the mitochondrial trifunctional protein cause deficiency of LCHAD. In Finland, a guanine cytosine transposition, G1528C, and in America, a

glutamic acid to glutamine change, E474Q, have been identified.[57,58] The latter group estimates that 1 in 175 of their population is heterozygous for E474Q and, therefore, that 1 in 62,000 pregnancies results in LCHAD deficiency. Affected fetuses do not metabolize long-chain fatty acids completely, resulting in accumulation of abnormal and highly toxic intermediates in the heterozygous mother's liver, and the acute clinical picture we recognize as AFLP. It is also hypothesized that fat accumulation may occur in the placenta and that this may induce the clinical picture of preeclampsia. Preeclampsia has been described in pregnancies with fetuses affected by homozygous LCHAD deficiency more commonly than would be expected, and more than in pregnancies in the same women with unaffected fetuses.[59]

It is not certain what proportion of cases of AFLP may be due to LCHAD deficiency. It is likely that this will vary between countries, depending in part on the prevalence of the known (and unknown) genetic mutations in the local populations. Mansouri and colleagues[60] reported no carriers of the G1528C mutation in 14 histologically proven cases of AFLP, but Treem and coworkers[61] found that 75% of 12 women with AFLP had LCHAD levels compatible with carrier status. A larger study identified LCHAD mutations in 5 of 27 women with AFLP, all of whom had a fetus with LCHAD deficiency.[62] All 5 affected fetuses had at least one copy of the E474Q mutation, and the authors therefore recommended screening for this mutation in the children of women who have had pregnancies complicated by AFLP. In contrast, the same study demonstrated that only 1 of 81 women with HELLP had an LCHAD mutation, and this was not inherited by the fetus, indicating that it is not justified to screen the offspring from all pregnancies affected by HELLP.

Conversely, not all pregnancies in which the baby has LCHAD deficiency will result in AFLP or other serious maternal liver disease. Ibdah and colleagues[63] found that in 15 of 24 pregnancies in which the baby had LCHAD deficiency, either AFLP (n = 12) or HELLP (n = 3) syndrome developed; in the other 9 pregnancies, there were no complications. These women had 11 other pregnancies with unaffected babies in which maternal liver disease did not occur. Similarly, Tyni and associates[59] found some form of liver disease of pregnancy and/or preeclampsia in 15 of 29 pregnancies in which the fetus was homozygous for LCHAD deficiency and described 7 of the remaining 14 pregnancies as completely normal; none of the other 34 pregnancies from these women (when the fetus did not have homozygous LCHAD deficiency) was complicated by significant liver disease.

Management Options

The ultimate management option is to deliver the baby, because this seems to be the optimal way to improve the maternal condition and to protect the fetus. The decision to deliver brings with it a not uncommon conundrum for obstetricians: A vaginal delivery minimizes the risk of maternal hemorrhage in the face of a coagulopathy but may take several hours or longer to achieve, and this could be significantly detrimental to the mother or fetus; a cesarean section allows delivery to be achieved more quickly but may be complicated by bleeding. An individual decision regarding the severity of the maternal and fetal conditions needs to be made. Often, induction of labor can be started while the maternal condition is stabilized and blood products made available, and then the ongoing management can be reviewed according to the current balance of concerns. A further challenge is the best choice of analgesia and anesthesia, because regional blockade may be contraindicated if coagulopathy ensues, but general anesthesia can worsen hepatic encephalopathy.

From the maternal perspective, she should have one-to-one nursing on the delivery suite, preferably in a high-dependency area. All vital signs should be measured and recorded clearly on a 24-hour spread sheet; it is usually advisable to insert a central line early in the course of the disease before coagulopathy ensues. Glucose assessments should be made at least every 2 hours, and hypoglycemia treated with large doses of high-concentration intravenous glucose via a long line. PT should also be measured every 6 hours along with LFTs, renal function tests and electrolytes, and full blood count. Formal assessment of level of consciousness must be made hourly, because hepatic coma is a potential complication of AFLP.

One of the keys to successful management is a multidisciplinary approach. Senior obstetric, anesthesiology, hematology, and hepatology colleagues should be involved at an early stage. If no hepatologists are in-house, the obstetrician should liaise directly with the nearest liver transplant unit. This serves several purposes: (1) it provides expert advice on both the investigations and the management and (2) it alerts the transplant team who are usually able to accept transfer after delivery if recovery does not commence. Most women will be transferred from the delivery suite to the intensive care unit after delivery.

Follow-up and Recurrence

Once they have recovered, all women affected by AFLP should have the opportunity with their partners to be debriefed about the complications of their pregnancy. In women who survive and do not need a transplant, complete recovery of the liver is expected without long-term sequelae.

Pediatricians should consider screening all babies of women with AFLP for LCHAD deficiency, either by measuring LCHAD activity in cultured skin fibroblasts or liver or by doing DNA studies looking for the common mutations. Affected babies should be placed on the appropriate dietary restrictions. Not only does this screening minimize the complications for the index baby, but also it allows the couple to make an informed choice about the risks to the mother and fetus in a future pregnancy.

The risk of recurrence of AFLP depends largely on whether the baby has LCHAD deficiency. If he or she does, the rate is between 15% and 25% for future pregnancies from the same partnership; if the baby does not, then the recurrence risk is very much lower, although it is difficult to give a precise figure because so many women decide against a further pregnancy.

When a woman has had an affected baby previously, prenatal diagnosis of LCHAD is possible in subsequent pregnancies by enzyme assay in amniocytes[64] or DNA analysis from chorionic villus sampling (CVS).[63]

Acute Fatty Liver of Pregnancy

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
None, unless previous pregnancy is affected, in which case, confirm previous diagnosis, check LFTs, advise risk of recurrence.	IV/C	56
Consider screening for LCHAD deficiency.	III/B	59,63
Prenatal		
If previous AFLP, check baseline LFT; advise to report any new symptoms; start home testing for urinary protein from 24 wk; monitor BP every 2 wk.	—/GPP	—
Establish diagnosis, resuscitate.	—/GPP	—
Intensive care/high dependency setting	—/GPP	—
Provide supportive therapy (see "Labor and Delivery").	—/GPP	—
Plan delivery or end pregnancy.	—/GPP	—
Labor and Delivery		
Maternal resuscitation by correction of		
• Hypoglycemia.	—/GPP	—
• Fluid balance.		
• Coagulopathy.		
Use multidisciplinary approach ideally in liaison with liver unit to manage liver failure.	—/GPP	—
Use intensive fetal monitoring.	—/GPP	—
Perform urgent delivery when maternal condition is stabilized, vaginal delivery preferable for mother.	—/GPP	—
Maintain meticulous hemostasis.	—/GPP	—
Postnatal		
Continue intensive care management	—/GPP	—
Watch for postpartum wound hematoma formation and sepsis, postpartum hemorrhage.	—/GPP	—
Recurrence risk is difficult to estimate, perhaps as high as 10%–20%.	—/GPP	—
Support contraceptive measures.	—/GPP	—
Full hepatic recovery expected without further sequelae; occasionally emergency liver transplant needed.	—/GPP	—
Pediatricians to consider screening baby for LCHAD deficiency.	—/GPP	—
Prenatal diagnosis of LCHAD possible by amniocentesis/CVS if previous baby affected.	III/B	63,64

AFLP, acute fatty liver of pregnancy; BP, blood pressure; CVS, chorionic villus sampling; GPP, good practice point; LCHAD, long-chain hydroxyacyl coenzyme A dehydrogenase; LFT, liver function test.

LIVER HEMATOMA AND NONTRAUMATIC LIVER RUPTURE

General

Liver hematoma is an uncommon and potentially dangerous problem in pregnancy, its most hazardous complication being hepatic rupture. Rupture of the liver capsule occurs in between 1 in 45,000 and 1 in 225,000 deliveries.[65,66]

The vast majority of cases are reported in association with preeclampsia, and a very high proportion are in multiparous women older than 30 years. Only a few cases have been described in the puerperium following a normal pregnancy.[67] In over 85% of cases, the right lobe of the liver is affected. Rinehart and coworkers[68] reviewed the literature and presented figures for the common symptoms and signs of hepatic rupture. Not surprisingly, they found that almost 70% of

patients had epigastric pain, 65% had hypertension, and over 50% were shocked. However, there was a wide range of other presentations, including some women with mild symptoms prior to massive circulatory collapse. HELLP syndrome seems to be particularly associated with intrahepatic hemorrhage, subcapsular hematoma, and capsular rupture.

The pathogenesis is debated. One attractive theory suggests that preeclampsia causes hepatic ischemia via intravascular volume depletion, which results in local necrosis and hemorrhage. Subsequently, neovascularization occurs, and these vessels are especially susceptible to rupture and further hemorrhage, particularly during hypertensive episodes. Subcapsular hematoma may then expand sufficiently to result in hepatic rupture.[68]

Maternal and Fetal Risks

Hepatic rupture is dangerous for mother and baby. Maternal mortality is between 16% and 60%, and perinatal mortality is between 40% and 60%.[69,70] Current management options have contributed greatly to lowering the mortality rates.

Management Options

The management will obviously be determined by the seriousness of the situation. There should be a low threshold for imaging the liver in older, multiparous women with preeclampsia and epigastric pain. Ultrasound will usually be readily available and is helpful in diagnosing subcapsular hematomas. CT (Fig. 47–3) and MRI hepatic digital subtraction angiography may have greater sensitivity for identifying small amounts of intraperitoneal blood and small hematomas but have the disadvantage of being less readily available and less portable if the patient is unwell.

Treatment of hepatic rupture is based on resuscitating the patient and stopping the hemorrhage. If the diagnosis is suspected, a midline laparotomy with the involvement of an experienced surgeon should be considered: This allows the diagnosis to be confirmed, the baby to be delivered (which will improve the maternal circulation and remove the baby to a place of safety), and treatment to be instituted. If unexplained hemoperitoneum is found at a Pfannenstiel laparotomy for presumed abruption or uterine rupture, careful exploration of the upper abdomen, preferably by an
experienced general or hepatic surgeon and possibly with an upper midline incision to improve access, must be strongly considered.

A wide variety of therapeutic maneuvers for liver rupture have been described. Currently, the most successful seem to involve digital compression of the hepatic artery and portal vein to temporarily arrest the hemorrhage (Pringle's maneuver),[69] evacuation of the residual hematoma, and temporary packing with large dry gauze swabs.[71] Packs are removed at a further laparotomy 24 to 36 hours later, once correction of hypovolemia, coagulopathy, acidosis, and hypothermia is complete. Liver resection and transplantation have also been described, but not surprisingly, the mortality rate is very high.

Unruptured small hematomas have been managed conservatively, following delivery of the baby, with serial imaging of their size to exclude expansion.[69] Delayed rupture 6 weeks after initial diagnosis has been reported,[72] so care must be taken if this option is adopted. Tense, large, or expanding hematomas should probably be evacuated surgically to obviate the impending rupture. Hepatic embolization has been described in these circumstances (and in others) but seems to carry a high risk of ischemic necrosis of the liver, liver failure, and sepsis[73] and may not be accessible to many units; others have described this technique as a "gold standard."[67]

SUMMARY OF MANAGEMENT OPTIONS

Liver Hematoma and Rupture

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
None.	—/GPP	—
Prenatal		
Treat upper abdominal discomfort seriously, especially in parous women with PET or HELLP; consider imaging the liver.	—/GPP	—
Labor and Delivery		
Consider liver rupture in a woman with unexplained shock or if unexpected hemoperitoneum is found at cesarean section.	—/GPP	—

Management Options	Evidence Quality and Recommendation	References
Management:		
• Resuscitation.	—/GPP	—
• Laparotomy and stop hemorrhage (by liver surgeon preferably) with temporary occlusion of portal vein and packing.	IV/C	69,71
• Embolization has varied success.	III/B	67,73
• Manage unruptured hematomas conservatively (though danger of delayed rupture).	IV/C	69
Postnatal		
Patients who survive do not have permanent liver damage.	—/GPP	—
Recurrence has been recorded but very rarely.	—/GPP	—

HELLP, hemolysis, elevated liver enzymes, low platelets; GPP, good practice point; PET, preeclampsia.

HYPEREMESIS GRAVIDARUM

General

Nausea and vomiting affect up to 50% of pregnant women. Most women are able to maintain fluid and nutrient intake by dietary modification, and the symptoms will resolve by the end of the first trimester. Hyperemesis gravidarum affects 0.5% to 1% of pregnancies and causes severe and protracted vomiting that results in ketosis, dehydration, and weight loss. The cause of hyperemesis gravidarum remains unidentified, but it is thought to result from a combination of endocrine, biochemical, and psychological factors. Seropositivity for *Helicobacter pylori* is more common in women with hyperemesis than in controls.[74,75]

Diagnosis

The onset of hyperemesis gravidarum is always in the first trimester. In addition to nausea, vomiting, and weight loss, women often report ptyalism (excessive salivation), and there may be signs of dehydration, including postural hypotension and tachycardia. Hyperemesis gravidarum is a diagnosis of exclusion (Table 47–5), and it is important to make a thorough clinical assessment and to ensure that investigations are performed for common and serious causes of vomiting.

An ultrasound of the uterus should be performed to confirm pregnancy, to establish the number of fetuses, and to exclude hydatidiform mole.

Laboratory investigations commonly reveal hyponatremia, hypokalemia, and raised hematocrit. A biochemical hyperthyroidism and abnormal LFTs may also be present. These are both markers of the severity of the disease and resolve with successful treatment. Women with biochemical hyperthyroidism should be examined for signs of hyperthyroidism, but these are rarely present.

Maternal and Fetal Risks

Maternal Risks

Serious maternal morbidity and mortality may result if hyperemesis gravidarum is not managed correctly. Wernicke's encephalopathy can develop as a result of thiamine (vitamin B_1) deficiency. This is associated with diplopia, sixth nerve palsy, nystagmus, ataxia, and confusion. If untreated, Wernicke's encephalopathy may lead to Korsakoff's psychosis (amnesia, impaired ability to learn) or death. Other vitamin deficiencies may occur, for example, peripheral neuropathy and anemia may result from deficiency of vitamins B_{12} and B_6.

TABLE 47–5

Differential Diagnosis of Hyperemesis Gravidarum

SYSTEM	DIAGNOSIS	INVESTIGATION/INITIAL ASSESSMENT
Genitourinary	Urinary tract infection	Mid-stream urine specimen
	Uremia	Urea and electrolytes
	Molar pregnancy	Ultrasound of the uterus
Gastrointestinal	Gastritis/peptic ulceration	*Helicobacter pylori* antibodies
	Pancreatitis	Amylase, blood glucose, calcium
	Bowel obstruction	Plain supine abdominal radiograph
Endocrine	Addison's disease	Urea and electrolytes, early-morning cortisol, short synacthen test with ACTH
	Hyperthyroidism	Surveillance for symptoms and signs of hyperthyroidism, TFTs, thyroid autoantibodies
	Diabetic ketoacidosis	Blood glucose, urinary dipstick for ketones, glucose tolerance test
CNS	Intracranial tumor	CNS examination, brain imaging
	Vestibular disease	CNS examination
Drug-induced	—	Discontinue agent

ACTH, adrenocorticotrophic hormone; CNS, central nervous system; TFT, thyroid function test.

Hyponatremia (plasma sodium < 120 mmol/L) can cause confusion, seizures, and respiratory arrest. If hyponatremia is severe, or if it is treated too rapidly, women may develop central pontine myelinolysis. This is caused by symmetrical destruction of myelin at the center of the basal pons and can result in pyramidal tract signs, spastic quadraparesis, pseudobulbar palsy, and impaired consciousness.

Other risks include deep venous thrombosis that may result from dehydration and reduced mobility, Mallory-Weiss tear due to prolonged vomiting, and muscle wasting with weakness.

Fetal Risks

The infants of women with hyperemesis gravidarum with low pregnancy weight gain (<7 kg) are more likely to be small for gestational age and to be born before 37 weeks' gestation.[76] These poor outcomes were not seen in the offspring of women with hyperemesis who gained 7 kg or more in pregnancy. If the mother develops Wernicke's encephalopathy, the fetal outcome is worse; of 45 cases in the published literature, only 44% were reported as having been born alive.[77]

Management Options

Rehydration and Vitamin Supplementation

Fluid replacement therapy should be with either normal saline (NaCl 0.9%; 150 mmol/L Na$^+$) or Hartmann's solution (NaCl 0.6%; 131 mmol/L Na$^+$). Dextrose-containing fluids should not be used because they do not contain sufficient sodium to correct hyponatremia, and Wernicke's encephalopathy can be precipitated by intravenous dextrose and carbohydrate-rich foods. Double-strength saline should not be used to correct hyponatremia in hyperemesis gravidarum, because central pontine myelinolysis can occur if the serum sodium level is corrected too rapidly. Potassium supplements should be added to the intravenous fluid replacement therapy as required. Thiamine supplements should be given, as a daily dose of either 50 to 150 mg orally or 100 mg diluted in 100 mL normal saline as an intravenous infusion.

Urine output should be monitored and dipsticks used to assess ketonuria. Women should be weighed on admission and regularly thereafter if their symptoms do not resolve. Serial assessments of electrolytes should be carried out.

Antiemetics

There is no evidence for teratogenicity following treatment with dopamine antagonists (metoclopramide, domperidone),[78,79] phenothiazines (chlorpromazine, prochlorperazine),[80,81] anticholinergics (dicyclomine),[82] or antihistamine H$_1$-receptor antagonists (promethazine, cyclizine). One of these should be tried in the first instance. Women with hyperemesis often find nonoral preparations preferable.

In women with severe hyperemesis who have not responded to these antiemetic therapies, promising results have been reported with both corticosteroids and 5-hydroxytryptamine$_3$ (5-HT$_3$) receptor antagonists (ondansetron, cisapride).

Corticosteroids

Corticosteroids have been reported to be an effective treatment for hyperemesis gravidarum in several case reports.[83–85] In an American double-blind study of 40 women with hyperemesis who were randomized to receive either oral methylprednisolone 16 mg or oral promethazine 25 mg (three times daily for both), the response to both drugs was similar after 2 days, but no women who received methylprednisolone were readmitted within 1 week of discharge. In contrast, 5 (25%) women who received promethazine were readmitted with hyperemesis.[86] A British double-blind study of 25 women who were randomized to receive either 40 mg prednisolone or placebo daily demonstrated a trend toward improved nausea and vomiting and reduced dependence on intravenous fluids, but this did not reach statistical significance.[87] However, steroid therapy did result in an improved sense of well-being, improved appetite, and weight gain compared with placebo.[87] Overall, the studies of corticosteroid treatment for hyperemesis suggest that the treatment is effective for some patients. We recommend starting intravenous hydrocortisone 100 mg three times a day in women with severe and resistant symptoms who are unable to tolerate fluids, followed by prednisolone 40 mg once daily. This should be reduced by approximately 5 mg every 5 days, provided symptoms are controlled.

5-Hydroxytryptamine Receptor Antagonists

Ondansetron is a 5-HT$_3$ receptor antagonist and a potent antiemetic drug for the treatment of chemotherapy-associated and postoperative nausea. It has been used to treat hyperemesis successfully in several case reports, in which it was given for between 2 and 19 weeks.[88–90] In all cases, there were no known adverse fetal events. One double-blind, controlled trial in which 30 patients were randomized to receive either 10 mg intravenous ondansetron or 50 mg intravenous promethazine failed to demonstrate any significant difference in the degree of nausea, weight gain, or days of hospitalization between the two groups.[91] However, the entry criteria for this study were less stringent than for the randomized, double-blind studies of corticosteroid treatment for hyperemesis gravidarum.[86,87] Therefore, it remains likely that ondansetron may be an effective treatment for women with more severe disease.

Other Treatment Options

There has been one double-blind, randomized, cross-over trial of the efficacy of powdered root ginger and placebo in which women reported a reduced severity and greater relief of symptoms in the period in which ginger was given and no side effects were observed.[92] Several authors have reported success in managing severe hyperemesis gravidarum using enteral and parenteral nutrition.[93–95] However, because the complications can be serious, such treatment is usually reserved for women whose symptoms are sufficiently severe as to be life-threatening to the mother. In one series of 16 cases with good pregnancy outcomes, there were 3 cases of line sepsis and pneumothorax, thrombosis, and dislodgement of the line.[95]

It is advisable to give thromboembolic deterrent stockings and thromboprophylaxis such as enoxaparine 40 mg daily to women with hyperemesis while they are inpatients.

SUMMARY OF MANAGEMENT OPTIONS
Hyperemesis Gravidarum

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Discuss recurrence risk.	—/GPP	—
Give advice on treatment options and provide psychological support at an early stage.	—/GPP	—
Give folate supplements.	—/GPP	—
Prenatal		
Remember alternative diagnoses.	—/GPP	—
Rehydrate with intravenous fluid and electrolyte therapy.	—/GPP	—
Supplement nutrients and vitamins (especially thiamine).	—/GPP	—
Consult dietician, provide parenteral nutrition in extreme cases.	III/B	93–95
Provide psychological and social support.	—/GPP	—
Provide thromboprophylaxis.	—/GPP	—
Treatment:		
• First line = conventional antiemetics.	III/B	77–81
• Alternative agent = corticosteroids.	Ib/A	83–87
• Alternative agent = 5-HT$_3$ antagonist if no response.	Ib/A	88–91
Antigastroesophageal reflux measures may help some.	—/GPP	—
Provide fetal growth surveillance	—/GPP	—
Labor and Delivery		
Women on corticosteroids prenatally should have intravenous hydrocortisone to cover labor/delivery.	—/GPP	—
Postnatal		
Review nutritional status.	—/GPP	—
Wean off steroids; most will not need short synacthen test to exclude adrenal suppression.	—/GPP	—
Discuss contraception.	—/GPP	—

GPP, good practice point; 5-HT$_3$, 5-hydroxytryptamine$_3$.

PEPTIC ULCERATION

General

Dyspepsia is common, affecting up to 50% of pregnant women.[96] It usually worsens as pregnancy progresses, and it is more prevalent in women who are older, multiparous, or carrying multiple pregnancy or have a prepregnancy history of heartburn.[97]

Peptic ulceration, affecting the stomach, duodenum, or lower esophagus is uncommon in pregnancy.[98] In the absence of nonsteroidal anti-inflammatory drug (NSAID) use, nearly all duodenal and most stomach ulceration is caused by *H. pylori*. Eradication of *H. pylori* is very successful in curing peptic ulcer disease and reduces recurrence of ulceration and prevents rebleeding. In pregnancy, some women with established peptic ulcer disease report symptomatic improvement. This is thought to be secondary to reduced gastric acid output and increased protective mucus production associated with raised progesterone levels, in addition to a healthier diet and increased medical supervision.

Diagnosis

It is important to have a high index of suspicion for peptic ulcer disease because the classic symptoms of epigastric pain, nausea, and dyspepsia may be absent or confused with normal features of pregnancy. Also, symptoms may not correlate with severity of disease. Patients who are smokers and have a previous history of peptic ulcer disease or previous NSAID use are at highest risk.

Investigations should include blood tests for hemoglobin, electrolytes, and serum amylase as well as LFTs. An abdominal ultrasound is useful to exclude cholelithiasis and pancreatitis secondary to gallstones. However, if peptic ulcer

disease is suspected from the history and examination, _H. pylori_ antibodies should be measured, and if a woman has positive serology, treatment should be considered (Table 47–6). Although endoscopy is the investigation of choice outside pregnancy and is safe in pregnancy,[99] too few cases have been reported for the frequency of complications to be assessed. However, endoscopy does allow direct visualization of upper gastrointestinal tract pathology, permits biopsies to be taken for histopathology, and provides a therapeutic option (e.g., injection of adrenaline for acute bleeding ulcers).

Zollinger-Ellison Syndrome

This syndrome is caused by pancreatic gastrin-secreting tumors that result in a marked increase in gastric acid secretion. If untreated, the condition causes severe gastroesophageal reflux, peptic ulceration, and malabsorption, and therefore, the acid secretion usually requires treatment. There have been reports of the successful management of Zollinger-Ellison syndrome in pregnancy.[100,101]

Maternal and Fetal Risks

Maternal Risks

Complications of peptic ulcer disease in the general, non-pregnant population include bleeding and perforation. These are rarely reported in pregnancy.

Acute gastrointestinal bleeding presents with hematemesis, melena, or the passage of fresh blood from the rectum. It can be associated with hypotension and tachycardia and may result in anemia. It is important to insert a nasogastric tube if gastrointestinal bleeding is suspected. This will allow upper and lower gastrointestinal bleeding to be distinguished and will help to ensure a clear view for endoscopy. When endoscopy is performed, pregnant women should be placed in the left lateral position to reduce inferior vena caval obstruction and reduced venous return. Large-bore cannulae should be sited, the woman should be fasting, and a transfusion should be commenced if acute bleeding is confirmed and the clinical scenario warrants it.

Ulcer perforation is rare in pregnancy. Clinical features include abdominal pain with abdominal guarding and rebound tenderness, nausea, vomiting, pyrexia, dehydration, hypotension, and a leukocytosis. If suspected, an abdominal or chest radiograph should be performed to investigate for the presence of pneumoperitoneum or free gas in the abdomen.

Fetal Risks

The fetus may be compromised if there is major maternal hemorrhage or perforation of a peptic ulcer. Otherwise, few fetal risks arise from the drugs are used to treat peptic ulcer disease, with the exception of sodium bicarbonate–containing preparations and misoprostol (see the subsequent section on "Misoprostol").

Management Options

Antacids, H_2-antagonists, or proton pump inhibitors can be used to treat established peptic ulcer disease in pregnancy, including Zollinger-Ellison syndrome. If gastrointestinal bleeding is present, therapeutic endoscopy or surgery is indicated, and perforation requires surgical management.

Antacids

Aluminum- and magnesium-containing antacids are generally considered to be safe in pregnancy and breast-feeding,[102,103] as are the nonabsorbed alginate-containing drugs such as Gaviscon[104] and the mucosal protective agent sucralfate.[105] Magnesium-based antacids may be preferred to aluminum-based ones, because the latter can be associated with constipation. Sodium bicarbonate–containing antacids should be avoided because they may cause respiratory alkalosis and fluid overload in the mother and fetus.[106]

Acid-Suppressing Drugs

Several studies have indicated that H_2-receptor antagonists[107–110] and proton pump inhibitors[108–111] are safe in pregnancy. Three studies have compared the rate of congenital malformations in pregnancies in which there was first-trimester exposure to either H_2-receptor antagonists or omeprazole. A Swedish cohort study in which H_2-receptor antagonists had been taken in 255 pregnancies, proton pump inhibitors in 275, and both in 20 pregnancies did not demonstrate an increased rate of congenital malformation compared with all births at that time.[108] Similar results were found in a study of 447 British and 108 Italian women with first-trimester exposure to ranitidine, cimetidine, or omeprazole.[110] Similarly, there was no evidence of increased risk of major malformations in a prospective, multicenter, controlled study in which two groups of 113 women were treated with either omeprazole or H_2-receptor antagonists and compared with the same number of controls.[109]

Less is known about lansoprazole than omeprazole, but there has been one reassuring report of good fetal outcomes

with lansoprazole treatment in six cases in which there was first-trimester exposure.[112]

One prospective, controlled, multicenter study of the use of cisapride, a 5-HT$_3$ receptor antagonist for the treatment of gastroesophageal reflux, gastrointestinal pain, and duodenal ulcer in pregnancy, showed no increase in the rate of major or minor malformations nor fetal distress.[113]

Triple Therapy for Helicobacter Pylori

If peptic ulcer disease is suspected, serology should be sent for *H. pylori* antibodies. If a woman has distressing symptoms, appropriate therapy will eradicate the infection and may improve the symptoms. Of the recommended therapeutic regimens at the time of writing, only three include the use of omeprazole (see Table 47–6). The others advise the use of alternative acid-suppressant drugs, about which there is little experience in pregnancy. We therefore recommend that one of the three regimens outlined in Table 47–6 be used for 7 days. The regimens containing amoxicillin are recommended for community-based use. Studies of the incidence of congenital abnormalities and adverse pregnancy outcomes in women who have taken these antibiotics indicate that there is no increased risk for amoxycillin,[114] clarithromycin,[115] or metronidazole.[116,117]

Misoprostol

Misoprostol is a synthetic prostaglandin E$_1$ analogue that has antisecretory and protective properties believed to promote healing of peptic ulcers. However, its use is contraindicated in pregnancy because it is a potent stimulant of uterine contractions and can induce spontaneous abortion or uterine bleeding. It is also teratogenic.[118–120]

Therapeutic Endoscopy and Surgery

There is very little experience of therapeutic endoscopy in pregnancy. Of four cases in the literature, thermocoagulation was performed in one for bleeding duodenal ulcer,[99] sclerotherapy for bleeding duodenal ulcer was performed in two,[99,121] and sclerotherapy for a bleeding Mallory-Weiss tear in the fourth.[122] The fetal outcome in three cases was good and was not specifically reported in the fourth.[122]

The indications for surgery are the same as in the non-pregnant patient. A perforated ulcer requires emergency surgery, and the patient should receive broad-spectrum antibiotics. Surgery should also be performed in patients with hemorrhage from peptic ulcers if they have not responded to a transfusion of 6 units of blood.

SUMMARY OF MANAGEMENT OPTIONS		
Peptic Ulceration		
Management Options	**Evidence Quality and Recommendation**	**References**
Prepregnancy		
Advise against agents that may exacerbate peptic ulcer disease (e.g., alcohol, smoking).	—/GPP	—
If taking bicarbonate-containing antacids or misoprostol, advise cessation of treatment.	III/B	118–120
Perform investigations to establish the cause of peptic ulceration.	—/GPP	—
Anticipate improvement in clinical symptoms with pregnancy.	—/GPP	—
Aluminum- and magnesium-containing antacids, mucosal protective agents, and histamine receptor blockers are safe in pregnancy.	IIb/B	102–105
Avoid bicarbonate-containing antacids (danger of respiratory alkalosis and fluid overload).	IV/C	105
Consider anti-*Helicobacter* treatment with positive immunologic diagnosis and if other therapy has been ineffective.	—/GPP	—
Endoscopy is also safe with an experienced operator if no response to medical management; surgery is rarely required and mainly needed for those with severe bleeding/perforation.	—/GPP	—
Postnatal		
Symptoms of dyspepsia are likely to improve postnatally.	—/GPP	—
Repeat endoscopy if indicated by initial findings.	—/GPP	—

GPP, good practice point.

CELIAC DISEASE

General

Definition and Incidence

Celiac disease, or gluten-sensitive enteropathy, is a common disorder in which gluten-containing foods trigger inflammation of the jejunal mucosa that improves when a gluten-free diet is taken. In England, it occurs in 1 in 1000, and in Ireland, in 1 in 300 individuals,[123] although more may have silent or undiagnosed celiac disease. It seems to be rare in black Africans, although this may reflect reporting bias. The cause is multifactorial. There is a genetic component, with 10% to 15% of first-degree relatives being affected.[124] However, 30% of identical twins are discordant,[125] suggesting additional factors are involved, such as viral infection.

Etiology

Gluten is present in the cereals wheat, barley, and rye, but not oats. There are four main gluten fractions, but α-gliadin is the most damaging to small intestine mucosa. The enzyme tissue transglutaminase, the main antigen of the endomysial antibody, modifies gliadin and enhances gliadin-specific T-cell responses in genetically predisposed individuals. This is one of several immunologic abnormalities that revert to normal when a gluten-free diet is assumed. Histologically, the small bowel shows partial villus atrophy, with crypt hypertrophy and chronic inflammatory changes, the extent of the damage decreasing toward the ileum as gluten is progressively digested into smaller and less damaging moieties.

Diagnosis

Clinically, celiac disease presents at any age and is more common in females than in males. The symptoms are variable and may include tiredness and malaise (often in conjunction with anemia), diarrhea, steatorrhea, abdominal pain or bloating, weight loss, mouth ulcers, osteoporosis, and neurologic symptoms from folate, B_6, or B_{12} deficiency. In pregnancy, the most common presentation is with nonspecific symptoms without overt malabsorption or with anemia.

A new diagnosis of celiac disease should be considered in pregnant women with iron-deficiency anemia or in the presence of otherwise unexplained folate- or B_{12}-deficiency anemia. There should be a low threshold for investigating unexplained iron-deficiency anemia, diarrhea, or weight loss in pregnancy, especially if the anemia responds poorly to iron supplementation or if folate or B_{12} deficiency is also present. In a study of premenopausal nonpregnant women, 1 in 16 asymptomatic but anemic volunteer blood donors were found to have celiac disease.[126] Among anemic pregnant women, 1 in 43 were found to have antiendomysial antibodies, although apparently none was investigated further for celiac disease.[127] The diagnosis of celiac disease is confirmed by finding endomysial, gliadin, or tissue transglutaminase antibodies, which have high specificity and sensitivity. Outside pregnancy, a jejunal biopsy is usually obtained. Within pregnancy, most experts feel that this is best avoided, although duodenoscopy can be performed if clinically indicated.

It is important not to miss the diagnosis of celiac disease, because left untreated, the condition causes significant morbidity for both the pregnant woman and her fetus and carries with it an increased lifetime increase in mortality, mostly from small bowel carcinomas and lymphomas. All of these risks can be ameliorated by assuming a gluten-free diet.

Maternal and Fetal Risks

Maternal Risks

Untreated celiac disease is associated with later menarche, earlier menopause, and a greater risk of secondary amenorrhea compared with control groups of either unaffected women or women with treated celiac disease.[128] Women with treated celiac disease who adhere to a gluten-free diet have no more gynecologic problems than a group of women without celiac disease. Infertility itself is more common in women with celiac disease than in the general population and has been reported to affect 4% to 8% of cases.[129,130] The pathophysiology of these problems remains uncertain.

Male subfertility is also reported in celiac disease. Abnormal sperm forms, which resolve once dietary gluten is withdrawn, have been observed in nearly half of men with untreated disease. Another group found that male fertility improved after treatment.[131–133]

Anemia is common in women with celiac disease. They should take iron and folate supplements throughout pregnancy; they may also need B_{12} supplementation, and so should be monitored appropriately. Women with celiac disease who are not anemic before pregnancy should be tested for anemia and iron, folate, and B_{12} deficiency regularly throughout the pregnancy. Hypocalcemia is less common but must be considered.

Ideally women with celiac disease should take 5 mg, not 400 μg, of folate preconceptually, in order to optimize their levels of folic acid. There is insufficient evidence to support, or refute, the claim that celiac disease increases the risk of neural tube defect. This may be because most series of women are too small to make meaningful conclusions.

Fetal Risks

Several reports show first-trimester pregnancy loss to be up to nine times more common in women with untreated celiac disease than in those who have received treatment and to be much more common in pregnancies in the same woman before compared with after treatment with a gluten-free diet.[134] Low–birth weight babies are nearly six times more common in women with untreated compared with treated celiac disease, and in a cohort of 12 women, once they assumed a gluten-free diet, the number of low–birth weight babies born fell from nearly 30% to 0%.[140] Similarly, a gluten-free diet increased the duration of breast-feeding more than twofold.

Gasbarrini and colleagues[135] investigated a group of 83 women with either two or more consecutive miscarriages or an unexplained growth-restricted baby (<10th percentile) and 50 controls. In the poor-outcome groups, 8% and 15%, respectively, had immunologic and histologic features of celiac disease, compared with none of 50 controls.[135] They hypothesize that treatment with a gluten-free diet might improve pregnancy outcome. Martinelli and associates[136]

found similar results in an Italian population: Among 845 pregnant women screened for celiac disease, 12 cases were discovered and these women had more small–for–gestational-age infants than the other women.

More recently, an intriguing hypothesis suggests that men with celiac disease may father more pregnancies complicated by low birth weight than other men do. In a prospective, population-based cohort of 10,000 pregnancies in Sweden, babies of the 27 fathers with celiac disease were delivered at the same gestational age as the rest of the population, but weighed on average 266 g less and were five times more likely to weigh less than 2.5 kg.[137] Babies of fathers with a wide range of autoimmune conditions were not similarly affected. The babies of the 53 mothers with celiac disease had outcomes similar to those of the babies born to fathers with celiac disease. No difference was noted for babies with siblings or other relatives with celiac disease (*n* = 512). The exact mechanism for this is uncertain but indicates the importance of non-nutritional factors for neonatal outcome in parents with celiac disease. Genetic factors must be implicated.[137]

Management Options

Women with celiac disease should have a strict gluten-free diet prior to conception to minimize the risk of miscarriage. They should persist with this throughout pregnancy to minimize the risks of growth restriction, prematurity, and anemia. In order to achieve this, they should ideally have prepregnancy advice. Once they are pregnant, a management plan should include growth scans, testing for anemia, and iron and possibly folate and B_{12} supplementation. Some women with celiac disease malabsorb calcium: A baseline measurement should be taken, and a calcium-rich diet recommended. Supplementation may be necessary for some women.

SUMMARY OF MANAGEMENT OPTIONS
Celiac Disease

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Provide preconception counseling and gluten-free dietary control.	IIa/B	135,144
Supplement folic acid.	—/GPP	—
Prenatal		
Provide careful gluten-free dietary surveillance by dietician.	IIa/B	135,144
Supplement folic acid.	—/GPP	—
Monitor nutritional status.	—/GPP	—
Replace vitamins, minerals as indicated.	—/GPP	—
Give iron; check for anemia.	—/GPP	—
Screen for fetal abnormality, especially neural tube defect.	—/GPP	—
Monitor fetal growth and well-being.	III/B	135,136
Postnatal		
Monitor nutritional and vitamin adequacy, particularly with lactation.	—/GPP	—
Provide contraceptive advice and caution with oral preparations if disease active.	—/GPP	—

INFLAMMATORY BOWEL DISEASE

General

The term *inflammatory bowel disease* describes Crohn's disease and ulcerative colitis, as well as other less common forms of colitis. Crohn's disease is a chronic, granulomatous inflammatory disease of the intestine in which affected segments of bowel are often separated by normal bowel (skip lesions). It most commonly involves the terminal ileum. Common symptoms are abdominal pain and diarrhea, and there may also be anemia and weight loss, fresh blood or melena per rectum, fistulas, or perianal sepsis. Nonintestinal tract manifestations of the disease include aphthous ulcers, sacroiliitis, sclerosing cholangitis, and uveitis.

Ulcerative colitis is a chronic inflammatory disease of the colon and rectum. It commonly presents with diarrhea and rectal passage of mucus and blood. Typically, the disease starts in the rectum and spreads proximally, without skip lesions. Severe attacks are characterized by passage of a large number of bowel movements a day and can be complicated by fever and abdominal distension (toxic megacolon), which can be fatal. Other complications include anemia, weight

loss, hypoalbuminemia, electrolyte imbalances, and carcinoma of the colon (with long-standing disease). Nonintestinal features are similar to those seen in Crohn's.

Although Crohn's disease and ulcerative colitis are both chronic inflammatory disorders of the gastrointestinal tract, the cause of the inflammation does not appear to be the same in each condition. Both are thought to be caused by immune dysregulation in response to constituents of normal gut flora in genetically predisposed individuals. The inflammatory response in Crohn's disease is driven by interleukin-12 (Il-12) and interferon-γ (IFN-γ),[138] whereas in ulcerative colitis it is caused by Il-13 release by natural killer T (NKT) cells in a murine model.[139]

There is evidence for a genetic origin in both Crohn's disease and ulcerative colitis. One study reported that in siblings with similar genetic susceptibility for inflammatory bowel disease, smoking was associated with an increased risk of Crohn's disease and nonsmoking was associated with the development of ulcerative colitis.[140] Laboratory studies have also demonstrated mutations in *NOD2*, a gene that encodes an intracellular receptor for bacterial lipopolysaccharide, in a subgroup of patients with Crohn's ileitis, but not in patients with colitis or anorectal disease.[141]

Diagnosis

If a woman has known inflammatory bowel disease and is complaining of symptoms consistent with an exacerbation, stool culture should be performed to exclude infection. Blood specimens should be taken to establish whether she has anemia, electrolyte imbalance, or hepatic impairment, and inflammatory markers should be checked. The erythrocyte sedimentation rate is raised in normal pregnancy, but the C-reactive protein is not and is of value in the assessment of patients with Crohn's disease and ulcerative colitis. If a flare-up of inflammatory bowel disease is confirmed, care should be shared between obstetricians and gastroenterologists. If there is severe disease or if toxic megacolon is suspected, an abdominal radiograph should be performed, and the woman should be referred for a surgical opinion.

In a woman who does not have a history of inflammatory bowel disease, the diagnosis is based on imaging of the upper and lower gastrointestinal tract, colonoscopy, and biopsy. Most women will have had the diagnosis made before they conceive, but if a new presentation of inflammatory bowel disease occurs in pregnancy, endoscopy and biopsy are preferable to barium studies.

Maternal and Fetal Risks

Maternal Risks

Fertility is reduced in women with active Crohn's disease and possibly in those with ulcerative colitis, but there is no evidence of reduced fertility with quiescent inflammatory bowel disease. The frequency of exacerbations of both Crohn's disease and ulcerative colitis is the same as outside pregnancy (30%–40% women/yr).[142] Flares may occur at any stage of pregnancy, although they occur most commonly in the first trimester.

Women who have had an ileostomy or colostomy usually tolerate pregnancy well, providing at least 50% of the small intestine remains. Complications that can occur in patients who have had gut resection include malabsorption of fat, fat-soluble vitamins, vitamin B_{12}, and water, and electrolyte imbalance. Also, women can have obstruction of ileostomy as pregnancy progresses.

The mode of delivery is not usually influenced by inflammatory bowel disease, even in those with an ileal pouch–anal anastomosis. There are few reports of the management of labor in such cases, but two studies have reported normal vaginal deliveries in the majority of women.[143,144] However, cesarean section should be considered in women with impaired anal continence, in those who have had extensive perineal surgery due to scarring causing skin inelasticity, or in women with active perianal disease, because episiotomy may result in fistula formation. These cesarean procedures may be complicated, and an experienced obstetrician should be present.

Postpartum flare is not a feature of ulcerative colitis but can occur in Crohn's disease.

Fetal Risks

For the majority of cases, if the maternal inflammatory bowel disease is quiescent at the time of conception, the fetal outcome is no different from that in unaffected pregnancies. However, active disease at the time of conception is associated with an increased rate of miscarriage, and flares during pregnancy result in low birth weight and prematurity.[145–147]

Because the etiology of inflammatory bowel disease has both hereditary and immune components, breast-feeding should be encouraged in an effort to reduce the risks to the children of affected women.

Management Options

Acute exacerbations of inflammatory bowel disease can be treated with 5-aminosalicylic acid (5-ASA)–containing compounds and corticosteroids taken rectally, and then orally if local therapy is not sufficient to control symptoms. In severe attacks, intravenous corticosteroids may be required. Loperamide can be used for the treatment of diarrhea. Metronidazole is used to treat anal disease and fistulas, particularly in active Crohn's disease. 5-ASA–containing compounds, corticosteroids, and the immunosuppressives azathioprine and 6-mercaptopurine can be used during remission to prevent relapse rates. Long-term management for recurrent Crohn's disease also includes attention to diet and vitamin supplementation. Pregnant women with inflammatory bowel disease should be advised to take high-dose folate (5 mg daily).

5-Aminosalicylic Acid Derivatives

Many women are now treated with 5-ASA derivatives. Sulfasalazine (Salazopyrin or Azulfidine) is a prodrug that is converted by colonic bacteria into sulfapyridine and 5-ASA. The efficacy of sulfasalazine in the treatment of inflammatory bowel disease resides in the 5-ASA component. Many of the side effects of the drug have been attributed to sulfapyridine, and therefore, newer preparations that do not have this component are now used more commonly than sulfasalazine. These include mesalazine (5-ASA), balsalazine (a prodrug of 5-ASA), and olsalazine (a dimer of 5-ASA that

is cleaved in the lower bowel). Both oral and topical preparations of 5-ASA and sulfasalazine are safe in pregnancy. In a U.S. study that included 186 cases in which the mother was treated with sulfasalazine, the fetal complication rate was lower than the reported rates in the general population.[148] A prospective Canadian study of 165 women who were exposed to oral mesalazine in pregnancy, 146 of whom had first-trimester exposure, demonstrated no increase in major congenital malformations when compared with matched controls who had not been exposed to teratogenic drugs.[149] In a French study designed to address whether treatment with high doses of mesalazine in pregnancy were associated with an adverse fetal outcome, 86 women who received less than 3 g mesalazine daily were compared with 37 who received more than 3 g daily. The results revealed no difference in the rates of congenital malformations, prematurity, or fetal death between the groups, and the prevalence of these complications was not different from the quoted rates from the general population.[150] Only very small amounts of 5-ASA pass into breast milk, and the drug is therefore also thought to be safe in lactating women.[151]

Corticosteroids

Corticosteroids taken orally in low doses may reduce recurrence rates, and in higher doses are used for acute intestinal symptoms, orally or intravenously. Distal disease can respond to steroid enemas.

Azathioprine

Azathioprine is an immunosuppressant that is metabolized to 6-mercaptopurine. There are many reports of renal transplant recipients who have conceived while taking azathioprine and who have had normal children. Thus, the drug is thought to not be teratogenic in humans. Azathioprine crosses the placenta, but the fetal liver lacks the enzyme that converts it to its active metabolite; this is thought to explain the fetal protection from teratogenic effects. There is no reason to suspect that the risks in women with inflammatory bowel disease should be different from those who have had renal transplants. One case series reported the outcome of 16 pregnancies in 14 women with inflammatory bowel disease who were treated with azathioprine.[152] There were no congenital abnormalities, and the children's growth and development were normal.

6-Mercaptopurine

There have been very few reports of 6-mercaptopurine use in pregnancy. In one large case series of patients with inflammatory bowel disease treated with the drug, two women had ongoing pregnancies after having stopped the drug at 3 and 4 weeks' gestation, respectively, and no congenital abnormalities were found in their children.[153]

Metronidazole

Because metronidazole is used to treat *Trichomonas vaginalis*, there have been several studies of its use in the first trimester. A Canadian meta-analysis of all studies that contained at least 10 women exposed to metronidazole in the first trimester and untreated controls did not find evidence that the drug is teratogenic.[116] A Spanish meta-analysis that included five cohort and case-control studies reported similar results.[117] This study included three series that were also included in the Canadian study.

Antidiarrheal Agents

Loperamide is a synthetic piperidine derivative that is used for the treatment of diarrhea. In a prospective, controlled, multicenter study of loperamide in pregnancy in which 105 women were studied and 89 were exposed to loperamide in the first trimester, there were no significant differences in the rate of major or minor congenital malformations when compared with matched controls.[154]

Biologic Therapy

The most commonly used biologic agent is infliximab, an immunoglobulin G₁ (IgG_1) antibody. Although infliximab does not cross the placenta in the first trimester, it can cross in the third trimester.[155] It is also detectable in the infant for several months after birth. The data on fetal risk following infliximab treatment in pregnancy are limited. However, there is no evidence of an increased congenital malformation rate in more than 100 pregnancies reported in the two largest registries (the TREAT registry[156] and the Infliximab Safety Database[157]). There is a theoretical concern that treatment with infliximab and other biologic agents could affect the infants' immune system, but there have not been sufficient numbers of cases treated in the third trimester to assess this at present. There are currently very limited data about the effects of other biologic agents in pregnancy.

SUMMARY OF MANAGEMENT OPTIONS
Inflammatory Bowel Disease

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Provide preconception counseling and control and encourage conception when disease is quiescent.	IIa/B	145,147
Consider modification of drug therapy to those with a good safety record in pregnancy (see later); steroids do not reduce the risk of relapse.	—/GPP	—
Ensure folate supplementation (5 mg/day).	—/GPP	—

SUMMARY OF MANAGEMENT OPTIONS
Inflammatory Bowel Disease—cont'd

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Continue appropriate drug therapy prenatally:		
• Salicylates.	IIa/B	148–150
• Corticosteroids (oral or rectal).	III/B	148
• Azathioprine.	III/B	152
• 6-Mercaptopurine—limited experience in pregnancy.	III/B	153
• Metronidazole.	III/B	116,117
• Loperamide.	IIa/B	154
Treat flares in the same way as outside pregnancy.	—/GPP	—
Pay attention to nutrition, iron, and folate supplementation	—/GPP	—
Monitor fetal growth.	IIa/B	145–147
Labor and Delivery		
Cesarean section is rarely indicated.	—/GPP	—
Exceptions are women with severe perianal disease, postoperative perineal scarring, or impaired anal continence with an ileal pouch–anal anastomosis.	—/GPP	—
Pay scrupulous attention to wound repair (abdominal and perineal) with Crohn's disease.	—/GPP	—
Postnatal		
If severe diarrhea and malabsorption are present, consider alternatives to oral contraceptives.	—/GPP	—
Breast-feeding is safe for women taking sulfasalazine, mesalazine, corticosteroids, and metronidazole.	IIa/B	116,117, 148–151
Data are currently insufficient about azathioprine and breast-feeding to give evidence-based guidance, although most experts in the field feel that the benefits of maintaining remission and achieving lactation outweigh the risks of discontinuing therapy.	III/B	152
An increased frequency of flares in the postpartum period is reported in Crohn's disease but not in ulcerative colitis.	—/GPP	—

Neurologic Complications

J. RICARDO CARHUAPOMA, MARK W. TOMLINSON,
and STEVEN R. LEVINE

INTRODUCTION

Neurologic conditions seen in reproductive-age women will be encountered during pregnancy. Table 48–1 shows the incidence of several such neurologic diseases. The relative rarity of many of these conditions limits the actual clinical experience of both the managing obstetrician and the neurologist. In addition, the individual practitioner is further hampered by the limited amount of pregnancy-specific information available. The frequent overlap of symptoms associated with common pregnancy complaints, the sometimes disabling and lethal consequences of the disease, and the fetal effects of maternal treatment make the diagnosis and management of neurologic disease during pregnancy an often-daunting task.

Optimal and effective management commonly requires the expertise of several disciplines. This obviously includes the obstetrician or maternal-fetal medicine specialist and the neurologist in combination. Involvement of an anesthesiologist is essential at the time of labor and delivery to provide appropriate analgesia or anesthesia. Early involvement of the pediatrician or neonatologist is important to anticipate neonatal needs and adequately care for the newborn. Drugs discussed are listed with a risk factor category used by the U.S. Food and Drug Administration (FDA). The categories and definitions are shown in Table 48–2.[1] There are very few randomized clinical trials to guide evidence-based medicine in the field of neurologic complications of pregnancy.

SEIZURES

Neurologic Complications of Preeclampsia/Eclampsia

Maternal and Fetal Risks

Preeclampsia and eclampsia are also discussed in Chapters 35 and 78. The reported incidence of eclampsia in both the United Kingdom and the United States is approximately 0.05% of births. As with preeclampsia, the specific etiology and pathophysiology leading to eclampsia are unknown. Postulated contributing factors include cerebral edema, vasospasm/cerebral vasculopathy, ischemia, hemorrhage, a cerebrovascular dysregulation or central dysautonomia, and hypertensive encephalopathy.[2]

Hypertension is an important factor associated with convulsions. Increasing systolic and diastolic blood pressures in a previously normotensive patient challenge the autoregulatory properties of cerebral blood vessels. In normotensive patients, autoregulation is preserved between mean arterial pressure (MAP) values from 50 to 150 mm Hg. Beyond this range, cerebral blood vessels lose their tone and an angiographic pattern of vasodilation with segments of vasoconstriction develops. The blood-brain barrier and its "tight junctions" are disrupted and vasogenic edema ensues.[3–8] This process occurs preferentially in the occipital lobes and in "watershed" areas of the brain.[9] The neuropathologic changes are widespread throughout the neuraxis.[10] Cerebral edema is evident and the presence of petechial hemorrhages surrounding arterioles is conspicuous, conceivably rendering certain neuronal populations hyperexcitable. Although hypertension through this cascade of events can initiate the pathogenic process of convulsions in many instances, it does not explain all cases. Eclampsia can be seen in patients without significant blood pressure elevations.[2] As many as 38% of all eclamptics have been reported to have no hypertension or proteinuria identified before the initial seizure.[11]

In addition to convulsions, a variety of visual symptoms may be seen. These may be nonspecific, but can include retinal detachments and cortical blindness, secondary to hypertension-induced retinal arteriolar dilation, papilledema,[12] central retinal artery occlusion,[13] and vasospasm.[14] Visual changes generally improve with delivery and hypertension control. Headache (see Table 48–7) is also a common complaint and may involve increased intracranial pressure (ICP) resulting from vasogenic edema.[15] More severe findings such as worsening headache, lethargy, focal neurologic findings, stupor, and coma in a preeclamptic patient should always raise the suspicion of an intracerebral hemorrhage or of worsening brain edema with the subsequent risk of brain herniation.[16]

Although maternal mortality has decreased over the past several decades, eclampsia continues to be a significant contributor, particularly in underdeveloped countries. In a large U.S. hospital system managing nearly 1.5 million births from 2000 to 2006, preeclampsia and its related complications was the leading cause of maternal deaths, accounting for

TABLE 48–2

Classification System for Fetal Risk Associated with Medications Used during Pregnancy

Category A	Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester (and there is no evidence of a risk in later trimesters), and the possibility of fetal harm appears remote.
Category B	Either animal reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women or animal reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).
Category C	Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or other) and there are no controlled studies in women or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.
Category D	There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (e.g., if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).
Category X	Studies in animals or human beings have demonstrated fetal abnormalities or there is evidence of fetal risk based on human experience, or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

16% of these deaths. The Confidential Inquiry into Maternal Deaths in the United Kingdom from 2003 to 2005, preeclampsia and eclampsia were the second leading cause of direct maternal mortality, accounting for 18% of the deaths.[17] In other series, approximately 1% of pregnancies complicated by eclampsia still resulted in maternal death.[11,18] In developing countries, maternal mortality is reported in 8% to 14% of patients with eclampsia.[19] Fetal and neonatal complication rates also tend to be high and are attributed to prematurity, placental insufficiency, and placental abruption.[20]

Management Options (See also Chapters 35 and 78)

PRENATAL, LABOR AND DELIVERY, AND POSTNATAL

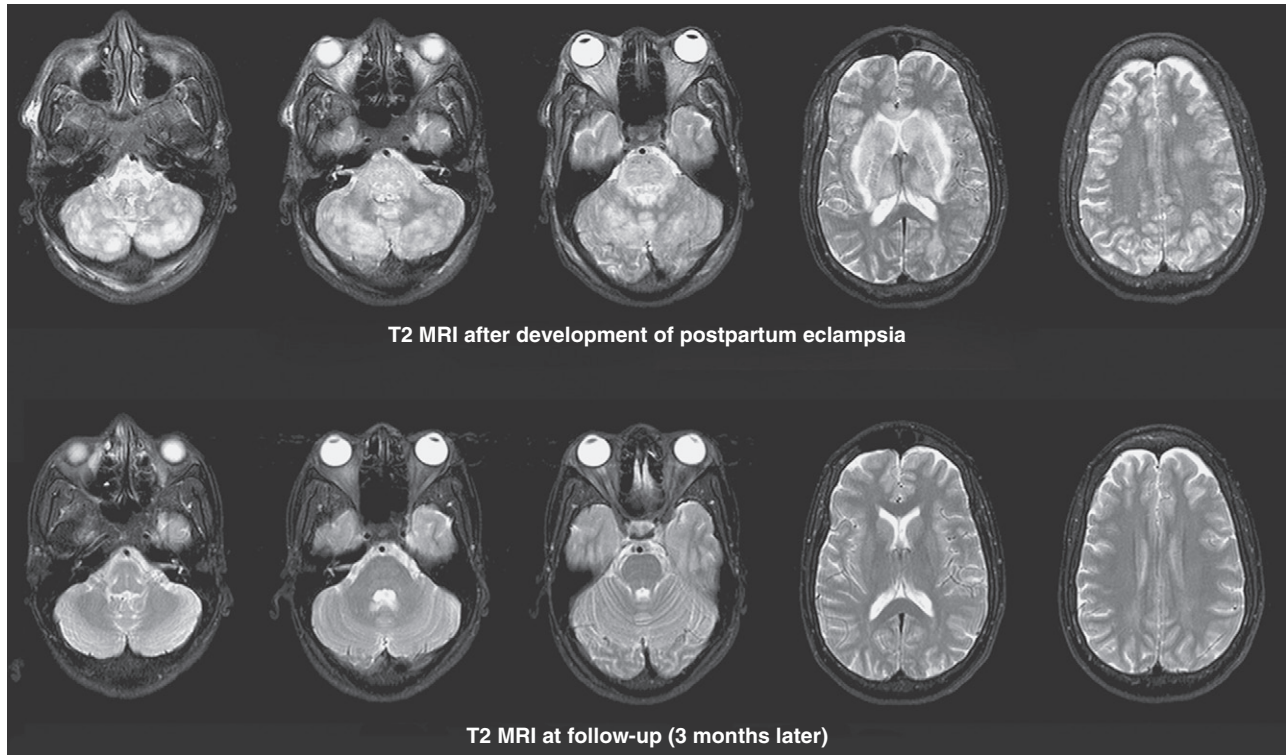
Eclampsia most frequently occurs during the antepartum and intrapartum periods, but approximately one third of cases are seen postpartum.[21] Between 28% and 56% of postpartum convulsions occur more than 48 hours after delivery.[22,23] The diagnosis is clinical, and additional diagnostic evaluation is not always necessary in cases in which typical preeclampsia precedes the seizure. When the presentation is not classic, however, imaging studies such as brain computed tomography (CT) and preferably magnetic resonance imaging (MRI) including diffusion weighted imaging can be helpful in identifying complications or other seizure etiologies such as hemorrhage, cerebral infarction, infection/inflammation, or cerebral venous thrombosis (Fig. 48–1).

Magnesium sulfate continues to be the mainstay of both seizure prophylaxis and abortive therapy in the United States.[24] The precise mechanism of action remains poorly understood. Current hypotheses include reduction in cerebral vasospasm through calcium antagonism and N-methyl-D-aspartate (NMDA) receptor channel blockade providing "neuroprotection" from ischemic injury resulting from vasospasm.[25–28] The efficacy of magnesium has been established.[29] Large trials provide compelling evidence that magnesium sulfate is superior to phenytoin and diazepam in both treatment and prophylaxis of eclamptic seizures.[30] A multicenter worldwide trial including more than 1600 eclamptic patients reported that magnesium sulfate was associated with a 52% lower risk of recurrent seizures than diazepam and a 67% lower risk than phenytoin. Furthermore, maternal and neonatal morbidity were lower in the magnesium group than in those receiving phenytoin. Magnesium sulfate has also been shown to be superior to placebo and phenytoin when used prophylactically to prevent seizures. A large North American study comparing the efficacy of magnesium and phenytoin for seizure prophylaxis was stopped early when interim analysis demonstrated that phenytoin provided ineffective seizure prophylaxis.[30] Management differences between eclampsia and epilepsy should not be surprising because the pathophysiology of the two conditions is likely to be different. A Cochrane Review showed that magnesium sulfate more than halves the risk of eclampsia and probably reduces the risk of maternal death (relative risk [RR] 0.41, 95% confidence interval [CI] 0.29–0.58).[29] Magnesium sulfate does not improve outcome of the newborn. The risk of placental abruption was also reduced.[29]

Specific dosing recommendations for magnesium sulfate have varied, but generally consist of a 4- to 6-g intravenous load given over 5 to 30 minutes. This is followed by a maintenance dose of 1 to 3 g/hr intravenously. Therapeutic serum levels are in the range of 4 to 8 mEq/L. The magnesium infusion is usually continued for approximately 24 hours into the postpartum period. The duration of therapy is empirical and based on the distribution of postpartum seizure risk. Complications associated with the use of magnesium center on its calcium antagonism at the neuromuscular junction, which can result in neuromuscular blockade. At levels above 10 mEq/L, deep tendon reflexes are lost. Lethargy and respiratory depression are also seen. Levels of 12 to 15 mEq/L result in respiratory paralysis. Higher levels can result in

Axial head T$_2$-weighted magnetic resonance imaging (MRI) scan of a woman with headaches, proteinuria, and postpartum seizures. There are multiple regions of T$_2$ hyperintensity in the cerebellum, pons, basal ganglia, and the hemispheric white matter consistent with changes seen in eclampsia. These radiologic abnormalities reversed on subsequent MRI evaluation that followed the complete clinical resolution of this patient's initial neurologic presentation.

T2 MRI after development of postpartum eclampsia

T2 MRI at follow-up (3 months later)


cardiac standstill. Management of overdose includes respiratory support, calcium gluconate (1 g), and cardiac monitoring.

Low-dose aspirin use in preeclampsia was evaluated in a meta-analysis involving over 40 trials and more than 30,000 women.[31] Limited data prevented conclusions regarding the use of aspirin to treat preeclampsia; however, a moderate decrease in the incidence of preeclampsia was found when aspirin was used prophylactically.

Blood pressure control is also important in both preventing and managing neurologic complications associated with preeclampsia/eclampsia.[32] Some investigators have suggested that a greater emphasis should be placed on blood pressure control, with the potential elimination of seizure prophylaxis. Hydralazine and labetalol are frequently used as first-line agents, with continuous intravenous infusions of nicardipine, sodium nitroprusside, and nitroglycerin used in refractory cases.

Simple first-aid measures (avoiding injury, nursing semi-prone, maintaining airway, and giving oxygen) should not be forgotten.[32] Maternal renal, liver, and coagulation status should be monitored together with the fetal condition if the eclampsia is prenatal. Fluid overload should be avoided. The majority of obstetricians would deliver the fetus once the mother is stable if the eclampsia occurs during pregnancy (see Chapters 35 and 78 for further discussion).

• Place in semiprone position.		
• Maintain airway.		
• Administer oxygen.		
• Monitor maternal and fetal condition.		

Epilepsy

Maternal and Fetal Risks

Epilepsy is probably the most common serious neurologic problem faced by obstetricians. There are approximately 1 million women of childbearing age with epilepsy in America, delivering roughly 20,000 babies annually. Seizures during pregnancy have an incidence of 0.15% to 10%.[33] The interrelationship of maternal epilepsy, antiepileptic drug (AED) metabolism and pharmacodynamics, genetics, drug-induced embryopathies, and maternal behavior is complex and has led to considerable controversy concerning epilepsy in pregnancy.

One area of unresolved controversy involves the effect of pregnancy on seizure frequency.[34–36] Approximately one third of patient's will have an increase in frequency, whereas the remainder will experience no change or a decrease.[35] Some of the change can be attributed to physiologic changes and psychological stress associated with pregnancy.[36] These factors include increased steroid hormone levels, sleep deprivation, and metabolic changes. More commonly, when seizure frequency is increased, deliberate patient noncompliance secondary to fear of fetal drug effects is likely to blame.[37] The effect of pregnancy on epilepsy may be inferred from the women's seizure frequency before pregnancy. As a rule, the fewer the number of seizures occurring in the 9 months before conception, the less the risk of worsening epilepsy during pregnancy.[35,37] If the seizure frequency is at least one seizure monthly before pregnancy, there is a high probability that increased seizure frequency will be seen during pregnancy. This is in contrast to women having only one seizure during the 9 months before pregnancy. These patients have only a 25% risk of seizing during pregnancy.

Decreases in most AED levels occur during pregnancy and can affect seizure frequency.[38] Gastrointestinal absorption decreases, whereas hepatic and renal clearance increase for most AEDs. Albumin levels decrease, leading to lower total drug levels.[39] Pregnancy-associated changes in specific agents are described in Table 48–3. Postpartum, these changes reverse with a resultant increase in drug levels. In reality, the availability of serum drug level testing allows women to maintain prepregnancy therapeutic levels. When this is accomplished, only 10% of patients will experience increased seizure frequency during pregnancy.[35]

The effects of AEDs on the fetus are complex and controversial.[40,41] The four most commonly used agents (carbamazepine, phenobarbital, phenytoin, and valproic acid) are known to cross the placenta and all are believed to have teratogenic effects. The rate of congenital malformations in patients using these drugs is approximately two to three times that of infants of nonepileptic mothers (i.e., 6%–8% in epileptic pregnancies).[37] Thus, more than 90% of mothers taking AEDs during pregnancy will deliver normal children.

Additional factors have been linked to the increased rate of anomalies seen in patients using AEDs. Multiagent therapy appears to enhance malformation rates.[42] In addition, phenytoin,[43] primidone,[44] and carbamazepine[45] have been associated with patterns of malformation that are quite similar. Common anomalies include a mildly dysmorphic face and fingers with stubby distal phalanges and hypoplastic fingernails, suggesting a "fetal antiepileptic drug syndrome."[37] A genetic predisposition might play a role in development of these malformations. Such a link has been reported for the enzyme epoxide hydrolase.[46] A reduction in the enzyme's

TABLE 48–3

Antiepileptic Drug Level Changes in Pregnancy Compared with Nonpregnant Baseline

DRUG	TOTAL DRUG LEVEL (%)	FREE DRUG LEVEL (%)
Phenytoin	−56*	−31
Phenobarbital	−55*	−50*
Carbamazepine	−42*	−28*
Valproic acid	−39*	+25

activity was seen in amniocytes of fetuses who developed findings of fetal hydantoin syndrome, but not in those lacking any findings. Further confusing the issue is evidence that some of the anomalies associated with AEDs are found in mothers with epilepsy but no exposure to these medications.[47]

Despite the etiologic uncertainty, individual drugs have been associated with specific anomalies. Cleft lip and palate, as well as cardiac and urogenital defects, are reported with phenytoin. Spina bifida is found in 1% to 2% of patients taking valproic acid.[48] The malformation pattern associated with phenobarbital is similar to that seen with phenytoin. Carbamazepine was felt to be the safest of the AEDs, but it too has been associated with spina bifida at a rate of approximately 1%.[42] Developmentally, most children have normal motor function but may have some degree of cognitive dysfunction. The latter-observed abnormalities appear more likely to relate to seizures during pregnancy and lower levels of paternal education rather than AEDs. Valproate appears to be an exception, however. It has been associated with increased cognitive impairment in children evaluated at 3 years of age compared with those taking carbamazepine, lamotrigine, or phenytoin.[49]

Coagulopathies have been reported in approximately half of all babies born to mothers taking phenobarbital, primidone, or phenytoin. A deficiency of vitamin K–dependent clotting factors is responsible. Few infants actually develop clinical symptoms.[50]

Levetiracetam (LEV; FDA category C) is an AED approved for use as adjunct agent in partial-onset seizures in adults and children aged 4 years or older. Recently, it has been approved as adjunctive therapy in the treatment of myoclonic seizures in adults and adolescents aged 12 years or older. Although not formally approved by the FDA for its use in primary generalized epileptic syndromes, its use as monotherapy or first-line therapy for generalized seizures is increasing. The mechanism of action of this drug is not well understood. The absence of hepatic clearing and lack of drug interactions make this drug particularly attractive in patients who are on multiple agents. The most common side effects—asthenia, somnolence, and dizziness—are mild to moderate and usually do not require discontinuation of the drug. Few data are available on human teratogenicity of LEV. In 11 pregnancies during treatment with LEV, 1 spontaneous abortion, 1 termination, and 9 live births were noted. None of the live births had evidence of malformations. Two infants were found to have low birth weight. Data from women with epilepsy treated with LEV suggest transfer of the drug from mother to fetus and into breast milk. However, infants had very low LEV levels and did not show signs of adverse effects. In general, women on LEV should be encouraged to breast-feed.[51–54]

Management Options
PREPREGNANCY

Ideally, patients are seen prior to conception to optimize antiepileptic therapy.[55] The patient should be evaluated in conjunction with a neurologist for withdrawal of AEDs. Some patients who have been seizure-free for greater than 2 years are potential candidates. However, other factors must also be considered before a decision is made. Age of onset, seizure type, electroencephalographic findings, and number of seizures occurring before control was achieved all affect the risk of recurrence.[56,57] If complete withdrawal is not possible or practical, monotherapy should be attempted to reduce the risk of fetal malformations. The drug chosen should be that which is most effective for a given seizure type.[37] Vaproate should be avoided in women of reproductive age whenever possible.

Those who will be continuing on AEDs should be counseled about the importance of seizure control and the current understanding of fetal risks for malformations. Such counseling may decrease the number of patients who inappropriately discontinue their medication. Initiation of folic acid supplementation should also be considered preconceptionally. Although there is no direct evidence of benefit in epileptic patients, the recommendation is based on findings demonstrating a decrease in recurrence of neural tube defects in women with a previously affected child. The goal of therapy is to maintain normal serum and red cell folate levels.[37]

PRENATAL

Patients on AEDs should have drug levels monitored.[55] They should be maintained on the lowest effective dose. If valproic acid must be used, multiple doses at intervals during the day are preferred. A fall in drug level is common and does not necessarily require an increase in dose. Decisions to change the drug dose should be based on the clinical status, with drug levels used to guide such changes. Free drug levels change to a lesser degree than the total levels and may be used to serially monitor the patient.[37] A targeted ultrasound examination should be performed in the second trimester to search for fetal anomalies. Maternal serum α-fetoprotein may be considered in addition to ultrasound to screen for neural tube defects in patients taking valproate or carbamazepine. Vitamin K can be given to the mother during the final 4 weeks of gestation to decrease the risk of fetal coagulopathy.[37] Should seizures recur, short-acting benzodiazepines may be used acutely. Free serum levels should be rechecked and drug dosage optimized.

In recent years, the use of new AEDs has become widespread in patients with epilepsy. However, the alterations in the pharmacokinetics of these agents during pregnancy have not been adequately studied. Data are lacking for drugs such as gabapentin, topiramate, tiagabine, oxcarbazepine, LEV, and zonisamide, but no definitive adverse effects have been demonstrated in humans. All these drugs are classified as category C. Their use during pregnancy should be based on an evaluation of the benefits of the drug in a given patient versus the unknown potential for adverse outcome.

The majority of AEDs are characterized by significant increases in clearance during pregnancy.[58] Limited studies of the newer AEDs (lamotrigine, OXC, TPM, and ZNS) indicate similar extensive transplacental transfer. Current recommendations are that ideal AED concentration should be established for each patient before conception and that monitoring of AED levels should be performed during each trimester and the last month of pregnancy.[58]

LABOR AND DELIVERY

Most patients with epilepsy are able to labor normally and achieve a vaginal delivery. Elective cesarean section may be considered in patients refractory to treatment during the third trimester or in those that exhibit status epilepticus (SE) with significant stress. During labor, repeated seizures that cannot be controlled or SE may require an operative delivery. Fetal asphyxia can occur with prolonged or repeated seizures. Cesarean delivery may also be considered when repeated absence or psychomotor seizures limit maternal awareness and ability to cooperate. Tonic-clonic seizures are seen in approximately 1% to 2% of women during labor. Lorazepam, a short-acting benzodiazepine, is the drug of choice for treating seizures acutely.[37] The drug is administered in 2-mg boluses every 5 minutes as necessary. Some use 5- to 10-mg boluses of diazepam as an alternative.

POSTNATAL

AED levels must be monitored after delivery because reversal of the physiologic alterations causing a decline in levels during gestation leads to a rise postpartum. If the medication dose was increased during pregnancy, the regimen should be returned to that used prior to pregnancy to avoid toxicity. During the first postpartum day, an additional 1% to 2% of women will have tonic-clonic convulsions. Again, lorazepam is the agent of choice for acute control. New-onset seizures in the postpartum period require complete evaluation to rule out intracerebral hemorrhage, cortical vein thrombosis, infection, or eclampsia.

Neonates should be given vitamin K 1 mg intramuscularly after birth to prevent a coagulopathy. All AEDs can cross into the breast milk, but breast-feeding is not contraindicated for most agents. The effects of diazepam on nursing infants are unknown and it should be used with caution. Phenobarbital should be used only when no alternatives exist because neonatal sedation can occur along with neonatal withdrawal upon weaning.[59]

Contraception is an important consideration for women with epilepsy. Although the condition itself does not limit the choice of method, anticonvulsant therapy can have a significant impact on contraceptive effectiveness. Many of the drugs increase hepatic enzymes, thus increasing drug metabolism. The World Health Organization (WHO) states that there are no contraindications to intrauterine devices (IUDs) or depomedroxyprogesterone acetate use. The benefit of hormonal implants or other injectable hormones outweighs the risks. Combined oral or progestin-only pills along with the patch and vaginal ring should be avoided, if possible, owing to the increased risk of failure. If oral contraceptives are to be used, low-dose estrogen formulations should be avoided.

Status Epilepticus

Maternal and Fetal Risks

SE is defined as ongoing seizure activity lasting greater than 30 minutes or recurrent seizures without full recovery of consciousness between episodes. The actual incidence

---

during pregnancy is unknown. The important causes are listed in Table 48–4. Predisposing factors include poor compliance with AEDs, central nervous system infections, trauma, and illicit drug use.[35] SE represents a medical emergency. Most seizures are generalized tonic-clonic. During the tonic phase, contractions of the respiratory muscles impair adequate maternal oxygenation, leading to fetal hypoxia and potentially asphyxia. During the convulsive (clonic) phase, metabolic acidosis ensues. Rhabdomyolysis occurs and can lead to acute renal failure. After 30 minutes of continuous brain electrical activity, even in the absence of the metabolic derangements, irreversible neuronal injury can occur. The hippocampus and amygdala of the temporal lobe are particularly sensitive to permanent damage.[60] Trauma from recurrent seizure activity can result in preterm labor, rupture of membranes, abruptio placenta, and fetal death.[35]

Management Options

ANTENATAL, LABOR AND DELIVERY, AND POSTNATAL

Diagnostic and therapeutic interventions should be performed simultaneously. A patent airway must be secured and supplemental oxygenation given. Hypotension should be avoided to prevent decreased cerebral perfusion pressure. Complete blood count (CBC) with differential, electrolyte profile, blood urea nitrogen, creatinine, urine toxicology screen, and AED levels should be obtained. Cerebrospinal fluid (CSF) analysis is performed if meningoencephalitis is suspected.

Intravenous benzodiazepines are used acutely. Again, lorazepam is the drug of choice. It is given in 2-mg boluses every 5 minutes. Simultaneously, the patient is loaded with phenytoin, 18 mg/kg, administered at a rate not exceeding 50 mg/min. The administration of intravenous valproic acid (20 mg/kg loading dose) is an alternative if phenytoin is otherwise contraindicated. The combination of phenytoin and benzodiazepines is effective in controlling 75% to 85% of SE patients. In those with persistent seizures, higher levels of phenytoin can be achieved with an additional 5 mg/kg. In refractory cases in which barbiturates or a continuous infusion of benzodiazepines is needed, elective intubation is required to protect the airway. Continuous electroencephalographic monitoring should also be initiated. Once identified, the underlying etiology should be treated.

SUMMARY OF MANAGEMENT OPTIONS
Epilepsy

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Check clinical control and serum anticonvulsant levels regularly.	Ia/A	37
Adjust anticonvulsant dose to control seizures with serum levels as a guide; avoid toxic doses.	Ia/A	37
Supplement folate.	Ia/A	55
Status Epilepticus		
First-aid measures (see "Preeclampsia/Eclampsia").	—/GPP	—
Investigate and treat simultaneously.	Ia/A	55
Control convulsions:		
• Anticonvulsant drugs (IV benzodiazepine as boluses plus either IV phenytoin or IV magnesium if eclampsia is the cause).	Ia/A	37
• Ventilate while maintaining anticonvulsants if anticonvulsants alone fail to control seizures.	—/GPP	—
Avoid hypertension.	—/GPP	—
Prenatal		
Check clinical control and serum anticonvulsant levels regularly.	Ia/A	37
Adjust anticonvulsant dose to control seizures with serum levels as a guide; avoid toxic doses.	Ia/A	37
Obtain detailed fetal anomaly scan at 20 wk.	Ia/A	37
Administer short-acting benzodiazepine acutely if seizures recur.	Ia/A	37
Information about safety of more recent anticonvulsants is lacking.	IV/C	58
Labor and Delivery		
Continue anticonvulsant medication.	—/GPP	—
Administer short-acting benzodiazepine acutely if seizures recur.	Ia/A	37
Postnatal		
Examine newborn to confirm normality.	—/GPP	—
Administer vitamin K to newborn.	—/GPP	—
Monitor seizure control and serum levels; dose adjustment may be necessary.	Ia/A	37

GPP, good practice point.

CEREBROVASCULAR DISEASE

Ischemic Stroke and Transient Ischemic Attacks

Maternal and Fetal Risks

For many years, it was believed that the incidence of cerebral ischemia is significantly higher during pregnancy. Currently, controversy exists because the evidence is inconclusive.[61] In a population-based report, the relative risk of stroke during gestation was found to be 0.7.[62] Most of the risk in the population-based report appears to be from increased occurrence of hemorrhagic stroke. The relative risk of stroke increased to 8.7 during the postpartum period. During the years 2000 and 2001, the incidence of pregnancy-associated stroke was found to be 34 cases/100,000 deliveries using the Nationwide Inpatient Sample from the Healthcare Cost and Utilization Project of the Agency for Healthcare Research and Quality.[63] The stroke-related mortality was 1.4 in 100,000 deliveries. For reasons that are unclear, there may be an overrepresentation of middle cerebral artery occlusions during pregnancy and internal carotid artery occlusions during the postpartum period.

Most of the conditions associated with "stroke in the young" are shared by pregnant women suffering cerebral ischemia and, therefore, demand an extensive diagnostic evaluation to identify the cause and provide optimal treatment. The etiologies can be divided into processes that

involve the "ABCs" of stroke: arteries, blood components, and cardiac sources of emboli. A detailed list of specific causes is given in Table 48–5. Pregnancy-specific complications that are associated with an increased risk of stroke include preeclampsia and gestational hypertension, postpartum infection, and postpartum hemorrhage, especially when blood transfusion is required.

Premature or accelerated atherosclerosis accounts for almost 25% of ischemic strokes in pregnant women. Women with hypertension, diabetes mellitus, tobacco use, hyperlipidemia, and family history of premature atherosclerotic disease are especially at risk for this stroke mechanism. Less common vascular etiologies include arterial dissection during labor and delivery,[64] inflammatory arteritis such as Takayasu's arteritis,[65] and fibromuscular dysplasia. The latter has been associated with cerebral ischemia as well as intracranial aneurysms, carotid artery dissection, and carotid-cavernous fistula.[64,66,67] Fibromuscular dysplasia appears to occur more commonly in young women and might also affect the renal arteries.[68]

Physiologic alterations seen in pregnancy may theoretically predispose the pregnant woman to develop cerebral ischemia. Increases in clotting factors including fibrinogen, increased platelet aggregability, decreased antithrombin III concentration,[69] and impaired fibrinolytic activity all occur during normal pregnancy.[70,71] These changes persist through the first several postpartum weeks and may be the only identifiable predisposing risk factors during pregnancy. The risk of thrombosis due to congenital deficiencies in
antithrombin III, protein C, or protein S is compounded by pregnancy (see also Chapters 41 and 42). Activated protein C resistance is a recently identified cause of thrombosis resulting from a point mutation in Factor V, rendering it resistant to inactivation by activated protein C. The abnormal Factor V (Factor V Leiden) is the most common hereditary cause of thrombosis.[72] The Leiden mutation may be a risk factor for stroke during pregnancy.[72] It has also been identified in neonates with cerebral ischemic or hemorrhagic infarct and placental infarcts.[73] Thrombotic thrombocytopenic purpura may initially present during pregnancy and is often mistaken for eclampsia.[74]

Substance abuse is an underrecognized cause of stroke, especially in poor, urban woman (see also Chapter 33). Cocaine (Fig. 48–2), amphetamines, heroin, and other sympathomimetics are associated with both ischemic and hemorrhagic stroke.[75,76] Mechanisms of injury include vasospasm (Fig. 48–3), vasculitis, endocarditis, drug-induced cardiomyopathy with cerebral embolism, foreign material embolism, rupture of preexisting arteriovenous malformations (AVMs) and aneurysms, and acute hypertensive hemorrhage.

Antiphospholipid antibody syndrome is also associated with cerebral arterial occlusive disease (Fig. 48–4) (see also Chapter 43).[77] The diagnostic criteria require the presence of one clinical and one laboratory criteria to be present. The clinical criteria include arterial or venous thrombosis, recurrent pregnancy loss prior to 10 weeks' gestation, one or more unexplained fetal losses after 10 weeks' gestation, premature birth due to placental insufficiency, and preeclampsia. Laboratory criteria consist of a medium or high titer of anticardiolipin immunoglobulin G (IgG) or IgM or positive lupus

FIGURE 48–3
Histopathology of a cerebral vessel shows an excessively corrugated internal elastic lamina (*arrows*) separated from the media seen after presumably prolonged vasospasm in a young mother with a massive stroke from crack cocaine use.
FIGURE 48–4

anticoagulant on two occasions at least 6 weeks apart. Only a portion of these patients has coexistent systemic lupus erythematosus. Patients with higher titers of IgG anticardiolipin antibodies may be at higher risk for recurrent thrombo-occlusive events.[78–84]

Sickle cell disease and sickle cell trait are associated with an increased risk of stroke. Vessel wall injury may occur during periods of crises. The recurrent vascular damage can lead to endothelial proliferation and subsequent vessel occlusion. Frequent blood transfusions can dramatically reduce the vessel damage.[85]

Congestive heart failure during pregnancy or the postpartum period is associated with significant maternal morbidity and mortality (see also Chapter 35). Pulmonary or systemic emboli occur in as many as 50% of these patients. Peripartum cardiomyopathy and rheumatic heart disease are causes of congestive heart failure in pregnancy. Emboli result from ventricular wall thrombosis secondary to a low cardiac output or atrial thrombosis from atrial fibrillation.[86] "Watershed infarction" in the brain has also been reported secondary to low cardiac output.[87]

Cerebral embolism has been associated with mitral valve prolapse (MVP) in case reports.[88] MVP is a common condition with a prevalence of 0.5% to 3% in the general population and as high as 17% in reproductive-age women.[89] The rarity of stroke in pregnancy makes it unlikely to be a significant complication for pregnant women with MVP. Complications associated with atrial septal defects (ASDs) are uncommon in reproductive-age women. However, ASD has been found in up to 50% of young patients with unexplained ischemic stroke.[90] Paradoxical emboli from the venous to the systemic circulation are the cause. Mechanical heart valves may also cause stroke in pregnant women secondary to emboli from valve thrombosis.[91,92] Bacterial endocarditis can also result in ischemic or hemorrhagic stroke.[93] Cardiac disease associated with systemic lupus erythematosus and antiphospholipid syndrome represents another potential etiology.[94]

Management Options
PRENATAL, LABOR AND DELIVERY, AND POSTNATAL

Any focal neurologic deficit in the pregnant woman, transient (<24 hr) or persistent, should raise the suspicion of cerebral ischemia. A careful history and physical examination often give enough information to narrow the diagnostic evaluation. An early imaging study of the brain is essential to exclude hemorrhage or a mass lesion. CT is not contraindicated in pregnancy under these circumstances. Abdominal shielding further limits the minimal fetal radiation exposure. MRI can also be used during pregnancy. Although it is more sensitive than a CT scan, it is tolerated less well by critically ill patients and is often less available.

Initial blood work should include a CBC with differential and platelet count, electrolytes, serum glucose, blood urea nitrogen, creatinine, and prothrombin time (PT)/activated partial thromboplastin time (aPTT). Antinuclear antibody, lupus anticoagulant, and anticardiolipin antibodies, rheumatoid factor, Venereal Disease Research Laboratory (VDRL), and HIV testing should be obtained. Other blood studies include Factor V Leiden, prothrombin gene mutation and with serum protein, and hemoglobin electrophoresis. Protein C and antithrombin III assays may also be done if there is a suggestive family history because these abnormalities are uncommon especially in the absence of such a history. Protein S normally decreases in pregnancy, and testing should be deferred until after pregnancy, if possible, owing to the difficulty in interpreting the results. Blood and urine toxicology evaluation should be obtained. Carotid and transcranial Doppler should be considered. If cardiac etiology is

suspected, an electrocardiogram, echocardiogram, Holter monitor, and possibly evaluation for deep venous thrombosis can be performed. A lumbar puncture may also be indicated. In the absence of identified etiology, cerebral angiography is recommended. Despite a thorough evaluation, the etiology of ischemic stroke remains elusive in 20% to 40% of nonpregnant patients. Although no specific data are currently available, this probably holds true for pregnant patients as well.

The use of antithrombotics or anticoagulants for stroke prevention in the first trimester of a pregnancy woman with a history of stroke is controversial and without an evidence base. A recent survey of neurologists through the American Academy of Neurology found that 75% of neurologists would recommend some form of antithrombotic therapy for a history of stroke not related to pregnancy and 88% for women with a history of prior stroke related to pregnancy.[95] Aspirin and low-molecular-weight heparin were chosen by 51% and 7%, respectively, for stroke unrelated to pregnancy and by 41% and 25%, respectively, for stroke related to pregnancy. There remains a significant amount of disagreement over which drugs to use.

When anticoagulation is deemed necessary, heparin is the agent of choice in most instances. Warfarin is an option, but first-trimester embryopathy and the potential for fetal hemorrhage limit its usefulness. Heparin does not cross the placenta and is shorter = acting than warfarin. This decreases fetal risk while making peripartum management easier and more predictable. Complications associated with heparin include thrombocytopenia and osteopenia in addition to bleeding.[96,97]

Prophylactic doses of heparin tend to need to be higher in pregnancy and increase with increasing gestational age.[88] Typical doses are 7500 to 10,000 IU/mL subcutaneously every 12 hours. As in the nonpregnant patient, full anticoagulation aims to maintain the aPTT at 1.5 times control. Therapy is individualized with subcutaneous heparin two to three times daily.

Low-molecular-weight heparin is now commonly used in pregnancy. Advantages over unfractionated heparin include longer duration of action, more reliable antithrombotic effect, and a suggestion of decreased risk of thrombocytopenia and osteopenia.[98,99] Increasing data on use during pregnancy suggest it is safe and effective in preventing noncerebral thrombotic complications.[100,101] Treatment of acute ischemic stroke with low-molecular-weight heparin is of uncertain benefit. Patients with inherited thrombophilias requiring full anticoagulation before pregnancy should be placed on therapeutic doses of heparin preconceptually or once pregnancy is discovered. The optimal therapy for activated protein C resistance during pregnancy is unknown, but likely should at least utilize prophylactic doses of heparin.

Current recommendations for the management of antiphospholipid antibody syndrome in patients with a previous thrombotic episode include therapeutic anticoagulation with unfractionated or low-molecular-weight heparin and low-dose aspirin (60–80 mg/day).[78,79] In those without a prior history of thrombosis, low-dose aspirin should be used. The addition of prophylactic unfractionated or low-molecular-weight heparin is more controversial; however, most authorities would recommend its use. The role of corticosteroids, immunosuppression or plasma exchange, and

intravenous gamma globulin is not well defined. In patients with cardiomyopathy or atrial fibrillation, heparin has been used in both prophylactic and therapeutic doses.[102]

Thrombolytic therapy for acute ischemic stroke is indicated in carefully selected patients within a carefully defined time window from symptom onset using a defined protocol. Such time window is currently 180 minutes, but recent evidence strongly suggest that it could be expanded to 4.5 hours.[103] Its use in pregnancy is uncertain, however, because pregnant or lactating women were excluded from the trial that demonstrated efficacy. Case reports have documented the relative safety of intravenous and intra-arterial thrombolysis for neurologic and medical indications throughout pregnancy.[104,105] Nevertheless, the widespread use of thrombolytics during pregnancy cannot be recommended, and they should be used only after a careful discussion of the risks and benefits of this form of treatment with the patient or surrogates and documented in the medical record. Plasmapheresis has been used successfully in some patients with thrombotic thrombocytopenic purpura.[106]

Cerebral Venous Thrombosis

Maternal and Fetal Risks

Cerebral venous thrombosis has been traditionally associated with pregnancy, especially the puerperium. The condition is seen throughout gestation but most commonly is identified during the second to third week postpartum.[107–109] The incidence is highest in developing countries. The original description of severe headache, papilledema, and seizures has evolved through the years. Additional findings at presentation include focal neurologic deficits, bilateral long tract signs, aphasia, visual disturbances, headache, focal seizures, and the syndrome of idiopathic intracranial hypertension. When the deep cerebral venous system is involved, lethargy and coma are common manifestations. The superficial venous sinuses, particularly the superior sagittal sinus, are commonly involved.

Cerebral venous thrombosis has classically been associated with infection and dehydration. Other underlying conditions such as hemoglobinopathies, hyperviscosity syndromes, anemia, leukemia, collagen vascular diseases, malignancy, AVM, and paroxysmal nocturnal hemoglobinuria should be sought.[110] In addition, hypercoagulable states such as protein C and S deficiencies have been implicated.[71,111] More recently, activated protein C resistance,[112,113] lupus anticoagulants, and anticardiolipin antibodies have been identified in patients with cerebral venous thrombosis.[78,114,115]

Management Options

PRENATAL, LABOR AND DELIVERY, AND POSTNATAL

Timely diagnosis of cerebral venous thrombosis requires a high index of suspicion. During pregnancy, the initial evaluation begins with a brain CT without contrast. A partially filled posterior segment of the superior sagittal sinus is seen (empty delta sign) (Fig. 48–5). MRI with magnetic resonance venography can identify the thrombus. It provides greater sensitivity and is currently the test of choice within the limitations previously described.

FIGURE 48–5

Axial head computed tomography (CT) scan demonstrates cerebrovenous thrombosis of the straight sinus (*arrowhead*) and the empty delta sign (*arrow*).
FIGURE 48–6

Conventional cerebral angiography documents large, bilateral cerebral arteriovenous malformations (*arrows*).
The only prospective, randomized, case-control study evaluating acute treatment found systemic anticoagulation to be the treatment of choice, even in the presence of intracerebral hemorrhage.[116] Thrombolytic therapy is an emergent therapeutic approach; however, owing to the lack of experience in pregnant patients, caution should be exercised.[117] In selected cases of refractory brain edema and ICP elevation, the use of decompressive hemicraniectomy can be entertained.[118] The overall prognosis is generally good in the absence of coma, recurrent seizures, or rapid decline in neurologic function. Long-term outcome is generally better than for arterial stroke. Prolonged anticoagulation with warfarin is required postpartum.

Subarachnoid Hemorrhage

Maternal and Fetal Risks

Subarachnoid hemorrhage (SAH) is a rare but often catastrophic event that can occur during pregnancy. The incidence of SAH is 1 to 5 per 10,000 pregnancies. Maternal mortality is 30% to 40%, but rates as high as 80% have been reported.[119] Fetal outcome parallels that of the mother and reflects the maternal condition as well as gestational age at delivery.[119] The primary etiology during gestation is ruptured cerebral aneurysms or AVMs. Less common causes include Moyamoya disease,[120] dural venous sinus thrombosis, mycotic aneurysm, choriocarcinoma, vasculitides, brain tumors,[121] and coagulopathies. Drugs such as cocaine and

phenylpropanolamine have also been linked with SAH in pregnant patients.[122–124]

Aneurysms and AVMs are believed to develop secondary to congenital defects in cerebral vasculature formation. Aneurysms are generally located at an angle of vessel bifurcation in or near the circle of Willis. AVMs, conversely, can be located anywhere between the frontal region and the brainstem, but occur with a higher frequency in the frontoparietal and temporal regions (Fig. 48–6). The anatomic distribution of both lesions is similar to that in the nongravid population.[119] Information describing the natural history of intracranial aneurysms during pregnancy is scarce. In the nonpregnant patient, asymptomatic lesions account for 95% of intracranial aneurysms and are typically identified incidentally. They rupture at a rate of 1% to 2% per year.[125] Activities reported to precede aneurysmal rupture include emotional strain, heavy lifting, coughing, coitus, urination, and defecation. Outcomes of patients with AVMs are influenced by the presenting symptoms and subsequent treatment. Most present with spontaneous bleeding, and these patients have the worst prognosis. Other presenting symptoms in order of frequency include seizures, headache, and neurologic deficit. If left untreated, there is an annual hemorrhage rate of 4%.[125]

Rarely, unruptured aneurysms are first identified during pregnancy. Because SAH is uncommon during gestation, the effect of pregnancy on cerebral aneurysms or AVMs remains controversial. More than 85% of SAH cases occur during the second or third trimester.[126] Several physiologic changes

occur during pregnancy, which may theoretically predispose these cerebrovascular abnormalities to bleed. These factors include increases in blood volume, stroke volume, and cardiac output. Estrogen levels are also increased and may result in vasodilation of already abnormal vessels. The many dynamic events occurring during labor and delivery would seem to make this a particularly high-risk time.

Despite the associated physiologic changes, pregnancy does not appear to increase the incidence of SAH, and surprisingly, bleeding during the time of labor and delivery is infrequent.[119,127] Most pregnancies complicated by SAH are preceded by unaffected gestations. In a review of 154 patients prepared by Dias and Sekhar,[119] only 25% were nulliparous, and the mean parity of patients with aneurysmal and AVM ruptures were 2.0 and 1.4, respectively. Barno and Freeman[128] reviewed 24 years of maternal mortality in Minnesota resulting from SAH. The mean parity among the 37 deaths was 2.9. Forster and coworkers[127] reported their experience with AVMs in reproductive-age women. Although the annual hemorrhage rate was higher when these women were pregnant than when not (9.3% vs. 4.5%), it was no different from the 9.6% annual rate in reproductive-age women who never became pregnant. Although Horton and colleagues[129] identified a lower annual rate of hemorrhage in both their pregnant and their nonpregnant patients with AVMs (3.5% vs. 3.1%), they too concluded that pregnancy was not a risk factor for bleeding.

Once bleeding has occurred, the patient's course is significantly modified by the patient's neurologic condition at presentation. The Hunt and Hess classification system has prognostic implications and is shown in Table 48–6. Untreated, half of all nonpregnant patients will die as a result of the initial event, with another 25% to 35% succumbing to a subsequent bleed. Other factors affecting the patient's ultimate outcome are neurologic status, presence of vasospasm, and blood pressure. Maternal mortality associated with aneurysmal bleeding is not increased owing to pregnancy.[119] Conversely, AVM-associated mortality appears to be increased in gravid compared with nongravid patients. This is likely related to the poor neurologic condition of these patients at presentation.[119]

Pregnancy does not significantly alter the clinical presentation of SAH. Signs and symptoms of aneurysmal or AVM bleeding are indistinguishable. A sudden-onset, "bursting" headache is generally the initial symptom. Frequently, other signs and symptoms accompany the headache. These may include nausea and vomiting, meningeal signs, decreased

level of consciousness, hypertension, focal neurologic signs, and seizures. Specific findings are dependent on the size, location, and rapidity of the bleed. When the hemorrhage is massive, the patient may be moribund at presentation.

Major complications associated with SAH include vasospasm and recurrent hemorrhage. Vasospasm is a serious problem seen in 30% to 40% of aneurysm patients, but much less commonly in those with AVMs. The resultant ischemia is a major cause of permanent disability and death. Recurrent hemorrhage is a particularly morbid complication. In the untreated nonpregnant, patient the risk of rebleeding is 6% during the first 48 hours. Rebleeding continues to occur at a rate of 1.5% per day for the remainder of the first 2 weeks.[125] Mortality increases with each successive bleed with a rate of 64% and 80% after the first and second rebleed, respectively. Although considerably fewer data are available for the pregnant patient, the risk of recurrent bleeding appears to be similar in this population.[126]

Management Options
PRENATAL

Owing to the rare and life-threatening nature of the condition, it is important to maintain a high index of suspicion. Occasionally, SAH is confused with eclampsia, resulting in diagnostic delays and often a worse outcome. All abnormal neurologic signs and symptoms in the gravida should be thoroughly evaluated. CT scan of the brain, lumbar puncture (if necessary), and cerebral angiography is the common sequence of testing. The CT scan can predict, with a high degree of accuracy, the type of hemorrhage and its site of origin. If the CT scan is normal, the cerebrospinal fluid (CSF) should be examined for blood or xanthochromia. Nonclearing bloody CSF found at lumbar puncture supports the diagnosis of SAH, but it may also be seen with other conditions such as preeclampsia. Cerebral angiography remains the best diagnostic tool for identifying any vascular abnormality. Angiography may fail to visualize the cause of SAH in 20% of patients, however. In these cases, a repeat angiogram may be necessary to rule out false-negative results secondary to vasospasm or clot filling of the aneurysm. MRI scan may also be helpful in situations in which the initial angiogram fails to identify the lesion. Abdominal shielding should be considered during any radiologic examination of the gravid patient.

Management of SAH is based on standard neurosurgical principles with only slight alterations during pregnancy. The clinical goals remain prevention and treatment of neurologic complications. Early aneurysm clipping (<4 days) is now commonly recommended in the post-SAH period for conscious patients. Early operation also allows for therapies such as induced hypertension and volume expansion to be instituted to combat vasospasm without increasing the risk of rebleeding. Improved outcomes for both the mother and the fetus have been realized with early surgical intervention in pregnant patients.[119] Patients with significant neurologic deficits are less likely to undergo early aneurysm clipping owing to an extremely high operative mortality. Advances with endovascular procedures in the treatment of cerebral aneurysms (e.g., guglielmi detachable coils [GDC]) allow the early securing of these vascular lesions in high risk patients.[130] Medical therapy alone and careful monitoring of

---

TABLE 48–6

Hunt and Hess Scale for Grading the Clinical Severity of Subarachnoid Hemorrhage

GRADE	EXAMINATION FINDINGS
I	Normal neurologic examination, mild headache, and slightly stiff neck
II	Moderate to severe headache and stiff neck; no confusion or neurologic deficit except for cranial nerve palsy
III	Persistent confusion and/or focal deficit
IV	Persistent stupor; moderate to severe neurologic deficit
V	Coma with moribund appearance

these high risk patients always remains as an alternative to any intervention if the patient is too unstable to leave the intensive care unit.

The proper timing for resection of AVMs is more controversial owing to the smaller number of cases. No clear benefit to surgery in these patients has been found,[119] with some surgeons advocating operative intervention in AVMs only to remove clinically significant hematomas. One alternative is embolization of the AVM under angiographic control prior to surgical excision.

A complete discussion of the neurosurgical and anesthetic principles of craniotomy for aneurysm clipping is beyond the scope of this chapter. However, there are two intraoperative therapies—hypotension and hypothermia—commonly instituted to reduce complications, which raise special concerns in the pregnant patient. Hypotension is sometimes instituted to reduce the risk of rupture of the aneurysm during surgical dissection. Although maternal hypotension may pose a threat to fetal well-being, it has been successfully induced with sodium nitroprusside or isoflurane in a number of cases.[131,132] Based on experimental evidence, administration of sodium nitroprusside in pregnant patients has raised concerns regarding potential fetal cyanide toxicity. Thus, if surgery is to be preformed during pregnancy, it is recommended that infusion rates not exceed 10 mg/kg/min.[132] The fetal effects of maternal hypotension should be evaluated throughout the perianesthetic period with electronic fetal heart rate monitoring. Adverse changes in fetal cardiac activity suggest the need for elevation in maternal blood pressure if safe and feasible from the maternal standpoint. Many of the drugs used in anesthesia may decrease fetal heart rate variability, thereby complicating fetal heart rate monitor interpretation. Excessive hyperventilation has been shown to further decrease uterine blood flow during sodium nitroprusside administration and should be avoided.[133,134] Because of the potential fetal risks of maternal hypotension, some authors recommend cesarean delivery immediately prior to intracranial surgery if the fetus is mature enough.[135]

Hypothermia is instituted during cerebral aneurysm clipping as a means of cerebral protection from potential ischemia due to aneurysm rupture, retraction injury, or hypotension. Stånge and Halldin[136] have suggested that hypothermia is well tolerated by the mother and fetus, provided that other confounding variables (such as respiratory exchange, acidosis, and electrolyte balance) are controlled. However, the majority of experience with hypothermia and hypotension in pregnancy is anecdotal. Regardless of the neurosurgical technique employed, maternal outcome remains the most important predictor of eventual fetal outcome.

Adjunctive medical therapy for SAH is directed toward reducing the risks of rebleeding and cerebral ischemia due to vasospasm. Patients are generally confined to bedrest in a dark, quiet room. They are administered stool softeners and analgesics. Because of the presumed benefits of volume expansion, colloid solutions are frequently administered. Nimodipine, a dihydropyridine calcium channel blocker, is often given because it has been shown to improve neurologic outcome following SAH. Caution is advised in using this drug in pregnancy because the fetal effects have not been completely defined. In a small number of preeclamptic patients taking nimodipine for seizure prophylaxis, no

apparent adverse fetal outcomes were reported.[137] However, in an animal model, nicardipine (another dihydropyridine calcium channel blocker) led to the development of fetal acidosis and hypoxemia.[138]

Epsilon-aminocaproic acid (EACA) and tranexamic acid have been used to block the activation of plasminogen, a precursor of plasmin, a major fibrinolytic protein, and decrease the incidence of rebleeding. Initial clinical trials did find a reduction in the incidence of rebleeding with these agents; however, later work failed to demonstrate significant improvement in outcome.[139] EACA, because of the lack of proven benefit and potential interference with fetal fibrinolysis, which may be linked to the development of hyaline membrane disease, is not used in current clinical practice.[140]

Cerebral edema can result in elevated ICP. Intracranial invasive monitoring may be necessary. If there is ICP elevation secondary to cerebral edema, mannitol, an osmotic diuretic, may be used. Typically, 1 g/kg of mannitol is administered intravenously, as frequently as needed to keep the ICP below 20 mm Hg. The development of hyperosmolality due to dehydration is a potential hazard of mannitol therapy and can be monitored by frequent determinations of the patient's intravascular volume status. Normal values are 280 to 300 mOsm/L; the drug should be withheld when a level of 315 to 320 mOsm/L is reached. Care must be taken to prevent hypovolemia resulting from the accompanying diuresis, which could aggravate both cerebral and placental hypoperfusion. The use of hypertonic saline solutions (2% and 3% sodium chloride/acetate) is becoming a popular alternative to mannitol owing to their efficacy and hemodynamic profile. Nevertheless, their safety during pregnancy is not defined, and the use of these solutions should, therefore, be limited to only extreme cases of refractory ICP elevation.

LABOR AND DELIVERY

After a successful repair of an aneurysm or AVM, the most frequent obstetric concern relates to mode of delivery. Earlier authors routinely recommended elective cesarean section for these patients. This was particularly true along with consideration of sterilization if an AVM was responsible for the SAH.[141] More recent data and reanalysis of some older studies suggest that labor and vaginal delivery pose no additional risk to mother or fetus.[119,127,129,142] These recommendations probably also hold true for the patient who begins labor before surgical correction is attempted or in the case in which the intracranial lesion is inaccessible to surgical intervention, but the data are very limited. Young and associates[143] have suggested that the rise in physiologic blood pressure known to occur in labor are counterbalanced by a parallel increase in CSF pressure, offering a potential explanation for the foregoing clinical observations. Despite the suggested safety of labor, minimizing the hemodynamic stresses of labor is still advocated by using epidural anesthesia and shortening the second stage of labor with outlet forceps. In reality, with cesarean section rates exceeding 30% in the United States, many of these patients will be delivered by elective cesarean section to minimize any perceived risk. Ultimate management decisions should be individualized based primarily on the maternal condition with modifications for fetal intervention based on gestational age.

Coincidental conditions (e.g., cerebral vasculitis or brain tumor)

HEADACHE

Maternal Risks

Headaches during pregnancy and postpartum are extremely common. The most common categories are migraine and tension-type. Although a new-onset headache during pregnancy and in the postpartum period is most likely either a migraine or a tension-type, it may be the first manifestation of an intracranial process that needs immediate attention[144,145] (Table 48–7). Such conditions include aneurysm rupture, AVM, intracranial hypertension, cerebral ischemia, cerebral venous thrombosis, meningitis, sinusitis, and intracranial masses. In addition, benign intracranial hypertension or pseudotumor cerebri may be seen with pregnancy, but it is uncommon. Patients receiving spinal or epidural analgesia or anesthesia may experience a spinal headache during the postpartum period.

Evaluation of the pregnant patient with headache represents a clinical challenge. The ailment's prevalence and typically benign nature make it desirable to minimize costs by limiting diagnostic testing while being certain to promptly diagnose the uncommon but more serious conditions. The medical history is usually very helpful. Migraines are often associated with a history of similar previous episodes. With a past history suggestive of migraine headaches, a normal neurologic examination, and resolution with simple measures, the patient may be followed clinically. A new-onset headache severe enough to justify an emergency room visit or a preexisting condition becoming progressively worse, presence of an "aura," or a new neurologic deficit warrants a diagnostic evaluation.

Migraine

Maternal and Fetal Risk

Migraines can be subdivided into those with and those without an aura. The aura is described as the presence of transient neurologic signs or symptoms before, during, or even after the headache. The pain is often associated with nausea, vomiting, and photophobia. Sleep often provides relief. As with headaches in general during gestation, the course of migraines is variable. A decrease in frequency is seen in 50% to 80% of women, particularly in the third trimester.[144] Those patients experiencing migraines associated with menstruation are especially likely to show improvement. The headaches tend to worsen postpartum with as many as 40% of patients complaining of pain during this time. Migraine recurred during the first week after childbirth in about one third of women.[146] Migraines may present for the first time during the puerperium in 4.5% of patients, however, and an aura may initially appear during this time period. There is no demonstrated adverse fetal outcome associated with migraines.[147]

Management Options

PRENATAL, LABOR AND DELIVERY, AND POSTNATAL

A carefully obtained history and physical examination are essential. With a prior personal or family history of migraine and a typical presentation, no further investigation is needed. New-onset migraines represent a diagnosis of exclusion. In the absence of a past history or with focal neurologic findings, neuroimaging studies such as brain CT or MRI are indicated.[144] It is desirable to minimize x-ray exposure to the abdomen and pelvis and avoid contrast agents if possible. Radiologic studies should not be avoided on the basis of pregnancy alone, however. Prothrombin time, aPTT, fibrinogen, and CBC with platelets should be obtained. Additional investigations should include anticardiolipin antibodies, antithrombin III, and protein C as indicated to exclude thrombophilias. Physiologic decreases in protein S levels make these levels difficult to interpret in pregnancy. Lumbar puncture is indicated once the absence of an intracranial mass effect has been ruled out by imaging studies. A normal opening pressure (range 5–15 mm Hg) excludes pseudotumor cerebri.

Migraine treatment during pregnancy is complicated by the fact that most drugs cross the placenta and many have potential adverse fetal effects. As a result, physicians often avoid indicated drug therapy despite relatively safe and effective options.[144] Therapy can be divided into abortive and prophylactic measures. The latter approach is reserved for patients with debilitating headaches or those with a frequency, for example, exceeding three migraine episodes per month. β-Blockers (categories B and C) are often helpful in this situation. Tricyclic antidepressants (most category D) are a useful second-line approach.

A variety of interventions are available once a headache has begun. In patients in which normal daily function is not significantly compromised, nonpharmacologic measures are advised. Such strategies include coping mechanisms such as ice, massage, sleep, and biofeedback. Reassurance is also of value, because many migraine sufferers experience improvement during gestation. When drug therapy is needed, acetaminophen and low-dose caffeine (both category B) can be used as first-line agents. During the first two trimesters, a short course of nonsteroidal anti-inflammatory drugs (NSAIDs) can be tried (many are category B in early pregnancy). Extended use of NSAIDs should be avoided,

however, because of potential constriction of the fetal ductus arteriosus and oligohydramnios particularly in the later part of gestation (category D in the third trimester). Narcotics such as meperidine, morphine, and hydromorphone (category B) can be used if severity warrants.[148] Glucocorticoids (category B) are safe when used for short periods and may help in migraines refractory to standard treatment. Magnesium sulfate can be used for prophylactic or abortive therapy. Benzodiazepines (category D), ergot derivatives (category D), and sumatriptan as well as the newer triptans (category C) should be avoided.[149] Although the association of benzodiazepines with birth defects is not clear, neonatal depression and withdrawal are problems encountered with use during the latter part of pregnancy. Vasoconstriction caused by the ergot derivatives may lead to fetal vascular disruption. In addition, these agents may increase uterine activity by an oxytocin-like action. In the most extreme cases, intravenous hydration, prochlorperazine 10 mg intravenous, and intravenous narcotics or corticosteroids may be necessary.[144]

Nausea is a common accompanying complaint. Mild symptoms can usually be successfully treated with phosphorylated carbohydrate solution (emetrol) or doxylamine succinate (category B) and pyridoxine (vitamin B_6). In more severe cases, trimethobenzamide (category C) and some phenothiazine compounds including chlorpromazine, prochlorperazine, and promethazine (all category C) can be used parenterally or as suppositories. Most of the medications described previously enter the breast milk. Those that can be used in pregnancy can continue to be utilized during breast-feeding. Chlorpromazine is an exception, because it can cause neonatal lethargy.

Tension-type Headaches

Maternal and Fetal Risks

Tension-type headaches are characterized by daily headaches of mild to moderate severity with a global distribution. They typically worsen throughout the day, and nausea and vomiting are seldom reported. Patients may exhibit symptoms such as depressed mood, anorexia, and insomnia. In contrast with migraine, tension-type headache symptoms do not improve during pregnancy, and may actually worsen. The pathogenesis is unclear. Contracture of the neck muscles and stretching of aponeurotic connections may be the result rather than the cause of the headache. Characteristically, the neurologic examination is normal and no neuroimaging studies are required.

Treatment is aimed at behavioral aspects of the condition. Mild analgesics are indicated only in the presence of considerable pain. Acetaminophen is preferable to aspirin. If depression is a cardinal component, antidepressant agents can be used. Despite their classification, the tricyclic antidepressants (most category D) appear to be relatively safe during pregnancy and can be used when clinically indicated. The serotonin uptake inhibitors (most category C) have been associated with a neonatal abstinence syndrome characterized by jitteriness, poor tone, and mild respiratory morbidity. The available information suggests that these agents may also be used relatively safely when indicated.[150,151]

Spinal Headache (See also Chapter 70)

Maternal Risks and Management Options

Spinal headaches are commonly seen after accidental dural puncture during epidural placement. The typical history is that of a moderate to severe headache that is exacerbated with sitting or standing and palliated with lying flat. The frequency of symptoms is related to the large-bore needle used. Such headaches less commonly follow the use of spinal anesthesia. The symptoms are believed to be due to leakage of CSF and subsequent CSF hypotension. Initial management consists of intravenous hydration and bedrest lying flat. If the patient fails to show improvement within 24 hours of conservative management, a blood patch is indicated and brain imaging should be strongly considered. About 2 to 3 mL of autologous blood is injected near the area of the dural puncture. Dramatic resolution of symptoms is typically observed,[152] although it may take 1 to several days for resolution.

Benign Intracranial Hypertension (Pseudotumor Cerebri)

Maternal Risks

Benign intracranial hypertension is characterized by the presence of diffuse global headache, nausea, vomiting, papilledema, and at times, horizontal diplopia. It is typically worse during early morning hours. The cause of increased ICP is due to either increased production or decreased reabsorption of CSF.[153] This condition is seen more frequently in young, obese, reproductive-age women. There is no evidence that the incidence is higher during pregnancy. Although benign intracranial hypertension can develop throughout pregnancy, it is most often seen during the first half of gestation. Other causes of increased ICP are listed in Table 48–8.

CSF, cerebrospinal fluid.

Management Options

PRENATAL AND LABOR AND DELIVERY

The diagnosis is one of exclusion. It is confirmed by demonstrating a high opening pressure at the time of lumbar puncture in the presence of a normal CT scan. Although weight reduction is a part of treatment in nonpregnant individuals, it is not encouraged during pregnancy. Excess weight gain should be avoided. Treatment is aimed at avoiding visual complications.[154] Acetazolamide, a carbonic anhydrase inhibitor (category C), is used along with repeated lumbar puncture and CSF drainage. Refractory cases may be treated with a lumbar subarachnoid-peritoneal shunt. When vision is threatened, optic nerve sheath fenestration can be performed to relieve pressure on the optic nerve.

Cesarean section is reserved for obstetric indications. Because lumbar puncture is a mainstay of treatment, regional anesthesia with either spinal or epidural is not contraindicated.

SUMMARY OF MANAGEMENT OPTIONS
Headache

Management Options	Evidence Quality and Recommendation	References
General		
Indications for Further Investigation	—/GPP	—
• Focal/abnormal neurologic signs.		
• Impaired intellect.		
• Worsening and/or intractable pain.		
• Pain that disturbs sleep.		
Migraine		
Avoid Precipitating Factors; Nonpharmacologic Measures	IV/C	144,148
• Bedrest.		
• Avoidance of light.		
• Coping mechanisms.		
• Ice.		
• Massage.		
• Sleep.		
Analgesics		
Simple agents (e.g., acetaminophen)	IV/C	144,148
Short course of NSAIDs in first two trimesters but not third.	IV/C	144,148
Narcotics (e.g., meperidine, morphine) for severe cases.	IV/C	144
Short course of adjuvant glucocorticoids for refractory cases (**avoid** benzodiazepines, ergot preparations, and sumatriptan).	IV/C	144,149
Prophylaxis	IV/C	144,148
Propranolol (trial excluded pregnant women).		
Tricyclic antidepressants.		
Antiemetics		
Phenothiazines (Trial excluded pregnant women.)	IV/C	144,148
Tension Headaches		
Provide reassurance, bedrest.	—/GPP	—
Use simple analgesia.		
Administer tricyclic antidepressants in extreme cases.		

SUMMARY OF MANAGEMENT OPTIONS
Headache—cont'd

Management Options	Evidence Quality and Recommendation	References
Spinal Headache		
No evidence that injection of physiologic saline at time of dural tap/puncture is of benefit.	—/GPP	—
Analgesia.	—/GPP	—
Lying flat.	Ib/A	7
Autologous blood patch if analgesia and lying flat fail to work after 24 hr.	Ib/A	7
Benign Intracranial Hypertension		
Exclude other causes of raised intracranial pressure.	—/GPP	—
Monitor visual function.	—/GPP	—
Avoid excess weight gain.	III/B	154
If evidence of visual function deterioration, consider		
• Acetazolamide.	III/B	154
• Serial lumbar puncture.	III/B	154
If these conservative measures fail (extrapolated from management in nonpregnant subjects):		
• Shunting.	—/GPP	—
• Optic nerve sheath fenestration if vision is still threatened.	—/GPP	—

GPP, good practice point; NSAIDs, nonsteroidal anti-inflammatory drugs.

VENTRICULOPERITONEAL SHUNTS

Maternal Risks

Advances in extracranial shunt technology during the 1960s have improved the prognosis for patients with hydrocephalus. As a result, an increasing number of women with ventriculoperitoneal shunts in place are reaching reproductive age and becoming pregnant.[155] Pregnancy is associated with signs and symptoms of elevated ICP in as many as 58% of patients with previously well-functioning shunts.[156] Several case reports would suggest that shunt malfunction is more common in the third trimester. The causes of the malfunctions have been postulated to be functional rather than mechanical, due to increased intraperitoneal pressure associated with advancing gestational age.[157]

Management Options
PREPREGNANCY

A baseline CT scan or MRI preconceptually may be of value. Further investigation is indicated if there is any suggestion of shunt malfunction.[156] The baseline study can also be of benefit for comparison purposes in the diagnostic evaluation of symptoms suggestive of increased ICP that may occur later in pregnancy. Patients using AEDs should have their therapy reevaluated. Genetic counseling and preconceptual folic acid should be provided in cases in which a maternal neural tube defect is present.

PRENATAL

Patients should be monitored for evidence of increased ICP including headaches, nausea, vomiting, visual changes, and altered sensorium. In the presence of these symptoms, a CT scan or MRI should be obtained. With radiologic evidence of elevated ICP, conservative management with bedrest, fluid restriction, and corticosteroids may be tried. More rapid relief and direct measurement of the ICP can be obtained during aspiration of the shunt reservoir.[158] Pumping of the shunt may also provide symptomatic relief.[159] This method is less invasive and theoretically can decrease the risk of shunt infection. Shunt replacement should be reserved for those patients who fail conservative treatment.

LABOR AND DELIVERY

Intrapartum management of women with ventriculoperitoneal shunts centers on the optimal mode of delivery and the need for prophylactic antibiotics. The majority of reported cases were allowed to labor and deliver vaginally. No complications were noted.[155] Concern with the potential for intra-abdominal scarring associated with surgery and the favorable outcomes seen with vaginal delivery would suggest that cesarean section should be reserved for routine obstetric

indications. Shortening of the second stage with forceps or vacuum can be considered, but it does not appear to be universally necessary.[155] Analgesia and anesthesia choices during labor and delivery are limited. Narcotic use should be minimized because of the potential further increase in ICP and altered sensorium. Epidural anesthesia can be used with caution. In patients with elevated ICP or a neural tube defect, regional anesthesia should be avoided and general anesthesia used.

The use of prophylactic antibiotics during the intrapartum period is controversial, but the presence of a foreign body with a direct connection to the brain makes prophylaxis theoretically sensible.[156] No adverse outcomes have been reported in several patients managed without the routine use of prophylaxis.[157] It should be noted, however, that the number of involved patients was small and increased experience will be required before a true lack of benefit is determined.

SUMMARY OF MANAGEMENT OPTIONS
Ventriculoperitoneal Shunts

Management Options	Evidence Quality and Recommendation	References
Prepregnancy		
Check clinically for symptoms suggestive of shunt malfunction; MRI/CT if suspected (? useful as baseline for pregnancy even if asymptomatic).	Ib/A	156
Review and rationalize anticonvulsant medication (see earlier under "Epilepsy").	—/GPP	—
Administer folate for all and provide specific genetic counseling if neural tube defect.	Ib/A	156
Prenatal		
Maintain vigilance for raised intracranial pressure (and shunt malfunction).	—/GPP	—
MRI/CT if suspected.	—/GPP	—
If confirmed:	IV/C	158,159
• Bedrest.		
• Fluid restriction.		
• Reservoir aspiration or pumping.		
Replace shunt for those who fail conservative measures.	—/GPP	—
Labor and Delivery		
Vaginal delivery is acceptable; assisted procedure only for normal obstetric indications.	III/B	155
Epidural with care; avoid narcotic analgesia (raises intracranial pressure).	GPP	
No evidence of need for prophylactic antibiotics.	III/B	155,156

CT, computed tomography; GPP, good practice point; MRI, magnetic resonance imaging.

SPINAL CORD INJURY

Maternal Risks

Modern rehabilitation practices allow many patients with spinal cord injuries to lead increasingly independent lives. Often included is the desire to develop a family. Many of the medical problems common to patients with spinal cord problems may be exacerbated during pregnancy. Urinary tract infections (UTIs) often with resistant organisms are common in all patients with spinal cord injury owing to incomplete bladder emptying and indwelling or intermittent catheterization. During gestation, 75% or more women will develop a UTI. This increases the risk of pyelonephritis.[160] Anemia is present in 60% to 100% of patients. Chronic constipation, another problem seen in nearly all patients with spinal cord injury, is compounded both by pregnancy itself and by iron supplementation used in anemia treatment.[161] Immobility associated with many spinal lesions places patients at risk for pressure ulceration. One quarter to a half of gravid patients develop pressure sores, with gestational weight gain a potential aggravating factor. Patients with lesions above T10 may not feel contractions, resulting in failure to appreciate the onset of term or preterm labor, increasing the risk of precipitous or preterm delivery.

Autonomic dysreflexia is a potentially life-threatening complication, which can occur in patients with spinal cord lesions at or above T5. The condition results from stimulation of pelvic or abdominal organs with resultant

sympathetic activation uncontrolled by higher centers. Clinical manifestations can include headache, flushing, sweating, cardiac arrhythmias, and hypertension. Several activities common to pregnancy may precipitate autonomic dysreflexia, making this a time of particular concern, including bowel or bladder distention, bladder catheterization, labor, and even vaginal examination.

Management Options
PRENATAL

Management is aimed at minimizing the risk of the common complications. Urine should be screened for bacteria with appropriate treatment when significant bacteriuria is identified. Prophylactic antibiotics for suppression may be considered. If bladder catheterization is necessary, intermittent is preferred over an indwelling catheter. Dietary changes, stool softeners, or enemas may be necessary to control constipation, with manual disimpaction in extreme cases. Attention to padding and position changes is important to avoid skin breakdown. Patients should be monitored for preterm labor. Uterine palpation and serial cervical examinations can be utilized.

LABOR AND DELIVERY

Unnecessary stimuli that may lead to autonomic dysreflexia should be avoided. Because uterine contractions are often associated with the condition, epidural anesthesia may be placed early in labor to eliminate sympathetic tone. This should be done even if the patient does not feel the pain of contractions.

SUMMARY OF MANAGEMENT OPTIONS
Spinal Cord Injury

Management Options	Evidence Quality and Recommendation	References
Prenatal		
Administer prophylactic antibiotics.	—/GPP	—
Screen for bacteriuria.	III/B	160
Provide dietary adjustment and bowel softener.	—/GPP	—
Provide nursing care including attention to pressure areas.	—/GPP	—
Maintain vigilance for preterm labor.	—/GPP	—
Labor and Delivery		
Avoid unnecessary stimuli; epidural even if no sensation.	—/GPP	—

GPP, good practice point.

NEUROMUSCULAR DISEASES: MONONEUROPATHIES

Facial Nerve Palsy ("Bell's Palsy")
Maternal Risks

Peripheral facial nerve palsy is characterized by acute onset facial-weakness, occasionally preceded by ipsilateral retroauricular pain. The sense of taste may be diminished over the anterior two thirds of the tongue in lesions proximal to the origin of the corda tympani. Viral infection may play an etiologic role. Bell's palsy appears to be more prevalent during pregnancy, with an increased frequency during the third trimester and postpartum. More than three quarters of the pregnancy-related cases occur during this time period. The reported incidence is approximately 50 per 100 000 pregnancies, but only 17 per 100 000 in nonpregnant women of childbearing age.[162]

Management Options

Although the benefit of prednisone (category B) is uncertain, it is frequently used at a dose of 1 mg/kg daily for 5 to 7 days. Success rates are higher if therapy is started within 7 days of the onset of symptoms. The eye should be protected with drops and glasses or a patch. The outcome is quite favorable, with most women recovering completely within 3 to 6 weeks.

Carpal Tunnel Syndrome
Maternal Risks

Carpal tunnel syndrome results from entrapment of the median nerve in the carpal tunnel of the wrist. It is one of the most common mononeuropathies encountered during pregnancy, with a prevalence of up to 20%.[163] The syndrome is manifested by wrist pain and numbness in the first three digits (and occasionally part of the fourth) of the affected hand. The symptoms may often be severe enough to interfere with the sleep; however, significant weakness and muscle wasting are uncommon. Excessive weight gain and fluid retention are predisposing factors. Symptoms typically begin in the second half of pregnancy; however, carpal tunnel syndrome may initially present in the puerperium.[164,165]

Management Options

The diagnosis is typically made clinically. Electrophysiologic studies may be used if necessary. A decreased conduction velocity in the median nerve across the wrist is seen.

Initial therapy is conservative and consists of rest and wrist splinting. Resolution of symptoms usually occurs within a few weeks after delivery. In those cases that first present postpartum, resolution is seen 2 to 3 weeks after breastfeeding is stopped. Very few patients will require surgical nerve decompression.

Lateral Femoral Cutaneous Neuropathy (Meralgia Paresthetica)
Maternal Risks

Meralgia paresthetica is a minor but bothersome sensory disturbance caused by stretching or compression of the lateral femoral cutaneous nerve under the inguinal ligament.[166] Numbness, tingling, burning, or pain in the lateral aspect of the thigh and no other neurologic deficits characterize it. Standing or walking aggravates the symptoms. Symptoms usually begin during the third trimester and are often associated with obesity and exaggerated lumbar lordosis. Prolonged labor may cause or precipitate this neuropathy due to straining with hips flexed.

Management Options

During pregnancy, pain relief can usually be achieved with sitting. Resolution occurs postpartum without treatment in most instances. Occasionally, AEDs or antidepressant drugs such as carbamazepine or amitriptyline, respectively, may be required. Local steroid or lidocaine injections may be useful.

Lumbar Disk Disease
Maternal Risks and Management Options

Lower back pain is one of the most common complaints during pregnancy, affecting more than 50% of pregnancies from the mid-second trimester onward.[167] Significant lumbar disk disease is relatively uncommon, however. Clear clinicoradiologic evidence of herniated disk was found in only 5 of nearly 49,000 consecutive deliveries.[168] Fifty-six of 6048 (0.92%) interviewed women had a confirmed new nerve injury of the lower extremities.[169] Factors associated with nerve injury were nulliparity and prolonged second stage of labor. Median duration of symptoms was 2 months. Diagnostic studies include nerve conduction velocities and electromyography. MRI studies should be used cautiously because there is a significant prevalence of disk bulges and frank disk herniations in asymptomatic individuals.[170] Patients who are refractory to medical therapy after delivery may benefit from lumbar laminectomy. Intraoperative positioning during cesarean section may cause sciatica neuropathy.[171]

SUMMARY OF MANAGEMENT OPTIONS
Mononeuropathies

Management Options	Evidence Quality and Recommendation	References
Facial Nerve Palsy (Bell's Palsy)		
Administer high-dose steroids, especially if severe and early presentation, though it may not be as effective in pregnancy.	III/B	162
Protect eye on affected side.	—/GPP	—
Carpal Tunnel Syndrome		
Provide explanation and reassurance.	III/B	163,164
Perform wrist exercises during day; use elevation at night.	III/B	163,164
Splint wrist.	III/B	163,164
Diuretics have been used in severe cases.	III/B	165
Administer local steroid injection for relief of symptoms.	III/B	165
Surgical decompression is not usually necessary in pregnancy.	III/B	165
Lateral Femoral Cutaneous Neuropathy (Meralgia Paresthetica)		
Provide explanation and reassurance.	IV/C	166
Relief with certain positions, especially when sitting.	IV/C	166
Rarely are anticonvulsants (carbamazepine) or antidepressants (amitriptyline) required.	—/GPP	—
Lumbar Disk Disease		
Use conservative approach (bedrest, firm supporting mattress).	III/B	167,168
Surgery reserved for cases refractory to conservative measures persisting after pregnancy.	III/B	167

GPP, good practice point.

NEUROMUSCULAR DISEASES: POLYNEUROPATHIES

Acute Inflammatory Demyelinating Polyneuropathy (Guillain-Barré Syndrome)

Maternal Risks

Acute inflammatory demyelinating polyneuropathy is an acquired condition characterized by demyelination of the motor roots and the proximal segments of the peripheral nerves.[172] Pregnancy appears to have no effect on the incidence or course of the disease. Guillain-Barré syndrome also does not adversely affect pregnancy.[173,174] Presentation usually consists of ascending paralysis associated with lower back pain and radicular symptoms. Deep tendon reflexes are typically very depressed or lost. In the most severe cases, respiratory muscle paralysis is seen and mechanical ventilation is required. Viral infections such as cytomegalovirus (CMV), Epstein-Barr virus (EBV), HIV-1, and hepatitis virus may play a causative role. Flulike symptoms often precede the onset of weakness by 2 to 3 weeks. In addition, *Campylobacter jejuni* has been implicated as an etiologic agent.

Management Options

The diagnosis is made based on the history and physical examination. Confirmation is obtained with electrophysiologic studies. Abnormal findings become evident more than 7 days after the onset of symptoms. Plasmapheresis has been used in the treatment during pregnancy since 1980.[175]

Volume status and fetal well-being should be monitored during therapy because significant hypovolemia can result from fluid shifts occurring during therapy. Intravenous immunoglobulins have been used as an alternative to plasmapheresis.[176] Intubation and mechanical ventilation along with appropriate supportive care should be utilized as indicated. Spontaneous labor and vaginal delivery can be allowed. There is no contraindication to epidural anesthesia.

Chronic Inflammatory Demyelinating Polyneuropathy

Maternal Risks

Chronic inflammatory demyelinating polyneuropathy is a condition with clinical features similar to those of Guillain-Barré syndrome. A protracted course extending beyond 6 months and a tendency to relapse differentiates the two conditions. During pregnancy, recurrence is seen more often in the last half of gestation.[177] There are no known adverse fetal effects.

Corticosteroids, plasmapheresis, and immunoglobulins have been used therapeutically individually or in combination. Treatment response is variable, and sometimes, poor outcomes result. Data during pregnancy are limited, but labor and delivery are usually uneventful.

Multifocal motor neuropathy has been reported to worsen during pregnancy and to improve with intravenous immunoglobulin (IVIG).[178]

SUMMARY OF MANAGEMENT OPTIONS
Polyneuropathies

Management Options	Evidence Quality and Recommendation	References
Acute Inflammatory Demyelinating Polyneuropathy		
Monitor respiratory function; ventilatory support may be necessary.	—/GPP	—
Provide nursing and physiotherapy care.	—/GPP	—
Administer prophylactic heparin.	—/GPP	—
Therapy options:		
• Plasmapheresis.	IV/C	175
• IVIG.	Ib/A	176
Chronic Inflammatory Demyelinating Polyneuropathy		
Management similar to Guillain-Barré syndrome.	IV/C	177
Treatment with	IV/C	177
• Corticosteroids.		
• Plasmapheresis.		
• IVIG.		
• Interferon.		

GPP, good practice point; IVIG, intravenous immunoglobulin.

NONINFLAMMATORY MYOPATHIES (MYASTHENIA GRAVIS IS DISCUSSED IN CHAPTER 43)

Myotonic Dystrophy

Maternal and Fetal Risks

Myotonic dystrophy is an autosomal dominant genetic condition characterized by a progressive distal muscle weakness and wasting. There is an associated delay in relaxation in affected muscles. The effect of pregnancy on myotonic dystrophy is variable. Symptoms may first present during pregnancy,[179] exacerbations may occur particularly in the third trimester,[180] or the patient may remain asymptomatic.[181] Cardiac disease can occur in association with myotonic dystrophy, presenting as conduction defects, arrhythmias, or congestive heart failure.[182,183]
