Particle swarm optimization parameters set as: population size is 200, iterations gen = 3000, $c_1 = c_2 = 2$. There are eighteen times to achieve the average level of satisfaction in the twenty experiments, the eligible results of the experiment as shown in Table 2.

On the basis of satisfying the satisfaction level, the optimal experimental results are: two cars driving 232.35 km and total distribution cost is 1361.75 yuan, average customer satisfaction was 0.85. The optimal experimental results are shown in Table 3.

In order to compare the optimization results of the proposed model and the VRPMTW model, using the PSO algorithm to solve the case in accordance with the VRPMTW model ignored the customer fuzzy time windows, the experimental results are compared shown in Table 4. According to the comparison of the experimental results can be found that on the basis of vehicle routing problem

with multiple fuzzy time windows, keeping a higher average customer satisfaction degree can effectively reduce vehicle travel distances and lower distribution costs. Secondly, decision maker can set satisfaction degree parameters according to his own different emphasis on distribution costs and satisfaction degree and change distribution strategies. Compared to VRPMTW, this model is more flexible and realistic.

5 Conclusions

The vehicle routing problem with multiple fuzzy time windows has been widely used in the practical life, but the study of such problems are relatively few recently. Based on the multiple fuzzy time windows provided by customers, this paper adopts the membership function of start service time to quantify customer satisfaction degree, and establish universal vehicle routing problem with multiple fuzzy time windows as well as solve mathematical model by means of the particle swarm algorithm to minimize the total distribution costs and maximize customer satisfaction degree. The results of numerical example show that compared with VRPMTW, this model can reduce distribution costs more effectively. In addition, the flexible setting of customer satisfaction parameters and the expansion of the time window can further reduce the distribution cost, it has more realistic meaning and reference value for decision makers.

However, there are more complex and uncertain factors in practical applications such as vehicle travel time, the demand of customers and so on. The exploration of such extensive problems will be the main research focus on the next step.

Optimization of Operating of the Systems with Recurrent Service by Delays

Asaf Hajiyev(✉) and Narmina Abdullayeva

Institute of Control Systems, Azerbaijan National Academy of Sciences, Baku, Azerbaijan
asaf.hajiyev@gmail.com

Abstract. For systems with recurrent service delays of the beginning service are introduced. It is shown that for some systems delays reduce a customer average waiting systems. The class of so called stochastic systems for which it is advisable to introduce delays is described. Numerical and graphical examples demonstrating results are given. There are given also examples, when introducing of delays can increase a customer waiting time before service.

Keywords: Systems with recurrent service · Delays of beginning service · Customer average waiting time · Stochastic systems

1 Introduction

Consider a queuing system, where: $t_1, t_2, \cdots, t_n$ is random sequence when service starts in the system, x is customer arrival instant. At each instant ti all customers who arrived at the interval $[t_{i-1}, t_i)$ immediately will get service (see, Fig. 1). Such models are typical for applications and can be used in traffic, communication systems, network of computers and others. Denote $t_1^*, t_2^*, \cdots, t_n^*$ is (random sequence) service starts in the system with delays of beginning service (see, Fig. 1).

The problem is: Is it possible by introducing delays to reduce a customer average waiting time? May be it is a Paradoxical Idea to introduce delay of the beginning service for reducing a customer average waiting time? Idea to introduce delays of beginning service belong to various authors [1–4]. Below we will give some examples of queueing systems with delays of beginning service.

Example 1. The Main Building of M.V. Lomonosov Moscow State University. There are several lifts in the hall (see, Fig. 2).

If at least two lifts are coming to the first floor almost at the same time, then one of them must be delayed!. Mathematical model has the following form (see, Fig. 3).

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_70

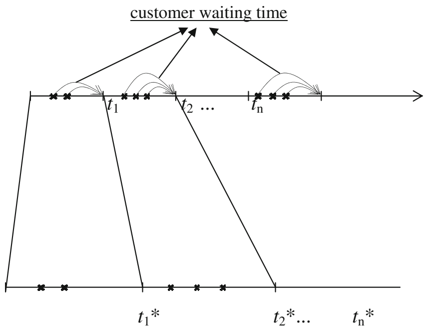

Fig. 1. General mathematical model

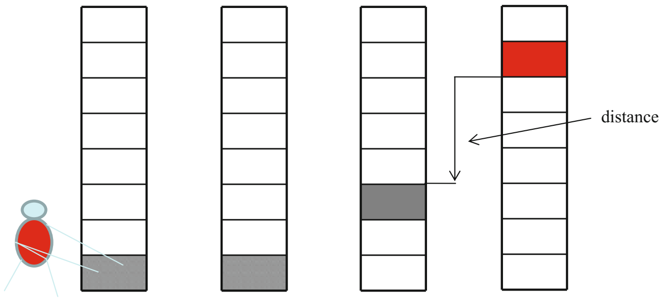

Fig. 2. Model with several elevators

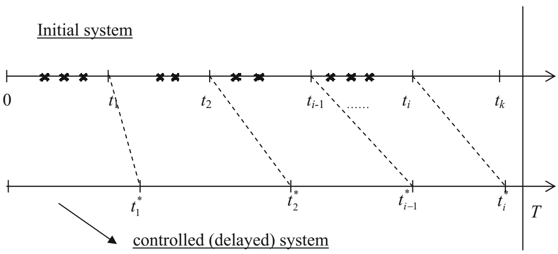

Fig. 3. Mathematical model with delays

If in the system, during the time-interval T there are k services in an initial system, but in a controlled system there are i services and $i < k$, but $w^* < w$? PARADOX? This mathematical model can be used in communication systems (Fig. 4).

2 Communication System

How long time we can keep communications?

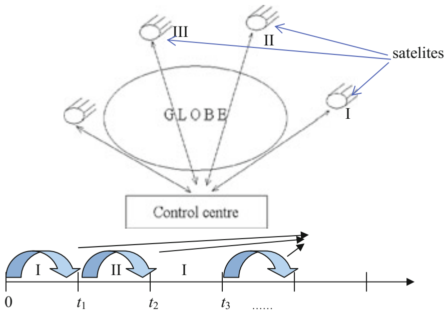

Fig. 4. Mathematical model of communication system

3 Mathematical Models

Denote $\eta_1 = t_1 \eta_2 = t_2 - t_1, \cdots, \eta_n = t_n - t_{n-1}; \eta_1, \eta_2, \cdots, \eta_n$ are independent and identically distributed random variables with distribution function $F(x)$, $E\eta_1 = \mu$, $Var\eta_1 = \delta 2$.

Stationary flow of customers arrives to service. At the each instant t_i all customers, who arrived at the interval $[t_{i-1}, t_i)$ immediately will get service. Denote w is customer average waiting time before service (Fig. 5).

From the sequence $t_1, t_2, \cdots, t_n$ we pass to the new sequence for which we have

$$\eta_1^* = t_i^* - t_{i-1}^* = \eta_i + g(\eta_i), \quad (\eta_i = t_i - t_{i-1}),$$

where $g \in G$ is a class of measurable and nonnegative functions. Denote $w(g)$ is customer average waiting time before service in a system with

$$M_F(g) = w(g) - w, \quad c = \frac{E\eta_1^2}{2E\eta_1},$$

control function $g(.)$.

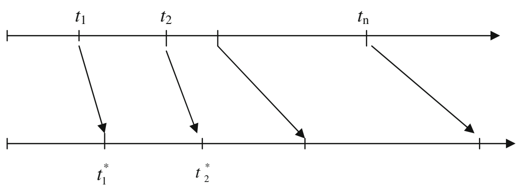

Fig. 5. Simple mathematical model with delays

Definition 1. Service can be improved if there exists $g \in G$ such that $M_F(g) < 0$.

Below will be formulated some results without proof but an explanations of these theorem will be given.

Theorem 1. *Service can be improved if and only if* $\exists x_0 < c$ *such that* $F(x_0) > 0$ *(Figs. 6 and 7).*

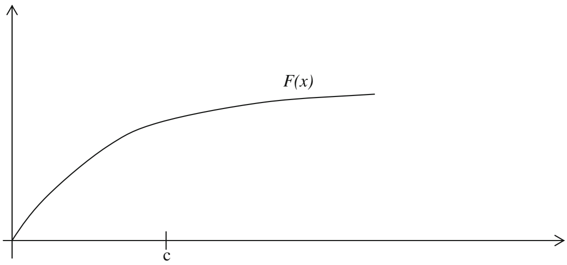

Fig. 6. Service can be improved

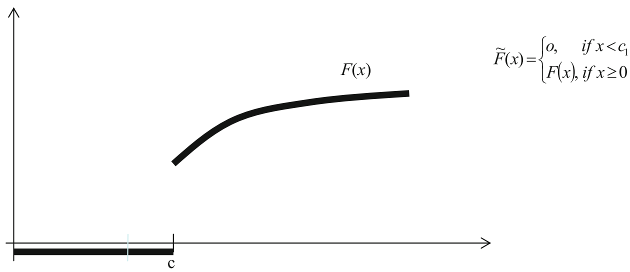

Fig. 7. Service can not be improved

Definition 2. Function $g^*(x) \in G$ is called an optimal function if

$$\min_{g \in G} M_F(g) = M_F(g^*).$$

Theorem 2. *Under the conditions of Theorem 1 an optimal function has the form* $g^*(x) = \max(0, c_1 - x) = (c_1 - x)^+$, *where* c_1 *is a unique solution of the equation*

$$c_1^2 = \int_{c_1}^{\infty} (c_1 - x)^2 dF(x).$$

Example 2. $F(x) = 1 - e - x$, $x \geq 0$. Poisson flow of customers with bounded intensity arrives to service. Simple calculations yield $w = 1$, $g^*(x) = (0,9 - x)+$, $w* = 0.9$; The gain in customer average waiting time is 10%.

Example 3. Let $t_1, t_2, \cdots, t_n, \cdots$ be times when service starts in some system. We assume $t_i = i_d^+ x_i, i = 1, 2, \cdots$, where d is a constant $x_1, x_2, \cdots, x_n$ is a sequence of independent and identically distributed random variables ($i.i.d.r.v.$) with $d.f.$

Such a scheme describes, for example, the behavior of a public transport system where $id(i = 1, 2, \cdots)$ is the ideal timetable (schedule) for the arriving transport and $id + x_i (i = 1, 2, \cdots)$ is the real timetable (schedule). We denote $\eta_I = t_i - t_{i-1} = i_d + x_i - (i-1)d - x_i - 1 = d + x_i - x_{i-1}$. Let w and σ^2 be the expectation and the variance of the customer waiting time until service. If $t_1, t_2, \cdots, t_n, \cdots$ is a stationary renewal process, $t_n = \eta_1 + \eta_2 +, \cdots + \eta_n$, then we have

$$w = \frac{E\eta^2}{2E\eta}, \ \sigma^2 = \frac{E\eta^3}{3E\eta} - \left(\frac{E\eta^2}{2E\eta}\right)^2,$$

where η is a random variable with d.f. $F(x)$. It is clear that

$$w_* = \frac{E\eta_*^2}{2E\eta_*}, \ \sigma_*^2 = \frac{E\eta_*^3}{3E\eta_*} - \left(\frac{E\eta_*^2}{2E\eta_*}\right)^2,$$

In our case $\eta_1, \eta_2, \cdots, \eta_n, \cdots$ are identically distributed random variables, but they are dependent. The flow of customers is stationary with intensity $\mu < \infty$ and independent of $t_1, t_2, \cdots, t_n$. At the instant t_i all customers, which arrived during the time interval $[t_{i-1}, t_i)$ are served immediately, in particular we assume that service time equals zero. For this case also it is succeded to get similar formula for w and σ, but we need to use for that wellknown Campell's formula.

Theorem 3. *Service in the model A can be improved by delays if and only if there exists $x_0 < c$ such, that $F(x_0) > 0$ where*

$$c = \frac{E\eta^2}{2E\eta}.$$

Definition 3. We call $\tilde{g}(x)$ an optimal function if

$$\min_{g \in G} M_F(g) = M_F(\tilde{g}).$$

Theorem 4. *Under the conditions of Theorem 1, the optimal function has the following form*

$$\tilde{g}(x) = \max\{0, \ (c_1 - x)\} = (c_1 - x)^+,$$

where c_1 is the unique solution of the equation

$$c_1^2 = \int_{c_1}^{\infty} (c_1 - x)^2 dF(x).$$

Theorem 5. *Under the conditions of Theorem 1, we have* $\sigma^2(c_1) \leq 2(c_2) \leq \sigma^2, c_2 \leq c_1$.

Example 4 (numerical). Let $t_1, t_2, \cdots, t_n, \cdots$ be times when service starts in system. We assume $t_i = id + x_i, \ \ i = 1, 2, \cdots$, where d is a constant $x_1, x_2, \cdots, x_n$ is a sequence of independent and uniformly distributed random variables on $[-1/2, 1/2]$.

Denote $\xi_i = t - t_{i-1} = (i+1)d + x_i - id - x_i - 1 = d + x_i - x_i - 1 = 1 + x_i - x_i - 1$, put $d = 1$, $E\xi_i = 1$, $\ \ E\xi_i 2 = 13/12$, $\ \ w = E\xi_i 2/2E\xi_i = 0.54$.

Simple calculations yield $g^*(x) = \max(0, 0.53 - x)$, $w^* = 0.53$; Gain in customer average waiting time is 1.8%.

3.1 Realization at the Practice 1

(1) Bus Stop

It is necessary to calculate c_1, for instance, in the Example 1, $c_1 = 0.9$; d is an interval between departure previous bus and coming to the stop next bus If $d < c_1$, then bus will be delayed for $(c_1 - d)$, otherwise nothing is changed (Fig. 8).

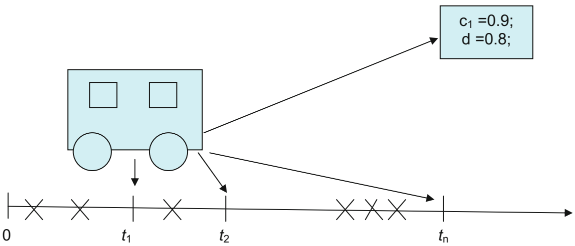

Fig. 8. Electronic plate at the bus stop

Consider two different service systems: $w_1(g)$ and $w_2(g)$ are customer average waiting time with delay function $g(x)$. Problem is: when

$$\frac{w_1(0)}{w_1(g_1^*)} > \frac{w_2(0)}{w_2(g_2^*)} \quad ?$$

i.e. where (in which system) service can be improved more strong? Introduce k, which means variation coefficient, i.e.

$$k = \frac{E\eta^2}{(E\eta)^2}; \quad \sqrt{k_1} > \frac{k_2}{1 + \sqrt{k_2 - 1}} \Rightarrow \frac{w_1(0)}{w_1(g_1^*)} > \frac{w_2(0)}{w_2(g_2^*)}.$$

Let us consider Examples 1 and 2.

Consider the random variable η has d.f. $F_1(x) = 1 - exp(-\lambda x)$, $x \geq 0$, $\lambda = 1$. $E\eta = (1/\lambda) = 1$, $E\eta^2 = 1/\lambda^2 + 1/\lambda = 2$, $k_1 = 2$. Gain in customer average waiting time was 10%. Random variable $\xi_i = 1 + x_i - x_i - 1$, where x_i has uniform distribution at the $[-1/2, 1/2]$. $E\xi_i = 1$, $E\xi_i^2 = 7/6$, $k_2 = 13/12$. Gain in a customer average waiting time was 1.5%. Our formula gives: if $(k_1)^{1/2} = 1.4 > k_2/[1 + (k_2 - 1)^{1/2}) = 0.83$; then gain is greater (Fig. 9).

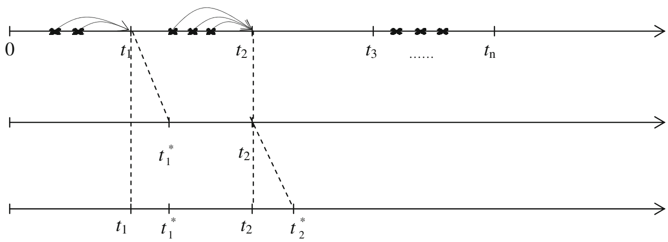

Fig. 9. Complicated mathematical model with delays

Model B:

$$\eta_1^* = \eta_1 + g_1(\eta_1),\ \eta_2^* = (\eta_1 + \eta_2 - \eta_1^*)^+ + g_2(\eta_1 + \eta_2 - \eta_1^*),$$

$$\eta_n^* = (\eta_1 + \eta_2 + \cdots + \eta_n - \eta_1^* - \eta_2^* - \cdots \eta_{n-1}^*)^+ + g_n(\_, \cdots).$$

From construction it is clear that the model has complicated form and to apply directly formula for calculation of a customer average waiting time not so easy. We will try to get new formula for calculation of a customer average waiting time before service.

Lemma 1.

$$w = \lim_{N\to\infty}\left[\frac{\frac{1}{N}\sum_{i=1}^{N} E\eta_i^2}{\frac{1}{N}2\sum_{i=1}^{N} E\eta_i}\right];$$

Generalization of Khinchin's formula

Suppose $1, 2, \cdots, n$ *is i.i.d.r.v.* $E\eta_1 =, Var\eta_1 = \sigma^2$, $F(x)$ *is d.f.*

Theorem 6. *Service can be improve* $\Leftrightarrow \sigma^2 > 0$.

Definition 4. System is called stochastic if $\sigma^2 > 0$

Remark 1. In any stochastic system service always can be improved.

Theorem 7. *For stochastic system optimal function has the form*

$$\tilde{g}(x) = (\mu - x)^+ = \max(0, \mu - x).$$

Example 5. $F(x) = 1 - e - x, \quad x \geq 0.$

$$w = 1;\ \sigma^2 = 1;\ g^*(x) = (1 - x)^+,\ w^* = 0.5;\ \sigma^{2^*} = 0.$$

The gain in customer average waiting time is 50% and variance equals zero (Fig. 10).

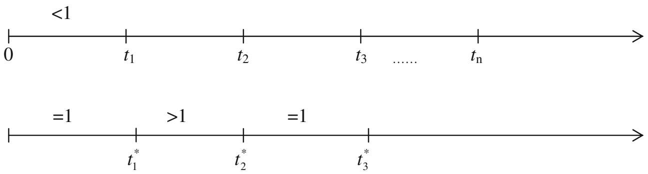

Fig. 10. Realization at the practice

(2) Shuttle Systems with Finite Volume

Denote $\eta_1 = t_1$, $\eta_2 = t_2 - t_1, \cdots$, $\eta_n = t_n - t_{n-1}$. $\eta_1, \eta_2, \cdots, \eta_n$ is independent and identically distributed random variables with distribution function $F(x)$, $E\eta_1 = \mu$, $Var\eta 1 = \delta^2$.

At the each instant ti all customers, who arrived at the interval $[t_{i-1}, t_i)$ immediately will get service, w is customer average waiting time before service .

Our aim: reduce w by introducing delay of beginning service.

Introduce delay, hence from the sequence $t_1, t_2, \cdots, t_n$ we pass to the new sequence for which we have t_1^*, t_2^*, $\cdots$, t_n^*,

$$\eta_1^* = t_i^* - t_{i-1}^* = \eta_i + g(\eta_i), \ \ (\eta_i = t_i - t_{i-1})$$

Denote m volume of Shuttle.

Theorem 8. *Service can be improved if the conditions: $\lambda E\eta_1 < m$ $x_0 < c$ such that $F(x_0) > 0$ are hold. Denote $\zeta(t)$ number of customers in a system at the instant t.*

Theorem 9. *Optimal function has the form*

$a(x) = \inf\{t : \xi(x + t) \geq m\}$ *where c_1 is a unique solution of the equation*

$$c_1^2 = \int_{c_1}^{\infty} (x - c_1)^2 dF(x).$$

3.2 Realization at the Practice 2

It is necessary to calculate c_1, for instance, in the Example 1, $c_1 = 0.9$; d is an interval between previous bus departure and coming to the stop next bus If $d < c_1$, then bus will be delayed either until the instant when number of the passengers at the interval becomes m or for $(c_1 - d)$ (Figs. 11 and 12).

Theorem 10. *Service can be improved if $\lambda E\eta_1 < m$, $\sigma^2 > 0$.*

Theorem 11. *Optimal function has the form*

$$\tilde{g}(x) = \max\{0, \min(a(x), \mu - x)\}.$$

Denote $\xi(t)$ number of customers in the system at the Instant

$$a(x) = \inf\{t : \xi(x + t) \geq m\}.$$

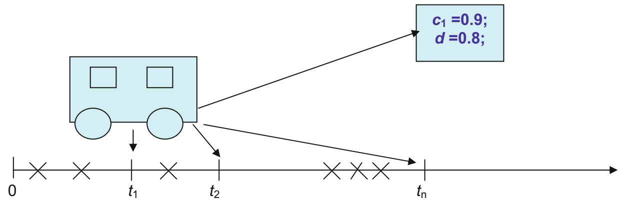

Fig. 11. Electronic plate at the bus stop

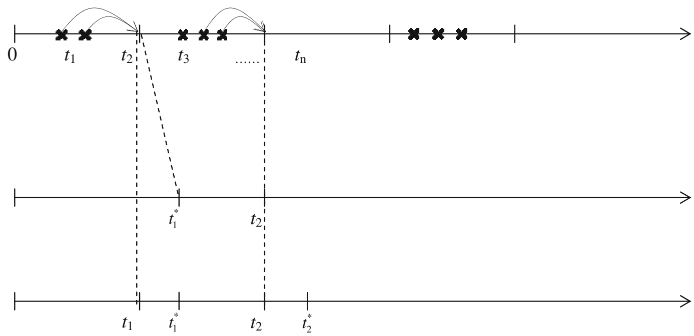

Fig. 12. Model B'

Theorem 12. *Optimal function has the form* $\tilde{g}(x) = \max\{0, \min(a(x), c_1 - x)\}$, *where* c_1 *is a unique solution of the equation* $c_1^2 = \int\limits_{c_1}^{\infty} (x - c_1)^2 dF(x)$.

3.3 Realization at the Practice 3

$E\eta = \mu$ is given or can be calculated from statistics. d is an interval between previous bus departure and coming to the stop next bus. If $d < \mu$, then bus will be delayed either until the instant when number of the passenger at the interval becomes m or for $(\mu - d)$ (Fig. 13).

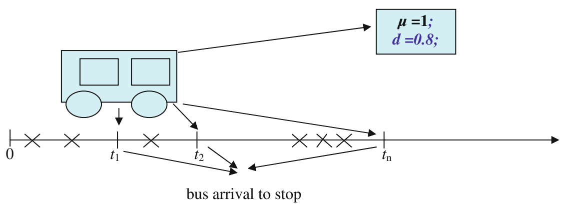

Fig. 13. Electronic plate at the bus stop

Remark 2. The proof of some results can be found in [3,4].

An Epidemic Spreading Model Based on Dynamical Network

Yi Zhang(✉)

Mathematics School, Yibin University,
Yibin 644007, People's Republic of China
245806513@qq.com

Abstract. This paper proposes a epidemic spreading model considering dynamic change of networks. A function $p(t)$ reflecting the dynamic change of network is established, which is a probability that the infected from the susceptible at time t. This function replaces the constant rate in the traditional model and a variant of the SIR model was built. This model can reflect the dynamic change of network. At the same time, a dynamic analysis of the model was conducted. Then, epidemic spreading model simulations are conducted with different parameters in ER random networks. The results show that epidemic spreads faster and more broadly in network when the smaller the parameter c, the larger parameter q. That is, epidemic often spread faster and more broadly when people take protection measures slowly and moving speed of people is slow.

Keywords: Epidemic spreading · Dynamical change · Moving speed

1 Introduction

Human beings are still at the risk of the outbreak of epidemic diseases now even after the development of modern medicine and the appearance of antibiotics [1,2]. The epidemic disease cause big disaster to human in history. For example, the SARS outbreak in 2003 and the H1N1 outbreak in 2009. These epidemic disease swept the globe in a short time, and caused a great loss, even more change the life way of human. With the worsening environment, epidemic disease is break out more frequently, and affect the humanity's survival and development. Therefore, the epidemic rule, transmission mechanism and the strategy of preventing disease are major problem which need to be solved. These problems have attracted many researchers attention increasingly.

The mathematical modeling of epidemic disease spreading has been extensively studied for a long time [13]. The main mathematical approach is the so-called compartmental models which are composed of ordinary differential equations [6–8,11]. In this kind of approach, the entire population are divided into different compartments and each compartment corresponds to an epidemiological state which depends on the characteristics of the particular disease being

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_71

modeled. The commonly used compartment; the susceptible (S), is not infected but likely infected individuals, the exposed (E) is already infection but don't have infectious individuals, the infected (I) consists of individuals who have been infected and had infectious, the removed (R) consisting of individuals who have been restored or death. A classical compartmental model is the SIR model, which was constructed by Kermack and Mckendric in 1927, and they also proposed SIS model in 1932. Based on these research, a lot of compartmental model were proposed. According to the different propagation process of disease, common epidemic model are: SI, SIS, SIR, SIRS, SEIR, SEIRS, SEI and SEIS.

However, most of research of epidemic on complex networks assume that the network structure remains the same, it does not fit the reality. Some papers have realized the dynamic nurture in epidemic spreading. A model was built to investigate the disease spreading dynamics and synchronization behavior on complex networks [12]. A SIRS epidemic model with feedback mechanism on adaptive scale-free networks is presented [9]. The real social network is the evolution of dynamic interaction between nodes and links [5]. In fact, people cut back on frequency of going out once the outbreak of epidemic, and the government take some measures to reduce mobility of people. Because of action of self-protection and government protection, the topology of the network is dynamic change. That is, the mobility of people change topology of networks, thus change the topological feature of network and the way of epidemic spreading. Therefore, it is significant that dynamic network affected by action of protection is considered in epidemic model. And it is goes some way to providing an in-depth understanding of epidemic spreading and how to control such epidemic spreading on dynamic social networks.

In this paper, We establish a function to quantify the dynamic change of the network, and propose a epidemic spreading model which consider both the change of network and the speed of the change. In this model, the function can dynamically measures the probability that the susceptible becomes the infected. A variant of the SIR model is then built, in which the traditional fixed parameters replaced with our probability function, and conduct the stability analysis of model. Then investigate how different values for parameters can effect epidemic spreading using MATLAB in ER random networks. Finally, we conclude this paper and provide several avenues for further research.

2 Epidemic Spreading Model

In this section, we construct a function of time t which considers the dynamic change of networks. Then, with this function added as a parameter to a differential dynamic spread model, a new epidemic propagation model is proposed.

2.1 Function

Consider a population of N individuals and E links respectively representing individuals and their interactions, each of individuals is in one of three states

S (susceptible), I (infected), or R (removed). At each time step t, each individual comes into contact with one other individual, drawn randomly from the population.

In epidemic spreading process, the behaviors of protection of the individuals are ignored. In reality, people will reduce the probability of going out because they are afraid of being infected when the epidemic is outbreak, and they will take some protection measures, for example, doing more exercise. With the moving of the people, the topology of network is changed, and the object they contact is also changed. Generally speaking, as time passes, because of the behavior of protection, the probability that the susceptible contact the infected is decrease gradually, and go to zero finally. Moreover, we believe that the speed at taking the measure of protection should be considered. If people do protection behavior quickly, the epidemic effect is small, but in a contrary situation, the epidemic effect is far greater.

This function is a probability $p(t)$ that an susceptible become a infected at time t, which is affected by the topology of networks. Therefore, $p(t)$ reflects the dynamical behaviors of networks at time t. In light of the above analysis, the probability at time t can be denoted as

$$p(t) = e^{-ct}, 0 < c \leq 1, t \geq 1,$$

where c is the parameter to reflect the speed of taking the measure of protection. A larger c indicates that the individual take the measure of protection in a shorter time. Figure 1 shows the probability as a function of t, given a different c. When c tends to zero, the speed of taking the measure of protection slows down. We have carefully checked that $p(t)$ decreases sharply when $c \in (0.1, 1)$, it is suggested that parameter $c < 0.1$.

In this case, the parameter for c was (0.1, 1). $p(t)$ is the probability, and in (0, 1), $p(t)$ reflects the probability that an individual become a infected from an susceptible. Therefore, $p(t)$ tends to zero as times passes.

2.2 Model

Denote $S(t)$, $I(t)$, $R(t)$ as the density of the susceptible, infected, removed at time t, $S(t)+I(t)+R(t)=1$. As shown in Fig. 2, the epidemic spreading rules can be summarized as follows:

(1) When a susceptible individual contacts an infected individual, the susceptible individual becomes a infected individual at the rate of $p(t)$, which is affected by the topology of networks. Therefore, the reduced speed of the susceptible $dS(t)/dt$ is proportional to the number of the susceptible $S(t)$ and infected $I(t)$, so we get the differential equation:

$$\frac{dS(t)}{dt} = -p(t)S(t)I(t). \tag{1}$$

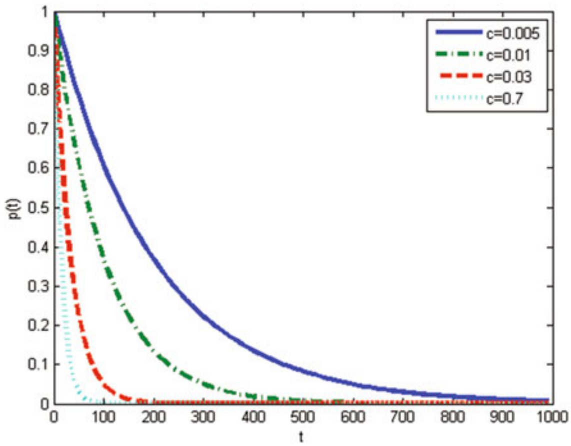

Fig. 1. Probability as a function of t

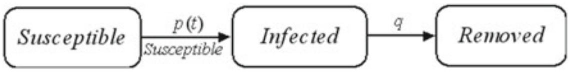

Fig. 2. Structure of epidemic spreading process

(2) At each time step, some infected individuals become removed individuals because of death or immunity. We suppose that the above case happens at probability q. Therefore, the reduced speed of the infected individuals $dI(t)/dt$ is proportional to the number of the infected individuals $I(t)$, Additionally, an susceptible individual becomes a infected individual at the rate of $p(t)$, so we have

$$\frac{dI(t)}{dt} = p(t)S(t)I(t) - qI(t). \tag{2}$$

(3) The increasing speed of the removed individuals $dR(t)/dt$ is proportional to the number of existing $I(t)$ from (2), so we get

$$\frac{dR(t)}{dt} = qI(t). \tag{3}$$

Based on the previous discussion, by integrating Eqs. (1)–(3), the following global expected model can now be formulated for the epidemic spreading process:

$$\begin{cases} \frac{dS(t)}{dt} = -p(t)S(t)I(t) \\ \frac{dI(t)}{dt} = p(t)S(t)I(t) - qI(t) \\ \frac{dR(t)}{dt} = qI(t) \\ S(0) = S_0, \quad I(0) = 1 - S_0, R(0) = 0. \end{cases} \tag{4}$$

2.3 Steady-State Analysis of Model

In the epidemic spreading process, initially the system has only the susceptible and the infected. Finally, the system has only the susceptible and the removed as it reaches an equilibrium state. So here, we analyze the system's steady-state in this period.

Because $S(t) + I(t) + R(t) = 1$, and the differential Eqs. (1) and (2) are not related to the $R(t)$, we only consider the differential Eqs. (1) and (2). Then the reduced limiting dynamic system is given by

$$\begin{cases} \frac{dS(t)}{dt} = -p(t)S(t)I(t) \\ \frac{dI(t)}{dt} = p(t)S(t)I(t) - qI(t) \\ S(0) = S_0, \quad I(0) = 1 - S_0 > 0. \end{cases} \tag{5}$$

From differential equations theory, system (4) and (5) are homogeneous, which means that analyzing the properties of system (5), is equal to analyzing the properties of system (4). First, a required theorem is introduced.

Our model is a non-autonomous differential dynamic system, the general form of which is

$$\begin{cases} \frac{d\mathbf{x}}{dt} = \mathbf{f}(t, \mathbf{x}) \\ \mathbf{f}(t, 0) = 0, x \in R^n. \end{cases} \tag{6}$$

Suppose that $I = [t_0, +\infty]$, $U = \{\mathbf{x} \mid \| \mathbf{x} \| \leq h\}$, and $V(t, \mathbf{x})$ is a continuous differentiable function defined in $I \times U.W(\mathbf{x})$ is a continuous differentiable function defined in U.

Theorem 1. [10] *Suppose that $V(t, \boldsymbol{x})$ is a positive definite function in $I \times R^n$, which has an infinitesimally small upper bound and an infinite lower bound, and $\dot{V}(t, \boldsymbol{x})$ is a negative semi-definite, so the zero solutions for system (6) are global uniformly asymptotically stable.*

According to the differential equations theory, we can get two theorem as follows.

Theorem 2. *$P^* = (S^*, 0)(0 \leq S^* < 1)$is the equilibrium of the system (5).*

Proof. Let the right side of each of the differential Eq. (8) be equal to zero in the system which gives the equation

$$-p(t)S(t)I(t) = 0, \tag{7}$$

$$p(t)I(t) - qI(t) = 0. \tag{8}$$

The feasible region for the equations is R^2, and so we study the equations in a closed set $A = \{(S, E, I) \in R^2 \mid S + I \leq 1, S, I \geq 0\}$

From Eq. (8), we can get $I(t) = 0 (p(t) \neq q)$. Substituting $I(t) = 0$ into Eq. (7), we can get the system has the equilibrium $P^* = (S,\ I) = (S^*, 0)$ $(0 \leq S^* < 1)$. □

Therefore, we can obtain the equilibrium for the system (4) $Q^* = (S^*, 0, R^*)$, where $S^* + R^* = 1$; that is, the epidemic must disappear with time, and all S^* and R^* that satisfy $S^* + R^* = 1$, represent stable situations. Next, we look at the stability of the equilibrium $P^* = (S^*, 0, 0)$.

Theorem 3. *The equilibrium P^* is globally uniformly asymptotically stable.*

Proof. Let the Liapunov function be $V(S, I) = F(S) + G(I)$, and taking the derivative of V versus t along the solution for the equations, we have

$$V'(S, I) = -F'(S)p(t)S(t)I(t) + G'(I)[p(t)S(t)I(t) - qI(t)].$$

In order to ascertain $V(S, I)$ and $V'(S, I)$, and taking the value $F'(S) = 1$, $G'(I) = 1$, we get $V(S, I) = S + I$, and

$$V'(S, I) = -p(t)S(t)I(t) + p(t)S(t)I(t) - qI(t) = -qI(t) \leq 0.$$

So we get $V(S, I)$, which is positive definite, $0 \leq V(S, I) \leq 1 + S$, that is, it has an infinitesimally small upper bound and an infinite lower bound, and $V'(S, I)$ is a negative semi-definite in the feasible region $A = \{(S, I) \in R^2 | S+I \leq 1, S, I \geq 0\}$.

From Theorem 1, the equilibrium P^* is globally uniformly asymptotically stable. □

3 Results and Analysis

The probability that a susceptible individual becomes a infected individual is given a constant over the whole spreading process in traditional epidemic propagation models, but dynamical network needs to be considered in the model as

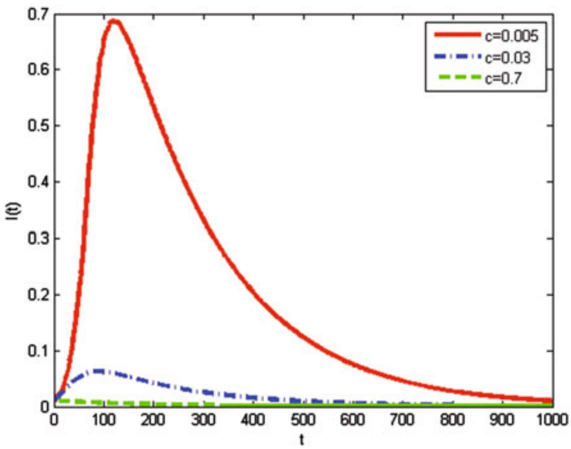

Fig. 3. Density of the infected with different c on a random network

can be seen in the above analysis. Therefore, the probability is a variable which changes over time in our model. In the following sections, we examine the results with a different values for parameter c to demonstrate how the act of isolated affects epidemic propagation. Simulations were carried out using MATLAB.

To compare the results, the proposed model with different value for c was tested on a artificial networks–ER random networks with the network size at $N = 10000$ and the average degree $<k> = 16$ [4]. Two different nodes are connected with a probability of $p = 0.0016$, so we can get random networks with N nodes, and $\frac{pN(N-1)}{2}$ edges. ER random networks degree-distributions are an approximate Poisson distribution $<k> = pN \approx p(N-1)$. This distribution reaches its peak value at the average degree $<k>$ [3].

Given that the other parameters are fixed, we compared the epidemic spreading processes on the random networks with different values for c. So here, we set $c = 0.005$, $c = 0.03$, $c = 0.7$ when $q = 0.05$ respectively. Figure 3 illustrates how the density of the infected changes over time for different values of c in a random network. From a macroscopic perspective, we found that as parameter c decreased, the number of the infected peaked increased, because a smaller c indicates a faster movement speed. The green line indicates a scenario in which the individuals move quickly, that is, the topology of network change quickly. The blue line represents a scenario in which the individuals move speed is slow relatively, and the red line represents a scenario in which the individuals hardly move. It can be seen that the higher parameter c is, the smaller the infected peak value. Figure 4 describes how the density of the removed changes with changes in the parameter c. We found that as parameter c decreased, the number of the end the size of the removed increased, because a smaller c indicates a faster movement speed. The final value for the removed density $R(t)$ is greater, which indicates the number of people affected by an epidemic when c is smaller.

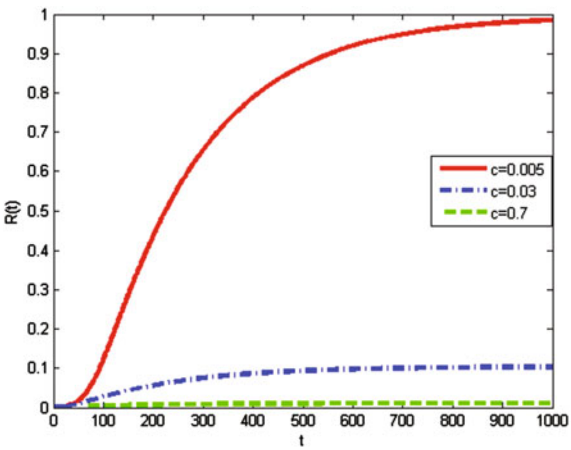

Fig. 4. Density of the removed with different c on a random network

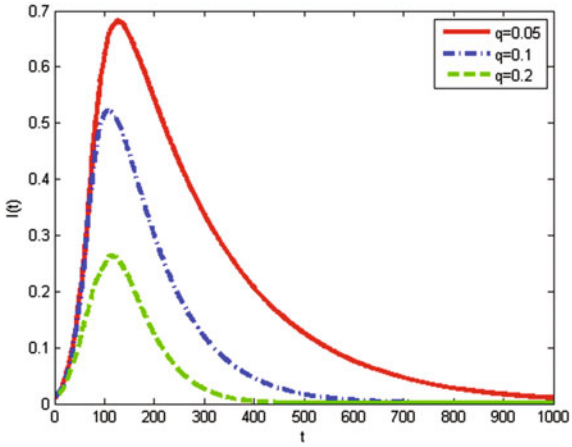

Fig. 5. Density of the infected with different q on a random network

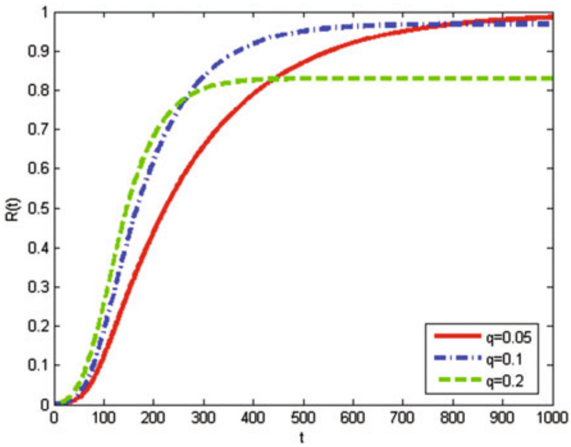

Fig. 6. Density of the removed with different q on a random network

Clearly, the smaller the value of c when other parameters are fixed, the broader the epidemic's influence. A smaller c indicates that if the individuals have a faster movement speed, less susceptible individuals change into removed individuals, and therefore the influence of the epidemic decreases. Generally speaking, it can be seen that epidemic spread more broadly and last longer when c is smaller. However, there is a more significant impact from protection measures in random networks.

Given that the other parameters are fixed, we compared the epidemic spreading processes with different values for q. we set $q = 0.05$, $q = 0.1$, and $q = 0.2$. Figures 5 and 6 illustrates how the density of the infected and removed changes over time for the different values of q. From the Fig. 5, we can see that the bigger the value of q, when other parameters are fixed, the smaller peak value of the infected. It can be seen that the higher parameter q is, the larger the infected peak value, and the slower the epidemic terminates. From the Fig. 6, it is easy to find that the final value for the removed density $R(t)$ is greater, which indicates the number of people is infected when q is smaller. Clearly, q is the transformation probability that infected individuals become removed individuals, in reality, along with the increase of q, there is more infected individuals become removed individuals. As a result, the number of removed increases, the influence of the epidemic decreases.

4 Conclusions

In this paper, we proposed a variant of the SIR epidemic spreading model by considering the dynamic change of networks because of the behavior of protection of individuals. In our model, we established a function $p(t)$ to describe the dynamic change of networks. $p(t)$ also was a probability that the infected from the susceptible at time t. The parameter c of $p(t)$ reflecting the change speed of taking measure of protection. If the individuals take protection measures quickly, c is greater, with the epidemic effect is small. On the contrary, if c is smaller, the epidemic effect is greater. Generally speaking, as time passes, because of the behavior of protection, the probability that the susceptible contact the infected is decrease gradually, and go to zero finally. This function as a parameter was added to dynamic differential equations, and a variant of the SIR model was built. At the same time, a dynamic analysis of the model was conducted.

We then do the simulation results from our epidemic spreading model using a different values for c, q in ER random networks. The simulations showed that epidemic spread faster and more broadly when c is smaller. That is, epidemic often spread faster and more broadly when people take protection measures slowly. At the same time, the simulation results suggested that the spread of epidemics is influenced significantly by parameter c in a random network. q is the transformation probability that infected individuals become removed individuals, in reality, along with the increase of q, the infected peak value is large, and the epidemic terminates slowly. These results indicated that epidemic spreads faster and more broadly in network when the smaller the parameter c, the larger parameter q.

The dynamic networks plays an important role in epidemic spreading. With this in mind, in the future we plan to study feature of dynamical networks. In addition, further studies will be conducted on epidemic control strategies according to different network topologies.

Abstract. In this paper, we propose a evaluation system for the enterprise microblog marketing effectiveness, combine DEA method to establish the evaluation model, and applying the quantitative evaluation method of input and output to evaluate the effect of microblog marketing among different enterprises. In the empirical part, in order to verify the feasibility of the model, we compare the effectiveness of the relative marketing effect of 50 official microblog in 5 different industries based on Sina microblog. The result shows that microblog marketing effect among different enterprises is different. In the five major industries, the integrated marketing effect of mobile phones industry is best, followed by Home Furnishing, skin care, snacks, the worst is the women's clothing industry. In the end, by combining the development characteristics and situation of each industry, the paper puts forward some measures to improve the marketing effect of enterprise microblog.

Keywords: Microblog marketing · Enterprise microblog · Marketing effectiveness · DEA

1 Introduction

CNNIC [10] has pointed out that as of June 2016, Chinese netizens has reached 710 million, the size of microblog users to 242 million. The huge user resources of microblog provide a rich fertile soil of marketing activities for enterprises. Many companies have realized the importance of microblog. Therefore, they launch the online marketing on microblog. However, how to assess the effectiveness of microblog marketing becomes the practical problems faced by enterprises.

With the Matthew effect of microblog is gradually prominent, the number of the domestic and foreign scholars who study on the effect of microblog marketing are on the rise. Scholars on microblog marketing research mainly focused on three aspects: marketing effect, the impact of microblog marketing and marketing strategy. In the study of the marketing effect of microblog, Leung [13] attempted to explore the marketing effectiveness of two different social media sites (Facebook and Twitter) in the hotel industry, Integrated the attitude-toward-the-ad

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_72

(Aad) model with the concepts of attitude-toward-social-media-page, and finally proposed a theoretical model of hotel social media marketing effectiveness. For different groups of people, microblog marketing may have different influence, Barry [2] assessed whether alcohol companies restrict youth/adolescent access, interaction, and exposured to their marketing on Twitter and Instagram. Clark [9] found that due to the youth presence on Twitter and the clinical uncertainty of the long term health complications of electronic cigarette consumption, the protection of public health warrants scrutiny and potential regulation of social media marketing. Chen [8] explored young consumers' interpretation of Twitter and marketing information on this particular social media platform from the perspective of consumers. Good marketing strategy is very important for enterprises, Liu [14] developed a guideline for advertisers to make the best marketing practices by visualizing and studying the evolution of popular Twitter hashtags. In order to understand how social media affect the hospitality and tourism field has increased, Park [15] discussed and demonstrated social media analytics using Twitter data referring to cruise travel, finally provided feasible marketing strategies. Kafeza [12] introduced a novel methodology to achieve information diffusion within a social graph that activates a realistic number of users, the methodology is useful to marketers who are interested to use social influence and run effective marketing campaigns.

To sum up, the innovation of this paper is to put forward the microblog marketing activity is input and output activities, through the introduction of DEA model, we establishes the comprehensive evaluation index system using quantitative method to calculate the input-output efficiency of enterprises microblog marketing, and then evaluate the effect of enterprise microblog marketing.

2 Related Work

2.1 Enterprise Microblog Marketing Effect Evaluation System

There are relatively abundant indicators to assess the effect of microblog marketing. Through quantities of case studies and quantitative research methods, some scholars found that there are many factors which have influence on the enterprise microblog marketing effectiveness. Xue [18] found that sales promotion is easy to promote consumer to make information share by forwarding to a friend or to make comments. In addition, Chang [5] thought liking or sharing social media messages can increase the effects of popular cohesion and message diffusion. What's more, Zhu [20] argued that social media marketing efforts need to be congruent and aligned with the different needs of social media users.

Bi [3] thought that the comments and reposts can reflect the microblog marketing effects. Saulles [16] considered not only the simply counting Twitter followers and volumes of tweets as indicators of effectiveness but also utilises social authority scoring from the digital marketing analysts. Based on the above findings, this paper selects the number of fans, the number of microblog, the frequency of releasing microblog, and prizes value as the input evaluation indexes. The selected output evaluation indexes are the number of fans forwarding, the number of fans comments, the number of fans point of praise, and non negative sentiment index.

From the input index perspective, this paper puts forward active comments and passive comments. Active comments means that the numbers of blogger's active replies to followers. Here the follower's comments do not express the tendency of doubt or the desire to get any responds from the blogger. However, the passive comments refer to the number of the replies. The replies are the blogger who make to answer the doubts or the questions which fans put forward to. In fact, there are obvious marks in these comments. For example, these comments consist of the symbol@, or the interrogative and obvious punctuation, microblog expressions.

From the output index perspective, the original microblog forwarded and the original microblog comments were proposed. The reason is that the official microblog generally contain original and non-original microblog(namely forwarding other's microblog). The total numbers of the original microblog forwarded also contain the original microblog forwarded and the non-original forwarded. Therefore, in order to more clearly measure the spread of the original microblog, the article puts forward the two indicators.

Based on the above analysis, the evaluation index system of enterprise microblog marketing effectiveness is established, as is shown in Fig. 1.

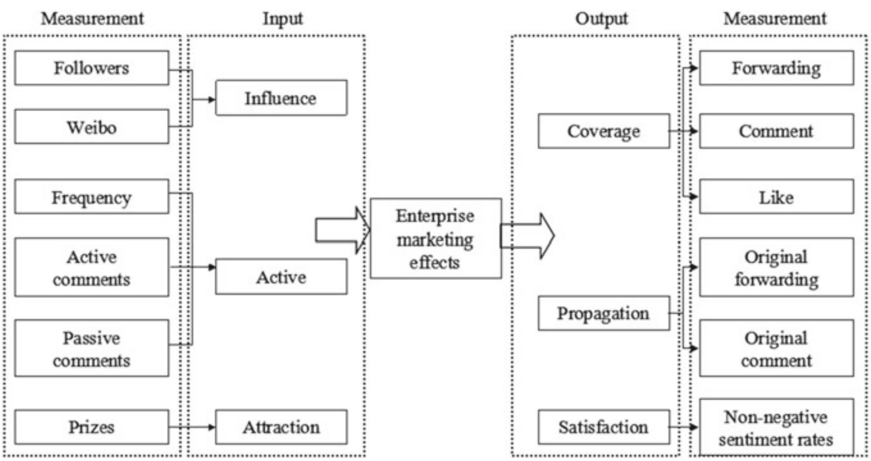

Fig. 1. Enterprise microblog marketing effect evaluation index system

2.2 Analytic Approach

Data Envelopment Analysis which can be used for evaluating the relative efficiency of decision-making units in organizations was first proposed by Charnes et al. [6]. While DEA prototype can be traced back to 1957, in the analysis of British agricultural productivity, Farrell [4] put forward the thought of envelope.

Later, the related DEA methods are mostly building on the idea of Farrell to develop a mathematical programming model. Other than comparing efficiency across DMUs within an organization, DEA has also been used to compare efficiency across firms.

DEA model has many forms. This paper selects the BCC model which can evaluate the effectiveness of scale and technical. Sun [17] proposed that we can suppose there are n decision-making units, each unit $\mathrm{DMU}_j(j = 1, 2, \cdots, n)$ has m inputs and s outputs. Respectively, they are showed by input X and output Y.

$$X_j = (x_{1j}, x_{2j}, \cdots, x_{nj}), \quad Y_j = (y_{1j}, y_{2j}, \cdots, y_{nj})^T, \quad j = 1, 2, \cdots, n.$$

To evaluate DMU_j, Cooper [11] thought that we can use the linear programming model (P) and dual programming model (D), as shown below:

$$(p) = \begin{cases} \max \mu^T y_0 = V_p \\ \omega^T x_j - \mu_i^T \geq 0 (j = 1, 2, ..., n) \\ \omega^T x_0 = 1 \\ \omega \geq 0, \mu \geq 0, \end{cases} \tag{1}$$

$$(D) = \begin{cases} \min V_D = \theta \\ \sum\limits_{j=1}^{n} x_j \lambda_j + s^- = \theta x_0 \\ \sum\limits_{j=1}^{n} y_j \lambda_j - s^+ = y_0 \\ \lambda_j \geq 0, (1 \leq j \leq n) \\ s^+ \geq 0, s^- \geq 0. \end{cases} \tag{2}$$

In the above formula, s^- and s^+ are slack variable. λ_j is the weights coefficient of input and output indicators. θ represents the ratio of input reduction. If $\theta^* = 1, s^{-*} = s^{+*} = 0$, the unit is considered to be valid. If $\theta^* = 1$, the s^{-*}, s^{+*} are not all 0, the unit is considered weak effective. If $\theta^* < 1$, the unit is considered to be invalid. When using the model to measure technical efficiency, technical efficiency can be decomposed into pure technical efficiency and scale efficiency.

3 Data Collection

3.1 Sample Selection

The research time was setting on March 5, 2014-March 11, 2014. When choosing the brands, this paper discretionarily chooses five different industries, which is Women's Clothing, Mobile Phones, Skin Care, Home Furnishings, and Snacks. Then the microblog of enterprises who have the sina official certification will be determined to as the study sample. The final choice of enterprises list is as shown in Table 1.

Table 1. The chosen enterprises in this research

Category	Women's clothing	Mobile phones	Skin care	Home furnishings	Snacks
1	Ochirly	Apple	EsteeLauder	Lin shi mu ye	Three squirrel
2	HSTYLE	Samsung	Pechoin	Bell Land	Be & Cheery
3	Vero Moda	MIUI	Lancome	Gudxon	Haoxiangni
4	ELF SACK	Huawei	Laneige	Coleshome	FERRERO ROCHER
5	Artka	VIVO	L'Oreal	QuanU	ZHOUHEI YA
6	INMAN	Coolpad	Kiehl's	Flisa	Lou lan mi yu
7	GIRDEAR	Nokia	MEIFUBAO	Hegou	BESTORE
8	ONLY	HTC	Marykay	KUKa	Xinnongge

10	PeaceBird	Lenovo	CHCEDO	YIMILOVE	Houstage

3.2 The Experimental Data Preprocessing

This paper collects 1363 microblog and 128483 comments on the 50 sina official microblog. In the all comments, there are 123782 fans comments, 2584 active comments and 2117 passive comments. The definition of main input and output indicators are as follows:

(1) The input indicators
Followers and microblog are all gotten from the pameng crawler.

The frequency of releasing microblog (FRW). This paper collects microblog of enterprise during 7 days. The frequency of post microblog = the numbers of microblog/7.

The number of active comments (NAC). This paper invites two researchers to judge the emotion of the comments. When judge the comments, the researcher according to the emotion and tone in the sentence pretend to be a follower to determine whether the comment has the tendency to question.

The number of passive comments (NPC). Use the similar collecting method with the active comments.

Prizes value (PV). Through sina advanced search, screening the microblog which contain prizes information. Then, recording the number of prizes and price. At last, this paper calculates the price of the total prize according to the market price.

(2) The output indicators
The number of microblog forward (NWF), the number of fans praise (NWL), the original microblog forwarded (OWF), the original microblog comment (OWC). They are all gotten from the pameng crawler.

The number of follower comments (NWC). Follower comments = microblog comments − active comments − passive comments.

Non negative sentiment rates (NNS). Non negative sentiment rates = positive emotion + neutral emotion)/all kinds of emotion. This represents the ratio of non-negative sentiment occupying the total emotional. This rate can also reflect the ratio of negative emotion from the side. The enterprise collects negative emotions to effectively understand the user, and then help enterprises to improve the service.

In order to improve the accuracy of the emotional data, this paper use artificial method to judge the emotion in the comments. When collecting the comments, this paper regards the spam comments as the neutral emotion to avoid its interference.

After the comments collection is to classify the emotion of the comments. This paper use the content analysis method. Then, these two researchers will classify the comments which belong to one enterprise that is chosen randomly among 50 enterprises. These comments will be used to practice the researcher repeatedly to ensure the accuracy. Then, the Kappa Statistic in reliability studies will be used to test the researcher. As a result, the researcher's kappa value is 0.87. That shows a good consistency. Therefore, these two researchers can be used in the phase of emotional classification. Finally, we can get the number of positive comments, negative comments and neutral comments. Average these three comments are the brand's corresponding comments. We can use these data in our study.

Then, each brand's microblog indexes in 7 days (except for the frequency to send microblog, the prize value, non-negative sentiment index) are also on average. Due to the numerous tables, this paper only selects the ladies enterprises' data, as shown in Tables 2 and 3.

From the table we can see, there are many data whose value is 0 in the column of active comments, passive comments and prize value. That is because that different enterprise has different marketing strategy. Thus, some input data value of enterprises is 0. Besides, this paper uses the infinitesimal (0.0001) to replace the 0 due to the forbiddance that the input DEA data cannot be 0.

3.3 Experimental Result

This paper uses the transverse, longitudinal comparison to do the comprehensive analysis in the part of results analysis.

Table 2. The input indicators of Women's Clothing enterprises

Transverse analysis is a method of comparative analysis of different enterprises' microblog marketing effect between input and output efficiency within the same industry. Longitudinal analysis refers to the comparative analysis of different industries. First, arranging all the 50 brands DEA results data in a table. Then regarding the comprehensive technical efficiency as the key word, according to the descending order, to compare the input and output efficiency of different industries.

(1) The Transverse Comparison
This paper is based on BCC model of DEA which assumes that scale reward is variable. DEAP2.1 software is applied to this experiment. Through calculating, we can obtain the evaluation results. Because of the 50 brands, the number of relate tables are also very large. In this thesis, the representative list is only shown in Table 4.

If the value of the comprehensive efficiency of an enterprise is 1, that shows that the input-output efficiency of the enterprise marketing activities is ideal, namely the enterprise marketing effect is good. The irs in the table represents the enterprises marketing activity is in the state of increasing, drs represents the decreasing state.

The comprehensive technical efficiency is the measurement and evaluation of the ability of resource allocation and resource utilization of the decision-making unit. Pure technical efficiency is the production efficiency of enterprises due to the factors such as management and technology, and the specific meaning is the ability to get the maximum output under the given input. Scale efficiency is the production efficiency which is influenced by the scale of enterprise. It reflects the gap between the actual size and the optimal production scale. According to the production status of activities in the part of returns to scale, the scale efficiency can be divided into three states, increasing returns to scale (irs) and decreasing returns to scale (drs) and constant returns to scale (crs).

It can be seen from Tables 3 and 4, in the 10 brands of Women's Clothing category, only 4 enterprises reach the ideal input-output ratio. They are Ochirly, VEROMODA, GIRDEAR and ONLY. HSTYLE, Artka, INMAN, LIEBO's marketing effect are not ideal, because the pure technical and scale efficiency are invalid. In addition, they are in a state of increasing return of scale. This shows that its allocation of resources and the scale of investment are not good enough. The low comprehensive efficiency of ELF SACK is due to the invalidation of scale. The best method to improve the condition is to increases the scale of activities and expands its exposure rate.

After the comprehensive comparison of the data table of other industry, the article finds that in five industries, the integrate marketing effect of mobile phone is best. 80% enterprises achieve the satisfied efficiency. Then the following is Home Furnishing 70%, Skin Care 60%, and Snacks 50%. The worst result is Women's Clothing industry, only 40%. The low satisfaction of Women's clothing industry may be due to the fans' activity participation is not high because of its boring and unattractive contents. Its microblog mostly show new products, seldom interacting with fans. So the official microblog is similar to enterprise's advertising platform, rather than a communication platform with fans. Lacking of interaction and humanization, the marketing effect of the product is naturely not very good.

(2) The Longitudinal Comparison

In order to better evaluate the microblog marketing effect between the five major industries, this paper proposes to use the overall ranking of comprehensive technical efficiency in DEA results in the table to identify the success or failure of enterprise marketing effect. Ranking the Comprehensive technical efficiency value of the 50 brands from high to low sequence, if the technical efficiency is equal, the brands are in same ranking. After that, the ranking will be as the enterprise scores. Higher ranking namely that the ranking order is more backward explains that the enterprise marketing effect is poorer. Calculate every

Table 5. The ranking status of comprehensive technical efficiency which is not 1

Ranking	Enterprises	Crste	Vrste	Scale	
31	Pechoin	0.99	1	0.99	irs
32	Lin shi mu ye	0.968	1	0.968	irs
33	Haoxiangni	0.956	1	0.956	irs

50	Gudxon	0.001	1	0.001	irs

enterprise's score, and then classified calculate the score of each category. The higher score shows that the category's marketing effect is poorer.

Experimental data shows that the top 30 enterprises' marketing effects are very ideal, because the comprehensive technical efficiency, pure technical efficiency and scale efficiency value are 1. The comprehensive technical efficiency of last 20 enterprises are different, as shown in Table 5.

The data shows that in the top 30 enterprises, mobile phones companies have 8, accounting for 26.7%; Home Furnishing class has 7, accounting for 23.3%; skin care companies have 6, occupying 20%; snacks has 5, accounting for 16.7%; women's clothing enterprises have 4, occupying 13.3%.

In whole 50 enterprises, achieving the satisfactory efficiency of enterprises in the mobile phones industry accounted for 16%, followed by home furnishing for 14%, skin care for 12%, snacks for 10%. Women's clothing class accounts for only 8%. The above data shows that in five industries, the microblog marketing effect of mobile phones companies are doing relatively well, women's relatively weak.

Then, classifying the ranking scores of all brands, mobile phone has the lowest score 78 points. Home furnishing gets 138 points. Skin care is 155 points. Snack is 223 points. Women's clothing gets the highest score 246 points. Therefore, from the perspective of input and output, the input-output ratio of mobile phones is the most ideal, which show that there are good microblog marketing effect in this category. The home furnishing and skin care industries are also relatively well. The input of snacks, women's clothing is redundant, while the output is insufficient. They should properly adjust the resources reasonably, display the resources value to maximize to increase enterprise microblog marketing effect.

In summary, this paper finds the marketing effect of different goods of different types of enterprises on sina microblog is different. The best effect is mobile phones industry, followed by Home Furnishing, skin care, snacks. The worst is the women's clothing industry.

3.4 Results

(1) Microblog Marketing Input-Output Analysis
As can be seen from the previous section, the invalid marketing effects of enterprises have 3 kinds:

- The technical efficiency, pure technical efficiency, scale efficiency are all not 1;
- The technical efficiency, pure technical efficiency is not 1, scale efficiency is 1;
- The pure technical efficiency is 1, the technical efficiency, scale efficiency is not 1.

The paper selects the first representative case to analyze. There are some enterprises satisfying the condition, randomly select one company. As a result, this paper chooses Be & Cheery as the sample. Table 6 is Be & Cheery's unit adjusted value: Table 6 The adjustment values of Be & Cheery.

The comprehensive efficiency value of Be & Cheery is 0.142. The pure technical efficiency value is 0.143. The scale efficiency value is 0.999. The comprehensive efficiency and pure technical efficiency value are very low, that shows there is a big problem. From the table we can see, there are input redundancy in 6 input indexes, especially on the number of followers. The original value of followers is 80.650, but the actual target value is 5.508. Be & Cheery spends too much energy on the increasing number of followers, and this part of input do not actually convert into the corresponding output, which cause a great waste of resources. Be & Cheery releases 42 microblog within 7 days, with high number of active and passive comments. Relatively speaking, official microblog is active, but the active behavior does not bring good interaction. The average number of forwarding and comments are all only 5, the number of praise is 2. The output is significantly inadequate. Besides, the prizes of Be & Cheery are attractive, the price reaching 1489 yuan. However, they do not get corresponding fans participation. In addition, Be & Cheery is good at guiding the followers' emotion and controlling the scale of marketing. The future improvement is mainly on the allocation of resources. To sum up, the above adjustment values can provide an important basis for the evaluation of enterprise marketing effects.

Table 6. The adjustment values of Be & Cheery

(2) The Improve Measurement for Enterprises
Through calculation of the DEA model, this paper finds that the microblog marketing effect of firms in different industries is different. According to the different situation of the enterprise, this paper puts forward the following measures to help enterprises improve.

① Increase the enterprise's official microblog exposure, propagandize enterprise microblog through many ways.
According to the "2015 electric business microblog development report" released by sina microblog, the current number of active electric business enterprises in sina microblog account for a total of more than 1600. If you want to highlight your own business account in so many official accounts, you must understand the main way for users to pay attention to enterprise. Seize the basic demands for user to follow the enterprise.

The sina "2015 microblog user development report" shows, users follow the enterprise's microblog primarily through three ways: advertising, others forwarding and corporate propaganda. Besides, Baird [1] thought the establishment of social customer relationship, seized the customer psychology, and the use of interactive communication strategy were also important. In addition to the above measures, the enterprise can also increase the promotion in the major holidays and special time point.

② Pay attention to negative emotions, encourage the positive emotions, and guide the neutral mood.
Chatterjee [7] said that consumers always believe the negative information have more critical value than the positive information when they make purchase decisions or scan the comments. Therefore, they always have greater degree of dependence on the negative information. Through microblog to guide consumers is the main reason for some enterprise to do the microblog marketing. The negative

comments may cause certain extent damage to the product of enterprise. Therefore, some enterprises must pay much attention to the negative emotion and know the origin of it. That can help the enterprise to eliminate the negative emotion.

For the positive emotions, the enterprise should take the initiative to interact with the followers and encourage users to maintain this positive emotion, then to increase the reputation of enterprise. For the neutral emotions, the enterprise should show its advantage to consumers with the objective data.

③ Both active and passive comments should be concerned
Most followers want to get reply or attention when they give comments to the blogger. If bloggers can timely find this kind of behaviors of followers, and then give timely response, that can largely reduce the negative emotions and increase the positive interaction with followers.

④ Diversify the types of microblog
Zhang [19] believed that the types of microblog can to a certain extent influence the browsing and forwarding of fans. Generally the type of blog is divided into: pictures, short chain, video, text, or a mixture of the four types. In order to maintain the freshness of microblog, the enterprise should cross use multiple types of posts to give user a new experience.

4 Conclusions

This paper through the literature research, put forward the evaluation indicators of the microblog marketing effect in enterprises, and set up a set of comprehensive evaluation system.

Combining with the method of data envelopment analysis (DEA), this paper proposes the evaluation model, with input and output of the quantitative evaluation method to evaluate the microblog marketing effect between different enterprises. In the empirical part, this paper selects 50 different enterprises to verify the feasibility of the model. According to the objective data, this paper makes a comparison of different enterprise marketing effect, and provides a feasible improvement measures for it.

In fact, this paper also has certain limitation in the selection of indicators. The article does not use the enterprise actual sales as the evaluation index. Besides, this paper only studies the different enterprises in the short period. The future research can increase the time and carry on deeper research on microblog marketing effects.

Abstract. Motivated by a Canadian national survey on child safety seat use, we propose a procedure for incorporating non-ignorable missingness in a binary response using logistic regression model with random effects. The proposed method applies an expectation maximization (EM) algorithm to the Penalized quasi-likelihood of the artificially completed data. We provide closed form formulae for estimating the covariance of the regression coefficients as well as the odds ratios of interest and probabilities of missingness. The proposed algorithm can be easily implemented by using familiar statistical packages that fit generalized linear mixed models. The method is illustrated by applying it to data from Canadian national survey on child safety seat use.

Keywords: Generalized linear mixed model · EM algorithm · Non-ignorable missingness · Data augmentation · Logistic regression · Child safety

1 Introduction

Subjects are likely to decline participation in a survey if the variables measured are socially sensitive. This, raises the issue of non-ignorable missingness whereby, the missignness mechanism depends on the value of the response itself. The current research was motivated by data from a large Canadian survey in which 200 retail parking lots across Canada were random chosen and vehicles entering to the parking lot were asked consent to participate in a survey which measured the correct use of child safety seats in vehicles. Age, height, weight and type of car safety seat used were recorded for up to three children in the participating vehicles. By using these variables, a binary correct use variable was then defined.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_73

Unfortunately, drivers of more than 50% of the vehicles refused to participate in the survey. Since correct uses of children in the same participating vehicle are correlated, in addition to the missing responses, the data presented also a cluster correlation feature.

Ibrahim et al. [3] have developed an EM algorithm for the generalized linear mixed models (GLMM) with normal random effects and non-ignorable missingness in the responses by using MCMC sampling techniques. Ibrahim et al. [3] modeled the respondent data as a function of covariates by using GLMM with logit link and likewise they modeled the non-response data as a function of the same set of covariates as well as the response itself. Thus, they captured the non-ignorable nature of the non-response through a logit link as well. The authors then, proposed an EM (Expectation Maximization) algorithm along with MCMC sampling for estimating the various parameters of the model.

Ibrahim and Molenberghs [8] have recently given an exhaustive review of methods for accommodating non-ignorable missingness in longitudinal data. Also, Huang and Carriere [2] discussed accommodation of incomplete responses data in small sample longitudinal data.

In this paper, we propose a direct method which does not require Monte Carlo sampling. The method proposed here is based on the penalized quasi-likelihood of Breslow and Clayton [1] (PQL) which utilizes Laplacian method of integral approximation of integrals. We use GLMM to model the respondent data, thus accommodating the clustering. On the other hand, we model the dependence of the non-response on covariates and on the true values of the response itself through generalized linear model GLM as was done in Ibrahim et al. [3]. However, we use the PQL method of Breslow and Clayton via Laplace transform and Taylor series approximation [1,6] in order to eliminate the random effects. We then apply an EM algorithm to estimate the regression coefficients and Louis's method [4] to obtain formulae for the their covariances. Following Zeger et al. [9], and by using delta method, we compute marginal probabilities of the response as well as odd ratios and probabilities of non-response and their respective confidence intervals. The proposed method can be easily implemented through familiar statistical software that fit GLMM. In Sect. 2 we give technical details of the model and the algorithm used for fitting it as well as formulae for variances of the various parameters of interest. In Sect. 3 we apply the method to the Canadian national survey on child safety seat use. Finally, in Sect. 4, we give some discussions.

2 The Proposed Method

2.1 Model Details

Let y_i be a binomial variable with size m_i and success probability p_i. Suppose that the complete data consists of a sample $\mathbf{y} = (y_1, \cdots, y_n)'$, from such distribution. Given an n-dimensional vector $b = (b_1, \cdots, b_n)'$ of random effects, we assume that $y_i \mid b$ follows generalized linear mixed model (GLMM), that is

$$y_i \mid b \sim \text{Binomial}\,(m_i, p_i)\,,$$
$$b \sim MVN\,(0, \mathbf{D})\,,$$

where MVN stands for multivariate normal distribution with covariance matrix $\mathbf{D}$, $n \times n$ diagonal matrix with diagonal elements σ^2.

Let $\beta = (\beta_0, \beta_1, \cdots, \beta_p)'$ be a vector of fixed effects regression coefficients associated with the vector of covariates $x_i = (1, x_{i1}, \cdots, x_{ip})'$. Let also, t_i be an $1 \times n$ vector of explanatory variables for the random effects associated with the ith observation. The ith component of t_i is 1 and the rest are all 0. Such vectors can be compacted for all $i = 1, \cdots, n$ in an $n \times n$ identity matrix $T = (t_1, \cdots, t_n)$, which is simply the design matrix associated with the random effects. By standard theory of GLMM, $y_i \mid b$ has the density

$$f(y_i \mid x_i, \beta, \sigma^2, b) = \exp\left\{ y_i \log(p_i/(1-p_i)) + m_i \log(1-p_i) + \log\binom{m_i}{y_i} \right\}, \tag{1}$$

with the first two moments given by

$$E(Y_i \mid b) = \mu_i(b) = m_i p_i \tag{2}$$
$$\text{Var}(Y_i \mid b) = m_i p_i (1-p_i). \tag{3}$$

We use the logit link function to relate covariates (both fixed and random) and the p_i as follows

$$\log(p_i/(1-p_i)) = \eta_i(b) = x_i'\beta + t_i'b = x_i'\beta + b_i. \tag{4}$$

We introduce a missing data indicator variable r_i for each y_i observation in the complete data,

$$r_i = \begin{cases} 1, & \text{if } y_i \text{ is missing;} \\ 0, & \text{if } y_i \text{ is observed.} \end{cases}$$

Now, as in [3], we assume that the missingness indicators, $\mathbf{r} = (r_1, \cdots, r_n)'$, are independent of the random effects, b_i, but depend on the covariates x_i as well as on the value of the response, y_i, through a logistic regression model. Thus, by setting $z_i = (x_i, y_i)'$ to be the vector of explanatory variables for the non-response model with corresponding regression coefficients, $\alpha = (\alpha_0, \alpha_1, \cdots, \alpha_{p+1})'$, we can write the density of the r_i as

$$f(r_i | z_i, \alpha) = \exp\left\{ r_i z_i'\alpha - \log\left(1 + \exp\{z_i'\alpha\}\right)\right\},$$

where the logit link function is again used to connect covariates and probability of non-response $\pi_i = \Pr(r_i = 1 \mid x_i, y_i)$ as follows

$$\log(\pi_i/(1-\pi_i)) = z_i'\alpha.$$

The log-marginal likelihood of $\mathbf{y}$ can now be written as

$$\log f(\mathbf{y}|x, \beta, \sigma^2) = \log \int f(\mathbf{y} \mid x, \beta, \sigma^2, b) f(b) db = \log \int e^{h(b)} db, \tag{5}$$

where $h(b) = \log f(\mathbf{y} \mid x, \beta, \sigma^2, b) + \log f(b)$.

Since the random effects are assumed to be normal, we have

$$\log f(b) = -\frac{1}{2}b'\mathbf{D}^{-1}b - \frac{n}{2}\log 2\pi - \frac{1}{2}\log|\mathbf{D}|$$

and hence,

$$\begin{aligned} h(b) &= \log f(\mathbf{y} \mid x, \beta, \sigma^2, b) + \log f(b) \\ &= \log f(\mathbf{y} \mid x, \beta, \sigma^2, b) - \frac{1}{2}b'\mathbf{D}^{-1}b - \frac{n}{2}\log 2\pi - \frac{1}{2}\log|\mathbf{D}|. \end{aligned}$$

The log-likelihood in Eq. (5) is not easy to deal with as it involves a high dimensional integral. To simplify it, we apply the Laplace approximation of [1,6,7], based on a second-order Taylor series expansion,

$$\log \int e^{h(b)}db \doteq h(\hat{b}) + \frac{n}{2}\log 2\pi - \frac{1}{2}\log\left|-\frac{\partial^2 h(b)}{\partial b \partial b'}\right|, \tag{6}$$

where $\hat{b}$ is solution to

$$\left.\frac{\partial h(b)}{\partial b}\right|_{b=\hat{b}} \left. T'(\mathbf{y} - \mu(b)) - \mathbf{D}^{-1}b\right|_{b=\hat{b}} = 0.$$

It can be shown that [6],

$$-\frac{\partial^2 h(b)}{\partial b \partial b'} = (T'WT\mathbf{D} + I)\mathbf{D}^{-1}, \tag{7}$$

where W is the $n \times n$ diagonal matrix with diagonal element $w_i = m_i p_i(1 - p_i)$.

By using Eqs. (6) and (7), the log-likelihood in Eq. (5) can be approximated by

$$\log f(\mathbf{y}|x, \beta, \sigma^2) \doteq \log f(\mathbf{y} \mid x, \beta, \sigma^2, \hat{b}) - \frac{1}{2}\hat{b}'\mathbf{D}^{-1}\hat{b} - \frac{1}{2}\log|T'WT\mathbf{D} + I|,$$

or equivalently,

$$\begin{aligned} \log f(\mathbf{y}|x, \beta, \sigma^2) \doteq \sum_{i=1}^{n} \Bigg[& y_i\eta_i(\hat{b}) - m_i \log\left(1 + \exp\left\{\eta_i(\hat{b})\right\}\right) + \log\binom{m_i}{y_i} - \frac{1}{2}\frac{\hat{b}_i^2}{\hat{\sigma}^2} \\ & - \frac{1}{2}\log\left(m_i\left(\exp\left\{\eta_i(\hat{b})\right\} / \left(1 + \exp\left\{\eta_i(\hat{b})\right\}\right)^2\right)\hat{\sigma}^2 + 1\right)\Bigg]. \end{aligned} \tag{8}$$

The log-likelihood so obtained is the penalized quasi-log-likelihood and most of the available statistical software can fit such model.

Finally, the joint log-likelihood of the complete data and the missingness indicator can be written as

$$\begin{aligned} l(\alpha, \beta, \sigma^2|\mathbf{r}, \mathbf{y}, x) &= \log f(\mathbf{r}, \mathbf{y}|x, \alpha, \beta, \sigma^2) \\ &= \sum_{i=1}^{n} \left[\log f(r_i \mid z_i, \alpha) + \log f(y_i \mid x_i, \beta, \sigma^2)\right]. \end{aligned}$$

This implies that the i^{th} observation's contribution to the log-likelihood is

$$l_i(\alpha, \beta, \sigma^2 | r_i, y_i, x_i) = \log f(r_i \mid z_i, \alpha) + \log f(y_i \mid x_i, \beta, \sigma^2)$$

and so, the i^{th} observation's contribution to the expected log-likelihood is

$$E[l_i(\alpha, \beta, \sigma^2 | r_i, y_i, x_i)] = \begin{cases} \sum_{y_i=0}^{m_i} w_i(y_i) l_i(\alpha, \beta, \sigma^2 | r_i, y_i, x_i), & \text{if original } y_i \text{ is missing;} \\ l_i(\alpha, \beta, \sigma^2 | r_i, y_i, x_i), & \text{if original } y_i \text{ is observed,} \end{cases}$$

where the weights $w_i(y_i)$ are

$$w_i(y_i) = \frac{f(r_i \mid z_i, \alpha) f(y_i \mid x_i, \beta, \sigma^2)}{\sum_{y_i=0}^{m_i} f(r_i \mid z_i, \alpha) f(y_i \mid x_i, \beta, \sigma^2)}, \tag{9}$$

and $f(y_i \mid x_i, \beta, \sigma^2)$ is the marginal density of y_i obtained from Eq. (8). Note that if the original y_i is observed, then $w_i(y_i) = 1$. Now, the expected log-likelihood for all n observations in the complete binomial sample is

$$L(\alpha, \beta, \sigma^2) = \sum_{i=1}^{n} \sum_{y_i=0}^{m_i} w_i(y_i) \log f(r_i \mid z_i, \alpha) + \sum_{i=1}^{n} \sum_{y_i=0}^{m_i} w_i(y_i) \log f(y_i \mid x_i, \beta, \sigma^2). \tag{10}$$

This last equality indicates that the model for the complete data and that of the missingness indicator can be separated as in Ibrahim et al. [3], and therefore, estimation of the regression parameters can be carried out separately.

2.2 Estimating the Regression Coefficients

The regression coefficients of the model can be estimated by using Eq. (10). First, we create an augmented data set (y_i, r_i, x_i), in which each missing observation y_i is replaced by its $m_i + 1$ possible values, then we apply the following algorithm on the augmented data set.

(1) Set the initial weights to 1 and fit ordinary weighted GLMM to the augmented (complete) data $(\mathbf{y}, \mathbf{x})$ by using any statistical software that fits GLMM via penalized quasi-likelihood methods, and hence, obtain the starting values of β, b, and σ^2.
(2) Set the initial weights to 1 and fit weighted GLM to the missing indicator data $(\mathbf{r}, \mathbf{z})$ and obtain the starting values of α.
(3) By using (9), update the weights $w_i(y_i)$ based on the current values of β, α, b, and σ^2.
(4) Update β, b, and σ^2 by fitting weighted GLMM to the augmented (complete) data $(\mathbf{y}, \mathbf{x})$ with the current values of $w_i(y_i)$.
(5) Update α by fitting weighted GLM to $(\mathbf{r}, \mathbf{z})$ with the current values of $w_i(y_i)$.
(6) Update the weights $w_i(y_i)$ based on the new β, α, b, and σ^2.
(7) Repeat steps 4–6 until β and α converge.

The final estimates of β, α, σ^2 are obtained upon convergence of the above algorithm. Following Louis [4], the estimated observed Fisher information matrix of the parameters $(\beta, \alpha, \sigma^2)$ can be computed as

$$\mathscr{I}(\hat{\alpha}, \hat{\beta}, \hat{\sigma}^2) = Q(\hat{\alpha}, \hat{\beta}, \hat{\sigma}^2) - H(\hat{\alpha}, \hat{\beta}, \hat{\sigma}^2),$$

where

$$\begin{aligned} H(\hat{\alpha}, \hat{\beta}, \hat{\sigma}^2) = & \left[\sum_{i=1}^{n} \sum_{y_i=0}^{m_i} \hat{w}_i(y_i) S_i(\hat{\alpha}, \hat{\beta}, \hat{\sigma}^2 | r_i, y_i, x_i) S_i(\hat{\alpha}, \hat{\beta}, \hat{\sigma}^2 | r_i, y_i, x_i)' \right] \\ & - \sum_{i=1}^{n} U_i(\hat{\alpha}, \hat{\beta}, \hat{\sigma}^2 | r_i, y_i, x_i) U_i(\hat{\alpha}, \hat{\beta}, \hat{\sigma}^2 | r_i, y_i, x_i)', \\ \hat{w}_i(y_i) = & \frac{f(r_i \mid z_i, \hat{\alpha}) f(y_i \mid x_i, \hat{\beta}, \hat{\sigma}^2)}{\sum_{y_i=0}^{m_i} f(r_i \mid z_i, \hat{\alpha}) f(y_i \mid x_i, \hat{\beta}, \hat{\sigma}^2)}, \\ U_i(\hat{\alpha}, \hat{\beta} | r_i, y_i, x_i) = & \sum_{y_i=0}^{m_i} \hat{w}_i(y_i) S_i(\hat{\alpha}, \hat{\beta}, \hat{\sigma}^2 | r_i, y_i, x_i). \end{aligned}$$

The score vector $S_i(\hat{\alpha}, \hat{\beta}, \hat{\sigma}^2 | r_i, y_i, x_i)$ is given by

$$\begin{aligned} S_i(\hat{\alpha}, \hat{\beta}, \hat{\sigma}^2 | r_i, y_i, x_i) = & \left. \frac{\partial l_i(\alpha, \beta, \sigma^2 | r_i, y_i, x_i)}{\partial(\alpha, \beta, \sigma^2)} \right|_{(\alpha, \beta, \sigma^2) = (\hat{\alpha}, \hat{\beta}, \hat{\sigma}^2)} \\ = & \left((r_i - \hat{\pi}_i), (r_i - \hat{\pi}_i) x_{i1}, \cdots, (r_i - \hat{\pi}_i) z_{ip}, (r_i - \hat{\pi}_i) y_i, d_i, d_i x_{i1}, \right. \\ & \left. \cdots, d_i x_{ip}, \partial l_i / \partial \sigma^2 \right)', \end{aligned}$$

where

$$\begin{aligned} d_i = & \; y_i - \hat{\mu}_i(\hat{b}) - \frac{m_i \hat{\sigma}^2 \hat{p}_i (1 - \hat{p}_i)(1 - 2\hat{p}_i)}{2(m_i \hat{\sigma}^2 \hat{p}_i (1 - \hat{p}_i) + 1)}, \\ \frac{\partial l_i}{\partial \sigma^2} = & \; \frac{\hat{b}_i^2}{2\left(\hat{\sigma}^2\right)^2} - \frac{m_i \hat{p}_i (1 - \hat{p}_i)}{2(m_i \hat{\sigma}^2 \hat{p}_i (1 - \hat{p}_i) + 1)}. \end{aligned}$$

The matrix
$$Q(\hat{\alpha}, \hat{\beta}, \hat{\sigma}^2) = \begin{pmatrix} Q_1(\hat{\alpha}) & 0 \\ 0 & Q_2(\hat{\beta}, \hat{\sigma}^2) \end{pmatrix}$$
is such that the (j, k)th element of $Q_1(\hat{\alpha})$ is given by

$$Q_{1,jk}(\hat{\alpha}) = - \left. \frac{\partial^2 L(\alpha, \beta, \sigma^2)}{\partial \alpha_j \partial \alpha_k} \right|_{\alpha = \hat{\alpha}},$$

and the $(j, k)th$ element of $Q_2(\hat{\beta}, \hat{\sigma}^2)$ is

$$Q_{2,jk}((\hat{\beta}, \hat{\sigma}^2) = - \left. \frac{\partial^2 L(\alpha, \beta, \sigma^2)}{\partial \beta_j \partial \beta_k} \right|_{\beta = \hat{\beta}, \sigma^2 = \hat{\sigma}^2},$$

for $j,k = 0,1,\cdots,p$ and $Q_{2,p+1,p+1}(\hat{\beta},\hat{\sigma}^2) = -\frac{\partial^2 L(\alpha,\beta,\sigma^2)}{\partial\sigma^2\partial\sigma^2}\Big|_{\beta=\hat{\beta},\sigma^2=\hat{\sigma}^2}$. These matrices are, respectively, the usual Fisher and penalized Fisher information matrices associated with the GLM and GLMM models and they can be easily extracted from existing software upon convergence of the EM algorithm described above.

2.3 Computing the Marginal Response Probabilities and Probabilities Of Missingness

In binary response studies, investigators are often interested in the marginal probabilities of the response of interest, $\bar{p}_i = P(Y_i = 1)$. This is, in fact, not easy in a random effects model in which a logit link function has been used, due to the non-linearity of the logit function. A way about this difficulty is to use a Taylor approximation of the type proposed by Zeger et al. [9] in which $\bar{p}_i$ are approximately estimated by

$$\hat{\bar{p}}_i = \hat{E}(y_i) \approx \frac{\exp\left\{\hat{k}x_i'\hat{\beta}\right\}}{1+\exp\left\{\hat{k}x_i'\hat{\beta}\right\}},$$

where $\hat{k} = (1+c^2\hat{\sigma}^2)^{-1/2}$ and $c = 16\sqrt{3}/(15\pi)$. By applying delta method to $\hat{\eta}_i = g(\hat{\beta},\hat{\sigma}^2) = \hat{k}x_i'\hat{\beta}$, we obtain estimators of $\hat{\bar{p}}_i$,

$$\hat{V}(\hat{\eta}_i) \approx \hat{G}'\hat{\Sigma}\hat{G},$$

where $\hat{\Sigma}$ is the estimated asymptotic covariance matrix of $\hat{\beta},\hat{\sigma}^2$, that is the lower right block of $\mathscr{I}^{-1}(\hat{\alpha},\hat{\beta},\hat{\sigma}^2)$, and

$$G = \begin{pmatrix} \frac{\partial g(\beta,\sigma^2)}{\partial\beta}\big|_{\hat{\beta},\hat{\sigma}^2} \\ \frac{\partial g(\beta,\sigma^2)}{\partial\sigma^2}\big|_{\hat{\beta},\hat{\sigma}^2} \end{pmatrix}.$$

An approximate 95% confidence interval for η_i is then given by

$$(\hat{\eta}_i^L,\hat{\eta}_i^U) \equiv \left(\hat{\eta}_i - 1.96\sqrt{\mathrm{Var}(\hat{\eta}_i)}, \hat{\eta}_i + 1.96\sqrt{\mathrm{Var}(\hat{\eta}_i)}\right),$$

whereas an approximate 95% confidence interval for $\bar{p}_i = \exp\{\eta_i\}/(1+\exp\{\eta_i\})$ is

$$\left(\frac{\exp\{\hat{\eta}_i^L\}}{1+\exp\{\hat{\eta}_i^L\}}, \frac{\exp\{\hat{\eta}_i^U\}}{1+\exp\{\hat{\eta}_i^U\}}\right).$$

Finally, $\hat{V}(\hat{\bar{p}}_i)$ can be computed by a second delta method as $\hat{V}ar(\hat{\bar{p}}_i) \approx [\hat{\bar{p}}_i(1-\hat{\bar{p}}_i)]^2\hat{V}ar(\hat{\eta}_i)$. The probabilities of non-response, $\hat{\bar{\pi}}_i$, can be easily obtained from the output of the GLM model fit as these probabilities depend only on the regression parameters α_i.

3 Application

The data analyzed in this example are based on a Canadian child safety seats survey described in Snowdon et al. [5]. The main objective of the survey was to measure whether children traveling in vehicles on Canadian roads are correctly restrained in safety devices that are appropriate for their ages, weights and heights. Drivers of vehicles entering in 200 randomly selected retail parking lots across Canada were asked to participate in the survey. For the vehicles whose drivers agreed to participate in the survey, heights, weights, ages and type of safety restraints used were recorded for up to three child occupants in the vehicle. For vehicles whose drivers refused to participate in the survey, the number of children in the vehicle were recorded. In general, there is no consensus on the definition of correct seat for a child. There are several criteria of correct use based on one or combination of age, weight and height. In this article, we employed correct use definition given in Table 1, based only on child's age. We defined the number of children who are correctly restrained in a vehicle as y_i, assumed

Table 1. Definition of correct use of CSS based on the child's age groups

Child safety seats	Age groups
Rear-facing infant seat	(Age $\leqslant$ 1 year)
Forward-facing infant seat	(1 years $<$ Age $\leqslant$ 4 years)
Booster seat	(4 years $<$ Age $\leqslant$ 9 years)
Seat belt	(Age $>$ 9 years)

to be Binomial(m_i, p_i), where $m_i = 1, 2, 3$. For vehicles whose drivers refused to participate in the survey, y_i is not observed but only m_i is known. Therefore, our objective is to incorporate this missingness into the estimation of the probabilities of correct use, p_i, and probabilities of missingness, π_i, for the various provinces of Canada. The covariates of interest in this study are the dummy codings for 10 Canadian provinces and territories, $x_{1i}, x_{2i}, \cdots, x_{10i}$. We assumed the province of Ontario to be the reference province. We then applied the EM algorithm proposed in this article and summarized results in Tables 2, 3, 4 and 5. In Table 2, we reported the estimated adjusted marginal probabilities of correct use for the various provinces as well as for the entire Canada. It is clear that the adjusted rates exhibit downward bias as compared to the raw proportions.

ON	74.18%	77.95%	72.44%	66.15%	59.24%
PEI	43.62%	45.68%	38.47%	31.73%	25.68%
QC	65.53%	68.76%	62.07%	54.89%	47.49%
SK	69.83%	71.30%	64.88%	57.86%	50.52%
Nation	68.74%	72.73%	67.14%	61.02%	54.54%

In Tables 3 and 4, we reported the estimated regression coefficients, $\hat{\beta}$, and odds ratios based on these parameters. The provinces of Alberta, Manitoba, Newfoundland, Prince Edward Island and Quebec have significantly lower odds of correct use as compared to Ontario. In Table 5, the missing indicator regression parameters, $\hat{\alpha}$, are reported. We clearly see that the coefficient of y_i, α_{11}, is statistically significant, which indicated that the missingness is non-ignorable. In Table 6, we reported the non-response proportions as well as non-response proportions estimated from the EM model. The probabilities of non-response decrease as the number of correctly restrained children in a vehicle increase. These probabilities are denoted by $\hat{\pi}_i$, where $i = 0, 1, 2, 3$ is the number of correctly restrained children in the vehicle.

4 Conclusion

In this manuscript, we proposed a method for handling non-ignorable missing responses in a clustered binary data. We employed GLMM along with penalized quasi-likelihood estimation method for fitting the parameters of the complete data and GLM for fitting those of the missingness mechanism and combined them via the EM algorithm. Procedures for estimating the marginal probabilities of the response are derived via delta method. The proposed methods are then applied to a Canadian national survey for estimating rates of correct use of child safety seats in vehicles. The proposed methods are attractive in the sense that they only require existing statistical software that have capabilities for fitting GLMM and GLM.

Abstract. This paper presents a decentralized multi-objective bi-level model for water resources planning, in the upper level of the model, the regional authority as the leader determines to allocate how much water to each sub-area to maximize equity and minimize the environmental pollution, and then the sub-areas in the lower level make decisions on allocating water to water sectors based on different allocation principles with the analysis of relationship between supply and demand to maximize the benefits. In the decision making process, fuzzy random environment is considered to describe the internal uncertainty, an expected value operator is used to deal with the fuzzy random variables. Finally, a case study is used to verify the applicability of the proposed model.

Keywords: Water resources allocation · Equity · Sustanability · Bi-level programming · Fuzzy random variable

1 Introduction

In the water resources allocation system, there exists the interaction between regional authority and sub-areas in a river basin [11,12]. Efficiency and sustainability of water resources allocation often conflict with each other, for without considering ecological water to destroy the sustainability of water resources allocation, other water sectors that can generate economic benefits can obtain more water, the efficiency of water resources allocation will improve [4,5,8]. In addition, to guarantee the efficiency and sustainability of water using will lead the contradiction between two-level decision makers (i.e., regional authority and sub-areas).

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_74

Rogers and Louis [9] pointed out that there were a variety of activities and objectives in a water system as well as complicated supply and demand contradictions, which brought pressures to regional authority and sub-areas managers, because these contradictions and ineffectiveness management limit the economic development and environment protection. Therefore, an equitable and efficient water resources allocation is an important measure to deal with water crisis and improve water management, especially when it is very lack of water.

Based on the above, this paper considers to establish a user-friendly water resources allocation model, with two-level structure, in which the regional authority and sub-areas are the upper level and lower level decision makers respectively, as there are multiple decision makers in the lower level, it is a decentralized bi-level model. In the model, the regional authority as the leader aims to maximize the equity (i.e., minimize the Gini coefficient), the sub-areas as the followers expect to maximize the economic benefits. In addition, practical water resources allocation process faces complex uncertain environments, technology progress and equipment update and climatic change will bring uncertainty to parameters in the water transport process, and it is hard to describe the uncertainty using simple random variable or fuzzy variable, therefore, the fuzzy random variable is considered. Based on the discussion above, a decentralized multi-objective bi-level model with fuzzy random coefficients will be established in this paper.

The reminder of this paper is structured as follows. In Sect. 2, the problem statement is given, including the bi-level structure of the model and the motivation to consider fuzzy random variable. Then an expected decentralized bi-level model is established in Sect. 3. In Sect. 4, a case study is conducted to verify the applicability of the model. Finally a conclusion remark is given in Sect. 5.

2 Problem Statement

For a regional water resources allocation system, in the case of insufficient water supply, the limited water should be allocated optimally to each sub-area, and then be allocated by each sub-area to different water sectors (i.e., ecological water, municipal water, industrial water, agricultural water) [10]. The fair allocation of water can balance the contradiction between water supply and demand, therefore, the regional authority the leader in the upper level expects to maximize the equity of water allocation, in the lower level, the sub-areas hope to maximize the benefits through water allocation based on different allocation principles (i.e., efficiency principle, stress principle, priority principle) with the analysis of relationship between supply and demand. The bi-level structure of the water allocation model is shown in Fig. 1.

The need to address uncertainty in water allocation system is widely recognized, there is a strong motivation for considering the fuzziness and randomness in water resources planning problems [1,3,6]. For example, the loss ratio of water transfer is not fixed because of the effect of many uncertain elements such as lack of historical data, technology progress and equipment update, dynamics of

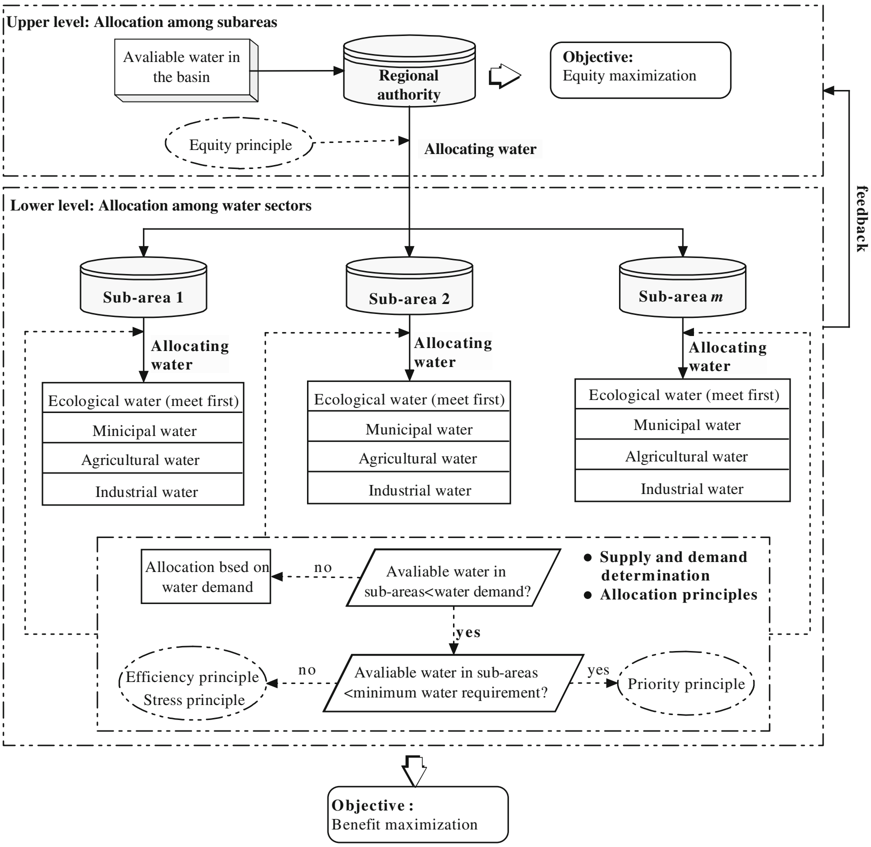

Fig. 1. Bi-level model structure of water allocation

water resources systems, in this case, it is appropriate to use a fuzzy variable to describe the loss ratio of water transfer, which is the fuzziness of the loss ratio of water transfer. The decision making is happen in the future, some experts will be asked to describe the variable using different ranges, which is the randomness of the loss ratio of water transfer. In this study, triangle fuzzy number is used to describe the fuzziness, normal distribution random variable is used to describe the most possible value in the triangle fuzzy number. Therefore, fuzzy random variable is used to describe the two-hold uncertainty of the loss ratio of water transfer, the flowchart of the loss ratio of water transfer as a fuzzy random variable is shown in Fig. 2.

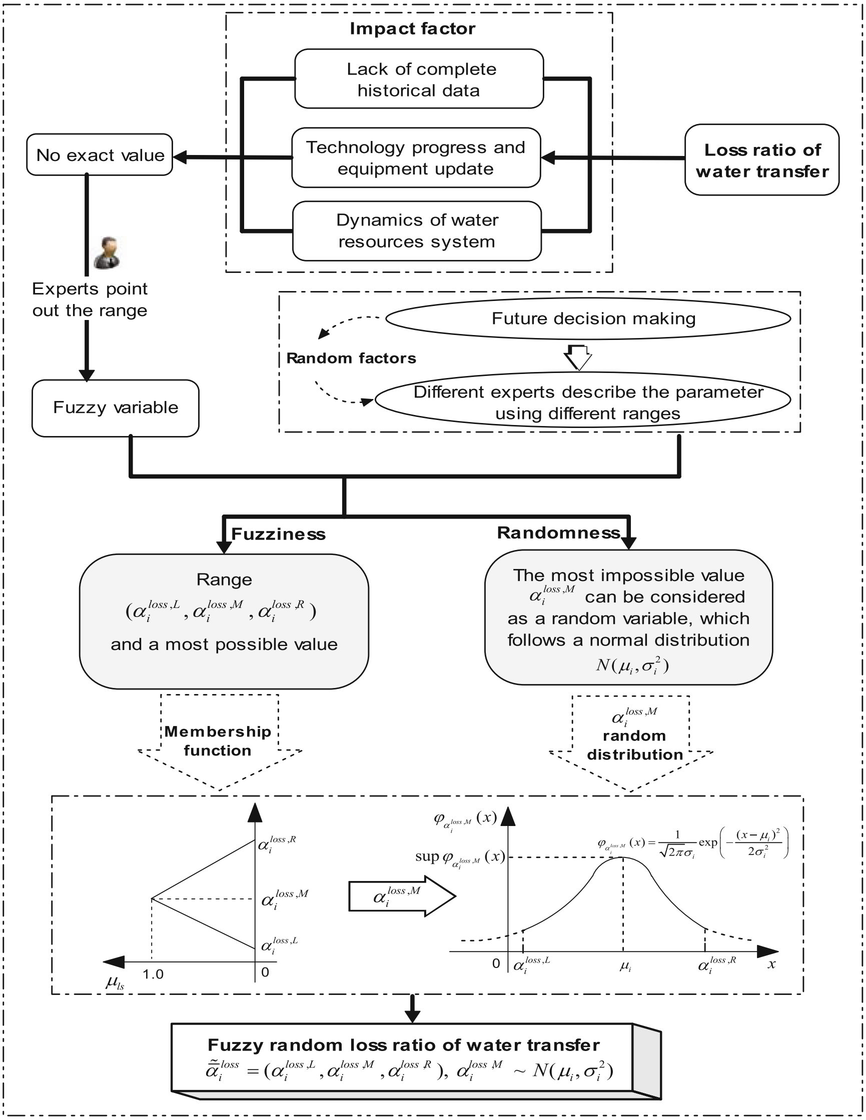

Fig. 2. The flowchart of the loss ratio of water transfer as a fuzzy random variable

3 Modelling

3.1 Assumptions

The following assumptions are considered for constructing the model.

(1) All available water is from a river basin.

(2) The leader (i.e., regional authority) and the followers (i.e., sub-areas) will make rational decision makings for avoiding unsatisfying solutions.
(3) Loss ratio of water transfer is considered as a fuzzy random variable, in which the parameters are determined using data analysis based on historical data and experience.

3.2 Notations

Indices
i: index of sub-area;
j: index of water sector;
k: index of special water sector that requirements should be met;

Parameters
Q: available water of basin;
$e_{i,j}$: economic benefit for using water of water sector in sub-area;
e_i: economic benefit for using water in sub-area;
$o_{i,j}$: amount of the pollutant BOD in unit wastewater discharge of water sector in sub-area;
$w_{i,j}$: wastewater discharge coefficient of water sector in sub-area;
v_i: economic benefit of sub-area;
q_i: water source of sub-area;
$Z_i^{\min}$: minimum capacity of the physical connection between water source and sub-area;
$Z_i^{\max}$: maximum capacity of the physical connection between water source and sub-area;
$S_i^{\max}$: maximum capacity of sub-area;
$d_{i,j}^{\min}$: minimum water requirement of water sector in sub-area;
$d_{i,j}^{\max}$: maximum water requirement of water sector in sub-area;
$ed_{i,j}^{\max}$: minimum ecological water requirement of sub-area;

Fuzzy random variables
$\tilde{\bar{\alpha}}_i^{\text{loss}}$: loss ratio of water transfer from water source to sub-area;

Decision variables
x_i: water allocated to sub-area;
$y_{i,j}$: water allocated to water sector in sub-area

3.3 Model Formulation

Based on the problem statement and the above preparatory work, the decentralized bi-level model for water resources allocation with analysis of supply and demand is established as follows.

$$\max_{\mathbf{x}} G = \frac{1}{2m\sum_{k=1}^{m}\frac{x_k}{e_k}}\sum_{k=1}^{m}\sum_{l=1}^{m}\left|\frac{x_k}{e_k}-\frac{x_l}{e_l}\right| \tag{1}$$

$$\min_{\mathbf{x}} P = \sum_{i=1}^{m}\sum_{j=1}^{n} 0.01 o_{i,j} w_{i,j} y_{i,j} \tag{2}$$

$$\text{s.t. } \sum_{i=1}^{m} x_i \le Q \tag{3}$$

$$(1 - E[\tilde{\bar{\alpha}}_i^{\text{loss}}])x_i + q_i \ge \sum_{k=1}^{t} d_{i,k}^{\min}, \quad \forall i \tag{4}$$

$$z_i^{\min} \le x_i \le z_i^{\max}, \quad \forall i \tag{5}$$

$$(1 - E[\tilde{\bar{\alpha}}_i^{\text{loss}}])x_i + q_i \le s_i^{\max}, \quad \forall i \tag{6}$$

For given $\mathbf{x}, \mathbf{y}$ solves

$$\max_{\mathbf{y}} v_i = \sum_{j=1}^{n} e_{i,j} y_{i,j}, \quad \forall i \tag{7}$$

$$\text{s.t. } d_{i,j}^{\min} \le y_{i,j} \le d_{i,j}^{\max}, \quad \forall i, j \tag{8}$$

$$(1 - E[\tilde{\bar{\alpha}}_i^{\text{loss}}])x_i + q_i - \sum_{j=1}^{n} y_{i,j} \ge ed_i^{\min}, \forall i \tag{9}$$

Equation (1) represents the first objective of the leader (i.e., regional authority), which aims to maximize the equity of the water allocation based on Gini coefficient [13]. Equation (2) represents the second objective of the leader (i.e., regional authority), which aims to minimize the environmental pollution to achieve the sustainability in water using at most. Constraint in Eq. (3) requires the water allocated to all sub-areas should be less than the available water in the river basin. Constraints in Eq. (4) require the water allocated to sub-area should meet the water using of special waters in sub-area. $E[\bullet]$ is the expected value operator proposed in Liu [7]. Constraints in Eq. (5) describe the range of water allocated to sub-area. Constraints in Eq. (6) restrict all water sub-area can get should be less than its maximum capacity. Equations in Eq. (7) represent the objectives of the followers (i.e., sub-areas), which aim to maximize the economic benefit of all the sub-areas. Constraints in Eq. (8) define the range of water allocated to water sector of sub-area. Constraints in Eq. (9) require that the ecological water should be met in each sub-area.

4 Model Analysis

From the decentralized bi-level model, the following results can be obtained.

(1) When $(1 - E[\tilde{\bar{\alpha}}_i^{\text{loss}}])x_i + q_i - ed_i^{\min} < \sum_{j=1}^{3} d_{i,j}^{\min}$, allocation principle: equity principle in the upper level, priority principle in the lower level.

(2) When $(1 - E[\tilde{\bar{\alpha}}_i^{\text{loss}}])x_i + q_i - ed_i^{\min} \geq \sum_{j=1}^{3} d_{i,j}^{\min}$, $x_i \geq \left(\sum_{j=1}^{3} d_{i,j}^{\min} + ed_i^{\min} - q_i\right) / (1 - E[\tilde{\bar{\alpha}}_i^{\text{loss}}])$, and $e_{i1} = e_{i2} = e_{i3}$, allocation principle: equity principle in the upper level, stress principle in the lower level.

(3) When $(1 - E[\tilde{\bar{\alpha}}_i^{\text{loss}}])x_i + q_i - ed_i^{\min} \geq \sum_{j=1}^{3} d_{i,j}^{\min}$, $x_i \geq \left(\sum_{j=1}^{3} d_{i,j}^{\min} + ed_i^{\min} - q_i\right) / (1 - E[\tilde{\bar{\alpha}}_i^{\text{loss}}])$, and $e_{i1} \neq e_{i2} \neq e_{i3}$, allocation principle: equity principle in the upper level, benefit-based principle in the lower level.

5 Case Study

Qujiang basin is taken as a case example to illustrate the proposed model. Qujiang river is the largest tributary of Jialing river basin in the upper reaches of Yangtze, it is across three provinces in southwest China, in this paper, the part of Qujiang basin in Sichuan Province is studied (see Fig. 3). From Fig. 3, the available water is supplied to five sub-areas: Bazhong (BZ), Nanchong (NC), Guang'an (GA), Guangyuan (GY), Dazhou (DZ). The data for the related parameters can be seen in Tables 1, 2 and 3.

Before solving the proposed model, the expected values of loss ratios of water transfer should be given. For the loss ratios of water transfer are triangle fuzzy random variables, in which the random parameters follow normal distributions. The expected value operator for triangle fuzzy random variables proposed in Xu et al. [12] can be applied to deal with fuzzy random loss ratios of water transfer. Thus, the model can be subsequently processed with the expected value of loss ratios of water transfer.

For dealing with the multiple objectives in the upper level, the weighted sum method based on satisfactory degree proposed by Gang et al. [2] is applied, the

BZ	5550	51917	11410	47955
NC	6050	36349	5675	39364
GA	21858	33187	6697	39792
GY	4850	3322	659	12298
DZ	23289	104172	21702	50490

weights are set as: for the first objective (i.e., the equity objective), for the second objective (i.e., the pollution control objective). Based on the data in Tables 1, 2 and 3, the water allocation planning of this case can be shown in Table 4.

From the results in Table 4, we know that the total available water in Qujiang basin (i.e., 4089×10^6 m^3) is less than the total minimum demand in all sub-areas, but is more than the total minimum demand for agricultural sectors and municipal sectors, which can be known that the water shortage situation is serious currently in the basin. In this paper, the regional authority makes decisions on allocating water based on equity (mainly) and pollution control. Through the comparison of the results with the practical allocation, it can be found that there is scarce water, the minimum demand for agricultural and municipal water sectors of all sub-areas can be satisfied using the proposed model. However, for more economic benefits, more water is allocated for industrial sectors, and the minimum demand for agricultural and minimal using cannot be satisfied in practice, which is not reasonable for the steady and development of the river basin. What's more, the decision making of the proposed model can effectively control the pollution under the premise of guaranteeing equity.

6 Conclusion

This paper proposed a decentralized multi-objective bi-level model considering equity, economic benefit and ecological environment for water resources allocation. In the upper level of the model, the regional authority aimed to achieve two objectives of equity and environmental pollution control by allocating water to sub-areas, in the lower level of the model, the sub-areas expected to get the maximal economic benefit by allocating water to different water sectors. In the model, fuzzy random loss ratio of water transfer was considered. Finally, a case study was conducted to verify the applicability of the proposed model. The comprehensive research on equity, sustainability and effectiveness of water resources allocation under different uncertain environments will be the future research direction.

SCADA and Artificial Neural Networks for Maintenance Management

Alberto Pliego Marugán(✉) and Fausto Pedro García Márquez

Ingenium Research Group, Universidad Castilla-La Mancha, 13071 Ciudad Real, Spain
alberto.pliego@uclm.es

Abstract. Nowadays, the reliability of the wind turbines is essential to ensure the efficiency and the benefits of the wind energy. The SCADA system installed in a wind turbine generates lot of data that need to be processed. The information obtained from these data can be used for improving the operation and management, obtaining more reliable systems. The SCADA systems operate through different control rules that are predefined. However, a static control of the wind turbine can generate a miscorrelation between the control and the real conditions of the wind turbine. For example, two wind turbines can be separated several kilometers in the same wind farm, therefore, the operation conditions must be different and the control strategy should not be unique. This research work presents a method based on neural networks for a dynamic generation of the control strategy. The method suggests that the thresholds used for generating alarms can vary and, therefore, the control of the wind turbine will be adapted to each specific wind turbine.

Keywords: Wind turbine · Reliability · SCADA systems · Advanced control analytics · Artificial neural networks

1 Introduction

The wind energy is currently the most important renewable energy, the capacity installed currently is more than 420 GW and it is estimated to be more than 1000GW in 2030 [3]. The maintenance and operation costs of conventional wind turbines are 12% of the total costs, but the wind energy is evolving towards the offshore location. It causes an important increase of these costs, being for offshore wind farms around 23% of the total costs [12].

SCADA systems are widely introduced in wind turbines (WTs) due to their effectiveness has been proved in other industries for detection and diagnostics of failures [9,11,16]. They are presented as an inexpensive and optimal solution [20] to control feedback for the health monitoring while reducing the operation and management costs [19]. Nevertheless, they also present some minor disadvantages due to the operational or reliability conditions [14,21]. These systems consider a large amount of measurements such as temperatures or wind and energy conversion parameters [18]. Data have raised considerable interest in different areas, e.g. wind power forecasting [17], production assessment [22] or fault detection [4,6,8,10].

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_75

In the case of WTs, the introduction of SCADA systems verifies the efficiency when their components are deteriorated. This degradation can indicate problems of different nature such as misalignments in the drive-train, friction caused by bearing or gear faults. The basic elements of the performance monitoring consist on a first collection of raw values by the sensors. After the application of the appropriate filters, anomalies are detected. Finally, a diagnosis will be provided. The anomaly detection includes a series of techniques that range from simple threshold checks to statistical analyses [5,7,15].

It has been demonstrated that the WT suffers a gradual loss of production. Figure 1 shows that the power has a decrease year by year (this study has been developed by Sheffield university in the OPTIMUS project [2]). The SCADA data has been considered over 5 years and the wind speed-power curve has been estimated.

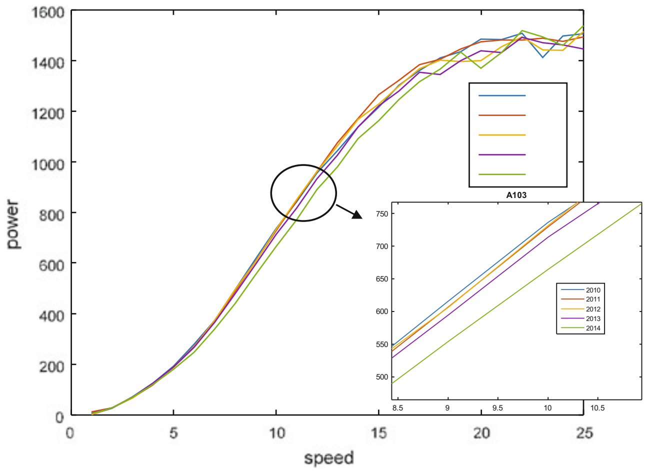

Fig. 1. Loss of power of a WT over the time

This paper present a signal processing considers the minor changes in the behavior of the WT. Some alarms will be affected by the decrease of the power shown in Fig. 1. The following alarms will be activated considering the power as a cause.

- Activation of the ice safe mode: One of the statements considered for this alarm is that the power is low for the measured wind.
- High aerodynamic deterioration: It is considered for low power with high wind.

If the power presented a minor reduction, then some false alarms would be activated because the SCADA was prepared for a higher power. However, if the control laws are dynamic, this problem will be solved.

2 Proposed Method

The method proposed aims to improve the control of the system by following a supervised iterative process. The objective is to determine if the SCADA control is coherent

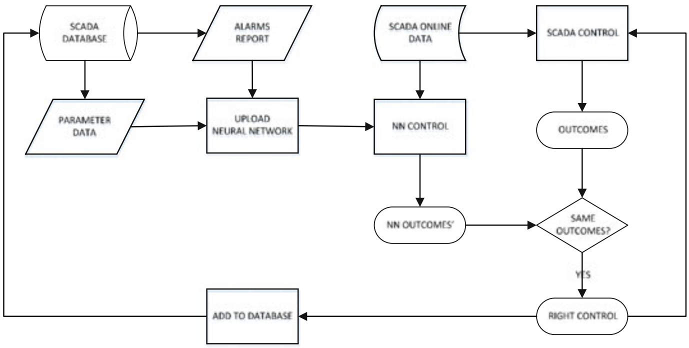

Fig. 2. Flowchart of the method proposed

with the historical data and, therefore, if the system has changed. The main capability of the method is to find differences in the behavior of the system over the time. Figure 2 shows a flowchart of the method proposed.

The iterative process starts with a database of the historical SCADA data. In this paper, two different types of data are considered: the value of the measured parameters and an alarm report. This data is employed to build an artificial neural network (NN) with a supervised training. The values of the parameters are employed as the inputs and the alarms will represent the outputs of the NN.

NN are used in problems that cannot be formulated as an exact method or an analytical solution. NN learns by itself and provides a good solution for the problem simulating the biological neurons in a reasonable time. An artificial NN consists of neurons that are simple processing units and weighted connections between those neurons [1].

It can be used for improving the control of the WT when the NN that defines the logic of the system has been generated. The SCADA system will provide online data of the condition of the WT. These data will be processed following two different evaluations: the SCADA system processing and the NN processing. Both outcomes will be compared. If the outcomes are equal, then the data will be added to the database, there for the NN processing will became an adaptive process.

3 Case Study

The European Optimus project [2] has provided the SCADA data used in this work. It measures a lot of parameters, but after a filtering process, only 34 parameters (see Table 1) have been considered for the analysis presented hereby. The values of this parameters will be considered as inputs for the NN.

Basically, the NN receives a dataset and make a training process to recognize several patterns. The training process fits the different weights to provide the output. If the output is known, then the training is defined as supervised, otherwise, it is called unsupervised training. The condition of the WT corresponds to the desired outputs of the NN. The data used to design the NN is divided in following groups:

Table 1. Inputs and outputs for neural network

No	Signal	No	Signal
1	General accumulator blade 1 pressure	18	Environmental temperature
2	General accumulator blade 2 pressure	19	Drive end side generator bearing temperature

- Training set: Around 75% of the total amount of data.
- Validation set: Around 15% of the total amount of data.
- Testing set: Around 15% of the total amount of data.

The NN is expected to be able to learn from data and predict the output when a generic input is considered.

The output of the NN will be specified by a Report of Alarms generated by the SCADA [2]. The data available consists of a serial of alarms registered from 01/10/2012 to 15/05/2015, where there are different types of alarms identified by a specific code. The codes are not indicated for reasons of confidentiality. In this work, only 5 different scenarios have been considered to simplify the example. These scenarios correspond to 4 different alarms and the absence of alarms.

Therefore, the NN will be created following the structure shown in Table 2.

The design of the NN has been carried out using the geometrical pyramid rule [13]. Figure 3 shows the structure of the NN built. This rule express an approximation of the number of neurons h at the hidden layer. It is defined by:

$$h = \sqrt{m \times n},$$

where m is the number of elements of each input and n is the number of possible outputs, being $m = 34$, $n = 5$, and therefore, $h = 13.03$.

Figure 4 shows the statistics of the NN generated by using the SCADA data. This is a global confusion matrix and corresponds to the sum of the training, validation and testing sets. The rows of the matrix show the outcomes of the NN for the dataset used.

Table 2. Inputs and outputs for NN

6	100% 0.0%	81.8% 18.2%	81.8% 18.2%	100% 0.0%	92.3% 7.7%	92.9 7.1%

Fig. 4. Results of the neural network: confusion matrix

The columns show the real output, i.e. the output established by the alarms. The diagonal of this matrix (grey cells) contains the desired solutions. The sixth row and the sixth column show a summary of the rights (green percentage) and wrongs (red percentage).

The outcomes of the NN agree more than 90% with the alarms that the SCADA system generates. The method proposed establishes that the control of the SCADA needs to be uploaded when the alarms cannot be predicted by the NN with enough accuracy. If the SCADA control and this NN have the same response, then the data processed will be added to the database. Therefore, a "healthy" dataset will be created and the control will be adapted to the real conditions over the time.

4 Alarm Prediction

The method proposed here by also allows for predicting a possible alarm. In the previous Sect. 3, a NN was generated by inputting the data that the SCADA system employs for generating the alarms. In this section, the input will be the data obtained before the alarm is activated, i.e. the objective is to predict an alarm before the SCADA system generates it. The NN is performed using the same techniques that in previous section. In this case the NN will be designed to distinguish whether alarm will be activated or not. Figure 5 shows the scheme used for the prediction. The inputs employed for performing the NN are the dataset collected before the alarms are activated.

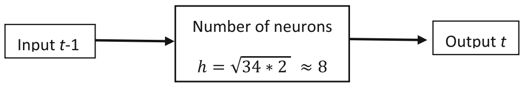

Fig. 5. Structure of the second neural network

Following the structure of Fig. 5, a NN has been performed obtaining the results shown in Fig. 6. This confusion matrix shows that the NN can predict a 20.1% of the alarms. Despite it is a low percentage when the NN suggests an alarm, it has a success of 62.1%.

Output \ Target	1	2	
1	5580 96.5%	143 2.5%	97.5% 2.5%

Fig. 6. Results of the second neural network: confusion matrix

This method can be used for determining the predictability of some alarms. This can be a useful tool to identify possible alarms before the WT can be damaged.

5 Conclusions

In this work, a new methodology is presented for extracting information from SCADA dataset. The methodology is based on the generation of neural network from the quantitative (value of parameters) and qualitative dataset (alarms) of the SCADA system. The methodology has two different purposes. In first place, the adaptation of the SCADA control rules to the variable condition of the wind turbines. A neural network has been generated to determine which data should be added to the database. The creation of a "healthy" database allows for adapting the SCADA control rules to the real condition of the wind turbine over the time. Secondly, an additional neural network has been created for making predictions of the activation of alarms. This can be used to identify an abnormal state of the wind turbine earlier than the SCADA.

Advances in Engineering Management of the Eleventh ICMSEM

Advances in Green Supply Chain, Resource Optimization Management, Risk Control and Integrated Project Management Based on the Eleventh ICMSEM Proceedings

Jiuping Xu(✉)

Uncertainty Decision-Making Laboratory, Sichuan University,
Chengdu 610065, People's Republic of China
xujiuping@scu.edu.cn

Abstract. Management Science and Engineering Management (MSEM) have significantly contributed to developments in society and economy, especially in management and control processes. In this paper, we first describe the basic concepts covered in the eleventh ICMSEM proceedings Volume II. We then conduct a review of engineering management (EM) research to identify the key areas, from which green supply chain, resource optimization management, risk control and integrated project management were found to be the most widely discussed research areas. After a summary of the key research achievements in the four areas, the high frequency EM keywords in the proceedings volume II are identified using NodeXL. The research trends both from MSEM journals and the ICMSEM are then summarized using the CiteSpace tool. As always, we are committed to providing an international forum for academic exchange and communication through the ICMSEM and plan to continue our innovative MSEM progress in the future.

Keywords: Green supply chain · Resource optimization management · Risk control · Integrated project management

1 Introduction

Management Science and Engineering Management, which emphasizes the theories, methods and engineering practice of complex management decision making, has been playing a vital role in both scientific endeavor and societal development. The increase in MSEM research in the past few decades has brought new vitality to management and engineering practice. At the same time, through the continuing and expanding development of innovative managerial tools, MSEM has significantly contributed to advancements in domestic and international economic development and increased general scientific management consciousness. MSEM is a complex synthesis with a broad research focus that combines complex management theories and practical engineering solutions to successfully solve management practice problems. This kind of cross-functional,

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_76

multidisciplinary research supports real world management execution, improves management efficiency, and contributes to energy conservation.

MSEM research is widely applied to management problems that involve extensive engineering concepts. In proceedings volume I, the focus is on management science (MS) and its future development trends. Engineering management (EM) is therefore the main focus of proceedings volume II. Kocaolgu's defined EM as a field that examines engineering management using comprehensive scientific research to develop innovative engineering solutions that can improve technical organization, technical resources, and technical systems [5], in areas such as manufacturing, construction, design engineering, and industrial engineering. The ICMSEM proceedings Volume II focuses on four key EM areas; the green supply chain, resource optimization management, risk control, and integrated project management.

2 Literature Review

To better analyze the pertinent research fields and possible research directions, we reviewed the most popular research areas in the most recent EM research. What emerged was that the green supply chain, resource optimization management, risk control, and integrated project management have been the most widely studied in recent years. In this section, we review the related literature to analyze the developmental tracks in these four areas.

2.1 Green Supply Chain

The supply chain management concept emerged in the early 1980s, with the green supply chain (GSC) being first proposed by Michigan State University Manufacturing Research Association in 1996. Lambert et al. defined supply chain management as the integration of key business processes from the end user to the original suppliers to provide products, services, and information to add value for customers and other stakeholders [8]. Brazil Sarkis examined the social and cultural dimensions in green supply chain management and found that cultural boundaries govern the type of management skills and control processes used [7]. To empirically investigate the construction and scale of green supply chain management (GSCM) implementation by manufacturers, Zhu et al. tested two GSCM implementation measurement models and compared them using confirmatory factor analysis [19]. As a supply chain grows in scale and operation, its structure becomes more complicated. Some scholars have taken a fresh look at integrated green supply chain management [4, 13, 14] to ensure continuing sustainability.

2.2 Resource Optimization Management

Resource optimization management (ROM) is the efficient and effective deployment and allocation of an organization's resources when and where they are needed. Such resources may include financial resources, inventory, human skills, production resources, or information technology. Resources and energy shortages have become the main factors restricting the sustainable development of national economies, as low resource efficiency and high energy consumption can result in a serious waste of resources putting significant pressure on resources and environmental governance. Vadenbo presented a general multi-objective mixed-integer linear programming (MILP) optimization model aimed at providing decision support for waste and resource management in industrial networks [15]. Further, energy resource shortage problems associated with rapid social and economic development have been of critical concern to both national and local governments worldwide for many decades [9]. Water, as one of the most important resources on earth has therefore received a great deal of research attention, with water optimization management being a major focus in the past few years [1, 12, 18]. ROM involves all aspects of social life, so research strives to further develop this area using modern computer technology.

2.3 Risk Control

Risk control (RC) is the coordinated and economic application of resources to minimize, monitor and control the impact probability of unfortunate events, or to maximize the realization of opportunities after the identification, assessment and prioritization of risks. Muriana and Vizzinib presented a deterministic technique for assessing and preventing project risks by determining the risk of the Work Progress Status [10]. Valtonen et al. studied public risk management related to the use of public land development by analyzing case studies in Finland and the Netherlands, both of which have strong public land development traditions [16]. By identifying risks, specific state support and special project management measures have been developed to limit the negative influence of the possible project risks [17]. Therefore, developing a general framework to analyze corporate risk management policies and ensure risk control is vital [6]. In brief, RC includes transferring risk to another party by avoiding risk, reducing the negative effects of risk, and accepting some or all of the consequences of a particular risk.

2.4 Integrated Project Management

Integrated project management (IPM) is a philosophy that recognizes the different elements involved in projects to apply strong team leadership and encourage a collaborative ethos with clear purposes and strategies to ensure success. Planning, organizing, securing, and managing resources to successfully complete specific project goals and objectives are the main IPM research areas, the applications for which have been used in manufacturing, construction, design engineering, industrial engineering, technology, production and many other areas. Atkinson provided some thoughts about the success criteria for project management in which cost, time, and quality have become inextricably linked to project management success over the last 60 years [2]. An integrated methodology was developed for planning construction projects under uncertainty that relied on a computer supported risk management system to identify the risk factors in the integrated project [11]. IPM has also been applied to integrated waste management systems to identify the optimal breakdown between materials and energy recovery from municipal solid waste [3]. In all, integrated project management is a complex subject and needs to be examined from several perspectives.

3 Central Issues in the Proceedings Volume II

Keywords are an important index for the identification of essential content in research articles. The keywords in the 75 articles in Volume II were extracted to a database to allow for a tendency analysis. The keywords were sorted using the Keywords Match software that matched the keywords that were uniform or similar. Finally, the matched keywords were imported into NodeXL software to obtain the initial visual image shown in Fig. 1.

Fig. 1. DAS literature mining

With EM as the key component, the open source software tool NodeXL was used to facilitate the learning of the concepts and methods. To begin with, some key words were processed to unify expressions and keywords with the same meaning. This preliminary process reduced the number of keywords, making it possible to develop an efficient network. At the same time, the vertices' shapes were set to determine the betweenness and closeness centrality. When the degree of a vertex's betweenness and closeness centrality was more than five, the shape of this vertex was a red diamond in the resulting figure. The aim of this analysis was to determine the key EM concepts that connected with other research topics through the primary nodes. After calculating, clustering and filtrating, the results in Fig. 2 illustrate the important research relationships.

The above analysis highlighted the key areas focused on in the proceedings volume II; green supply chain management, resource optimization management, risk control and integrated project management problems related to green and pro-environment concepts. Tao focuses on a simplified manufacturing and distribution supply chain planning network focused on carbon emission constraints, for which a bilevel programming model was mathematically formulated. Through the study of related emissions policies, Lu finds that under different carbon policies, revenue sharing contracts are able to coordinate the supply chain with the manufacturer's revenue sharing proportion under

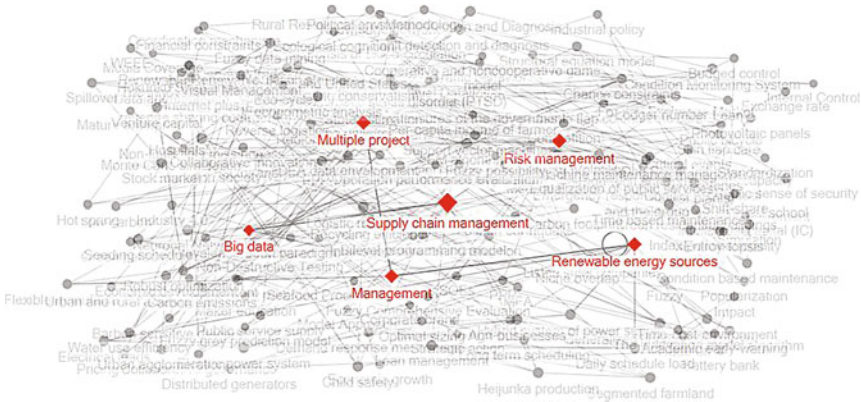

Fig. 2. Research topics in EM for the Eleventh ICMSEM

a cap-and-trade being always less than a situation in which there is no carbon emissions constraint. Machado and Duarte present an overview of Industry 4.0, a new developing concept in the field of industrial engineering, and lean and green supply chain management, for which a conceptual model is developed. Wang et al. concludes that when big data suppliers are part of the supply chain competition and one party gains a dominant supply chain position, collaborative decision-making is the key to enhancing overall supply chain profitability. These studies highlight the many new characteristics involved in green supply chains, such as big data and carbon emissions reductions.

Resource optimization management primarily covers resource processing, exploitation, production, and consumption. Arifjanov and Zakhidov consider an issue for the development of methods for the estimation of electrical loads for various electricity customers in residential and public buildings, and address issues related to the integration of distributed generators to the UES to ensure the optimal management of technological modes. Gómez Munoz et al. develops an optimal maintenance strategy that includes the NDT system to reduce costs and increase the competitiveness of renewable energy sources. For water resource optimization, Tu et al. proposes an equity and sustainability based model that considers equity, economic benefit, and ecological environment and Liu et al. uses a DEA method to establish an evaluation model to empirically study the urban agglomeration of Chengdu city from 2008–2014. Because of the wide use and serious shortage of some resources around the world, scientific research into resource optimization management has increased to assist governments and enterprises around the world.

Risk control is important in all organizations and enterprises. In this section, Zhou et al. presents a model to mitigate the risk of budget overruns during raw materials procurement, and Chen et al. provides a risk allocation model using a fuzzy comprehensive evaluation method aimed at optimizing risk allocations, reducing transaction costs, and enhancing comprehensive benefits from the perspective of state-owned enterprises. Beside these studies, to better control risks occurring in financial markets, Shibli et al. investigates the link between the foreign exchange markets and the stock market in

Bangladesh by examining the volatility spillover between the markets, volatility persistence, and the asymmetric effect of information on the volatility of these two financial markets. In addition, Zhang et al. studies a projection pursuit risk assessment model using a combined method to model PPP risk under the background of Big Data. Effective risk control can reduce potential risk factors and assist managers gain increased benefits.

The last section in Volume II focuses on the developments in integrated project management. Elchan defines the scientific problems associated with management at the beginning stages of an innovation project in the departments of a technology park at a higher education school in Azerbaijan. Based on principal-agent theory and game theory, a theoretical framework for a knowledge network conflict coordination mechanism is constructed by Wei, which divides the conflict coordination mechanism into three levels; contract mechanism, self-implementation mechanism, and a third-party conflict coordination mechanism. Sheng et al. proposes suggestions and countermeasures for the equalization of public services in urban and rural areas from three integrated project aspects and Tu et al. develops two staged fuzzy DEA models with undesirable outputs to evaluate the banking system. The overall process of leading, organizing, staffing, planning, and controlling activities requires managers to use systems viewpoints, methods, and theories to optimize the work involved when seeking effective integrated project management under limited resource constraints.

4 Evaluation of EM and ICMSEM Development Trends

In this section, we evaluate the ICMSEM to validate that the research trends are in line with the trends emerging in current MSEM journals. At first, CiteSpace, an information visualization technology developed by Chen, was utilized to draw the a scientific knowledge map that display the development trends in a discipline or knowledge domain over a certain period, and identifies the possible evolution through an analysis of the research frontiers.

"Advanced search" with "engineering management" was used as the identifier in the "web of science" database with a timespan from 2000 to 2017. Initially, 42499 published articles were identified and after the final screening using TI = (engineering management) 2963 articles were reviewed.

4.1 The Development Trends of EM

The statistics from the 2963 articles recorded output were saved and converted into CiteSpace which transformed the data into a format that could be identified by the software to allow for parameter selection. In this operation, the time span was from 2000 to 2017 with the time slice set at one year and the theme selection based on the titles, abstract subject words, identifiers, and keywords to allow for node selection. Then, each zone with the 30 highest keyword records were clustered and analyzed, from which a map was drawn for the minimum spanning tree. As shown in Fig. 3, by setting the

"Threshold = 30", a total of 348 nodes were obtained, with the overall network density being 0.0098. Therefore, the system frequency identified green supply chain management, environmental management, project management, risk management, and models and systems as the highest ranked areas. This not only displayed the most popular research fields in engineering management but also implied the future EM development trends.

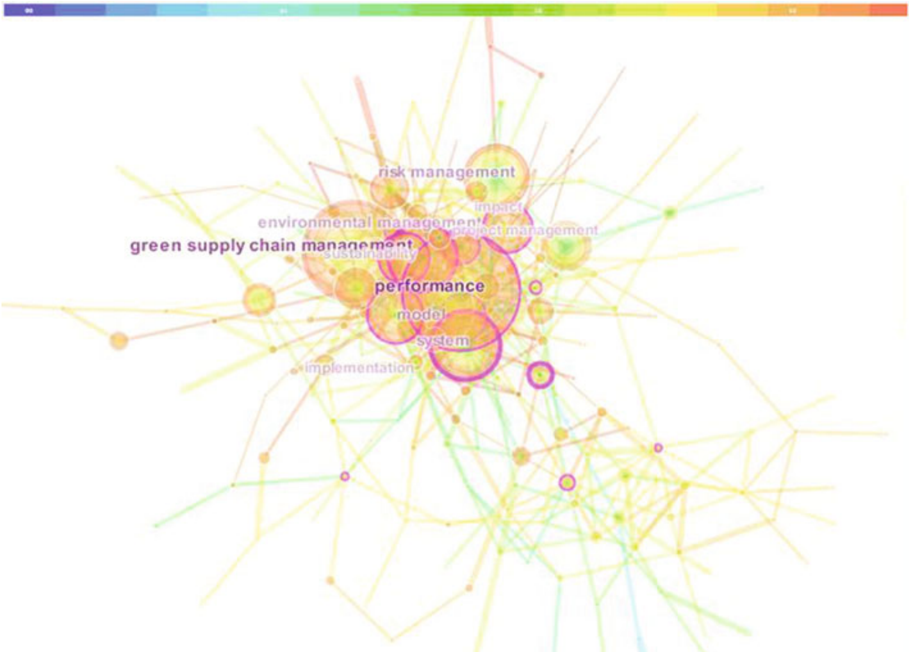

Fig. 3. The results of co-occurring keywords in EM

With a reference frequency running from high to low, the top thirty were analyzed from the 348 keywords. As shown in Table 1, the keywords such as green supply chain management, risk management, environmental performance and sustainability had a relatively high centrality.

Using the keyword with the label title clustering, 40 categories were identified; however, only the top 10 categories are shown in Fig. 4. The other topics were relatively dispersed so are not displayed, which indicated that scientific engineering management research was relatively loose. In particular, the new keywords for 2015 and 2016 have not resulted in significant research attention.

23	0	2003	Peripheral Vascular Disease

quency research areas and timezone view diagram were identified, as shown in Fig. 5. Most of these high frequency words appeared in the early days, indicating that engineering management research has been focused around these topics for quite a long time. The analysis of the top 30 most frequent words (Table 2), found that engineering, business and economics, computer science, environmental science and operations research are currently the most popular research areas.

From Tables 1 and 2, the papers presented in this year's ICMSEM proceedings volume II closely reflect the most pertinent engineering management research areas; green supply chain (systems management, industry, green and environmental protection), resource optimization management (environmental sciences, water resources, engineering education), integrated project management (project management, industry, integrated project) and risk control (risk management, risk, design, information). In addition, the computer science and environmental science research highlights how high-tech can spur social progress and environmental protection.

We believe that EM should focus on the study of specific EM problems as well as popularizing MS knowledge. Excellent academic research can effect developments across the world, but a further focus on regional areas is also needed. To ensure a bright EM future, there is a need for inspiration, practical theories, effective methods, and extensive applications in future developments. To achieve this, EM knowledge needs to be popularized, which is the duty of all MSEM academics. In the future, more focus on low carbon emissions, environmental protection, big data, energy utilization, and other popular EM issues are needed.

5 Conclusion

Engineering management is a complex area that involves all engineering aspects. The open source software tool NodeXL identified the four areas covered in the eleventh ICMSEM proceedings Volume II, from which we summarized the key research in this year. To analyze the EM and ICMSEM development trends, we identified the main search terms and keywords using CiteSpace. Our key objective is to continue to improve the quality of papers in the proceedings and to ensure the ICMSEM organization is dynamic and appealing to EM researchers worldwide. EM research is continuously developing and new trends are appearing every year; however, more research is necessary so as to popularize EM developments and provide a more active research forum.

Green Supply Chain

Modelling a Supply Chain Network of Processed Seafood to Meet Diverse Demands by Multi-branch Production System

Koichi Murata[1(✉)], Seiichiro Isobe[1], and Hiroshi Katayama[2]

[1] College of Industrial Technology, Nihon University, Tokyo, Japan
murata.kouichi30@nihon-u.ac.jp
[2] Faculty of Science and Engineering, Waseda University, Tokyo, Japan

Abstract. The demand for processed seafood has recently increased owing to diversity of taste and the crises of food supplies. Processed seafood companies have the potential to manufacture various products by combining fish varieties and processing methods. They also associate with many customers such as other food processing companies, food service industries, FMCG companies, and end users. This study aims to reveal the supply chain model of processed seafood to multi-customers by the multi-branch production system. A model is constructed to understand the practical system from a theoretical perspective. The main finding of the study is that four paths of the proposed network model between a seafood processing company and customers exist: (1) defrosting to processing, (2) cleaning to service, (3) processing to service, and (4) seasoning to retail. These findings clarify the supply chain network in the industry and help consider business opportunities.

Keywords: Food supply chain management · Seafood processing industry · Model approach

1 Introduction

Fish and seafood have recently become important materials to meet diversified customer needs resulting from the food crisis caused by population explosion and the requirement of seafood which is essentially healthy (i.e. low calorie count and nutrient intakes) and which provides convenient meals for a two-income family, a child-rearing family, and aging society in advanced counties. To match the resultant explosive demand, the globalization of the seafood supply chain has increasingly progressed with technological innovation. For example, the cold chain has expanded to maintain the freshness of materials through improvement of freezing technologies for transport worldwide [11]. A traceability system has been developed to obtain the trust of customers by informing them of the safety of materials by a physical sensor system and information technologies [6].

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_77

In the Japanese context, to aim for the creation of a tourism nation and for the next summer Olympic Games in 2020, an enrichment of the food supply chain is required. The Japanese dietary culture called 'Washoku', registered as a 2013 Intangible Cultural Heritage by UNESCO, must be a powerful weapon for executing the strategy. Processed seafood, one core ingredient of 'Washoku', is manufactured in small and medium enterprises (SMEs) mostly located in the area that experienced the Great East Japan earthquake (Higashi Nihon Daishinsai) on 11 March 2015. Furthermore, the occurrence of climate change including global warming and abnormal weather and over-fishing by neighbouring countries causes a decrease of marine resources in the Pacific Ocean. These SMEs operate on a small scale and sell processed seafood to identified customers according to their requirements. For the future, they must overcome difficulties and reinvent themselves to obtain new markets and customers worldwide through business innovation.

Many studies related to the seafood supply chain have presented new perspectives, including open innovation of seafood value chain [12], an international distribution system [1,2], firm structure [4], quality assurance with labelled seafood products [7], a sustainable system [3], marketing and economic innovation [5,9,14], seafood supply chain management [10], and an inventory system [8]. However, there are not enough studies related to innovation of the business model which give an overall perspective to change the present business structure.

Based on the recognition of current practical and academic conditions, the present study aims to explore the business model of the processed seafood industry with the concept level as the starting point of the study. Specifically, the network between a food processing company and its customers is focused on understanding the exciting business style of the food processing company and grasping the possibility of cultivating routes to new customers.

2 Methodology

This study tries to draw the network structure between one food processing company and its candidate customers because a clarification of the relation among participants firstly needs to retrieve investment points for business expansion. The description is performed based on an observation and an interview of several seafood processing companies in the rebuilding project after the Great East Japan earthquake for three years. The authors of the present study have gradually understood these companies business structure through investigation and a trial-and-error method. This study presents the results. The method to build the described model is business modelling which reveals the following things pursuant to the aim of the study [15]:

The business model is emerging as a new unit of analysis.

- Business models emphasize a system-level, holistic approach to explain how firms 'do business'.
- Firm activities play an important role in the various conceptualizations.

- Business models seek to explain how value is created, not just how it is captured.

This research also reference typical models related to a production system, such as make-to-order (MTO) and make-to-stock (MTS) models [13].

Four steps are adopted in this study. The first is based on the seafood cooking process. Seafood processing companies cook materials at the location of mass customers. The step will be useful to identify fundamental processes in a production system for seafood processing. The second is the deployment of candidates of a customer. They are other food processing companies, food service companies, fast-moving consumer goods (FMCG) companies, and consumers. This step describes the details of the four customers because the purpose of the step is to become aware of new customers that differ from existing customers. In the third step, a network model is constructed to visualize a possibility of new business through a combination of outputs in the first and second steps. The final step is a confirmation of the capability of the constructed network through an initial discussion of business expansion in the future. The flowchart of all steps is provided in Fig. 1.

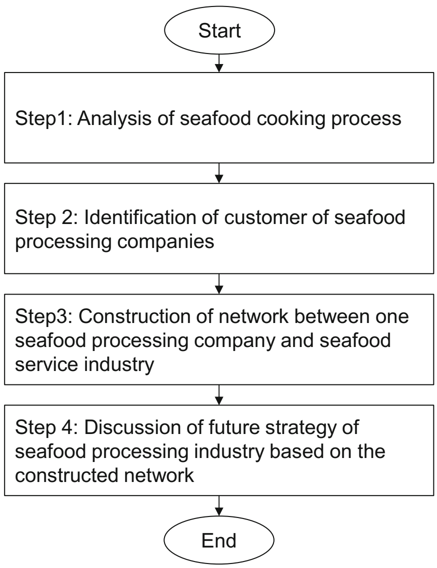

Fig. 1. Research procedure.

3 Construction of Seafood Supply Chain Model

This section describes the result of each step illustrated in Fig. 1.

3.1 Seafood Cooking Process (Step 1)

The journey to develop a processed seafood business model in this study starts with the understanding of daily eating habits as follows. The main processes to eat seafood have not changed from ages past, as shown in Fig. 2: fishing, cleaning, processing, seasoning, and eating. The middle three processes exist mainly to add value to fresh fish. These can be omitted and exchanged in the cooking process. Many techniques and skills are included to make the materials taste even better. The detailed explanation of each type is as follows:

(1) Fishing process

This process is considered a preparation part for processed seafood production involving obtaining the materials. The quality level of the materials depends on size, weight, appearance, freshness, variety, and so forth. Over-fishing and climate change seriously affect a haul of fish. A fishing quota by multiple nations and enclosed aquaculture with the newest biotechnologies are countermeasures for sustainable marine resources.

(2) Cleaning process

The complicated body of fish and seafood causes a decline in the productivity of seafood processing. It is basic and important to protect customers' safety from dangerous parts which they cannot eat (i.e. hard fish, thick bone, and the internal organs of a fish including poisonous substances). The variety of processes includes carving, boning, scaling, and filleting. Accurate fileting of large fish like salmon requires immense skill with yield rate and waste disposal.

(3) Processing process

This process is the main portion of seafood processing. Representative methods of the process are grilling, reducing, frying, steaming, and drying. The selection of each method relates to a core business of a seafood processing company with a large investment in production facilities. The design of the process profile of production by the selected method is a company secret relating to the organoleptic feel of processed seafood because many companies adopt the common categories of methods noted above.

(4) Seasoning process

This process is the portion that adds tastiness and flavour-value to a processed item. In Japan, there are five traditional popular seasonings, such as sugar (Sato), salt (Shio), vinegar (Su), soy sauce (Shoyu), and soybean paste (Miso). They characterize the taste of Japanese seafood called 'Washoku', which was registered as a 2013 Intangible Cultural Heritage by UNESCO. Chemical seasoning widens the possibility of new ways to enjoy processed seafood.

(5) Eating process

This is the final process to synthetically evaluate the quality of the four processes by consumers. In this stage, not only the taste of processed seafood, but also a dishing, including a selected plate and a side dish, influences the total impression. The family styles of advanced countries, such as a two-income family, a child-rearing family, and the aging society, also require the convenience of a microwave oven and reheat pouches.

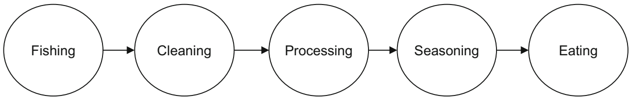

Fig. 2. Basic process to eat seafood

In the present age, the division of the five processes between fisheries and consumers depends on consumers' requirements. It indicates the following five models proposed in Fig. 3.

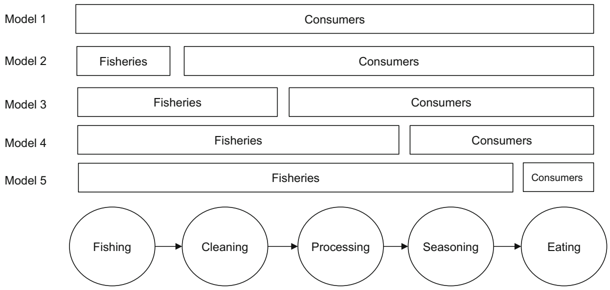

Fig. 3. Division of roles between fisheries and consumers

Consumers do not need support from fisheries in Model 1, which constitutes a hobby. In the case of Model 2, the fishing industry will exist in a market near a fishing port with consumers. In the three models consisting of two processes and more by fisheries (i.e. Models 3 to 5), the division of roles occurs among three industries: (I) fishing industry, (II) seafood processing industry, and (III) seafood service industry including restaurant and retail businesses. The division is considered based on the two following assumptions:

- The fishing industry is necessarily in charge of the fishing process.
- The orders of the three industries do not become reversed.

Nineteen sub-models of the three models are summarized in Table 1. Models 3, 4, and 5 contain 3, 6, and 10 sub-models. Processed seafood is sold directly to consumers or through a mail-order system and internet service when the sub-model consists of (I) the fishing industry and (III) the seafood service industry. (II) The seafood processing industry asks (III) the seafood service industry to sell their products in addition to the above-mentioned selling methods when these two entities exist in the sub-model. This table shows that (II) the seafood processing industry can choose, in theory, appropriate sub-models from the alternatives. The flexibility seems to suggest the possibility of expanding the business of each seafood processing company.

Table 1. Sub-models of Models 3 to 5

Model	Fishing	Cleaning	Processing	Seasoning	Note
3	I	I	-	-	Selling directly to customers
	I	II	-	-	Selling by a service industry or directly to customers
4	I	I	I	-	Selling directly to customers
	I	I	II	-	Selling by a service industry or directly to customers
	I	I	III	-	Selling directly to customers
	I	II	II	-	Selling by a service industry or directly to customers
	I	II	III	-	Selling directly to customers
	I	III	III	-	Selling directly to customers
5	I	I	I	I	Selling directly to customers
	I	I	I	II	Selling by a service industry or directly to customers
	I	I	I	III	Selling directly to customers
	I	I	II	II	Selling by a service industry or directly to customers
	I	I	II	III	Selling directly to customers
	I	I	III	III	Selling directly to customers
	I	II	II	II	Selling by a service industry or directly to customers
	I	II	II	III	Selling directly to customers
	I	II	III	III	Selling directly to customers
	I	III	III	III	Selling directly to customers

(I) fishing industry, (II) seafood processing industry, and (III) seafood service industry.

3.2 Customers of Processed Seafood Industry (Step 2)

Customer candidates for (II) the processed seafood industry are rich in variety. The main candidates are four types of seafood service companies: other food processing companies, food service companies, fast-moving consumer goods (FMCG) companies, and consumers. The explanations of each type are as follows:

(1) Other food processing companies

These customers use the product supplied from seafood processing companies as one material of their final products. For example, raw materials are supplied from a company which manages a large-capacity frozen warehouse to store them cheaply and in huge quantities. Cleaned materials (i.e. seafood paste and fish cut into small cubes) also have high value for customers who do not have technical know-how.

(2) Food service companies

These customers are food service companies including restaurant businesses; home-delivery services; services for the provision of meals by a school, hospital, or welfare facilities. They basically have a kitchen which has the capacity for making and serving meals with materials supplied from seafood processing companies to their customers. Moreover, if their business model is a franchise chain, they construct a supply network with a central factory which executes the middle processing of materials for speedy and effective servicing of meals at all their shops.

(3) FMCG companies

These customers are types of FMCG companies (e.g. a convenience store, supermarket, shopping mall, or department store). They mainly offer two services. One is the direct sale of goods supplied from seafood processing companies. The other is the sale of a daily dish including simple processed/cooked materials. Their customers are end users who live near these small shops. FMCG companies obtain large sales accumulated across their many branches, but the number of end users is limited for one store.

(4) Consumers

Seafood processing companies usually do not directly access end users except in face-to-face sales like at a regional festival and special sales once a year. They contact end users to sell their products through a mail-order system with mass-communication and a system of online electronic commerce. This opportunity will increase in the era of the internet.

3.3 Network Between Seafood Processing Company and Seafood Service Industry (Step 3)

Figure 4 illustrates the relationship between one seafood processing company and seafood service companies. The left side of the figure is a typical production system in a seafood processing company. This system mainly consists of four processes: defrosting, cleaning, processing, and seasoning. The first one is a process to prepare frozen materials and deliver them to maintain their freshness while restraining freezer burn if possible, by a fishing company, and to maintain a sufficient inventory. The other three processes add appropriate values to the defrosted materials described in the previous section. The notable characteristic of the system is a multi-branch production system with the potential to supply semi-processed products as final products to customers.

Owing to the capability of the industry, candidate customers are rich in variety, as shown in the right side of the figure. Main candidates are the four types of seafood service companies mentioned above (i.e. other food processing companies, food service companies, FMCG companies, and consumers). While centring on seafood processing companies, they should consider all combinations between processes of seafood processing and four types of seafood service companies. In particular, the following four paths are useful for food service companies to realize their service while reducing initial workloads.

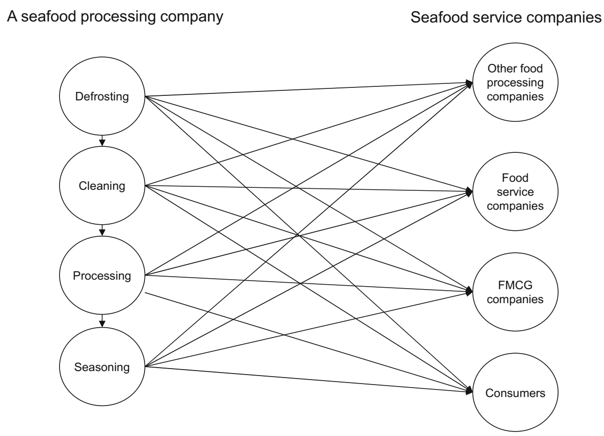

Fig. 4. Relationship between a seafood processing company and seafood service companies.

(1) A path from defrosting to processing (DTP)

In this path, seafood processing companies supply frozen/defrosted materials to other food processing companies. The added-value is a supply system of materials sufficient both in quality and quantity. Seafood processing companies must improve the refrigeration capacities of inventory and transportation. Owing to these functions, other food processing companies outsource procurement operations.

(2) A path from cleaning to service (CTS)

In this path, seafood processing companies supply frozen materials to seafood service companies. The added-value is a system to clean masses of fish and seafood. The seafood processing company must improve its capability through training of skills related to the operation and its automation. Owing to this function, food service companies will concentrate on creative cooking and close servicing, which are considered to be their core functions.

(3) A path of processing to service (PTS)

In this path, seafood processing companies supply processed materials to seafood service companies. The added-value is a mass production system of processed seafood. Seafood processing companies should improve the main process in their business. Owing to this function, food service companies will provide effective and uniform services to their customers with simple cooking.

(4) A path of seasoning to retail model (STR)

In this path, seafood processing companies supply seasoned materials to FMCG companies. The added-value is a mass supply system of processed seafood. Seafood processing companies should improve the main processes in their business. Owing to this function, retail companies can sell various moderately priced and tasty items to end users every day.

3.4 Future Strategy for Seafood Processing Company (Step 4)

To confirm the utility of the constructed network model in the previous sections, a future strategy of seafood processing companies will be considered in this section.

Most SMEs continue to do business along one path of the network model described in the proposed network in Fig. 4. They may consider the path as the only possibility for their business with limited management resources. However, they should understand two characteristics of their industry.

One is the flexibility of their production system. It is possible to supply products from any process in their production system. For example, if the current path of the network model is STR, semi-products of the path become fully final products for the other three paths (i.e. DTP, CTS, and PTS) without large facility investment. The other is that they have many candidate customers. If the current path of the network model is CTS, the same product could be supplied by PTS. The development of a new path is naturally difficult, even if the potential of the path is recognized. However, it will be a valuable trial to expand business in the future.

The utility of the proposed network is confirmed because it is useful to consider a subject to realize new business possibilities with the characteristic production system based on the above discussion.

4 Concluding Remarks

This study aims to reveal the supply chain model of processed seafood to multiple customers via a multi-branch production system. The findings consist of four paths: (1) DTP, (2) CTS, (3) PTS, and (4) STR. They clarify the supply chain network in the industry and consider the opportunity of the business. A future study could provide a mathematical formulation of the network model to quantitatively simulate and evaluate the impact of each path.

Hybrid Global Supply Chain Design Considering Product Families and Layered Cellular Design

Jue Jiang and Gürsel A. Süer(✉)

Department of Industrial and Systems Engineering,
Ohio University, Athens, OH 45701, USA
suer@ohio.edu

Abstract. This paper proposes a new hybrid global supply chain strategy for a global blood sugar manufacturing company. In this approach, products are analyzed based on product families. Product families can share cells across the globe if needed. The results are compared with the host market strategy where three manufacturing plants located in three regions to meet world demand. Manufacturing plants are designed considering layered cellular design approach under stochastic demand. This approach allows three cell types; (1) dedicated cells where each dedicated cell can be used only by one family, (2) shared cells where a cell can be shared by two product families, and (3) remainder cells where a cell can be used by three or more families. The main focus of this paper is to compare both alternatives with respect to number of manufacturing cells and number of machines needed. In this case, number of machines remained the same for both approaches. However, the proposed new approach led to more dedicated cells.

Keywords: Global supply chain · Layered cellular manufacturing · Stochastic demand

1 Introduction

This research aims designing a manufacturing system for a global blood sugar strip manufacturer. Three manufacturing facilities located in different continents are assumed to meet the demand of these regions. By using layered cellular manufacturing concepts, number and type of manufacturing cells are determined for each manufacturing facility considering stochastic demand data and production rates. Later, this supply chain strategy is compared with the proposed one in this paper where some cells are shared globally. A probabilistic method is used to design the cells.

The type of a manufacturing system mostly depends on the layout of the manufacturing system. As mentioned in Süer, Huang and Maddisetty [19], manufacturing systems can be classified into four categories based on the layout: process layout, fixed layout, cellular layout and product layout. Fixed Layout

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_78

is used when products are heavy and large and therefore are mostly stationary. Therefore, products typically stay in the same position and workers, machines and equipment are brought to the products to perform the tasks [19]. Product Layout is appropriate when production volume is high and product variety is low. Product layout is usually very efficient since it can be configured to perfection for a single product but this makes it an inflexible system. Process Layout is the best system for low production volume systems with high product variety [19]. These systems are very flexible since they can handle many different products but unfortunately they are not very efficient since they requires extensive material handling and thus lead to long leadtimes. On the other hand, Cellular Layout is more flexible than Product Layout and more efficient than Process Layout. It suits well for high product variety with low to moderate demand [19]. Figure 1 shows the classification of four layout types. Obviously, a manufacturing system can indeed consist of any number of layout types as well such both Cellular Layout and Process Layout etc.

Cellular Manufacturing is based on the grouping of similar products with respect to similar processes into one or more similar cells as required. In the real manufacturing world, many uncertainties exist in the system such as demand uncertainty, supply uncertainty and processing uncertainty. These uncertainties have been discussed extensively in many research works. Süer, Huang and Maddisetty [19] proposed to consider the uncertainties of product demand and processing times. By probabilistic market demand calculation, the part-family assignment is achieved [19]. Then, low utilized cells are grouped to increase the utilization of the system i.e., to reduce the number of machines and thus investment, even though some of these cells may no longer be pure cells. These different cell types, namely, dedicated (DC), shared (SC) and remainder (RC) cells are also shown in Fig. 1.

Supply chain is the network connecting suppliers, manufacturers, distribution centers and customers [16]. Dicken [7] discussed many supply chain models.

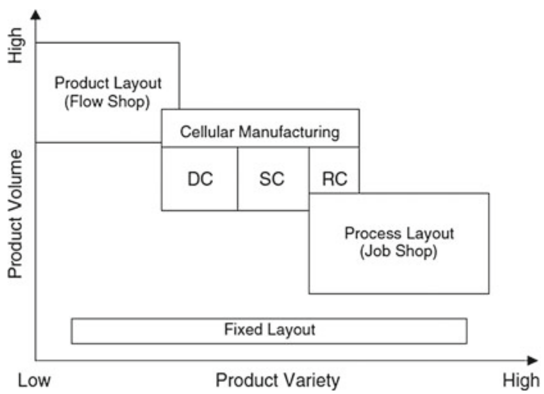

Fig. 1. Four types of manufacturing layout [19]

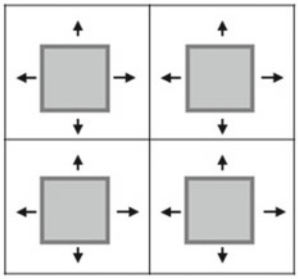

Fig. 2. Host market production model [7]

Among them, host market production model is illustrated in Fig. 2. In this strategy, each of the geographic regions covers its own demand. In this study, this strategy will be compared with the newly proposed hybrid global supply chain strategy that considers product family definitions and layered cellular approach.

2 Literature Review

Literature regarding global supply chain and cellular manufacturing systems is summarized in this section.

Chopra and Meindl [6] introduced that supply chain model includes three logistical drivers and three cross functional drivers. They defined logical drivers as facilities, inventory and transportation and three cross functional drivers as information, sourcing and pricing. Brush, Maritan and Karnani [2] mentioned that many factors affected a network of multinational manufacturing facilities. Besides considering facility selection, Haug [9] also considered production shifting. A facility location model was developed to study the location decision of high technology firms. The model identified the international manufacturing facility location based on domestic and potential international production markets. This allowed production to be transferred from domestic manufacturing facilities to foreign facilities. This allowed production to be transferred from domestic manufacturing facilities to foreign facilities. Lowe, Wendell and Hu [13] included production capacity to develop a two-phase multi-screening approach to incorporate uncertainty about exchange rates and exchange rate risk. Canel and Das [4] improved national market into global supply chain market by considering connection among global markets. Canel and Das [4] developed an integrative mathematical model to connect global manufacturing and marketing. Jiang and Suer [11] compared two supply chain strategies in their work. The paper is based on their work and hybrid supply chain strategy is developed as an alternative approach. Ates [1] designed supply chain for the same product category and later simulated competition among four global manufacturers.

Group Technology (GT) was introduced to improve productivity in the Cellular Manufacturing System (CMS). Hyer and Wemmerlov [10] discussed Group

Technology in cellular manufacturing. Rajamani, Singh and Aneja [17] also mentioned that GT played an important role in cellular manufacturing. Singh and Mohanty [18] observed that not many works in the literature used fuzzy concepts to deal with multi-objective framework in the process planning. Chen and Cheng [5] proposed a supplementary procedure to solve the limitation of Adaptive Resonance Theory (ART). They mentioned that the performance of ART depended on the initial matrix of bottleneck process. The proposed supplementary procedures could improve the reliability of results. Moreover, a new mathematical model based on cell utilization was conducted by Mahdavi, Javadi, Fallah-Alipour and Slomp [15]. A comparison of part-machine grouping from this proposed method with the mathematical model from Chen and Cheng [5] was tested. The model from Mahdavi, Javadi, Fallah-Alipour and Slomp [15] tended to produce better results. A mixed integer non-linear model was analyzed by Bulgak and Bektas [3] for CMS. In this paper, the proposed model was an integrated approach to combine production planning and system reconfiguration. This CMS model was a new model, which includes sequence, duplicate machines, capacity of machines and lot splitting.

The literature reviews discussed so far included the deterministic CMS problem. However, cellular manufacturing is difficult to design in the real world due to uncertainty of manufacturing process. In order to deal with the uncertainty of product demand along with processing time, another research is proposed by Süer, Huang and Maddisetty [19]. A heuristic methodology was conducted to distinguish cell types in the CMS - Dedicated Cell (DC), Shared Cell (SC) and Remainder Cell (RC). The product family configuration and cell allocation are accomplished by mathematical analysis. The designed manufacturing system turned to successfully solve the uncertainty of product demand and processing time through simulation method. The methodology conducted by Süer, Huang and Maddisetty [19] is implemented in the current research for the purpose of designing the manufacturing system given the market demand, part-family formations, and the operations required to process the products. Erenay, Suer, Jing [8] also developed a mathematical model for designing alternative layered cellular system and they compared both works.

3 Problem Definition

In this research, a blood glucose test strip manufacturer is studied and alternative global supply chain strategies are compared. The strategies compared are, (1) independent facilities per region (host market strategy) and (2) newly proposed hybrid approach that allows family-based cell sharing across multiple facilities. Customers from three continents are considered in this study and they are Europe, Asia and North America. Three manufacturing facilities are assumed to produce these products and they are located in Ireland, China and Puerto Rico. The production data and manufacturing processes are obtained from Lobo [12]. All of the data are converted into common units by considering market share, revenue, and product price from Ates [1].

In most manufacturing systems, different products require to be processed on different machines. Due to high product variety, products are grouped into several families based on their similarity. Table 1 shows an example of product-machine incidence matrix. In this table, “1” in row i and column j indicates that product i needs to be produced on machine j. For example, Product 2 ($P2$) is processed on Machine 1 ($M1$) and Machine 3 ($M3$). One can observe that products with similar manufacturing processes are grouped together. Table 2 shows families and cells they are assigned to for this example.

However, in real life manufacturing systems, some product families may have quite high demand, which means they cannot be produced in one cell. Table 3 shows this multiple cell production system. For example, due to high demand, product families 1, 2 and 3 may need 2, 2 and 3 cells, respectively.

In many cases, demand values for product families follow a probabilistic distribution. In these situations, expected utilization for some cells of families may be low and as a result it may be desirable to share one cell by multiple families. A Dedicated Cell (DC) is assigned to one product family. A Shared Cell (SC) can run two product families, which have relatively similar operations. A Remainder Cell (RC) handles more than two product families. Both Shared Cells and Remainder Cells usually handle product families that have medium or low expected utilization values for some of its cells. Table 3 shows the cell sharing between three product families. For example, Cell 1 ($C1$) is Dedicated Cell for Product Family 1 ($F1$). C2 is also Dedicated Cell for $F2$. $C4$ is a Remainder Cell to be shared by $F1$, $F2$ and $F3$. Finally, $C3$ is a Shared Cell between $F1$ and $F2$ (Table 4).

Table 1. An example of product-machine incidence matrix

Product	Machines					
	$M1$	$M2$	$M3$	$M4$	$M5$	$M6$
$P1$	1	1	1	-	-	-
$P2$	1	-	1	-	-	-

$F2$	-	1	1	1
$F3$	-	-	-	1
	(DC)	(DC)	(SC)	(RC)

4 Alternative Supply Chain Designs

In this section, two alternative supply chain design strategies are discussed. Strategy 1 is the host market strategy where each facility in a continent covers the demand of the same continent. Strategy 2 discusses the proposed hybrid global supply chain strategy where cell sharing opportunities are explored across various facilities with product families in mind.

4.1 Strategy 1: Independent Supply Chain Design

In this strategy, each region produces many types of products to meet the demand of its own demand. Products are produced independently in different facilities, which lead to no transportation and information sharing between different regions. Figure 3 shows that the blood sugar strips are produced in three manufacturing facilities-China, Ireland and Puerto Rico [11].

4.2 Strategy 2: Hybrid Global Supply Chain Design

In this strategy, each region produces some of their own products. For example, products in Family 1 and Family 2 are produced in their own facilities in their continents. However, products in family 3 are produced in a single location and distributed to the remaining regions. Obviously, manufacturing cell(s) producing products in $F3$ are shared by various regions while this requires transportation of some products (Fig. 4).

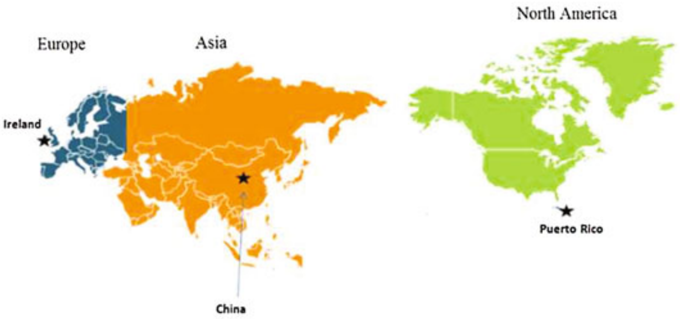

Fig. 3. Independent manufacturing systems

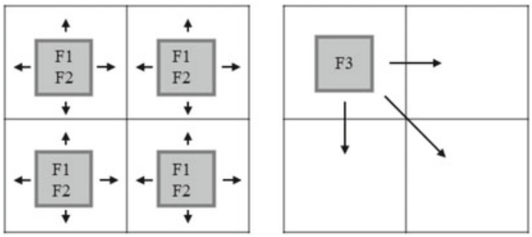

Fig. 4. The proposed hybrid global supply strategy

5 The Methodology Used

In each manufacturing facility, there are both fabrication and packaging cells. Products have been already divided into five families and this is out of scope of the paper. Two alternative strategies are discussed. Most of the computations are identical for both strategies. The only difference is how shared and remainder cells are created. To be more specific, in the host market strategy, DC, SC and RC are defined for each facility independently while, in the newly proposed strategy these opportunities are sought across multiple facilities potentially located in different continents. The general methodology is illustrated in Fig. 5. Cell utilizations are calculated by using cell capacity, product demand, etc. Each cell capacity is assumed 2000 h annually.

6 Mean Capacity Requirements and Standard Deviation

Historical demand values of four companies - Roche, LifeScan, Bayer and Abbott from 2002 to 2010 are used to forecast the 2011 demand [1]. In this research, demand values for families are assumed to follow normally distribution. Standard Deviation (σ) values for each product family are generated as a percentage of the corresponding mean demand (20%–25%). From [1], mean demand by family in all markets is shown in Table 5 along with Standard Deviations (σ).

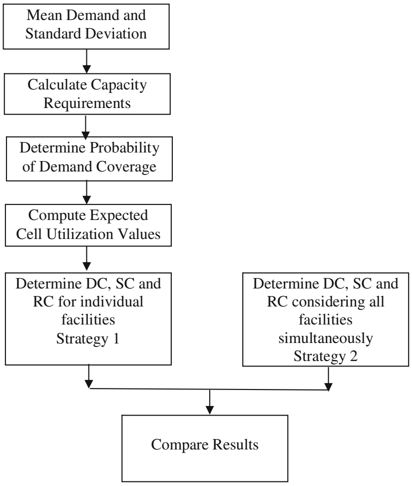

Fig. 5. The general methodology followed in this paper

Table 5. Mean demand and standard deviation by family in three regions

Family	China (C)			Ireland (I)			Puerto Rico (PR)		
	Mean	%	STDEV	Mean	%	STDEV	Mean	%	STDEV
1	1,422,286	25	355,571	1,422,925	25	355,731	1,337,087	25	334,271
2	7,098,188	24	1,703,565	7,101,377	24	1,704,330	6,672,986	24	1,601,516
3	6,711,423	24	1,610,741	6,714,438	24	1,611,465	6,309,389	24	1,514,253

Once mean demand and standard deviation values are known, the mean capacity requirements by product family are calculated by using Eq. (1) in [14]. Bottleneck Processing Time is defined as the longest processing time among operations in the cell.

$$\mathrm{MCR}_{\mathrm{FamilyNo}} = \mathrm{Mean}_{\mathrm{Demand}} \times \frac{\text{Bottleneck Processing Time}}{60}(hr). \tag{1}$$

For example, the mean capacity requirements for Product Family 2 in the manufacturing system of China region is decided by Mean Demand of Product Family 2 in China region which is 7,098,188. BPT (Bottleneck Processing Time) is $1/80 = 0.0125$ min in China region. The results of Mean Capacity Requirements and Standard deviation for different regions are shown in Table 6.

$$\mathrm{MCR}_{F2} = 7,098,188 \times \frac{0.0125}{60} = 1479 \text{ h},$$

$$\text{Standard Deviation}_{\mathrm{Capacity}_{F2}} = \sqrt{1,703,565^2 \times \frac{0.0125^2}{3600}} = 335.$$

Table 6. Mean demand and standard deviation by family in three regions

Family	China (C)		Ireland (I)		Puerto Rico (PR)	
	MCR	STDEV	MCR	STDEV	MCR	$\text{STDEV}_{\text{pity}}$
1	296	74	296	74	279	70
2	1479	355	1479	355	1390	334
3	1868	448	1869	449	1756	421
4	5065	1064	5068	1064	4762	1000
5	654	163	654	163	614	154

7 Calculating Demand Coverage Probabilities

The demand coverage probability is calculated for various cell levels. It shows the probability that a given number of cells will meet the demand. Capacity Requirements are assumed to follow the normal distribution. Each cell is available 2000 h per year. Demand Coverage Probability (DCP) for a family and cell combination is calculated by Eq. (2).

$$\text{DCP}_{\text{FamilyCell}} = \text{Normsdist}\left(\frac{2000 \times \text{CellNo.} - \text{MCR}_{\text{FamilyNo}}}{\text{STDEV}_{\text{Capacity}}}\right). \tag{2}$$

Demand Coverage Probability for all cells and families are calculated based on Mean Capacity Requirement and Standard Deviation. The Mean Capacity Requirement for Product Family 2 for China region is 1479 and Standard Deviation is 355. Based on these values, the Demand Coverage Probability for the first cell for family 2 is 93%. In other words, one cell covers demand at a very high level.

$$\text{DCP}_{F1C1} = \text{Normsdist}\left(\frac{2000 \times 1 - 1479}{335}\right) = 0.93.$$

All of the results of Demand Coverage Probability for different regions are shown in Table 7. For family 2 in China facility, by adding a second cell, the Demand Coverage Probability jumps to 99.99%.

7.1 Expected Cell Utilization Calculation

Expected Cell Utilization is determined by using Demand Coverage Probability, Mean Capacity Requirements and Standard Deviation as shown in Eq. (3)

$$\begin{aligned} E(C = X) = & P(CR > X) \times PU_1 + PX - 1 \leq CR \leq X \times PU_2 \\ & + P(CR < X - 1)PU_3, \end{aligned} \tag{3}$$

Table 7. Demand coverage probabilities

Family	China (C)					Ireland (I)					Puerto Rico (PR)				
	1	2	3	4	5	1	2	3	4	5	1	2	3	4	5
1	1.00	-	-	-	-	1.00	-	-	-	-	1.00	-	-	-	-
2	0.93	1.00	-	-	-	0.93	1.00	-	-	-	0.97	1.00	-	-	-
3	0.62	1.00	-	-	-	0.61	1.00	-	-	-	0.72	1.00	-	-	-
4	0.00	0.16	0.81	0.99	1.00	0.00	0.16	0.81	0.99	1.00	0.00	0.22	0.89	0.99	1.00
5	1.00	-	-	-	-	1.00	-	-	-	-	1.00	-	-	-	-

where

$E(C = X)$: Expected cell utilization for the X^{th} cell in a product family;
$P(CR > X)$: Probability that Capacity Requirements (CR)exceed $> X$;
PU_1: Percentage utilization of the X^{th} cell when $CR > X$, $PU_1 = 1.0$;
$P(X-1 \leq CR \leq X)$: Probability that CR between $X - 1$ and X;
PU_2: Percentage utilization of X^{th} cell when CR between $X-1$ and X;
$P(CR < X-1)$: Probability that $CR < X - 1$;
PPU_3: Percentage utilization of X^{th} cell when $CR < X - 1$, $PU_3 = 0.0$

PU_2 is solved by Eq. (4).

$$PU_2 = \int_{2000(X-1)}^{2000X} \frac{y \times f(y)}{2000 \times A} dy - (X - 1), \tag{4}$$

where

y: Variable represents CR;
$f(y)$: Probability density formation for CR;
A: Probability that CR between $X - 1$ and X

$f(y)$ and A are calculated by Eqs. (5) and (6)

$$f(y) = \frac{1}{\sigma\sqrt{2\pi}} e^{-(y-\mu)^2 \frac{1}{2\sigma^2}}, \tag{5}$$

$$A = P(X - 1 \leq CR \leq X). \tag{6}$$

For example, Expected Cell Utilization of Product Family 1 for China region is decided by Probability that the Cell Required number larger than 1, Percentage utilization of 1st cell when $CR > 1$, Probability that CR between 0 and 1 and Percentage utilization of 1st cell when CR between 0 and 1.

$$
\begin{aligned}
E(C=1) &= P(CR > 2000) \times PU_1 + P(0 \le CR \le 2000) \times PU_2 + P(CR < 0) \times PU_3 \\
&= 0 \times 1 + 1 \times PU_2, \\
PU_2 &= \int_0^{2000} \frac{y}{2000 \times 1} \times \frac{1}{74 \times \sqrt{2\pi}} e^{-(y-296)^2 \times \frac{1}{2 \times 74^2} dy} = 0.1480.
\end{aligned}
$$

All of the results of Expected Cell Utilization calculations for different regions are given in Table 8.

8 The Heuristic Algorithm for Layered Cellular Design

Having determined Expected Cell Utilization values for all possible cell segments, Dedicated Cells (DC), Shared Cells (SC), and Remainder Cells (RC) are identified using the heuristic algorithm described briefly here. The heuristic algorithm by Süer, Huang and Maddisetty [19] is used for identifying cell types. Expected Cell Utilization values are sorted in the decreasing order first. The assignment starts with the highest Expected Cell Utilization. If the expected cell utilization is 100%, this cell is considered to be a Dedicated Cell (DC). If the expected cell utilization is larger than 50%, a cell will be allocated to a product family. Then other similar product families are allocated to the cell to make the cell coverage close to 100% by considering similarities among families. These cells are named Shared Cells (SC) if they process only two product families and remainder cells if they process three or more product families.

Threshold value is the lowest acceptable similarity coefficient that allows two families to be grouped in a cell. The Similarity Threshold is set to 77%

in this paper. For example, when sorting the *ECU* for Ireland region, the highest *ECU* is 100% for Family 4 in Cell 1. Then Product family 4 is allocated to cell 1. When the second cell with 92% utilization is considered, it is allocated to a new $cell - Cell2$. Table 10 is used to search the similar Families with Product Family 4. From Table 9, Families 1, 2 and 5 can be considered to share a cell with Product Family 4 (similarity coefficient > 0.77). However, merging this cell with Family 1 or Family 5 will exceed 10% utilization. The only option is to merge Cell 2 (1% utilization) of Family 2 with Family 4. In Ireland case, there are two Dedicated Cells, two Shared Cells and one Remainder Cell. The results are summarized in Table 10. The heuristic procedure is given in Fig. 6.

9 The Proposed Hybrid Global Supply Approach

The proposed approach looks into global supply chain and explores the opportunities for forming shared cells and remainder cells across global facilities. In this paper, a new cell (cell 6) is opened in China where the entire Family 5 is produced to meet the global demand. In the same facility, demand for product family 4 original assigned to Puerto Rico facility is re-assigned to China facility. The Puerto Rico facility is thus reduced to four cells with three DCs and one RC. Ireland facility is also changed to 3 DCs, one SC and one RC as shown in

Table 13. Comparison of results

Parameters	Independent supply chain				New hybrid supply chain
	China	Ireland	P.R.	Total	
# of DCs	2	2	2	6	9
# of SCs	2	2	2	6	3
# of RCs	1	1	1	3	3
# of total cells	5	5	5	15	15
# of Cell Util > 0.9	3	3	3	9	11
# of workers	82	82	82	246	234
# of machines	66	66	66	198	198

Table 12. In short, China facility becomes a global supplier for Product Family 5 and partial global supplier for Product Family 4. All three facilities supply their own markets with respect to product Families 1, 2 and 3 (Table 11).

10 Conclusion

The comparison between two designs is presented in Table 13. It shows that total number remains the same for both designs. However, the number of workers is reduced in the new design. This is due to balancing issues in the cells. In other words, each cell is equipped with all the machines needed to run all the families (maximum number of machines) while some of them remained idle while running different families. Another benefit was that there were more dedicated cells under the new design. Furthermore, number of cells with a utilization value greater than 0.90 was higher. It is expected that flowtimes will be shorter in dedicated cells. This in turn reduces the work-in-process inventory. For a more complete analysis, transportation costs, labor costs as well as investments costs have to be included. These results could not be included due to space concerns.

Abstract. In this paper, a closed-loop supply chain model with efficient operation strategy (CLSC-OS) is proposed. In the CLSC-OS, various facilities which can be used in forward logistics (FL) and reverse logistics (RL) are taken into consideration. A mathematical formulation is proposed to design the CLSC-OS and it is implemented using genetic algorithm (GA) approach. In numerical experiment, for efficient operation strategy, several scenarios using various factors such as remanufacturing rate, profit premium rate, discount rate, and return rate based on revenue-cost rate is considered and analyzed. Experimental results shows that discount rate and profit premium rate have a significant influence on revenue-cost rate.

Keywords: Closed-loop supply chain · Efficient operation strategy · Forward logistics · Reverse logistics · Genetic algorithm

1 Introduction

In general, designing closed loop supply chain (CLSC) model is to maximize the utilization of resources. Especially, return management such as reuse and resale of the recovered parts and products has been focused on many companies. For example, by 1997, approximately 73,000 U.S. companies had earned $53 billion though resale activities of remanufactured products [1]. This means that return management using used product becomes more and more important.

Return management using used product is usually consisted of three aspects. The first aspect is the operational management of returned product, the second one is that of remanufacturing activity, and the third one is that of secondary market [6]. Ozkir and Basligil considered the operational management of returned product [8]. They found that regulating the rate of returned product can increase the total profit and revenue. Subramoniam found that remanufacturing activities can increase profit, save resource and energy, create new market [9]. Van Daniel et al. suggested that con-sidering both new market with new product activity and secondary market with resale activity can get more profit than the new market alone [7].

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_79

However, unfortunately, little attention to the relationship among the three aspects of return management has been done in conventional studies. Therefore, in this paper, we consider the relationship based on various scenarios using remanufacturing rate, profit premium rate, discount rate, and return rate and analyze which factor can be an important one to increase total profit.

For achieving this objective, a CLSC model with efficient operation strategy (CLSC-OS) is proposed in Sect. 2. The CLSC-OS is consisted of various facilities such as supplier, product manufacturer, retailer, recovery center, and secondary market at each stage. In Sect. 3, a mathematical formulation is proposed for implementing the CLSC-OS. The mathematical formulation is represented as a nonlinear mixed integer programming (NIMIP). The NIMIP is implemented using a genetic algorithm (GA) approach in Sect. 4. In numerical experiment of Sect. 5, the CLSC-OS is presented and various scenarios using the CLSC-OS is considered. For various scenarios, remanufacturing rate, profit premium rate, discount rate, and return rate are considered and they all are used for analyzing the revenue-cost rate resulting from the implementation of the CLSC-OS. Some conclusions and a room for improvement to future study are followed in Sect. 6.

2 Proposed CLSC-OS

The proposed CLSC-OS is an integrated model combining forward logistics (FL) and reverse logistics (RL), which is consisted of suppliers in areas 1, 2, 3, and 4, product manufacturer, part inventory distribution center, product distribution center and retailer in FL and customer, collection center, recovery center, secondary market and waste disposal center in RL. For effective use of the recovered parts from recovery center, part inventory distribution center is also taken into consideration. The conceptual network structure of the proposed CLSC-OS is shown in Fig. 1.

In Fig. 1, the production and recovery flows are as follows. New part types 1, 2, 3, and 4 (NP1, NP2, NP3, and NP4) are produced at the suppliers of areas 1, 2, 3, and 4, respectively. NP1, NP2, NP3, and NP4 are then sent to part inventory distribution center. Recovered parts (RP1, RP2, RP3, and RP4) from recovery center are also sent to part inventory distribution center. Product manufacturer produces product using NP1, NP2, NP3, NP4, RP1, RP2, RP3, and RP4 from part inventory distribution center. The product is sent to retailer through product distribution center and sold to customer. The returned product from customer is collected at collection center and then sent to recovery center. At recovery center, the returned product is checked and classified into recoverable and unrecoverable products. The quality of the recoverable product with a_1% is recovered at recovery center and then resold at secondary market. The unrecoverable product is disassembled into recoverable and unrecoverable parts. The quality of the recoverable part with a_2% is recovered at recovery center and then sent to part inventory distribution center. The unrecoverable part with a_3% is sent to waste disposal center to be burned or landfilled.

Especially, in the proposed CLSC-OS, the part inventory distribution center can regulate the transportation amount of NP1, NP2, NP3, NP4, RP1, RP2,

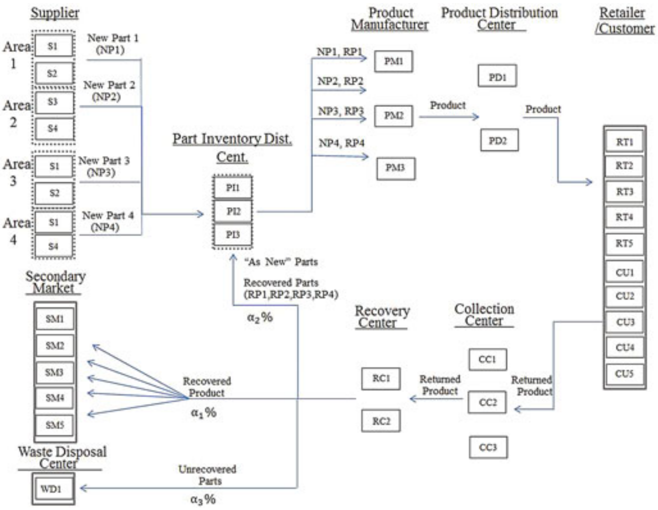

Fig. 1. The conceptual network structure of the CLSC-OS

RP3, and RP4. For instance, if product manufacturer want to produce 100 products and a_2 is 10% (10 recovered parts = 100 returned product $\times$10%), then part inventory distribution center sends 90 NP1, 90 NP2, 90 NP3, and 90 NP4 as new parts and 10 RP1, 10 RP2, 10 RP3, and RP4 as recovered parts to product manufacturer.

3 Mathematical Formulation

Beofre suggesting the mathematical formulation for the CLSC-OS, the following assumptions should be considered.

- Single product is produced within a fixed period.
- New market (retailer) and resale market (secondary market) are separated.
- The qualities of the new parts (NP1, NP2, NP3, and NP4) from supplier and those of the recovered parts (RP1, RP2, RP3, and RP4) from recovery center are identical.
- All products (new and recovered products) at retailer and secondary market are sold to customer.
- The number of facilities at each stage is known.
- All facilities at retail/customer, secondary market, and waste disposal center should be opened. However, only one facility at supplier, product manufacturer, product distribution center, part inventory distribution center, collection center, and recovery center should be opened, which means that the other facilities at each stage should be closed.
- Fixed costs of all facilities are different and known.
- Unit handling costs of all facilities at same stage are identical and known.

- Unit transportation costs of all facilities at each stageare different and known.
- The handling capacity of the facilities at a stage is the same or greater than that of previous ones.
- The return rate from customer is fixed.
- The discount rates of recovered product and part are calculated according to the quality of returned product and part.

The index sets, parameters, and decision variables for the mathematical formulation are as follows.
Index set

a : index of area at supplier; $a \in A$;
b : index of new product; $b \in B$;
h : index of supplier; $h \in H$;
i : index of part inventory distribution center; $i \in I$;
j : index of product manufacturer; $j \in J$;
k : index of product distribution center; $k \in K$;
l : index of retailer/customer; $l \in L$;
m : index of collection center; $m \in M$;
n : index of recovery center; $n \in N$;
o : index of secondary market; $o \in O$;
p : index of waste disposal center; $p \in P$

Parameter

FDS_{ha} : fixed cost at supplier h of area a;
FDI_i : fixed cost at part inventory distribution center i;
FDO_j : fixed cost at product manufacturer j;
FDD_k : fixed cost at distribution center k;
FDC_m : fixed cost at collection center m;
FDR_n : fixed cost at recovery center n;
UHS_{ha} : unit handling cost at supplier h of area a;
UHO_j : unit handling cost at product manufacturer j;
UHD_k : unit handling cost at product distribution center k;
UHC_m : unit handling cost at collection center m;
UHR_n : unit handling cost at recovery center n;
UHE_e : unit handling cost at secondary market e;
UHW_p : unit handling cost at waste disposal center p;
UTS_{hai} : unit transportation cost from supplier h of area a to part inventory distribution center i;
UTI_{ij} : unit transportation cost from part inventory center i to product manufacturer j;
UTO_{jk} : unit transportation cost from product manufacturer j to product distribution center k;
UTD_{kl} : unit transportation cost from product distribution center k to retailer/customer l;

UTA_{lm} : unit transportation cost from retailer/customer l to collection center m;
UTC_{mn} : unit transportation cost from collection center m to recovery center n;
UTE_{no} : unit transportation cost from recovery center n to secondary market o;
UTI_{ni} : unit transportation cost from recovery center n to part inventory distribution center i;
UTL_{np} : unit transportation cost from recovery center n to waste disposal center p;
KCI_{i} : holding cost at part inventory distribution center i;
UPN_{b} : unit price of new product b;
PRN_{b} : profit premium rate for new product b at retailer l

Decision variables
TCs_{ha} : treatment capacity at supplier h of area a
TCi_{i} : treatment capacity at part inventory distribution center i
TCo_{j} : treatment capacity at product manufacturer j
TCd_{k} : treatment capacity at product distribution center k
TCu_{l} : treatment capacity at retailer/customer l
TCc_{m} : treatment capacity at collection center m
TCe_{n} : treatment capacity for recovered product at recovery center n
TCi_{n} : treatment capacity for recovered part at recovery center n
TCl_{n} : treatment capacity for unrecovered part at recovery center n
TCe_{e} : treatment capacity at secondary market e
TCw_{p} : treatment capacity at waste disposal center p
Q : quantity of new product
Rt : return rate
DS_o : discount rate for recovered product
DS_i : discount rate for recovered part
ys_{ha} : takes the value of 1 if suppler h at area a is opened and 0 otherwise
yi_i : takes the value of 1 if part inventory distribution center i is opened and 0 otherwise
yo_j : takes the value of 1 if product manufacturer j is opened and 0 otherwise
yd_k : takes the value of 1 if product distribution center k is opened and 0 otherwise
yc_m : takes the value of 1 if collection center m is opened and 0 otherwise
yr_n : takes the value of 1 if recovery center n is opened and 0 otherwise

Using the above mentioned index sets, parameters, and decision variables, the mathematical formulation is suggested as follows:

Maximize Total Revenue (TR)

$$\begin{aligned}\mathrm{TR} = {} & \text{revenue of new product} + \text{revenue of recovered product} \\ & + \text{revenue of recovered part}\end{aligned} \tag{1}$$

$$= \sum_i Q \times \mathrm{PRN}_b + \sum_o Q \times \mathrm{UPN}_b \times \alpha_1 \times DS_o + \sum_o Q \times \mathrm{UPN}_b \times \alpha_2 \times DS_i, \quad (2)$$

where

$$\mathrm{UPN}_b = (\mathrm{TCF} \times (1 + \mathrm{PRN}_b))/Q. \quad (3)$$

Minimize Total Cost (TC)

$$\mathrm{TC} = \text{total cost of FL (TCF)} + \text{total cost of RL (TCR)}. \quad (4)$$

$$\begin{aligned}
\mathrm{TCF} &= \text{total FL fixed cost} + \text{ total FL handling cost} \\
&\quad + \text{total FL transportation cost} \\
&= \sum_a \sum_h (\mathrm{FDS}_{ha} \times ys_{ha}) + \sum_i (\mathrm{FDI}_i \times yi_i) + \sum_i (\mathrm{FDO}_j \times yo_j) \\
&\quad + \sum_a \sum_h (\mathrm{UHS}_{ha} \times TCs_{ha} \times ys_{ha}) + \sum_j (\mathrm{UHO}_j \times TCo_j \times yo_j) \\
&\quad + \sum_j (\mathrm{UHD}_k \times TCd_k \times yd_k) + \sum_a \sum_h \sum_i (UTS_{hai} \times TCs_{ha} \times ys_{ha} \times yi_i) \\
&\quad + \sum_{ij} (\mathrm{UTI}_{ij} \times TCi_i \times yi_i \times yo_j) + \sum_{jk} (\mathrm{UTO}_{jk} \times TCo_j \times yo_j \times yd_k) \\
&\quad + \sum_{kl} (\mathrm{UTD}_{kl} \times TCd_k \times yd_k),
\end{aligned} \quad (5)$$

$$\begin{aligned}
\mathrm{TCR} &= \text{total RL fixed cost} + \text{total RL handling cost} \\
&\quad + \text{total RL transportation cost} + \text{holding cost} \\
&= \sum_m (\mathrm{FDC}_m \times yc_m) + \sum_i (\mathrm{FDR}_n \times yr_n) + \sum_a \sum_h (\mathrm{UHC}_m \times TCc_m \times yc_m) \\
&\quad + \sum_n (\mathrm{UHR}_n \times TCe_n \times yr_n) + \sum_n (UHR_n \times TCi_n \times yr_n) \\
&\quad + \sum_n (\mathrm{UHR}_n \times TCl_n \times yr_n) + \sum_e (\mathrm{UHE}_e \times TCe_e) + \sum_p (\mathrm{UHW}_p \times TCw_p) \\
&\quad + \sum_{lm} (\mathrm{UTA}_{lm} \times TCu_l \times yc_m) + \sum_{mn} (\mathrm{UTC}_{mn} \times TCc_m \times yc_m \times yr_n) \\
&\quad + \sum_{no} (\mathrm{UTE}_{no} \times TCe_n \times yr_n) + \sum_{ni} (\mathrm{UTI}_{ni} \times TCi_n \times yr_n) \\
&\quad + \sum_{ni} (\mathrm{UTL}_{np} \times TCl_n \times yr_n) + \sum_i (\mathrm{KCI}_i \times yi_i)
\end{aligned} \quad (6)$$

$$\text{s.t. } \sum_h ys_{ha} = 1, \forall a \in A \tag{7}$$

$$\sum_i yi_i = 1 \tag{8}$$

$$\sum_j yo_j = 1 \tag{9}$$

$$\sum_k yd_k = 1 \tag{10}$$

$$\sum_m yc_m = 1 \tag{11}$$

$$\sum_n yr_n = 1 \tag{12}$$

$$\sum_h (UHS_{hai} \times ys_{ha}) - \sum_i (TCi_i \times yi_i) = 0, \forall a \in A \tag{13}$$

$$\sum_i (TCi_i \times yi_i) - \sum_j (UHO_j \times yo_j) = 0 \tag{14}$$

$$\sum_i (\mathrm{UHO}_j \times yo_j) - \sum_k (\mathrm{UHD}_k \times yd_k) = 0 \tag{15}$$

$$\sum_k (\mathrm{UHD}_k \times yd_k) - \sum_l TCu_l = 0 \tag{16}$$

$$\sum_l TCu_l - \sum_m (\mathrm{UHC}_m \times yc_m) = 0 \tag{17}$$

$$\sum_i (TCi_i \times yi_i) - \alpha_2 \sum_n (\mathrm{UHR}_n \times yr_n) \geq 0 \tag{18}$$

$$\sum_n (HCrc_n \times x\_rc_n) - \alpha_3 \sum_p (UHW_p \times yw_p) \geq 0 \tag{19}$$

$$\sum_n (\mathrm{UHR}_n \times yr_n) - \sum_o (\mathrm{UHC}_m \times yc_m) = 0 \tag{20}$$

$$\sum_n (\mathrm{UHR}_n \times yr_n) - \alpha_1 \sum_e \mathrm{UHE}_e \geq 0 \tag{21}$$

$$ys_{ha} = \{0, 1\}, \forall h \in H, a \in A \tag{22}$$

$$yi_i = \{0, 1\}, \forall i \in I \tag{23}$$

$$yo_j = \{0, 1\}, \forall j \in J \tag{24}$$

$$yd_k = \{0, 1\}, \forall k \in K \tag{25}$$

$$yc_m = \{0, 1\}, \forall m \in M \tag{26}$$

$$yr_n = \{0, 1\}, \forall n \in N \tag{27}$$

$$\begin{aligned} &\mathrm{UHS}_{hai}, \mathrm{UHO}_j, \mathrm{UHD}_k, \mathrm{UHC}_m, \mathrm{UHR}_n, \mathrm{UHE}_e, \mathrm{UHW}_p \geq 0 \\ &\forall h \in H, a \in A, \forall i \in I, j \in J, \forall k \in K, \\ &\forall m \in M, \forall n \in N, \forall e \in E, \forall p \in P \end{aligned} \tag{28}$$

The objective function is divided into two parts. First part is to maximize total revenue and second one is to minimize total cost. Maximizing the total revenue is represented in Eq. (2) and minimizing the total cost is in Eq. (4). Each objective function should be maximized and minimized under satisfying all constraints which represented from Eqs. (7)–(28). Equations (7)–(12) mean that only one facility at each stage should be opened. Equations (13)–(21) show that the capacity of each opened facility is the same or greater than that of the previous one. Equations (22)–(27) means that each decision variables can take the value 0 or 1. Equation (27) refers to non-negativity.

4 Genetic Algorithm (GA) Approach

Genetic Algorithm (GA) approach was proposed by Goldberg [5] and has been used to solve many optimization problems [3,4,10]. GA approach starts with producing a random initial population and each individual in the population represents a potential solution. The next step is that each individual is selected by evaluating the measure of fitness and producing a next new population. All individuals in the new population are undergoing crossover and mutation operators. For crossover and mutation opera-tors, various methodologies such as one-point crossover operator (1X), two-point crossover operator (2X), and random mutation operator have been developed. After applying the crossover and mutation operators to each individual, an offspring is produced and the fitness is evaluated. These procedure is repeated until a pre-defined stop condition is satisfied or optimal solution already known is located. Finally, the optimal solution is produced.

The GA approach [2,3] for implementing the mathematical formulation in Sect. 3 is as Fig. 2:

```
procedure: GA approach
input: problem data, GA parameters
output: best solution
begin
    t = 0;
    generate initial population randomly P(t) satisfying constraints;
    evaluate P(t) using fitness test by decoding routine;
    while (not termination condition) do
        create N(t) from P(t) by two cut-point crossover routine;
        create N(t) from P(t) by random mutation routine;
        reproduce P(t + 1) from P(t) and N(t) by elitist selection rou-
tine;
        t = t + 1
    end
    output best solution
end;
```

Fig. 2. The GA approach

5 Numerical Experiments

In numerical experiment, various scenarios are considered for evaluating the rate of the total revenue in Eq. (1) and the total cost in Eq. (4). First, a scale for the proposed CLSC-OS is presented in Table 1. As shown in Table 1, numbers of the suppliers (S) at each area, part inventory distribution center (PI), product manufacturer (PM), product distribution center (PD), retailer/customer (RT), collection center (CC), recovery center (RC), secondary market (SM), waste disposal center (WD) are displayed.

Table 1. Scale of the CLSC-OS

No. of S Area 1, 2, 3, 4	No. of PI	No. of PM	No. of PD	No. of RT	No. of CC	No. of RC	No. of SM	No. of WD
4	2	4	2	10	4	2	10	2

Table 2 shows various cases of remanufacturing for returned product at recovery center. a_1, a_2, and a_3 refer to the rates of recovered product, recovered part, and unre-covered part, respectively. For instance, Case 1 means that (i) 60% of all returned products are recovered and sent to secondary market, (ii) 30% of them are recovered and sent to part inventory distribution center and (iii) 10% of them are unrecovered and sent to waste disposal center.

Table 2. Various cases of remanufacturing

Case	a_1	a_2	a_3
1	0.6	0.3	0.1
2	0.6	0.2	0.2
3	0.6	0.1	0.3
4	0.7	0.2	0.1
5	0.7	0.1	0.2
6	0.8	0.1	0.1

Table 3 shows various scenarios. Each scenario has four factors using the case of remanufacturing, return rate, discount rate and profit premium rate. By the each scenario, various relationships between total revenue and total cost are compared. For instance, Scenario 1 indicates that various cases in Table 2 and various profit premium rates ($P_m = 0.4, 0.3, 0.2, 0.1,$ and 0.0) under the fixed values at return rate and discount rate are considered to solve the two mathematical formulations in Eqs. (1) and (4). The computation results are used for comparing the relationships between total revenue and total cost.

Each scenario in Tables 2 and 3 under the scale of the proposed CLSC-OS is implemented using GA approach. The parameters used in GA approach is that population size is 20, crossover rate 0.5, and mutation rate 0.3. The GA approach is executed under the following computation environment: Matlab R2015 under

Table 3. Various scenarios

Scenario	Case	Return rate	Discount rate	Profit premium rate
1	1, 2, 3, 4, 5, 6	1.0	0.5	0.4, 0.3, 0.2, 0.1, 0.0
2	1	1.0	0.5	0.4, 0.3, 0.2, 0.1, 0.0
3	1	1.0	0.5, 0.4, 0.3, 0.2	0.4, 0.3, 0.2, 0.1, 0.0
4	1, 2, 3, 4, 5, 6	0.9	0.5	0.4, 0.3, 0.2, 0.1, 0.0

IBM compatible PC 3.40GHZ processor (Inter Core i7-3770 CPU), 8GB and Window 7.

Figure 3 shows the computation results of total revenue-cost rates in Scenario 1. Each curve with different colors shows the changes of the total revenue-cost rates under the changes of profit premium rate. For instance, the top blue-colored curve shows a fixed values of 1.4 in the total revenue-cost rates of all cases under the fixed values of 0.4 profit premium rate, 100% return rate and 0.5 discount rate. Similar situations are also shown in the other colored-curves. Therefore, the results shown in Fig. 3 indicates that the changes of remanufacturing rate has no significant influence on the increase of total profit.

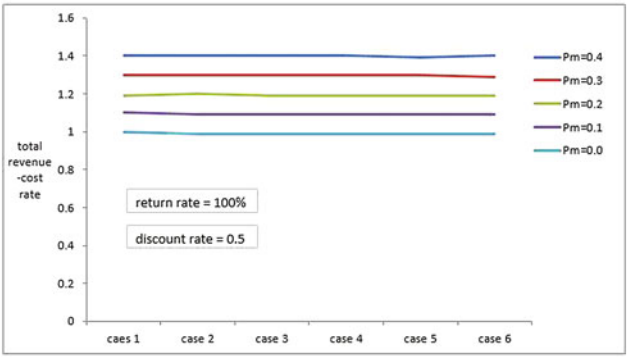

Fig. 3. Computation results of total revenue-cost rates in Scenario 1

Figure 4 shows the changes of the total revenue-cost rates under various profit premium rates, when return and discount rates are fixed at 100% and 0.5, respectively. As the changes from profit premium rate 0.4 to 0.0, the total revenue-cost rate is continuously decreasing. Therefore, the results shown in Fig. 4 indicate that the profit premium rate has significant influence on the increase of total profit.

Figure 5 shows the changes of the total revenue-cost rates for each profit premium rate under various discount rates, when return rate is fixed at 100%. For instance, the top blue-colored curve shows that total revenue-cost rates is

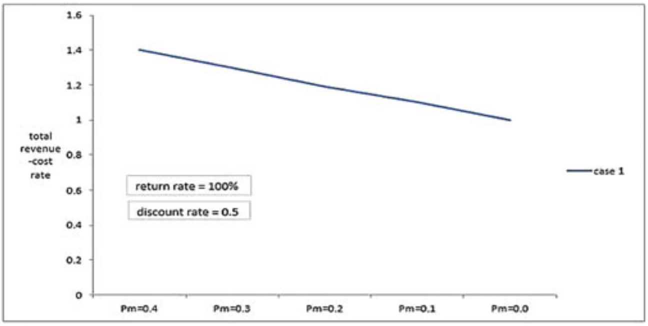

Fig. 4. Computation results of total revenue-cost rates in Scenario 2

increasing according to the changes of discount rate from 0.5 to 0.2. Similar situations are also shown in the other colored-curves. Therefore, the results shown in Fig. 5 indicate that the change of discount rates has significantly influence on the increase of total profit.

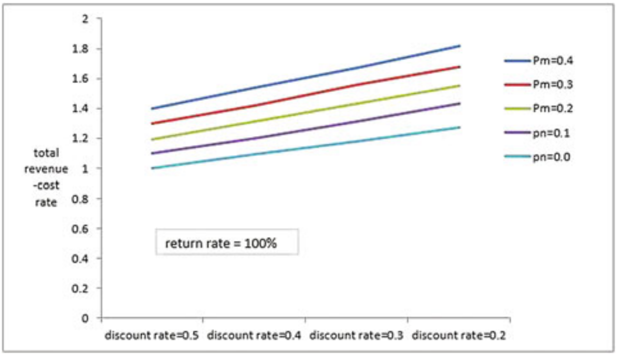

Fig. 5. Computation results of total revenue-cost rates in Scenario 3

Similar to Figs. 3 and 6 shows the computation results of total revenue-cost rates in Scenario 4. Each curve with different colors shows the changes of the total revenue-cost rates under the changes of profit premium rate. For instance, the top blue-colored curve shows a little change around 1.55 for each case when the discount rate and profit premium rate are fixed at 90% and 0.4, respectively. Similar curves are also shown in the profit premium rates 0.3 and 0.0. However, the curves of profit premium rates 0.2 and 0.1 do not show any changes for each case. Therefore, the results shown in Figs. 3 and 6 indicate that the changes of remanufacturing rate and return rates has no significant influence on the increase of total profit, though there is a little changes according to each case.

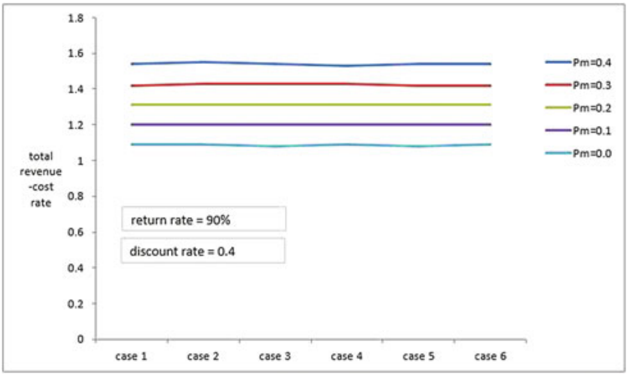

Fig. 6. Computation results of total revenue-cost rates in Scenario 4

6 Conclusion

The first objective of this study is to design a CLSC-OS with various facilities at each stage and the second one is to find a good alternative for increasing total profit under the changes of remanufacturing rate, discount rate, profit premium rate, and return rate.

For achieving the two objectives, the CLSC-OS has been proposed. The proposed CLSC-OS has supplies at areas 1, 2, 3, and 4, product manufacturer, product distribution center, and retailer in FL and customer, collection center, recovery center, secondary market and waste disposal center in RL. This is represented in a mathematical formulation which has two objectives of the maximization of total revenue and the minimization of total cost under various constraints. The mathematical formulation is implemented using GA approach. In numerical experiment, four types of scenarios with the changes of remanufacturing rate, discount rate, profit premium rate, and return rate have been considered and executed using GA approach. The experimental results have shown that the changes of the profit premium rates and the discount rates have no significant influence on the increase of total profit, but the changes of the profit premium rates and the discount rates have significant influence on the increase of total profit. Therefore, decreasing the profit premium rates and the discount rates can be a good alternative for increasing the total profit (= total revenue − total cost) in the proposed CLSC-OS.

However, in this paper, since only four scenarios have been considered, more various scenarios with larger-scaled CLSC-OS will be considered to compare the changes of remanufacturing rate, discount rate, profit premium rate, and return rate. This will be left to future study.

Optimization of Supply Chain Based on Internet Plus

Wen Hua(✉)

School of Tourism and Economic Management,
Chengdu University, Chengdu 610000, People's Republic of China
846937934@qq.com

Abstract. "Internet plus supply chain" one of the internet plus strategic action, basing on information technology and platform, promotes the high fusion of elements of supply chain and modern science & technology, and upgrades efficiency of supply chain. The basic factors-information technology guarantee and information sharing, which keep the supply chain operation efficiently, protect the "three flow"-material flow, information flow and fund flow efficient and order movement on the supply chain. This paper analyses the situation and the problem about "three flow", and discusses how to improve the efficiency of supply chain system, from client, to manufacture, and to logistics and financial service with the help of internet technology.

Keywords: Internet plus · Logistics management · Supply chain management

1 Introduction

In 2015, China Premier Li Keqiang puts forwards the "Internet plus" strategic action plan in the government work report to integrate the Internet with traditional industries by means of the Internet platform and information technology, to encourage industrial networks and Internet banking, and to guide Internet-based companies to increase their presence in the international market.

The internet provides information and communication technology and platform for enterprises, promotes the effective communication and coordination between enterprises, business partners, customers and inner-enterprise, and makes it possible to implement supply chain effectively. The enterprises in supply chain can make the synergistic responds quickly, reduce costs of supply chain effectively and improve enterprise efficiency. Even The ratio of logistics cost to GDP keeps declining from 18.4% in 2007 to 16.0% in 2015, and is 0.6% lower than the year earlier [8], it is still higher. The logistics cost in our country is 5% higher than developed countries, which shows the obvious gap. Global Logistics Performance Index (LPI) issued by the World Bank every two years is a international index that demonstrates the domestic logistics abilities of one country or

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_80

one region to participate global supply chain. The 2016 assessment result shows China ranks at 27^{th} [9] and is in the second echelon. As a whole, the status quo of the weak soft power in circulation filed, such as high cost, low efficiency, low intensive level, insufficient industrial support and issues of trust, standard, talents, safe and environmental protection, constraints the efficient operation of supply chain.

The supply chain is a sequential and interconnected organization structure including the design, production and sales and a value chain involving suppliers, manufacturers, transportation and all other components. Meanwhile, the supply chain links business activities to achieve accurate forecast, less inventory and meet real-time needs based on information system. This paper starts with the situation and the problem about "three flow", and discusses how to improve the efficiency of supply chain system, from client, to manufacture, and to logistics and financial service with the help of internet technology.

2 Current Situation of Logistics, Information Flow and Fund Flow in the Supply Chain in China

In the Internet plus era, the supply chain is showing a trend of flat model to ensure that logistics, information flow and fund flow perform effectively and orderly in the system. As globalization lengthens and broadens the supply chain, the competition is more and more intense and the competition between enterprises becomes the competition between supply chains.

2.1 Logistics in Supply Chain

Modern logistics links every supply chain activity from raw material procurement to retails, achieving external integration and reflecting integration advantage. With the speeding up of globalization, raw material procurement and product sales expand in scale in China's manufacturing enterprises. Procurement and sales are attached with the same importance. In terms of transportation, owing to China's road especially expressway construction, consummation and construction of highway networks and transformation of consumption patterns, the road transportation scope was widen and highway logistics accounted for 75.52% of the total freight volume (2015) as shown in Table 1.

Table 1. Annual traffic volume of transportation (10000 ton)

Year	Railway	Highway	Water transportation	Civil aviation	Total
1990	150681	724040	80094	37.0	970602
2000	178581	1038813	122391	196.7	1358682
2015	336000	3150000	614000	625.3	4171000

Source: National Bureau of Statistics et al., China Statistics Yearbook

The data has shown [3] that: In China, there exist over 7 million logistics companies with more than 16 million vehicles and an average of 2 cars for each company. The trucks empty driving rate is 50% and the cargo are transferred 5 to 6 times before transport drivers. As the individual drivers owe more than 90% of road transport capacity, the road logistics has low degree in scale and intensification and road transport is in small, scattered, chaotic, disorder state. All in all, long-distance road transportation has no advantage in economy and environmental protection.

Revenue composition of logistics enterprises: transport and warehousing business make up for 60%, freight forwarding business for 13.9%, distribution and distribution processing for 5% [2], indicating that logistics enterprises focus on transport and warehousing that are the base business with low profit margins. And for profit margin: integrated logistics enterprises accounts for 8.9%, warehousing enterprises for 6.9% and transportation enterprises for 3.3%.

In general, for the majority of small and medium-sized logistics enterprises, they are lack of fund, labor force, capacity and application of information technology; the labor-intensive operation relies on a large number of labors; they have insufficient capacity to provide value-added logistics service since their business focus are basic logistics services such as transportation, warehousing. What's more, the general low profitability can be attributed to two reasons. One is that demand of logistics services reduces as China's economy slows down. At the same time, logistics enterprises has weak ability to provide quality service and low efficiency, which cannot meet the current market demand or meet in the way the market needs.

2.2 The Information Flow in Supply Chain

The value of information technology application and information sharing among upstream and downstream enterprises in supply chain is widely concerned and recognized by scholars and enterprises. From 2013, the National Bureau of Statistics released information technology application and e-commerce situation according to enterprise types, indicating that the application of information technology has increasing impact on China's economy. Table 2 suggests the enterprise information and e-commerce situation in 2014. The proportion of enterprises with websites in manufacturing and transportation industry as well as warehousing industry were separately 70% and 45%, but enterprises dealing with e-commerce accounted for only 8.6% and 4%. The website is mainly used for non-transactional corporate propaganda and product display.

Logistics information technology is divided into four categories: data acquisition technology (such as bar code, RFID technology), information technology, warehousing management technology and transportation management technology, and respectively the proportion of technology used by Chinese logistics enterprises is 56%, 94.9%, 73.8%, 88.5% [7]. According to the market research report on China's logistics industry in 2015, the utilization rate of logistics applications are as follows: storage management system accounts for 17.21%, transportation management system for 17.21%, and vehicle tracking system for

Table 2. Information technology application and E-commerce of enterprises in 2014

Project	Number of enterprises	Number of computers used per 100 workers	Number of enterprises with websites	Number of websites owned by per 100 enterprises	Dealing with E-commerce	
					Number of enterprises	Percentage (%)
Manufacturing	347376	18	244822	70	29938	8.6
Transportation, warehousing, postal service	35187	25	15908	45	1402	4

Source: National Bureau of Statistics et al., China Statistics Yearbook (http://www.stats.gov.cn/tjsj/ndsj/2015/indexch.htm)

19.35% [3]. Application of logistics information technology and the software does not mean that the supply chain has achieved information sharing, collaborative response and quick response. Only by breaking the blocked business model and interest chain established by the system and institution can we cross the boundaries of organizations, regions and industries.

2.3 Fund Flow in Supply Chain

On the whole, the financing difficulties are the bottleneck of enterprise development for many SMEs. With the concept of supply chain management is strengthen, the overall foundation of the supply chain is increasingly apparent. This development has gone through three stages. The first stage, logistics' factors combine with financial activities. The second stage, the development of supply chain finance moves from factors to integrating management of logistics operation, business operation and financial management. The third stage, internet + supply chain finance relieve information asymmetry and reduce the costs of information access and information processing, and the industry supply chains are optimized through financial resources [10]. The Supply chain finance takes the core enterprise as the starting point, and the systematically arranges financing for all member enterprises in the supply chain. Supply chain finance inputs the funds into the small and medium-sized upstream and downstream enterprises in the supply chain, which provides the financial support for the supply chain. The application of Internet achieves financial support for supply and demand, that is, the third-party payment platform reduces financing costs for enterprises in supply chain, and consequently the bottleneck of funding is alleviated.

3 The Optimization of Supply Chain

The essence of "Internet plus" is to online and digitalize the traditional industry. When the commodity display and transaction behaviors shift to Internet and online, information and data can flow, exchange, mine, transfer and share. Besides, supply and demand can be connected at the lowest cost. However, the enormous information and data are featured with scattered property, low value intense, low connection. In this case, big data, cloud storage, data mining and other technologies are adopted to provide valuable information for decision-making by data integration, processing and analysis.

The integration of Internet and industry moves forwards generally from the downstream to the upstream in the supply chain and changes consumers in the first place. According to the Internet Statistical Report of 2015, the popularity rate of Chinese netizens is 50.3%, among which there are 413 million, that 60.03% of the netizens [4] making up for 30.20% of the total population conduct online shopping and transactions (26.68% in 2014). Reports [1] have shown that China's online retail market has 3.8 trillion yuan volume, which accounts for 12.7% of total retail sales(10.6% in 2014), represent the proportion of retails that applying Internet. The application rate of E-commerce, from the consumer → retail → production → transport services along the supply chain, are respectively 26.68%, 10.6%, 8.6%, 4.0% in 2014 as shown in Fig. 1.

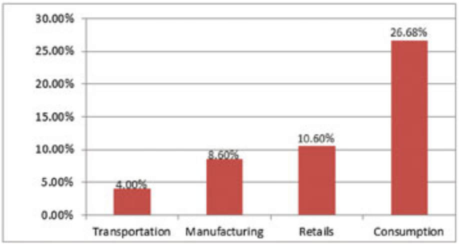

Fig. 1. Application rate of E-commerce in different links of supply chain (Year 2014)

3.1 Demand Side Management-Define and Expand Effective Demands

In the open network environment, the demand of the increasing amount of end users participating in innovation and revolution must be given prominent attention by the supply side and placed in the logic starting point and attention center of enterprise decision making. Otherwise, once the consumers' upgrading needs are not responded, then the low-cost, convenient external resources are their alternatives, which results in decrease of internal demand.

(1) Demand side management-Define and expand effective demands
Diversification and uncertainty of demand reduce the versatility of the product and increase the inventory of supply side and make production and management more difficult. Thanks to the application of Internet information technology, it reduces the cost of collecting, integrating and utilizing consumer information, thus the enterprise is sensitive to marketplace and explores and meets the end-user demand in more convenient, fast, efficient and low cost way. What's more,

business to customer model achieves disintermediation effect, which greatly weakened the profits divided by the distributors, retailers and other traditional business roles in the supply chain and is conducive to get access to first hand market information because supply chain is directed to end users. Data analysis, cloud computing and other tools utilize the multi-dimensional information connect by the internal and external network platform to dock, integrate, analysis trend. Enterprises are enabled to increase supply chain forecasting and decision-making capabilities and conduct scientific regulation of production, inventory, logistics and other key activities in supply chain.

(2) Exploit and foster consumer market by innovative activities
Efficient supply chain must be the interaction, feedback and balance between efficient supply and demand. The supply side should strengthen understanding and awareness of the market demand and positive response, maintaining this market demand is true, reliable and sustainable. Supply chain finance provides credit support for a large number of SMEs in the supply chain, and consequently the consumer finance of supply chain has emerged. The typical representative such as Alibaba, Jingdong Mall and Suning use their own funds to provide online supply chain financial services, among which installment and other shopping financing services increase the consumption by 30%–50%.

By fully utilizing these trading platforms, supply side sells in domestic and overseas markets as well as expands sales channels at a lower cost. Owing to the strategic cooperation with the e-commerce, large-scale production enterprises combine the market development, capital operation and brand upgrading together, improve the ability to meet consumption experience based on Internet and actively respond to market demand for quality products and services. These efforts made by supply side improve brand awareness and acceptance and consequently improve the company's position in the value chain. What's more, the global business opportunities in supply chain are added.

(3) Guide the consumers to deeply participate in supply chain activities
The emergence of E-commerce has changed the objects of orders and logistics delivery from retailers to consumers. Since business opportunities are found from the user's selection and behavior changes, production and service enterprises should attach importance to user experience and customer voice to ensure consumers have more opportunities to participate in the supply chain activities. Consumers become a crucial factor in supply chain management. On one hand, the demand side influences the product and service design of supply chain through order, feedback, reviews and so on. On the other hand, the supply side can effectively analyze preference trends, behavior characteristics and potential demands of consumers through large data analysis, and accordingly make customized designs based on personalized needs. It means that by application of Internet technology, the ideas of individual end consumer become reality products and services. The customized design innovation featuring "User-Generated Content" is becoming the big trends [6].

The visual distribution of E-commerce Suning, a kind of offline services assisted with the "Internet plus", brings great fun for users and enhance the user experience by giving a sense of involvement and control. Now a lot of outstanding enterprises are marching in deepening their involvement in the supply chain management. They not only collect customer information, but also focus on guiding consumers to participate in collaborative intelligent development of product development, customized products, and experience processes. Enterprises are expected to improve the ability to satisfy customer needs based on the Internet and enhance the quality of supply capacity.

3.2 Supply Side Management-Improve Quality Supply

Supply and demand coexist. The supply side reform means that we shouldn't only focus on demand stimulation and it should be emphasized that the economic growth can't simply depend on stimulating the demand. In the long run, the main supporting factor lies in effective supply's response to high-quality demand and guidance. (Jia Kang, 2015) [5] While, the supply side reform should utilize the production factors including the labor, land, resources, capital, technology to achieve the intensive production model characterized by economic innovation and efficiency, and to achieve the upgrading from low-level supply to high-level supply through knowledge, technology, products and institutional innovation.

(1) Data Analysis Transformation-Big Data Analysis
With the speeding up of convenient Internet and wide application of new technologies, the consumption patterns of end-users have changed and demand expectations are becoming diversified and personalized. In this case, manufacturing enterprises should quickly respond to external changes and effectively mine the data potential in order to solve supply chain management issues such as demand forecasting, replenishment forecasting, inventory optimization, foundry collaboration, production arrangements and supplier management. Besides, the manufacturing enterprises should monitor and manage the process and results including process tracking, exception reminder, order tracking, transaction history data and so on. The solution is the big data analysis which is characterized by dynamic real-time, multi-dimension, public sharing and low cost. Based on the connection of data, big data can help all the node enterprises in the supply chain to watch and control every activity including product design, purchasing, manufacturing, order processing, logistics, financial services and consumers. Besides, it can display inventory, production, orders, circulation, distribution and other activities in real time, and assist the enterprises to optimize, forecast and adjust the balance of supply and demand.

The production systems can cope with the uncertainty brought by the rapidly changing environment. By application of information technology and Internet, the production system can do as follows: ① Grasp the true needs of the market. Process the fragmented information through big data, cloud computing and other information technology, thus the demand trends will assist decision-making; ② Improve production flexibility. It means to promote the production management that quickly responds to multiple products, small batch and rapidity. The "rigid" production mode of large-scale production transforms to the adaptable and "flexible" production mode; ③ Integrate external advantage resources timely.

The enterprises in supply chain can share information at a lower cost through the information platform.

(2) Manufacturing and production transformation-Quick response
O2O model, characterized by small batch, multiple species and fast response, has become a popular market demand. The "Internet plus" mode accelerates this consumption and further improve the consumer expectations. The changes are so fast that manufacturing enterprises are confronted with the following situations: ① Due to poor versatility of personalized products, inventory risk is greatly increased. ② As the technology and product updates speed up, the marketability value of the inventory and performance are reduced, bringing huge economic losses. Therefore, it is necessary to adjust the established production management, system arrangement, equipment selection, logistics and warehousing business pattern that targeted for large-scale production, instead, to transform to flexible manufacturing by full application of Internet technology.

From perspective of production management, it is necessary to adjust the production arrangement timely, quickly and frequently and adopt a flexible and diversified combination of production factors. Besides make full use of internal and external resources advantages to prevent excessive production and meet the market demand at the same time. From the perspective of production equipment, various artificial intelligence tools, manufacturing equipment and computing methods are widely used in the manufacturing process. Manufacturing intelligence is fully utilized in the scheduling, design, processing, control, planning and other aspects of the production. Manufacturing enterprises must comprehensively utilize manufacturing technology, management science, computer science, information technology, and conduct comprehensive processing of internal and external information and reasonably schedule the procurement, logistics and production. The flexible production system based on information technology can respond to the changing production and sales, and reduce response time to changes, besides, production costs can fluctuate with the amount fluctuation.

(3) Structural transformation of supply side-Provide quality supply
On one hand, the overcapacity is prominent when shortage economy is shifting towards surplus economy in China. On the other hand, as Chinese per capital income continues to grow, the basic needs upgrade to development demands and the demands are diversified and personalized. In the Internet era, consumers have more choices in products, service, consumption channels and manners. The popularity of overseas purchase heat demonstrates that people welcome continuous protected products of high quality and fair, just and honest service. When consumers are dissatisfied with the products and services, they turn to lower cost channels as alternatives. Therefore, the effective way to resolve overcapacity and overstocked products is to change the export-oriented supply system to improve the effective domestic demand, provide favorable environment for domestic high-quality supply enterprises to ensure supply keep ups with the pace of demand.

Expanding domestic demand has always been an important means of China's economic development. In practice, domestic demand growth comes mainly from investment as the contribution of terminal consumers is limited. Supply side structural reform, in essence, is the effective supply and utilization of production factors. In particular, it gives full play to the role of capital and technology factors. It means we should introduce advanced management ideas, improve management capacity, reduce costs, eliminate backward production capacity, get rid of low-cost competition, improve supply quality, and create space for the upgrading of industry and supply chain.

To start with the supply side, it is necessary to resolve the contradiction between consumer demands for quality products and services and the existing low-end products provided by production and service enterprises. "Internet plus" information technology reallocates the resources and provide a strong platform to eliminate the information asymmetry caused by mismatched contradictions.

3.3 Enhance Logistics and Financial Services Capabilities

The modern logistics industry provides material flow service for collaborative activities of enterprise in supply chain node, and improves the interconnection and interdependence among the supply chain nodes. The financial innovation in supply chain on this ground provides the financial support for supply chain development. However, the high financing and logistics costs have restricted the competitiveness of China's industries, affecting the efficiency of the entire industrial structure. Therefore, China's supply side reform not only involves the production field, but also includes the reform on the transaction behaviors, systems and circulation and service areas among the manufacturers, agents, dealers, retailers in the supply chain.

(1) Integrate the fragmented logistics services and improve logistics supply capacity and level
The development direction for the logistics industry to enter into network and organized service is to integrate resources, expand logistics enterprises scale, improve the introduction and application of information technology to provide one-stop service for consumers, expand the logistics services scope and provide value-added logistics services. The logistics platform gathering large sums of fund and technology will become the breakthrough of logistics industry integration.

Various forms of logistics network platform coordinate the goods and capacity, integrate scattered transport resources and sources of goods and improve the efficiency of material circulation. When the supply chain efficiency is low, the supply of raw materials cannot make timely production. Then most of the manufacturers will prepare front-end raw material storage and back-end finished products storage, it might cause high inventory costs and overstock inventory. With the development of the logistics platform and popularization of smart phones and networks, the highway logistics APPs have emerged. These APPs help obtain real-time logistics information conveniently, breaks information asymmetry, matches freight resources effectively and reduce resources wasting. Many small micro-logistics enterprises link the supply side and demand side through the supply chain. With the supply chain information platform, theses companies can rapidly accumulate massive data, accurately research into demand and participate in supply chain services in real time.

(2) Overall penetration of financial innovation on "Internet plus"
To provide financial guarantee for the supply side reform, it is necessary to stimulate innovation through policies, improve the total factor productivity, rationalize the imbalance of supply and demand structure, make the capital flow to the real economy and optimize the allocation of financial resources. Financial innovation should have all-round penetration on "Internet+" in the economy and living. Supply chain finance means that regarding with the real business context and the credit level of the core enterprises of the supply chain, the financial institution provides credit support to small and medium-sized enterprises in the upstream supply chain and consumer finance for downstream consumers. Since core enterprises are the backbones of the supply chain system, they must establish an efficient resource sharing system to provide a sharing platform, maintain membership cooperation, find value creation methods and finally improve the competitiveness of the whole supply chain system.

4 Conclusion

The wide coverage and availability of the Internet has transformed the supply chain from a single, linear, discontinuous information flow into a complex information network, which increases the possibility of choosing excellent supply chain partners and expands the access of quality products and service for consumers. The impact of "Internet plus" on the supply chain, on one hand, is reflected in the application of information technology and big data, by which companies achieve real-time information, data collection and analysis, resulting that business decision-making is no longer simply based on structured data; on the other hand, the impact is reflected in the changes of production mode and the circulation ways. The Internet plus promotes the development of multi-industry convergence and transformation and upgrading of traditional industries, and fundamentally reduces the contradictions between high inventory and low consumption satisfaction as well as between overcapacity and sluggish manufacturing.

The transformation process from the traditional supply chain management to the "Internet plus supply chain" is not the simple application of information technology to supply chain management, but the conversion and innovation of information technology from subordinate roles to the dominant rules, which promote customers' true demands capturing, supply chain visualization process, agile manufacturing, real-time data acquisition and sharing, and partner collaboration, in the environment of continuous technology development of internet, big data and cloud computing. A reviewed way of thinking, about market, custom, production and enterprise value even the business ecosystem, is revealed.

Assessing the Recycling Efficiency of Resource in E-Waste Based on MFA of Reverse Logistics System

Minxi Wang, Xiaoling You, and Xin Li(✉)

College of Management Science, Chengdu University of Technology, Chengdu, The People's Republic of China
Lixin2012@mail.cdut.edu.cn

Abstract. The waste electrical and electronic equipment (WEEE, e-waste) has caused many issues, such as waste of resource and environmental pollution. This paper applied material flow analysis (MFA) method to analyze the flows of recycled resource from WEEE and process of reverse logistics from recycling to reuse. And analyzed the discarded TV data in K company (a leading television producer in China), and calculated the recycling efficiency of metals. The research showed that recycling efficiency of the metals from discarded TV in K company is 12.3%, which is far below the criterion (In Japan, the "Household appliance recycling and reuse" recycling efficiency of useful resource from discarded television by the television manufacturers must be above 55%). At last, we gave some suggestions for developing recycling efficiency of manufacturing enterprises and recovery enterprises in China: (1) Improving the recycling efficiency of manufacturer, retailer and consumer can contribute to improve the recycling efficiency in the whole reverse logistics system; (2) Improving the technological level of decomposition and dismantling of e-waste in the recycling process can increase the recycled material; (3) Manufacturing enterprises should have the green production concept and the participants in the supply chain should follow the concept of EPR (Extended Product Responsibility).

Keywords: Reverse logistics · Recycling efficiency · MFA · WEEE

1 Introduction

WEEE is the waste of electrical or electronic products, it covers a wide spectrum ranging from consumer goods such as discarded refrigerators, air conditioners, washing machines, televisions and computers, mobile phones to capital goods such as some unqualified products, parts and scraps in the production and repair processes [6].

Because of containing precious metals (such as gold, copper, aluminum and silver) and plastic, the reutilization of WEEE has magnificent recovery value and

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_81

environmental protection advantages. Recycling resource from the WEEE has long-term strategic significance, not only can reduce the waste of resource, promote social development and regional economic growth, but also can reduce the serious threat from toxic and harmful substances in e-waste to the environment and human health.

Many researchers have made a large amount of researches on the recycling in reverse logistics system and e-waste recycling. In the aspect of reverse logistics system mainly focused on architecture design for the network, model establishing and waste management in reverse logistics system. Reverse logistics network can be divided into different branches according to the type of goods in reverse logistics system, applying the mixed-integer linear program (MILP) or integrating the analytical hierarchical process (AHP) can address the complex network configuration of a reverse logistics system [2,9,11]. In order to design the network of reverse logistics system, the capacities of each nodes and the number of recycling facilities should be considered. By applying some models can minimize the costs, and simultaneously can consider green and social issues to design a reverse logistics network [10]. In addition, establishing the model of reverse logistics also can solve some practical problems, for instance Ehab Bazan established the model based on the economic order/production quantity (EOQ/EPQ) and the joint economic lot size (JELS) settings for reverse logistics inventory systems [5]. Waste management is an important part in reverse logistics system, and waste recycling is a multi-disciplinary problem, a holistic view and viewpoints from different decision levels should be considered when modelling a reverse logistics system for waste management [7]. Setting up the waste management strategies can help firms to reduce waste and have a healthy reverse logistics system [15]. In the aspect of e-waste recycling, developing model and applying method can analyze the WEEE based on a real world case. For instance, Ayvaz, B created the two stage stochastic programming model provides acceptable solutions to make efficient decisions for reverse logistics network design of e-waste [4]. By applying the material flow analysis method can make a detailed analysis for recycling and stock of e-waste, as well as the recycling efficiency assessment and optimization in the closed-loop supply chain [1,14].

This paper combine recovery system with material flow analysis method in reverse logistics system and analyze the process of resource recycling of e-waste. Take recovery of discarded televisions of K company (a leading television producer in China) as an example in this thesis, its recycling efficiency of metal in the discarded television is calculated and assessed, based on that we gave some suggestions for the manufacturing enterprises and recovery enterprises in China.

2 Theory and Methodology

2.1 Reverse Logistics and Reverse Logistics Network

A complete definition of reverse logistics is put forward by the European Working Group on Reverse Logistics, and is formulated as follows: "The process of planning, implementing and controlling backward flows of raw materials, in-process inventory, packaging and finished goods, from a manufacturing, distribution or use node, to a node of recovery or node of proper disposal" [3].

Reverse logistics network is the nodes distribution and the arrangement of transportation routes between each node in the reverse logistics system. Typical reverse logistics network is shown in Fig. 1.

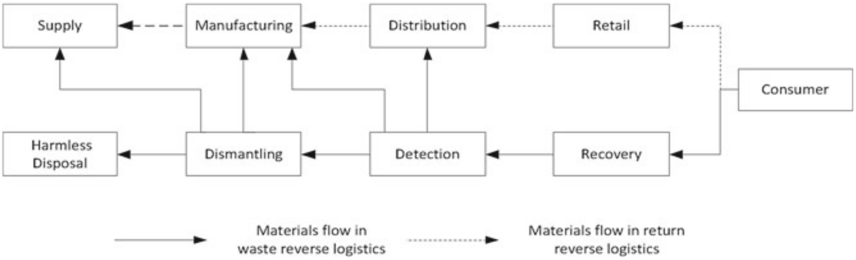

Fig. 1. Typical reverse logistics network

2.2 Material Flow Analysis

Material flow analysis (MFA) is "a systematic assessment of the flows and stocks of materials within a system predefined in space and time". The method mainly

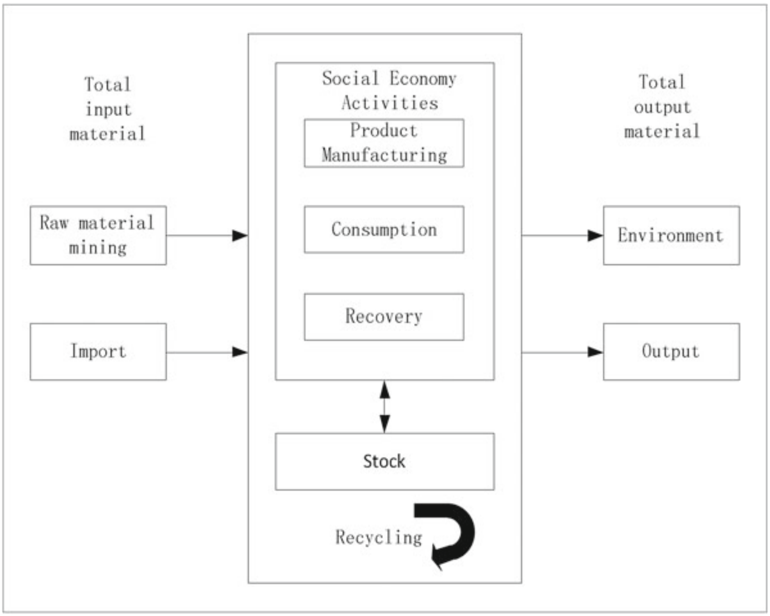

Fig. 2. The basic framework of material flow analysis method

involved the material inputs, outputs, and inventories [8]. According to the law of conservation of mass, MFA could get an ultimate conclusion that indicates the status of material input, stock and output in each stage of life cycle. It is based on the material balance theory (Total material input = Total material output + Stock), by means of material flow analysis, we can estimate and evaluate the condition of development, utilization and waste management of natural resources and various substances. The basic framework of material flow analysis method is shown in Fig. 2.

2.3 Material Flow Analysis of Reverse Logistics System

MFA of reverse logistics system is the main methodology in this paper which is a way to analyze the material flow of e-waste in reverse logistics system.

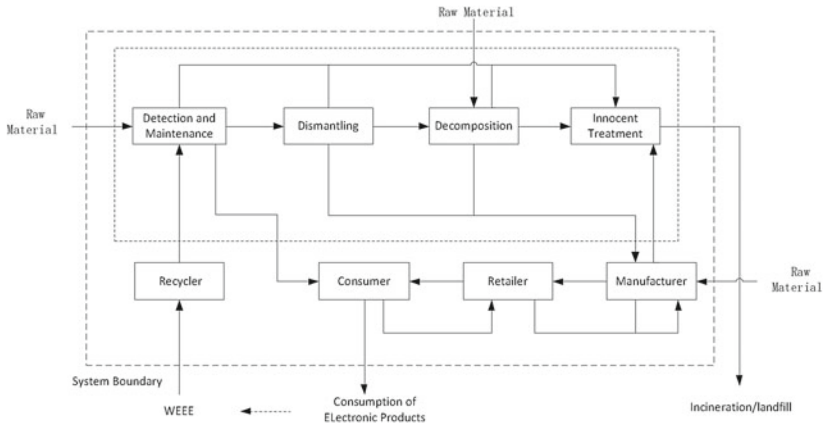

Fig. 3. The material flow analysis frame of the reverse logistics system

As shown in Fig. 3, participants in the frame are recycler (which mainly responsible for four recycling process: detection and maintenance, dismantling, decomposition and innocent treatment), manufacturer, retailer and consumer.

3 Analysis and Discussion

3.1 Reverse Logistics Process for the WEEE

As a special kind of reverse logistics, the recovery process for e-waste includes five aspects. Figure 4 shows the principal stages in the recovery process.

(1) Recovery

Recovery phase is the first and most important stage in the whole recovery process. At present, the main sources and recovery channels of e-waste in China are shown in Table 1.

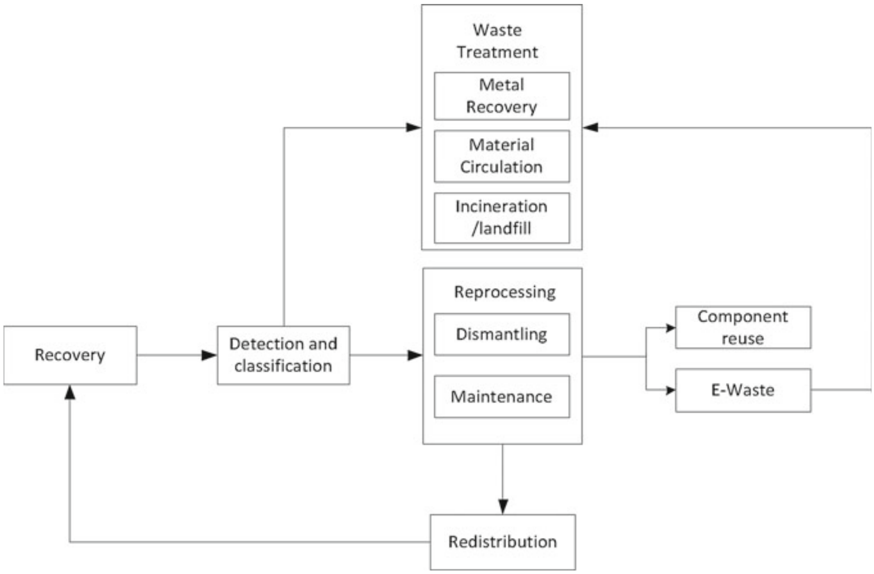

Fig. 4. Recovery process for the WEEE

Table 1. The main sources and recovery channels for e-waste

Category	Comment
Main source	The daily life of the residents; Electronic products and household appliances manufacturers and sellers; Illegal imports of e-waste from abroad.
Recovery channel	Door-to-door recovery; For trading-in old one for new one in the Shop; Flea Market of electronic products and household appliances; Garbage recycling by government/The glean and collect scrap man; After-service station

(2) Detection and Classification

E-waste has a wide variety of categories, and each category can be divided into small classes and the corresponding value of it is different. Therefore, the work that must be done is rigorous detection and classification for the recycling of e-waste according to their characteristics such as structure or components function to determine the subsequent process, such as after maintenance to resale, reuse the parts after dismantling, material recycling after decomposition or waste treatment.

(3) Reprocessing

In the reprocessing stage, e-waste can be reacquired the value that reuse, remanufacture or recycle through reasonable reprocessing for recycled products or parts. Reuse only aims at the recycled products can be used directly through cleaning or simple maintenance, such as the toner cartridge which can be used again through the simple work. Remanufacturing aims at the e-waste can enter the manufacturing stage again after dismantling, replace or repair. And the recycle aims at the parts, glass and plastic in the recycled e-waste.

(4) Redistribution

The recycled e-waste can be as commodity to reuse and enter the consumer market or donate to the consumers in poor areas directly after the inspection and reprocessing stage. In this stage, distribution is the most important work, which can make the entire recovery process for the WEEE operate efficiently.

(5) Waste Treatment

For the e-waste that has no circular economic value or can bring large harm to the environment, the available material in them can as the recycling resources to be reused through the reasonable treatment, such as dismantling, melting, refining and electrolysis. While for the e-waste cannot be reused, the disposing is partitioned in two ways, one which is stored them in landfills; the other approach is sent them to an incinerator.

3.2 MFA in Reverse Logistics System for E-Waste

(1) Date Acquisition

In this paper, according to the MFA of reverse logistics system, we built a reverse logistics system for e-waste based on the self-operated recovery system of the K television manufacturing company in China. Take the recycling efficiency of the metal resources (copper, aluminum, iron) of the company as the concrete calculation example. Through collecting television sales data of the company over the years and applying the market supply method A [12] to forecast the amount of discarded TV of the K television manufacturing company in 2016.

Through the existing research [13] can get the duration of use and the waste rate of the television is shown in Table 2.

Table 2. The duration of use and the waste rate of the television

Duration of use(year)	< 8	8–9	9–10	10–11	11–12	12–13	13–14	14–15	15–16	> 16
Waste rate	6%	6%	10%	13%	15%	15%	13%	10%	6%	6%

The sales date of K television manufacturing company over the years is shown in Table 3.

The market supply method A formula as follows:

$$Q = \sum S_i \times P_i, \qquad (1)$$

Table 3. Sales of television over the years

Year	Sales (Million)
2000	1.06
2001	1.09
2002	1.63
2003	2.41
2004	2.43
2005	3.99
2006	3.99
2007	3.54
2008	4.01
2009	5.8
2010	6.02
2011	6.41
2012	7.56
2013	8.05
2014	9.67
2015	9.92

where, Q represents the amount of discarded televisions a year, S_i represents the sales of televisions i years ago (assuming all the sales of televisions are used), P_i is the waste rate represents the proportion of the discarded television in sales i years ago.

By using this model, it can be concluded that the amount of waste television in 2016 is 2.12million. Combining with the relevant information from the related industry, 50% of discard television can be recovered, and the dismantling rate (after dismantling can be recycled parts ratio) is set to 35%, and the decomposition and utilization rate is set to 56%. The average weight of a television is 20 kg, the content of copper in a television is 5.4%, the content of aluminum in a television is 5.4%, and the content of iron in a television is 5.3% [18]. Because the resource loss of recycled metal to the environment in each stages, and in order to facilitate the research, so the following assumptions are given:

(1) The structure of resource recycling in reverse logistics system is a closed loop network, all the discarded television after disposing would return to manufacturer;
(2) The return production from consumer must be sent to the manufacturer for processing;
(3) The product could be reused after detection and maintenance would be resold and enter the consumer market;
(4) All the discarded television (which could be recycled) must be recycled by the recycler.

Therefore, the amount of recycled metal from discarded television is 3413.2 tons. The specific data are shown in Fig. 5.

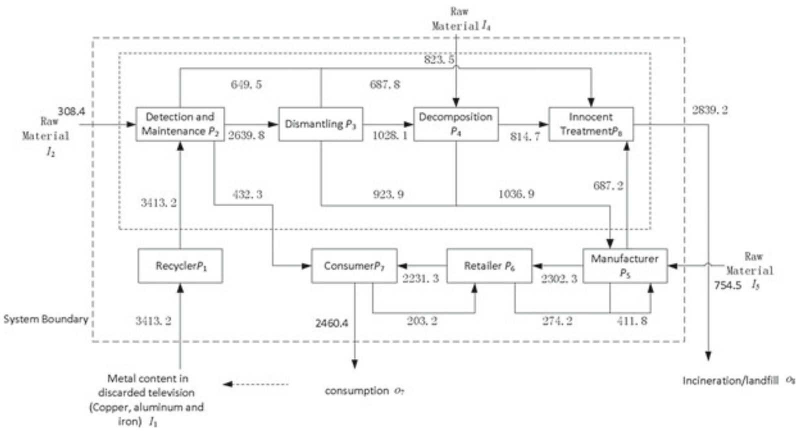

Fig. 5. The specific data in reverse logistics system of discarded television. All units measures in tons

(2) Empirical Analysis

According to the data in Fig. 5, the input-output table of reverse logistics system of discarded television is shown in Table 4.

Table 4. The input-output table. All units measures in tons.

	P_1	P_2	P_3	P_4	P_5	P_6	P_7	P_8	I_0
P_1	0	0	0	0	0	0	0	0	3413.2
P_2	3413.2	0	0	0	0	0	0	0	308.4
P_3	0	2639.8	0	0	0	0	0	0	0
P_4	0	0	1028.1	0	0	0	0	0	823.5
P_5	0	0	923.9	1036.9	411.8	274.2	0	0	754.5
P_6	0	0	0	0	2302.3	0	203.2	0	0
P_7	0	432.3	0	0	0	2231.3	0	0	0
P_8	0	649.5	687.8	814.7	687.2	0	0	0	0
O_0	0	0	0	0	0	0	2460.4	2839.2	0

In order to quantify the relationship of various stages of metal cycle in reverse logistics system, we give the mathematical expression of input-output relationship based on material balance theory as Eqs. (1) and (2), x_k is the total flow in P_k, f_{kj} is the flow of P_j to P_i.

$$x_k = \sum_{i=1}^{n} f_{kj} + I_k \qquad k = 1, 2, \cdots n, \tag{2}$$

$$x_k = \sum_{i=1}^{n} f_{ik} + O_k \qquad k = 1, 2, \cdots n. \tag{3}$$

According to the Eqs. (2) and (3), the total flow of each node is shown in Table 5. In order to assess the overall recycling efficiency of the system, we give the mathematical expression Eq. (4)–(6).

Table 5. The total flow of each node

Node	Amount (tons)
P1	3413.2
P2	3721.6
P3	2639.8
P4	1851.6
P5	2989.5
P6	2505.5
P7	2663.6
P8	2839.2

$$n_i = \frac{I_i + \sum_{j=1}^{n} f_{ij}}{o_i + \sum_{j=1}^{n} f_{ji}}, \tag{4}$$

$$R_i = \frac{n_i - 1}{n_i}, \tag{5}$$

where, n_i is the relation of the input and the final output of a single node. When $n_i = 1$ indicates that the recycled metal resources through the node i, but not returned to the node i for recycling. When $n_i > 1$ indicates that the recycled metal resources through the node i, and returned to the node for recycling with a direct or indirect way.

n_i is recycling efficiency of a single node. When $R_i = 0$ indicates the flow of the recycled metal resources through the node i is unidirectional. When $R_i > 0$ indicates the recycled metal resources through the node i can return the node for circulating and using.

Table 6. The calculation results of n_i and R_i

	1	2	3	4	5	6	7	8
n_i	1	1	1	1	1.14	1.09	1.19	1
R_i	0	0	0	0	12.30 %	8.30%	16%	0

The calculation results of n_i and R_i are shown in the following Table 6.

According to weighted method, we use the recycling efficiency of each node can get the overall recycling efficiency C in the system.

$$C = \frac{s_c}{s} = \frac{\sum_{i=1}^{n} R_i \times x_i}{\sum_{i=1}^{n} x_i} = \frac{1001.841}{8158.6} \approx 12.3\%, \tag{6}$$

where, S_c is the total recycling flow, S is the overall flow of nodes which the recycling efficiency of a single node is not equal to zero [16].

Therefore, the overall recycling efficiency of the system is 12.3 %. That is the recycled metal resources after the whole recovery process, 12.3% metal resources in discarded television can be reused.

4 Conclusions

According to the analysis and discussion above, we concluded that the recycling efficiency of metal resources in waste television of K television manufacturing company which is representative in the television industry, so the recycling efficiency has a certain reference value for home appliance manufacturing industry in China.

There is not a sound assessment standard to evaluate the recycling efficiency in China, so this paper take Japanese experience as reference. In Japan, the "Household appliance recycling and reuse" started from 2001 specifies that the recycling efficiency of useful resource (metal in the majority) from discarded television by the television manufacturers must be above 55% [17]. Obviously, the recycling efficiency of the television company was hard to reach the criterion with the present resource recycle level, so it is feasible to make optimization for reverse logistics recycling system of e-waste in China, and improve circulation efficiency of the recycling system, so we give the following suggestions:

(1) From the above calculation process, the overall recycling efficiency lever mainly depends on P_5, P_6 and P_7 (Fig. 5). Thus, we can increase the numerical value of P_5, P_6 and P_7 (Table 6) to increase the overall recycling efficiency, that means improving the flow of manufacturers, retailers and consumers is the key problem to improve the recycling efficiency of the system.

(2) Improving the secondary utilization ratio of the material in the recycling system, such as improving the technological level of decomposition and dismantling of e-waste in the recycling process, the recycled material in e-waste can be increased, but the input of raw material can be reduced, and then minimize the wastage of resource from the external environment.

(3) Chinese electronic products and household appliances manufacturing enterprises should have the green production concept to decrease the amount of waste that can't be reused. In addition, the participants in the entire supply chain should follow the concept of EPR (Extended Product Responsibility). That means not just the manufacturer, the distributor, retailer and consumer should also strengthen mutual cooperation and bear their respective responsibilities, for the purpose of promoting the level of reuse and recycling of resources.

Acknowledgements. We would like to thank all anonymous reviewers for their constructive comments and suggestions. This research was supported by the fund of the Excellent Innovation Research Team at Chengdu University of Technology (KYTD201406).

wanghongchun@bucea.edu.cn

Abstract. The combination of big data theory and supply chain management theory has brought the subversive change for the enterprise cooperation mode, the paper considered that when the big data suppliers to participate in the competition of the supply chain, the condition of overall profit of the supply chain in the two cases of cooperation and non-cooperation decision making. Firstly, the profit model of each member enterprise is established by the demand function theory, and the whole profit model of the supply chain is obtained in the case of decentralized decision-making, then, the profit model for common decision making of supply chain based on the maximization of supply chain is analyzed. After compared the two profit models, the conclusion was obtained that when big data suppliers join supply chain competition and one party gains the dominant position in the supply chain, collaborative decision-making is the key to enhancing the overall profitability of the supply chain.

Keywords: Big data · Supply chain collaboration · Competition · Cooperation

1 Introduction

The method of supply chain management based on mutual cooperation between enterprises is one of the most effective business strategies adopted by enterprises in the fierce market competition, and the rise of big data industry is injected new blood on Supply Chain Management. Data analysis methods are applied to all aspects of supply chain management to effectively curb the procurement shortage, lag of logistics, production bottlenecks. There are some significant achievements in the area of big data supply chain management. Firstly, supply chain management has been intelligent, and a new generation of radio frequency identification technology can provide more reliable data for supply chains, these data flow in the supply chain nodes, so that enterprises can exchange information timely, the operating mechanism of the system can be optimized and the decision making become automated. In addition, big data has also brought disruptive changes for the supply chain logistics. At present, enterprises can already

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_82

achieve real-time monitoring of logistics and route optimization in the use of big data technologies. Transport capacity and efficiency have been greatly improved than before. The focus of future research is to predict supply chain behavior rely on large data. Accurate forecasting is one of the effective measures to help enterprises save costs, and the accuracy of large data projections is not reached by other methods.

Current research on competition and cooperation model of the supply chain is very mature, Yang and Bai, who build up on the Hotelling model to analyze profit-sharing contracts between the supplier and the core firm, and study the impact of upward decentralization on the core firm and the whole supply chain under the assumption that the supplier does not have any advantage on production costs [12]. Wu and Han, who researched the optimal production decisions in closed-loop supply chains consisted of two competing manufactures and one retailer with remanufacturing costs disruptions [9]. Xu et al. [11] gave a literature review of supply chain contracts selection and coordination based on the supply chain under competing multi-manufactures. Shi, who studied in non-cooperative static game and Stackelberg game optimal advertising strategy in supply chain under master-slave, proves that relevance of the manufacturer and the retailer's own ads level and cost and overall supply chain advertising level and costs [3]. Strategic of partner selection of supply chain model was constructed by Xin and others based on game theory, and get optimal strategies for select partners in the case of incomplete information [10]. Zhang, who thought the whole supply chain benefits and members of associated enterprise level knowledge sharing is very important, In light of this, he builds supply chain profit distribution model based on knowledge-sharing cost [14]. Chen et al. [1] proposed the question of how "big data analysis affects the value creation of the supply chain", and it was answered through the use of dynamic capability theory as a unique information processing capability.

Research on supply chain based on the theory of large scale data, Wu [8] based on dynamic differential game theory constructed the dynamic corporation model of three-level supply chain under retailer paid contract, union pay contracts, with big data service providers to participate in, and discusses contract parameters on the profit impact of supply chain. Wang and Cong, [7] who studied the cloud computing service providers involved in two-stage supply chain coordination problem and introduced in the competition model of supply chain revenue-sharing contract and punished the contract so as to verify that the supply chain coordination and decision. Waller [5] established a matrix model to solve when it should be applied or avoid data analysis, theory of how to use predictive analytics improve issues such as promoting lower total logistics costs. Tan [4] through impedimented to data acquisition analysis, set up a corresponding data infrastructure framework, the framework of internal data, available through collection of deep mining, collection capacity required data to build a data network and helped provide supply chain optimal decision. A systematic framework for the SAM (Roadmap, Strategic Consolidation, and Assessment) roadmap was roadmap to help companies avoid getting caught in a mess of data by Sanders [2]. And the concept of supply chain analysis (SCA) driven by big data was proposed and the function, process-based, collaborative and agile SCA Maturity Mode was established by Wang and Angappa [6].

This paper analyzes the overall profitability of the supply chain under different decision-making situations when the big data suppliers participate in the supply chain competition. The supplier and manufacturer's demand curve is taken as the input to construct the profit model of the supplier and the manufacturer when the manufacturer assumes the big data cost respectively. Through the analysis of the model, the profit model of the supplier and the manufacturer is obtained respectively in the decision - The overall profitability of the supply chain. After comparing the two profit models, we get the corresponding conclusion.

The rest of the paper is organized as follows. In Sect. 2, the problem of is described and some assumptions is proposed. In Sect. 3, the model of decentralized decision-making profit and common decision making are built. In the Sect. 4, two models are compared and analyzed. And there is a numerical analysis in Sect. 5. In Sect. 6, conclusions are given.

2 Problem Description and Model Assumptions

The paper considers the supply chain system as a kind of supply and demand relationship between a supplier and a manufacturer. The manufacturer produces a product with a fixed life cycle and mature market demand. The supplier provides raw materials. The input-output ratio of the raw material to the final product is 1: 1. In order to solve the problem of lagging information transmission among member firms and to improve the accuracy of market demand forecasting, the third-party big data enterprise is used to help the supply chain to build a big data decision platform. The cost is borne entirely by the manufacturer. Because of exists of the supply chain big data platform, the information on the supply chain is completely symmetrical. Assuming that the profit-sharing problem in cooperative decision-making has already reached a corresponding contract between supply and demand, the paper will not consider it.

Suppose that the manufacturer's market demand function is $D(p_A) = a - bP_A + bK(t)$, then we can get the manufacturer's price curve $P_A = \frac{a}{b} - \frac{1}{b}D$, for the convenience of calculation, let $\frac{a}{b} = m$, $\frac{1}{b} = \mathrm{n}$, then there is $P_A = m - nD + K(t)$. It is worth noting that, where m is the limit price that the market can afford [13], that is to say, at this price, the purchase rate of the commodity is 0; Suppose that the market demand function of the suppliers is $D(p_B) = \alpha - \beta P_B$, we can get $P_B = \frac{\alpha}{\beta} - \frac{1}{\beta}D$, let $\frac{\alpha}{\beta} = s$, $\frac{1}{\beta} = t$, then $P_B = s - tD$, empathy, s is the limit price that the market can afford.

The symbols involved in the article are described as follows:

D : Market demand;
P_A : The price of the product produced by the manufacturer;
P_B : The price of the raw materials supplied by the supplier;
G_B : The prices of the raw materials supplied by the sub-suppliers;
$K(t)$: Big data horizontal curve;
r : Big data cost coefficient;
Φ_A : The profits of the manufacturers;
Φ_B : The profits of the suppliers;
Φ_{AB} : The total profit of the supply chain when making decisions together

Among them, the big data cost is $F = \frac{rt}{2}D$, that is, the manufacturer's output is positively correlated with the big data costs, the higher the output, the greater the cost of the big data.

3 Building of the Model

3.1 Decentralized Decision-Making Profit Model

In the case of decentralized decision making, the manufacturer's profit depends on the market price of its own products and the price of raw materials from the suppliers, In addition, because of the cost of big data suppliers to join the supply chain is entirely borne by the manufacturer, so the profits are:

$$\Phi_A = (P_A - P_B) \times D - \frac{rt}{2}D. \tag{1}$$

The profit of the suppliers depends on the price of the product to the manufacturer and the purchase price of the raw material. Therefore, the profit of the suppliers is:

$$\Phi_B = (P_B - G_B) \times D. \tag{2}$$

It can be known from the supplier's demand function that $D = \frac{s - P_B}{t}$. Therefore, its profit is:

$$\Phi_B = \frac{1}{t}\left[s\left(P_B - G_B\right) - {P_B}^2 + P_B G_B\right].$$

Find the partial derivative of P_B in the supplier profit model and let it be equal to 0, and then the function of raw material price provided by the suppliers and cost is obtained:

$$\frac{\partial \Phi_B}{\partial P_B} = \frac{1}{t}\left[s - 2P_B + G_B\right] = 0,$$
$$P_B = \frac{s + G_B}{2}. \tag{3}$$

The manufacturer's profit formula can be known from formulas (3) and (1):

$$\Phi_A = [(m - nD + k(t) - \frac{s + G_B}{2})] \times D - \frac{rt}{2}D.$$

Find the partial derivative of D and make it equal to 0, the manufacturer's optimal production decision can be obtained:

$$\frac{\partial \Phi_A}{\partial D} = (m - 2n + k(t) - \frac{s + G_B}{2}) - \frac{rt}{2} = 0,$$
$$D = \frac{m + k(t) - \frac{s+G_B}{2} - \frac{rt}{2}}{2n}. \tag{4}$$

The manufacturer's profit under the optimal production decision can be known through formulas (3), (4) and (1):

$$\Phi_A = [(m - nD + k(t) - \frac{s + G_B}{2})] \times \frac{m + k(t) - \frac{s+G_B}{2} - \frac{rt}{2}}{2n} - \frac{rt}{2} \times \frac{m + k(t) - \frac{s+G_B}{2} - \frac{rt}{2}}{2n}.$$

It can be known after finishing:

$$\Phi_A = \frac{(m + k(t) - \frac{s+G_B}{2} - \frac{rt}{2})^2}{4n}. \tag{5}$$

Because of the existence of the big data platform, the information on the supply chain is completely symmetric. Therefore, the production decision of the supplier is based on the optimal production decision determined by the manufacturer. Then, the profit of the supplier under the manufacturer's optimal production decision can be obtained through formulas (3) and (4):

$$\Phi_B = \left(\frac{s + G_B}{2} - G_B\right) \times \frac{m + k(t) - \frac{s+G_B}{2} - \frac{rt}{2}}{2n}.$$

It can be known after finishing:

$$\Phi_B = \frac{(s - G_B) \times (m + k(t) - \frac{s+G_B}{2} - \frac{rt}{2})}{4n}. \tag{6}$$

According to the big data platform of the supply chain, in the case of decentralized decision-making, the manufacturer preferentially determines its own production decision and puts its own decision data on the big data platform. Based on the information obtained through the big data platform, the supplier produces the corresponding number of parts, and then the total profit of the supply chain at this time is:

$$\Phi = \Phi_A + \Phi_B = \frac{(m + k(t) - \frac{s+G_B}{2} - \frac{rt}{2})^2}{4n} + \frac{(s - G_B) \times (m + k(t) - \frac{s+G_B}{2} - \frac{rt}{2})}{4n}.$$

It can be known after finishing:

$$\Phi = \frac{(m + k(t) - \frac{s+G_B}{2} - \frac{rt}{2})(m + k(t) - \frac{3s-G_B}{2} - \frac{rt}{2})}{4n}. \tag{7}$$

3.2 Common Decision-Making Profit Model

In the model of collaborative decision-making, suppliers and manufacturers rely on the big data platform for effective correlation, considering the overall interests of the supply chain to jointly determine the optimal production decision. Therefore, the function of the collaborative decision-making profit is expressed by the original profit function of the supplier and the manufacturer:

$$\varPhi' = \varPhi_A + \varPhi_B = (P_A - P_B) \times D - \frac{rt}{2} D + (P_B - G_B) \times D.$$

It can be known after finishing:

$$\varPhi' = \left(m - nD + k(t) - G_B - \frac{rt}{2}\right) \times D. \tag{8}$$

Find the partial derivative of D and make it equal to 0, it can be known that the optimal number of producers and suppliers at the time of collaborative decision-making is:

$$\begin{aligned} \frac{\partial \varPhi'}{\partial D} &= m - 2nD + k(t) - G_B - \frac{rt}{2} = 0, \\ D &= \frac{m + k(t) - G_B - \frac{rt}{2}}{2n}. \end{aligned} \tag{9}$$

The total profit model of supply chain can be known when the optimal production quantity has been determined under the condition of common decision through formula (8) and formula (9):

$$\varPhi' = \left(m - n \times \frac{m + k(t) - G_B - \frac{rt}{2}}{2n} + k(t) - G_B - \frac{rt}{2}\right) \times \frac{m + k(t) - G_B - \frac{rt}{2}}{2n}.$$

It can be known after finishing:

$$\varPhi' = \frac{\left(m + k(t) - G_B - \frac{rt}{2}\right)^2}{4n}. \tag{10}$$

4 Comparative Analysis

Through the above analysis, it obtains the profit model of the supplier and the manufacturer in the case of decentralized decision-making and collaborative decision-making when the manufacturer is fully committed to the big data cost.

In the case of decentralized decision-making, suppliers and manufacturers do not take into account the overall interests of the supply chain to maximize, but entirely from the perspective of their own interests to make decisions. Because of the existence of big data platform, although the suppliers and manufacturers make decisions discretely, the transmission of information flow is transparent. The manufacturer makes the decision first, and the supplier makes its own production decision according to manufacturer's production plan.

In the case of collaborative decision-making, to achieve the overall profit maximization of the supply chain is the premise of cooperation between suppliers and manufacturers, manufacturers take into account the supplier's production capacity constraints, logistics conditions and other objective factors, and then the two sides can achieve collaborative decision-making. The overall profit model of the supply chain is determined according to the market demand function of both parties, so that the production decision can be made with the maximum profit of the supply chain.

The profit model of the two cases is compared and analyzed, and then:

$$\begin{aligned}\Delta\Phi =&\Phi' - \Phi = \frac{(m + k(t) - G_B - \frac{rt}{2})^2}{4n} \\ &- \frac{(m + k(t) - \frac{s+G_B}{2} - \frac{rt}{2})(m + k(t) - \frac{3s-G_B}{2} - \frac{rt}{2})}{4n},\end{aligned}$$

for the convenience of calculation, let $e = m + k(t) - G - \frac{rt}{2}$, then there is

$$\begin{aligned}\Delta\Phi =& \frac{(e - G_B)^2}{4n} - \frac{(e - \frac{s+G_B}{2})(e - \frac{3s-G_B}{2})}{4n} \\ =& \frac{(e - G_B)^2}{4n} - \frac{(2e - s - G_B)(2e - 3s + G_B)}{16n} \\ =& \frac{(s - G_B)^2 + 4[(e - G_B)^2 - (e - s)^2]}{16n}.\end{aligned}$$

According to the above it can be known that s is the limit price that the market can afford, so there must be $G_B \langle s$, so, $(e - G_B)^2 - (e - s)^2 \rangle\, 0$, and easy to proof that $\Delta\Phi \rangle\, 0$, that is to say the profit in cooperative decision-making is higher than that in decentralized decision-making.

It can be known that manufacturers dominate the entire supply chain and completely control the supply chain's big data platform by analyzes and contrasts the two models, but it does not mean that the manufacturer can control the information flow entirely. Because in the case of decentralized decision-making, manufacturers do not take into account the conditions of suppliers when making decisions, so the interests of suppliers are damaged and lead to supply chain breaks. In the case of cooperative decision-making, manufacturers and suppliers, under the condition of ensure their own interests, determine the optimal number of production according to the conditions of both factors. After reaching the corresponding contract, the cooperation tends to be stable, which is to make the overall profit maximization of the supply chain as a prerequisite.

The above analysis can also prove that only cooperation can make the supply chain system to achieve the maximum profit, the joining of big data suppliers does not change the competition pattern of supply chain. Although manufacturers dominate the supply chain, choose to cooperate with suppliers will achieve a win-win situation.

5 Numerical Analysis

In this secondary supply chain, the overall profit of the supply chain with the raw material prices and market demand changes, Suppose that $K(t) = \frac{t^2}{2}$ and large data cost coefficient $r = 0.5$, consider the profit situation of supply chain when $t = 10$, raw material price and market limit price change, the concrete numerical analysis is shown in Table 1.

Table 1. Profitability of raw material price and market time price change

m	s	G_B	Φ	Φ'	$\Delta\Phi$	Rate of profit increase
35	25	10	812.5	1314.1	501.6	61.80%
35	25	15	820.3	1139.1	318.8	72.00%
35	30	10	664.1	1314.1	650	50.50%
35	30	15	675	1139.1	464.1	59.20%
40	25	10	962.5	1501.6	539.1	64.10%
40	25	15	970.3	1314.1	343.8	73.8%
40	30	10	801.6	1501.6	700	53.30%
40	30	15	812.5	1314.1	501.6	61.80%

It can be seen from the numerical analysis that when the price of raw materials is kept constant, the market limit price of the supplier is unchanged and the increase of the market limit price of the manufacturer will increase the overall profit of the two supply chains; The limit price of manufacture does not change and the increase of the market limit price of supplier has no effect on the overall profit of the supply chain. In addition, from the table can clearly see the common decision-making big data supply chain profits than traditional supply chain profits increase of at least 50.5%.

6 Conclusion

Big data theory has spawned many new service and industry models, and it is challenging for traditional industries to use big data to change their supply chains operating. How big data can be used to implement change, what should be targeted to gain competition advantage is the first issue enterprise should consider.

The model constructed in the paper focuses on the competition problem brought by big data suppliers join to the supply chain, and examines the supply chain cooperation mode from the profit perspective. It is not sharing big data cost by manufacturers and suppliers in the model, which is a common phenomenon in practice. In order to gain a dominant position in the supply chain, one enterprise chooses to bear the cost of big data alone to achieve the control of big data platform. But it does not means that the enterprise will be able to achieve an increase in profits, partly because of the cost of containment, on the other hand the stability of cooperation could be impacted after enterprise obtaining a dominant position, and the overall profit of the supply chain maybe reduced in that condition. Therefore, the supply chain member companies choose to cooperate with each other and make decisions collaboratively is the key to improve the overall profit of supply chain through introducing the third-party big data providers. The analysis of the article is also just to verify this conclusion.

Abstract. The per-capita income of farmer is an important technology index which is the measured level of agriculture development and the status of farmers' life. This paper aims at developing a new fuzzy grey predicting model to predict the per-capita income of farmer. The fuzzy possibility is used to check the error of the proposed model, and the test results show that the accuracy of the model is quite high, providing a scientific basis for policy makers.

Keywords: The per-capita income of farmer · Fuzzy grey prediction model · Fuzzy possibility

1 Introduction

In the past few decades, China has experienced rapid economic growth and significant reduce of poverty [3]. However, at the same time, a lot of contradictions and problems have exposed. In recent years, the problem of slow growth in farmers' income has become the focus of the society from all walks of life. The difficulties faced by the current farmers' income growth have become a big obstacle to the virtuous cycle of the whole national economy. Therefore, the study of farmers' income growth is of far-reaching significance.

Since the reform and opening, China has carried out a series of significant reform in the countryside. In 1978, the rural reform which is market-orientation is a historic turning point of the agricultural development of China: not only break the bondage of the traditional system but also promoted the growth of farmers' income greatly. From 1978 to 2008, the per capita net income of farmers increased from 134 to 4761 [1]. In particular, over the past 30 years, the changes

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_83

of the growth of farmers' income in China are as follows. With the inflation factors deducted, from 1978 to 1985, it is growing at 15.2% yearly; from 1986 to 1991, at 2.7% yearly; from 1992 to 1996, at 5.6% yearly. Besides, after 1980, 1996 is the fastest growth year of farmers living income at the rate of 9% [7]. After 1997, enter the stage of slow growth while the growth rate of farmers' income was 4.6% which was the half of 1996. In 1998, their income continued going down while the speed of growth was only 4.3%. The year of 1999 and 2000 were the same and the speed of growth was 3.8% in 1999. The farmers' income was into a trough at 2.1% in 2000. In 2001, there was a recovery growth at 4.8%. However, it reduced to 4.3% in 2003. It achieved a steady increase from 2004 to 2008 and 2008 was at 8% [6].

In conclusion, there is a large change of growth range of per farming capita income and it will cause a negative influence to the development of rural economy even the whole national economy.

As a result, the prediction of per farming capita income becomes the focus of public concern. The key of long-term agriculture development is solving the problem of agriculture, rural areas and farmers (the three agriculture-related issues) reasonably and effectively. And the problem of per capita income of farmers is not only the core of this issue but also the key to solve the problem of the three agriculture-related issues. According to the history of the economic development of China, it's clear that the per capita income of farmers has an obvious change trend. In order to solve the problem of the three agriculture-related issues better, it needs to forecast the per capita income of farmers and grasp the change trend of it accurately as much as possible. However, some uncertain factors which are in the statistical process have become the chief problem of the prediction. For per capita income of farmers, there are many kinds of uncertain factors such as quantitative and non-quantitative factor, known and unknown factor.

Neglecting those non-quantified and unknown factors, the uncertain factors affecting the per capita income of farmers can be divided into two categories: (1) The part of production grew and sold by farmers themselves; (2) The production cost of agriculture.

There are many methods for forecasting the uncertain factors. In this paper, the prediction is based on the fuzzy gray prediction model.

The gray forecasting method has been applied in the modeling process of the dynamic system successfully in different fields such as agriculture, ecology, economy, statistics, industry and environment. In the absence of long-term historical data, it can use a system model to predict the incomplete or uncertain information.

According to the statistical method of per farming capita income from the statistical yearbook, the factors affecting per farming capita income (P) mainly include: the total income of farmers (TI), the total population of agriculture (IP). The relationship between them can be expressed by the following formula: $P = \frac{TI}{IP}$.

Leshan city of Sichuan province, as an area with World double-heritages, will be used as a case to study. The problem faced by the area with World double-heritages is how to exploit protectively. That is to say, the local natural and cultural heritages should be protected while the economy is developed and historical culture is promoted. Thus, there is a problem of degree. How to grasp this degree plays a vital role of the development of local economy and cultural protection which is also a model to the other areas with World double-heritages.

The purpose of this paper is to establish a fuzzy gray forecasting model to predict the per capita income of local farmers, get its changed trend and approve the effectiveness of the model.

2 Problem Statement

At present, per farming capita income is an important index which reflects the development of rural economy [5]. Therefore, it is very significant to predict and grasp accurately the changed trend of per farming capita income. This part will introduce the condition of per farming capita income of Leshan city and use it as an example to forecast per farming capita income with the fuzzy gray prediction model.

Due to the continuous application of the agricultural science and technology and the continuous improvement of the policies supporting agriculture by government, the total agricultural income of Leshan city has risen from 677.67 to 1992.15 million yuan in the past ten years. As shown in Fig. 1.

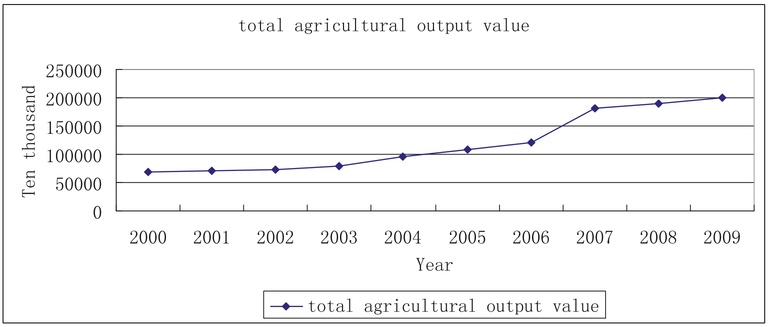

Fig. 1. The total agricultural output value of central district of Leshan city

From 2000 to 2009, the total agricultural output value of central district of Leshan city increased at a stretch. In addition to the year of 2006 and 2007, the data increased from 107.71 million yuan to 1.7 billion yuan. The overall increase in agricultural output value is in a small range and a lower growth rate. In order to a sustained and rapid growth of agricultural economy, the process of agricultural production should use advanced agricultural science and technology to increase the production and quality of agricultural products. At the same time, the policies published by government also need to be further improved.

Due to the implementation of the family control policy (a basic national policy) and the continuous improvement of the comprehensive qualities of local people, the agricultural population of central district had a tendency to reduce in Leshan city. As shown in Fig. 2.

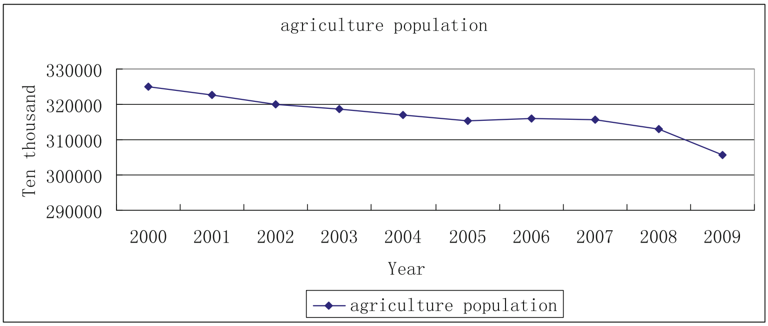

Fig. 2. The agriculture population of central district of Leshan city from 2000 to 2009

From 2000 to 2009, although there was a slight rebound from 2005 to 2007, the agricultural population of central district, Leshan city is of the gradual decline in the trend of change. The main reasons are as follows: On the one hand, affected by the Asian financial turmoil, from 2000 to 2005, crop prices were generally low and the enthusiasm of farmers was severely affected. However, since 2006, with the effect of financial crisis declining, the price of agricultural products rebounded and the enthusiasm of farmers was encouraged again. On the other hand, along with the rapid development of Chinese economy, the construction of urbanization is carried out in the vast rural areas. The acceleration of the urbanization process makes the local farming population decrease continuously. Thus, the agricultural population in central district, Leshan city also showed a decreasing trend. In summary, the total value of agricultural production of central district, Leshan city, has followed an increasing trend while the number of agricultural population has continued to decrease. Affected by the total value of agricultural production and the number of agricultural population, per capita income of farmers should also show an upward trend, as shown in Fig. 3.

From 2000 to 2009, the per capital income of farmers was increasing continuously with slow speed and low growth rate. The reasons are as follow: First, with the progress of science and technology, many kinds of advanced science and technology have been widely applied to agricultural production; second, the Chinese government has introduced various policies to support agricultural development which reduces the burden of farmers. For a sustained, rapid and steady growth of per capita income of farmers, it is necessary to improve the conversion rate of agricultural science and technology and perfect the various supporting policies of agriculture constantly.

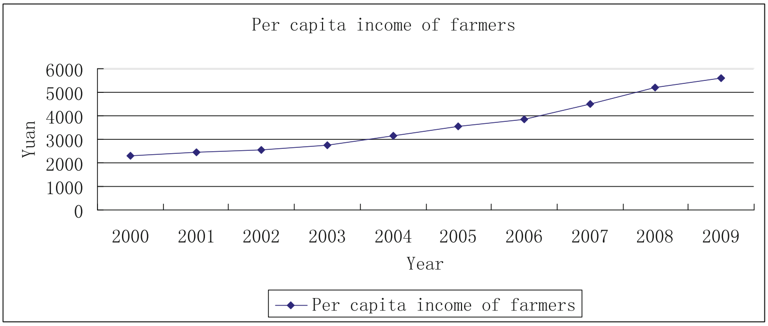

Fig. 3. The per capital income of farmers in central district, Leshan city between 2000 and 2009

3 Modeling

The gray system theory was first proposed by Deng [2], who used the differential equation as the forecasting model and the least square method to obtain the coefficient of the equation which has a wide range of application. In the gray forecasting system, the original data is defined as an accurate. However, in fact, the original data is not accurate which unable deal with the fuzzy phenomenon in reality effectively. In this paper, define the original data of per capita income of farmers as triangular fuzzy number and forecast the fuzzy numbers with gray forecasting system. Thus, this model consists of two parts: one is the fuzzy part; the other is the gray forecasting part.

3.1 Fuzzification

As mentioned earlier, the per capita income of farmers is affected by two factors: the total value of agricultural production (TI) and the agricultural population (IP). The relationship between them is: $P = \frac{TI}{IP}$.

When calculating the per capita income of farmers, this method has some shortcomings. Due to some indicators which unable get accurate enough data, it can only be estimated by experience. As a result, it will reduce the accuracy and scientificalness of the end result.

In the statistical process of the total income of farmers, some indicators unable be calculated accurately such as the part of self-production and marketing and the agricultural production cost of farmers. The self-production and marketing is the process to cost their own agricultural products. These agricultural products do not enter the market so that their value can not be measured accurately. In fact, the agricultural production cost includes labor costs while farmers own labor costs always unable be carried out. As a result, it unable be measured accurately. In these two parts of the statistical process, some indexes are often judged by experts' experience which is lack of precision.

Thus, the total income of the farmers in a region is only an estimate rather than an exact value. In this situation, it can be obscured by triangular fuzzy number to obtain a triangular fuzzy number of per capita incomes of farmers.

In order to solve the above problem, Zadeh proposed the fuzzy theory in 1965. Zadeh represent the fuzzy set by membership function following the idea that general set is represented by feature function [8].

Definition 1. Any mapping from domain X to closed interval [0, 1]. $\mu_A : X \to [0,1], x \to \mu_A : (X)$. Determine a fuzzy set A of X, μ_A is called the membership function of A, $\mu_A : (X)$ is called the membership degree of X to A, fuzzy set A is written as $A = \{(x, \mu_A) | x \in X\}$.

Definition 2. Set A as a fuzzy set in domain X. If $\forall_\alpha \in [0,1]$, the α- cut sets of A are all convex set so that the fuzzy set A is called as the convex fuzzy set.

Definition 3. If the fuzzy set M is a normal convex fuzzy set which is defined in the real field R, it is satisfied: (1) There is a unique point $x_0 \in$ R, making $\mu_M(x_0) = 1$(x_0 is called as the mean value of M); (2) $\mu_M(x)$ is continuous from left to right, then M is called as a fuzzy number. The meaning of the fuzzy number M is "the approximate real number of x_0".

From the definition of fuzzy number, the α- cut sets of M_α actually is a closed interval in real number field R: $M_\alpha = \{x \in \mathrm{R} | \mu_M(x) \geq \alpha\} = [m_\alpha^l, m_\alpha^r]$ m_α^l and m_α^r represent severally the left and right end points of the closed interval M_α.

The general expression of the fuzzy number M is $\mu_M(x) = \{L(x), l \leq x \leq m; R(x), m \leq x \leq r\}$; and $L(x)$ is the right continuous increasing function, $R(x)$ is the left continuous decreasing function, $0 \leq L(x), R(x) \leq 1$. If both the function $L(x)$ and $R(x)$ are linear functions, M is called as triangular fuzzy number, often denoted as $M(l, m, r)$. The total income of farmers is converted to triangular fuzzy number and expressed as $M(TI^-, TI, TI^+)$. The membership function shown in Fig. 4.

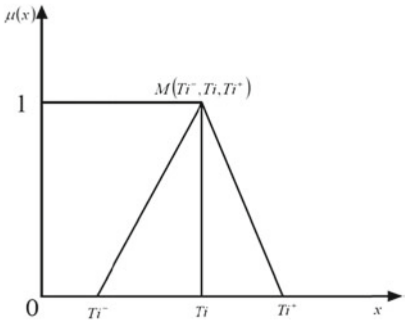

Fig. 4. The membership function of triangular fuzzy number

The relationship between the per capita income of farmers and the total income of farmers is:

$$P = \frac{TI}{TP}.$$

We can get the triangular fuzzy number of the historical data of the per capita income of farmers: $M(P^{-}, P, P^{+})$.

3.2 GM(1.1) Model

The GM(1,1) forecasting model is described below: Regard the original data of the per capita income of farmers as a set of original data series $p^{(0)}$, we can get:

$$p^{(0)} = \{(p^{(0)^-}(1), (p^{(0)}(1), p^{(0)^+}(1)), \cdots (p^{(0)^-}(n), (p^{(0)}(n), p^{(0)^+}(n))\}$$

and

$$p^{(1)} = \{(p^{(1)^-}(1), (p^{(1)}(1), p^{(1)^+}(1)), \cdots (p^{(1)^-}(n), (p^{(1)}(n), p^{(1)^+}(n))\}.$$

The relationship between the two sequences is as follows:

$$p^{(1)^-}(i) = \sum_{m=1}^{i} p^{(0)^-}(m), i = 1, 2, 3 \cdots, n,$$

$$p^{(1)}(i) = \sum_{m=1}^{i} p^{(0)}(m), i = 1, 2, 3 \cdots, n,$$

$$p^{(1)^+}(i) = \sum_{m=1}^{i} p^{(0)^+}(m), i = 1, 2, 3 \cdots, n,$$

$$\hat{p}^{(1)}(i+1) = (p^{0}(1) - \frac{y}{z})e^{-ai} + \frac{y}{z}.$$

According to the least squares method, we can conclude:

$$\hat{p}^{0}(1) = \hat{p}^{1}(1).$$

Then, the final formula is obtained:

$$\hat{p}^{0}(i+1) = \hat{p}^{1}(i+1) - \hat{p}^{1}(i).$$

4 Application

In order to get the triangular fuzzy number of per capita income of farmers in central district, Leshan city, it's necessary to fuzzify the historical data of per capita income of farmers in this area in the past ten years. The historical data are as shown in Table 1:

Table 1. The original data of per capita income of farmers in central district, Leshan city between 2000 to 2009

Year	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009
Value (Yuan)	2306	2408	2573	2748	3154	3753	3829	4497	5192	5608

We suppose that:

$$\begin{aligned} P_0(k) &= (P_K^-, P_k, P_k^+), \\ P_k - P_k^- &= \alpha, \\ P_k^+ - P_k &= \beta. \end{aligned}$$

According to expert experience and related theories, suppose $\alpha = \beta = 100$. According to the above method, it can get the triangular fuzzy number of per capita income of peasants in central district, Leshan city by fuzzifing the data in the above table, as shown in Table 2:

Table 2. The triangular fuzzy number of original data of per capita income of peasants in central district, Leshan city between 2000 to 2009

Year	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009
P^-	2206	2308	2473	2648	3054	3653	3729	4397	5092	5508
P	2306	2408	2573	2748	3154	3753	3829	4497	5192	5608
P^+	2406	2508	2673	2848	3254	3853	3929	4497	5292	5708

By now, input the triangular fuzzy numbers of historical data of the per capita income of farmers in the central district of Leshan city to the gray forecasting model and get the predicted values are as Tables 3 and 4 shown:

Table 3. The predicted values of per capita income of farmers in the central district of Leshan city between 2001 to 2009

Year	2001	2002	2003	2004	2005	2006	2007	2008	2009
P^-	2260	2532	2838	3180	3563	3993	4474	5014	5619
P	2166	2435	2737	3077	3459	3888	4371	4914	5524
P^+	2354	2630	2938	3283	3667	4097	4578	5114	5714

5 Result Analysis and Suggestion

Per capita income of farmers is an important indicator to reflect the development of agricultural economy and the living conditions of farmers. Whether the

Table 4. The predicted values of per capita income of farmers in the central district of Leshan city between 2001 to 2009

Year	2010	2011	2012	2013	2014	2015
P^-	6209	6980	7847	8821	9916	11147
P	6454	7302	8262	9349	10578	11968
P^+	6384	7132	7968	8902	9945	11111

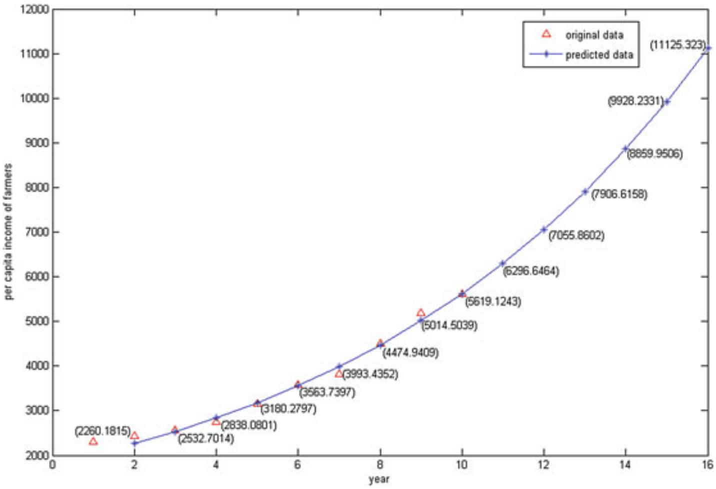

Fig. 5. The actual values and predicted values of P_K^-

per capita income of farmers has a sustained and rapid growth is important to the development of the entire national economy and the construction of a harmonious socialist society. According to the above forecast results, per capita income of farmers in central district, Leshan city is in the overall upward trend. In addition, the higher degree of fit between the predicted value and the original data indicates the validity of the fuzzy-gray forecasting model and also proves the scientificity of the predicted value. (As shown in Figs. 5, 6 and 7).

In the past decade, due to the continuous progress of agricultural science and technology and the continuous improvement of agricultural supporting policies, to a certain extent, it improved the productive rate of agriculture and reduced the burden on farmers. However, the per capita income of farmers is growing at a low speed with a low growth rate. Although there is a rising tendency, the per capita income of farmers is fluctuated because of some related economic factors.

In this view, the suggestions are as follows:

First of all, establish the work thinking of how to achieve stable increasing in income of farmers. The overall work thinking: the aim is to improve the income of farmers; the orientation is market; the support is resource; the basis is the structural adjustment; the driving force is science and technology; the way is

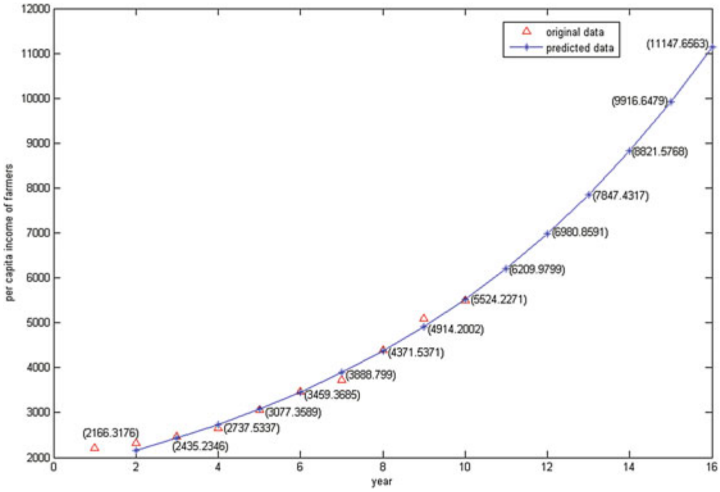

Fig. 6. The actual values and predicted values of P_K

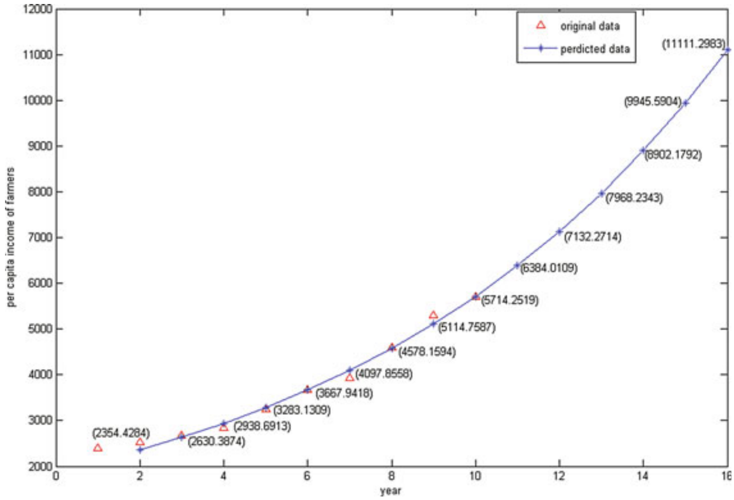

Fig. 7. The actual values and predicted values of P_K^+

industrialization and agricultural processing; the key is reducing agricultural population; develop green food, ecological agriculture and characteristic-brand agriculture vigorously [4].

Second, deepen the reform of the system and overcome the external factors that restrict farmers' income. China's history has proved repeatedly that when the state land and its property policy are correct and secure, when the enthusiasm of farmers is high, the income level has also a corresponding increase.

Third, the Government should implement the policy and measures to ensure that farmers' income increase. (1) It is of great significance for agricultural development and farmers' incomes to increase financial investment reasonably and carry out the agricultural subsidy policy. The funds for supporting agriculture should focus on poverty alleviation, agriculture foundational facilities, the research and application of agricultural technology and the green ecological agriculture. (2) Deepen the reform of rural financial. In the innovation of rural financial system, developing small and medium-sized banks and rural financial guaranty companies will solve the problems of rural finance fundamentally and provide a strong financial support for the development of three agriculture-related issues. It has an important role in regulation and protection to improve the production and income with the development of rural economy.

Finally, continue to promote the strategic adjustment of agricultural structure and improve the quality and efficiency of agriculture comprehensively. At this stage, improving the efficiency of agriculture should be market-oriented focusing on high quality and diversification of agricultural varieties. It means a change from yield-oriented to quality and efficiency.

6 Conclusion

Through the analysis of the per capita income of the farmers during the 30 years of reformation and opening, it is found that there are still problems in the growth process such as low growth rate and large fluctuation. Steady growth of farmers' income supports strongly for the economic with rapid growth of China and the smooth progress of reformation and opening.

In this paper, a forecasting model of the per capita income of farmers is established by fuzzy theory and gray forecasting system. As a case for our study, the central district, Leshan city provides with the relevant data. First, use the correlation theory of triangular fuzzy number to deal with the uncertain question; then use the gray forecasting model to predict the triangular fuzzy number which ensures the accuracy of the forecast results. At the same time, it provides a scientific basis for the formulation and implementation of relevant policies.

Eco-Cycle Comprehensive Operation Performance Evaluation–A Case Study of Baotou Steel Group

Yuyan Luo, Zhong Wang(✉), Yao Chen, Yahong Wang, and Jiming Xie

College of Management Science, Chengdu University of Technology,
Chengdu 610059, People's Republic of China
wangzhong2012@mail.cdut.edu.cn

Abstract. With the advent of circular economy, enterprises have no longer given priority to the economic benefits, but also focus on social responsibility and sustainable development. In order to accelerate the ecological change of enterprise system, every enterprise vigorously carries out green technology innovation and development. Therefore, how to evaluate the performance of ecological cycle has become a problem for management personnel. This paper takes Baotou steel group as an example, which is one of the largest steel companies in China, and establishes an ecological cycle performance evaluation index system from the aspects of economic operation, resource impact control and ecological circulation innovation. Based on that, the entropy-topsis model is used to evaluate the performance of ecological cycle in Baotou steel group. Through the evaluation, we find out that the ecological cycle performance of Baotou steel rose before 2010 and still at the middle and primary stage of its eco-cycle development. The results show the evaluation index system and method can help management personnel to realize the status of their company's eco-cycle development. It also can help policy makers to make better green policies and strategies, promoting the eco-cycle transformation in China.

Keywords: Eco-cycle · Operation performance evaluation · Entropy-topsis

1 Introduction

In recent years, with the transforming of the concept of ecological civilization construction, to realize low carbon development and cycle development has been the important goal of the international economic development, the development and the transformation of the target. The development direction of enterprise has changed from a single to rely on economic benefit as the guidance to the ecological cycle of performance oriented transformation. The evaluation of ecological cycle operating performance has become an important research topic, which

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_84

specifically reflected the enterprise transformation and put forward applicable suggestions for the future development of enterprise.

In the whole performance evaluation, building the evaluation index system is the critical part, reviewing the related literature, a large number of scholars have discussed the different content of the evaluation index system.

Such as the research using the three dynamic indicators including economic growth, environmental improvement and technical features to differentiate the enterprise ecological performance into 13 types including senior evolution to severe degradation [6]. Besides, there are some researches focusing on the circular economy developing standard of industrial park to evaluate, such as constructing the circular economy evaluation index system of industrial park including economic development, resource utilization, pollution control and material recycling indicators and using the TOPSIS method to evaluate [13] and based on AHP and FCE method, through economic development, the material reduction and circulation, pollution control and park management to build comprehensive evaluation model of circular economy of industrial parks [12], also, some researchers are committed to have assessment for the performance of enterprises and industrial parks, such as incorporating research and development (R&D) and marketing policy to build a innovative supply chain performance measurement system [15], to use discounted cash flow (DCF) and multi-attribute global inference of quality (MAGIQ) methods to evaluate the economic, environmental and social performances of eco-industrial park (EIP) pilot project [1], and based on principal component analysis and set pair analysis (SPA) and the fuzzy mathematics method to construct the performance evaluation system [5,8]. In addition, some use Delphi, LCA technique to select indicators to evaluate the green public procurement [14], setting the economic indicator and three generally applicable simplified environmental indicators (raw material consumption, energy consumption, and CO_2 emission) as the eco-efficiency indicators to evaluate the ecology efficiency of EIP [14], using the non-radial DEA model to evaluate the eco-efficiency [10], taking advantage of R cluster and factor analysis to have quantitative selection for indicators to build the green industry evaluation system including three criterion layers of green production, green consumption, and green environment [4], applying data envelopment analysis (DEA) to study the resource efficiency of cities [2], and presenting a compliance-based multidimensional trust evaluation system (CMTES) and also using improved TOPSIS technique to derive trustworthiness from compliance values [9].

Through the above review, a large number of methods such as the entropy-topsis, principal component analysis, gray correlation analysis, AHP and FCE, factor analysis, DEA model, the fuzzy comprehensive evaluation method and other evaluation methods have been widely used in the indicator system.

Based on the circular economy and industrial theory, this article builds the system of ecological cycle operation performance evaluation index and then takes the Baotou steel group as a case study, and analyzes the current eco-cycle operation performance and finally puts forward the corresponding countermeasures and suggestions.

2 Construction of Eco-Cycle Operation Performance System

The evaluation index system should accurately reflect the actual situation of enterprise's production and operation management. The establishment of index system is a key part of the whole ecological cycle operating performance's evaluation. It is essential to select the right index and guarantee the credibility of the results, therefore, this paper combines with the construction principles including system's scientificity and accuracy, effectiveness and comparability, stability and dynamic, operability, combination of qualitative and quantitative and so on, and based on a large number of research results of scholars and the actual work of ecological cycle transformation in enterprises, using analytic hierarchy process and expert-consulting method to select the indicators, builds the eco-cycle operational performance evaluation index system which includes economical operation, resource impact control, technology research and development and eco-cycle innovation. However, based on the performance evaluation of ecological recycling operation of Baotou steel, this research is aimed at finding that there exists missing data of the related index data in development of the technology and pollution control investment and resource compensation at resource impact control layer by collecting concrete data of Baotou steel such as annual report, social responsibility report and so on. Thus considering the actual operation of Baotou steel, we delete the indicators including R & D investment proportion of total amount, the number proportion of R & D in technology research and development level and pollution control investment growth rate and resource compensation fee increase rate in resource impact control layer. The final ecological recycling performance indicators are as follows in Fig. 1.

3 Entropy-Topsis Mode

On the basis of system theory, entropy is an ordered metric reflecting degree of disorder in the system [11]. Therefore, the smaller information entropy is, the lower disorder of information is, and the greater the effect of the information value and the weight information are, and vice versa [7]. Using entropy to reflect the size of information can come to the more objective and fair conclusions. Analytic hierarchy process (AHP) is usually used to determine the weighting factor of evaluation index in TOPSIS method, Because of its strong subjective factors, we use the improved entropy weight method to determine the weight of the evaluation index and to some extent avoid the influence of subjective factors. When the relative importance of evaluation index is difficult to determine, using the weight of entropy calculation index is more reasonable [3].

The general idea for using entropy weight method: To construct the index system and standard weighted matrix, and normalization of the relevant data into the model in the moment. Specific steps are as follows:

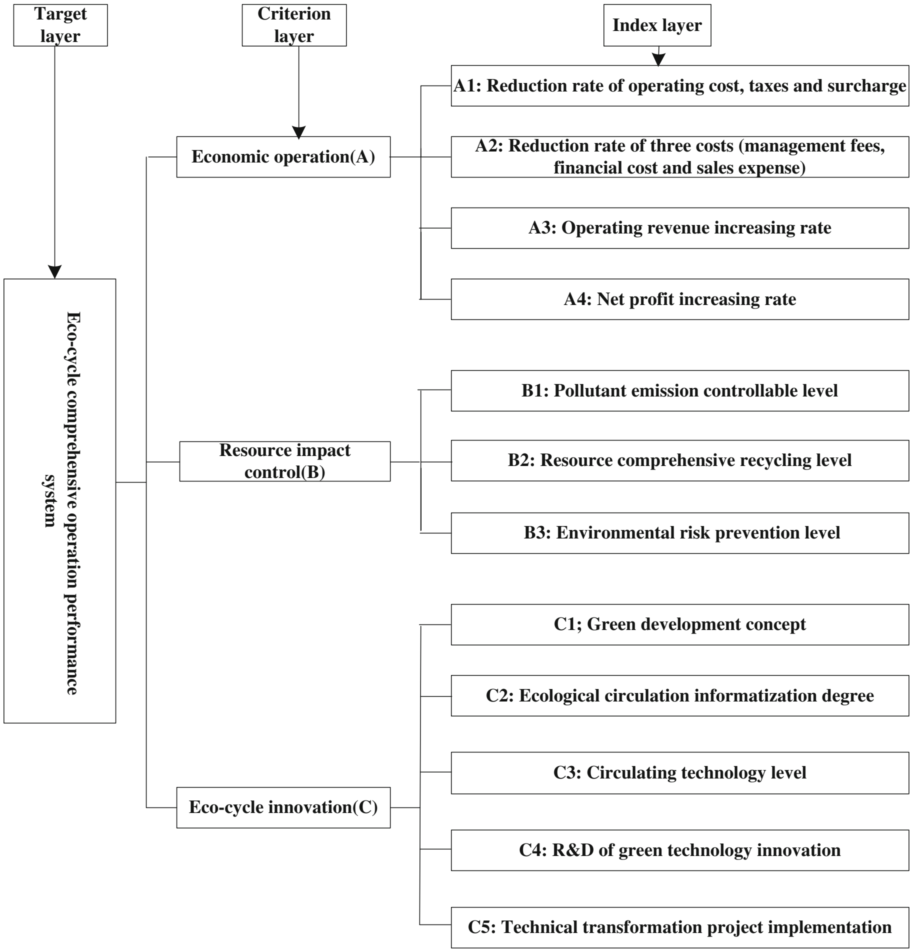

Fig. 1. Eco-cycle comprehensive operation performance system

(1) Data standardization
The evaluation system has n objects to be evaluated, m evaluation indicators, the evaluation matrix is $X = (x_{ab})_{n\times m}$ $(a = 1, 2, \cdots, n;\ b = 1, 2, \cdots, m)$.

For benefit type index:

$$y_{ab} = \frac{x_{ab} - \min x_b}{\max x_b - \min x_b}\ (1 \le a \le n, 1 \le b \le m). \tag{1}$$

For cost type index:

$$y_{ab} = \frac{\max x_b - x_{ab}}{\max x_b - \min x_b}\ (1 \le a \le n, 1 \le b \le m). \tag{2}$$

Normalization:

$$Q_{ab} = \frac{y_{ab}}{\sum_{a=1}^{n} y_{ab}} \; (1 \le a \le n, 1 \le b \le m). \tag{3}$$

(2) Calculation of entropy index

$$P_b = -1/\ln n \sum_{a=1}^{n} Q_{ab} \ln Q_{ab} \; (1 \le b \le m). \tag{4}$$

(3) Determine the index weight

$$\varphi_b = (1 - P_b)/\sum_{b=1}^{m} (1 - P_b), \tag{5}$$

where φ_b satisfies the two conditions $0 \le \varphi_b \le 1$ and $\sum_{b=1}^{m} \varphi_b = 1$:
(4) Standardized weighting matrix is obtained from normalized matrix and index weight.

$$W = (w_{ab})_{n \times m} = (\varphi_b y_{ab})_{n \times m}. \tag{6}$$

(5) Determine the positive and negative ideal solution
Positive ideal explanation imagines each index to achieve the most satisfactory solution, with W^+ and negative ideal solution is to imagine each index to achieve the most satisfactory solution, with W^-.

$$W^+ = \{\max w_{ab} | \, b \in V^+, \min w_{ab} | \, b \in V^-\} = \{w_1^+, w_2^+, \cdots, w_m^+\}, \tag{7}$$

$$W^- = \{\min w_{ab} | \, b \in V^+, \max w_{ab} | \, b \in V^-\} = \{w_1^-, w_2^-, \cdots, w_m^-\}, \tag{8}$$

where V^+= Benefit index set, V^-= Cost index set.
(6) Calculated distance
Each evaluation object to the government ideal sister distance with D_a^+, D_a^-, said, calculated by the following formula:

$$D_a{}^+ = \sqrt{\sum_{b=1}^{m} (w_{ab} - w_b^+)^2} (a = 1, 2, \cdots, n), \tag{9}$$

$$D_a{}^- = \sqrt{\sum_{b=1}^{m} (w_{ab} - w_b^-)^2} (a = 1, 2, \cdots, n). \tag{10}$$

(7) Calculate the relative closeness of each evaluation object

$$H_a = D_a{}^- / (D_a{}^- + D_a{}^+)(a = 1, 2, \cdots, n), \tag{11}$$

where H_a is the a object and how close the solution to, the value of H_a is between 0 and 1, the larger the value of H_a, the smaller the distance between the evaluation object and the positive ideal solution, the greater the distance from the negative ideal solution, the closer to the optimal level.

4 Case Study

Baotou steel group (hereinafter referred to as Baotou steel) is one of the earliest construction of iron and steel industrial bases after the founding of the People's Republic of China, it was first constructed in 1954 and was put into production in 1957. Turned into a corporate enterprise in 1998, it is the most important iron and steel industrial base and the largest rare earth industrial base in China, and one of the biggest rare earth scientific research and production bases as well. Always committed to diversify development, except to the major business of steel and rare earth, it also owns the mining and the steel industry. During the "twelfth five-year"? "big steel"? will be built and commit to become the world's largest production base of rare earth steel and the most competitive rare earth production and scientific research unit and its annual sales revenue will reach more than 100 billion yuan. By 2015, the group's total assets have amounted to 144.9 billion yuan, 33459 people have been employed and 22.501 billion yuan of sales income has been achieved. At present, Baotou steel has entered the ranks of tens of millions of tons of iron and steel enterprises in China, and has an important influence in the world. In recent ten years, Baotou steel has been committing to adhere to lead innovation, promoting the ecological cycle transformation and upgrading, keeping the environmental protection concept and setting the image of green development. Therefore, based on the practical situation of Baotou steel, evaluating its performance helps to future development selection and strategic decision-making.

(1) Data selection
According to the availability of data, this paper selects Baotou steel annual reports during the ten years from 2006 to 2015, part of the data are obtained by calculations, and others are obtained by the expert scoring method.

(2) Empirical results
In the process of analyzing of the index data, in order to eliminate the influence of dimension to the data, we use the formulas (1) and (2) to get the standardized data shown in Table 1, then take use of formula (3) to give normalized treatment to the data and finally get the weight P and the entropy ϕ.

As is shown in Table 2, the weight of the indicators for economic operation ranges between 0.02 and 0.033, the weight of the indicators for resource impact control is weighted between 0.06 and 0.12, the weight of the indicators for ecological circulation innovation range between 0.04 and 0.132. Therefore, the indicators of resource impact control have a great effect on the ecological cycle performance of Baotou steel.

Most of the indicators are at a low level, comprehensive index of ten years in a similar seven years posted schedule H below the 0.1 level. But it had a great reversal in 2010, whose comprehensive value of H reached the level of 0.04607, the value of H for economic operation even reached at 0.7 or so, and the value of H for resource impact control and the ecological circulation innovation were also at a high stage the ten years (Table 3).

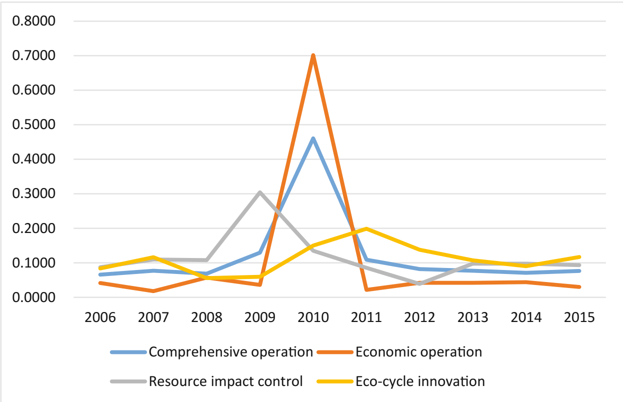

Fig. 2. The trend of closeness of each evaluation object and positive ideal solution

In order to reflect the current operating state of Baotou steel more intuitively and clearly, we make a brief line chart, it shown in Fig. 2.

The chart can reflect the development status of the last few years clearly and objectively, and combining with the specific content from annual report of Baotou steel, the following conclusions can be reached.

Baotou steel's comprehensive performance is at huge ups and downs. From 2006 to 2009, the overall ecological cycle operation of Baotou lagged behind slightly, but still grew steadily. But in the year of 2010, the business of Baotou steel had a great leap forward trend. The value of H rose from about 0.1 in 2009 to nearly 0.5. For Baotou steel, the year of 2010 is not only glorious, but also a sharp peak of development. The ecological cycle is good, which is the result of continuous accumulation. However, after 2010, Baotou steel business, abruptly suffered a great depression. In 2011, the value of H straightly dropped to about 0.05, and then was continuously declining during 2012, and was in a state between 0.05 and 0.1 from 2012 to 2015. So it's obvious to see that after Baotou steel's ecological cycle operates to a certain stage, the development of the operation will slow down, the challenge of industrial upgrading will increase.

As the same as the composite index, there also existed a parabola change trend for economic operation. The value of H reached 0.7 in 2010, but years after that it stayed between 0.01 and 0.057, which is similar to the analysis in (1). To be brief, Baotou steel business was in a condition of lower stage at first, but later went through such a huge revolution in 2010 and showed a trend of rapid increase. Thus it can be said that the year of 2010 is an important turning point in Baotou. Meanwhile, at the annual report. In previous years, Baotou steel has been committing to the construction of R & D center, and by the time of 2010, R & D center has been building more perfect. So it is not hard to explain before 2010, Baotou economy gradually increased, to show the reason for the substantial increase in 2010, and after a few years, Baotou research devoted to technology, may it lead to the decline in corporate profits.

Ecological circulation doesn't grow as such amazing speed as economic operation, but takes on a smooth curve of innovation. It presents a substantial increase in 2009 to 2011, makes a breakthrough in 2011, and gradually decline after 2011, finally is under the stable state. In general, compared with the 2000s, the ecological circulation innovation level in 2010s goes up. However, in comparison with the former two kinds of curve, the ecological circulation innovation reaches peak in 2011, but the economic performance and the comprehensive ecological cycle performance is relatively weak. Through the phenomenon and combining with the annual report of Baotou steel, during 2009 to 2011, Baotou steel has been promoting science and technology innovation and green development, introducing the resources recycling project to have an ecological cycle transformation, which leads to decline in the economic benefits. And then shows a trend of decline of ecological circulation innovation, it can draw that when ecological circulation innovation to achieve in a certain state, the growing rate slows down and breakthroughs are much more difficult to realize.

The trend of resource impact control is different from the former three. Through the line chart, we can clearly see that the sharp change of resource impact control is 2009 rather than 2010 or 2011, so, it appeared earlier than the year of vast change, and it can be seen in the line changes, the resource control increased in the previous year, then it would lead to eco-cycle comprehensive performance rising the next year, in the same way, when the resource impact control had a downward trend, after a year it would lead to a decline in the economic operation and eco-cycle comprehensive performance. Thus we can speculate that resource impact control is the foundation of ecological cycle of enterprise innovation and the daily basic implementation of enterprise resource recycling also determines the enterprise's operation and development.

Besides, usually, we can divide the H into five levels, lower stage ($N < 0.2$), primary stage ($0.2 \leq N < 0.4$), middle stage ($0.4 \leq N < 0.6$), relatively advanced stage ($0.6 \leq N < 0.8$), and advanced stage ($0.8 \leq N < 1.0$). So it's obvious to come out that the highest H values 0.46, the eco-cycle development of Baotou steel is in the middle and primary stage. Therefore, we can draw the conclusion that before 2010, the performance of Baotou steel's ecological cycling operation increased slowly, until 2010, the ecological cycle achieved a good level, but after 2010, industry innovation tended to be slow gradually, Baotou group operating performance gradually tumbled and the eco-cycle development of Baotou steel is in the middle and primary stage.

5 Conclusion

In view of the above empirical results, we conclude that the ecological performance of Baotou Steel rose in 2010, reached a peak in 2010, then decreased gradually, and the eco-cycle development of Baotou steel is in the middle and primary stage. And in the case of data support analysis, we confirm the reliability of the conclusion. So based on the conclusion of Baotou Steel Company, some suggestions are purposed as follows:

(1) Increase resource recycling and sustainable development. In the above analysis we can clearly observe the resource control impact indicator is the cornerstone of enterprise ecological cycle operation. Benign circulation of resources under the guidance of national policy is conducive to the development of enterprises. In the indexes we studied we can also know that controlling pollutant emissions, building chain impact prevention level, achieving effective material use and effective cycle are the measures to promote the development of enterprise resources. Of course, we can also through other ways such as optimization of industry leading and the construction of new production lines and other methods to improve the level of corporate resources impact control.

(2) Increase investment in green technology research and development. Drawn from the above analysis, eco-cycle innovation plays an important role in the eco-cycle comprehensive development of enterprises, so the ecological cycle innovation as a part of leading enterprise development is greatly important and cannot be ignored, therefore, increasing investment in green technology research and development is very important. The policy of the country now is to encourage the development of green industry and environmental protection enterprises, only to meet the mainstream trend is the real development, and Baotou as a high energy consumption and high pollution steel enterprise, designing and creating for the theme of environmental protection industry chain is the priority among priorities of Technology in recent years.

(3) Improve the energy structure. Increasing the recycling of resources and investment in green technology research and development are currently the most urgent task and measures based on the current. And for the future development of ten years, Baotou Steel Company should start in the long run, improve the energy structure of enterprise, deepen the reform and build

a green enterprise whose development conforms to the trend of the times. This is also the most useful measure in the future development.

Abstract. In this paper, a closed-loop supply chain (CLSC) model with part and module inventory centers is proposed and optimized. Part supplier, module assembler, manufacturer, distribution center and retailer in forward logistics (FL) and customer, collection center, recovery center, secondary market and waste disposal center in reverse logistics (RL) are taken into consideration for constructing the proposed CLSC model. Especially, for the reuses of recovered part and module, part and module inventory centers are also considered. The proposed CLSC model is represented by a mathematical formulation, which is to minimize the sum of various costs resulting from each stage of FL and RL under satisfying various constraints. The mathematical formulation is implemented by an adaptive hybrid genetic algorithm (a-HGA) approach. In numerical experiment, various scales of the proposed CLSC model are presented and the performance of the a-HGA approach are compared with those of several conventional approaches. In conclusion, the efficiency of the proposed CLSC model and the a-HGA approach are proved.

Keywords: Closed-loop supply chain · Part and module inventory centers · Forward and reverse logistics · Adaptive hybrid genetic algorithm

1 Introduction

Closed-loop supply chain (CLSC) model is generally consisted of forward logistics (FL) and reverse logistics (RL). For FL, part supplier, manufacturer, distribution center and retailer are considered. For RL, customer, collection center, recovery (remanufacturing or refurbishing) center, secondary (used) market and waste disposal center are taken into consideration. In general, the objective for implementing the CLSC model can be divided into two aspects as follows:

- Constructing various facilities which can be used in FL and RL stages and considered in real-world situation.
- Optimizing the CLSC model.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_85

There are many conventional studies considering the above two aspects in the CLSC model [1–4,7,10,12].

For constructing various facilities, Fleischmann et al. [4] proposed the CLSC model with three activities of product production, resale and waste disposal in customer, reused market and disposer market, respectively. Amin and Zhang [1] proposed the CLSC model with reuse activity. For the reuse activity, they considered the new part from supplier as well as the reusable part from refurbishing center so that all parts are used for producing product at manufacturer in FL. Wang and Hsu [12] suggested the CLSC model with reuse activity, that is, recycler in RL classifies the returned product into reusable and unusable materials, respectively. The reusable materials are then reused at manufacturer in FL and unusable materials are disposed in landfill area. Similar to Wang and Hsu [12], Chen et al. [3] also suggested the CLSC model with various reuse activities. In this CLSC model, recycling center collects the returned product from customer and then classifies them into reusable and unusable products. The reusable product is reused at retailer in FL and the unusable product is disassembled into reusable and unusable materials. The reusable material is reused at manufacturer and the unusable material is treated at waste disposal plant in RL.

For optimizing the CLSC model, Amin and Zhang [1] and Wang and Hsu [12] minimized the total costs resulting from each stage of FL and RL. However, Chen et al. [3] maximized the total profit consisting of total revenue and total cost.

Although, the conventional studies mentioned above considered various activities of each facilities in FL and RL, they do not explained exactly how to use the reusable part (or material) for the facilities in FL. Therefore, in this paper, we propose a new CLSC model with two inventory centers (part and module inventory centers) so that the reusable part (or material) is exactly and effectively used for the facilities in FL. In Sects. 2 and 3, the proposed CLSC model is represented by a mathematical formulation, which is to minimize the sum of various costs resulting from each stage of FL and RL under satisfying various constraints. The mathematical formulation is implemented by an adaptive hybrid genetic algorithm (a-HGA) approach in Sect. 4. In Sect. 5 for numerical experiment, various scales of the proposed CLSC model are presented and the performance of the a-HGA approach are compared with those of several conventional approaches. Finally, in Sect. 6, as a conclusion, the efficiencies of the proposed CLSC model and the a-HGA approach are proved.

2 Proposed CLSC Model with Two Inventory Centers

The proposed CLSC model is consisted of part suppliers in areas 1, 2, 3 and 4, module assembler, product manufacturer, distribution center and retailer for FL and customer, collection center, recovery center, secondary market and waste disposal center in RL and two inventory centers (part and module inventory centers). Its conceptual structure is shown in Fig. 1.

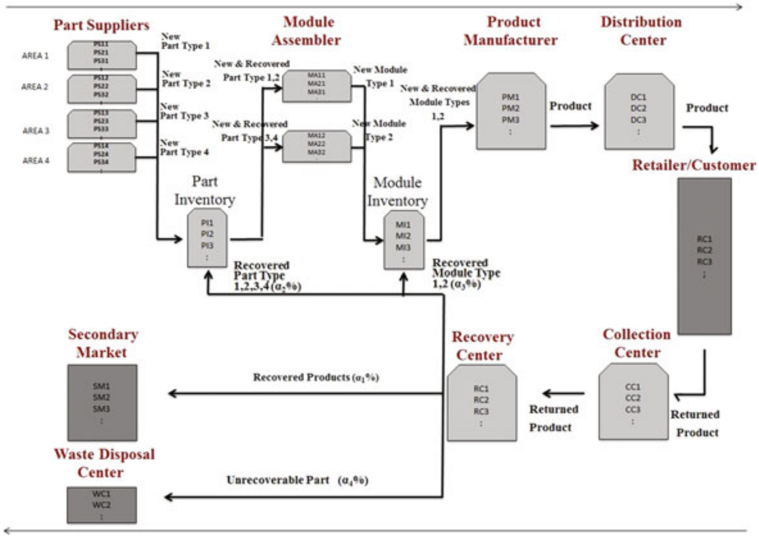

Fig. 1. Conceptual structure of the proposed CLSC model

The difference between the proposed CLSC model and the conventional CLSC models [1,3,12] is that the former considers two inventory centers and the latter does not taken into account them. The detailed logistics are as follows. Each part supplier at areas 1, 2, 3, and 4 respectively produces new part types 1, 2, 3, and 4 and then send them to part inventory center. Also, each module assembler assembles new module types 1 and 2 and then send them to module inventory center. Recovery center checks the returned product from collection center and then classifies them into recovered modules (recovered module types 1 and 2) and recovered parts (recovered part types 1, 2, 3, and 4). Each recovered part and module are sent to part and module inventory centers, respectively. Each inventory center has a function that new part and module in FL and recovered part and module in RL can be used for respectively assembling and producing module and product in module assembler and product manufacturer in FL. The recovered product and unrecovered module at recovery center are sent to secondary market and waste disposal center so that they are resold and land filled, respectively.

3 Mathematical Formulation

First, some assumptions are presented.

- Only single product is produced.
- The numbers of facility at each stage are already known.
- Among all facilities at each stage, only one facility should be opened.
- Fixed cost for operating each facility are different and already known.

- Unit handling cost considered at same stage is the same and already known.
- Unit transportation cost considered between each facility are different and already known.
- All products from customer are returned to collection center.
- The qualities of recovered part and module at recovery center are identical with those of new part and module.

Under considering the above assumption, the mathematical formulation for the CLSC model is proposed. Some indexes, parameters and decision variables are defined.

Index Set:
a : index of part supplier; $a \in A$;
p : index of area of part supplier; $p \in P$;
b : index of module assembler; $b \in B$;
m : index of area of module assembler; $m \in M$;
v : index of part inventory center; $v \in V$;
g : index of module inventory center; $g \in G$;
d : index of product manufacturer ; $d \in D$;
e : index of distribution center; $e \in E$;
y : index of retailer/customer; $y \in Y$;
j : index of collection center; $j \in J$;
z : index of recovery center; $z \in Z$;
i : index of secondary market; $i \in I$;
k : index of waste disposal center; $s \in S$.

Parameters:
BS_{ap} : fixed cost at part supplier a of area p;
BI_v : fixed cost at part inventory center v;
BM_{bm} : fixed cost at module assembler b of area m;
BV_g : fixed cost at module inventory center g;
BP_d : fixed cost at product manufacturer d;
BD_e : fixed cost at distribution center e;
BC_j : fixed cost at collection center j;
BR_z : fixed cost at recovery center z;
LS_{ap} : unit handling cost at part supplier a of area p;
LI_v : unit handling cost at part inventory center v;
LM_{bm} : unit handling cost at module assembler b of area m;
LV_g : unit handling cost at module inventory center g;
LP_d : unit handling cost at product manufacturer d;
LD_e : unit handling cost at distribution center e;
LC_j : unit handling cost at collection center j;
LR_z : unit handling cost at recovery center z;
TSI_{apv} : unit transportation cost from part supplier a of area p to part inventory center v;
TIM_{vbm} : unit transportation cost from part inventory center v to module assembler b of area m;

TMV_{bm} : unit transportation cost from module assembler b of area m to module inventory center g;
TVP_{gd} : unit transportation cost from module inventory center g to product manufacturer d;
TPD_{de} : unit transportation cost from product manufacturer d to distribution center e;
TDT_{ey} : unit transportation cost from distribution center e to retailer/customer y;
TTC_{yj} : unit transportation cost from retailer/customer y to collection center j;
TCV_{jz} : unit transportation cost from collection center j to recovery center z;
TVU_{zk} : unit transportation cost from recovery center z to secondary market k;
TVI_{zv} : unit transportation cost from recovery center z to part inventory center v;
TVV_{zg} : unit transportation cost from recovery center z to module inventory center g;
TUW_{zk} : unit transportation cost from recovery center z to waste disposal center k;

Decision Variables:
ii_v : handling capacity at part inventory center v;
im_{bm} : handling capacity at module assembler o of area e;
iv_g : handling capacity at module inventory center g;
ip_d : handling capacity at product manufacturer d;
id_e : handling capacity at distribution center e;
ir_y : handling capacity at retailer/customer y;
ic_j : handling capacity at collection center j;
iv_z : handling capacity at recover center z;
iu_i : handling capacity at secondary market i;
iw_k : handling capacity at waste disposal center k

$$ps_{ap} = \begin{cases} 1, \text{ if part supplier } p \text{ of area } a \text{ is opened} \\ 0, \text{ otherwise} \end{cases}$$
$$pi_v = \begin{cases} 1, \text{ if part inventory center } v \text{ is opened} \\ 0, \text{ otherwise;} \end{cases}$$
$$pm_{bm} = \begin{cases} 1, \text{ if module assembler } b \text{ of area } m \text{ is opened} \\ 0, \text{ otherwise;} \end{cases}$$
$$pv_g = \begin{cases} 1, \text{ if module inventory center } g \text{ is opened} \\ 0, \text{ otherwise;} \end{cases}$$
$$pp_d = \begin{cases} 1, \text{ if product manufacturer } d \text{ is opened} \\ 0, \text{ otherwise;} \end{cases}$$
$$pd_e = \begin{cases} 1, \text{ if distribution center } e \text{ is opened} \\ 0, \text{ otherwise;} \end{cases}$$
$$pc_j = \begin{cases} 1, \text{ if distribution center } j \text{ is opened} \\ 0, \text{ otherwise;} \end{cases}$$

$$pr_z = \begin{cases} 1, \text{ if distribution center } z \text{ is opened} \\ 0, \text{ otherwise.} \end{cases}$$

Objective function and constraints are as follows:
Minimize Total Cost (TC)

$$\begin{aligned} TC = &\sum_p \sum_a (BS_{ap} ps_{ap}) + \sum_v (BI_v \times pi_v) + \sum_b \sum_m (BM_{bm} \times pm_{bm}), \\ &+ \sum_g (Bv_g \times pv_g) + \sum_d (BP_d \times pp_d) + \sum_e (BD_e \times pd_e) + \sum_j (BC_j \times pc_j) \\ &+ \sum_z (BR_z \times pr_z) + \sum_a \sum_p (LS_{pa} \times is_{pa} \times ps_{pa}) + \sum_v (LI_v \times ii_v \times pi_v) \\ &+ \sum_m \sum_b (LM_{bm} \times im_{bm} \times pm_{bm}) + \sum_g (LV_v \times iv_g \times pv_g) + \sum_d (LP_d \times ip_d \times pp_d) \\ &+ \sum_e (LD_e \times id_e \times pd_e) + \sum_j (LC_j \times ic_j \times pc_j) + \sum_z (LR_z \times ir_z \times pr_z) \qquad (1) \\ &+ \sum_p \sum_a \sum_v (\mathrm{TSI}_{apv} \times is_{pa} \times ps_{pa} \times pi_v) + \sum_v \sum_m \sum_b (\mathrm{TIM}_{vbm} \times ii_v \times pi_v \times pm_{bm}) \\ &+ \sum_m \sum_b \sum_g (\mathrm{TMV}_{eoc} \times im_{bm} \times pm_{bm} \times pv_g) + \sum_g \sum_d (\mathrm{TVP}_{gd} \times iv_g \times pv_g \times pd_d) \\ &+ \sum_d \sum_e (\mathrm{TPD}_{de} \times p_d \times pp_d \times pd_e) + \sum_e \sum_y (\mathrm{TDT}_{ey} \times id_e \times pd_e) \\ &+ \sum_y \sum_j (\mathrm{TTC}_j \times ic_j \times pc_j) + \sum_j \sum_z (\mathrm{TCV}_{jz} \times ir_z \times pr_z \times pv_j) \\ &+ \sum_z \sum_v (\mathrm{TVI}_{zv} \times ir_z \times pr_z \times pi_v) + \sum_z \sum_g (\mathrm{TVV}_{zg} \times ir_z \times pr_z \times pv_g) \\ &+ \sum_z \sum_i (\mathrm{TVU}_{zi} \times ir_z \times pr_z) + \sum_z \sum_k (\mathrm{TVW}_{zk} \times ir_z \times pr_z). \end{aligned}$$

$$\text{s. t.} \sum_{\mathrm{p}} \mathrm{ps}_{\mathrm{ap}} = \mathbf{1}, \forall \mathbf{p} \in \mathbf{P}, \tag{2}$$

$$\sum_{\mathrm{v}} \mathrm{pi}_{\mathrm{v}}, \tag{3}$$

$$\sum_{\mathrm{m}} \mathrm{pm}_{\mathrm{bm}} = \mathbf{1}, \forall \mathbf{m} \in B, \tag{4}$$

$$\sum_{\mathrm{g}} \mathrm{pv}_{\mathrm{g}} = \mathbf{1}, \tag{5}$$

$$\sum_{\mathrm{d}} \mathrm{pp}_{\mathrm{d}} = \mathbf{1}, \tag{6}$$

$$\sum_{\mathrm{e}} \mathrm{pd}_{\mathrm{e}} = \mathbf{1}, \tag{7}$$

$$\mathrm{pr}_{\mathrm{z}} = \{0, 1\}, \quad \forall z \in Z, \tag{29}$$

$$\begin{aligned} &\mathrm{ps}_{\mathrm{ap}}, \mathrm{pi}_{\mathrm{v}}, \mathrm{pm}_{\mathrm{bm}}, \mathrm{pp}_{\mathrm{d}}, \mathrm{pd}_{\mathrm{e}}, \mathrm{pc}_{\mathrm{y}}, \mathrm{pr}_{\mathrm{z}} \mathrm{pu}_{\mathrm{i}}, \mathrm{pw}_{\mathrm{k}} \geq 0, \forall p \in P, \quad \forall a \in A, \quad \forall v \in V, \\ &\forall m \in M, \quad \forall b \in B, \quad \forall d \in D, \quad \forall e \in E, \quad \forall y \in Y, \quad \forall z \in Z, \quad \forall i \in I, \quad \forall k \in K, \\ &\forall j \in J. \end{aligned} \tag{30}$$

The objective function of Eq. (1) is to minimize the total sum of fixed costs, handling costs and transportation costs. Equations (2)–(9) means that only one facility is opened at each stage. Equation (10) implies that the sum of the handling capacity at each supplier in areas 1, 2, 3 and 4 is the same or greater than that of the module inventory center. The same meaning is considered in Eqs. (11)–(17). Equation (18) implies that the sum of the recovered products at each recovery center is the same or greater than that of the recoverable products with $a_1\%$ at each collection center. Equation (19) restricts that the sum of the handling capacity at all part inventory center is the same or greater than that of the recoverable product with $a_2\%$ at all recovery centers. Equations (20)–(21) indicate the same meanings of the Eqs. (18) and (19). Equations (22)–(29) restrict the variables to integers 0 and 1. Equation (30) means non-negativity.

4 A-HGA Approach

The mathematical formulation is implemented using the a-HGA approach. The a-HGA approach is a hybrid approach with adaptive scheme. For the hybrid approach, conventional GA and Cuckoo search (CS) are used and for the adaptive scheme, Srinivas and Patnaik's approach [11] is used. Using the hybrid approach can achieve a better improvement of solution rather than using a single approach does. By using the adaptive scheme, the rates of crossover and mutation operators used in GA are automatically regulated. The detailed implementation procedure [5,6,8] is as follows.

Step 1. GA approach
- **Step 1.1.** Representation 0–1 bit representation scheme is used for effectively representing opening/closing decision of all facilities at each stage.
- **Step 1.2.** Selection Elitist selection strategy in enlarged sampling space is used
- **Step 1.3.** Crossover Two-point crossover operator ($2X$) is used.
- **Step 1.4.** Mutation Random mutation operator is used.
- **Step 1.5.** Reproduce offspring

Step 2. CS approach Apply Levy flight scheme [8] to the offspring of GA and produce new solution.

Step 3. Adaptive scheme Apply the adaptive scheme used in Srinivas and Patnaik [11] to regulate crossover and mutation rates.

Step 4. Termination condition If pre-determined stop condition is satisfied, then stop all Steps, otherwise go to Step. 1.2.

5 Numerical Experiments

In numerical experiment, three scales of the proposed CLSC model are presented. Each scale has various sizes of part suppliers in areas 1, 2, 3 and 4, par inventory center, module assembler in area 1 and 2, module inventory center, product manufacturer, distribution center and retailer in FL and customer, collection center, recovery center, secondary market, and waste disposal center in RL. The detailed sizes of each scale are showed in Table 1. For each scale, 1,500 products are produced in FL and handled in RL. The rates at recovery center for handling the returned products from collection center are as follows: $\alpha_1 = 60\%$,

Table 1. Various scales of the proposed CLSC model

Scale	Part supplier				Part inventory center	Module assembler		Module inventory center	Product manufacturer	Distribution center	Retalier/customer	Collection center	Recovery center	Secondary market	Waste disposal center
	1	2	3	4		1	2								
1	4	4	4	4	1	3	3	1	4	3	10	4	3	10	1
2	12	12	12	12	2	8	8	2	12	8	15	12	8	15	2
3	23	23	23	23	3	20	20	3	23	20	25	20	20	25	3

Table 2. Each approach for comparison

Approach	Description
GA	Conventional GA [5]
HGA	Conventional HGA by Kanagaraj et al. [6]
a-HGA	Proposed approach in this paper
Lingo	Conventional optimization solver by Lindo Systems [8]

Table 3. Measures of performance comparison

Measure	Description
Best solution	Best value of the objective functions under satisfying all constraints
Average solution	Averaged values of the objective functions under satisfying all constraints
Average time	Average value of the CPU time (Sec.) used for running each approach
Percentage difference	The difference of the best solutions of GA, HGA and a-HGA when compared with that of Lingo

$\alpha_2 = 20\%$, $\alpha_3 = 15\%$ and $\alpha_4 = 5\%$, for recoverable products, parts, modules and unrecoverable modules, respectively.

To prove the efficiency of the a-HGA approach, two conventional approaches (GA, HGA) and Lingo [9] as a benchmark are used and they are summarized in Table 2. The performances of each approach are compared using various measures of performance as shown in Table 3.

All approaches ran on a same computation environment (IBM compatible PC 1.3 Ghz processor-Intel core $I5 - 1600$ CPU, 4 GB RAM, OS-X EI) and programmed by MATLAB version R2014a. The parameter settings for GA, HGA and a-HGA are as follows: For each scale, total number of generations is 1,000, the population size is 20, the crossover and mutation rates are 0.5 and 0.3 respectively. Total 30 trials were independently done for eliminating the randomness in

Table 4. Computation results of each approach

		Best solution	Average iteration	Average solution	Average time	Percentage diff.
Scale 1	GA	149,789	15	150,754	8.1	−7.41%
	HGA	149,789	17	150,520	8.30	−7.41%
	a-HGA	149,789	21	149,789	138.50	−7.41%
	LINGO	161,777	-	-	-	0.00%
Scale 2	GA	149,868	35	152,381	8.33	−10.12%
	HGA	149,852	42	152,679	8.83	−10.13%
	a-HGA	149,765	54	151,616	193.70	−10.18%
	LINGO	166,747	-	-	-	0.00%
Scale 3	GA	151,572	53	153,919	9.00	−9.31%
	HGA	149,943	54	153,610	9.07	−10.27%
	a-HGA	149,895	42	153,365	313.30	−10.30%
	LINGO	167,103	-	-	-	0.00%

the search processes of the GA, HGA and a-HGA. Table 4 shows the computation results by GA, HGA, a-HGA and Lingo.

In the scale 1 of Table 4, the a-HGA including the GA and HGA has the same re-sult and their performances are greater than that of Lingo in terms of the best solution and percentage difference. In terms of the average solution, the a-HGA shows the best performance compared with the GA and HGA. However, in terms of the average time, the a-HGA shows the worst performance and the GA is the best performer. In scale 2, the performance of the a-HGA is more efficient than the GA and HGA in terms of the best solution and average solution. The difference in terms of the percentage difference means that the a-HGA is 0.05% and 0.06% advantageous compared with the HGA and GA. However, in terms of the average time, the a-HGA is the slowest and the GA is the quickest.

Similar results are also shown in the scale 3, that is, the a-HGA shows the best performances in terms of the best solution, average solution and percentage difference when compared with the GA, HGA and Lingo. However, the search speed of the a-HGA is about thirty times slower than those of the GA and HGA.

Figure 2 shows the convergence behaviors of GA, HGA and a-HGA until the generation number is reached to 200.

In Fig. 2, all approaches show rapid and various convergence behaviors during initial generations. However, after about 50 generations, each approach does not show any more convergence behaviors and the a-HGA shows to be more efficient behaviors than the GA and HGA.

The result of the detailed material flows in the a-HGA for the scale 3 is shown in Fig. 3. The opened facilities at each stage are displayed as white-coloured boxes. The 975 new parts in each area are produced and then sent to part inventory center. The recovery center recovers the quality of the returned products

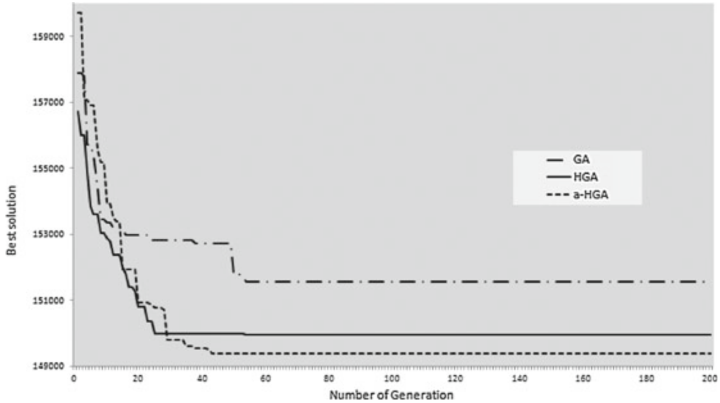

Fig. 2. Convergence behaviors of GA, HGA and a-HGA

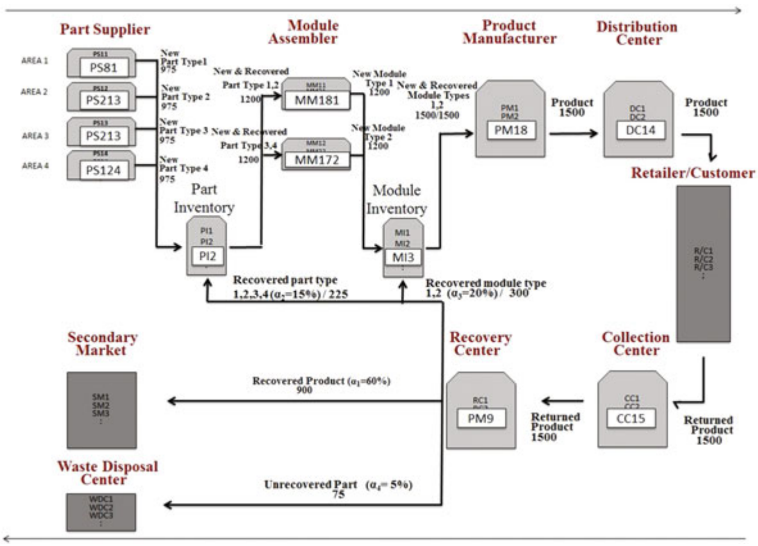

Fig. 3. Detailed material flows and facility numbers opened at each stage

and then sent 225 recovered parts to part inventory center. Part inventory center stores 975 new parts and 225 recovered parts. Total 1,200 parts (= 975+225) are shipped to module assembler. Module assembler assembles 1,200 parts and produces 1,200 new modules. Recovery center recovers the quality of the returned products and then sent 300 recovered modules to module inventory center. Module inventory center stores 1,200 new modules and 300 recovered modules. Total 1,500 modules are sent to product manufacturer for producing 1,500 products. 1500 products are sent to each retailer via distribution center. In RL, 1,500 products from all customers are returned to recovery center through collection center. 900 recovered products (= 60% × 1,500) of all returned products are resold at secondary markets. 75 unrecovered parts (= 5% × 1,500) of all returned products are sent to waste disposal center.

Based on the results of Table 4, Figs. 2 and 3, we can reach the following conclusions.

- The proposed CLSC model can represent the detailed material flows at each stage and effectively handle the recovered part and module by using two inventory centers, when compared with the conventional models of Amin and Zhang [1], Wang and Hsu [12], and Chen et al. [3].
- The a-HGA approach shows to be more efficient in many measures of performance than the GA, HGA and Lingo, which implies that the former can explore whole search space rather than the latter do.
- The search speed of the a-HGA is significantly slower than those of the GA and HGA, since the former has an adaptive scheme to regulate crossover and mutation operators and the search structure requires many times.

6 Conclusion

In this paper, we have proposed a new type of the CLSC model. The proposed CLC model has part suppliers at areas 1, 2, 3, and 4, module assembler, product manufacturer, distribution center and retailer for FL and customer, collection center, recovery center, secondary market and waste disposal center for RL. Especially, for effectively handling recovered part and module, two inventory centers (part and module inventory centers) have been used.

The proposed CLSC model has been represented by a mathematical formulation, which is to minimize the sum of handling cost, fixed cost and transportation cost resulting from each stage of FL and RL under satisfying various constraints. The mathematical formulation has been implemented by the a-HGA approach. The a-HGA approach is a hybrid algorithm with GA and CS approach. Also, using an adaptive scheme, the rates of crossover and mutation operators are automatically regulated in a-HGA approach. The a-HGA approach has been implemented in various scales of the proposed CLSC model to compare its performance with those of GA, HGA and Lingo. The experimental results have shown that the a-HGA approach is more efficient in terms of various measures of performance than the GA, HGA and Lingo. However, since the search speed of the a-HGA approach is significantly slower than those of the others, a room for improvement is still left in the a-HGA approach.

The Innovation Research of College Students' Academic Early-Warning Mechanism Under the Background of Big Data

Yu Li and Ye Zhang(✉)

University of Electronic Science and Technology,
Chengdu, People's Republic of China
zhangye_uestc@126.com

Abstract. With China's higher education from "elite education" to "mass education", students' academic problems have become increasingly serious. In the big data era, building college students' academic early-warning mechanism is of great significance for the training of qualified college students and improving the quality of higher education to keep pace with the times. However, in recently, the college students' research of academic early-warning mechanism based on the big data is relatively rare. This paper introduces the current research status of academic early-warning mechanism and the background of big data, and summarizes the characteristics of big data. Then it expounds the impact of big data thinking on the traditional academic early-warning mechanism about the four aspects: decision-making, forecasting, service and evaluation. This article focuses on putting forward an innovation model of academic early-warning mechanism concerning the information collection system, information processing and analysis system, program-making system and information release system based on big data, which will guide the practice of big data in the field of college students' academic early-warning.

Keywords: Academic early-warning · Big data · Impact · The innovation model

1 Introduction

After the reform and opening up, China's higher education has changed from elite education to mass education. The admission rate of college entrance examination has risen from 7% to 80% Since the 1980s, but the quality of students has been declining and the academic problems have been increasing year by year. For instance, the number of students who demote and dropped out of school increased obviously. Therefore, it is necessary to establish the academic early-warning mechanism to solve these problems.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_86

Academic early-warning is an impact on individual students in serious academic situation, and promptly reminds the students themselves and informs the parents. It is a academic early-warning system through the communication and collaboration of school, parents and college students, targeting to take appropriate preventive measures between the undergraduate students in the learning situation to give timely guidance to help students solve their academic problems and successfully complete their studies. In recent years, the research on college students' academic early-warning mechanism has lots of ideas. Chen [4] put forward the design idea of the colleges' early-warning mechanism from the aspects of the connotation, goal, function, warning system and the early warning level on account of the angle of the credit system of teaching management in colleges and universities. Cao [3] showed various reasons of academic problems behind the "learning difficulty students", putting forward the establishment of "learning difficulty students" assistance mechanism of academic pre-warning. Ding [5] and his colleagues took Science and Technology University in Suzhou province of China as an example, comparing and analyzing the data of school enrollment of academic early-warning mechanism. Hua [7] introduced the regulations and characteristics of academic early-warning system of Taiwan Universities in China, and then discuss the study of academic early-warning mechanism of college students in Mainland China. According to the document of Ministry of Education, which gives many opinions to improve the quality of teaching on further deepening reform of undergraduate teaching in 2007, it proposed to strengthen the management of personnel training process. "National Medium and Long Term Education Reform and Development Plan (2010–2020)" clearly published: establishing the assistance mechanism of students with learning difficulties, improving the excellent student training methods. In August 2007, the Ministry of Education promulgated "Academic Early-warning" as one of 171 new Chinese Words. The above studies and documents indicate that the system of academic early-warning is of great significance to the cultivation of talents in colleges and universities.

With the advent of the big data era, data increases fast, and the date range is expanded, which contribute to the formation of educational database. The information plan of national education offered "two platforms" (the public service platform of national education resources, the service platform of national education management) based on the concept of big data in wisdom campus construction and the large-scale opening online courses' teaching practice. In the whole sample data, mining the regulation of educational development is conducive to the guidance of education in colleges and universities to improve the accuracy of decision-making. To a certain degree, in the construction of educational information at different levels has taken a historic step, furthermore, it also lays the foundation for the practice of big date in the field of academic early-warning. However, although many scholars have explored the application of big data in education field at present, the theoretical and applied research on big data in the academic early-warning mechanism of college students in China and abroad is still in a preliminary stage. Therefore, this article will analyze the impact of big data on the traditional academic early-warning mechanism and design the model of college students' academic early-warning mechanism under the background of big data, and expect to provide basis for the follow-up research and application of big data in the field of college students' early-warning mechanism.

2 The Brief Introduction of Big Data

There is no uniform definition of big data at present, citing the McKinsey Global Institute's description of The Next Frontier in Innovation, Competition and Productivity: big data refers to the date process that is different from traditional software tools [8]. Although the definition of big data is not uniform, the characteristics of big data are clear and recognized. (1) The huge data volume. A variety of terminal equipment and sensors produce a lot of data, PB-scale data sets can be described as normal. (2) The variety data types. In the era of big data, more and more unstructured data, including network log, audio, video, pictures, geographical information. These different types of data needs higher requirements on data processing. (3) Processing speed. The most significant features is to distinguish big data technology from traditional data technology. In the face of massive amounts of complex data, big data can deal with real-time data faster. (4) Low value density. The value density is inversely proportional to the size of the data, for an hour video, the useful data may be only one or two seconds in the continuous monitoring.

The first feature of big data is large-scale, with the development of information technology, a variety of information systems, databases, cloud storage, Internet, Web of Things and mobile intelligent terminals, especially in recent years, increase rapidly in social system. The data sharing becomes very easy, so that the data scale is expanding constantly. At the same time, big data also has a complex and diverse data structures, owing to large, complex and volatile date, it is becoming more and more difficult to obtain hidden, useful knowledge, traditional data warehouse and data mining-related processing mode has been unable to meet the requirements, big data has a stronger decision-making power, insight and process optimization capabilities, which brings new changes to data processing, storage and conversion.

The latent value of big data is the correlation between the data, big data thinking is a conversion from the traditional causal analysis to the relevant analysis. More and more countries, governments, industries, enterprises and other institutions have realized that big data is becoming the organization's the most important asset, the capabilities of data analysis is becoming the organization's core competitiveness [11]. At present, the government has put big data into application to promote people's daily lives, the internet has penetrated into various industries. Big data has brought about an enormous effect on education. It has been integrated with education and is promoting the reform of educational model. Besides, it grounds for the application in college students' academic early-warning mechanism.

Big data is a prediction method based on objective data that has been obtained rather than on subjective inferences. This analysis method is based on the huge data, which is obviously different from the sample analysis method which has been used in the past. It can correct the error of the sampling method and improve the accuracy of the analysis result. Big data analysis can get the precise results, easier access to the user's trust, and thus has a wide utilization. The application of big data technology in college students' academic early-warning mechanism will have more timely and accurate early-warning.

3 The Impact of Big Data Thinking on the Traditional Academic Early-Warning Mechanism

3.1 Rational Decision-Making

The main object of universities and colleges is college students who as the most dynamic and most potential individuals, college students' thinking, behavior and personality are diverse. Due to the invisible and complex nature of thinking, it is hard to understand one's mind. In the past, we could only make judgments on the basis of individual experience and simple sample statistics. This traditional subjective decision-making method and the statistical analysis method of small sample data will play a certain role in the traditional academic pre-warning, but the cost of manpower, material and financial resources is huge, and the accuracy of academic early-warning needs to be improved. In the era of big data, we can effectively make more scientific judgments, more rational decision-making. Big data can provide a data basis for us to make the rational decision through the real-time monitoring of students learning and lives in and out of class. We can also analyze the students' thoughts and behavior through the internet, forming regular recognizing of them by the analysis of vast amounts of date to achieve scientific decision-making.

3.2 Precise Prediction

Forecast is the core of big data, the big data analysis method applied to the massive data, so as to predict the possibility of occurrence, to achieve the purpose of prediction. A large number of data not only allows us to predict the development of things, but also makes our prediction of human behavior possible. In the era of big data, the behavior data that is interdependent and associated of college students have been recorded and preserved. We can find the link between their behaviors and predict trends through the depth analysis and integration of behavioral data, so that we are able to react quickly to guide and intervene in advance.

3.3 Personalized Service

The big data has opened the way of individualized education, it can reveal the students' learning pattern through the data tracking and analysis of the students' learning process, formulating individualized educational programs for them, and giving the practical direction for individualized education. College students are highly individualized groups. They pay attention to strong character hoping to be treated as a unique individual. In the past, students worked only from the overall work programs, which ignore the personal differences and individual needs. Big data concerns every person, and will make a big change to our students work. It will make us re-examine the work of students not only from the overall picture, but also pay more attention to individual work to carry out specific work to promote individualized development of each college student. Through the whole, timely and dynamic record of each student's learning, life and social situation, the big data contribute to a better understanding personality and growth needs of students so that we can adopt ideological and political education measures, career planning, psychological counseling, comprehensive quality education to achieve personalized service of college students.

3.4 Scientific Evaluation

In the past, it is difficult to quantify the college students work whether it is the ideological evaluation of students or students' the economic situation of the family. It is inevitable that there is a certain bias resulting in a highly subjective evaluation that is because of the information only from counselors, class teachers, students and other channels. But the big data can promote the scientific evaluation of teaching to achieve more effective academic early-warning. To assess the economic situation of students in their family, for example, we can clearly grasp the specific period of time students' income and expenditure through their campus cards consumption records, shopping consumption records, mobile payment list, personal account records, thus we can make an accurate judgment of their personal economic situation as an important basis for judging the economic status of their families to avoid the errors caused by the subjective analysis. In the evaluation of the students' ideological situation, the analysis of the massive data can be more deterministic to test the dynamics of their thoughts and behavior to reflect the information of their ideological characteristics by data processing.

4 The Innovation Research: The Building of Academic Early-Warning Mechanism Under the Big Data Environment

In the era of big data, the academic early-warning mechanism consists of four major systems: information collection system, information analysis and processing system, program-making system and information release system.

4.1 Information Collection System

The collection of information is the primary work of the academic early-warning system, and it is the key to the work of academic early-warning as well. In the coming of big data, the basis of college students' work is to master the huge data which can really understand the characteristics of the behavior of college students to effectively find out the education, management and service countermeasure. First, colleges and universities should conduct the top-level design that is an overall vision of an integrated data platform inside their own campus. Considerable universities in the development of the wisdom campus's construction, different departments of the university only consider the work of the department needs, so that it is difficult to achieve data sharing and integration. So the school should set up a coordination department and academic pre-warning department to build a data center to gather the information of the office, academic affairs, school work, library and other related departments in order to form information platform. Secondly, building a system of online data collection platform to form a large database of students across the school in order to ensure the timely and complete collection of all students of all data. At the same time, colleges and universities should from the overall point of view do a good job of data classification, hierarchical collection and planning work to ensure the diversify of data sources and data types. Thirdly, colleges and universities should take the initiative to share the social database contributing to the establishment of big database of education. In this paper, the educational data can be divided into three categories: explicit data, behavioral data and system data (Fig. 1). Explicit data is the data input or output by the end user. Behavior data can also be called control data, which is designed by the developer for the purpose of recording the data of the operation process of the user, generally only seen by the administrator. System data is automatically generated by the system, behavioral data and system data are hidden data [9].

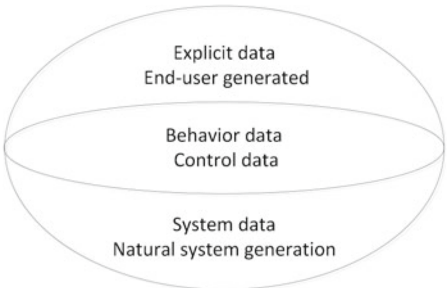

Fig. 1. The three categories educational data

4.2 Information Analysis and Processing System

The amount of information is large and have different structure, and a lot of information have no effect on the academic early-warning, so we need information processing and analysis system to sorting, deleting unnecessary information, and find useful details to making the academic early-warning mechanism more effective. The work of this system is to dynamically monitor the behavior of college students inside and outside the classroom, using the data mining technology of big data to analyze the collected information, and discover the abnormal phenomenon or behavior of college students. Under the big data environment, we use the technology of Outlier Mining Algorithm to find out the data away from the regular objects and launch the analysis of the outlier data. From the data itself, outlier data are deviations from normal data, which may be produced due to errors in the data formation process, and are often eliminated directly in early data analysis. However, due to data from reality, a lot of outlier data is not coming into being due to the errors, but the corresponding data source itself does contain a special behavior that may also mean a very important information that indicates the emergence of a new situation, which need us to distinguish, so the mining and analysis of outlier data is of great significance. The general idea of outlier mining is that: in a data set with n data objects, a desired outlier objects k ($k \leq n$) is given, and dig out a number of outliers data that are significantly different from the rest of the objects in the data set [1]. There are a number of outlier mining algorithms, including statistic-based, distance-based and bias-based detection algorithms, and outlier-based data using conventional data mining algorithms. Through scientific monitoring and analysis, we can timely identify the adverse factors, issue academic early-warning to avoid the depravation in academic.

4.3 Program-Making System

The Course Signals System divides students into three groups: green, yellow, and red according to the current state [2]. The green signal indicates that the students are likely to achieve the goal if he or she continues the current learning state. The yellow signal indicates that the student has potential difficulties in learning the courses, while the red signal indicates that students may fail in the exams. Under the big data background, we are able to output the visualization of the early-warning signals by using the technology of big data mining and analysis, so that students can continue to maintain the current status or make corresponding improvements.

(1) The early-warning program of the red signal: for red alert students, firstly, we need to analyze the reasons of their learning difficulties one by one, and arrange mutual help with each other. Counselor or class teacher would better chant with each students as much as possible to help them find causes of learning decline, and then seek out appropriate learning methods to improve academic grade. Secondly, for red warning students, we can be appropriate to reduce their extracurricular activities, and increase learning time, learning content. At the same time, we should not encourage them to take too much non-professional training curriculum.
(2) The early-warning program of the yellow signal: it is better to give encouragement to the yellow alert students. We could not only affirmed their existing achievements, but also put forward higher requirements. What's more, the

yellow warning for students can also be divided into two types to be treated in different. Some students study hard but not get good achievements. Their academic performance is not good, which is not caused by laziness. They take a lot of time to learn, but do not learn too much, we can arrange study-well students to give them one-on-one help, and offer guidance on learning methods. Other students lack initiative in learning, it is better to carry out strict management measures to require poor autonomy students. For example, we can take certain treatment measures, such as the centralized management, self-study at night, roll-call system.

(3) The early-warning program of the green signal: the green students are very excellent. We should pay attention to control their complacency, and put forward higher requirements to keep the existing achievements and continue to improve their comprehensive ability. Besides, we should ask them to learn well in the professional courses, doing well in the minor course at the same time, and inspire them to reach high standards in its computer level and English ability.

4.4 Information Release System of Academic Early-Warning

Release system is helpful for university students to understand their current academic situation by setting up information release system of academic early-warning. The school provides corresponding help for the students' academic difficulties. The parents strengthen supervision and guidance, it will achieve better warning effect through tripartite linkage among the school, family and students. On one hand, when the students log on to their academic early-warning system, the relevant early-warning information will automatically inform and highlight prompt, students can timely understand their own learning status by this confidential and practical warning, and they can form a certain psychological warning to take some self-remedial measures according to their specific circumstances. So we can set up release system by the method of abnormal affecting elements feedback [6].

Abnormal Affecting Elements Feedback
The key attribute subspace kas (p) of outlier object P is the main cause of data outliers, and can be used to accurately feedback the students' academic abnormalities with kas (p). Release system from two aspects of the q test results for output. Release system output test results of q times from tow aspects.

(1) Personalize abnormal elements analysis of outlier objects. Set the key attribute subspaces of the same outlier object p from every test are kas(p), $i = 1, 2, \cdots, p$. If P in the i time is not outlier, then kas(p) is an empty set. Set P is outlier in q_o, c_j is the occurring times of attribute a_j in all $kas(p)$. Apparently, the bigger is c_j, the more times of attribute a_j affecting P to outlier. Appraisal the affecting of attribute a_j to P abnormal study by c_j/p_o, to draw personalize abnormal elements affection chart. For example, one student is judged as abnormal 7 times in 10 tests data in one week, which

is more than 10/2, so he gets an orange warning and his personal affecting elements and their degree of affecting are: Job performance is 5/7, times of being late in class is 2/7, internet surfing duration is 4/7, downstream flow is 3/7, community activity duration is 3/7, staying in dormitory duration is 1/7, which shows the student's constitute of study abnormal elements by Fig. 2.

(2) Total degree of affecting analysis of element a_j, set the abnormal degrees of affecting of a_j in every test are c_j/k, $i = 1, 2, \cdots, q$. Draw elements continuously affecting chart to show the total situation of study abnormal affecting elements.

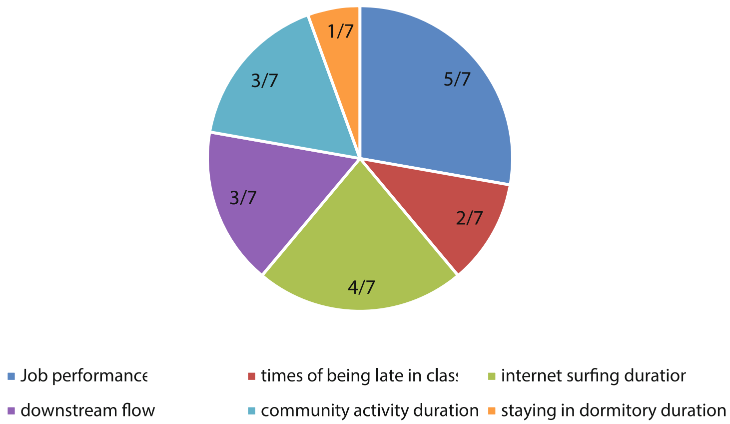

Fig. 2. The individual influence about abnormal factors

5 The Process Model of Academic Early-Warning Mechanism

In the big data environment, the main process of academic early-warning mechanism is information collection, information analysis, and information prediction and information release [10]. The process model of academic early-warning of college students is constructed based on the technology of big data. As shown in Fig. 3.

(1) The information collection system of academic early-warning: using the large database of information collection in university and the large database of education outside the university collects the internal and external information in colleges and universities, and using big data technology to initialize and classify them.

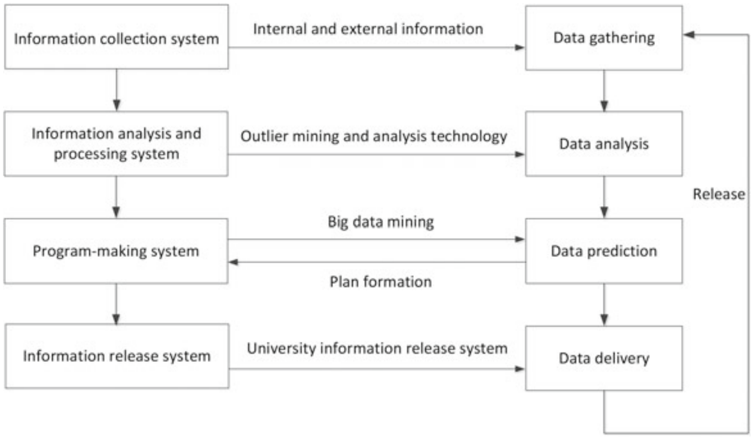

Fig. 3. The process model of academic early-warning of college students is constructed based on the technology of big data.

(2) The information analysis and processing system of academic early-warning: further cleaning and transforming to the collected information by using the big data analysis and processing technology, and using the outlier data mining and analysis technology of the big data to analyze the large number of data, focusing on the abnormal information and identifying adverse factors to make an early prevention.
(3) The program-making system of academic early-warning: according to Course Signals System, the early-warning of academic is divided into green, yellow and red pre-warning, and the big data is used to visualize the early-warning signals.
(4) The information release system of academic early-warning: college students get the feedback of results, and take measures to adjust learning state, which will provide feedback information to begin the next round of information collection.

6 Conclusion

Big data can collect data that is unable to obtain or acquire costly in the past, and more easily utilize their teaching level and management ability in the process of teaching analysis to fully enhance students' academic performance, and it will also set off a huge revolutionary by bringing influence in the field of education. However, the goal of education is the growth of each person that driving people to recognize things with a rational thinking, and gradually form a relatively perfect thinking of self-consciousness, which is so complex and hard to make perfect forecast. Therefore, on one hand, big data services for education in the academic early-warning system to be required cautious implementation in the practical application. On the other hand, it is so attractive and challenging to create personalized education through big data, more confidence should be given to design more detailed academic early-warning mechanisms to find more targeted interventions.

tetsuya_sato@aoni.waseda.jp

Abstract. Integration of plural local DCs (Distribution Centers) into a large-scale DC with automatic warehouse system is considered as an effective strategy among logistics industries for responding to the diversifying needs of customers and markets, optimizing distribution operations and resource saving. However, as numerous items must be handled in such integrated DC, adequate design of the components such as warehouse, sorting-packing lines and their operation system is a critical issue for maintaining competitive advantage. This paper, focusing on the last issue, discusses the utility of TCM (Target Chasing Method) based dispatching policies for bottleneck management of entire process. Various PCVs (Pseudo Control Variables) are examined to utilized, which represent the state of the system, easy to observe but indirectly controllable (e.g. number of items and waiting time in queue, work load rate in each sorting-packing line). Performance analysis is examined by simulation experiments and obtained results suggest that smooth flow of items in each stage of sorting-packing line is realized by the proposed dispatching policies. Especially, dispatching policy for Just-In-Time delivery to customers that intends to adapt delivery time to customers, reveals the weak portion of the entire system.

1 Introduction

In recent years, responding to the diversifying needs of customers and markets with optimizing distribution operations and resource saving are the trends among logistics industries. However, it requires to handle various types of products in small lots and the efficiency of each operation are decreased in conventional supply chain with plural local DCs (Distribution Centers). Thus, integration of local DCs into a large-scale DC with AWS (Automatic Warehouse System) is considered as an effective strategy for improvement of products flow in entire

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_87

supply chain. As numerous items must be handled in such integrated DC, adequate design of the components such as warehouse, sorting-packing lines and their operation system is a critical issue for maintaining competitive advantage.

For optimizing products flow in entire process of large-scale integrated DC, this paper discusses the utility of TCM (Target Chasing Method) [2,4–7] based dispatching policies. TOC (Theory of Constraints) [1] identifying and improving the bottleneck processes in multi-stage operations is an effective way for betterment of productivity. In this study, various PCVs (Pseudo Control Variables) [3,8] are examined to utilized, which represent the state of the system, easy to observe but indirectly controllable. Performance analysis is examined by simulation experiments and obtained results suggest that smooth flow of items in each stage of sorting-packing line is realized by the proposed dispatching policies. Especially, dispatching policy for Just-In-Time delivery to customers that intends to adapt delivery time to customers, reveals the weak portion of the entire system.

2 Experimental Method

2.1 Target Chasing Method (TCM)

TCM, which is frequently used in automotive industry, is a heuristical algorithm of sequencing method. Basically, TCM controls the order of job entry for minimizing the gap between ideal and real resource usage of the facility at each timing. Figure 1 shows the schematic diagram of TCM. Vertical and horizontal axes are the order of job entry and resource usage in the facility, respectively. From this figure, it is noticed TCM intends to pursue Heijunka (load levelling) production by controlling the order of job entry. The objective function of TCM is expressed in Eq. (1).

Objective Function:

$$\min\left(D_k\right) = \min_{i \in I} \sqrt{\sum_{j=1}^{R} \left(\frac{k \times N_j}{Q} - X_{jki} \right)^2}. \tag{1}$$

Symbols:

k : Order of job entry;
i : Lot number;
j : Resource type;
I : Set of the products;
R : Number of total resource;
Q : Total number of all products;
N_j : Usage of resource j for manufacturing all products;
X_{jki} : Usage of resource j for manufacturing from 1st to k^{th} product i;
D_k : The gap between ideal and real resource usage after k^{th} job entry.

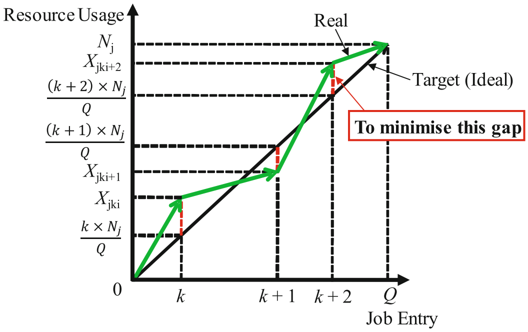

Fig. 1. Schematic diagram of target chasing method

2.2 Pseudo Control Variables (PCVs)

This paper focuses on the utility of PCVs [3,8], which represents the state of the system, easy to observe but indirectly controllable (e.g. number of items and waiting time in queue, work load rate in each sorting-packing line), for TCM-based dispatching policy. Figure 2 shows the schematic diagram of the controlled behavior of TCM using PCVs. Vertical and horizontal axes of Fig. 2 are the PCV values of each resource. In this case, there are two facilities in the same operational stage and the target of PCVs (diagonal line in Fig. 2) is defined as the same values between PCV1 and PCV2. Therefore, TCM controls current status of PCVs to the target line for Heijunka production. For example, the value of PCV2 is higher than PCV1 on the point P of Fig. 2, thus TCM tries to control PCV2 to decrease and PCV1 to increase for reducing the gap between actual and target PCVs.

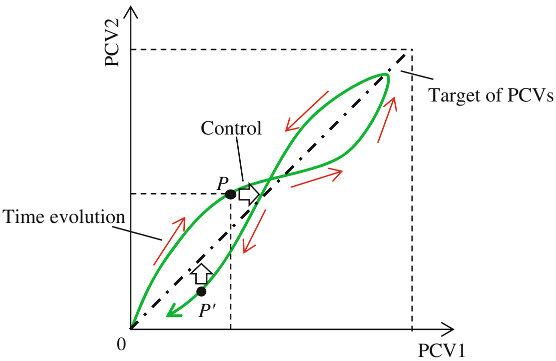

Fig. 2. Schematic diagram of target chasing method using pseudo control variables

2.3 Objective System

The objective system which is the multi-stage sorting-packing system in the large-scale DC with AWS is shown in Fig. 3. Dotted arrows in this figure are the routes of products flow from arrival to shipment. At first, handled products are arrived from plural local suppliers and warehoused to AWS. Products in the warehouse are sorted by AWS and dispatched to packing area. Products are re-installed to AWS after packing operation. This process is repeated in terms of multi-stage operation and packaged products are shipped to local assemblers. Table 1 shows the facilities and details of the operations in each stage of the objective DC. The 1st and 2nd stage of sorting and packing operations are the target to optimize by TCM based dispatching policies in this study, which is indicated by asterisks in Table 1. From Fig. 3, bottleneck management of the products flow at each packing station is required for efficient Just-In-Time delivery to the customers.

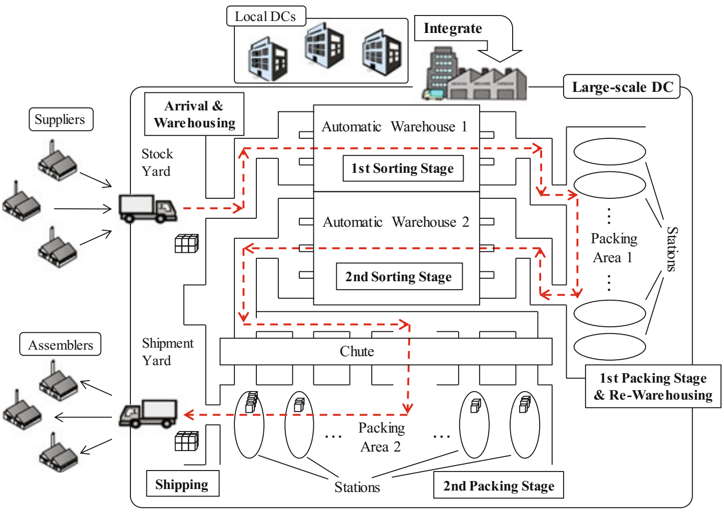

Fig. 3. Schematic diagram of objective large-scale distribution center

2.4 Simulation Model

This paper analyzes the performance of proposed TCM-based dispatching policies by simulation experiments for a downscaled problem, as original large-scale system is too complicated to tackle with. Figure 4 shows the schematic diagram of the defined simulation model. The buffers before each conveyor and AWS are inserted for dividing and identifying the bottlenecks of products flow in each stage.

Table 1. Details and facilities of the operations in each stage of the objective distribution center

Operation	Detail of operation	Facility
Arrival	Products arrive from suppliers	Stock Yard
Warehousing	Arrived products are stored to buckets and transferred to Automatic Warehouse	Stock Yard
1st sorting stage*	Warehouse system controls the dispatch order and the dispatched station of each product by the unit of a bucket	Automatic Warehouse 1
1st packing stage*	Products are extracted from the buckets and labeled. After labeling operation, the products are packed to inner boxes and re-stored to the buckets	Packing Area 1
Re-warehousing	Products are re-installed to Automatic Warehouse	Packing Area 1
2nd sorting stage*	Warehouse system controls the dispatch order and the dispatched station of each product by the unit of a bucket	Automatic Warehouse 2
2nd packing stage*	Required quantity of inner boxes with products are packaged to shipping boxes (or pallets)	Packing Area 2
Shipping	Products are shipped to assemblers	Shipment Yard

* Table 1 indicates the sub-processes of "Warehousing" and "Re-Warehousing"

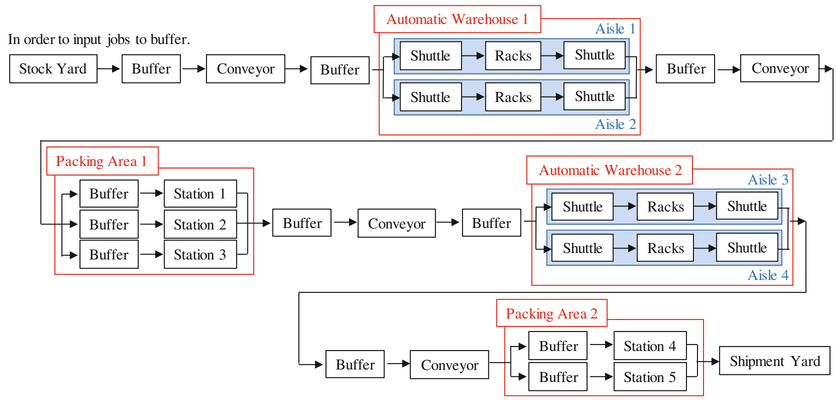

Fig. 4. Schematic diagram of the downscaled simulation model

The aim of this paper to analyze the performance of dispatching policies in AWS at each sorting stage; therefore, this paper unconsiders warehousing policy of AWS. The parameters of the simulation experiments are defined by properly deformed figures as follows:

- Number of product types: 3 (Product 1–3);
- Maximum load of the conveyors: 3 buckets;
- Supplying pitch of the conveyors: 1 bucket per unit time;
- Number of racks in each aisle: 100 racks;

Table 2. Facilities, processing time and lot size of each operation

Operation	Facility	Processing time	Lot size
1st sorting stage	Aisle 1 in Automatic Warehouse 1	$(2+3=)5^*$	1
	Aisle 2 in Automatic Warehouse 1	$(2+3=)5^*$	1
1st packing stage	Station 1 in Packing Area 1	3	1
	Station 2 in Packing Area 1	3	1
	Station 3 in Packing Area 1	4	1
2nd sorting stage	Aisle 3 in Automatic Warehouse 2	$(2+3=)5^*$	1
	Aisle 4 in Automatic Warehouse 2	$(2+3=)5^*$	1
2nd packing stage	Station 4 in Packing Area 2	15	6
	Station 5 in Packing Area 2	12	4

* Processing time of the aisles in each sorting stage are the sum of traveling times on the shuttles and the conveyors, respectively.

Table 3. Part of the generated lists of job entry and shipping order

(a) The list of job entry (Input)				(b) The list of shipping order (Output)				
Time of job entry	Product code	Station of packing Area 1	Station of packing Area 2	Shipping order	Product code	Lot size	Station of packing Area 1	Station of packing Area 2
1	1	3	4	1	3	4	2	5
2	2	3	4	2	1	4	1	5
3	1	3	4	3	1	6	2	4
4	2	3	4	4	2	4	2	5
5	1	3	4	5	2	4	2	5
6	3	3	5	6	3	6	2	4
7	2	3	4	7	2	6	1	4
8	3	3	5	8	2	4	1	5
9	3	3	5	9	2	6	3	4
10	3	3	4	10	3	6	2	4
11	3	2	4	11	3	6	1	4

13	3	2	5	13	2	6	3	4
14	2	2	5	14	1	4	1	5
15	1	2	4	15	3	6	2	4
...				...				
2000	1	2	5	410	2	6	2	4

- Buffer capacity of each packing station: 50 buckets;
- Number of job input to a queue: 2,000 products (expected as warehousing products in a week);
- Facilities, processing time and lot size of each operation: shown in Table 2.

The lists of job entry and shipping order of packaged products have been generated randomly in advance, which are shown in Table 3. Note that all products are assigned to operational stations in each packing stage beforehand of warehousing based on the job entry list which described the details of the packing operations in each station.

Performances of the proposed dispatching policies are analyzed by the number of items and waiting time in queue and work load rate in each sorting-packing line. Work load rate in sorting line (AWS) is defined as the rack occupancy. The definitions of waiting time and work load rate in packing lines are expressed in Eqs. (2) and (3), respectively.

Waiting time in queue:

$$QT_i^{x_j} = OT_i^{x_j} - IT_i^{x_j}. \tag{2}$$

Work load rate in packing line:

$$WR^{x_j} = \frac{\sum_{i=1}^{N^{x_j}} ST_i^{x_j}}{T}. \tag{3}$$

Symbols:

x_j : The j^{th} facility x;
OT_i^{xj} : Dispatched time of product i from facility x_j;
QT_i^{xj} : Waiting time of product i in facility x_j;
IT_i^{xj} : Job entry time of product i into facility x_j;
WR^xj : Work load rate in facility x_j;
T : Total processing time of entire operations;
N^{xj} : The number of products of which operation is finished in facility x_j.

The proposed TCM-based dispatching policies in each stage of sorting operation using AWS are shown in Table 4. The multi-stage operations are improved by a combination of the policies in the 1st and 2nd sorting stage. Regarding to the policy code $S - Xa$ or $S - Xb$, its components, i.e. S, X, a or b, represent the stage of the sorting operations, the index of the policies and number of items or waiting time in queue for PCVs, respectively. For example, the combination of policy codes 1-1a and 2-0 represents adoption of indicated dispatching rule to the 1st sorting stage and dispatching rule to the 2nd sorting stage described in Table 4, respectively.

3 Experimental Results and Discussion

3.1 Analysis of the Present Dispatching Policy (Benchmark)

At first, this paper analyzes the performance of the present dispatching policy that is used as a benchmark. Figure 5 shows the time series of the number of items in queue at each packing station, where the policies 1-0 and 2-0 are applied. As a result, the number of items in each queue are changed independently by the corresponding policies in each packing stage. Especially, from Fig. 5(a), it is observed that buffer capacities of each station that is defined as 50 buckets in Packing Area 1 tend to be fully occupied.

Table 4. Proposed TCM based dispatching policies for each stage sorting operations

1st Sorting stage		2nd Sorting stage		Notes
Policy	Detail	Policy	Detail	
1-0*:	<Benchmark> To dispatch the transactions by FCFS (First-Come, First-Served) principle	2-0*:	<Benchmark> To dispatch the transactions lot where all the items are ready to pack in the 2nd packing stage	In case of the order of shipping schedule is *not considered.*
1-1a:	To dispatch the transactions to the station by TCM, where number of items in queue is less than other stations at the 1st packing stage	2-1a:	To dispatch the transactions to the station by TCM, where number of items in queue is less than another station at the 2nd packing stage	
1-1b:	To dispatch the transactions to the station by TCM, where waiting time in queue is shorter than other stations at the 1st packing stage	2-1b:	To dispatch the transactions to the station by TCM, where waiting time in queue is shorter than another station at the 2nd packing stage	
1-2a:	To dispatch the transactions to the station by TCM with consideration of shipping schedule, where number of items in queue is less than other stations at the 1st packing stage	2-2a:	To dispatch the transactions to the station by TCM with consideration of shipping schedule, where number of items in queue is less than another station at the 2nd packing stage	In case of the order of shipping schedule is *considered*.
1-2b:	To dispatch the transactions to the station by TCM with consideration of shipping schedule, where waiting time in queue is shorter than other stations at the 1st packing stage	2-2b:	To dispatch the transactions to the station by TCM with consideration of shipping schedule, where waiting time in queue is shorter than another station at the 2nd packing stage	

* Current dispatching policies at each sorting stage.

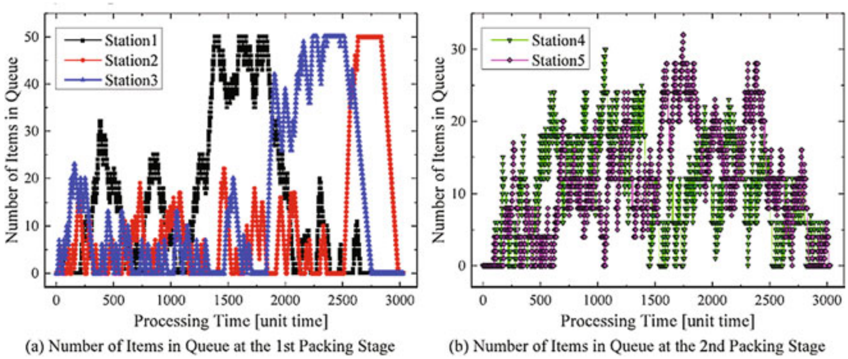

Fig. 5. The time series of the number of items in queue at each packing station in case of policies 1-0 and 2-0

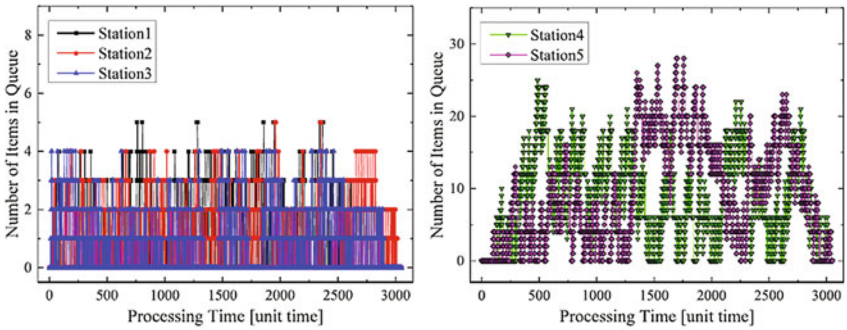
Table 5 shows the summary of criteria values in each operation in case of policies 1-0 and 2-0. The number of items and waiting time in queue of Packing Area 1 are both worse values than Packing Area 2 as well as the work load rate. Thus it is noticed that the 1st packing stage is the worst bottleneck operation in entire system.

Table 5. Averages and standard deviations of the criteria values in case of policies 1-0 and 2-0

	(a) Number of items in Queue [units]				(b) Waiting time in Queue [unit time]				(c) Work load rate			
	AWS1	Packing Area 1	AWS2	Packing Area2	AWS1	Packing Area 1	AWS2	Packing Area2	AWS1	Packing Area 1	AWS2	Packing Area2
Ave	0.661	38.681	44.011	21.503	1.000	57.524	30.803	31.534	0.33%	50.01%	22.01%	83.44%
SD	0.813	52.552	35.066	18.402	0.000	55.398	30.315	18.612	0.46%	49.94%	7.80%	37.17%

3.2 Bottleneck Management of the 1st Packing Stage

Based on the results in the last section, this paper analyzes the performance of proposed TCM-based dispatching policy applied to the worst bottleneck operation observed in the 1st packing stage. Figure 6 shows the time series of the number of items in queue at each packing station where the policies 1-1a and 2-0 are applied. In this case, policy 1-1a uses the number of items in queue as PCVs for TCM-based dispatching policy. From Fig. 6(a), the number of items in queue try to mutually equalize the same PCV values of other stations at the 1st packing stage by TCM-based dispatching. Note that the products are re-installed after the 1st packing operation and dispatched from AWS2 by policy 2-0, as in the last section. Thus, Fig. 6(b) are slightly changed from Fig. 5(b); nevertheless, the tendency is similar to the benchmark result.



(a) Number of Items in Queue at the 1st Packing Stage (b) Number of Items in Queue at the 2nd Packing Stage

Fig. 6. The time series of the number of items in queue at each packing station in case of policies 1-1a and 2-0

Table 6 shows the summary of criteria values in each operation in case of policies 1-1a and 2-0. The number of items and waiting time in queue at Packing Area 1 are extremely decreased from the benchmark result described in Sect. 3.1 and the work load rate in AWS1 is increased. For this reason, it is expected that the proposed TCM-based dispatching policies using PCVs facilitates Heijunka production effectively in the objective system.

In addition, policy code 1-1b uses the waiting time in queue as PCVs for TCM-based dispatching policy; however, the tendency of the criteria values is similar. Thus, this paper discusses only the cases that use the number of items in queue as PCVs in the following sections.

Table 6. Averages and standard deviations of the criteria values in case of policies 1-1a and 2-0

	(a) Number of items in Queue [units]				(b) Waiting time in Queue [unit time]				(c) Work load rate			
	AWS1	Packing Area 1	AWS2	Packing Area2	AWS1	Packing Area 1	AWS2	Packing Area2	AWS1	Packing Area 1	AWS2	Packing Area2
Ave	68.191	2.967	45.355	17.671	58.185	3.527	32.874	25.967	34.10%	49.58%	22.68%	82.73%
SD	72.045	3.912	36.089	15.591	75.736	3.209	34.045	17.020	21.77%	49.94%	7.73%	37.80%

3.3 Bottleneck Management of Entire System

From the benchmark result in Sect. 3.1, the second worst bottleneck operation in the system is identified, that is Packing Area 2. Due to this reason, this paper analyzes and discusses the proposed TCM-based policy for improving products flow of both the 1st and 2nd packing stages in this section. Figure 7 shows the time series of the number of items in queue at each packing station where the policies 1-1a and 2-1a are applied. From this figure, the number of items, which is defined as PCV in the policies, in each station at both the 1st and 2nd packing stages try to mutually equalize the same PCV values by TCM-based dispatching.

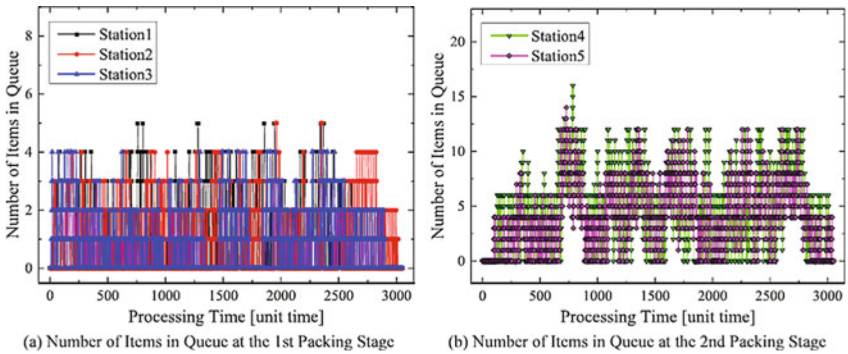


Fig. 7. The time series of the number of items in queue at each packing station in case of policies 1-1a and 2-1a

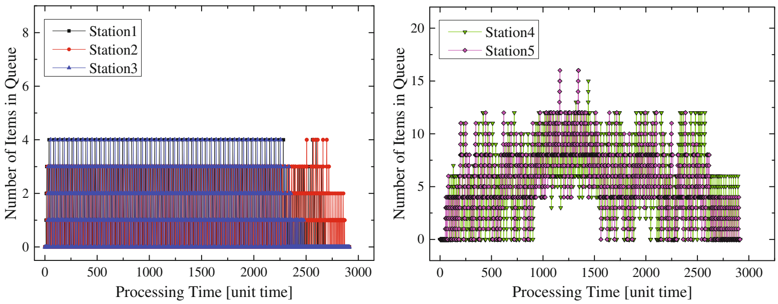
Table 7 shows the summary of criteria values in each operation in case of policies 1-1a and 2-1a. The number of items and waiting time in queue of the 2nd packing stage are decreased from the result of the last section, not only the 1st stage. Therefore, proposed TCM-based dispatching policies are utilized for bottleneck management with Heijunka concept of entire operation. On the other hand, the work load rate of Packing Area 2 in Tables 5, 6 and 7 are almost the same level. This is caused by the lot sizes and the processing time of each station at Packing Area 2 which are larger and longer than other processes, that is, after the improvement of this section, the bottleneck operation of the entire system, which is the 2nd packing stage, has not been transferred to other operations from the result of the last section. Thus, more improvement of operations throughput in Packing Area 2 is required for efficient improvement of the entire system, not only the preceding stages.

Table 7. Averages and standard deviations of the criteria values in case of policies 1-1a and 2-1a

	(a) Number of items in Queue [units]				(b) Waiting time in Queue [unit time]				(c) Work load rate			
	AWS1	Packing Area 1	AWS2	Packing Area2	AWS1	Packing Area 1	AWS2	Packing Area2	AWS1	Packing Area 1	AWS2	Packing Area2
Ave	68.191	2.967	54.340	8.358	58.285	3.527	39.689	11.755	34.10%	49.58%	27.17%	82.73%
SD	72.045	3.912	44.170	7.497	75.736	3.209	47.651	7.435	21.77%	49.94%	10.19%	37.80%

3.4 Bottleneck Management with Consideration of the Shipping Schedule

Finally, this paper analyzes bottleneck management with consideration of the shipping schedule. The assignment of all products to the operational stations at each packing stage in Table 3(a) decreases the degree of freedom in optimization of dispatching policy; therefore, product jamming is occurred by optimization with consideration of the shipping order. For this reason, the investigation of this section focuses the utility of dynamic reassignment of the products to each operational station. Figure 8 shows the time series of the number of items in queue at each packing station considering scheduled shipping order as Table 3(b), where the policies 1-2a and 2-2a are applied. As a result, the number of items in each station at both the 1st and 2nd packing stages try to mutually equalize the same PCV values, which is similar to the analyzed result of the last section.



(a) Number of Items in Queue at the 1st Packing Stage (b) Number of Items in Queue at the 2nd Packing Stage

Fig. 8. The time series of the number of items in queue at each packing station in case of policies 1-2a and 2-2a

Table 8 shows the criteria values in each stage in case of policies 1-2a and 2-2a. In addition, the proposed dispatching policy dependent characteristics of the number of items in queue, waiting time in queue and the work load rate at each stage are summarized in Fig. 9. The bar and line charts in this figure are the averages and standard deviations of the criteria values, respectively. From Table 8, the work load rate in AWS 1 is decreased from the result of the last section shown in Table 7(c); nevertheless, the number of the items and the waiting time in queue of AWS 1 are extremely decreased from Table 7(a) and (b). This is

Table 8. Averages and standard deviations of criteria values in case of policies 1-2a and 2-2a

	(a) Number of items in Queue [units]				(b) Waiting time in Queue [unit time]				(c) Work load rate			
	AWS1	Packing Area 1	AWS2	Packing Area2	AWS1	Packing Area 1	AWS2	Packing Area2	AWS1	Packing Area 1	AWS2	Packing Area2
Ave	4.807	3.554	50.920	10.444	5.154	4.180	36.578	14.222	2.40%	51.92%	25.46%	86.62%
SD	11.048	4.554	46.495	8.753	20.815	3.276	74.151	7.768	7.18%	49.90%	12.27%	34.04%

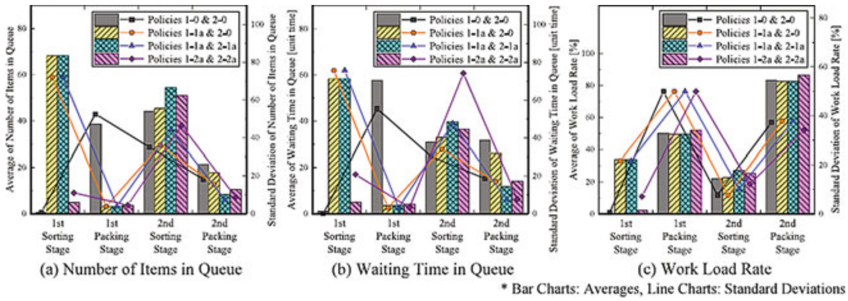


Fig. 9. Dispatching policies dependent characteristics of criteria values at each stage

caused by efficient dispatching is realized by dynamic reassignment of products to each operational station at the 1st packing stage. In contrast, the criteria value of AWS 2 and Packing Area 2 in Table 8 are almost the same level as in Table 7. This is caused by the lot sizes and the processing time of each station at Packing Area 2 which are larger and longer than other processes as similar to the last section. Therefore, proposed TCM-based dispatching policies with dynamic reassignment are utilized for efficient bottleneck management with Heijunka production of the entire operation.

4 Concluding Remarks

This paper examined the performance and the effectiveness of the proposed TCM-based dispatching policy using PCVs for bottleneck management of multi-stage sorting-packing operations in large-scale AWS-based DC. From the results, Heijunka production in each packing stage is expected to realize by the proposed dispatching policies. Moreover, this paper analyzed the case of given scheduled shipping order. In this case, dynamic reassignment of the transactions to each operational station at the 1st and 2nd packing stage facilitates optimization of dispatching operation effectively. Therefore, the proposed TCM-based dispatching policies with dynamic reassignment are utilized for effective bottleneck management for realizing Heijunka operation of the entire system.

The aim of this paper is the performance analysis of dispatching policies at each sorting stage in AWS for its relevant installation. Heijunka of the work load rate of each aisle at multi-stage AWS and operations at each stage are required for further improvement of throughput; which is a possible subject for future analysis.

Abstract. This paper focuses on a simplified supply chain planning network consisting of manufacture and distribution in the context of carbon emission constraint. The problem is formulated as a bilevel programming model mathematically. An effective solution strategy is then presented to handle the bilevel model. A numerical example is proposed to illustrate the proposed model and algorithms. This study highlights the impact of carbon emissions constraint on the operational decisions of supply chain.

Keywords: Bilevel programming model · Supply chain planning · Carbon emissions · Carbon footprint

1 Introduction

More evidences show that human activity leads to global climate change via carbon emissions. Curbing the carbon emissions and controlling climate change have become a great challenge that all humanity has to face. As the main carbon emitters, firms must take their carbon emissions seriously.

A conventional thinking to curb the carbon emissions is to improve energy efficiency and install emissions control devices. However, such initiatives require capital investments. Meanwhile, efficient business practices and operational policies are another way to change carbon emissions. Different manufacture or order frequency may result in different emissions. Obviously, this way is more cost-effective, in contrast to the way of investing novel equipments. Some researchers have focused on the strategy to reduce the carbon emission through supply chains. Benjaafar et al. [5] integrated the carbon emission concerns into the operational decision-making with regard to procurement, production, and inventory management. They provided a series of operational models under different regulatory policies. Lee [15] used empirical case study of HMC (Hyundai Motor Company) and its key supplier's front bumper product to illustrate the issue of carbon footprint in supply chain management. Absi et al. [1] modeled the integration of carbon emission constraints in lot-sizing problems. Helmrich et al. [11] showed that lot-sizing with an emission capacity constraint is NP-hard and proposed several solution methods. Hua et al. [13] investigated how firms manage carbon footprints in inventory management under the carbon emission trading mechanism. Chen et al. [9] provided analytical support for the notion that it may be possible, via

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_88

operational adjustments alone, to significantly reduce emissions without significantly increasing cost. He et al. [10] examined the production lot0sizing issues of a firm under cap-and-trade and carbon tax regulations, respectively.

All the models in the literature mentioned above assume that there is a only decision maker and formulate as the problems as single level models. Single level decision-making structures don't reflect the real supply chain management. A supply chain naturally involves multiple decision components, which are collected in a hierarchical way. Individual activities are often governed by separate supply chain components which have their own, often mutually conflicting, objectives [7,17,19]. In addition, different participant components in the supply chain network may not operate with the same level of information. Some may possess more information, while other may possess less information, this may lead to information distortion [12,22,23].

Using a bilevel programming model, we study how carbon emission concerns can be integrated into supply chain planning. We examine how the values of emission control policies affect cost and emissions. An interactive approach is proposed to solve the model.

The rest of this paper is organized as follows. In Sect. 2, we make a problem statement as the motivation. In Sect. 3, we formulate a bi-level programming model for the supply chain planning problem under with strict carbon caps. An interactive approach is depicted in Sect. 4. In Sect. 5, we use the model to obtain managerial insights from the numerical experiment and discuss the implications of these insights to management practice and to public policy making. We summarize key findings and offer ideas for future research in Sect. 6.

2 Problem Statement

A simple supply chain normally consists of several manufacturing plants and one warehouse or distribution centre (DC), with several products (see Fig. 1).

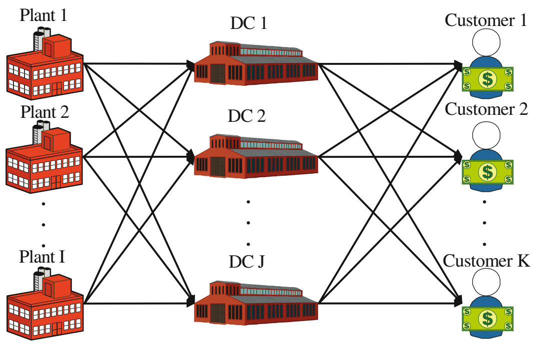

Fig. 1. A supply chain network

Given there is common decision maker who manages the whole supply chain, the supply chain planing problem can be formulated as an single level decision-making model. However, An alternative, more realistic, way to pose this problem is by recognizing: (i) the natural hierarchy that exists between the production and the distribution part of the supply chain and (ii) the fact that full information against the distribution part may not be really available at the production part and vice versa.

Without carbon emission considerations, the plants and the DCs determine the production amount and the inventory amount, respectively. Their objective In the presence of carbon emission considerations, the plants and the DCs must account for the emissions associated with various decisions regarding ordering, production, and inventory holding. In order to develop the mathematical model, we make some condition assumptions as follows:

(1) The emissions are linearly increasing in the associated decision variables;
(2) All the plant belongs one owner and all the DCs belongs to the other owner. DCs' owner has priority in decision;
(3) Customers' demands are stochastic;
(4) There is only one period in a planning horizon.

3 Model Formulation

In this section, we develop a mathematical model for the problem described above.

3.1 Notations

Before formulating the mathematical model, the needed notations are listed as follows.

Indices:
i: Plant $(1,\cdots,I)$;
j: DC $(j,\cdots,J)$;
k: Customer $(1,\cdots,K)$;
l: Product $(1,\cdots,L)$.

Parameters:
α_{il}: Capacity coefficient of product l at plant i;
β_{il}: Resource coefficient of product l at plant i;
γ_{jl}: Resource coefficient of product l at plant j;
a_{il}: Production cost coefficient for product l at plant i;
b_{ijl}: Transportation cost coefficient for product l from plant i to DC j;
h_{jkl}: Inventory holding cost coefficient for product l at DC j for customer k;
tr_{jkl}: Transportation cost coefficient for product l from DC j to customer k;
$\tilde{a}_{il}$: Emission coefficient due to production for product l at plant i;
$\tilde{b}_{ijl}$: Emission coefficient due to transportation for product l from plant i to DC j;
$\tilde{h}_{jkl}$: Emission coefficient due to inventory for product l at DC j for customer k;
$\widetilde{tr}_{jkl}$: Emission coefficient due to transportation for product l from DC j to customer k;
$\widehat{M}_{kl}$: Demand of product l at customer k;
P_i: Production capacity of plant i;
Q: Resources available to all the plants;

C_P: Emission cap for plants;
C_D: Emission cap for DCs.

Decision variable:
Y_{ijl}: Production amount of l at plant j for DC j;
X_{jkl}: Inventory of product l at DC j for customer k.

3.2 Modelling

For the owner of the plants, his (or her) to minimize the costs, which consists of its manufacturing cost and distribution cost between plants and DCs. Hence the objective of the production part Z_{PC} can be developed as

$$\min_{Y_{ijl}} Z_{PC} = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{l=1}^{L} a_{il}Y_{ijl} + \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{l=1}^{L} b_{ijl}Y_{ijl}. \tag{1}$$

We consider the strict emission cap regulation, the cap on carbon emissions of production part cannot be exceeded, i.e.,

$$\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{l=1}^{L} \tilde{a}_{il}Y_{ijl} + \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{l=1}^{L} \tilde{b}_{ijl}Y_{ijl} \le C_P. \tag{2}$$

Since production amounts from the plants should meet the levels required at the DC, we have

$$\sum_{i=1}^{I} Y_{ijl} \ge \sum_{k=1}^{K} X_{jki}, \quad \forall j, l. \tag{3}$$

The plant capacities are formulated as

$$\sum_{l=1}^{L}\sum_{j=1}^{J} a_{il}Y_{ijl} \le P_i, \quad \forall i. \tag{4}$$

Common used resources may be shared by all the plants, that is

$$\sum_{l=1}^{L}\sum_{i=1}^{I}\sum_{j=1}^{J} \beta_{il}Y_{ijl} \le Q. \tag{5}$$

For the distribution part, the decision maker's objective is to minimize the costs, then

$$\min_{X_{jkl}} Z_{DC} = \sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{l=1}^{L} h_{jkl}X_{jkl} + \sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{l=1}^{L} tr_{jkl}X_{jkl}, \tag{6}$$

in which the first term denotes inventory holding cost including material handling cost at DCs and the second indicates transportation cost from warehouses to customers. The carbon emissions from the distribution part also satisfies the emission cap, so

$$\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{l=1}^{L} \tilde{h}_{jkl}X_{jkl} + \sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{l=1}^{L} \widetilde{tr}_{jkl}X_{jkl} \le C_D. \tag{7}$$

Sums of individual DCs' holding should meet demands of customers, that is

$$\sum_{j=1}^{J} X_{jkl} \geq \widehat{M}_{kl}, \ \ \forall k,l. \tag{8}$$

Demands' constraints (8) are stochastic types. In other words, we cannot ensure that the constraints are satisfied before the exact values of $\widehat{M}_{kl}$ are known. Some techniques have been developed to handle the stochastic case like this. Here, the chance-constrained technique proposed by Charnes and Cooper [8] is applied. Let θ_{kl} denote prescribed confidence levels. Applying chance-constrained technique to (8), the corresponding constraints are

$$Pr\left\{\sum_{j=1}^{J} X_{jkl} \geq \widehat{M}_{kl}\right\} \geq \theta_{kl}, \ \ \forall k,l, \tag{9}$$

where Pr means *probability*.

Inventory levels are limited by individual DC capacities, so

$$\sum_{k=1}^{K}\sum_{l=1}^{L} \gamma_{kl} X_{jkl} \leq R_j, \ \ \forall j. \tag{10}$$

In many cases, the decision maker has priority decisions on the production part are affected by parameters which are decided by the distribution part. For instance, production levels are decided from given information regarding the inventory conditions. Thus the supply chain planning model can be posed as the following bilevel decision-making problem:

$$\left\{\begin{array}{l}
\min\limits_{X_{jkl}} Z_{DC} = \sum\limits_{j=1}^{J}\sum\limits_{k=1}^{K}\sum\limits_{l=1}^{L} h_{jkl}X_{jkl} + \sum\limits_{j=1}^{J}\sum\limits_{k=1}^{K}\sum\limits_{l=1}^{L} tr_{jkl}X_{jkl} \\
\text{s.t.} \left\{\begin{array}{l}
\sum\limits_{j=1}^{J}\sum\limits_{k=1}^{K}\sum\limits_{l=1}^{L} \tilde{h}_{jkl}X_{jkl} + \sum\limits_{j=1}^{J}\sum\limits_{k=1}^{K}\sum\limits_{l=1}^{L} \widetilde{tr}_{jkl}X_{jkl} \leq C_D \\
Pr\left\{\sum\limits_{j=1}^{J} X_{jkl} \geq \widehat{M}_{kl}\right\} \geq \theta_{kl}, \ \ \forall k,l \\
\sum\limits_{k=1}^{K}\sum\limits_{l=1}^{L} \gamma_{kl}X_{jkl} \leq R_j
\end{array}\right. \\
\text{where } Y_{ijl} \text{ solves} \\
\left\{\begin{array}{l}
\min\limits_{Y_{ijl}} Z_{PC} = \sum\limits_{i=1}^{I}\sum\limits_{j=1}^{J}\sum\limits_{l=1}^{L} a_{il}Y_{ijl} + \sum\limits_{i=1}^{I}\sum\limits_{j=1}^{J}\sum\limits_{l=1}^{L} b_{ijl}Y_{ijl} \\
\text{s.t.} \left\{\begin{array}{l}
\sum\limits_{i=1}^{I}\sum\limits_{j=1}^{J}\sum\limits_{l=1}^{L} \tilde{a}_{il}Y_{ijl} + \sum\limits_{i=1}^{I}\sum\limits_{j=1}^{J}\sum\limits_{l=1}^{L} \tilde{b}_{ijl}Y_{ijl} \leq C_P \\
\sum\limits_{i=1}^{I} Y_{ijl} \geq \sum\limits_{k=1}^{K} X_{jki}, \ \ \forall j,l \\
\sum\limits_{l=1}^{L}\sum\limits_{j=1}^{J} a_{il}Y_{ijl} \leq P_i, \ \ \forall i \\
\sum\limits_{l=1}^{L}\sum\limits_{i=1}^{I}\sum\limits_{j=1}^{J} \beta_{il}Y_{ijl} \leq Q \\
X_{jkl} \geq 0, \ \ \forall j,k,l \\
Y_{ijl} \geq 0, \ \ \forall i,j,l.
\end{array}\right.
\end{array}\right.
\end{array}\right. \tag{11}$$

4 Algorithm

Algorithms are the bridges between the theoretical models and the practical applications. The NP-hardness of bilevel programming problems make it full of challenges to design efficient algorithms. Researchers have proposed many approaches to solve bilevel programming problems [2, 4, 6, 14, 16, 18]. Among these algorithms, the interactive fuzzy programming methods are popular in recent years [3, 20, 24].

Model (11) can be reformulated in a general bilevel programming framework as follows:

$$\begin{cases} \max\limits_{\boldsymbol{x}\in R^{n_1}} F(\boldsymbol{x},\boldsymbol{y}) \\ \text{s.t.} \begin{cases} G(\boldsymbol{x},\boldsymbol{y}) \leq 0 \\ \text{where } \boldsymbol{y} \text{ solves:} \\ \begin{cases} \max\limits_{\boldsymbol{y}\in R^{n_2}} f(\boldsymbol{x},\boldsymbol{y}) \\ \text{s.t. } \ g(\boldsymbol{x},\boldsymbol{y}) \leq 0, \end{cases} \end{cases} \end{cases} \tag{12}$$

where, $\boldsymbol{x} \in R^{n_1}$ is the decision vector for the upper-level decision maker (leader) and $\boldsymbol{y} \in R^{n_2}$ is decision variable for the lower-level decision maker (follower); $F(\boldsymbol{x},\boldsymbol{y})$ is the objective function of the upper-level model and $f(\boldsymbol{x},\boldsymbol{y})$ is objective function of the lower-level model; $G(\boldsymbol{x},\boldsymbol{y})$ is the constraint of the upper-level programming and $g(\boldsymbol{x},\boldsymbol{y})$ is the constraint of the lower-level model.

The key idea is that the decision makers at both levels consider individual objectives separately as the initialization. Let $D = \{\boldsymbol{x},\boldsymbol{y} | G(\boldsymbol{x},\boldsymbol{y}) \leq 0, g(\boldsymbol{x},\boldsymbol{y}) \leq 0\}$. For each of the objective functions, assume that the decision makers have fuzzy goals such as "the objective should be substantially less than or equal to some value". The individual best values

$$F^{\min} = \min_{(\boldsymbol{x},\boldsymbol{y})\in D} F(\boldsymbol{x},\boldsymbol{y}),\ f^{\min} = \min_{(\boldsymbol{x},\boldsymbol{y})\in D} f(\boldsymbol{x},\boldsymbol{y})$$

and the individual worst values

$$F^{\max} = \max_{(\boldsymbol{x},\boldsymbol{y})\in D} F(\boldsymbol{x},\boldsymbol{y}),\ f^{\max} = \max_{(\boldsymbol{x},\boldsymbol{y})\in D} f(\boldsymbol{x},\boldsymbol{y})$$

are referred to when the decision makers elicit membership functions prescribing the fuzzy goals for the objective functions. The decision makers determine the membership functions $\mu_1(F(\boldsymbol{x},\boldsymbol{y}))$ and $\mu_2(f(\boldsymbol{x},\boldsymbol{y}))$ which are strictly monotone decreasing for objective functions, consulting the variation ratio of degree of satisfaction in the interval between the individual best values and the individual values. The domains of the membership functions of leader and follower are the interval $[F^{\min}, F^{\min}]$ and $[f^{\min}, f^{\min}]$, respectively. For the sake of simplicity, in this paper, we adopt a linear membership function, which characterizes the fuzzy goal of the decision maker at each level. The corresponding linear membership function $\mu_1(F(\boldsymbol{x},\boldsymbol{y}))$ and $\mu_2(f(\boldsymbol{x},\boldsymbol{y}))$ are defined as:

$$\mu_1(F(\boldsymbol{x},\boldsymbol{y})) = \begin{cases} 0 & \text{if } F(X_1,X_2) > F^{\max} \\ \frac{F^{\max}-F(\boldsymbol{x},\boldsymbol{y})}{F^{\max}-F^{\min}} & \text{if } F^{\min} \leq F(\boldsymbol{x},\boldsymbol{y}) \leq F^{\max} \\ 1 & \text{if } F(\boldsymbol{x},\boldsymbol{y}) < F^{\min}, \end{cases} \tag{13}$$

and

$$\mu_2(f(\boldsymbol{x},\boldsymbol{y})) = \begin{cases} 0 & \text{if } f(X_1,X_2) > f^{\max} \\ \frac{f^{\max}-f(\boldsymbol{x},\boldsymbol{y})}{f^{\max}-f^{\min}} & \text{if } f^{\min} \le f(\boldsymbol{x},\boldsymbol{y}) \le f^{\max} \\ 1 & \text{if } f(\boldsymbol{x},\boldsymbol{y}) < f^{\min}. \end{cases} \tag{14}$$

After eliciting the membership functions, leader subjectively specifies a minimal satisfactory level $\hat{\delta} \in [0,1]$ for his/her membership function $\mu_1(F(\boldsymbol{x},\boldsymbol{y}))$. Then, follower maximize his/her membership function subject to the condition that leader's membership function $\mu_1(F(\boldsymbol{x},\boldsymbol{y}))$ is larger than or equal to $\hat{\delta}$ under the given constraints, that is, followers solves the following problem:

$$\begin{cases} \max\limits_{\boldsymbol{x} \in R^{n_1}} \mu_2(f(\boldsymbol{x},\boldsymbol{y})) \\ \text{s.t.} \begin{cases} \mu_1(F(\boldsymbol{x},\boldsymbol{y})) \ge \hat{\delta} \\ (\boldsymbol{x},\boldsymbol{y}) \in D. \end{cases} \end{cases} \tag{15}$$

If an optimal solution to problem (15) exists, it follows that DM1 obtains a satisfactory solution having a satisfactory degree larger than or equal to the minimal satisfactory level specified by leader's own self. However, the larger the minimal satisfactory level is assessed, the smaller follower's satisfactory degree becomes. Consequently, a relative difference between the satisfactory degrees of leader and follower becomes larger and it is feared that overall satisfactory balance between both levels cannot maintain.

To take account of overall satisfactory balance between both levels, leader needs to compromise with follower on leader's minimal satisfactory level. To do so, a satisfactory degree of both decision makers is defined as

$$\lambda = \min(\mu_1(F(\boldsymbol{x},\boldsymbol{y})), \mu_2(f(\boldsymbol{x},\boldsymbol{y}))).$$

and the following problem is substituted for problem (15):

$$\begin{cases} \max \lambda \\ \text{s.t.} \begin{cases} \mu_1(F(\boldsymbol{x},\boldsymbol{y})) \ge \hat{\delta} \ge \lambda \\ \mu_2(f(\boldsymbol{x},\boldsymbol{y})) \ge \lambda \\ \lambda \in [0,1] \\ (\boldsymbol{x},\boldsymbol{y}) \in D. \end{cases} \end{cases} \tag{16}$$

For problem (16), consider the auxiliary problem

$$\begin{cases} \max \lambda \\ \text{s.t.} \begin{cases} \mu_1(F(\boldsymbol{x},\boldsymbol{y})) \ge \lambda \\ \mu_2(f(\boldsymbol{x},\boldsymbol{y})) \ge \lambda \\ \lambda \in [0,1] \\ (\boldsymbol{x},\boldsymbol{y}) \in D. \end{cases} \end{cases} \tag{17}$$

By solving problem (17), we obtain a solution maximizing a smaller satisfactory degree between those of both decision makers.

If an optimal solution $(\boldsymbol{x}^*,\boldsymbol{y}^*)$ to problem (17) satisfies the condition that $\mu_1(F(\boldsymbol{x}^*,\boldsymbol{y}^*)) \ge \hat{\delta}$, it follows that leader obtains a satisfactory solution. However, the solution $(\boldsymbol{x}^*, \boldsymbol{y}^*)$ does not always satisfy the condition. Then the ratio of satisfactory degree between both levels

$$\Delta = \frac{\mu_2(f(\boldsymbol{x}^*, \boldsymbol{y}^*))}{\mu_1(F(\boldsymbol{x}^*, \boldsymbol{y}^*))} \tag{18}$$

is adopted.

If $\Delta > 1$, i.e., $\mu_2(f(\boldsymbol{x}^*, \boldsymbol{y}^*) > \mu_1(F(\boldsymbol{x}^*, \boldsymbol{y}^*))$, then leader updates the minimal satisfactory level $\hat{\delta}$ by increasing its value. Receiving the updated level $\hat{\delta}'$, follower solves problem (15) with $\hat{\delta}'$ and then leader obtains a larger satisfactory degree and follower accepts a smaller satisfactory degree. Conversely, if $\Delta < 1$, i.e., $\mu_2(f(\boldsymbol{x}^*, \boldsymbol{y}^*) < \mu_1(F(\boldsymbol{x}^*, \boldsymbol{y}^*))$, then leader updates the minimal satisfactory level $\hat{\delta}'$ by decreasing its value, and leader obtains a smaller satisfactory degree and follower accepts a larger satisfactory degree. The interactive process terminates when two conditions hold [21].

5 Numerical Example

Consider supply chain consisting of three plants, two DCs, three customers, with two products. The values of parameters are listed in Table 1. The demands follow the normal distribution, defined as

Table 1. Parameter values

$\alpha_{11} = 4$	$\alpha_{12} = 3$	$\alpha_{21} = 5$	$\alpha_{22} = 2$	$\alpha_{31} = 3$	$\alpha_{32} = 3$
$\beta_{11} = 7$	$\beta_{12} = 10$	$\beta_{21} = 12$	$\beta_{22} = 6$	$\beta_{31} = 8$	$\beta_{32} = 9$

$$\widehat{M}_{11} \sim \mathcal{N}(200,10),\ \ \widehat{M}_{12} \sim \mathcal{N}(300,20),\ \ \widehat{M}_{21} \sim \mathcal{N}(240,10),$$
$$\widehat{M}_{22} \sim \mathcal{N}(180,10),\ \ \widehat{M}_{31} \sim \mathcal{N}(280,20),\ \ \widehat{M}_{32} \sim \mathcal{N}(160,10).$$

The resources available to all the plants are 10000. The production capacities of the plants are 1800, 1500 and 1200, respectively. Assume that all $\theta_{kl} = 0.8$.

Let $C_P = C_D = 6000$. Suppose that the initial minimal satisfactory level as $\delta = 1.0$, and the lower and the upper bounds of Δ as $[0.6, 1.0]$. Using the algorithm described in Sect. 4, the decisions are obtained after three iterations:

$$\begin{aligned}
&X^*_{111} = 52.5,\ X^*_{112} = 22.1,\ X^*_{121} = 12.8,\ X^*_{122} = 26.8,\ X^*_{131} = 72.3,\ X^*_{132} = 44.2,\\
&X^*_{211} = 12.6,\ X^*_{212} = 62.5,\ X^*_{221} = 45.2,\ X^*_{222} = 92.5,\ X^*_{231} = 12.5,\ X^*_{232} = 14.5,\\
&Y^*_{111} = 82.5,\ Y^*_{112} = 72.5,\ Y^*_{121} = 62.5,\ Y^*_{122} = 20.2,\ Y^*_{211} = 32.0,\ Y^*_{212} = 26.5,\\
&Y^*_{221} = 65.3,\ Y^*_{222} = 34.5,\ Y^*_{311} = 17.5,\ Y^*_{312} = 42.5,\ Y^*_{321} = 54.3,\ Y^*_{322} = 62.5.
\end{aligned}$$

The corresponding costs of leader and follower are $Z^*_{DC} = 60512.8$ and $Z^*_{PC} = 32746.8$, respectively. The amounts of their emissions are $E^*DC = 26128.2$ and $E^*_{PC} = 11321.4$, respectively.

In order to test the effect the emission caps on costs, we use different emission caps to calculate the costs and actual emissions. For simplicity, let $C_{DC} = C_{PC}$. The results are shown by Fig. 2.

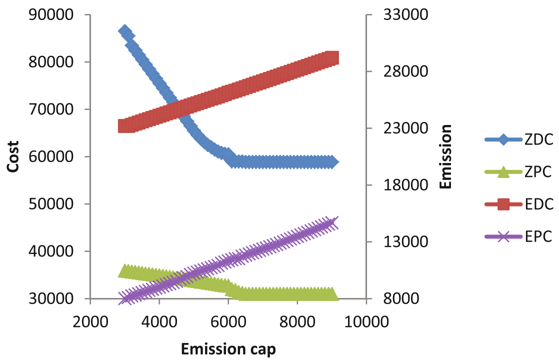

Fig. 2. The effect of emission cap on cost and carbon emission

Figure 2 shows the impact of varying the emission cap on the total cost and total emissions for the examples considered. Both the leader and follower have the similar trends. As expected, reducing the emission cap increases total cost and reduces total emissions. However, what is perhaps surprising is the fact that the emission cap can be significantly reduced without significantly affecting the total cost. In the example shown, reducing the emission cap from 6000 to 3000 reduces the average total amount of emissions by 50% but increases the average total cost by only 10%. Note that this reduction is obtained through adjustments in operational decisions only, namely, modifying order quantities in each period, could alone lead to significant reductions in carbon emissions while not significantly compromising overall cost.

6 Conclusions and Future Research

In this paper, we presented a bilevel decision-making model to illustrate how carbon footprint considerations could be incorporated into supply chain model. These insights highlight the impact of operational decisions on carbon emissions and the extent to which adjustments to operations can mitigate emissions. Our results show that operational adjustments alone can lead in some cases to significant emission reductions without significant increases in cost. More significantly, the results highlight the opportunity that exists to leverage collaboration across the supply chain to mitigate the cost of reducing emissions. Insights described in this paper revealed the importance of interactions between firms in determining overall emission levels and corresponding costs. The results in this paper will be helpful for the decision makers of supply chains to address challenges from strict emission caps regulation.

However, there are still some issues to worth attention.

(1) More quantitative analysis. The results in this paper are based on a numerical example. More quantitative analysis can reveal the essence behind the phenomenon, which is conducive to the application of the model.
(2) Scenario analysis under different regulatory emission control policies. In this paper, only the strict emission cap policy is considered. However, policies of the carbon tax, carbon offset and cap-and-trade are also used wildly. It is necessary to compare them deeply.

Abstract. To solve the problem of global warming, governments have carried out some corresponding policies to reduce carbon emissions. In this paper, we considered a two-echelon supply chain consisting of a supplier and a manufacturer, and researched the supply chain coordination by revenue sharing contract under two different carbon emission policies, Mandatory carbon emissions capacity and Cap-and-trade. The study indicates that: under both two carbon policies, the revenue sharing contract can coordinate the supply chain. Manufacturer's revenue sharing proportion under cap-and-trade is always less than the situation of no carbon emissions constraint. The expected profits of manufacturer under cap-and-trade can be greater than the situation without carbon emissions constraints in certain conditions.

Keywords: Supply chain coordination · Revenue sharing contract · Mandatory carbon emissions capacity · Cap-and-trade

1 Introduction

It is a common knowledge that large amount of carbon emissions directly leads to global warming which has brought serious challenges to human survival and development. The best way to solve this problem is changing the way of production and life. So realize the sustainable development of low-carbon economy is becoming a hot spot of global attention. Nowadays, different governments including China have carried out the corresponding carbon emissions regulation policy according to their national conditions. Typical carbon policies are Mandatory carbon emissions capacity (Cap) and Cap-and-trade. Both the two policies are carbon constraints under the regulation of government, and the government will assign different initial carbon emissions quota to different enterprises. As we know, cap policy is a kind of mandatory constraint. The enterprises cannot sale or buy the carbon emissions quota in carbon trading market when the initial is overmuch or insufficient. However, cap-and-trade policy allows enterprises sale or buy the carbon emissions quota in carbon trading market when the initial is overmuch or insufficient, in order to meet the production requirements and

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_89

improve yields [13]. The earliest implementation of Cap and Cap-and-trade policies is European Emissions Trading System (EU ETS), and has now become the world's largest carbon emissions trading market [2].

The implementation of carbon policy in operation management has brought new challenges to the enterprise. It makes enterprise management more complex in performance target for decision-making (dual goals of increasing profits and reducing carbon emissions), the decision variables (production, order, pricing and other traditional decision variables and carbon emissions, carbon trading decision variables) and decision environment (production capacity, capital and other traditional and limitation of carbon constraints). As we all know, carbon emissions are throughout the entire supply chain, however, the existing researches on carbon policies in practice are mainly based on the perspective of individual enterprise. If only focus on individual enterprise, and cannot effectively solve the supply chain coordination problem of upstream and downstream enterprises, we cannot fundamentally promote carbon policy's implementation, and achieve the ultimate goal of reducing carbon emission [15].

Revenue sharing contract is a common supply chain coordination mechanism. Downstream enterprise buys goods from upstream enterprise at a relatively low wholesale price, but shares the sales revenue with upstream enterprise [3]. In this paper, we analyze the supply chain coordination problem based on revenue sharing contract, and research to solve the following problems:

(1) Whether revenue sharing contract could coordinate the supply chain under different carbon policy?
(2) How does the different carbon policy affect the revenue sharing ratio?
(3) How does the different carbon policy affect the manufacturer's expected profit?

The rest of this paper is organized as follows: Sect. 2 reviews the relevant literatures; Sect. 3 describes the problem and assumptions; Sect. 4 presents the model and analysis; and discussion is presented in Sect. 5; finally Sect. 6 concludes this paper.

2 Literature Review

In this paper, we review literature spanning across two streams. The first section addresses literature on supply chain coordination by revenue sharing contract. The second section addresses literature on supply chain coordination under different carbon policies.

2.1 Supply Chain Coordination by Revenue Sharing Contract

From the perspective of economics, Mortimer et al. [16] carried on the empirical research on the application of revenue sharing contract in the DVD rental industry. Giannoccaro et al. [10] systematically studied the problem of supply chain coordination by revenue sharing contract. Cachon and Lariviere [4] comprehensively analyzed of the advantages and limitations of revenue sharing contract. The results showed, although the revenue sharing contract could achieve supply chain coordination, the upstream enterprise did not achieve the optimal as this mechanism was instable. Kong et al. [14] analyzed the supply chain coordination by revenue sharing contract under the circumstance of information disclosure. Govindan et al. [11] took PC industry as an example, and analyzed the reverse supply chain coordination problem based on revenue sharing contract. The results indicated that revenue sharing contract could coordinate the reverse supply chain effectively. Arani et al. [1] introduced a novel mixed revenue-sharing option contract to coordinate a retailerCmanufacturer supply chain.

2.2 Supply Chain Coordination Under Different Carbon Policies

Ghosh et al. [8] took garment industry as an example, and studied the influence of green level on prices and profits, then put forward a kind of contract including two parts of tax to coordinate the green supply chain. Swami et al. [17] considered the consumers' environmental consciousness, and thought that green operation efforts of the retailers and manufacturers in the supply chain would affect consumer demand, then designed a cost sharing contract to realize supply chain coordination. Jaber et al. [12] considered a two-stage supply chain consisting a manufacturer and a retailer, and studied the supply chain coordination mechanism under Cap-and-trade policy when manufacturer undertook the cost of carbon emission. Based on the newsboy model, Choi [6] analyzes the impact of wholesale price and price subsidies contract under Cap-and-trade policy on retailers procurement source selection. Du et al. [7] considered a two-stage supply chain consisting of a carbon emission dependent enterprise and a carbon emission supplier under Cap-and-trade policy, and designed a supply chain coordination mechanism using the non-cooperative game theory. Ghosh and Shah [9] explored supply chain coordination issues arising out of green supply chain initiatives and explore the impact of cost sharing contract on the key decisions of supply chain players undertaking green initiatives. Xu [18] analyzed the decision behavior and coordination mechanisms for a two-echelon sustainable supply chain under a cap-and-trade regulation. Cao et al. [5] investigated the government's role in allocating the appropriate emission quota to maximize social members' utilities and analyzes how the emission-dependent enterprise improves revenues of both itself and the whole system through supply chain collaboration.

Through literature review, we found that the revenue sharing contract was a widely used supply chain coordination mechanism. But most of the researches did not consider the impact of different carbon policy on supply chain coordination mechanism. In order to fill the gap, we will analyze the supply chain coordination problem based on revenue sharing contract under different carbon policies.

3 Problem Description and Assumption

In this paper, taking the two echelon supply chain (one supplier and one manufacturer) which is dominant by supplier as the research object, we analyze the supply chain coordination problem based on revenue sharing contract under Cap and Cap-and-trade policy.

Before the sales season, the manufacturer purchases raw materials Q at wholesale price w from supplier. The manufacturer faces the random demand D with probability density $f(x)$ and distribution function $F(x)$, and sells the product at retail price p. At the end of the sales season, the salvage value per unit product is v, the shortage cost per unit product is g. The manufacture keeps $\varphi_i \in [0,1]$ $(i = 1,2,3)$ part of own revenue, and gives $1-\varphi_i$ part to the supplier, where $i = 1,2,3$ respectively represents the situation of no carbon constraint, Cap policy and Cap-and-trade policy. The supplier's purchasing cost is c_{s}, the manufacture's producing cost is c_{m}, carbon emission for producing unit product is e, trading price for unit carbon emission quota is k, and the carbon Cap set by the government is E.

For the convenience of description, considering the decentralized decision, let $Q_{\varphi 1}^*$, $Q_{\varphi 2}^*$, $Q_{\varphi 3}^*$ present manufacture's optimal order quantity under no carbon constraint, Cap and Cap-and-trade policy respectively; considering the integrated decision, let Q_1^*, Q_2^* and Q_3^* present supply chain's optimal order quantity under no carbon constraint, Cap and Cap-and-trade policy respectively. In addition, for the convenience of research, we make the following assumptions:

(1) The supplier and the manufacturer are risk neutral and perfectly rational, and the information between supply chain enterprises is completely symmetrical.
(2) The product's selling cycle is short, the market is stable, and during the sales period, the product's price remains the same.
(3) Carbon policy only applies to manufacturer.
(4) $p > w + c_m$ indicates that the sale price of product is always greater than the manufacturer's production costs, and the manufacturer is profitable.
(5) $w > c_s$ indicates that supplier's wholesale price is always greater than cost, supplier is also profitable.

4 Model and Analysis

4.1 The Base Model Without Carbon Emission Constraint

In this scenario, we get the manufacturer's expected profit

$$E\left[\pi_{m1}\left(Q_{\varphi 1}\right)\right] = \varphi_1 p S\left(Q_{\varphi 1}\right) + \varphi_1 v I\left(Q_{\varphi 1}\right) - g L\left(Q_{\varphi 1}\right) - \left(w + c_m\right) Q_{\varphi 1}, \quad (1)$$

where $S\left(Q_{\varphi 1}\right) = Q - \int_0^{Q_{\varphi 1}} f\left(x\right) dx$ presents the expected sales volume, $I\left(Q_{\varphi 1}\right) = \int_0^{Q_{\varphi 1}} \left(Q_{\varphi 1} - x\right) f\left(x\right) dx$ presents the expected inventory volume, and $L\left(Q_{\varphi 1}\right) = \int_{Q_{\varphi 1}}^{+\infty} \left(x - Q_{\varphi 1}\right) f\left(x\right) dx$ presents the expected shortage volume.

While the supplier's expected profit is

$$E\left[\pi_{s1}\left(Q_{\varphi1}\right)\right]=\left[w-c_s+\left(1-\varphi_1\right)v\right]Q_{\varphi1}+\left(1-\varphi_1\right)\left(p-v\right)S\left(Q_{\varphi1}\right). \qquad (2)$$

As $\frac{dE[\pi_{m1}(Q_{\varphi1})]}{dQ_{\varphi1}}=\left[\varphi_1\left(p-v\right)+g\right]\left[1-F\left(Q_{\varphi1}\right)\right]-\left(w+c_m-\varphi_1 v\right)$, $\frac{d^2E[\pi_{m1}(Q_{\varphi1})]}{d^2Q_{\varphi1}}=-\left[\varphi_1\left(p-v\right)+g\right]f\left(Q_{\varphi1}\right)<0$, there exists a unique optimal order quantity $Q^*_{\varphi1}$ which maximizes $E\left[\pi_{m1}\left(Q_{\varphi1}\right)\right]$.

Let $\frac{dE[\pi_{m1}(Q_{\varphi1})]}{dQ_{\varphi1}}=0$, we get optimal order quantity $Q^*_{\varphi1}=F^{-1}\left(\frac{\varphi_1 p+g-w-c_m}{\varphi_1(p-v)+g}\right)$. To coordinate the supply chain, we have to make $Q^*_1=Q^*_{\varphi1}$, that is $F^{-1}\left(\frac{p+g-c_s-c_m}{p+g-v}\right)=F^{-1}\left(\frac{\varphi_1 p+g-w-c_m}{\varphi_1(p-v)+g}\right)$, we get $\frac{p+g-c_s-c_m}{p-v+g}=\frac{\varphi_1 p+g-w-c_m}{\varphi_1(p-v)+g}$, so $\varphi_1=\frac{(p-v)(c_m+w)+(w-c_s)g+vg}{(p-v)(c_m+c_s)+vg}$.

In order to guarantee both sides accept this contract, we must ensure that their respective benefits under the revenue sharing contract are greater than those before, namely realizing Pareto improvement. We should have

$$\frac{E\left[\pi_{s1}\left(Q^*_1\right)\right]}{E\left[\pi_{s1}\left(Q^*_{\varphi1}\right)\right]}>1, \qquad (3)$$

$$\frac{E\left[\pi_{m1}\left(Q^*_1\right)\right]}{E\left[\pi_{m1}\left(Q^*_{\varphi1}\right)\right]}>1. \qquad (4)$$

As $E\left[\pi_{s1}\left(Q^*_1\right)\right]+E\left[\pi_{m1}\left(Q^*_1\right)\right]=E\left[\pi_{T1}\left(Q^*_1\right)\right]$, $E\left[\pi_{s1}\left(Q^*_1\right)\right]=\left(1-\varphi_1\right)E\left[\pi_{T1}\left(Q^*_1\right)\right]$, $E\left[\pi_{m1}\left(Q^*_1\right)\right]=\varphi_1 E\left[\pi_{T1}\left(Q^*_1\right)\right]$, put into the formula, we get $\frac{(1-\varphi_1)\,E[\pi_{T1}(Q^*_1)]}{E\left[\pi_{s1}\left(Q^*_{\varphi1}\right)\right]}>1$, $\frac{\varphi_1 E[\pi_{T1}(Q^*_1)]}{E\left[\pi_{m1}\left(Q^*_{\varphi1}\right)\right]}>1$. To simplify, we get $\frac{E\left[\pi_{m1}\left(Q^*_{\varphi1}\right)\right]}{E\left[\pi_{T1}\left(Q^*_1\right)\right]}<\varphi_1<1-\frac{E\left[\pi_{s1}\left(Q^*_{\varphi1}\right)\right]}{E\left[\pi_{T1}\left(Q^*_1\right)\right]}$.

The result indicates although revenue sharing contract can coordinate supply chain without carbon emission constraint, sharing proportion must meet a certain relationship to make the Pareto improvement for both sides; otherwise the contract shall be invalid.

According to the assumption, $\varphi_1\in[0,1]$, that is $0\le\frac{(p-v)(c_m+w)+(w-c_s)g+vg}{(p-v)(c_m+c_s)+vg}\le 1$, then $\left(p-v\right)\left(c_m+w\right)+\left(w-c_s\right)g\le\left(p-v\right)\left(c_m+c_s\right)$, we can proof $w\le c_s$.

It shows that supplier must make the wholesale price less than or equal to the purchase price to achieve supply chain coordination, then the supplier's profits drop. Therefore, the manufacturer must share enough revenue to make up for the loss of supplier, and make him gain more profits.

4.2 The Cap Model

In this scenario, we get the manufacturer's expected profit

$$\begin{cases} E\left[\pi_{m2}\left(Q_{\varphi2}\right)\right]=\varphi_2 pS\left(Q_{\varphi2}\right)+\varphi_2 vI\left(Q_{\varphi2}\right)-gL\left(Q_{\varphi2}\right)-\left(w+c_m\right)Q_{\varphi2} \\ s.t.\ \ Q_{\varphi2}\le\frac{E}{e} \end{cases} \qquad (5)$$

While the supplier's expected profit is

$$E\left[\pi_{s2}\left(Q_{\varphi 2}\right)\right]=\left[w-c_s+\left(1-\varphi_2\right)v\right]Q_{\varphi 2}+\left(1-\varphi_2\right)\left(p-v\right)S\left(Q_{\varphi 2}\right). \tag{6}$$

Proposition 1. *There exists a unique optimal order quantity which maximizes manufacturer's expected profit by revenue sharing contract under Cap policy. When $Q_{\varphi 2}^* \le \frac{E}{e}$, the optimal order quantity is $Q_{\varphi 2}^* = F^{-1}\left(\frac{\varphi_2 p+g-w-c_m}{\varphi_2(p-v)+g}\right)$, when $Q_{\varphi 2}^* > \frac{E}{e}$, it is $Q_{\varphi 2}^* = \frac{E}{e}$.*

Proof. As $\frac{dE[\pi_{m2}(Q_{\varphi 2})]}{dQ_{\varphi 2}} = \left[\varphi_2\left(p-v\right)+g\right]\left[1-F\left(Q_{\varphi 2}\right)\right]-\left(w+c_m-\varphi_2 v\right)$, then $\frac{d^2E[\pi_{m2}(Q_{\varphi 2})]}{d^2Q_{\varphi 2}} = -\left[\varphi_2\left(p-v\right)+g\right]f\left(Q_{\varphi 2}\right)<0$, there exists a unique optimal order quantity $Q_{\varphi 2}^*$ which maximizes $E\left[\pi_{m2}\left(Q_{\varphi 2}\right)\right]$.

Let $\frac{dE[\pi_{m2}(Q_{\varphi 2})]}{dQ_{\varphi 2}} = 0$, we get optimal order quantity $Q_{\varphi 2}^* = F^{-1}\left(\frac{\varphi_2 p+g-w-c_m}{\varphi_2(p-v)+g}\right)$.

When $Q_{\varphi 2}^* \le \frac{E}{e}$, the Cap policy doesn't play a role to the supply chain, it can be seen as the situation without carbon emission constraint, $Q_{\varphi 2}^* = F^{-1}\left(\frac{\varphi_2 p+g-w-c_m}{\varphi_2(p-v)+g}\right)$.

However, when $Q_{\varphi 2}^* > \frac{E}{e}$, the Cap policy plays a role to the supply chain, as the manufacturer's profit function is concave function, and it is monotone increasing at the left hand of $Q_{\varphi 2}^*$. That makes the optimal order quantity be $Q_{\varphi 2}^* = \frac{E}{e}$. This completes the proof.

□

Proposition 2. *When $Q_2^* \le \frac{E}{e}$, and $Q_2^* \le \frac{E}{e}$, the supply chain can coordinate by revenue sharing contract in the scenario of Cap policy where $\varphi_2 = \frac{(p-v)(c_m+w)+(w-c_s)g+vg}{(p-v)(c_m+c_s)+vg}$. And when $\varphi_2 \in \left(\frac{E\left[\pi_{m2}\left(Q_{\varphi 2}^*\right)\right]}{E\left[\pi_{T2}\left(Q_2^*\right)\right]}, 1-\frac{E\left[\pi_{s2}\left(Q_{\varphi 2}^*\right)\right]}{E\left[\pi_{T2}\left(Q_2^*\right)\right]}\right)$, it can realize Pareto improvement for both supplier and manufacturer; when $Q_{\varphi 2}^* \le \frac{E}{e} < Q_2^*$, the supply chain can coordinate where $\varphi_2 = \frac{g\left[1-F\left(\frac{E}{e}\right)\right]-w-c_m}{F\left(\frac{E}{e}\right)(p-v)-p}$, when $Q_2^* > Q_{\varphi 2}^* > \frac{E}{e}$, the supply chain can coordinate where $\varphi_2 = 1$.*

Proof. (1) When $Q_2^* \le \frac{E}{e}$ and $Q_{\varphi 2}^* \le \frac{E}{e}$, the Cap policy doesn't play a role. To achieve supply chain coordination, we should make $Q_2^* = Q_{\varphi 2}^*$, that is, $F^{-1}\left(\frac{p+g-c_s-c_m}{p+g-v}\right) = F^{-1}\left(\frac{\varphi_2 p+g-w-c_m}{\varphi_2(p-v)+g}\right)$, we get $\frac{p+g-c_s-c_m}{p-v+g} = \frac{\varphi_2 p+g-w-c_m}{\varphi_2(p-v)+g}$. To simplify, we obtain $\varphi_2 = \frac{(p-v)(c_m+w)+(w-c_s)g+vg}{(p-v)(c_m+c_s)+vg}$.

In order to make sure that both sides realize Pareto improvement, we should have $\frac{E[\pi_{s2}(Q_2^*)]}{E\left[\pi_{s2}\left(Q_{\varphi 2}^*\right)\right]} > 1$, $\frac{E[\pi_{m2}(Q_2^*)]}{E\left[\pi_{m2}\left(Q_{\varphi 2}^*\right)\right]} > 1$. As $E\left[\pi_{s2}\left(Q_2^*\right)\right] + E\left[\pi_{m2}\left(Q_2^*\right)\right] = E\left[\pi_{T2}\left(Q_2^*\right)\right]$, $E\left[\pi_{s2}\left(Q_2^*\right)\right] = \left(1-\varphi_2\right) E\left[\pi_{T2}\left(Q_2^*\right)\right]$, $E\left[\pi_{m2}\left(Q_2^*\right)\right] = \varphi_2 E\left[\pi_{T2}\left(Q_2^*\right)\right]$, put into the formula, we get $\frac{\varphi_2 E[\pi_{T2}(Q_2^*)]}{E\left[\pi_{m2}\left(Q_{\varphi 2}^*\right)\right]} > 1$. To simplify, we get $\frac{E\left[\pi_{m2}\left(Q_{\varphi 2}^*\right)\right]}{E\left[\pi_{T2}\left(Q_2^*\right)\right]} < \varphi_2 < 1-\frac{E\left[\pi_{s2}\left(Q_{\varphi 2}^*\right)\right]}{E\left[\pi_{T2}\left(Q_2^*\right)\right]}$.

(2) When $Q_{\varphi 2}^{*} \le \frac{E}{e} < Q_2^{*}$, the Cap policy plays a role. Let $Q_2^{*} = Q_{\varphi 2}^{*}$, that is $F^{-1}\left(\frac{\varphi_2 p+g-w-c_m}{\varphi_2(p-v)+g}\right) = \frac{E}{e}$. To simplify, we obtain $F\left(\frac{E}{e}\right) = \frac{\varphi_2 p+g-w-c_m}{\varphi_2(p-v)+g}$, then $\varphi_2 = \frac{g\left[1-F\left(\frac{E}{e}\right)\right]-w-c_m}{F\left(\frac{E}{e}\right)(p-v)-p}$.

(3) When $Q_2^{*} > Q_{\varphi 2}^{*} > \frac{E}{e}$, as $Q_2^{*} = Q_{\varphi 2}^{*} = \frac{E}{e}$, the supply chain doesn't need to coordinate, the manufacture keeps all the profit, now $\varphi_2 = 1$.

This completes the proof. □

This proposition suggests that, when carbon cap doesn't play a role, supply chain can coordinate by revenue sharing contract under Cap policy and realize Pareto improvement for both sides; when carbon cap plays a role, although we can find the condition which can achieve supply chain coordination, it is unable to realize the Pareto improvement for both sides. Because the Cap policy damages the whole supply chain's profit, it is difficult to achieve supply chain coordination in reality.

4.3 The Cap-and-Trade Model

In this scenario, we get the manufacturer's expected profit

$$\begin{cases} E\left[\pi_{m3}\left(Q_{\varphi 3}\right)\right] = \varphi_3 pS\left(Q_{\varphi 3}\right) + \varphi_3 vI\left(Q_{\varphi 3}\right) - gL\left(Q_{\varphi 3}\right) & \text{when } Q_{\varphi 3}^{*} \ge \frac{E}{e} \\ \qquad - \left(w+c_m\right) Q_{\varphi 3} - k\left(eQ_{\varphi 3} - E\right) & \\ E\left[\pi_{m3}\left(Q_{\varphi 3}\right)\right] = \varphi_3 pS\left(Q_{\varphi 3}\right) + \varphi_3 vI\left(Q_{\varphi 3}\right) - gL\left(Q_{\varphi 3}\right) & \text{when} Q_{\varphi 3}^{*} < \frac{E}{e}. \\ \qquad - \left(w+c_m\right) Q_{\varphi 3} + \varphi_3 k\left(E - eQ_{\varphi 3}\right) & \end{cases} \tag{7}$$

When $eQ_{\varphi 3}^{*} \ge E$, $k\left(eQ_{\varphi 3} - E\right)$ presents the cost of buying carbon quota, and when $eQ_{\varphi 3}^{*} < E$, $k\left(E - eQ_{\varphi 3}\right)$ presents the revenue of selling carbon quota.

While the supplier's expected profit is

$$\begin{cases} E\left[\pi_{s3}\left(Q_{\varphi 3}\right)\right] = \left[w - c_s + \left(1-\varphi_3\right)v\right] Q_{\varphi 3} & \text{when } Q_{\varphi 3}^{*} \ge \frac{E}{e}; \\ \qquad + \left(1-\varphi_3\right)\left(p-v\right) S\left(Q_{\varphi 3}\right) & \\ E\left[\pi_{s3}\left(Q_{\varphi 3}\right)\right] = \left[w - c_s + \left(1-\varphi_3\right)v\right] Q_{\varphi 3} & \\ \qquad + \left(1-\varphi_3\right)\left[\left(p-v\right) S\left(Q_{\varphi 3}\right)\right. & \text{when } Q_{\varphi 3}^{*} < \frac{E}{e}. \\ \qquad \left. + k\left(E - eQ_{\varphi 3}\right)\right] & \end{cases} \tag{8}$$

Proposition 3. *There exists a unique optimal order quantity which maximizes manufacturer's expected profit by revenue sharing contract under Cap-and-trade policy. When* $Q_{\varphi 3}^{*} \ge \frac{E}{e}$ *the optimal order quantity is* $Q_{\varphi 3}^{*} = F^{-1}\left(\frac{\varphi_3 p+g-w-c_m-ke}{\varphi_3(p-v)+g}\right)$*; when* $Q_{\varphi 3}^{*} < \frac{E}{e}$*, it is* $Q_{\varphi 3}^{*} = F^{-1}\left(\frac{\varphi_3 p+g-w-c_m-\varphi_3 ke}{\varphi_3(p-v)+g}\right)$.

Proof. (1) When $Q_{\varphi 3}^{*} \ge \frac{E}{e}$, $E\left[\pi_{m3}\left(Q_{\varphi 3}\right)\right] = \left[\varphi_3\left(p-v\right)+g\right] S\left(Q_{\varphi 3}\right) - \left(w + c_m + ke - \varphi_3 v\right) Q_{\varphi 3} - gu + kE$. As $\frac{dE\left[\pi_{m3}\left(Q_{\varphi 3}\right)\right]}{dQ_{\varphi 3}} = \left[\varphi_3\left(p-v\right)+g\right]\left[1 - F\left(Q_{\varphi 3}\right)\right] - \left(w + c_m + ke - \varphi_3 v\right)$, $\frac{d^2 E\left[\pi_{m3}\left(Q_{\varphi 3}\right)\right]}{d^2 Q_{\varphi 3}} = -\left[\varphi_3\left(p-v\right)+g\right] f\left(Q_{\varphi 3}\right) < 0$, there exists a unique optimal order quantity $Q_{\varphi 3}^{*}$ which maximizes $E\left[\pi_{m3}\left(Q_{\varphi 3}\right)\right]$.

Let $\frac{dE[\pi_{m3}(Q_{\varphi 3})]}{dQ_{\varphi 3}} = 0$, we get optimal order quantity $Q^*_{\varphi 3} = F^{-1}\left(\frac{\varphi_3 p+g-w-c_m-ke}{\varphi_3(p-v)+g}\right)$.

(2) When $Q^*_{\varphi 3} < \frac{E}{e}$, $E\left[\pi_{m3}\left(Q_{\varphi 3}\right)\right] = \left[\varphi_3\left(p-v\right)+g\right]S\left(Q_{\varphi 3}\right) - \left(w+c_m+\varphi_3 ke-\varphi_3 v\right)Q_{\varphi 3} - gu + \varphi_3 kE$. As $\frac{dE[\pi_{m3}(Q_{\varphi 3})]}{dQ_{\varphi 3}} = \left[\varphi_3\left(p-v\right)+g\right]\left[1-F\left(Q_{\varphi 3}\right)\right] - \left(w+c_m + \varphi_3 ke-\varphi_3 v\right)$, $\frac{d^2E[\pi_{m3}(Q_{\varphi 3})]}{d^2Q_{\varphi 3}} = -\left[\varphi_3\left(p-v\right)+g\right]f\left(Q_{\varphi 3}\right) < 0$, there also exists a unique optimal order quantity $Q^*_{\varphi 3}$ which maximizes $E\left[\pi_{m3}\left(Q_{\varphi 3}\right)\right]$.

Let $\frac{dE[\pi_{m3}(Q_{\varphi 3})]}{dQ_{\varphi 3}} = 0$, we get optimal order quantity $Q^*_{\varphi 3} = F^{-1}\left(\frac{\varphi_3 p+g-w-c_m-\varphi_3 ke}{\varphi_3(p-v)+g}\right)$. This completes the proof. □

Proposition 4. *When $Q^*_{\varphi 3} \geq \frac{E}{e}$, the supply chain can coordinate by revenue sharing contract in the scenario of Cap-and-trade policy where $\varphi_3 = \frac{(p-v)(c_m+w+ke)+(w-c_s)g+vg}{(p-v)(c_m+c_s+ke)+vg}$; when $Q^*_{\varphi 3} < \frac{E}{e}$, the supply chain can coordinate where $\varphi_3 = \frac{(p-v)(g-c_m-w)-(p-ke)g+(w-c_s)g}{(p-v)(g-c_m-c_s)-(p-ke)g}$. And when $\varphi_3 \in \left(\frac{E\left[\pi_{m3}\left(Q^*_{\varphi 3}\right)\right]}{E\left[\pi_{T3}\left(Q^*_3\right)\right]}, 1-\frac{E\left[\pi_{s3}\left(Q^*_{\varphi 3}\right)\right]}{E\left[\pi_{T3}\left(Q^*_3\right)\right]}\right)$, it can realize Pareto improvement for both supplier and manufacturer.*

Proof. (1) When $Q^*_{\varphi 3} \geq \frac{E}{e}$, let $Q^*_{\varphi 3} = Q^*_3$, that is $\frac{p+g-c_s-c_m-ke}{p-v+g} = \frac{\varphi_3 p+g-w-c_m-ke}{\varphi_3(p-v)+g}$, to simplify, we have $\varphi_3 = \frac{(p-v)(c_m+w+ke)+(w-c_s)g+vg}{(p-v)(c_m+c_s+ke)+vg}$.

(2) When $Q^*_{\varphi 3} < \frac{E}{e}$, let $Q^*_{\varphi 3} = Q^*_3$, that is $\frac{p+g-c_s-c_m-ke}{p-v+g} = \frac{\varphi_3 p+g-w-c_m-\varphi_3 ke}{\varphi_3(p-v)+g}$, to simplify, we obtain $\varphi_3 = \frac{(p-v)(g-c_m-w)-(p-ke)g+(w-c_s)g}{(p-v)(g-c_m-c_s)-(p-ke)g}$.

In order to make sure that both sides realize Pareto improvement, we should have $\frac{E[\pi_{s3}(Q^*_3)]}{E\left[\pi_{s3}\left(Q^*_{\varphi 3}\right)\right]} > 1$, $\frac{E[\pi_{m3}(Q^*_3)]}{E\left[\pi_{m3}\left(Q^*_{\varphi 3}\right)\right]} > 1$. As $E\left[\pi_{s3}\left(Q^*_3\right)\right] + E\left[\pi_{m3}\left(Q^*_3\right)\right] = E\left[\pi_{T3}\left(Q^*_3\right)\right]$, $E\left[\pi_{s3}\left(Q^*_3\right)\right] = \left(1-\varphi_3\right)E\left[\pi_{T3}\left(Q^*_3\right)\right]$, $E\left[\pi_{m3}\left(Q^*_3\right)\right] = \varphi_3 E\left[\pi_{T3}\left(Q^*_3\right)\right]$, put into the formula, we get $\frac{(1-\varphi_3)E[\pi_{T3}(Q^*_3)]}{E\left[\pi_{s3}\left(Q^*_{\varphi 3}\right)\right]} > 1$, $\frac{\varphi_3 E[\pi_{T3}(Q^*_3)]}{E\left[\pi_{m3}\left(Q^*_{\varphi 3}\right)\right]} > 1$. To simplify, we obtain $\frac{E\left[\pi_{m3}\left(Q^*_{\varphi 3}\right)\right]}{E\left[\pi_{T3}\left(Q^*_3\right)\right]} < \varphi_3 < 1-\frac{E\left[\pi_{s3}\left(Q^*_{\varphi 3}\right)\right]}{E\left[\pi_{T3}\left(Q^*_3\right)\right]}$.

This completes the proof. □

This proposition shows that, whether carbon emission quota is enough or not, supply chain can coordinate by revenue sharing contract under Cap-and-trade policy. However, sharing proportion must meet a certain relationship to make the Pareto improvement for both sides; otherwise the contract shall be invalid.

5 Discussions

Through the analysis above, we notice that revenue sharing contract can coordinate the supply chain under no carbon emission constraint, Cap and Cap-and-trade policy. Next, we will discuss the effect of carbon policy on revenue sharing ratio and manufacturer's expected profit.

5.1 Effect of Carbon Policy on Revenue Sharing Ratio

Proposition 5. *When* $eQ_2^* \leq E \leq EQ_3^*$*,* $\varphi_2 > \varphi_3$*.*

Proof. We have known when $Q_2^* \leq \frac{E}{e}$, $\varphi_2 = \frac{(p-v)(c_m+w)+(w-c_s)g+vg}{(p-v)(c_m+c_s)+vg}$, when $Q_3^* \geq \frac{E}{e}$, $\varphi_3 = \frac{(p-v)(c_m+w+ke)+(w-c_s)g+vg}{(p-v)(c_m+c_s+ke)+vg}$, $\varphi_2 - \varphi_3 = ke\,(p-v)\,(p-v+g)\,(c_s-w)$, according to the assumption $p > v$, we know $p - v > 0$, $p - v + g > 0$. So we mainly discuss whether $c_s - w$ is positive or negative.

As $\varphi_2 \in [0,1]$, that is $0 \leq \frac{(p-v)(c_m+w)+(w-c_s)g+vg}{(p-v)(c_m+c_s)+vg} \leq 1$, then $(p-v)\,(c_m+w) + (w-c_s)\,g \leq (p-v)\,(c_m+c_s)$, we can prove $w \leq c_s$. As $\varphi_3 \in [0,1]$, the same theory proves that $w \leq c_s$.

In conclusion, as $c_s - w > 0$, that is $\varphi_2 - \varphi_3 > 0$, then $\varphi_2 > \varphi_3$. This completes the proof. □

This proposition shows that, under cap policy, when the carbon cap doesn't play a role (that is no carbon emissions constraint), the manufacturer's revenue share proportion is greater than it under Cap-and-trade policy. Obviously, in the situation of no carbon emission constraint, manufacturer's profit is bigger, so he can share a higher proportion of revenue.

5.2 Effect of Carbon Policy on Manufacturer's Expected Profit

When the initial carbon quotas assigned by government are enough under cap policy, it seems to be a problem without carbon emission constraint. In this paper, taking the manufacturer's expected profit without carbon emission constraint as a benchmark, we want to study the effect of carbon policy on manufacturer's expected profit. In addition, as the supply chain is coordinated by revenue sharing contract, we adopt the whole supply chain profit to represent the manufacturer's expected profit.

Proposition 6. *In the situation* $Q_2^* \leq \frac{E}{e}$*, when* $E > E^*$*,* $E\left[\pi_{T3}\left(Q_3^*\right)\right] > E\left[\pi_{T2}\left(Q_2^*\right)\right]$*; when* $E = E^*$*,* $E\left[\pi_{T3}\left(Q_3^*\right)\right] = E\left[\pi_{T2}\left(Q_2^*\right)\right]$*; when* $E < E^*$*,* $E\left[\pi_{T3}\left(Q_3^*\right)\right] < E\left[\pi_{T2}\left(Q_2^*\right)\right]$*; where* $E^* = EQ_3^* + \frac{1}{k}\left[E\left[\pi_{T2}\left(Q_2^*\right)\right] - E\left[\pi_{T2}\left(Q_3^*\right)\right]\right]$*.*

Proof. Compare $E\left[\pi_T\left(Q_2\right)\right]$ and $E\left[\pi_T\left(Q_3\right)\right]$.

If $E \leq EQ_3^*$, $E\left[\pi_{T3}\left(Q_3^*\right)\right] = E\left[\pi_{T2}\left(Q_3^*\right)\right] - k\left(eQ_3^* - E\right) \leq E\left[\pi_{T2}\left(Q_3^*\right)\right] < E\left[\pi_{T2}\left(Q_2^*\right)\right]$, we can get $E\left[\pi_{T3}\left(Q_3^*\right)\right] < E\left[\pi_{T2}\left(Q_2^*\right)\right]$.

If $E \geq EQ_3^*$, $E\left[\pi_{T3}\left(Q_3^*\right)\right] = E\left[\pi_{T2}\left(Q_2^*\right)\right] + k\left(eQ_2^* - E\right) > E\left[\pi_{T2}\left(Q_2^*\right)\right]$, we can get $E\left[\pi_{T3}\left(Q_3^*\right)\right] > E\left[\pi_{T2}\left(Q_2^*\right)\right]$.

As a result, there always exists $E^* \in \left(eQ_3^*, eQ_2^*\right)$, satisfy $E\left[\pi_{T3}\left(Q_3^*\right)\right] = E\left[\pi_{T2}\left(Q_2^*\right)\right]$, that is $E\left[\pi_{T2}\left(Q_3^*\right)\right] - k\left(eQ_3^* - E\right) = E\left[\pi_{T2}\left(Q_2^*\right)\right]$.

So we get $E^* = EQ_3^* + \frac{1}{k}\left[E\left[\pi_{T2}\left(Q_2^*\right)\right] - E\left[\pi_{T2}\left(Q_3^*\right)\right]\right]$. This completes the proof. □

This proposition indicates that the manufacture's expected profit under Cap-and-trade policy is greater than it in the situation without carbon emissions constraint under certain conditions. This is because the Cap-and-trade policy is a kind of mixed strategy combining market operation and government regulation. It not only control the total emission amount, but also offer an opportunity for the enterprises to buy or sell the carbon emission quota, and make them to guarantee production or gain more profits.

6 Conclusion and Future Research

In this paper, taking the two echelon supply chain (one supplier and one manufacturer) which is dominant by supplier as the research object, we analyze the supply chain coordination problem based on revenue sharing contract under Cap and Cap-and-trade policy. It provides several interesting observations.

(1) Revenue sharing contract can coordinate the supply chain under both Cap and Cap-and-trade policy, and can realize the Pareto improvement for both sides under certain conditions.
(2) When the carbon policy plays a role, the manufacture's revenue share proportion under Cap-and-trade policy is always less than it without carbon emission constraint. The manufacturer would buy carbon emission quota for the limitation of it. It produced a certain cost and reduced profits, so he would distribute less profit to the supplier.
(3) Under certain conditions, the manufacture's expected profit under Cap-and-trade policy is greater than it in the situation without carbon emissions constraint. Because Cap-and-trade policy not only control the total emission amount, but also offer an opportunity for the enterprises to buy or sell the carbon emission quota, and make them to gain more profits. However, the Cap policy do not has such function. As a result, theoretically speaking, Cap-and-trade policy is better than Cap policy.

The conclusions of this paper is beneficial to the upstream and downstream enterprises in such supply chain, at the same time they can also provide theoretical guidance for carbon emissions policy for the government. In future study, we can extend our research from one-to-one two-stage supply chain to one-to-many or three-stage supply chain.

Abstract. China is a big country on livestock production and Chinese livestock products output value is increased yearly. However, Chinese livestock products are still mainly dominated by self-employed farmer's production mode which leads to imbalance between supply and demand, periodic fluctuations in prices. In this paper an integration of livestock products supply chain is proposed to solve the imbalance problem. A sample of a duck farm is chosen to show the process of the integration. First a discrete-event simulation model is built by the supply chain which is composed of hatching, breeding, and packaging and transporting. Then production plan, transport routes and the number of fixed assets are adjusted to achieve the goal that the mean of supply-demand ratio is close to 1 and the variance is close to 0.

Keywords: Livestock products · Supply chain · Duck farm · Integration · Discrete-event simulation

1 Introduction

China is a big country on livestock production and Chinese livestock products output value is increased yearly. However, the construction of livestock products supply chain (LPSC) is inefficient. At present, Chinese big enterprises in the livestock products market have just started the integration of supply chain, and the livestock products market is still mainly dominated by self-employed farmer's production mode. Farmers neither share their information nor have any plans for production, so it leads to the imbalance between production and market demand. Once a product is sold well, farmers flock to produce it blindly. Then the price will fall, and farmers will switch to produce other products sold well, finally becoming a vicious circle. In addition, the production of livestock products has many shortcomings, such as low levels of automation, decentralized farmers. If we want to integrate the supply chain, the issue that matches supply with demand must be met. When the farmers make production plans, they're faced with the situation that demand is stochastic and production plans must be decided before they know the real demand [1]. From the experience of developed countries

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_90

for agricultural development, scale management on livestock products has an incomparable cost advantage. Therefore, this paper considers building integrated livestock products supply chain (ILPSC) to solve the mismatch between supply and demand.

The process of production, cultivation, processing, transportation and sale in LPSC will produce added value. Therefore, the LPSC is a value-added supply chain from upstream to downstream. However, if a peasant-oriented platform is just simply built, the information provided for each other may not be entirely true due to the opportunism between enterprises in supply chain. It is difficult to realize the information sharing in practice and this will cause supply and demand imbalance, eventually to make market price fluctuations. Building the ILPSC and formation of close cooperation are the emphases, which can integrate the information flow in the supply chain. But in the implementation process, there are still many issues to be resolved, such as the determination of the assets number, production planning and transportation routes. This paper builds an ILPSC model with simulation software, aimed at matching supply with demand, and eventually using a sample to prove the effectiveness and feasibility of the ILPSC model.

This paper is organized as follows. In Sect. 2, relevant literatures are reviewed. In Sect. 3 the ILPSC model is shown and analyzed. In Sect. 4, an empirical model of duck supply chain is presented and the supply-demand radio of the model is optimized. Section 5 gives some conclusions.

2 Literature Review

LPSC is a kind of agricultural products supply chain. Chinese research on agricultural supply chain started in 1999, and LPSC was later introduced. Chen and Luo [2] put forward the idea of building a new Chinese LPSC by adding the information agent to provide a scientific decision-making for strengthening the supply chain management of Chinese LPSC. Zhou [15] proposed some conclusions to promote the healthy and stable development of the pig industry. Yu and Li [14] proposed the market operation mode and structure of livestock products were no longer a single entity competition of production, processing and sales. The survival and development of livestock products were more and more dependent on the overall quality and comprehensive strength of the whole industry chain. In the basis of this, the supply chain model of the combination of third-party logistics and livestock products was used to improve the whole efficiency of LPSC. Wang and Huang [12] put forward the SCOR model of agricultural products based on information network, and constructed the agricultural supply chain logistics management mode under the information network environment. Then through the empirical analysis of Shanghai freshwater supply chain logistics management mode, they proved the effectiveness and practicability of agricultural logistics supply chain management mode. Liu, Sun and Wang [4] found that the researches of Chinese agricultural supply chain were mainly concentrated on the traditional mode of operation of agricultural supply chain, fresh agricultural products at the end of the supply chain supermarket and information technology under the traceability system and e-commerce environment. And he believed that the establishment of a new integrated production and marketing supply chain and circulation system to achieve the circulation of agricultural products and information network management, could make Chinese agricultural products enter further into the global supply chain.

Compared with China, the United States, the Netherlands, the European Union, Japan and other developed countries have been perfect on the development of agricultural supply chain, so there are many researches about LPSC, especially about beef and pork supply chain. Birthal and Pratap [10] proposed that the revolutionary progress in livestock production was demand-driven. The income elasticity of demand was higher compared to most other food commodities. And livestock would have a larger effect on poverty reduction compared to crop sector. Facchioli [3] used a computational simulation system tool to coordinate its flow of matter and information. Piewthongngam [8] developed a system dynamics model as a tool for managers to visualise the movement of the entire production chain. William, Norina and Cassavant [13] thought SCRA was a “production adjustment & consumer-driven” systems. Van Roekel, Kopicki and Broekmans [11] gave the basic four steps in the development of agricultural supply chains. Simchi and Kaminsky [9] pointed out that information sharing and task planning was the key to integrating supply chain. Min and Zhou [5] summarized the methods and applications of integrated supply chain modeling. It provided a reference to establishment of the ILPSC. Pan and Jean [7] analyzed the link between pork supply chain in China and the United States, and put forward that a mechanism of enterprises and peasants, a sound logistics operation system and an information network platform should be established so that the efficiency of Chinese pork processing supply chain could be improved. Robert and Jon [6] used a visual modelling environment to overcome the problems involved in implementing simulation models.

3 Model Description

3.1 Integrated Livestock Products Supply Chain Model

The ILPSC model refers to the integration of all members in the LPSC, based on the common goals, to achieve true sharing of information and integration of supply, production and sale. Figure 1 shows the whole ILPSC model, and there are mainly four parts. The first part is the process of producers which contains capital goods suppliers and flows. Capital goods suppliers weekly produce pups as per production plan which is designed by demand. Then, a collection of several suppliers makes up a flow. The combined production of a flow is kept together when it moves through the model. The second part is the process of manufacturers for a period of breeding activities. The third part is the process of processors where livestock products are processed and packaged. The fourth part is the process of sending products to market.

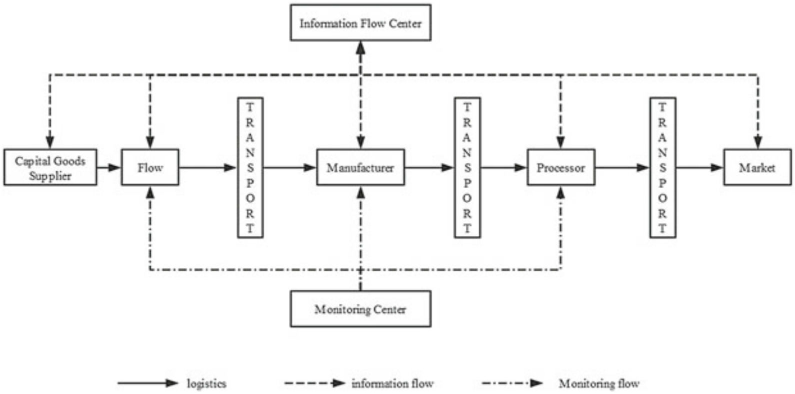

Fig. 1. The integrated livestock products supply chain model

In the whole model, the information flow center makes information flow in the whole supply chain smoothly and shares the information with every part in the model. At the same time, reasonable decisions are made on all links of the supply chain through the integrated information, such as production plan and transportation routes. And early in the supply chain construction, it can determine whether the number of assets to meet the market demand number by the weekly market demand plan. Monitoring center is mainly for flows, manufacturers and processors. Among them, the flows and manufacturers are mainly concerned about the health condition of livestock. What we want to monitor is whether the livestock are sick, whether the disease is contagious and whether the sick livestock are dead. In addition, the weekly sales of processors should be monitored, because the processor needs to sell products to the market weekly. And a batch of products is sent to market several weeks.

The ILPSC model is a two-way driving model. That is, on the one hand, the model needs the production plan of the most upstream companies to push the entire supply chain, on the other hand, it needs the final market demand to pull. Therefore, it's necessary to forecast market demand to pull the production to guarantee the matching of supply and demand information, and then push the production through the production plan. Events in the model take 1 week.

The goal of the model is to strike a balance between the supply of livestock products to market and the demand of the market. The supply-demand ratio can be used to response the situation about balance of supply and demand. Therefore, whether the target is achieved or not can be determined by analyzing the mean and variance of all processors' corresponded supply-demand ratio. If the mean of it is close to 1 and the variance is close to 0, it can be proved that the target is achieved. And a sub-goal may exist, such as the cost. The rule to transport products can be considered, when the transporter works. Distance between different parts in the model is affected by the rule, and the cost is affected by the distance. There are some uncertain factors in the model which is concerned with the goal of the model. The first one is the uncertainties associated with the health condition of livestock. It includes whether the livestock are diseased, which type of health episodes is caught, whether it has died after the illness and which week after the illness is the time livestock dead. Secondly, the week when the livestock products are sent to the market is also an uncertainty factor. All of them will affect the number transported to the market, through the uncertain production losses for the entire system caused by themselves. In this paper, these uncertainties are solved by simulation model.

The ILPSC model is suitable for livestock products, which mainly refer to livestock and poultry meat, and livestock including pigs, cattle, sheep and so on, poultry including chickens, ducks, geese and other poultry meat and wild birds. The characteristics of livestock products include that the number of production can be counted, production cycle is long, the sickness can result in uncertain production losses, it's easily restricted by the size of the farm, it will be transported between different farms and processing and packaging are needed.

3.2 Model Entities, Variables

To build a discrete-event simulation model, entities and variables must be determined.

Model entities. Livestock, transporters, capital goods suppliers, flows, manufacturers and processors are used in the ILPSC model as model entities.

Model variables. There are 12 variables in the ILPSC model, and the details are shown in Table 1.

3.3 Analysis of Model Process

There are many process in the model, and the processes of health condition and selection of flows to manufacturers are the most important and analyzed.

(1) Health Condition Process

Livestock may get sick during the breeding process, and the type of diseases may be different. The infectivity of different types of diseases is also different. If the disease is infectious, the diseased livestock need to be isolated from other healthy livestock. The flow chart of the process is shown in Fig. 2.

(2) Selection of Flows to Manufacturers Process (based on the shortest distance rule)

When livestock are transported from flows to manufacturers, a transportation rule can be considered such as the shortest distance rule. It is preferable to transport the products to the available manufacturer who is the nearest to the flow. At the same time, the number of livestock transported will be constrained by the capacity of transporters and manufacturer's assets. The flow chart of the process is shown in Fig. 3.

Table 1. Variables of ILPSC model

Variable name	Variable description	Notes
Transfer week	The number of weeks in the model before to be sent to the market	Updated weekly when the value is 0, it will be sent to the market in the week
Health condition	0 is showed healthy, 1 is showed sick	
Health episode	The type of illnesses, using 1 n as disease 1 disease n	
Sick week	The number of weeks before a sick livestock dead	Updated weekly when the value is 0, it will be dead due to illness
Week	The number of weeks the model runs	
Quarter	The number of quarters the model runs	
Min mile#	The nearest distance between the flow and the nearest available manufacturer	# is the number of flows, $1, 2, \cdots, m$
Supply#	The number of livestock products supplied to markets weekly	# is the number of processors, $1, 2, \cdots, t$
Transporter#	The number of livestock delivered by a transporter	# is the number of flows, $1, 2, \cdots, m$
Ill livestock#	The number of sick livestock per week for each flow	# is the number of flows, $1, 2, \cdots, m$
Rate#	Weekly supply-demand ratio	# is the number of processors, $1, 2, \cdots, t$
SD Rate#	The difference between the mean of the Rate# in the simulation period and 1 the value is closer to 0, the matching rate is higher	# is the number of processors, $1, 2, \cdots, t$

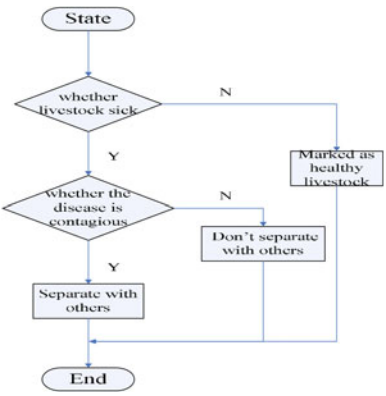

Fig. 2. The flow chart of the health condition process

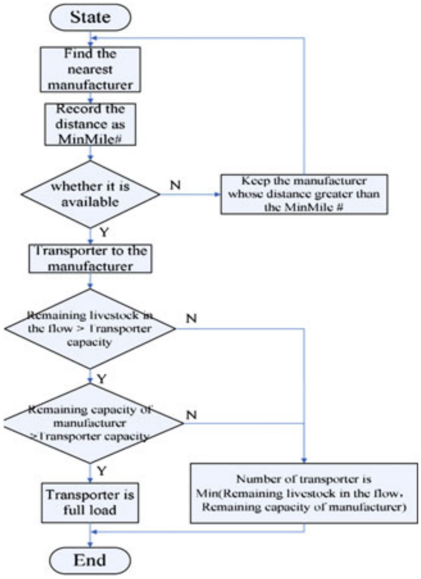

Fig. 3. The flow chart of the selection of flows to manufacturers process

3.4 Model Optimization Rules

To achieve the goal, the model needs to be optimized. There are many parts in the supply chain will have an impact on the goal. In this paper, three factors are mainly considered including the asset numbers of manufacturers, production plans and transportation routes.

(1) The asset numbers of manufacturers
It refers to the number of assets in the supply chain where manufacturers breed livestock. Manufacturers are used to breed pups provided by capital goods suppliers, and it's the key to connecting upstream and downstream of the supply chain. Therefore, when the production plans of capital goods suppliers have been decided with the change of the market demand, the asset number of manufacturers should change accordingly. So, whether the asset number of manufacturers is enough must be first determined in the establishment of the model. Only when the number of manufacturers' assets is sufficient can the model continue to be optimized.

(2) The production plans
A production plan is a schedule of the number of pups produced by capital goods suppliers. It directly determines the approximate size of the livestock products that are ultimately sent to the market. Therefore, the sum of livestock products transported to market will be closed to the sum of market demand by optimizing the production plan.

(3) The transportation routes
Transportation routes refer to the routes that transporters deliver livestock between the links of the supply chain. This paper mainly considers the route between manufacturers and processors. Since processors have their corresponding markets, processed livestock products can be distributed evenly by adjusting the routes, when the sum of supply is close to the demand.

4 Empirical Analysis

4.1 Model Overview

The empirical data in this article refers to the competition of the 2016 Arena Simulation Student Competition: Rockwell Duck Farm Supply Chain Optimization. Two schedules will drive the simulation model of the farm system: a market schedule, and a hatching farms schedule.

There are currently about 75 hatching farms in the system which produce a total of approximately 100,000 ducks each week. Hatching farms breed ducks per the hatching farms schedule, and a collection of several hatching farms makes up a flow to move together. The order for transport is carried out in descending order of flows and finds the nearest available growth/finish farms to receive the ducks with the shortest distance rules. Production will be affected by the health condition of ducks. There are four diseases to ducks showing in Table 2. The probability of getting sick in four quarters of every hatching farm and prevalence of the four diseases are based on the data provided in the competition.

Table 2. Four diseases to ducks

Disease types	Requires separation?	Sick weeks (week)	Output loss (%)
DED Exposed (Disease$_1$)	No	4	0.25
DED Naive (Disease$_2$)	No	4	1
DRRS Non-Vaccinated (Disease$_3$)	Yes	8	0.4
DRRS Vaccinated (Disease$_4$)	Yes	8	0.1

There are currently about 230 growth/finish farms in the system. The farms receive the ducks from the hatching farms until it is full. Ducks are breeding 22 weeks in the growth/finish farms. Because disease_3 and disease_4 need to be separated from other ducks, the growth/finish farm_27, growth/finish farm_199, growth/finish farm_1564, growth/finish farm_65, and growth/finish farm_179 are selected to receive the ducks suffering from the two diseases, which are relatively closer to each station.

There are 11 packers/plants in the system. After packaged and processed, ducks are sold for 6 weeks, the proportion shown in Table 3.

Table 3. Proportion of ducks sent to market weekly

Sales week	Sales ratio
Week 1	0.04
Week 2	0.08
Week 3	0.2
Week 4	0.25
Week 5	0.25
Week 6	0.18
Sum	1

Ducks are transported by truck in the system and each truck is loaded with 2,600 ducks. A distance matrix defines the miles between a central point of a flow's location to a particular growth/finish farm. The simulation time is two years or 104 weeks. Figure 4 shows the supply chain model of the duck farms established with visual simulation software. The lower left part of the facility interface is 75 hatching farms, the top part is 230 growth/finish farms and the lower right part is 11 packers/plants.

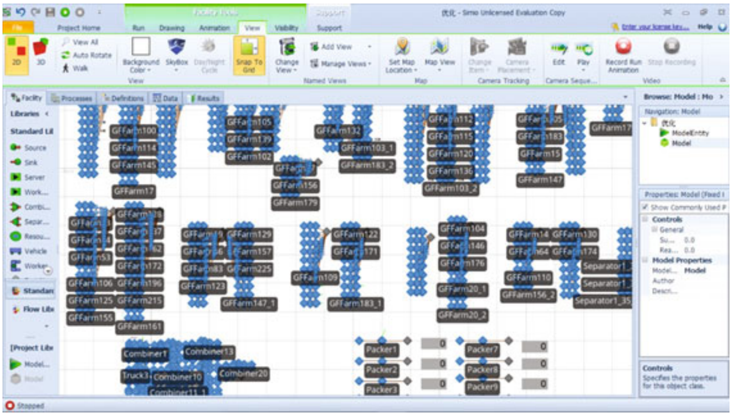

Fig. 4. The ILPSC model of duck farms established with visual simulation software

4.2 Model Optimization

When the model is run, it's found to be incorrect. The number of farms is insufficient to accommodate the duck. Therefore, there need more farms to meet the extra expectations. 16 growth/finish farms near the 16 flows are selected to form a group, three groups added. After running the model again, it's found that the supply of packer/plant$_5$ is zero. Therefore, transportation routes are adjusted per the results of operations. It's mainly solved through adjusting the corresponding packers/plants of the new three groups to the packers/plants whose supply is obviously insufficient. To find the optimal production plan, an experiment needs setting up. The controlled variable for the experiment is the number of hatchings per week for 75 hatching farms. The target is SD Rate# of 11 packers/plants. SD Rate# in 40 scenarios is shown in Fig. 5.

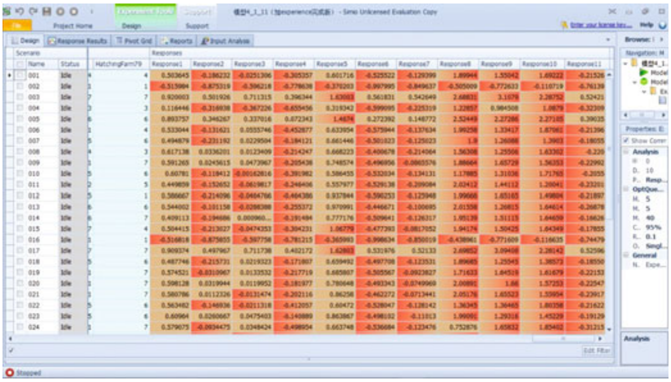

Fig. 5. SD Rate# in 40 scenarios after running experiment

Since the ultimate goal is to achieve the match of supply and demand, it can be achieved by finding a scenario where the supply-demand ratio is closer to 1 and the SD Rate# is closer to 0. Therefore, by comparing the mean and coefficient of variation (CV) of the absolute value of the SD Rate#, the scenario can be found where the mean and CV are closer to 0. It proves that the number of supply and demand is closer. An mean-CV line chart is shown in Fig. 6.

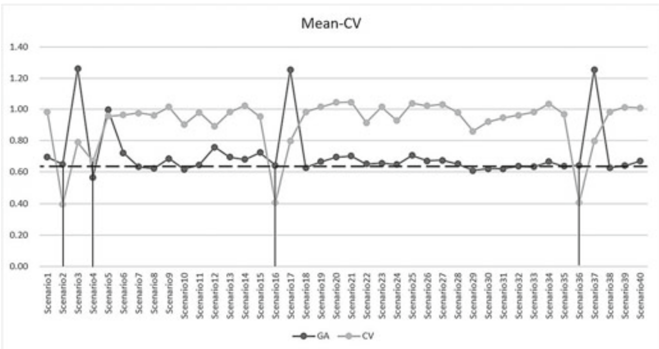

Fig. 6. Mean-CV line chart for 40 scenarios

Table 4. The adjustment scheme based on the result of experiment

Parker 1	Parker 2	Parker 3	Parker 4
G/F farm 15_4	G/F farm 65_4	G/F farm 63_2	G/F farm 54_4
G/F farm 20_4	G/F farm 179_4	G/F farm 20_2	G/F farm 183_4
G/F farm 63_4	G/F farm 224	G/F farm 36	G/F farm 16_4
G/F farm 147_4	G/F farm 178	G/F farm 207_4	G/F farm 76
	G/F farm 205_4	G/F farm 220_4	G/F farm 64
			G/F farm 16_2
			G/F farm 156_1
Parker 6	**Parker 7**	**Parker 8**	**Parker 10**
G/F farm 222	G/F farm 14	G/F farm 66	G/F farm 27_4
G/F farm 211	G/F farm 30	G/F farm 206	G/F farm 199_4
G/F farm 210	G/F farm 145		
G/F farm 209	G/F farm 208		**Parker 11**
G/F farm 95	G/F farm 34		G/F farm 156_4
G/F farm 213	G/F farm 17		
G/F farm 150	G/F farm 148		

The mean and CV of scenario 2,4,16,36 are all suitable. Finally, the production plan of scenario 4 is selected. Then the model is ran again and the transportation routes from the growth/finish farms to the packers/plants are adjusted based on the results. The adjustment scheme is shown in table 4(G/F farm represents Growth/Finish farm). Since the supplies of packer/plant$_5$ and packer/plant$_9$ are sufficient, they are not shown in Table 4.

The line graphs between the supply and demand of the 11 packaging plants in the original and the optimized model are shown in Fig. 7.

From Fig. 7, it can be seen the fluctuation range of the optimized model's supply is decreased compared with the original model, and supplies of every packer/plant are basically fluctuating up and down in demand. The supply-demand ratio of the original model and the optimized model is compared, as shown in Table 5. And the line chart is shown in Fig. 8.

According to Fig. 8, it can be seen that the overall supply-demand ratio of the 11 packers/plants of the optimized model is close to 1, and the fluctuation is obviously reduced. There are three changes seen from Table 5 the mean of supply-demand ratio of 11 packers/plants is reduced by 0.0836, the standard deviation is reduced by 0.6979 and the variation coefficient is reduced by 0.6478. Although the mean of the original model is also close to 1, the standard deviation is 0.8142 which means it is very volatile. And the standard deviation and the coefficient of variation after optimization is closer to 0, it can be seen that the optimized model can make the match of supply and demand better.

Fig. 7. The line graphs between the supply and demand of the 11 packaging plants in the original and the optimized model during 28-104th weeks

Table 5. The supply-demand ratio of the original model and the optimized model

Packer number	1	2	3	4	5	6	7
Supply-demand ratio	2.6161	1.0385	0.6777	1.1512	0	2.1518	0.6294
Optimized supply-demand ratio	0.994	1.0853	0.832	0.9447	1.0613	0.8967	0.7984
Packer number	8	9	10	11	Mean	*SD*	*CV*
Supply-demand ratio	0.4204	1.8445	0.7463	0.4056	1.062	0.8142	0.7667
Optimized supply-demand ratio	1.0332	1.1317	1.1111	0.8735	0.9784	0.1163	0.1189

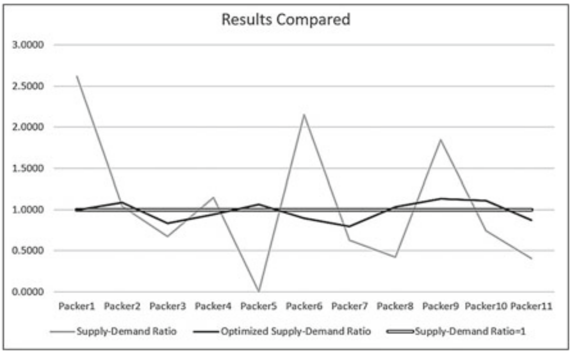

Fig. 8. The line chart for the supply-demand ratio of the original model and the optimized model

5 Conclusion

This paper establishes an ILPSC to integrate the entire supply chain, which ultimately matches the supply and demand of livestock products. The whole process of the ILPSC from the upstream capital goods suppliers to the downstream market is introduced, including the information flow center and the control center to control the information flows and uncertain factors. Then, an integrated supply chain model for a duck farm is constructed with simulation software. In the example, the number of assets in the growth farms is added, and the production plan of the hatching farms and the transportation routes between the growth farms and the packing plants are optimized. Finally, the mean of supply-demand ratio of the 11 packing plants is reduced by 0.0836, the standard deviation is reduced by 0.6979 and the variation coefficient is reduced by 0.6478. The construction of the ILPSC is a quite complex problem. Though the ILPSC can represent most of the integrated process of livestock products, it also can be extended to other aspects, for example, the question on reduction of transportation costs, and the question on increasing utilization of growth farms.

A Novel Multi-Objective Programming Model Based on Transportation Disruption in Supply Chain with Insurance Contract

Kai Kang(✉), Jing Zhao, and Yanfang Ma

School of Economics and Management, Hebei University of Technology,
Tianjin, China
kkang2000@sina.com

Abstract. Supply chain risk management is becoming increasingly a hot research issue. When the disruption occurs, insurance can be used to reduce the risk. In this paper, we set a novel multi-objective programming model based on transportation disruption in supply chain with insurance contract in order to protect the whole supply chain members. Then use a case to investigate the applicability of this model. From this mathematical model, we obtain the optimal order quantity and the pure premium, which can help the manufacture and the retailer make a better plan. And the insurance can protect the manufacturer and the retailer's profits. In the future, the insurance will be used in supply chains widely.

Keywords: Supply chain risk management · Transportation disruption · The optimal order quantity

1 Introduction

Since the 21st century, with the global procurement, non-core business outsourcing, and development of business models in supply chain management, such as the lean management, the space distance on the supply chain becomes longer and longer, while the time distance becomes shorter. The change of the temporal and spatial variation of the supply chain improves the possibility of an interrupt occurance. Every firm's supply chain is susceptible to a diverse set of risks, such as natural disasters, terrorism, war, financial crisis, supplier bankruptcy and transportation delays. A lot of strategies used by firms to mitigate disruption risks include emergence purchases, multi-sourcing, inventory reserve and some reliability improvement of supply process [6]. The awareness regarding the importance of supply chain risk management (SCRM) has grown in the recent years. Supply chains are becoming increasingly competitive and complex in order to effectively meet customer demands. Supply chain disruptions often lead to declining sales, cost increases, and service failures for the company. There are several kinds of mode of supply chain disruptions. Different scholars have different classifications for it. It can be clearly seen in Table 1.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_91

Table 1. The classifications of supply chain disruption

Year	Author	Classification
2013	Hishamuddin [3]	Supply disruption, transportation disruption
2015	Nooraie [7]	Financial risk, transportation disruption
2015	Heckmann [2]	Financial risk, demand disruption
2016	S. Tong [8]	Node disruption, chain disruption

Transportation disruption, in particular, is slightly different from other forms of SC disruptions, in that it only stops the flow of goods, whereas other disruptions may stop the production of goods as well. The transportation disruption of the supply chain is a non-negligible factor that it can reduce the manufacturer and the retailer's profits. For instance, in October 2000, two typhoons damaged the oil gas pipeline belonging to Shanghai Petroleum Natural Gas Co., Ltd. in China, leading to a 178-days service disruption of oil gas. Terrorist attacks on the world trade center on September 11, 2001, causing a stagnation of goods which came from the border of America. This led to a force to the Ford motor company to stop production activities temporarily. In March 2011, an earthquake happened in Japan, which caused 22 automobile manufacturing companies' shutdown, such as Toyota, Honda, nissan. Affected by the earthquake the Japanese exports of cars fell 12.5% in April compared with the year 2010, being the biggest drop since the 18 months. As you can see from the above cases, transportation disruption caused by emergency events not only leads manufacturers to stop production, but also brings irreparable damages to the downstream enterprises of the supply chain. Furthermore, a transportation disruption may affect the condition of the valuable goods in transit.

Once transportation interrupts, it has a great influence for each member on the supply chain, leading to transport delay, increasing the transportation time and the transportation cost, even bringing serious damage to related companies. Although realizing that there is a disruption risk in the supply chain, most of the enterprises in the aspect of risk management of supply chain disruptions have very little money and resources. To make sure for the firm's profit, we tend to make the insurance strategy according to the degree of risk. Purchasing an insurance for the emergency is a kind of protection for enterprises. The model that we have developed in this research addresses this vital aspect of transportation disruption.

This paper proposes a newly multi-objective programming model for a supply chain system subject to transportation disruption. In this model, we consider the insurance contract to deal with the transportation disruption risk.

The contents of this paper are organized as follows. Section 2 presents the related literature review. A description of the model and its formulation are given in Sect. 3. Section 4 shows the analysis of numerical example. Section 5 provides a conclusion of this paper and offers potential directions for future research.

2 Literature Review

There is a great deal of literature on supply chain. In recent years, the research in supply chain disruption is becoming a hot spot. Disruption has the characteristics of low probability of occurrence and big influence on the part of the supply chain, even the whole supply chain. Many scholars classified the types of supply chain disruption, and provided several operational strategies for managing disruption. But there are few papers which are mentioned the insurance to solve the risks.

Our study is related to studies focusing on the transportation disruption in supply chain. Zhen et al. [9] investigated four strategies: basic strategy, BI insurance strategy, backup transportation strategy, and mixed strategy, in order to deal with distribution centers' daily risk management. They used the mathematic model to compare BI insurance strategy with backup transportation strategy, and found that the choice of BI insurance strategy and the backup transportation strategy depended on transportation market, insurance market and distribution center's operational environments. Hishamuddin et al. [3] built a recovery model for a two-echelon serial supply chain when transportation disruption occurred. This model determined the optimal ordering and production quantities with the recovery window, and ensured the minimum total relevant costs. They developed an efficient heuristic to solve the problem. In 2015, they developed a simulation model of a three echelon supply chain system with multiple suppliers subject to supply and transportation disruptions [4]. The objective of the paper is to examine the effects of disruption on the system's total recovery costs. Hernn et al. [1] provided a novel simulation-based multi-objective model for supply chains with transportation disruptions, aiming to minimize the stochastic transportation time and the deterministic freight rate.

In this paper, we apply a novel multi-objective programming model for supply chain with transportation disruption. We reference about the method of calculating profit of Lin's paper [5] to study the problem of the manufacturer and retailer's profit when there is a transportation disruption. And we introduce the insurance contract to the model.

3 System Description and Modeling

In the following subsections, we address the system's description of the model. Then present the mathematical representation of the model.

3.1 System Description

In this study, we consider a single supply chain model which has a manufacturer and a retailer. We assume that the information between them is symmetrical. The manufacturer has production, while the retailer has inventory. Before the selling season, the manufacturer and the retailer agree on an insurance contract, but the retailer needs to pay part fees to the manufacturer. And the premium is decided by the insurance company. In our model, we assume that the transportation disruption occurs in the delivery from the manufacturer to the retailer, which interrupts the timely delivery of goods to the retailer. The transportation disruption may be caused by an accident or a natural disaster, such as a earthquake, or flood. In addition, the goods in transit may or may not be damaged during the disruption. Because of the transportation disruption, the insurance contract comes into action.

In this paper, we use a multi-objective programming model to solve the problem. The notations are explained as follows:

Denotes

m: represent the manufacturer;
r: represent the retailer;
I: represent the insurer;
D: the market demand;
π_m: the expected profit of the manufacturer;
π_r: the expected profit of the retailer.

Parameters

x: a random variable presenting the market demand D;
c: a unit cost of the product provided by the manufacturer;
w: a wholesale price that the manufacturer charges the retailer;
p: a retail price that the retailer serves the customers;
h: the shortage cost per unit;
c_t: the transport cost per unit;
s: the salvage value of any unsold product per unit;
α: the retailer's share of losses generated by the deviation of his order quantity from the market demand, and $\alpha \in [0, 1]$, so the manufacturer's share is $1 - \alpha$;
P: the pure premium that the insurer guarantees to pay the manufacturer with the transportation interruption insurance, and it's set by the insurer;
R: the rate of the pure premium to pay to the insurer;
β: the ratio that the retailer takes from the compensation, and $\beta \in [0, 1]$, so the manufacturer takes $(1 - \beta)$L;
$f(x)$: probability density function with the market demand D;
$F(x)$: cumulative density function with the market demand D.

Decision variable

q: an order made by the retailer and the manufacturer based on their forecast of the market demand D.

3.2 Model Formulation

When the transportation disruption occurs, the manufacturer and the retailer's expected profit will be decreased. But with the insurance contract, this situation can be mitigated. So the objective of the insurance contract is to maximize their profit. The objective functions are given as follows:

$$\begin{aligned} \max \pi_m =&(w-c)q - qc_t - (1-\alpha)\left[\int_0^q (p-s)(q-x)f(x)dx \right. \\ &\left. + \int_q^\infty h(x-q)f(x)dx\right] - PR + (1-\beta)P. \end{aligned} \tag{1}$$

Objective function (1) maximizes the manufacturer's expected profit, where $(w-c)q$ is the earnings of the product for the manufacturer with the order quantity from the retailer, qc_t is the cost of transportation, $\int_0^q (p-s)(q-x)f(x)dx + \int_q^\infty h(x-q)f(x)dx$ is the expected losses generated by the deviation of the retailer's order quantity from the market demand, and PR is the cost of the manufacturer paying to the insurer.

$$\begin{aligned} \max \pi_r =&(p-w)q - \alpha\left[\int_0^q (p-s)(q-x)f(x)dx + \int_q^\infty h(x-q)f(x)dx\right] \\ &+ \beta P. \end{aligned} \tag{2}$$

Objective function (2) maximizes the retailer's expected profit, where $(p-w)q$ is the earnings of the product for the retailer while the assumption is that the whole product can be sold out. When the transportation disruption happens, the retailer can get a compensation βP. When the transportation disruption happens, the insurance contract belongs to the third party liability insurance, and its rate is usually a fixed value.

In order to guarantee the integrity of the model, there are constraints as follows:

$$0 < s < c < w < p. \tag{3}$$

If the product have not been sold off, the salvage value of the unsold product s is less than its cost. This is equivalent to a kind of punishment for the exceed quantity. And to make sure for the manufacturer and the retailer's profit, the relationship of unit cost c, the wholesale price w and the retail price p need to be $c < w < p$.

$$0 < h < w. \tag{4}$$

The shortage cost h is less than the wholesale price w.

$$P \geq qc. \tag{5}$$

The purpose to purchase the insurance contract is to minimise the manufacturer and the retailer's profit, so the pure premium P is not less than the cost of the product.

$$alpha \in [0,1], \tag{6}$$
$$beta \in [0,1], \tag{7}$$

where α is the proportion of the expected losses, and β is the proportion of the pure premium.

3.3 Global Model

From the formulation above, a multi-objective model under transportation disruption for the supply chain has been deducted. The aims are to maximize the profit of the manufacturer and the retailer. The global model is given:

$$
\begin{aligned}
\max \pi_m =& (w-c)q - qc_t - (1-\alpha)\left[\int_0^q (p-s)(q-x)f(x)dx \right. \\
& \left. + \int_q^\infty h(x-q)f(x)dx\right] - PR + (1-\beta)P \\
\max \pi_r =& (p-w)q - \alpha\left[\int_0^q (p-s)(q-x)f(x)dx \right. \\
& \left. + \int_q^\infty h(x-q)f(x)dx\right] + \beta P \\
& s.t. \begin{cases} 0 < s < c < w < p \\ 0 < h < w \\ P \geq qc \\ \alpha \in [0,1] \\ \beta \in [0,1]. \end{cases}
\end{aligned} \tag{8}
$$

Theorem 1. *The optimal order quantity for the supply chain system will achieve the maximum only if the following condition is satisfied:*

$$
\alpha^* = \frac{p-w}{p-c-c_t}. \tag{9}
$$

Proof. With the insurance contract, the system's expected profit is

$$
\begin{aligned}
\max \pi = \max \pi_m + \max \pi_r = (p-c-c_t)q - \left[\int_0^q (p-s)(q-x)f(x)dx \right. \\
\left. + \int_q^\infty h(x-q)f(x)dx\right] - PR + P,
\end{aligned} \tag{10}
$$

$$
\frac{\partial \pi}{\partial q} = p - c - c_t - [(p-s+h)F(q) - h] = 0. \tag{11}
$$

Through the function of $\max \pi_m$ and $\max \pi_r$, we can acquire the optimal order quantity q_m^* and q_r^* solving the following equation:

$$
\frac{\partial \pi_m}{\partial q} = w - c - c_t - (1-\alpha)[(p-s+h)F(q) - h] = 0, \tag{12}
$$

$$
\frac{\partial \pi_r}{\partial q} = p - w - \alpha[(p-s+h)F(q) - h] = 0. \tag{13}
$$

Then the optimal order quantity is

$$
q^* = F^{-1}\left[\frac{p-c-c_t+h}{p-s+h}\right]. \tag{14}
$$

The the optimal order quantity of the manufacturer and the retailer is showed by:

$$q_m^* = F^{-1}\left[\frac{(1-\alpha)h + w - c - c_t}{(1-\alpha)(p - s + h)}\right], \tag{15}$$

$$q_r^* = F^{-1}\left[\frac{\alpha h + p - w}{\alpha(p - s + h)}\right]. \tag{16}$$

Generate Eq. (9) into Eqs. (15) and (16), then we can get $q_m^*{=}q_r^*{=}q^*$. So only when $\alpha^* = \frac{p-w}{p-c-c_t}$ is established, the order quantity is to the most optimal value. □

4 Numerical Analysis

In this section, we examine the model by numerical analysis. The data was obtained from the Lin's paper [5], which assumed that the market demand followed uniform distribution $D \sim [400, 500]$. The other parameters were as follows: $p = 18$, $w = 15$, $c = 12$, $s = 8$, $h = 3$, $\beta = 0.6$, $R = 15\%$, and $c_t = 1$.

Take the data into the formulations, and draw the trend chart Fig. 1, which shows that the manufacturer's optimal order quantity increases as α increases, while the retailer's optimal order quantity decreases as α increases.

Let $q_m^*{=}q_r^*$, then we get $\alpha^* = \frac{p-w}{p-c-c_t} = 0.6$. We can find $\alpha^* = 0.6$ from Fig. 1 that proves the model. And from Fig. 1, we can see that the crossing is the optimal order quantity q^* as Table 2, which is equal to 461. This is the best quantity for them. So the pure premium is not less than 5532, and the purchase to the insurer needs to be 830.

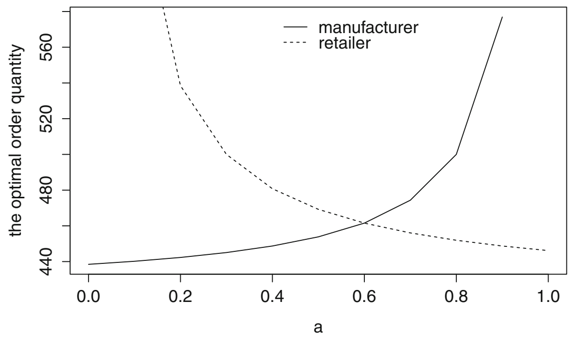

Fig. 1. The effects of α on the optimal order quantity

Table 2. The quantity under different α

Decision	0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1
m	438.46	440.17	442.31	445.05	448.72	453.85	461.54	474.36	500	576.92	∞
r	∞	653.85	538.46	500	480.77	469.23	461.54	456.04	451.92	448.72	446.15

5 Conclusion

In this paper, we describe the transportation disruption in supply chains. We set a mathematical model which we introduce the insurance contract to deal with transportation disruption the way from the manufacturer to the retailer, and use a case to investigate the applicability of this model. Although the insurance contract is effective in coordinating the supply chain, it also has some limitations. The most critical limitation is that the supplier incurs an administrative cost in monitoring the retailer's sales situation. The objective of the study is to determine the optimal order quantity in the case of the uncertainty of the market demand. This insurance contract transfers the risk from the manufacturer and the retailer to the insurance company, which protects the manufacturer and the retailer's profits and improves the efficiency of the supply chain. In particular, how much to purchase the insurance is discussed in this paper. The model is useful for decision makers to determine the product quantity.

There are several directions for this study to continue. We can extend the model to a complex supply chain with multiple manufacturers or retailers. In addition, we can apply different strategies to deal with transportation disruption.

lixiaoping@scu.edu.cn

Abstract. Electricity has become an indispensable part of human being's life. In China, regional electric power allocation, involving multiple groups who pursue the biggest social benefit, has been facing some serious problems and raising people's more and more concern. In this paper, an interval-parameter based two-stage stochastic model is built to solve the problem of planning of electric power allocation target in the perspective of the State Grid Corporation. In the model, the interval-parameter is used to deal with uncertainty of the problem and the two-stage decision making helps take corrective actions after a random events occurs. The application of the model was demonstrated efficiency and practicality with the case study in real world. Combining models proposed in this paper with some related policy implications, it is useful in improving actual operation and helping better decision.

Keywords: Interval-parameter · Two-stage stochastic programming · Electric power allocation

1 Introduction

The second industrial revolution marked the people entered the age of electricity. In recent years, the world electricity industry has experienced a great development and it played a vital role in human beings' life. According to Key World Energy Statistics by International Energy Agency (IEA), world electricity generation increased form 6131 TWh in 1973 to 23816 TWh in 2014, where the growth rate is as high as 288% [8]. However, electrical power systems are facing different problems such as economical and environmental issues. As for the electric power distribution, it is also a complex giant system which has been confusing electricity operators, and researchers have been committed to study it for a long time.

In China, during the last decades, a lasting market-oriented reform has been carried out in electric power industry. Improving the operation efficiency of electric power industry is the primal goal of the government of China, and 2016

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_92

marks the beginning of the second round of such reforms and the 13th Five-year Plan of China [3,4]. Besides, "Further strengthening the institutional reform of the electric power industry was promulgated by the State Council of China whose No. 4 attachment file is about opening electricity plan orderly to promote optimum allocation of electric power resources" [3]. Therefore, on the perspective of the national grid, how to guarantee the power supply and obtain more benefit at the same time are important questions they should face.

In the past years, many scholars studied problem of electric power allocation plan from different perspectives. Many innovative optimization techniques have been developed for allocating and managing electric power in more efficient benign ways [5,7,9,10,13]. Among these methods, linear programming is the basic and prior way to solve this problem. Recently, F. Chen et al [2] used fuzzy chance-constrained programming model to study electric power generation systems planning problem which can reflect uncertain interactions among random variables directly. For power generation systems planning, this approach can have a wider application scope than existing optimization models. However, Huang and his group proposed a new method that is interval-parameter two-stage stochastic program to solve resource management problem, such as water resource management and solid waste management [11,12,14]. This inspired us to apply this kind method to other resource management problem, for example, electric power allocation.

Birge and Louveaux introduced various kinds of two-stage and multi-stage stochastic programming problems [1]. Among them, two-stage stochastic programming is effective for analysing medium-to-long-term planning problem where the system data is characterized by uncertainty [12]. Decision makers will make an initial decision based on the future events and this is called first stage decision. Then, after the uncertainty things are resolved, the second stage decision will be made to correct the results of the first stage decision. Besides, introducing interval parameter into two-stage stochastic model can potentially address uncertainties of the problem.

The goal of the paper is to apply interval-parameter two-stage stochastic program to study problem of electric power allocation while simultaneously taking system uncertainties into account. It will be demonstrated that this kind of method can help decision makers to design more efficient plans and obtain more benefits. The paper is structured as follows: The next section is the statement of key problem. Section 3 presents process of modelling through using the method introduce in this paper. A simple case study was used to demonstrated the effective of the method in Sect. 4. In the end, the paper summarizes the main contents and contributions of this paper in Sect. 5.

2 Key Problem

This paper builds a interval-parameter two-stage stochastic programming model to better solve the problem of electric power allocation. Therefore, it is necessary to introduce some basic background of this problem.

In China, generally speaking, the State Grid Corporation and the government have joint ownership of electric power allocation right. They will make allocation decision overall considering the historical data, requirements of the local government and production capacity of electric power. The authority has an obligation to make a reasonable and scientific electric power allocation plan to achieve the best economic benefits with better resources saving because it will take a lot of resources in the process of electric power production.

Electric power allocation involves a region's residents life, industrial production and other unpredictable situations, so it is a complex system. All the groups need to know how much electric power they can expect because if the guaranteed amount cannot be provided, they have to make a change of their initial planning which may bring them a large loss. For example, the factories have to halt production and the residents have to stop their work that needs use electric power. At the same time, it is also hard for decision makers to make the allocation plan. In practice, there are many stochastic factors that will influence power supply which directly generates to the complexity of the problem. In this situation, this paper uses two-stage stochastic method to solve the problem where the authority will make two decisions. The first decision is to make allocation plan to guarantee basic demands according to historical data and the second decision is to make an compensate that is resulted by the first decision. At the same time, when the State Grid Corporation makes decisions, there are some uncertain factors such as weather, breakdown of machinery that would lead to a gap between demand and supply. Thus, treating uncertain number as interval parameter is a reasonable method to deal with problem's uncertainty.

Therefore, from this discussion, the problem can be solved by building a interval-parameter two-stage stochastic model to obtain more benefits. On one hand, the first decision of insufficient power supply can be made up by the second decision. On the other hand, by adjusting two-phase decision-making, the State Grid Corporation can acquire maximum benefits, which ensures the harmonious development of power industry to a certain extent. The mathematical form for this problem is given in the next section.

3 Modelling

In this section, a interval-parameter two-stage stochastic model with uncertain variables for electric power distribution is constructed. The mathematical description of the problem and the transformation process is given as follows:

3.1 Assumptions

(1) There is no loss during the electric power transmission process;
(2) Interval parameter of the upper and lower values can be obtained through the historical data.

3.2 Notations

To facilitate the problem description, the notations are introduced firstly.
Indices

i: index of provincial power user, where $i = 1, 2, \cdots, n$.

Decision variables

X_i: the first-stage decision variable, which is allocation target for electric power that is promised to user i;
Y_{iS}: the second-stage decision variable, which is shortage of electric power to user i when the actual allocation amount is S.

Uncertain parameters

B_i: net benefit to user i per billion kilowatt hour;
C_i: punish coefficient, which is loss to user i per billion kilowatt hour;
$D_{i\,\min}$: minimal demand of user i to ensure the normal operation of the society;
S_{ih}: the amount where the electric power allocation target is not meet for user i when actual amount of electric power supply is S_i with probabilities p_h,
S: random variable, actual total amount of electric power generation; letting S take values S_h^i with probabilities P_h.

Certain parameters

$S_{i\,\max}$: maximum allowable allocation amount for user i;
p_h: the probability of occurrence of shortage level h, where $h = 1, 2, \cdots, H$, $\sum_{h=1}^{H} p_h = 1$;
$h = 1$: actual power supply is very close to the demand and the shortage is smallest;
$h = 2$: actual power supply is relatively close to the demand and the shortage is medium;
$h = H$: actual power supply is far from to the demand and the shortage is highest.

Symbols

$+$: represent the upper limit of parameters;
$-$: represent the upper limit of parameters.

3.3 The Modeling Process

(1) Objective function

In this paper, we consider regional power grid company has the authority to allocating electric power to multiple users, with the objective of maximizing the total net benefit by optimizing allocation scheme. As these users need to know how much electric power they would be distributed so that they can make sound plans for their production activities to obtain the best social benefit. At the same time, a prescribed amount of electric power is promised to each user according to related provisions because both government and grig company have right to ensure basic function of the society. If the promised demand is met, there will bring benefits to the local economy, otherwise, power shortages could lead to many production activities cannot be carried out, resulting in economic loss. For objective target X_i, the grid company can obtain benefit $\sum_{i=1}^{n} B_i X_i$. However, when uncertain of uncovered electric power appears, the second-stage decision will be made to compensate for any adverse effect which was caused by the first stage of the decision. Therefore, the loss can be expressed as $E\left[\sum_{i=1}^{n} C_i Y_{iS}\right]$, where $E[\cdot]$ represent expected value of a random variable. So, the total net benefits is

$$\max f = \sum_{i=1}^{n} B_i X_i - E[\sum_{i=1}^{n} C_i Y_{iS}].$$

(2) Limitations

Owing to resource constraints and other reasons, there are 4 kinds of constraints and they are detailedly introduced as follows:

① Minimum power demand constraints

Local government has relative policies to promise minimum power demand of the area according to the historical data of electricity consumption so as to ensure normal social life without causing unrest. Based on the above description, we can get the constraint as follow:

$$X_i \geq D_{i\,\min}.$$

② Allowance electric power allocation constraints

For one region, the ability of electric power production is limited. Therefore, allowance allocation amount is also limited so that grid company can't distribute more than actual electric power generation volume to all users. This kind of constraints can be expressed as following:

$$Y_{iS} \leq X_i \leq S_{i\,\max}.$$

③ Available power constraints

In first-stage decision making process, X_i must be determined before actual total electric power supply S are known, while the shortage $Y_i S$ are determined during the second stage when electric power supplies are known but allocation amounts have been fixed. This kind of constraints mean that first-stage decision variable subtract second-stage decision variable should not be more than actual total supply amount. We can have this relationship expressed as:

$$\sum_{i=1}^{n} (X_i - Y_{iS}) \leq S_h^i.$$

④ Non-negative constraints

$$Y_{iS} \geq 0.$$

(3) Overall model

Based on the previous discussion, a two-stage stochastic programming can be built. In this problem, first stage decision must be made before unknown actual total supply amount. When the uncertainty of supply is uncovered, a second-stage decision can be made to compensate influence that is the result of the first-stage decision. We can formulate overall model using two-stage programming:

$$Maxf = \sum_{i=1}^{n} B_i X_i - E\left[\sum_{i=1}^{n} C_i Y_{iS}\right]$$
$$s.t.\begin{cases} X_i \geq D_{i\,\min} \\ Y_{iS} \leq X_i \leq S_{i\,\max} \\ \sum_{i=1}^{n} (X_i - Y_{iS}) \leq S_h^i \\ Y_{iS} \geq 0 \\ \forall i = 1, 2, \cdots, n. \end{cases}$$

(4) Model transformation

There are many uncertain factors in the power system. In real world problem, it is difficult to generate probability distributions for these parameters with small sample size. In this complex giant system, decision makers cannot make accurate prediction of available allocation of electric power in the system. Therefore, the target allocation X_i, net benefit B_i and punish coefficient C_i are uncertain. We introduce the concept of interval parameters to solve the problem of uncertainty, where interval number is defined as a range known upper and lower bounds [6]. Using "+" and "–" represents upper limit and lower limit of parameters respectively. Besides, to solve the problem through liner programming, the allocation S must be approximated as discrete values. In this paper, we let S take value S_i with probabilities $p_h (h = 1, 2, \cdots, H)$. Therefore, we have $E\left[\sum_{i=1}^{n} C_i Y_{iS}\right] = \sum_{i=1}^{n} C_i \cdot E\left[\sum_{i=1}^{n} Y_{iS}\right] = \sum_{i=1}^{n} C_i (\sum_{h=1}^{H} p_h S_{ih})$. Thus, the previous overall model can be converted to the following model:

$$Maxf^{\pm} = \sum_{i=1}^{n} B_{\mathrm{i}}^{\pm} \mathrm{X}_i^{\pm} - \sum_{i=1}^{n} \sum_{h=1}^{H} p_h C_i^{\pm} S_{ih}^{\pm}$$
$$s.t.\begin{cases} \mathrm{X}_i^{\pm} \geq D_{i\,\min}^{\pm} \\ S_{ih}^{\pm} \leq \mathrm{X}_i^{\pm} \leq S_{i\,\max} \\ \sum_{i=1}^{n} (\mathrm{X}_{\mathrm{i}}^{\pm} - \mathrm{S}_{\mathrm{ih}}^{\pm}) \leq S_h^{i\pm} \\ S_{ih}^{\pm} \geq 0 \\ \forall i = 1, 2, \cdots, n. \end{cases}$$

According to research of Wang and Huang [15], this model can be solved through convert interval-parameter two-stage stochastic model into two sub-models which correspond to the upper and lower bounds of the object-function value. It is difficult for decision makers to determine whether the upper bound X^+ or the lower bound X^- of the uncertain variable $X^{\pm}$ correspond to the upper bound of the total net benefit. Thus, maximized total benefit can be obtained by optimized target value. Letting $X_i^{\pm} = X_i^{-} + \Delta X_i z_i$ where $\Delta X_i = X_i^{+} - X_i^{-}$ is a fixed value and z_i is range from 0 to 1. Here, we introduce a new decision variable z_i to identify the optimized target value. Based on above statement, we can get a new transformation model as follows:

$$\max f^{\pm} = \sum_{i=1}^{n} B_{\mathrm{i}}^{\pm}(X_i^{-} + \Delta X_i z_i) - \sum_{i=1}^{n}\sum_{h=1}^{H} p_h C_i^{\pm} S_{ih}^{\pm}$$

$$s.t. \begin{cases} X_i^{-} + \Delta X_i z_i \geq D_{i\min}^{\pm} \\ S_{ih}^{\pm} \leq X_i^{-} + \Delta X_i z_i \leq S_{i\max} \\ \sum\limits_{i=1}^{n} (\mathrm{X_i^{-}} + \Delta \mathrm{X_i z_i} - \mathrm{S_{ih}^{\pm}}) \leq S_h^{i\pm} \\ S_{ih}^{\pm} \geq 0 \\ 0 \leq z_i \leq 1 \\ \forall i = 1, 2, \cdots, n. \end{cases}$$

It can be solved by reformulating above model as two submodels, and the lower bound of objective function value can be first introduced as follows:

$$\max f^{-} = \sum_{i=1}^{n} B_{\mathrm{i}}^{-}(X_i^{-} + \Delta X_i z_i) - \sum_{i=1}^{n}\sum_{h=1}^{H} p_h C_i^{+} S_{ih}^{+}$$

$$s.t. \begin{cases} X_i^{-} + \Delta X_i z_i \geq D_{i\min}^{+} \\ S_{ih}^{+} \leq X_i^{-} + \Delta X_i z_i \leq S_{i\max} \\ \sum\limits_{i=1}^{n} (\mathrm{X_i^{-}} + \Delta \mathrm{X_i z_i} - \mathrm{S_{ih}^{+}}) \leq S_h^{i-} \\ S_{ih}^{+} \geq 0 \\ 0 \leq z_i \leq 1 \\ \forall i = 1, 2, \cdots, n. \end{cases}$$

In addition, the upper bound of objective function value can be expressed as:

$$Max f^{+} = \sum_{i=1}^{n} B_{\mathrm{i}}^{+}(X_i^{-} + \Delta X_i z_i) - \sum_{i=1}^{n}\sum_{h=1}^{H} p_h C_i^{-} S_{ih}^{-}$$

$$s.t. \begin{cases} X_i^{-} + \Delta X_i z_i \geq D_{i\min}^{-} \\ S_{ih}^{-} \leq X_i^{-} + \Delta X_i z_i \leq S_{i\max} \\ \sum\limits_{i=1}^{n} (\mathrm{X_i^{-}} + \Delta \mathrm{X_i z_i} - \mathrm{S_{ih}^{-}}) \leq S_h^{i+} \\ S_{ih}^{-} \geq 0 \\ 0 \leq z_i \leq 1 \\ \forall i = 1, 2, \cdots, n. \end{cases}$$

In the above two models, we can get the optimal solution $S_{ih\mathrm{opt}}^{\pm}$ and $z_{i\mathrm{opt}}$, respectively. Then optimal objective function value is $f_{\mathrm{opt}}^{\pm}$ and it is easy to obtain $X_{i\mathrm{opt}}^{\pm} = X_i^{-} + \Delta X_i z_{i\mathrm{opt}}$. At the same time, optimal electric power allocation is $W_{i\mathrm{opt}}^{\pm} = X_{i\mathrm{opt}}^{\pm} - S_{ih\mathrm{opt}}^{\pm}$.

4 Case Study

A real case study is given in this section to demonstrate the efficiency of this method.

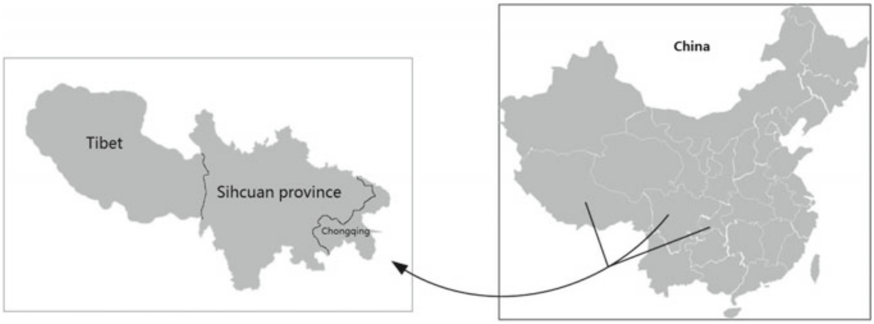

Fig. 1. The location of the case

(1) Description of case

In China, the State Grid Corporation has right to allocate and schedule electric power, which plays an important role in China's power industry. Owning to China covers a large territory, the State Grid Corporate is divided into six sectors in order to better and easier to management, which are North China branch, East China branch, Central China branch, Northeast China branch, Northwest China branch and Southwest China branch, respectively. Each branch has ability to finish their work to provide stable and reasonable power supply and in this process they can obtain benefit. Among them, Southwest China branch is mainly responsible for electric power business of Sichuan province, Tibet and Chongqing city, to manage such work as regional power grid scheduling, operation control and electric power trade.

Southwest China branch is a new sector which was founded in December, 2014. This paper chose Southwest China branch as case to study because this sectors is key to promote economic and social development of southwest of China, and to ensure the safety of national energy efficient supply in strategic height. Besides, this branch only has jurisdiction over the three region which can reduce the computation burden. And the location can be shown in Fig. 1. Therefore, through the case, we want to prove the method used in this paper is feasible.

(2) Data collection and dispose

The data was obtained from home page of State Grid Corporation, government report and market surveys. Table 1 shows the related electric power and economic data which contains demand of different user, punish coefficient and net benefit and so on. Besides, probabilities of degree of electric power shortage and the maximum allowable allocation amount are given in Table 2.

(3) Result analysis

Table 3 shows the results that indicates the most optimal electric power allocation under the different situation of power shortage. It can be seen that these interval solutions stem from uncertainty in input parameters. If the available electric power allocation can't meet the promised amount, there would bring huge loss to the users, resulting in competition among them for the limited

Electric power allocation target ($X_i^{\pm}$/billion kwh)	[2679.64,2991.56]	[631.85,667.93]	[41.25,44.08]

Table 2. The relevant probabilities and actual electric power generation

Probability (p_h)		Low ($h = 1$)	Medium ($h = 2$)	High ($h = 3$)
		0.85	0.10	0.05
Actual total amount of	$S_h^{1\pm}$	[2699.45,2734.21]	[2517.57,2683.82]	[2397.10,2503.78]
Electric power generation	$S_h^{2\pm}$	[627.56,661.08]	[608.49,625.24]	[588.67,605.23]
($S_h^{i\pm}$)/MKh	$S_h^{3\pm}$	[42.13,43.42]	[40.16,42.09]	[38.56,39.97]

electric power. Therefore, the decision making about electric power allocation target plays a vital role in the whole process of the allocation problem. The optimized targets for three uses can be obtained by letting $X_{i\mathrm{opt}}^{\pm} = X_i^{-} + \Delta X z_{i\mathrm{opt}}$, and it is 2679.42 billion kwh, 945.92 billion kwh and 43.2 billion kwh for Sichuan province, Chongqing and Tibet, respectively. At the same time, each shortage and the total benefit can be easy to know form the Table reftab:daijingqi3. From the results, the electric power would be first allocated to Sichuan province, next for Chongqing and the last for Tibet when the scarcity occurs because Sichuan province will bring State Grid Corporation the highest benefit.

In real world, suitable policy is important for decision makers to make plan of an area's sustainable electricity use. From the analysis above, solutions can be obtained by letting the different allocation targets under various policies. Different policy orientation will make the aspect of the consideration vary when decision makers think about the problem. Some policy implications will be given to help making better decision as follows. Firstly, to establish a relatively stable long-term trading mechanism where suppliers and demanders can trade on their own in the competition market. Secondly, improving the mechanism of inter-district electric power deals across the province which permits power generation companies, power users and electricity sell bodies can make occasional trade when electricity is in short supply in a day. Thirdly, environmental protection also is the topic that policy makers need to be concerned with. Thus, forming

market mechanism to promote renewable energy use to promise priority use of clean energy.

5 Conclusions

This paper studied interval-parameter two-stage stochastic model applying to the problem of electric power allocation. By using the proposed model, we considered not only how to make a more stable consumer plan, but also let decision makers can benefit more form it. In the process of model building, we overcame uncertainties of the problem through introducing interval-parameter into the model, which at the same time got over complexity of solving process. The initial model was transferred into two submodels so as to obtain solutions, avoiding system failure risk of interval solution. Of course, the approach was demonstrated effective by using data form Southwest branch of the State Grid Corporation of China as a case study. Through analysing result of the case study, some policy implications were proposed in the end which may offer help to regulators of electric power allocation to make decision.

Compared with previous studies, this kind of method is innovative to be applied in the electric power allocation which has good practicality value. However, this method was built based on the assumption that the upper and lower boundary is known. Besides, the probabilities of degree of electric power shortage are also directly given. The future research may focus on these two points to make the study more rigorous, which can better deal with the uncertainty. Besides, some suitable policy simulation also can be put forward to help better decision making.

Abstract. With the consumer's ecological cognition becoming more and more higher, remanufacturing has became a trend. It is imperative for contemporary enterprises to find out some ways to balance the profit of supply chain and the government. In this paper, we consider the closed loop supply chain that consists of the manufacturer, retailer and consumers. The retailer is responsible for the acquisition of used products from consumers, and sold them together to the manufacturer. Then the manufacturer producing new products and remanufactured products, they were sold together in the market. Based on the ecological cognition and value judgment of consumers, it is easy to derive the demand quantity of remanufactured products and new products. First, we formulate the cooperative and competitive game model to investigate the manufacturer's and retailer's pricing strategy. Next, in the case of different ecological cognition, we studied the behavior of government subsidy. A mathematical model is presented to formulate the problem to get the optimal decision for the government. Finally, we compare the characteristics of the two models, and draw the corresponding conclusions.

Keywords: Ecological cognition · Cooperative and competitive game model · Closed loop supply chain · Government subsidy

1 Introduction

In the competitive business environment, it is imperative for businesses to consider the resource shortage and environmental pollution. In our country, they are seriously restricting the development of society. Without doubt that recycling of solid waste is an effective way to save resources and reduce pollution. In the recent years, the government has advocated a resource-saving and environmentally friendly mode of production, and resulting in large-scale academic researches on remanufacturing. Therefore, Wei et al. [25] analyzed the obstacles and the incentive factors that should be given in the manufacturing process of China.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_93

In the process of reverse logistics, the factors affecting the recycling of used products are numerous. Pankaj et al. [6] have done a research on the possibility of three way recycling options. Llgin et al. [13] analyzed four major categories about remanufactured products. Fleischmann et al. [8] studied quantitative models for reverse logistics, and [5,11] researched on sustainable development of supply chain systems. In addition, Thierry et al. [24] researched strategic issues on recycling and management product. The spare parts research is also very important, so Ruud H et al. [23] considered the uncertain quality of the used products. Chari et al. [2] addressed a problem about the repairable spare parts to find the cost-optimal production strategy. In order to further study the acquisition price and the quantity of remanufactured products, Shaligram [21] studied the impact of the consolidation center and collection centers. Based on the study of Shaligram et al., Gönsch Jochen [10] supposed that the quantity of used products and replacement parts are unrestricted. Sung et al. [14] devoted to developing optimal production planningnings for different production strategies.

The production demand of remanufactured products is extremely uncertain, so Mitsutaka [17] and others predict the demand of the product by time series analysis. Shi et al. [22] developed an option pricing model to evaluate the acquisition price of used products under uncertain demand and return. For the sake of considering the actual situation of the remanufacturing process will be interrupted, B.C. Giri and S. Sharma [9] studied the complex production planningning under the uncertain demand when the product supply is interrupted. Because there is always a variety of products were produced at the same time, so Shi et al. [22] considered the demand of many kinds of products are uncertain. For solving the problem systematically, Cheng [26] studied the influence of the new product design on the pricing strategy. In order to solve the pricing strategy, a model is established by using the Brown model [16]. Chen et al. [4] used the dynamic programming method to obtain dynamic pricing strategy. Also consider the study of competition, such as Mitra [18] researched the competition strategy under the monopoly industry. Adem et al. [20] researched the competition between an original equipment manufacturer and an independent remanufacture. In the closed-loop supply chain, Chen and Chang [3] considered a remanufacturing models under cooperative and competitive.

Due to the emergence of remanufactured products, many consumers have a different treatment of remanufactured products and new products. Ferrera et al. [7] chosen differentiated prices for new products and remanufactured products. Benjamin et al. [12] considered the role of ambiguity tolerance in consumer perception of remanufactured products. [1,19] consider the impact of government subsidies on the remanufacturig activities. The scholar Li [15] divided the demand of products into two categories by the ecological cognition of consumers, and made a research on the policy of the government subsidy. In this paper, based on the above, we discuss the problem of remanufacturing in closed-loop supply chain, based on ecological cognition and government subsid, then formulate the cooperative and competitive game model to investigate the manufacturer's and retailer's pricing strategy.

This paper is organized as follows: model description is reviewed in Sect. 2 and the proposed model is given in Sect. 3. The key parameters are analyzed in Sect. 4 and the comparison of models will be given in Sect. 5. Finally, some conclusions are summarized in Sect. 6.

2 Model Description

In this paper, we consider three stakeholders, they are manufacturer, retailer and consumer. The manufacturer will produce remanufactured products and new products, and then sold them together to the retailer. The retailer sold remanufactured products and new products to consumers, and collected used products from the consumers, then provide them to manufacturers. The reverse logistics is commissioned by the manufacturer, the manufacturer gives the acquisition price to stimulate the retailers to collect the used products. Thus, the closed-loop supply chain model is shown in Fig. 1.

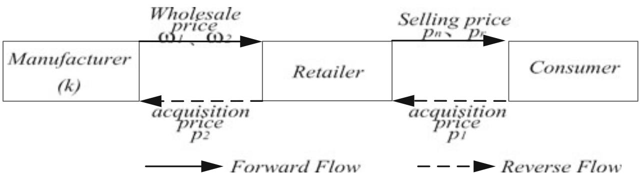

Fig. 1. Model structure of closed loop supply chain

The model structure studied the case of a single manufacturer and a single retailer. Besides, the manufacturer is the leader in the closed loop supply chain. In this paper, we only consider the government takes the corresponding policy mechanism to stimulate the manufacturer. The remanufacturer derives the market demand function of remanufactured products and new products based on the cognitive degree of consumers, then makes the production planning of the product and determines the wholesale price of the product. On the other hand, in order to ensure the orderly conduct of the manufacturing process, the acquisition price is determined by the manufacturers, and the corresponding used product planning is established. Retailers are the followers, according to the manufacturer's wholesale price and acquisition price to determine the retail price of finished product and acquisition price of used products, and optimize their own profit. Finally, we explore the effects of cooperative and competitive model on pricing strategies.

2.1 Notations

The following notations would be used throughout the model

Θ : Ecological cognition of remanufactured products;
p_n : The unit selling price of new product;
p_r : The unit selling price of remanufactured product;
C_1 : The unit cost of sales for new product;
C_2 : The unit cost of sales for remanufactured product;
p_1 : The unit acquisition price of the retailer to user;
p_2 : The unit acquisition price of the manufacturer to the retailer;
C_r : The unit production cost of remanufactured product;
C_n : The unit production cost of new products;
k : Government subsidies for the remanufacturer productions;
q_r : The demand quantity of remanufactured products;
q_n : The demand quantity of new products;
ω_r : The unit wholesale price of remanufactured products;
ω_n : The unit wholesale price of new product;
Π_r : The profit function for retail;
Π_n : The profit function for manufacturer;
Π : The profit function for the supply chain.

2.2 Assumptions

Assumption 1. The decision of the consumer to purchase the product is based on the utility of the product. Then we supposed the consumers' evaluation of new products is v, and supposed the v is uniformly distribution, its probability density function is:

$$f(x) = \begin{cases} 1, \, x \in [0,1] \\ 2, \, x \notin [0,1] \, . \end{cases}$$

Supposed that the market size is 1, and each consumer only buy one product.

Assumption 2. We defined the θ is the degree that consumer based on environmental awareness and willing to buy the remanufactured products. We supposed $0 \leq \theta \leq 1$, when $p_n > \theta v$, customers will not buy new products, when $p_r > \theta v$, customers will not buy remanufactured products. And if $p_n \leq v$, $p_n > \theta v$, meanwhile, $\theta v - p_r \leq \theta v - p_n$, consumers will choose the new products. When $p_n \leq \theta v$, $p_r \leq \theta v$, and $v - p_r \leq \theta v - p_n$, consumers will choose the remanufactured products.

Assumption 3. Due to make the production continue, here, we assume that $p_1 \leq p_2, C_r \leq C_n$.

Assumption 4. Manufacturers and retailers are based on complete information symmetry, it means that each of them fully learn of the cost of each other, pricing, strategy, and other relevant information, so that the next Steinberg game model can work well.

Assumption 5. Suppose that in the process of remanufacturing, the rate of production is 100%. It means that no waste products in the process of manufacturing. And used production can meet the market demand.

Assumption 6. According to the degree of consumers' cognition, the market demand function of remanufactured product and new products is derived:

$$q_n = 1 - \frac{p_n - p_r}{1-\theta}, \quad \frac{p_r}{\theta} \le p_n \le p_r + 1 - \theta,$$
$$q_r = \frac{\theta p_n - p_r}{\theta(1-\theta)}, \quad p_n + \theta - 1 \le p_r \le \theta p_n.$$

3 Model Development

Based on the above, we obtain the profit function of the manufacturer and the retailer, the profit function of manufacturer:

$$\pi_n = (\omega_n - c_n)q_n + (\omega_r - c_r - p_2)q_r + kq_r. \tag{1}$$

The first element on the right side of the equation is the profit of the manufacturer for selling new products; The second element on the right side of the equation is the profit of the manufacturer for selling remanufactured products; the third element on the right side of the equation is the profit of the manufacturer produces the remanufactured products and then gets the government subsidies.

The profit function of retailer:

$$\pi_r = (p_n - \omega_n - c_1)q_n + (p_r - p_1 - c_2 - \omega_r + p_2)q_r. \tag{2}$$

The formula on the right side of the first represent the profits of retailer for selling new products, of which second is stand for the profits for selling remanufactured products. So there is a total profit of the closed-loop supply chain:

$$\pi = \pi_n + \pi_r = (p_n - c_n - c_1)q_n + (p_r - p_1 - c_r - c_2 + k)q_r. \tag{3}$$

In this paper, we consider the following two cases in the closed loop supply chain.

3.1 Competitive Pricing Strategy

In the competitive pricing strategy, the manufacturer and the retailer take their own benefit maximization as the decision-making goal respectively. In this decision models, the manufacturer is in the dominant position, and the retailer is the follower. So the paper uses the reverse induction method to solve the model. The derivation of the above formula, we can get:

$$\begin{bmatrix} \partial^2\pi_r/\partial^2 p_n = 2/(\theta-1) & \partial^2\pi_r/\partial p_n \partial p_r = -2/(\theta-1) \\ \partial^2\pi_r/\partial p_r \partial p_n = -2/(\theta-1) & \partial^2\pi_r/\partial^2 p_r = 2/(\theta(\theta-1)) \end{bmatrix}.$$

In order to verify whether there is the optimal solution of the equation, we need to calculate the characteristic value of Hessian matrix and judge that they are negative. After that we get Matrix eigenvalue:

$$\begin{bmatrix} -(\theta-(5\theta^2-2\theta+1)^{(1/2)}+1)/(-\theta^2+\theta) & 0 \\ 0 & -(\theta+(5\theta^2-2\theta+1)^{(1/2)}+1)/(-\theta^2+\theta) \end{bmatrix}.$$

Next, we just need to prove it: $(\theta-(5\theta^2-2\theta+1)^{(1/2)}+1)/(-\theta^2+\theta)>0$. And then we can get the conclusion that the Hessian matrix is negative, so there is a corresponding maximum value. Due to the $\theta\in[0,1]$, the denominator is greater than zero, it is necessary to prove that the molecule is greater than zero. Easy to get $4\theta-4\theta^2$, so in this model, the retailer has the optimal retail price. We take the partial derivative of Eq. (2):

$$\partial\pi_r/\partial p_n=0\partial\pi_r/\partial p_r=0.$$

And obtain that:

$$p_n=(c_1-c_2-\theta-p_1+p_2+2p_r+\omega_n-\omega_r+1)/2, \tag{4}$$
$$p_r=(c_2+p_1-p_2+\omega_r-c_1\theta+2\theta p_n-\theta\omega_n)/2. \tag{5}$$

Using formula (4) and (5), we can get:

$$p_n=(c_1+\omega_n+1)/2, \tag{6}$$
$$p_r=(c_2+\theta+p_1+\omega_r-p_2)/2. \tag{7}$$

Put p_r and p_n into the Π_n, and then consider the equation:

$$\begin{matrix}\partial\pi_n/\partial\omega_n=0,\\ \partial\pi_n/\partial\omega_r=0\end{matrix}.$$

At last, we can obtain that:

$$\omega_n^*=(1/2)(c_n+1-c_1), \tag{8}$$
$$\omega_r^*=(1/2)(c_r-c_2+\theta-k-p_1+p_2). \tag{9}$$

Combine Eqs. (6), (7), (8) and (9), we can get that:

$$p_n^*=(1/4)(c_1+c_n+3), \tag{10}$$
$$p_r^*=(1/4)(c_2+3\theta-k+p_1-p_2+c_r). \tag{11}$$

In this paper, use * to represent the optimization.

3.2 Cooperative Pricing Model

Under this model, the manufacturer and the retailer take the Π as the objective function. This problem can be translated to the maximum value of the equation:

$$\pi=\pi_n+\pi_r=(p_n-c_n-c_1)q_n+(p_r-p_1-c_r-c_2+k)q_r. \tag{12}$$

The Hessian matrix of the equation is obtained as follows:

$$\begin{bmatrix} \partial^2\pi/\partial^2 p_n = 2/(\theta-1) & \partial^2\pi/\partial p_n \partial p_r = -2/(\theta-1) \\ \partial^2\pi/\partial p_r \partial p_n = -2/(\theta-1) & \partial^2\pi/\partial^2 p_r = 2/(\theta(\theta-1)) \end{bmatrix}.$$

In the same way, we can know that there is a optimal solution. And solved it, we can get that:

$$p_r^* = (1/2)(c_2 + c_r + \theta - k + p_1 + p_2), \tag{13}$$

$$p_n^* = (1/2)(c_1 + c_n + 1). \tag{14}$$

4 Numerical Example

In order to describe the effect of θ on p_n, p_r, q_n, q_r, we fixing the other parameters as the base setting: $C_1 = 0, C_2 = 0.05, C_n = 0.2, C_r = 0.15, k = 0.04, p_1 = 0.05$ and $p_2 = 0.08$. Then we made the Tables 1, 2, and compared the different in the two model. By the way, and in the next graphic analysis, if there is no special note, the value of the parameters as the same as the table. From the following table: In the cooperative pricing model, the government's regulation should be greatly strengthened. Because in the Table 2, the number of remanufactured products appear negative growth, and their sales prices are gradually increasing. It means that the remanufactured products is no profit at all, the only way is to continuously improve the sales price of remanufactured products to get profit. As can be seen from the table, the sales price of new product does not change with the increase of θ. The reason is that we use the reverse induction method to solve this model. The retailers is the first to determine the market price, then manufacturer get the price of wholesale. As a result, the sales price of new products is only related to the cost of sales and production cost of new products.

First, we make some graphic analysis in the model of competition. The effect of θ on market demand and market profits is now studied and the results are shown in Figs. 2 and 3 respectively.

For the analysis of the Fig. 2, we have the following conclusions: at the intersection, when the $\theta = 0.8781$, the market demand for new and remanufactured

Table 1. The effect of θ on parameter in competition

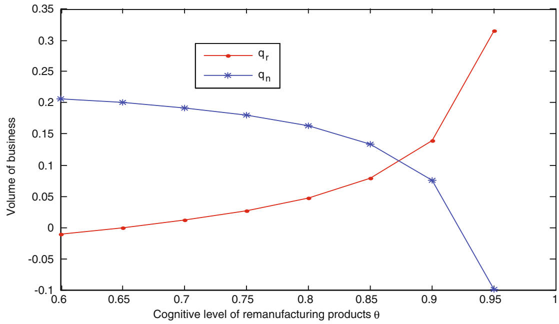

Fig. 2. The effect of θ on market demand.

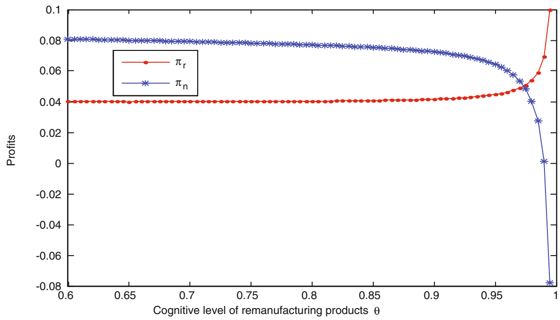

Fig. 3. The effect of θ on market profits

products is equal. At this case, when $\theta > 0.8781$, consumers tend to buy manufactured products. Manufacturer can only producing the remanufactured products when the remanufactured product is profitable enough. When $\theta = 0.9300$, manufacturers no longer produce the new products, because at this point, the demand for new products is zero. Why it happened? Maybe there is no bias towards the new products and remanufactured products, and the price of the remanufactured product is lower than the new product. In Fig. 3 we can draw that: when $\theta = 0.9735$, the remanufacturer and the retailer's profit is equal, and in this mode, the manufacturer produces remanufacturer products are negative profits. As in Fig. 2, with the increase number of remanufacturer products, the manufacturer's profits have been negative growth. And it is found that they can produce remanufacturer products to adjust the profit distribution between manufacturer and retailer. When θ is larger than 0.9901, the manufacturer is no longer profitable, if retailer and government do not adjust it in this case, the mode of production will no longer continue. It can be seen that the remanufacturing does not allow manufacturers to make a profit. As a result, the main incentive for manufacturers to make the profit will be to improve remanufacturing technology, save remanufacturing costs and get more government subsidies.

Here, we consider the situation: when the degree of ecological cognition is very low, in order to advocate environmental protection activities, how should the government make the decisions? We considered the following three cases, see the chart below.

From the Fig. 4, it is observed that when $\theta = 0.6000$, $k_1 = 0.05$, the retailer's profit appears to the minimum value. With the increase of K, which can reduce the number of new product and increase quantity of remanufactured products. The wholesale price of products will be reduced with the increase in government subsidies. As a result, the unit selling price of remanufactured product also begins to reduce. Due to the decrease in the number of new product, retailers' profits

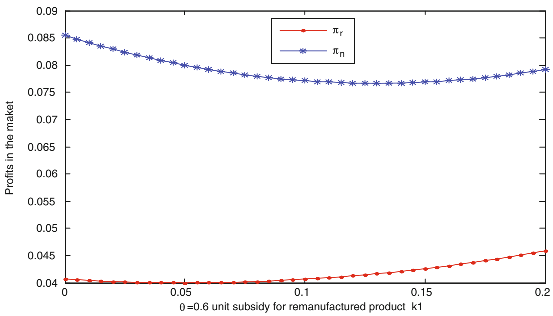

Fig. 4. The impact of government subsidies on market profit when $\theta = 0.6$

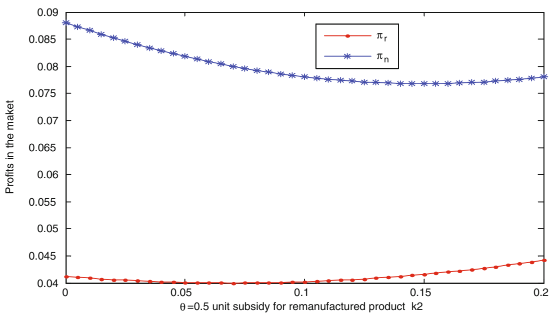

Fig. 5. The impact of government subsidies on market profit when $\theta = 0.5$

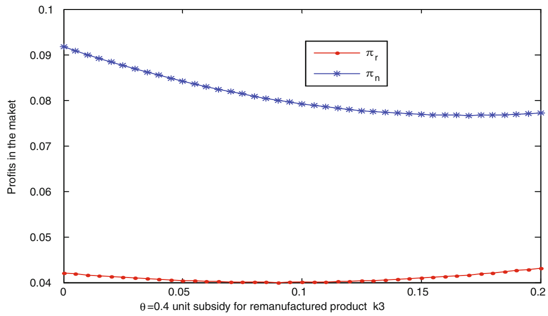

Fig. 6. The impact of government subsidies on market profit when $\theta = 0.4$

continue to decline. Only when the government subsidy is greater than 0.05, the retailer's profit began to grow. We can find the selling profits mainly come from new products. The pr decreases with the k_1 increase, that makes the consumer tends to buy remanufactured products. As a result, the demand of new product begin to decline. When the $k = 0.13$, because the government subsidies make up for the loss in remanufacturing, the manufacturers' profit function begins to grow, so the retailer's selling price also increased significantly. From the Figs. 4, 5 and 6 we can draw that: in the case of other variables are constant, the smaller the value of θ, the more serious decline in the profit function. It should be noted that with the decrease θ the lowest point of red and blue line start move to the right. We can draw that the higher cognition of remanufactured products, the government's subsidy will be smaller. The model also reveals that manufacturers and retailers will not be able to make a remanufacturing activity if the government does not take the policies and give subsidies.

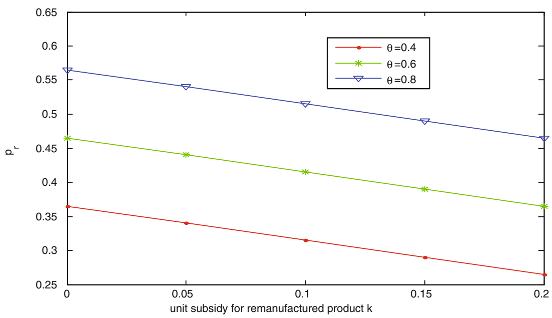

Fig. 7. The variation of p_r with respect to K under different θ

Next, we make some graphic analysis in the model of cooperation. In order to make more profits, the manufacturer and retailer set prices together. We assumed that other factors are constant, and then discuss the k if the government wants

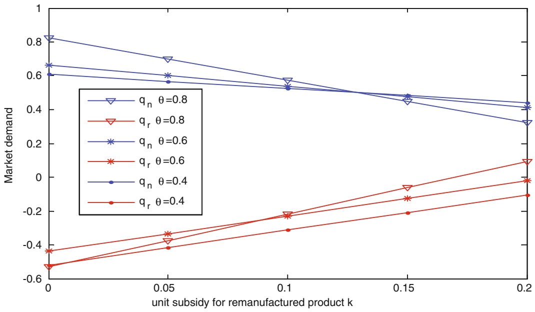

Fig. 8. The variation of market demand with respect to K under different θ

to make remanufacturing continue. From the previous discussion, we learn that the change of k does not affect the p_n. So we compared the effect of k on p_r in the following cases. As follows: from the Fig. 7, we can clearly see a linear relationship between the p_r and k, the ratio is -0.5. The more greater the k, the more smaller the unit retail price of remanufactured products. At the same time, we can also find that in the process of pricing, government subsidies are particularly important. At the same time, we also compared the demand function of new products and remanufactured products in the Fig. 8. It is obvious that when the θ is bigger, the demand market of remanufactured products or new products are more sensitive to the k. Because with the increase of θ, the more steep line. When the $\theta = 0.8$, the government needs to provide at $k = 0.17$, because the quantity of remanufactured products is zero at this point of $k = 0.17$. Only when k0.17, the closed loop supply chain can continue to remanufacturing. For the sake of reducing the subsidy, the government can do the following adjustments: to enhance ecological cognition of remanufactured products and increase the value of θ. Because in the Fig. 8, we can know that the θ is more bigger, the possibility is more higher for manufacturer to remanufacturing. Secondly, our government should establish a complete production system of closed loop supply chain, it can reduce the unnecessary cost waste. Besides, remanufacturing costs account for a large proportion of the cost of production, and it seriously hinders the development of remanufacturing. It is necessary for government to provide technical support for the remanufacturing. At last, if the government can destruct the joint policy of manufacturers and retailers, it will take profit to him. Because in the joint pricing strategy, the new products can bring more profits to them.

5 Comparison of Models

In this paper, we study cooperative and competitive game model in the closed loop supply chain. In the model of competition, due to the manufacturers and retailers make decisions respectively, there is competition between them. Producing the remanufactured products can adjust the interests of the relationship between the manufacturer and the retailer. It is benefit for the government to promote remanufacturing. And the retailer more like to make remanufactured products to compete interests with manufacturer. But From Tables 1 and 2 we can obviously find remanufacturing hurts the interests of manufacturer, retailer and consumer. So them will choose cooperative pricing model. In the Fig. 7, it is not difficult to find that the total profit of cooperation is always higher than the competition. Producing remanufactured products could not make profits, so the profits always decrease with the increase of the degree of cognition. When the θ from 0.9 to 0.95, there is a sharp decline in the total profit of the two models. The reason is the rapidly decrease in the number of new products and the number of remanufactured products rapidly increase. It proves again that produces the remanufactured products will not bring profit to manufacturers. The main reason of remanufacturing could not make profits is that the remanufacturing technology has not kept pace with the society. It also reveals that if the government not take any actions, it will happen nothing on remanufacturing.

6 Conclusion

In this paper, we consider the closed loop supply chain that consists of the manufacturer, retailer and consumers, discuss two models of cooperative and competitive game model. At the same time, we using the game theory to analysis the model and the conclusions are the following.

In the cooperative and competitive game model, if the government no support or no provide subsidy, remanufacturing will not be able to carry on. And in the cooperative game model, the government's regulation should be strengthened. Because the cooperation is not conducive to producing remanufactured products. As the number of new products and profits are declining, manufacturers have a reason to down the price of new products to get more quantity. But the optimal wholesale price in this paper has nothing to do with θ, maybe in this model we use the reverse induction method to solve the model, the retailers is the first to determine the market price, then manufacturer make the price of wholesale. What's more, producing remanufactured products can adjust the profit distribution between manufacturer and retailer. And in cooperation, it can bring higher profit to the supply chain. But it does not accord with the interests of the government. In order to save economic costs, the government is more willing to see them make decisions separately. With the θ raised, it will not good for manufacturers and retailers, but it is good for the government to take actions. The discussion of these two models is very important for our research in the future, and give the direction of the government to advocate green environmental protection. In the future work, we could consider the complex closed loop supply chain systems with multiple manufacturers and multiple retailers, and the used products will be pre-sale to the manufacturers. What's more, used products will be divided into different grades by the consolidation center. The consolidation center will be the new participator in the future model.

Abstract. In this paper, we firstly use simulation methods to reach the conclusion that the beds allocation scheme under centralized management mode is more advantageous to either elective surgery patients or day surgery patients, and the beds allocation scheme under decentralized mode is more equitable. Then we do a large number of experiments to explore the beds number allocate to day surgery patients under centralized management mode, and seek the allocation scheme which is advantageous to day surgery patients and the equity is closest to the same situation under decentralized mode. At last, based on the data we obtain from the experiments, regression and neutral network are used to predict the beds number allocated to day surgery patients under centralized management mode.

Keywords: Day surgery · Beds number prediction · Linear regression · Neural network

1 Introduction

There are three types of surgery management modes adopted overseas: day surgery center inside a hospital, free-standing day surgery center and operation room at the clinic [7]. The mainly adopted mode in our country is day surgery center inside a hospital under three different management modes: centralized management mode, decentralized management mode and the management mode combining centralized mode and decentralized mode. Centralized management mode is an integrated management mode where day surgery center, as the centralized management platform, assembles all patients together to conduct centralized admission, scheduling and follow-up visit. While decentralized management mode is a mode where day surgery is managed by departments.

In this paper, we study hospitals under the mode where centralized and decentralized management coexist. Under centralized management mode, day surgery patients are admitted in day surgery center where their admission, operation and discharge are arranged. Day surgery center is self-contained with wards

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_94

and operation room. The beds and operation rooms of day surgery patient are dedicated, not shared with elective patents. Under decentralized mode, wards and operation rooms of day surgery and elective surgery are managed by departments. The beds and operation rooms has no boundary between day surgery patients and elective surgery patients, i.e. to some extent, beds and operations are shared by day surgery patients and elective surgery patients.

We conduct simulation study on centralized and decentralized management modes in this paper. Through a large number of simulation experiments, we reach the conclusion that centralized management mode is more advantageous to either elective surgery patients or day surgery patients. And decentralized management mode is more equitable. While the development of day surgery is encouraged, centralized management mode is a better choice. But if beds allocation is far from equitable under centralized management mode, it will be exceedingly advantageous to one of the two types of patients. Thus, in this paper, we seek the beds number allocate to day surgery patients, under Centralized management mode, that is advantageous to day surgery patients and has Equity Closest to the same situation under Decentralized mode (CECD). Based on the large amount of simulation data, we screen out characteristic variables and use regression and neural network to predict the beds number allocate to day surgery patients under CECD. And then we verify the effectiveness of the regression equation and neural network model.

Technological and theoretical advances in computer science and mathematics offer new options to complement traditional statistical analysis [7]. A major focus of machine learning research is to automatically learn to recognize complex patterns and make intelligent decisions based on data. In the past decade, machine learning algorithms have revealed previously undetected trends in historical data [9,13]. Especially, artificial neural network and traditional linear regression are effective method. There are some studies use linear regression and neural network to predict the objective function value. Such as, Menke et al. [7] designed an artificial neural network to predict emergency department volume. Shi et al. [11] performed hierarchical linear regression and propensity score matching to test hospital/surgeon volume for associations with breast cancer surgery costs. Tsai [12] developed artificial neural network models to predict length of stay for inpatients with one of the three primary diagnoses: coronary atherosclerosis, heart failure, and acute myocardial infarction in a cardiovascular unit in a Christian hospital in Taipei, Taiwan. Li et al. [15] proposed an artificial neural network model to predict the severity of menopausal symptoms. Launay et al. [5] used artificial neural networks to predicate of prolonged length hospital stay in older patients hospitalized in acute care wards after an emergency department. Gholipour et al. [4] used a neural network for predicting survival and length of stay of patients in the ward and the intensive care unit of trauma patients and to obtain predictive power of the current method. Wise et al. [14] used artificial neural network model to provide vascular surgeons a discriminant adjunct to assess the likelihood of in-hospital mortality on a pending Ruptured abdominal aortic aneurysm admission. Some studies use linear regression and neural network to study the influencing factors of disease or identify influencing factors. Such as, Shakerkhatibi et al. [10] were conducted to evaluate the relationship between air pollutants and hospital admissions for cardiovascular and respiratory diseases using the artificial neural networks and conditional logistic regression modeling. Abdullah [1] aimed to model the relationship between Health Related Quality of Life variables using an integrated model of fuzzy inference system and linear regression. Bonellie [3] used regression and logistic regression models to investigate changes over time in size of babies particularly in relation to social deprivation, age of the mother and smoking. Some studies use linear regression and neural network do clustering and classification, Aguiar et al. [2] developed one artificial neural network model for classification and another risk group assignment for Pulmonary tuberculosis in hospitalized patients. And some studies focus on the methods improvement. Russell et al. [8] through their research discovered that bayesian linear regression provides a significantly more accurate estimate of the rate of change in mean sensitivity than the standard ordinary least squares linear regression approach.

Artificial neural network and traditional linear regression can be well applied to the prediction of the objective function value, the identification of the influencing factors, clustering and classification. In our paper, we use linear regression and neural network to predict the objective function value, the beds number under CECD.

2 Evaluation of Two Management Mode of Day Surgery Based on Simulation

2.1 Parameters

In this paper, taking Laparoscopic Cholecystectomy (LC) as an example, we build two simulation models. Model I is the centralized management model, where beds and operation rooms occupied by day surgery patients and elective surgery patients are independent. And there are dedicated beds and operation rooms for day surgery patients. That is day surgery patients wait in a queue for admission and operation according to the First Come and First Served (FCFS) policy, they can only occupy beds and operation rooms dedicated to day surgery patients on admission. And elective surgery patients wait in other queue for admission and operation according to the FCFS policy, they can only occupy beds and operation rooms dedicated to elective surgery patients on admission. Model II is the decentralized management mode, where beds and operation rooms occupied by day surgery patients and elective surgery patients are shared, i.e. day surgery patients has no dedicated bed or operation room. Day surgery patients and elective surgery patients wait in one queue for admission and operation according to the $FCFS$ policy.

Significant input parameters of the model are as follows.

B : total number of beds for day surgery patients and elective surgery patients;
B_D : number of beds for day surgery patients;
B_E : number of beds for elective surgery patients, $B_D + B_E = B$;
λ_D : arrival rate of day surgery patients (unit: person per day);
λ_E : arrival rate of elective surgery patients (unit: person per day);
OT_D : operation time of day surgery patients (unit: hour);
OT_E : operation time of elective surgery patients (unit: hour);
RT_D : length of hospital stay after operating day surgery (unit: hour);
RT_E : length of hospital stay after operating elective surgery (unit: hour);
WT_1 : average waiting time before admission (unit: hour), in this paper we define
$WT_1 =$ time of admission $-$ time of arrival;
A_D : number of day surgery patients arrived (unit: person);
A_E : number of elective surgery patients arrived (unit: person);
S_D : number of day surgery patients served (unit: person);
S_E : number of elective surgery patients served (unit: person);
S : total number of surgery patients served (unit: person), $S = S_D + S_E$

2.2 Simulation Results and Analysis

In this paper, we define the regular opening hour of each operation room as 8 h, at the end of each workday, operations still in progress should be finished with extra work, newly-opened operations are not allowed, and operation rooms are closed for weekends. When we conduct simulation in this paper, OT_D, RT_D, OT_E and RT_E are considered as random numbers generated according to the mean values and standard deviations in Table 1.

Table 1. Descriptive statistics result [6]

	Surgery type	N	Mean value	Min	Max	SD	SE mean
OT	Elective surgery	1841	72.2819	20	1116	56.92553	1.32672
	Day surgery	682	64.0176	20	674	33.30224	1.27521
RT	Elective surgery	1841	2696.3781	920	43285	2391.37266	55.73402
	Day surgery	682	1198.2361	600	8355	713.50039	27.32134

The simulation period of Model I and Model II are both 1 year, and the conclusion we reach through a large number of simulation experiments are in accordance. In this paper we only elaborate on the simulation result when $_D = 8$, $_E = 30$. The number of elective surgery patients arrived (A_D), number of elective surgery patients arrived (A_E), number of day surgery patients served (S_D), number of elective surgery patients served (S_E), total number of surgery

Table 2. Simulation result when $\lambda_D = 8$, $\lambda_E = 30$ (simulation period: 1 year, approximately 260 days)

Model	$A_D(p)$	$A_E(p)$	$S_D(p)$	$S_E(p)$	$S(p)$	$WT_1(h)$
Model I ($B_D = 4$)	2080	7800	1118	4324	5442	1397
Model I ($B_D = 5$)	2080	7800	1404	4247	5651	1308
Model II	2080	7800	1148	4306	5454	1382

patients served (S), average waiting time before admission (WT_1) are shown in Table 2.

According to Table 2, under the condition where $B_D = 4$, Model I has 30 fewer day surgery patients served than Model II, 18 more elective surgery patients served than Model II. To sum up, Model I has 12 fewer patients served than Model II, and 15 h longer average waiting time before admission than Model II.

While, under the condition where $B_D = 5$, Model I has 256 more day-surgery patients served than Model II, 59 fewer elective-surgery patients served than Model II. To sum up, Model I has 197 more patients served than Model II, and 74 h shorter average waiting time before admission than Model II.

The result shown in Table 2 indicates that, under centralized management mode, bed and operation room resources of day surgery and elective surgery are respectively independent, and it is advantageous either to elective surgery patients (under the condition where $B_D \leq 4$ in Table 2) or day surgery patients (under the condition where $B_D \geq 5$ in Table 2). While, under decentralized mode, bed and operation room resources are shared between day surgery patients and elective surgery patients, so it is more equitable. Under centralized management mode, when allocation is more advantageous to elective surgery patients (i.e. fewer beds are allocated to day surgery patients, and more elective surgery patients are served at the cost of having fewer day surgery patients served than decentralized mode), fewer patients are served within equal time period and the average waiting time before admission is much longer when compared to decentralized mode. When allocation is more advantageous to day surgery patients (i.e. more beds are allocated to day surgery patients, and more day surgery patients are served at the cost of having fewer elective surgery patients served than decentralized mode), a lot more patients are served within equal time period and the average waiting time before admission is much shorter when compared to decentralized mode. While the development of day surgery is encouraged, centralized management mode is a better choice. However, if bed allocation is far from reasonable under centralized management mode, it will be exceedingly advantageous to one of the two types of patients, such as the result in Table 2 when $B_D < 4$ or $B_D > 5$. For the convenience of applying the predictions in hospital management, the following work in this paper use simple calculation to explore the beds number allocate to day surgery patients under CECD, i.e. situation in Table 2 where $B_D = 5$, that is advantageous to day surgery and has equity closest to decentralized mode. Taking no account of limitation to operation room resource, we conduct a large number of simulation experiments in this paper and obtain the data of beds number under CECD with distinct arrival and service time. By screening out characteristic variables, we predict the beds number under CECD through linear regression and neural network in the following sections.

3 Linear Regression Prediction

In this section, we use linear regression to predict the beds number allocate to day surgery patients under CECD. Table 3 shows the value of parameters used in regression, where input parameters are shown in the first 11 columns, MV_{OT_D} denotes the mean value of OT_D, SD_{OT_D} denotes the SD of OT_D and so on. B_{CECD} denotes the output of predictions. 100 sets of experiment data are used.

Table 3. Value of input and output parameters used in regression

λ_D	λ_E	MV_{OT_D}	SD_{OT_D}	MV_{OT_E}	SD_{OT_E}	MV_{RT_D}	SD_{RT_D}	MV_{RT_E}	SD_{RT_E}	B	B_{CECD}
10	13	45	21	130	55	892	430	3470	1626	26	4
25	9	95	13	125	43	1098	132	1427	1046	24	13
13	16	44	25	165	58	744	451	1645	2394	11	2
...	...	...	...	...	...	...	...	...	...	...	...
26	11	53	17	78	22	1059	150	1151	949	18	9
25	11	55	26	67	54	1161	397	3167	1825	27	10

Let all the input and output in Table 3 stay unchanged, we enter them into regression equation and find redundant variables in the input parameters. Through stepwise regression, we identify MV_{OT_D}, SD_{OT_D}, MV_{OT_E}, SD_{OT_E}, SD_{RT_D} and SD_{RT_E} as redundant variables. In hospital management practice, the operation time is usually shorten than the length of hospital stay after surgery, so MV_{OT_D}, SD_{OT_D}, MV_{OT_E}, SD_{OT_E} are identified as redundant variables.

We let C_0 to C_5 represents constant, coefficient of λ_D, coefficient of λ_E, coefficient of MV_{RT_D}, coefficient of MV_{RT_E} and coefficient of B. The results of linear regression are shown as Tables 4 and 5.

Table 4. Coefficient of linear regression of the input

C_0	C_1	C_2	C_3	C_4	C_5
0.5248	0.2386	-0.4378	0.0036	-0.0008	0.2726

Table 5. Test indicators of linear regression

R^2 statistic	F statistic	p value	An estimate of the error variance
0.9162	205.5406	0.0000	1.0990

As can be seen from Table 5, the regression equation is valid. So B_{CECD}, the beds number allocate to day surgery patients under CECD can be represented by the formula (1).

$$\begin{aligned} B_{CECD} = 0.5248 + 0.2386\lambda_D - 0.4378\lambda_E + 0.0036MV_{RT_D} \\ - 0.0008MV_{RT_E} + 0.2726B. \end{aligned} \tag{1}$$

The actual beds number allocate to day surgery patients under CECD is integer, thus, we rewrite Eq. (1) by rounding it to integer and we obtain it denoted as ${B_{CECD}}^*$ by the formula (2).

$$\begin{aligned} B^*_{\text{CECD}} = \lfloor 0.5248 + 0.2386\lambda_D - 0.4378\lambda_E + 0.0036MV_{RT_D} \\ - 0.0008MV_{RT_E} + 0.2726B + 0.5\rfloor. \end{aligned} \tag{2}$$

The actual and the predicted beds number allocate to day surgery patients under CECD calculated according to formula (2) are shown in Figs. 1 and 2:

The pentagrams in Fig. 2 denote entirely accurate predictions. From Figs. 1 and 2, we can see that not much predictions are entirely accurate, but the maximum error is 3. The results of the key parameters which reflect regression effect are: $R^2 = 0.9162$, $F = 205.5406$, $p = 0.0000$. Parameter $R^2 = 0.9162$ indicates

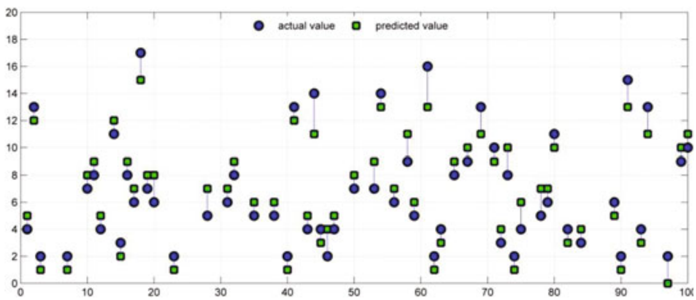

Fig. 1. The predictions with fluctuation using linear regression

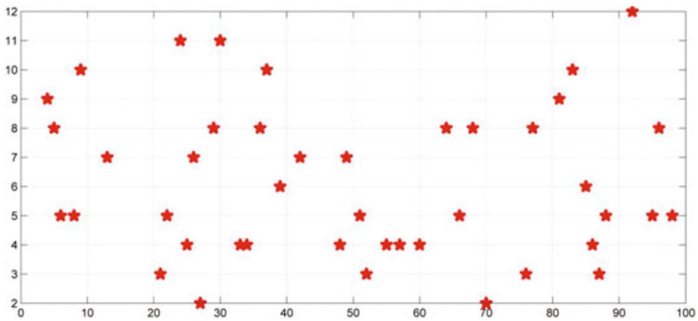

Fig. 2. The entirely accurate predictions using linear regression

that the fitting result of the model is satisfied, parameter $p < \alpha$, which indicates that selection of every variable in the regression equation is significant. The results of Table 5 indicate that Eq. (1) has a satisfied fitting result. The regression equation can provide decision supports for beds allocation under centralized management mode.

Next section, we predict the number of B^{*}_{CECD} with neural network method.

4 Neural Network Prediction

It has identified the input layer has five units. And there is one output unit represents the beds number allocate to day surgery patients under CECD. Neural network theory has been proved that if the number of hidden layer units can be set free, then with three's like I/O node characteristics can approximate any continuous function with any precision. Therefore, we choose networks with three architectures, that is only one hidden layer. And there are eight units at hidden layer.

The error trend after we trained 500 times are seen as Fig. 3.

Based on the neural network above, the results of prediction we obtained are as follows (Tables 6, 7 and 8).

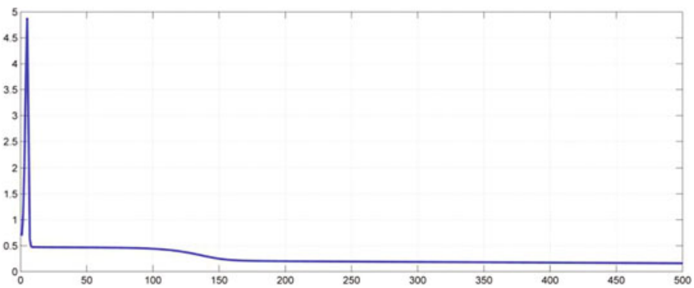

Fig. 3. The error trend using Neural Network Prediction

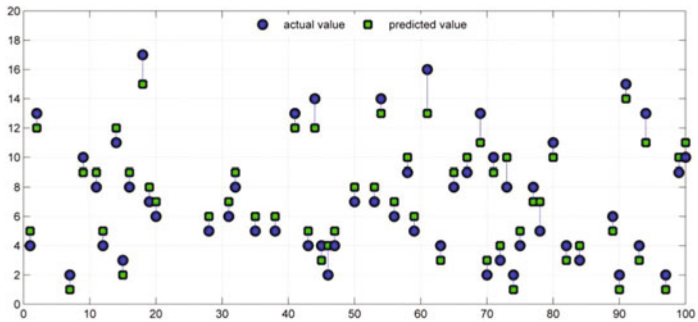

Fig. 4. The predictions with fluctuation using Neural Network Prediction

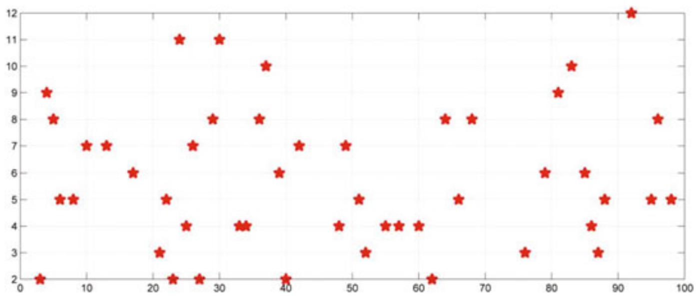

Fig. 5. The entirely accurate predictions using Neural Network Prediction

The pentagrams in Fig. 5 denote entirely accurate predictions. From Fig. 4 and Fig. 5, we can see that not much predictions are entirely accurate, but the maximum error is 3. And the neural network above can provide decision supports for beds allocation under centralized management mode.

5 Conclusion

In this paper, we firstly conduct a large number of simulation experiment using Matlab and prove that centralized management mode is more advantageous to either elective surgery patients or day surgery patients, it depends on the allocation of beds; while decentralized management mode is the most equitable. Then, based on the large amount of simulation data, we screen out characteristic variables and obtain the regression equation of the CECD beds number, the general linear regression equation is rounded to integer as

$$\begin{aligned} B^*_{\mathrm{CECD}} = \lfloor & 0.5248 + 0.2386\lambda_D - 0.4378\lambda_E + 0.0036MV_{RT_D} \\ & - 0.0008MV_{RT_E} + 0.2726B + 0.5\rfloor. \end{aligned}$$

The regression equation satisfied fitting results, the maximum error is 3, and only a few recorded errors are 3, most are 1 and 2 besides the accurate predictions. And the beds prediction equation in this paper, which is simple and convenient for calculation. Then we use artificial neural network to do the same prediction. And the results are similar to linear regression. The maximum error is 3, and only a few recorded errors are 3, most are 1 and 2 besides the accurate predictions. Both linear regression equation and the neural network above can provide decision supports for beds allocation under centralized management mode.

The deficiency in this paper is that we only consider beds number without considering the limitation to operation room resource. We will take account of the limitation to operation room resource to enrich our study next. Moreover, we will figure out other methods to improve accuracy of the prediction.

A Standardization Methodology for Visual Management in Lean Supply Chain Environments

André Simas(✉) and Virgilio Cruz-Machado

UNIDEMI (Department of Mechanical and Industrial Engineering), Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa, 2829-516 Caparica, Portugal
af.simas@campus.fct.unl.pt

Abstract. A rather important tool of Lean used in a plant is Visual Management, because people pay more attention to everything that is visual than any other sense. This kind of eyes management allows the abnormalities to stand out and simplify the work that needs to be done. Visual Management within an organization, assumes that all the tools used in the plant are standard, to be the same in the rest of the organization. In order to help organizations about the develop of visual standards, the author proposed to develop a Standardization Methodology divided in two sections, the Current Situation Analysis Methodology and a Future Design Methodology. The first one refers to all stages that precede the analysis of instruments of some plants, while the second one concerns the creation of improvements. The enhancement proposals were focused on processes that could be an advantage to the existence of a standard tool. Most of these tools are low cost of employment and there are some advantages in their use: they allow more transparency on processes and they make the shop floors look like cities.

Keywords: Lean · Visual management · Standardization · Methodology

1 Introduction

Nowadays, the consequences of the Great Recession are still quite noticeable, a downfall that started in 2008 with the Lehman Brothers Holding Inc., an investment bank, declaring bankruptcy. Several other banking institutions followed the same path after the beginning of crisis. After that period, the companies focused on a clear objective, use innovation to be more competitive.

The automotive industry has also suffered some financial distress, leading manufacturing organizations to start to think of new production methods and a better application of the tools used at the shop floor. This allows companies to pursue operational excellence with an improvement of their performance,

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_95

providing high quality products earlier in order to reduce costs [2]. Worldwide, the companies start to encourage a Lean culture on their employees due to the competitive nature of this industry, caused by emerging markets which produce similar products at lower prices. To face those markets, the automotive industry must be constantly updated, developing new products to customers.

Lean Thinking is the basis of implementation within companies, providing a guide on how they can do more with less, less effort, equipment, time and space. This can be divided in a set of five principles: value, value stream, flow, pull and perfection [10].

Implementing Lean can be a difficult process, but when it is well applied becomes an essential characteristic within an organization, playing a crucial role leading up to the intended results. Some authors said this philosophy is determinant for the survival and constant innovation of organizations. One tool from Lean culture is Visual Management, an important tool used at the shop floor, which is defined as signs and other forms of visual information used to simplify the workplace and make it easy to recognize abnormalities on processes [4].

2 Visual Management

Visual Management is a Lean tool that has the objective of giving visual information or displaying requirements to set directions [3]. This tool is frequently used at manufacturing industries, but has currently expanded to other business industries [1]. This concept was created to highlight abnormalities directly in the workplace, thus helping operations and processes as soon as a problem occurs [8]. Giving the right information to employees at the right moment is a vital characteristic to improve the performance of a company [3]. That kind of information can be provided by signs, labels or a colour code. The use of this type of information eliminates the "guess", searching and a cumulative of information or material [6].

Many authors, such as Wilson [9] don't use the term "visual management" but rather transparency, because this tool allows the observation of processes on time. An operator can see what is happening in a process and he can change or adjust it if an abnormality is to occur.

Within Visual Management there are tools that support operators' tasks and highlight any abnormalities on processes. There are two different sets of tools [3]:

- Understanding processes: tools mainly focused on visualising the information to allow a better understanding of the processes. Ex.: value stream mapping, flow charts, A3 and area name boards.
- Performance of processes: tools that are used to communicate requirements and manage the efficiency of the processes. Ex.: andon lights and boards, Kanban and KPIs screens.

Many of these signals were created to control robust processes, allowing to draw attention to many processes at once and act immediately [7].

Some authors argue that Visual Management is the basis of sustainable improvement, promoting the contribution of all operators in management activities and a quality enhancement of processes. This can only be obtained when the information is conveyed in a succinct and clear manner [5].

The use of Visual Management has many benefits:

- less time spent understanding the information;
- visible abnormalities, installation of devices/signals;
- speed, the problems are eliminated earlier;
- involvement of all, promoting a continuous improvement;
- standardization, processes up to date.

On this list, only some of the most important benefits were referred, there are many others that are related with this Lean technique. For Parry & Turner [8] visual management must be simplified, only information that adds value to the processes should be displayed.

3 An Approach to Establish a Standardization of Visual Tools

Mostly organizations that have visual management on the mindset of their employees and use it constantly, can make the process flow through these visual aids. Employees must interact with the tools from visual management to continue the process, if they don't have that support the process doesn't flow smoothly until the end.

Every workplace has visual aids. This aids can be presented in many shapes, for example: instructions of how to do a stage of process; directional signals; photographs and boards. However, this information is often neglected because many organizations don't follow the requirements of visual management. These requirements are all information to bring added value, easily understandable and must be placed at visible places and updated.

An organization that defines very good standards for visual controls has more benefits and employee efficiency. Then a methodology will be described, that provides a simple guide for organizations who want to standardise their visual tools.

3.1 Methodologies

A methodology characterizes all the stages to follow from a process. It is a detailed explanation of all actions of the work until the expected result is reached.

For better support, a Standardization Methodology divided in two sections was developed:

- Current Situation Analysis Methodology - this refers to all stages that precede the analysis of instruments of some plants;
- Future Design Methodology - this refers to the creation of improvements.

All stages must be strictly followed for the success of a project, if the implementer doesn't respect the stages, the results can't be truly trusted. This Methodology was designed for organizations that have multiple plants worldwide and the tools are often unequal, but can be used in all organizations with few adjustments.

(1) Current Situation Analysis Methodology

This Methodology is the initial phase of a standardization, representing the analysis of information that the implementer collects from an organization (Fig. 1).

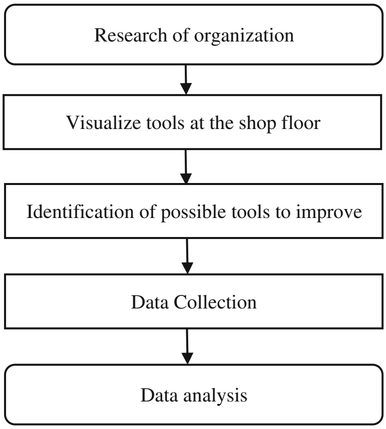

Fig. 1. Stages of current analysis methodology

① Research of organization

This phase must be the most detailed one considering the resources available, documents or procedures that are used by the organization in the composition of the workstation, which incorporates the visual controls. The person who wants to implement this methodology should know if the organization has some Lean policy that can match with this methodology.

② Visualize tools at the shop floor

The objective of this stage is to get used to the tools that are being used at the shop floor, through its visualization in operation. This knowledge is the transition from theory, studied in the previous phase, to practice. The need of seeing tools at the shop floor can clarify some misunderstandings of theory information from documents and can be a way to identify abnormalities on tool applications.

③ Identification of possible tools to improve

After observing the tools in operation, the implementer should use critical sense to identify possible tools for improvement. It is important to keep in mind the limitations of the organization, starting with a few number of improvements is better than start with a huge change on tools. Employees tend to accept changes if they are implemented slowly.

④ Data Collection

This is the critical phase of all the methodology, because at this stage is where the implementer gathers the information from plants related to the tools for improvement. This data collection combines interviews, by email or telephone, with photos to support what they said, and visits to other plants from the organization to check on how they apply the tools. The characteristics required from plants are based on how the tool is used, its appearance, to whom it is intended and where it is used inside the shop floor.

⑤ Data analysis

After the data collection is concluded, the information of all plants must be placed on paper at the beginning (like a draft). When the draft is completed, the implementer can introduce that in a computer and print it. It is recommended to print in large formats for easier comprehension. The disposal of information provides a good view of how tools are being used, if similar, or not, to the other plants. When a plant has a good practice of some tool, it must be used in total or partially for improvement of that tool.

(2) Future Design Methodology

This part of the Methodology is the development phase, which include the conception and the implementation at the shop floor (Fig. 2).

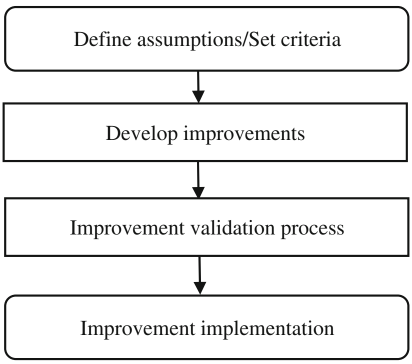

Fig. 2. Stages of future design methodology

① Define assumptions/Set criteria

The conception of improvements is a subject that has some rules and must be studied before presenting the improvements. If there aren't rules or a previous study those tools can be worse than the actual. For an initial phase, it should be guaranteed that some criteria are settled by the organization that uses this methodology. The criteria are:

- Objectivity: must be clear, to not confuse employees;
- Similar: if a plant has a good tool, that tool should suffer a few adjustments to be similar;
- Reliable: improvements proposals shall consider their economic reliability;
- Simple and intuitive: visual tools are easier to retain;
- Respect layouts and colours: when developing improvements, the rules established by organization must be respected.

The need to establish criteria is the basis for a successful implementation of a strategy and for a best probability of being validated by the Central Team.

② Develop improvements

Through analysis of collected information from plants, a brainstorming must be done for chosen tools, following the previously explained aspects. That brainstorming should be done with a team of 2 or more people. A team with more people can obtain multiple outputs, hence different tools. The improvements derive, more or less from the previous presentation, depending on the good level of effectiveness of the tool. The team presents all ideas for improvements. It is recommended to have more than one solution, but it isn't required.

③ Improvement validation process

This phase occurs when the team presents the improvements to the Central Team (team responsible for the application of Lean at plants, with the objective of choosing the best ones to apply). The validation process is the approval and standardization within an organization. A tool is accepted when the proposal shows a better potential than the tool being currently used and will bring more benefits. This comparison is made using a table with advantages and disadvantages of the old tools and the new ones. The Table 1 must fit the following layout:

Table 1. Table template for comparison of tools

Characteristics	New tool	Tool plant 1	Tool plant 2
Characteristic 1			
Characteristic 2			

There are no predefined characteristics, the organization must adapt that subject according to the nature of the tool. To fulfil the Table 1 above the organization must mark with "✓" if the tool has the characteristic or "♣" if not. Through this analysis it's possible to verify if the new tool has, in theory, more potential than the implemented tool.

④ Improvement implementation

After being approved by the Central Team, it's the right moment to start standardizing on all plants. It's a slow process because implementations take time, so it's recommended to act as quickly as possible. The output resulting from the application of this methodology is the implementation of the tools that were subject to improvements at the shop floor. This is the last step of information collection and analysis regarding plants from different regions.

3.2 Application of Methodologies

This subchapter will give the reader a better comprehension of this methodology applied in an organization from the automotive industry. Two topics will be approached where the methodology can be applied, for example, Stopping Points, a subject from routing, and the color code from plants.

Every plant has routes and this routes need stopping points, a specific location near the workplace where the tuggers' drivers do the collection or replacement of materials during the route. After getting the information from plants, through photos of the application of the tools at plants, it was verified that the tool's presentation is different in all plants within an organization. Figures 3, 4, 5, and 6 show the differences in stopping points between some plants.

Fig. 3. Stopping point plant 1

Fig. 4. Stopping point plant 2

Fig. 5. Stopping point plant 3

Fig. 6. Stopping point plant 4

The existence of several ways of presenting the stop signs shows the need to standardize this tool, so every plant can use the same tool.

Another concept that many plants have huge differences between them is the color code, normally used in floor marking. This tool is important to have for a well-organized workplace so it can prevent accidents and injuries. Many organizations use these markings with the intention of enhancing the visual management of the organization. To obtain the data from the plants interviews by phone were held, with photos to support what has been told on interviews. These photos in Figs. 7 and 8 show that there are enormous differences between the color code from each plant.

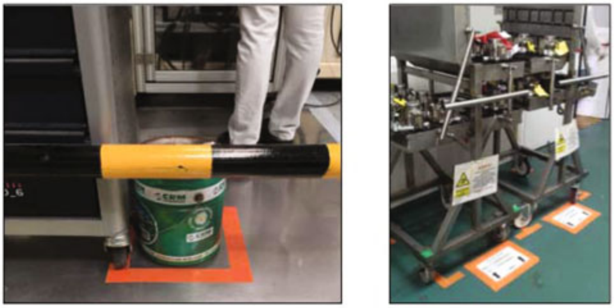

Fig. 7. Orange color for dangerous material [plant 1] (at left) and rework [plant 2] (at right)

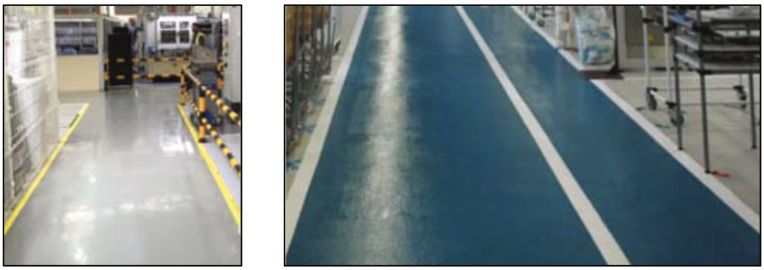

Fig. 8. Differences between two plants at aisles markings

When all information was collected, it was observed that there wasn't a common color code for all plants, every plant has their own code.

3.3 Results

Now, the improvements for the tools mentioned above will be described, including Stop Points and Color Code.

The appearance of Stop Points is a very useful visual tool in routing, they let the driver of the tugger know which route belongs to what and the number of the stop (usually are numbered with 1, the nearest stop from warehouse and so on). The decision was to design an easily visible tool with all the necessary information, so the driver doesn't have issues performing the route. The new tool is shown in the Fig. 9.

Fig. 9. New stop sign developed

In this case, this tool has the name of the route it belongs to, a frame with the color of the route and the number of the stop, the other aspects are only aesthetics. For the design of this tool, the criteria established by the methodology were considered. To compare this tool with the ones already implemented, the methodology requests a table with the comparison:

Table 2. Comparison of stop points

Characteristics	New tool	Tool plant 1	Tool plant 2	Tool plant 3	Tool plant 4
Fast interpretation	♡	♡	♣	♣	♣
Visible	♡	♡	♣	♡	♡
Low cost	♡	♣	♡	♣	♡

This tool can be quite financially viable. It is made with paper (A4 format), with the colors from the respective routes allowing a fast interpretation for the tugger's driver (Table 2).

As I said before, the color code is essential to mark workplaces and pedestrian access areas. Those marks should be visible and noticeable by operators, employees and visitors that walk at the shop floor. If a workplace has a tidy

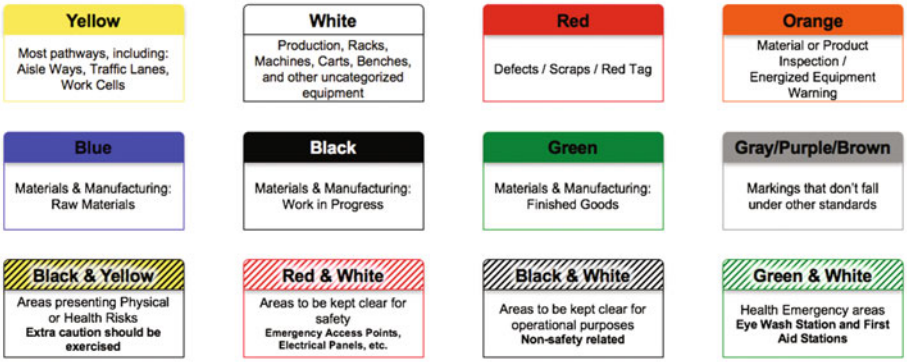

Fig. 10. New color code developed

working environment that stimulates a good performance of an operator. So, a color code was designed to be adopted by all plants within an organization:

From Fig. 10, the objective is the adoption by all plants of a single standardized color code in the organization. For the design of the code, the criteria established by the methodology were considered and was decided not to do the comparative table. Despite the differences, there is no comparison term for the color code. The colors present in the code are the minimum required for a plant, however, if any plant needs more combinations of colors they can define them.

4 Conclusions

Standardization of visual management within an organization, with a lot of plants, is a complex and long journey process. You need to transform an entire organization, from tools that are being standardized to the mindset of employees, who will contact with the new tools. The tools to improve must be requested as they come across a tool that can be improved.

The benefits of having all visual management standardized are huge: reduction of wasting time using confuse tools; an increased efficiency of operators, tools are designed for them; simplifies the work environment and the seek for excellence. Normally the output (improvement tools) manages to convey the basic principles of visual management, through "eye management", always prevailing simplicity, transparency, and clarity.

Resource Optimization Management

Online Fault Detection in Solar Plants Using a Wireless Radiometer in Unmanned Aerial Vehicles

Carlos Quiterio Gómez Muñoz(✉), Alfredo Peinado Gonzalo, Isaac Segovia Ramirez, and Fausto Pedro García Márquez

Ingenium Research Group, Castilla-La Mancha University, Ciudad Real, Spain
CarlosQuiterio.Gomez@uclm.es

Abstract. A novel Non-Destructive Test (NDT) is presented in this paper. It employs a radiometric sensor that measures the infrared emissivity of the solar panel surface embedded in an unmanned aerial vehicle. The measurements provided by the sensor will determine if the panel is healthy, damaged or dirty. A thermographic camera has been used to check the temperature variations and validate the results by the sensor. The study shows that the amount of dirt influences the temperature on the surface and the energy generated. Similarly, faults in photovoltaic cells influence the temperature of the panel. The NDT system is less expensive than traditional thermographic sensors or cameras. Early detection of these problems, together with an optimal maintenance strategy, allows to reduce costs and increase the competitiveness of this renewable energy source.

1 Introduction

1.1 Renewable Energies

The whole energy produced in the Earth has been obtained, directly or indirectly, from the Sun. Even fossil fuels, which come from the decomposition of plants that have previously needed the sun to perform photosynthesis. These fossil fuels are oil, coal and natural gas, and they are in limited reserves.

From the industrial revolution, fossil fuels consumption has increased without considering the environmental effects, such as global warming or climate change. However, as they are finite resources, alternative forms of fossil fuels must be sought to obtain energy and to avoid the pollution they produce. These measures are being carried out globally, led by the Intergovernmental Panel on Climate Change (IPCC).

The renewable energies are being developed and employed to use a clear production, e.g. in Spain they produce 28.6% of the energy consumed [9,16]. Renewable energies are those based on the use of virtually endless resources, e.g. the sun (Fig. 1), wind or ocean currents, or resources that are renewed periodically if they are used sustainably, such as biomass or biofuels. In general, its production is more expensive than

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_96

Fig. 1. China and Pakistan project for Solar plant Solar Quaid Azam installed in Pakistan (http://www.qasolar.com/)

fossil fuels, but if does not generate polluting emissions during their production. These include: Wind energy [14,22], tidal, solar (Fig. 1), biomass and biofuels, geothermal and hydraulic.

1.2 Non-Destructive Experimenting

Non-Destructive Experimenting (NDT) is a type of experiment that is performed on parts and pieces to verify its state and operation without interfering in the integrity of the material or its usefulness to the service [6,10,19,24]. They are carried out in recognition and preventive maintenance work in all types of industrial areas. These experiments are used to detect internal and surface defects [8,18,20,21]. Some of these experiments are: Radiography with X-ray and Gamma, magnetic particles, Eddy currents, ultrasound experimenting [7,11,17] and infrared thermography [1]. Infrared thermography consists in checking the state of a part or a structure from a thermal image. They are used in many industries and they can be applied in any production phase.

2 Infrared Thermography

2.1 Radiation

There are only three methods of heat transmission in physical terms: conduction, convection and radiation. In the case of radiation, a transmission medium is not necessary, the energy is transmitted due to the temperature of the emitter body. Depending on the temperature, the radiation emitted changes. The law of Stefan-Boltzmann, Eq. (1), is used to quantify it. It must be adjusted for real bodies, by adding the emitter parameter to the equation.

$$E_N(T) = \sigma \cdot T^4, \tag{1}$$

where E_N is the emittance of the body, is the Stefan Boltzmann constant, value 5,6710 B -8 W/m^{2}K^4)) and T the body temperature. This emittance is for of a black body, which must be corrected for real bodies through the emissivity. The Planck law is given by Eq. (2).

$$E_N^{\lambda}(\lambda, T) = \frac{C_1}{\lambda^5 (e^{\frac{C_2}{\lambda T}} - 1)}, \tag{2}$$

where E_N is the spectral emitted, C_1 and C_2 are constants, λ the wavelength and T the body temperature. Eq. (2) shows that most of the radiation emitted by bodies at low temperatures is found in the infrared region [15].

Emittance is the proportion of energy that a body can emit relative to the total. In a black body (maximum emitter) is the unit. In any other body, this magnitude is smaller and depends on the temperature. In addition, the characteristic wavelength of the bodies also depends on their temperatures, generating the electromagnetic radiation spectrum.

The thermal behavior of a real body is different from a black body. While the black body absorbs all the energy that reaches its surface and emits throughout the radiation region equally, a real body does not absorb all the energy and does not emit in the entire electromagnetic spectrum.

A real body does not absorb all the radiation, but part of it passes through it or reflects on its surface. In addition, this behavior also depends on the wavelength being studied, that depends the concept of emittance, given by Eq. 3. Emittance is the ratio of energy that a body emits with respect to the total that it can emit with a certain temperature and wavelength [15].

$$\varepsilon^{\theta,\varphi,\lambda}(\theta, \varphi, \lambda, T) = \frac{E^{\theta,\varphi,\lambda}(\theta, \varphi, \lambda, T)}{E_N^{\theta,\varphi,\lambda}(\theta, \lambda, T)} = \frac{I^{\theta,\varphi,\lambda}(\theta, \varphi, \lambda, T)}{I_{E,N}^{\theta,\varphi,\lambda}(\lambda, T)} \tag{3}$$

being ε the emissivity, θ and φ emission angles, E emittance and I the radiation intensity of the body. For this research work, infrared radiation is the most relevant, since it is the dominant thermal radiation in this temperature range. Therefore, the camera and the sensor are designed to collect this type of radiation.

2.2 Applications

The main function in this paper of infrared thermography is the visualization of elements whose surface temperature variations show their state [2,3,12]. Among its applications include the following:

(1) Electrical and mechanical systems: It is possible to observe the hot spots of the systems and areas subjected to higher thermal stresses by comparison on the surface of the system [13].
(2) Structures: Any irregularity in the temperature of the facade can correspond to different conditions in buildings, such as poor insulation, the emittance of an area with a greater amount of bricks than concrete, or even an insect nest within the facade.
(3) Welds: Temperature variations in a pipe are usually due to areas where welds have been made. If these variations show a very irregular appearance, it is probably due to a bad union
(4) Surveillance: Control of emissions, traffic, fire prevention, etc.
(5) Medicine: Monitoring of diseases and anomalies in the human body.

The infrared thermography is done by a non-radiometric camera to check the results obtained with the sensors.

3 Experimental Platform

3.1 Radiometer

They are used to check the temperature and the radiance of the measured targets. Both sensors are used to contrast the data obtained with each one in the different case studies.
(1) Campbell SI-111 Sensor

This sensor is connected to an Arduino board, which processes the voltage data and process that information to obtain the temperature in Celsius degrees. The system is capable of making accurate measurements to the bodies that are within its field of vision. The SI-111 Precision Infrared Radiometer features a thermistor to measure its internal temperature, and a thermopile for the target temperature using a germanium lens.

Using Stefan-Boltzmann's law of radiation, and the voltages in the thermopile and the thermistor, the target temperature is calculated [23].

The temperature measured by the sensor is the average of the temperatures of its view range, receiving between 95 and 98% of the infrared radiation of the view range and between 2 and 5% from outside. Figure 2 shows the view range of the SI-111 sensor with half-angle of 22.5o. The view range depends of the distance to the area and the inclination with respect to this area (see Fig. 2).

This sensor has been chosen because of its high accuracy, reaction rate to changes in temperature and the large range of temperatures that can operate. Its size and weight allow a great manageability. Its installation on the unmanned aerial vehicle allows the global system to performance more efficient and flexible inspections.

3.2 Arduino Platform and Wi-Fi Shield

For this research, Arduino Uno G3 motherboard is used and the Shield Wi-Fi extension, which grants wireless features to the original board. This device has been chosen due to its great extension in this type of applications and its low consumption. The Arduino

Fig. 3. Arduino Uno G3 (a) and Wi-Fi Shield expansion card (b)

Uno R3 (Fig. 3a) is a motherboard that uses the ATmega328 microcontroller and is powered by either USB cable connected to a computer or external power from a battery.

The Wi-Fi Shield component is an Arduino expansion card. It allows the transmission of data via wireless connection by Wi-Fi (Fig. 3b).

Data obtained by the sensor is processed and sent via Wi-Fi to the online platform Thingspeak to monitor the results (Table 1).

3.3 Thermographic Camera

The camera is non radiometric used to check the data obtained with the sensors and to see the temperature differences of the observed pieces. This camera consists in assigning a determined colour to each level of radiation that it receives. These levels are calculated for each resolution pixel that the camera has, creating a thermographic picture (Figs. 4 and 5).

Table 1. Technical characteristics of the Campbell SI-111 sensor

Input voltage	2.5V excitation for the thermistor.
Absolute accuracy	$\pm$ 0.2 °C between [−10 and 60] °C $\pm$ 0.5°C between [−40 and 70] °C
Response time	Less than 1 s for changes in target temperature.
Field of view	22° of half-angle
Operating environment	Highly water resistant designed for continuous outdoor use. Operating range −55 °C to 80 °C 0 to 100% relative humidity

Fig. 4. Thermographic camera Flir VUE

3.4 Photovoltaic Solar Panels

These panels were used in the experiments to check their temperature and voltage at the terminals. Their technical characteristics are shown in Table 2.

Table 2. Technical characteristics of photovoltaic solar panels

Manufacturer's name	TSM-170D
Max power	2.5 W
Maximum voltage	35.8 V
Maximum intensity	4.76 A
Open circuit voltage	43.6 V
Short circuit current	5.25 A
Maximum system voltage	700 V
Work temperature	[−40 °C,90 °C]
Dimensions	1581 × 809 × 40 mm
Cell type	Monocrystalline
Number and size of cell	72 pieces, 125 × 125 mm
Type of glass and width	3.2 mm tempered
Weight	15.6 kg

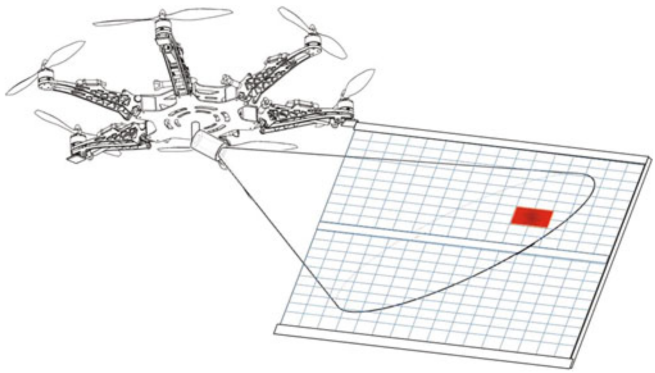

Fig. 6. Representation of the air vehicle taking a measurement with the wireless sensor mounted on the Gimbal mount

3.5 Unmanned Aerial Vehicle DJI Spreading Wings S900

This unmanned aircraft operated by remote control is designed for reconnaissance, monitoring and taking of measurements and images, thanks to its control system that allows a great stability and handling.

The hexacopter can operate around 18 min autonomously, following pre-established routes. It is made of carbon fiber to lighten weight, which allows a maximum load capacity of 8.2 kg. The gimbal is a crucial component for this application for increasing the stability and accuracy of the measurements. This support contains the measurement equipment (sensor, camera, Arduino card and electronic components) in the drone. A schematic representation of the drone collecting data in a photovoltaic plant is shown in Fig. 6.

This system allows to inspect solar plants in a totally automatic and autonomous way. It can inspect large areas, and a very large park can be inspected by sections. The system sends online all the information about the state of the plates (dirt and defects), generating alarms and reports of each module.

4 Case Study

The objective of the experiments was to detect dirt on the solar panels [4]. The experiments were carried out in three different scenarios: In the first scenario, the solar panel was clean; the second one, mud was added in half solar panel; third scenario, the solar panel was totally covered by mud. In each experiment, the temperature values collected by the radiometer and the volts generated by the solar panel were obtained.

The incidence of the sun is crucial in the emissivity values collected by the radiometer. For this reason, they were carried out three cases of study at different hours to study the incidence of the sun in the results. The first case study was performed at 10:00 am. The second case study at 12:00 noon. The last case study was carried out with absence of direct light because of clouds (Figs. 7, 8 and 9).

Fig. 7. Solar panel without dirt on its surface

Fig. 8. Solar panels covered in half of mud

Fig. 9. Solar panels totally covered of dirt

Table 3. Results obtained in the case study 1

	Temperature (°C)	Voltage (V)
Clean panel	46.2	36.2
Partially covered panel	44.7	35.7
Fully covered panel	44.1	35.3

4.1 Case Study 1: Incidence of Sunlight at 10:00 AM

Experiments have been performed at 10:00 am to check the temperature reached by the panels when, due to the incidence of light, the panel does not reach its maximum power generation. Table 3 shows the obtained temperature and generated voltage by the panel.

It is observed an evident difference of temperatures between the clean panel and the panel with dirt on the half of its surface. There are also minor differences between the half dirty panel and the panel totally covered by mud. Figure 10 shows the different temperatures obtained in the series of experiments represented by columns. The ambient temperature series has been added to contrast with those acquired by the panels in each case shown in the form of a line.

These relationships are proportional to the voltages generated by the solar panel. Figure 11 shows the influence of the mud in the voltage at 10:00 am [5].

4.2 Case Study 2: Incidence of Sunlight at 12:00 PM

These experiments have been performed to observe the differences in temperature and energy production of the panels when the panel reach its maximum of production, i.e. when the light strikes perpendicularly on the panels (Table 4).

The temperature variations are bigger than in the first case study, as well as the voltage. This is because of the intensity of the light is much greater and it makes more evident the cases where the panel is covered with dirt. Greater differences in temperature are observed in Fig. 12, as well as higher temperatures.

A greater voltage difference is shown in Fig. 13. It is due to a greater inequality of sunlight incident between the panel without dirt and completely covered.

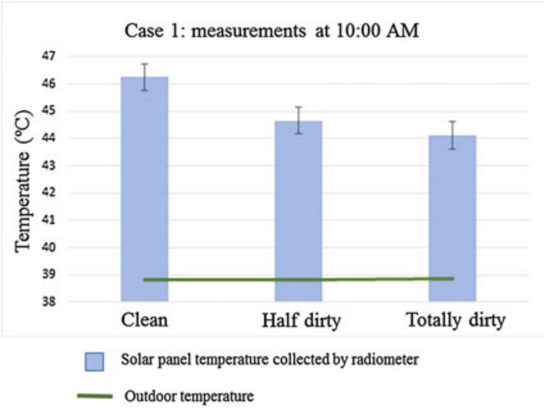

Fig. 10. Comparison between the different panel temperatures in case study 1

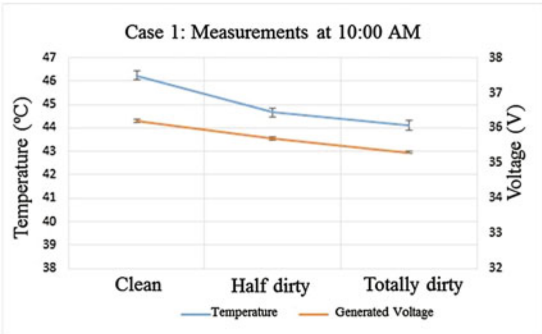

Fig. 11. Comparison between different panel temperatures and voltages in case study 1

Table 4. Results obtained in the second experiments

	Temperature (°C)	Voltage (V)
Clean panel	61.9	37.2
Partially covered panel	57.9	34.4
Fully covered panel	51.8	33.5

4.3 Case Study 3: Absence of Direct Light (18:00 P.M.)

These experiments have been performed at 18:00 pm with clouds to study the effectiveness of the system for the detection of dirt under these conditions. The temperature results obtained are shown in Table 5.

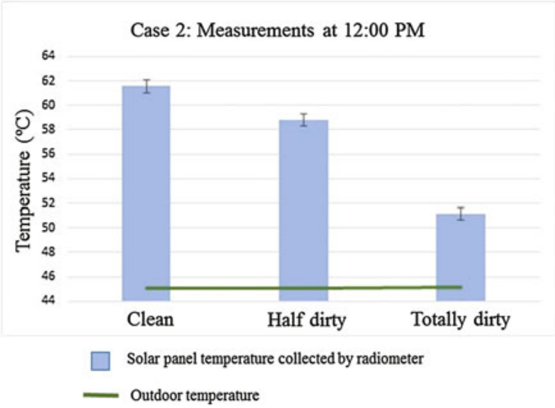

Fig. 12. Comparison between different panel temperatures in case 2

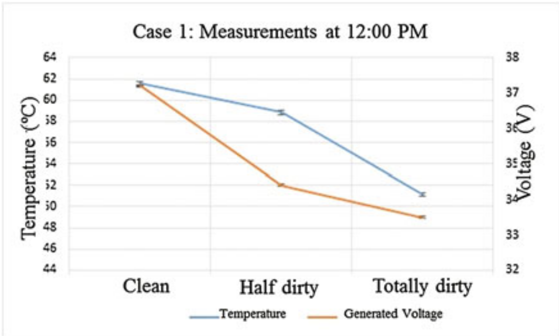

Fig. 13. Comparison between different panel temperatures and voltages in case study 2

Table 5. Measurements obtained in the case study 3

	Temperature (°C)	Voltage (V)
Clean panel	31.4	27.3
Partially covered panel	31.2	27.3
Fully covered panel	30.9	27.3

The differences of temperatures are lower, with a large margin of error that does not allow to know exactly the condition of the panel. Figure 14 shows the low temperature variations between the different experiments.

The voltage in each case are similar for all case studies. In these conditions, it is concluded that the system is not effective to detect the dirt in the solar panels.

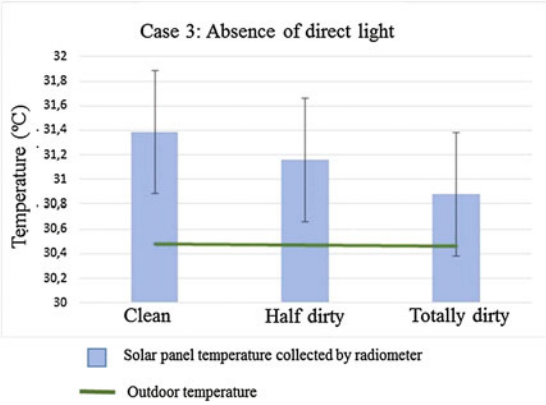

Fig. 14. Comparison between the different panel temperatures in case study 3

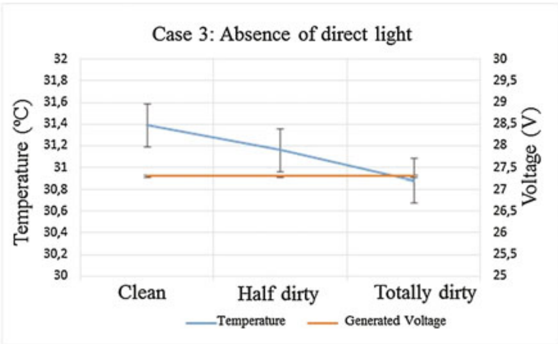

Fig. 15. Comparison between different panel temperatures and voltages in case study 3

5 Conclusions

Dirt and dust in solar panels is a common problem in photovoltaic plants, which are usually located in desert areas with lots of sand and dust. A novel non-destructive test system is proposed in this paper, based on: a radiometer; Arduino; a Wi-Fi Shield, and; a UAV for inspecting the state of the photovoltaic panels.

The low weight and cost of the system can reduce the costs in operation and maintenance of the whole solar plant. The system can be automated, reducing the inspection time and the costs (Fig. 15).

Three different conditions of the solar panel were analysed: Clean, half covered by mud and totally covered. The infrared radiometry of the panels was read and the voltage of the panels. The experiments were performed in three different solar conditions to increase the actuary of the experiments: at 10 am, 12:00 pm and with clouds and without direct sunlight. The absence of direct light does not allow identification among the three cases.

Abstract. Smart grid (SG) as a complex advanced electricity system is capable of facing with the growing energy demand, where energy consumers are connected not only to the conventional grid but also to some local energy markets for bidirectional energy trading. In this context, this paper presents an optimization problem the demand response problem where a hybrid energy trading system consisting of a conventional grid, a local trading system, a number of energy consumers, having distributed generators and battery, and some generator companies. In this case, it has been considered that the local trading center (LTC) is a non-profit oriented LTC which aims at benefiting the energy consumers and energy sellers. The optimization model is formulated as a mixed integer Linear Program (MILP) with a bounded number of variables and constraints. Furthermore, the solution can be obtained in polynomial time and provides the optimal scheduling for the problem such that the costs were minimized while the total demand is satisfied.

Keywords: Hybrid energy trading market · Demand response mechanism · Local trading center · Distributed generators · Battery bank

1 Introduction

Smart grid (SG) as a complex advanced electricity system is capable of facing with the growing energy demand in a reliable sustainable and economical manner [3]. Advanced two-way communication infrastructure of smart grids and efficient demand response mechanism (DR), according to which the energy consumers and energy sellers can schedule their energy consumption and energy supply, respectively, call attention to SG for achieving better performance than the conventional grid. Exclusively, bidirectional energy trading has been provided by expanded utilization of advanced smart metering systems in future SG and deployment of distributed energy sources. Accordingly, a precise design of control mechanism for both economical optimization and energy scheduling for energy consumers and sellers has been needed.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_97

Nowadays, photovoltaic (PV) generation has been considered as the most promising source of renewable energy. Moreover, the wide exploitation of PV storage facilities integrated into the utility power grid has been provided by the development of energy storage. On the top of that, the batteries can be used in order to shift peak PV generation to be in phase with peak energy demand [8].

There have been several related researches examining the energy trading mechanism and the related DR mechanism. These researches have been categorized into two groups. The first category includes those works, mainly, investigating optimal energy scheduling for energy consumers in response to the pricing of the retail market. Particularly, Mohsenian-Rad and Leon-Garcia [5], proposed an optimal and automatic residential energy consumption scheduling framework to achieve the desired trade-off between minimizing the electricity payment and minimizing the waiting time for the operation of each appliance in a household with considering a real-time pricing tariff combined with inclining block rates. They focused on a scenario which real time pricing is combined with inclining block rates to get a more balanced residential load with a low peak to average ratio. Chen et al. [2], formulated a problem to minimize the cost of energy drawn from the external grid while usage of appliances was subjected to individual delay constraints and a long-term average delay constraint. They supposed that the end user has an energy storage battery as well as an energy harvesting device lest harvested renewable energy can be stored and later used when the price is high. Kim et al. [4], formulated the energy scheduling problem as a non-cooperative game among self-interested customers, where each customer determines its own load scheduling and energy trading to maximize its own profit. They proposed a tiered billing scheme that can control the electricity rates for customers according to their different energy consumption levels in order to resolve the unfairness between heavy and light customers in the non-collaborative approach. Vaziri et al. [9], developed bi-objective integer linear programming model in order to minimize the energy costs with considering the revenue, renewable energy subsidies, and overtime costs, and minimize the displeasure of surgeons and patients in a hospital as a non-isolated micro grid. Ren et al. [7], proposed an optimization model for smart homes. The model finds out the optimal running schedule with considering annual running cost or annual CO2 emissions as the objective function to be minimized. Besides the energy flows among the equipment within the hybrid energy system, the economic information including electricity tariff and natural gas price, as well as some policy issues (e.g., buy-back price) are also accounted.

The second category subtends researches which investigated the pricing strategies for energy retailers as well as optimizing certain objectives, based on price-dependent energy scheduling. Qian et al. [6], proposed a real-time pricing scheme in order to reduce the peak-to-average load ratio through demand response management. The proposed scheme solved a two-stage optimization problem. Then, they proposed an algorithm based on simulated annealing to solve the non-convex price optimization problem. Chai et al. [1] studied DR mechanism with considering multiple utility companies and multiple residential users and a two-level game was proposed to model the interaction between these two levels. The competition among the utility companies was formulated as a non-cooperative game, while the interaction among the residential users was formulated as an evolutionary game. Then, they proved that the proposed strategies were able to make both games converge to their own equilibrium. Wu et al. [10] focused on a hybrid energy trading market consisting of an external utility company and a local trading market managed by a local trading center. First, they quantified the respective benefits of the energy consumers and the sellers from the local trading and then investigated how they can optimize their benefits by controlling their energy scheduling in response to the LTC's pricing.

The main contributions of this paper are summarized as follows. This paper first models a hybrid trading market that is comprised of multiple generator companies, multiple energy consumers, external power grid, and a local trading center. In the consumers' side, some distributed generators are considered. The consumers' appliances are categorized into three groups according to their features. The battery as a storage facility is considered for consumers so as to reduce the average peak load ratio.

The paper is organized as follows. Sect. 2 proposes the overview of the system and presents the mathematical model. Sect. 3 shows the numerical example and the results. Finally, the paper is concluded in Sect. 4.

2 Problem Definition

In this paper, a real-time scheme has been considered for a hybrid trading market in order to reduce the peak to average load ratio and maximize each user's objectives. A hybrid trading market consists of the number of Energy Consumers, Energy Sellers or Generator Companies (GenCo), a Local Trading Center (LTC) and Conventional Power Grid. Figure 1 shows a simplified illustration of the hybrid energy system.

Every energy consumer and energy seller is connected to both local trading center and the conventional power grid. Energy consumers are residential consumers which have the different type of electrical appliances, these appliances

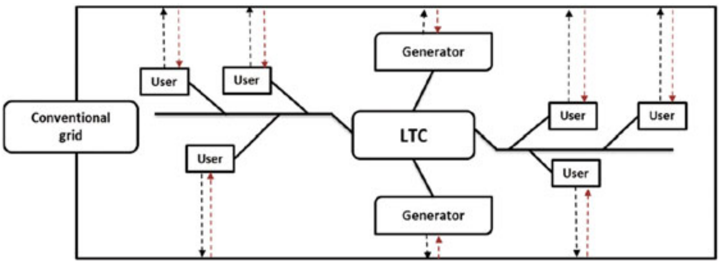

Fig. 1. A simplified illustration of the hybrid energy system

Fig. 2. An example of appliances type B

Fig. 3. An example of appliances type C

can be categorized into three main groups. The first category, A, named as non-flexible appliances, includes background appliances which are needed to be used at specific times and cannot be shifted; refrigerator, lightening appliances are some examples of this group.

The second category, B, named as semi-flexible appliances, consists of appliances which the time of using of these appliances can be shifted in a specific period of time. Figure 2 shows an example of these type of appliances. α and β are the start and end of the preferred time interval, respectively, for an appliance type B.

The third category of appliances, C, which is called as flexible appliances includes those appliances which their time of use can be shifted during a specific period of time as well as be disarticulated in the definite number of sub-activities. Figure 3 shows an example of appliance type C.

It is assumed that a number of energy consumers have Distributed Generators (DG). These DGs consist of a Photovoltaic system with a definite capacity and load availability, and a battery with a specific capacity. The battery is used to store energy surpluses during off- peak time, therefore, it can be charged via PV, LTC, and the grid; and it would be discharged only to supply power to load during peak demand hours.

In the GenCos' side, it is assumed that in every time slot h, there is a certain and constant amount of load available.

The objective of this problem is to minimize the cost of energy for consumers and maximize the income for GenCos. To implement the model, a day is divided into 24 time slots. To model the problem, the following notations are defined:

Indices:

i : Number of energy consumers $i = 1, \cdots, I$;
j : Number of generator companies $j = 1, \cdots, J$;
k : Number of sub-activities $k = 1, \cdots, K_{a_C}$;
h : Number of time slots $h = 1, \cdots, H$;
a_A : Appliances of type A $a_A = 1, \cdots, m$;
a_B : Appliances of type B $a_B = 1, \cdots, n$;
a_C : Appliances of type C $a_C = 1, \cdots, r$.

Parameters:

$[\alpha_{a_B}, \beta_{a_B}]$	: Start and finish time of appliance a_B;
$[\lambda_{a_C,k}, \gamma_{a_C,k}]$	: Start and finish time of subactivity k for appliance a_C;
l_{a_B}	: Activity time of appliance a_B;
$l'_{a_C,k}$	: Activity time of sub-activity k for appliance a_C;
$TL_{a_C,k}$	: Upper limit of the gap between two sub-activity of appliance a_C;
$TL'_{a_C,k}$	: Lower limit of the gap between two sub-activity of appliance a_C;
$d_{i,h}$	: Total energy demand of consumer i at time h;
$PV_{i,h}$	: Available load from PV system of customer i at time h;
E_{a_A}	: Total energy needed for appliances type A;
ε	: Self-discharge rate of the battery;
$\eta^{\text{discharge}}$	: Discharging efficiency of the battery;
η^{charge}	: Charging efficiency of the battery;
E^B_{capacity}	: Rated capacity of the battery (kWH);
μ	: Minimum residue coefficient of the battery
$B_{a_B,h}$	: Energy consumption of appliance a_B at time h;
M	: A large number;
$d'_{j,h}$	: Available load from GenCo j at time h;
$C_{a_C,k,h}$	: Activity k for appliance a_C at time h;
p_h	: Energy sell-out price for the grid at time h ($ /kW);
$W_{i,h}(.)$, $W_{j,h}(.)$	: A linear function for energy transmission loss ;
q_h	: Buy-back price for the grid at time h ($ /kW);
p'_h	: Energy sell-out price for LTC at time h. ($ /kW);
q'_h	: Buy-back price for LTC at time h ($ /kW)
u_h	: Buy-back price for the grid from consumers at time h ($ /kW);
u'_h	: Buy-back price for LTC from consumers at time h ($ /kW)

Decision variables:

$$ST_{a_B,h} = \begin{cases} 1, \text{ if appliance } a_B \text{ starts at time } h, \\ 0, \text{ otherwise;} \end{cases}$$

$$ET_{a_B,h} = \begin{cases} 1, \text{ if appliance } a_B \text{ finishes at time } h \\ 0, \text{ otherwise;} \end{cases}$$

$$ST'_{a_C,k,h} = \begin{cases} 1, \text{ if sub-activity } k \text{ of appliance } a_C \text{ starts at time } h, \\ 0, \text{ otherwise;} \end{cases}$$

$$ET'_{a_C,k,h} = \begin{cases} 1, \text{ if sub-activity } k \text{ of appliance } a_C \text{ finishes at time } h, \\ 0, \text{ otherwise;} \end{cases}$$

$$S_{a_B,h} = \begin{cases} 1, \text{ if the status of appliance } a_B \text{ at time } h \text{ is on} \\ 0, \text{ otherwise;} \end{cases}$$

$$S'_{a_C,k,h} = \begin{cases} 1, \text{ if the status of sub-activity } k \text{ of appliance } a_C \text{ at time } h \text{ is on} \\ 0, \text{ otherwise;} \end{cases}$$

$E_{i,h}^{\text{grid}}$: Total power purchased from the grid for customer i at time h (kW);
$E_{i,h,\text{sto}}^{\text{grid}}$: Power purchased from the grid for battery storage of customer i at time h (kW);
$E_{i,h,\text{self}}^{\text{grid}}$: Power purchased from the grid for self-use of customer i at time h (kW);
$E_{i,h}^{\text{LTC}}$: Total power bought from LTC for customer i at time h (kW);
$E_{i,h,\text{self}}^{\text{LTC}}$: Power purchased from LTC for self-use of customer i at time h (kW);
$E_{i,h,\text{sto}}^{\text{LTC}}$: Power purchased from LTC for battery storage of customer i at time h (kW);
$E_{i,h}^{PV}$: Total power of PV unit of customer i at time h (kW);
$E_{i,h,\text{self}}^{PV}$: Power out of PV unit of customer i at time h for self-use (kW);
$E_{i,h,\text{sto}}^{PV}$: Power out of PV unit of customer i at time h for battery charging (kW);
$E_{i,h,\text{salegrid}}^{PV}$: Surplus electricity from PV unit of customer i at time h sell to the grid (kW);
$E_{i,h,\text{saleLTC}}^{PV}$: Surplus electricity from PV of customer i at time h sell to LTC (kW);
$E_{i,h}^{B}$: Available power stored in the battery of customer i at time h (kW);
$E_{i,h,\text{self}}^{B}$: Power discharged from the battery of customer i at time h for self-use (kW);
$E_{i,h,\text{outLTC}}^{B}$: Power discharged from the battery of customer i at time h sell to LTC (kW);
$E_{i,h,\text{outgrid}}^{B}$: Power discharged from the battery of customer i at time h to the grid (kW);
${f_{i,h}}^{\text{grid}}$: Binary variable indicating the energy purchase from the grid for customer i
${f_{i,h}}^{B}$: Binary variable indicating the charging state of the battery of customer i
${f_{i,h}}^{\text{LTC}}$: Binary variable indicating the energy purchase from the LTC for customer i
${f_{i,h}}^{\text{grid,sto}}$: storage for battery from the grid for customer i
${f_{i,h}}^{\text{LTC,sto}}$: Binary variable indicating the energy storage for battery from the LTC for customer i
${f_{i,h}}^{PV,\text{sto}}$: Binary variable indicating the energy storage for battery from the PV for customer i
$X_{j,h}$: Total energy sold to the grid from GenCo j at time h (kW);
$Y_{j,h}$: Total energy sold to LTC from GenCo j at time h (kW)

The mathematical model for the aforementioned problem is proposed in the coming 24 h as follows. The objective function is minimizing the cost of buying Energy for customers and maximizing the income for energy consumers and sellers, respectively. These two objectives have been formulated in the following expression.

$$
\begin{aligned}
\min\ \ Z = & \sum_h \sum_i E_{i,h}^{\text{grid}} \times p_h + \sum_h \sum_i (E_{i,h}^{LTC} - W_{i,h}(E_{i,h}^{\text{LTC}})) \times {p'}_h \\
& - \sum_h \sum_i E_{i,h,\text{salegrid}}^{PV} \times u_h + \sum_h \sum_i E_{i,h,\text{saleLTC}}^{PV} \times {u'}_h \\
& - \sum_h \sum_j X_{j,h} \times q_h + \sum_h \sum_j (Y_{j,h} + W_{j,h}(Y_{j,h})) \times {q'}_h
\end{aligned} \tag{1}
$$

$$
\text{s.t.} \quad \sum_{h \geq \alpha_{a_B}}^{\beta_{a_B} - l_{a_B}} ST_{a_B,h} = 1; \forall a_B, \forall h \in H \tag{2}
$$

$$
\sum_{h \geq \alpha_{a_B} + l_{a_B}}^{\beta_{a_B}} ET_{a_B,h} = 1; \forall a_B, \forall h \in H \tag{3}
$$

$$
\sum_{h \geq \lambda_{a_C,k}}^{\gamma_{a_C,k} - {l'}_{a_C,k}} {ST'}_{a_C,k,h} = 1; \forall a_C, k, \forall h \in H \tag{4}
$$

$$
\sum_{h \geq \lambda_{a_C,k} + {l'}_{a_C,k}}^{\gamma_{a_C,k}} {ET'}_{a_C,k,h} = 1; \forall a_C, k, \forall h \in H \tag{5}
$$

$$
ST_{a_B,h} = ET_{a_B,h+l_{a_B}}; \forall a_B, \forall h \in H; \alpha_{a_B} \leq h \leq \beta_{a_B} - l_{a_B} \tag{6}
$$

$$
ST'_{a_C,k,h} = ET'_{a_C,k,h+{l'}_{a_C,k}}; \forall a_C, k, \forall h \in H; \lambda_{a_C,k} \leq h \leq \gamma_{a_C,k} - l'_{a_C,k} \tag{7}
$$

$$
S_{a_B,h} = S_{a_B,h-1} + ST_{a_B,h} - ET_{a_B,h}; \forall a_B, \forall h \in H \tag{8}
$$

$$
S'_{a_C,k,h} = S'_{a_C,k,h-1} + ST'_{a_C,k,h} - ET'_{a_C,k,h}; \forall a_C, k, \forall h \in H \tag{9}
$$

$$
\begin{aligned}
& TL'_{a_C,k} \leq h \times ST'_{a_C,k,h} - \sum_{h'=1}^{h} h' \times {ET'}_{a_C,k-1,h'} \leq TL_{a_C,k}; \\

Constraints (2)–(5) represent the start and finish time of each appliance. Continuity of appliances' activities have been avouched by constraints (6) and (7). The situation of appliances' activities (on or off) have been showed in Eqs. (8) and (9). Constraint (10) represents the limitation for the gap between each sub-activity for appliances type C; it means that the finish time of sub-activity $k-1$ and start time of sub-activity k must be in a definite limit. Constraint (11) shows that the total load available from PV system is consumed for self-use, storing in the battery, selling to the grid and LTC. Constraint (12) represents available load stored in the battery at time $h+1$ during charge and discharge process. It remarks that the stored load at time $h+1$ is equal to initial load at time h with considering the self-discharge percentage, plus incoming load from PV system, the grid, and LTC deducting the amount of load needed for the customers' demand. As the full discharge of the battery reduces its lifetime constraint (13) confines the state of charge and discharge of the battery. Constraints (14) and (15) prevent the battery from charging and discharging simultaneously. Constraints (16)–(19) prevent the process of charging from three sources (grid, LTC, and PV) simultaneously for the battery. Constraints (20)–(23) illustrate the limit of simultaneous buying and selling electricity load process for both grid and LTC. Equation (24) confines that the total energy demand for an energy consumer is coming from the total energy needed for appliances type A, B, and C, and the amount of energy needed for charging the battery. Equation (25) expresses that the energy demand can be met through the energy purchased from the grid or LTC, or the energy supplied through PV or battery; taking into consideration the amount of energy transmission loss from the LTC. The last expression (26) represents the constraint for the generators' side. Total load available from every GenCo at time can be sold to the grid or LTC. Transmission loss has been considered in the process of selling electricity to the LTC.

3 Numerical Example

In order to show the performance of the hybrid energy system consisting of the conventional grid, LTC, energy consumers with different types of appliances and GenCos, a numerical example is presented. Based on the structure of the hybrid energy system illustrated in Fig. 1, the numerical example is utilized to verify the optimization model. Figure 4 shows the energy demand for appliances of type B and the cumulative energy demand. It has been considered there are four appliances of type B.

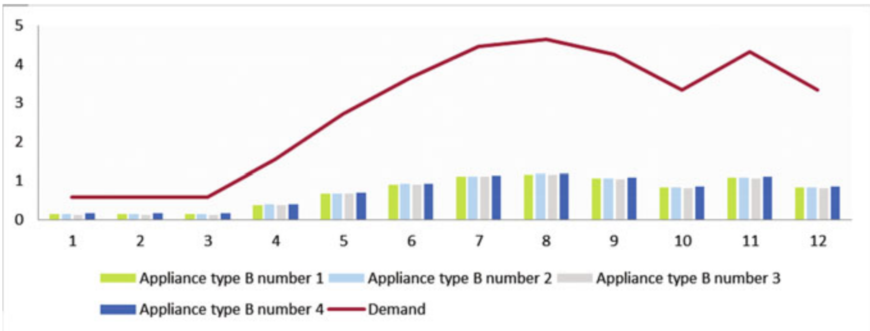

Fig. 4. Energy consumption of appliances type B and the total demand

Figure 5 shows the Energy sell-out and buy-back prices for both grid and LTC. In this example, it is assumed that the energy sell-out price for LTC is less than the energy sell-out price for the grid. Besides, the energy buy-back price for LTC is greater than energy buy-back price for the grid. The numerical example is carried out by using IBM ILOG CPLEX_Optimizer v12.3 on the PC with Intel(R) Core(TM) i7-4770 CPU@3.4 GHz and 8 GB RAM. Tables 1 and 2 represent the results. The consumer uses the PV energy and provides more energy with buying energy from LTC in order to meet energy demand in peak time.

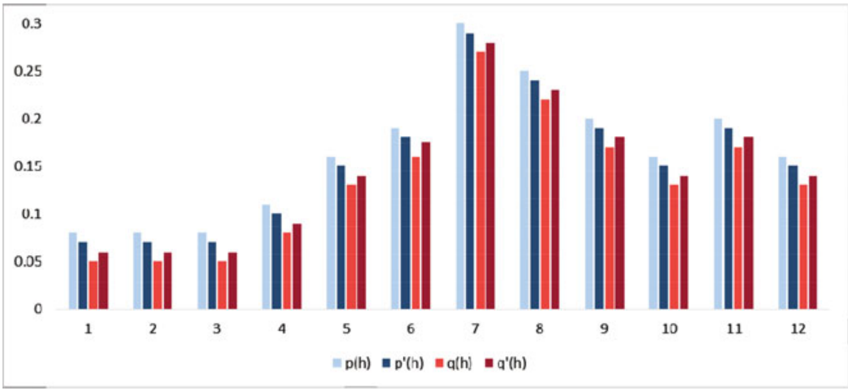

Fig. 5. Energy sell-out and buy-back prices for grid and LTC

Table 1. Energy buy-back schedule for the consumer

	Time slots											
	1	2	3	4	5	6	7	8	9	10	11	12
$E_{i,h,\text{self}}^{\text{LTC}}$	0.58	0.58	0.58	0.55	0.00	0.00	0.00	0.25	2.11	3.34	4.34	3.34
$E_{i,h,\text{self}}^{PV}$	0.00	0.00	0.00	0.99	2.72	3.66	4.46	4.41	2.16	0.00	0.00	0.00
sum	0.58	0.58	0.58	1.54	2.72	3.66	4.46	4.66	4.26	3.34	4.34	3.34

Table 2. Energy buy-back schedule for the GenCo

	Time slots											
	1	2	3	4	5	6	7	8	9	10	11	12
$Y_{j,h}$	0.13	0.13	0.13	0.51	0.82	0.99	0.79	0.95	0.88	0.54	0.99	0/89

4 Conclusion

Based on MILP theory, this paper formulated an optimization model to investigate the optimal operation strategy of the PV, battery, conventional grid, and LTC based residential hybrid energy trading system. Besides satisfying the residential electricity demands, total costs were minimized; moreover, the optimization scheme maximized the profit of GenCos. The LTC provides new opportunities for the energy consumers and GenCos to perform the local energy trading in a cooperative manner, as a result, they all can benefit. In this case, it has been considered that the LTC is a non-profit oriented LTC which aims at benefiting the energy consumers and energy sellers.

Numerical results are presented in order to validate the benefits of the considered hybrid energy market and the related DR mechanism.

A Fuzzy Multi-Criteria Evaluation Method of Water Resource Security Based on Pressure-Status-Response Structure

Talat Qadeer and Zongmin Li(✉)

Business School, Sichuan University, Chengdu 610064,
People's Republic of China
lizongmin@scu.edu.cn

Abstract. In many circumstances, water resources advancement and usage has come to or surpassed the global warning level. With expanding water request and shortage, utilities require compelling techniques for ideal utilization of accessible water resources. This paper proposes a fuzzy multi-criteria evaluation method for supporting the evaluation of water resources security. Firstly, this paper establishes a novel water resource security evaluation index system based on the Pressure-Status-Response (PSR) structure. Then, a revised TOPSIS method was utilized to handle fuzzy ratings and integrate the ranking outcomes. After that, data for 9 provinces from Yellow River basin are collected and the proposed methodology is applied to test the feasibility.

Keywords: Multi-criteria decision making · Water resource security · Fuzzy evaluation · Pressure-status-response · TOPSIS

1 Introduction

Water is a fundamental resource and indispensable material basis for energy, production, human society, and economic development [8,13,19]. The pivotal role of water is beyond doubt. However, when enjoying the benefits of water, the water conflicts between human and ecosystems are becoming increasingly acute. Despite having suffered the same dilemma many times throughout history and the rapidly developed technology, sharing water resources is not something societies tend to do well [13]. The long existing water conflicts, rapid population increases, climate change, water shortage and pollution have made water resource security an indispensable component of sustainable water resource management [20]. People in developing countries are particularly at risk because of severe water pollution, environmental damages, poor water supply conditions and even social conflicts caused by water problems.

Water resource security is a concept that was proposed in the late 20th century [6,7,21]. Nowadays, water security issue is becoming more and more

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_98

prominent and has attracted a worldwide attention and emphasis [3]. The evaluation and insurance of water security are the core issues of sustainable water resources management. There are increasing studies about water resource security evaluation. For example Jiang [6] studied on water resource safety strategy for China in the 21st century. Bitterman et al. [2] proposed a conceptual framework and candidate indicators for water security and rainwater harvesting. Chen [4] studied on water resources security concept and its discussion. Xia and Zhang [21] worked on water security in north China and countermeasure to climate change and human activity. Hall and Borgomeo [9] worked on risk-based principles for defining and managing water security. Norman et al. [14] worked on water security assessment: Integrating governance and freshwater indicators. Qian and Xia [5] worked on risk assessment of water security in Haihe River Basin during drought periods based on D-S evidence theory. However, a comprehensive evaluation of water resources security is such a complex, vague and multi-level evaluation process. Multi-criteria evaluation method of water security is still worthy depth research. In addition, due to the increasingly severe climate change, water scarcity and pollution, the problem of water resources security has becoming more and more important. Therefore, this paper presents a fuzzy multi-criteria evaluation method, which include indicator system under Pressure-Status-Response framework, uncertainty rating analysis, and aggregation method of TOPSIS with fuzzy judgments.

2 Evaluation Index System Establishment

Water resource security evaluation is multi-criteria in nature. This paper establishes the evaluation index system for water resources security evaluation based on the Pressure-Status-Response (PSR) approach, which is a causal one that covers causes and effects influencing a measurable state. In this sense, three categories of indicators are distinguished [15]:

- Indicators of environmental *Pressure* describe pressures on the environment originating from human activities, including quality and quantity of natural resources (e.g., emissions, mining of raw materials, fertilizer input).
- Indicators of environmental *State* are designed to describe the status quo of the environment and the quality and quantity of resources and their changes over time (e.g., forest area, protected areas).
- Indicators of societal *Response* show to which degree society is responding to environmental changes and concerns. This could be the number and kind of measures taken, the efforts of implementing or the effectiveness of those measures. Responses may range from public (e.g., legislation, taxation, promotion) to private sector activities (e.g., reduced consumption, recycling) [12].

The originally PSR approach is in this manner changed by presenting the monetary, biological and social perspectives of water resources security into the PSR model created on the established of key variables. The model still

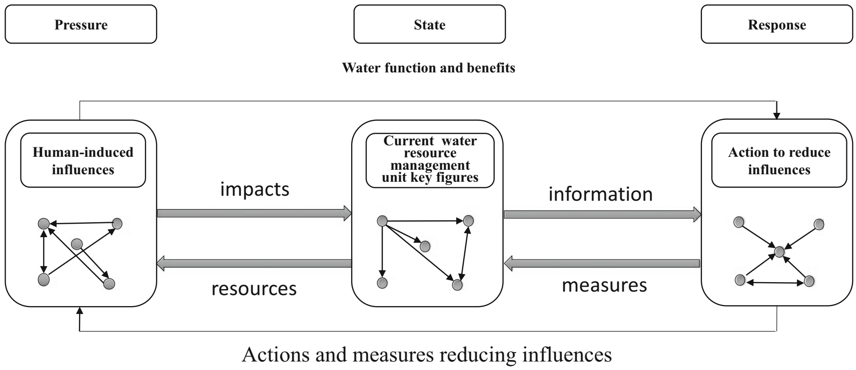

Fig. 1. Adapted pressure, state and response framework for evaluating security on the water resource management unit level

expands on the outstanding PSR structure (Fig. 1) including three boxes for Pressure, State and Response objects with the cases practically connected. Human-initiated Pressures incite impacts on State limitations by making utilitarian and monetary advantages additionally influencing the (societal) Response factors. The other way around Pressures utilize and deplete resources both subjectively and quantitatively (State) and undertaking information, choices and activities from Responses to control them. State and Response are connected by figures and material interchange on the one side and directly state-changing procedures on the other. Inside the three boxes, the structure is changed. Associations and impacts between variables are involved into evaluation by making system subsystems inside every case (Fig. 1) each pointer is appointed to each of the cases however conveying a different idea for the evaluation. Really, the examples of connotation will change among the groups since the pointers cover dissimilar PSR viewpoints for every indicator. This adjustment has been picked because a strict arrangement of indicator into boxes would mean loss of figures about the interconnections amongst indicator and their pertinence as per pressure, states and responses [18]. The interconnections between pointers are indicated by arrows in (Fig. 1).

Based on the PSR structure, we consider five criteria for water resource security, which are: water resources pressure (C_1), social-economic pressure (C_2), water resources state (C_3), social-economic state (C_4) and social-economic response (C_5).

3 Fuzzy Statement

The subjective evaluation part of water resource security evaluation, inevitably contains the evaluators' subjective judgments and preferences. This situation has further amplified the uncertainty of assessments inherent in the water resources security evaluation process. Evaluators cannot apply precise numbers to describe

Table 1. Linguistic variables and triangular IFNs for rating under the subjective evaluation criteria

Linguistic variables	Triangular IFNs
Very good (VG)	(0.9, 1.0, 1.0)
Good (G)	(0.7, 0.9, 1.0)
Medium good (MG)	(0.5, 0.7, 0.9)
Fair (F)	(0.3, 0.5, 0.7)
Medium poor (MP)	(0.1, 0.3, 0.5)
Poor (P)	(0.0, 0.1, 0.3)
Very poor (VP)	(0.0, 0.0, 0.1)

Table 2. Linguistic variables and triangular IFNs for rating the importance

Linguistic variables	Triangular IFNs
Very high (VH)	(0.7, 0.9, 1.0)
High (H)	(0.6, 0.7, 0.8)
Medium high (MH)	(0.4, 0.5, 0.6)
Medium (M)	(0.1, 0.3, 0.5)
Medium low (ML)	(0.1, 0.2, 0.3)
Low (L)	(0.0, 0.1, 0.2)
Very low (VL)	(0.0, 0.0, 0.2)

their assessments, however, they can utilize linguistic variables according to their professional knowledge and experience. Hence, the concept of fuzzy numbers can be integrated into the multi-criteria evaluation of water resources security.

Evaluators first make their own judgments of water resource security based on subjective evaluation criteria C_1–C_5. Ratings under subjective evaluation criteria are considered as linguistic variables. A linguistic variable is a variable whose value is a natural language phrase. It is very useful in dealing with situations which are ill-defined to be described properly in conventional quantitative expressions. Water resource security performance under each subjective evaluation criteria can be expressed on a 7-point rating scale: "very good","good", "medium good", "fair", "medium poor", "poor", and "very poor". Such linguistic variables are converted into triangular intuitionistic fuzzy numbers (IFNs) [1] as shown in Table 1. The linguistic variables and triangular IFNs for rating the importance are shown in Table 2. Figures for membership functions are shown in Figs. 2 and 3. IFNs are commonly used for solving decision-making problems, where the available information is imprecise. There are different shapes or forms of IFNs, among those, trapezoidal IFNs and triangular IFNs are the most commonly used. For example, Shaw and Roy [17] used trapezoidal IFNs for analysing fuzzy system reliability, while Vahdani et al. [22] applied triangular IFNs to fuzzy

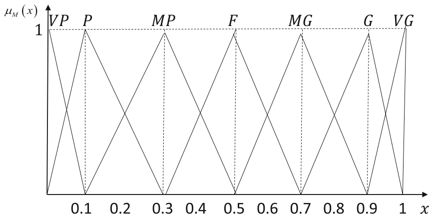

Fig. 2. Figure for membership functions of linguistic variables of rating under the subjective evaluation criteria

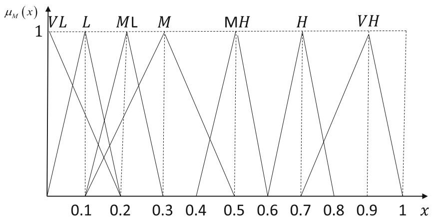

Fig. 3. Figure for membership functions of linguistic variables for rating under the importance

group decision-making problems with an application to the contractor selection. This paper chooses to use the triangular IFNs because of their conceptual and computational simplicities [11].

4 Aggregation Method

TOPSIS (Technique for Order Preference by Similarity to an Ideal Solution) method proposed by Hwang and Yoon [10] is adopted to aggregate all ratings. The basic principle of TOPSIS is that the chosen alternative must have the shortest distance from the ideal solution and the farthest distance from the negative-ideal solution [16]. The original TOPSIS is only applicable for crisp ratings. In this paper, all ratings are represented by triangle fuzzy numbers. Therefore, this paper extents the original TOPSIS to fuzzy environment. The detailed processes are listed as follows.

Suppose the fuzzy ratings under all criteria are denoted as $\boldsymbol{A} = [a_{ij}], (i = 1, \cdots, m, j = 1, \cdots, n)$.

Step 1. Normalize the evaluation index as: Compute the normalized fuzzy decision matrix ($\boldsymbol{V} = [v_{ij}]$). The normalized value n_{ij} is calculated as:

$$v_{ij} = \frac{a_{ij}}{\sqrt{\sum a_{ij}^2}}. \tag{1}$$

Step 2. Calculate entropy measure of every index the following equation:

$$p_{ij} = \frac{a_{ij}}{\sum_{i=1}^{m} a_{ij}}, \tag{2}$$

$$E_j = -K \sum_i [P_{ij} \times \ln P_{ij}], \quad \text{where} \quad K = \frac{1}{\ln(m)}. \tag{3}$$

Step 3. Define the divergence through:

$$d_j = 1 - E_j. \tag{4}$$

Step 4. Obtained the normalized weights of indexes as:

$$W_j = \frac{d_i}{\sum d_j}. \tag{5}$$

Step 5. Let $\tilde{a} = (a_1, a_2, a_3)$ and $\tilde{b} = (b_1, b_2, b_3)$ be two triangular fuzzy numbers, then the vertex method is defined to calculate the distance between them:

$$d(\tilde{a}, \tilde{b}) = \sqrt{\frac{1}{3}[(a_1 - b_1)^2 + (a_2 - b_2)^2 + (a_3 - b_3)^2]}. \tag{6}$$

Step 6. Determine the ideal and negative-ideal solution:

$$v_j^+ = v_i^+, \cdots, v_n^+ = [(\max v_{ij} | i \in I), (\min v_{ij} | i \in I)], \tag{7}$$

$$v_j^- = v_i^-, \cdots, v_n^- = [(\min v_{ij} | i \in I), (\max v_{ij} | i \in I)]. \tag{8}$$

Step 7. Calculate the separation measures, using the n-dimensional Euclidean distance. The separation of each alternative from the ideal solution is given as:

$$d_j^+ = \sqrt{\sum_{j=i}^{n} (v_{ij} - v_j)^2}, i = (1, 2, \cdots, m), \tag{9}$$

$$d_j^- = \sqrt{\sum_{j=i}^{n} (v_{ij} - v_j)^2}, i = (1, 2, \cdots, m). \tag{10}$$

Step 8. Calculate the relative closeness to the ideal solution. The relative closeness of the alternative a_j with respect to A^* is defined as:

$$C.L_i = \frac{d_j^-}{d_i^- + d_i^+}, I = 1, 2, \cdots, m. \tag{11}$$

Step 9. Rank the preference order. By ordering $C.\ L_i$ in descending order, provinces can be ranked from the best to the worst.

5 Case Study

This study presents a case study of 9 provinces from Yellow River basin. These 9 provinces of China are Qinghai, Sichuan, Gansu, Ningxia, Inner Mongolia, Shaanxi, Shanxi, Henan and Shandong. The original data are from Liu et al. [13]. Based on the original data, we have experts to make their fuzzy judgements for all the criteria (C_1–C_5). The decision table is Table 3.

We also have experts give their ratings about the importance of all criteria as shown in Table 4.

Based on Eqs. (1) and (2), we obtained results shown in Tables 5 and 7.

By using Eq. (3) results are $E_1, E_2, E_3, E_4, E_5 = (0.9, 0.9, 0.6), (0.8, 0.9, 0.9), (0.8, 0.9, 0.9), (0.6, 0.8, 0.9), (0.8, 0.8, 0.9)$ respectively (Table 6).

Henan	0.1, 0.1, 0.1	0.2, 0.2, 0.2	0.0, 0.1, 0.1	0.0, 0.1, 0.1	0.1, 0.1, 0.1
Shandong	0.1, 0.1, 0.1	0.1, 0.1, 0.1	0.0, 0.0, 0.0	0.0, 0.0, 0.1	0.0, 0.0, 0.1

Note: − and + signs denote the negative and positive criteria respectively.

After the weighted normalized decision matrix we obtain a fuzzy weighted decision table. Taking Qinghai as example, by applying the Eq. (6) results are given below:

$$\begin{aligned}
D_1^+ = &+\sqrt{\frac{1}{3}[(0-0.001)^2+(0-0.001)^2+(0-0.042)^2]}\\
&+\sqrt{\frac{1}{3}[(0-0.012)^2+(0-0.007)^2+(0-0.004)^2]}\\
&+\sqrt{\frac{1}{3}[(1-0.047)^2+(1-0.026)^2+(1-0.011)^2]}\\
&+\sqrt{\frac{1}{3}[(1-0.083)^2+(1-0.045)^2+(1-0.019)^2]}\\
&+\sqrt{\frac{1}{3}[(1-0.071)^2+(1-0.040)^2+(1-0.002)^2]}\\
=&2.756,\\
D_1^- = &+\sqrt{\frac{1}{3}[(1-0.001)^2+(1-0.001)^2+(1-0.042)^2]}\\
&+\sqrt{\frac{1}{3}[(1-0.012)^2+(1-0.007)^2+(1-0.004)^2]}\\
&+\sqrt{\frac{1}{3}[(0-0.047)^2+(0-0.026)^2+(0-0.011)^2]}\\
&+\sqrt{\frac{1}{3}[(0-0.083)^2+(0-0.045)^2+(0-0.019)^2]}\\
&+\sqrt{\frac{1}{3}[(0-0.071)^2+(0-0.040)^2+(0-0.002)^2]}\\
=&2.112.
\end{aligned}$$

Calculate the relative closeness to the ideal solution using Eq. (4), Qinghai's results are given below:

$$CL_{\text{Qinghai}} = \frac{2.112}{2.112 + 2.756} = 0.434.$$

By the TOPSIS method, we get the rank of 9 provinces as shown in Table 8.

Table 8. Table of ranks

Alternatives	TOPSIS index	Rank
Qinghai	0.434	1
Sichuan	0.403	5
Gansu	0.394	9
Ningxia	0.417	2
Inner Mongolia	0.405	4
Shaanxi	0.399	7
Shanxi	0.402	6
Henan	0.409	3
Shandong	0.396	8

Based on the ranking result of TOPSIS method, the water resources security degrees of the 9 provinces.

6 Conclusions

This paper presented a fuzzy multi-criteria evaluation TOPSIS method for the water resource security evaluation. 9 provinces within the Yellow River basin was ranked for the water resources security degree based on the proposed method. The structure of "pressure-state-response" was embedded in developing the methodology. A fuzzy multi-criteria was proposed not just to deal with the evaluation created on the established indicators, additionally to tackle the inherent suspicions. Based on the case study results, Qinghai, Ningxia, Henan, Inner Mongolia and Sichuan are ranked top 5 of the water security degree, with TOPSIS index greater than 0.4. Future research will be focused on the uncertainty analysis, innovative evaluation index system and aggregation methods of water resource security evaluation.

Abstract. Currently the concept of distributed power with application of renewable energy sources is gaining popularity and is becoming not only a supplement but also a real alternative of traditional energy supply from centralized networks. The distributed generators of electricity integrated into Unified Energy System (UES), represent difficult system in which communication between observable parameters and a system condition has difficult and ambiguous character. Therefore, the approach to management in the automatic control systems, based on management on output parameters, is inadequate as a matter of fact. In this case formation of operating influence should be carried out on the basis of data about a current condition of object of management. The daily schedules of electric load allow properly assess the mode of the work of electrical equipment and the enterprise as a whole, identify the bottlenecks and reserves, to set the optimal mode of the work. In this paper are considered an issue of the development of methods for the estimation of electrical loads for the various types of electricity customers in the residential and public buildings and addresses issues of the integration of distributed generators to the UES and ensuring the optimal management of technological modes of their work.

1 Introduction

The future power supply system should combine large power stations without which are problematic electro supply of large consumers and maintenance of growth of power consumption. Large power stations allow raising voltage with

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_99

generating to voltage of the main network on which there is a transport of the electric power to the large centers of consumption. Installations of the distributed generation, including on renewable energy sources (RES), work through distributive networks. The following level of a power supply system of the future will make mini-and micro-installations (mini-and micro-hydroelectric power station, wind generators, solar energy installations, fuel elements, etc.) which are connected on a low voltage and are established at small consumers, for example, in separate houses or on small enterprises, including agricultural [1,7].

In this regard, is currently the concept of distributed power with application of renewable energy sources (RES) is gaining popularity and is becoming not only a supplement but also a real alternative of traditional energy supply from centralized networks.

Distributed generation systems represent a hybrid power system consisting of various energy sources and are built in close proximity to the customer and to the maximum extent take into account the individual characteristics of the consumer's by power and profile (Fig. 1). They have such advantages as controllability, reliability, economy (including by eliminating the losses of transporting), scalability and flexibility [7].

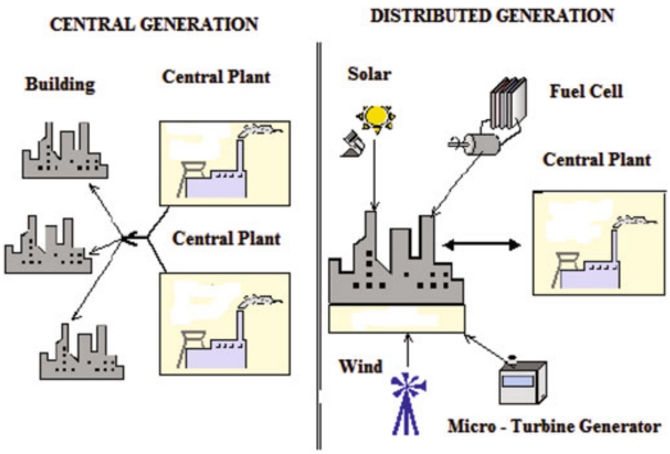

Fig. 1. A structural diagram a centralized and distributed power generation

In these systems electric energy is generated with use of solar photo-electric panels, wind turbines or other energy installations. Generating of thermal energy for systems of heating, hot water supply and technological processes is carried out with use of solar collectors (flat and vacuum tubular), geothermal systems, and also other converters of thermal energy. The combination of various renewable energy sources is not only presence of such elements, as solar collectors, photo-electric panels, wind turbines, thermal pumps, but also use of a uniform control system for maintenance of effective work of these elements that makes a basis of stable hybrid system of power supply.

As of today the distributed generation systems in most cases presented in the form of autonomous energy centers, as the connection of distributed generators to centralized networks so far is limited by the absence or imperfection of the regulatory framework and effective methods of controls of technological modes.

For an effective utilization of hybrid system of power supply with application of renewable energy sources (RES) it is necessary to co-ordinate intensity of receipt of energy with its expense consumers. Such coordination can be carried out on the basis of monitoring of the current information on receipt and power consumption and the management which is carried out by uniform system, constructed on the basis of modern information-communication technologies [2].

Control of the distributed generators is carried out as control of a micro network (micro grid) of the "virtual" power stations integrated into a global network (Unified Energy System-UES) and, thereby, in the electric power and capacity market that will promote increase of a role of the consumer in management of a power supply system [2].

On a way of creation of "virtual" power stations it is necessary to solve a number of the organizational-technological problems, one of which is the problem of connection of the distributed generators to a uniform network and management of their work. The distributed generators of electricity integrated into UES, represent difficult system in which communication between observable parameters and a system condition has difficult and ambiguous character. Therefore, the approach to management in the automatic control systems, based on management on output parameters, is inadequate as a matter of fact. In this case formation of operating influence should be carried out on the basis of data about a current condition of object of management [2].

The specific issues on usage of renewable energy sources as a distributed generator, as well the approach to the synthesis of the operational level of the active-adaptive system of automatic operation control of the combined plant as part of the UES were reviewed in the report [2].

The effectiveness of control by system of distributed generation of electrical energy, comprising renewable energy sources (RES), energy storages and intelligent control system is achieved through the ability to complex influence on the technological parameters of the generator modes.

For example, voltage regulation apart from the use of traditional means, may be implemented by change the generation of active or reactive power, by exposure on the energy storage means or by management of load.

This set of measures together with hardware and software represents the control system of system of distributed generation of electric energy.

The main purpose of this control system is the integration of distributed generators to the UES and to ensure the optimal management of technological modes of their work to meet the needs of consumers in the electrical energy.

Needs for electric power supply are characterized by the schedule of electrical loads. Dependence of load on time of day is called the daily schedule of electric load. It can be compiled for individual and group of electricity consumers, and for the Energy System, which includes a power plant or for large of the incorporated power system [6].

The daily schedules of electric load allow properly assess the mode of the work of electrical equipment and the enterprise as a whole, identify the bottlenecks and reserves, to set the optimal mode of the work.

Most fundamentally change in the electrical load associated with communal general needs. Fig. 2 represents the daily schedule, from which we see that the electrical load in the winter more than the summer and is sharply reduced at night hours [6]. The smallest of its value called of the minimum load. In the afternoon and evening hours is observed increasing of load and a more considerable change - in winter. There are two maximum loads-morning and evening. Schedule of electrical loads should be provided ("covered") on a mandatory basis. Therefore, aspire carry out all necessary renovations during the summer in order to virtually all equipment of power plant could be used to provide winter peak. This maximum is called the peak load.

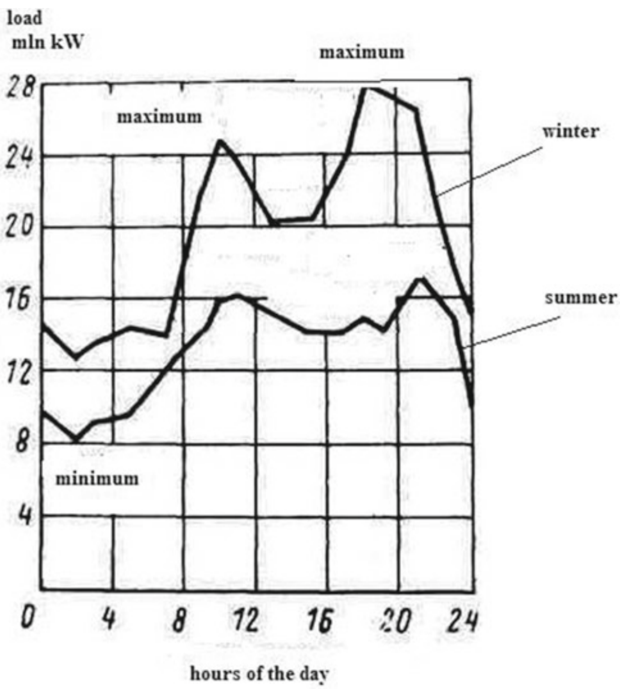

Fig. 2. Daily schedule of electric load

Calculation of the urban network load includes determining the load of individual consumers (residential buildings, public buildings, municipal services, etc.) and electrical elements of the system (distribution lines, transformer substations, distribution centers, power centers, etc.) [3].

In connection with the appearance of part of the population the possibility of use in the home of a wide range of modern household appliances and equipment, as well as in connection with the construction of urban and rural buildings on individual projects with luxury apartments, new specific standards of electrical loads should be determined based on the actual measurements electrical loads, taking into account their probabilistic nature and features of modern luxury apartments in new buildings of the city, analysis of electrical appliances market development and technology, the degree of saturation of apartments, both now and in the future.

In the cities, the problem of reliable determination of residential and public buildings loads, and provide energy savings is especially difficult, because of population growth and an increase the number of used electrical appliances. Along with the increasing number of electrical appliances used by the population grows and their installed capacity.

Modern residential buildings full of a lot of different power consumers. These include lighting and household appliances and power equipment. There is a constant process of improving housing comfort, and this in turn increases the amount of domestic power consumers and increased domestic electricity consumption. Increasing the number of storeys homes tightens the requirements for reliability and continuity of supply of electric networks.

The same features are characteristic and for public buildings, which include: a variety of institutions and the organization of management, finance, credit, state monopolies, education; pre-schools, libraries, archives, enterprises of trade, public catering, consumer services; hotels, hospitals, museums, entertainment and sports facilities.

In this regard, the reliable definition of electric loadings of residential and public buildings in the cities became very actual problem on which solution the end results of actions for energy saving in many respects depend. The normative document The electric facilities of residential and public buildings. Construction norms and rules using to calculate of loadings of residential buildings doesn't solve the designated problem, because the specific norms of electric loadings given in this document for various types of consumers of energy have been defined in the 80s last century and don't correspond to today's condition of power consumption in residential and public buildings. In many cases the calculated values of electric loadings of residential and public buildings defined according to this normative document with use of various correction coefficients aren't true [7].

2 The Problem Statement

Analysis of the existing regimes of power consumption in the urban electric network shows the need to develop new accounting standards specific to electrical loads for different types of residential and public buildings consumers, taking into account the current realities of power consumption in the residential and public sector [3–5].

Estimated electrical loads and dynamics of their growth in the future is the foundation that determines the nature of construction and the development of urban electrical networks. The electrical loads of houses and public buildings are random and depend on some of factors: the way of life of the various families, the number of power consumers and power and others. Therefore, the basis for determining the load is used the probabilistic and statistical approach to the load as a non-stationary random variable. Hence, the estimated electrical load or network element assumes to be probable maximum load value for an interval of 30 min.

To obtain reliable data while a design of standard charts and determine their numerical characteristics it is necessary correctly handle the experimental results, based on the position of mathematical statistics and probability theory. It should be borne in mind that, according to the law of large numbers and the theory of probability, the results determine the average aggregate will be valid when the number of tests or, in other words, the number of surveyed members together will be quite large. On the other hand, with an increase in the number of aggregate members, their examination is a huge work, and we have a problem of determining a sufficient number of members in the aggregate, that allow to obtain mean values with sufficient accuracy.

Therefore, for an assessment of this loading very often used some generalized indicators, coefficients, specific loadings and specific expenses of the electric power.

The existing algorithms of load calculation of the industrial power systems, determination of the maximum loads and the choice of electric equipment don't consider dynamics of growth and character of household loading, laws of its functioning, do not allow to take into account in calculating of the actual loading the relationship of load changes on a day of the week, time of day. Despite the large number of works on the subject, the daily schedule load model of residential and public buildings and their practical implementation are not well developed. There is not a program that gives to specify the load calculation data of residential and public buildings on the current state of the loads.

The method widely used for determining the maximum electrical load of electrical networks are based on the measurement of the average load of electrical consumers over a given time period t ($t = 8$ h or 0.5 h) with variable initial measuring point. The total number of electrical consumers, on which measurements are made should not be less than 20% of the total number of electrical consumers connected to the electric network (but not less than 15). Measurements should be carried out repeatedly and for a long time [2,7]. All these methods are characterized by a long time and a low accuracy of measurements; by a significant difference from the actual loads, especially the total; by significant errors in calculation (do not include the probabilistic nature of the electrical loads in the urban network). These methods also do not take into account the time factor of maximum electric load of each customer. In addition, these techniques are designed for installations with a regular operating mode and require large amounts of additional measurements and not possible to determine the desired value for a predetermined time period including at least three units.

The way of definition of the maximum load of electric consumers [6] according to which measure once individual loadings in various technological operating modes, total time of each technological mode for basic time and calculate the load group with a probability of exceeding no more than the required conditions of the problem.

However, this method does not provide sufficient accuracy while determining the estimated load for a group of different types of electric consumers, in particular, if even in the same technological modes individual electrical loads are not constant.

3 A New Method of Solving the Problem

A method for determining the maximum electrical load of electrical networks and individual electrical consumers patented by one of author of this paper [5].

This method significantly reduces the numbers and time of measurements and improve the accuracy and reliability of determining the maximum electrical load of consumers.

The essence of a way is electric loads of the certain consumers are measured in various technological operating modes for basic time. Then from set of the measured loads the maximum size of load of the certain consumers is determined. The maximum value of the electric load is defined as the highest value for all of the measured periods of typical daily schedules, with a maximum electrical load in a time interval 15-minute and 30-minute. Further calculation of loads of a network is conducted in a general view on a formula [4].

Let's us consider the essence and use of this new method. The essence of the new method for calculating the load of 0.4 kV and 6–10 kV electrical networks is to determine estimated load for each time period of the day according to the on typical daily schedule of customer load. It is found by summing of the mathematical expectations and the mean square deviations of all consumers. For the calculated maximum value of the total load is accepted its greatest value from all the calculating for hour or half-hour periods of the daily schedule.

The mathematical expectation for the construction of a typical load graph of homogeneous consumers will be equal [4]:

$$\overline{P_{cpi}} = \frac{\sum_{\beta=1}^{m} \times \sum_{\gamma=1}^{l} \times \sum_{j=1}^{n} Y_{ij\gamma\beta}}{m\,\ln},$$

where

P_{cpi} : mathematical expectation of the random load;

Y_{ij} : matrix of initial values of the loads daily schedule;

n : the number of points measured value of the daily schedule for a half-hour or hour interval;

l : the number of load measurements (in days) in each point at electrical network;

m : the number of homogeneous consumers, accepted as experimental.

So, the root-mean-square deviation equals:

$$\sigma_{\overline{p}i} = \sqrt{D_i} = \sqrt{\frac{\sum_{\beta=1}^{m} \times \sum_{\gamma=1}^{l} \times \sum_{j=1}^{n} Y_{ij\gamma\beta}^{2}}{m\,\ln} - \left(\frac{\sum_{\beta=1}^{m} \times \sum_{\gamma=1}^{l} \times \sum_{j=1}^{n} Y_{ij\gamma\beta}^{2}}{m\,\ln}\right)^{2}}.$$

The value of measured daily schedule load can be given as a matrix-current or power, where:

i : rows (at half-hour intervals $i = 48$ per day, at hourly intervals $i = 24$).

j : columns of the matrix (at 5-minute increments of the load curve in a half-hour interval $j = 7$, $j = 13$ in an hour interval).

Investigation of the electrical load of public buildings has its own peculiarity. Average maximum values of different groups of public buildings cannot be subjected to similar statistical processing as the load of residential buildings, so there are large variations in the average value of apartments load. Because absolute values of electrical loads for different by construction and character of public building have a very large variation of average values and do not provide sufficient accuracy of calculations. Therefore, it is necessary to conduct processing of public buildings statistical data for homogeneous consumers.

4 The Algorithm of a New Method Implementation

The algorithm of the new method is as follows [4]:

- The experimental investigations of urban power consumers and electrical loads conduct.
- Using the mathematical apparatus of the theory of probability and mathematical statistics are being built characteristic (model) daily schedules of electrical loads for all types of urban power consumers and the electrical load.
- On the basis of these daily schedule characteristic, using Lagrange, Newton, Stirling, Bessel, Chebyshev and others methods are determined analytical functions (equations, formulas) of curves (daily schedules) of mode changes each consumer.
- Next, by functions (equations, formulas), which are describes curve of the daily schedule load, analytically are defined of maximum coefficients Km.

In general, the equation describing the daily schedule of electric load has the form:

$$S\left(x\right) = U_{i=1,\cdots,24} S_i\left(x\right),$$

or

$$\begin{aligned}
S_3\left(x\right) &= \left(x_i^3 - 3x_i^2 x + 3x_i x^2 - x^3\right) + \left(x^3 - 3x^2 x_{i-1} + 3x x_{i-1}^2 - x_{i-1}^3\right) + \frac{f_{i-1}}{h_i} x_i \\
&\quad - \frac{M_{i-1}\cdot h_i^2}{6h_i} x_i - \frac{f_{i-1}}{h_i} x + \frac{M_{i-1}\cdot h_i^2}{6h_i} x + \frac{f_i}{h_i} x - \frac{f_i}{h_i} x_{i-1} - \frac{M_i \cdot h_i^2}{6h_i} x + \frac{M_i \cdot h_i^2}{6h_i} x_{i-1} \\
&= (M_i - M_{i-1}) \cdot \frac{x^3}{6h_i} + \frac{3}{6h_i} \cdot (M_i x_i - M_{i-1} x_{i-1}) x^2 + (M_i \cdot {x^2}_{i-1} - M_{i-1} \cdot {x^2}_i - 2f_{i-1}, \\
&\quad + M_{i-1} \cdot {h^2}_i - M_i \cdot {h^2}_i + 2f_i) x + (M_{i-1} \cdot {x^3}_i - M_i \cdot {x^3}_{i-1} + 6f_{i-1} \cdot x_i - 6f_i \cdot x_{i-1} \\
&\quad - M_{i-1} \cdot h_i^2 \cdot x_i + M_i \cdot h_i^2 \cdot x_{i-1}) \frac{1}{6h_i} \\
&= a_{i0} \cdot x^3 + a_{i1} \cdot x^2 + a_{i2} \cdot x + a_{i3},
\end{aligned}$$

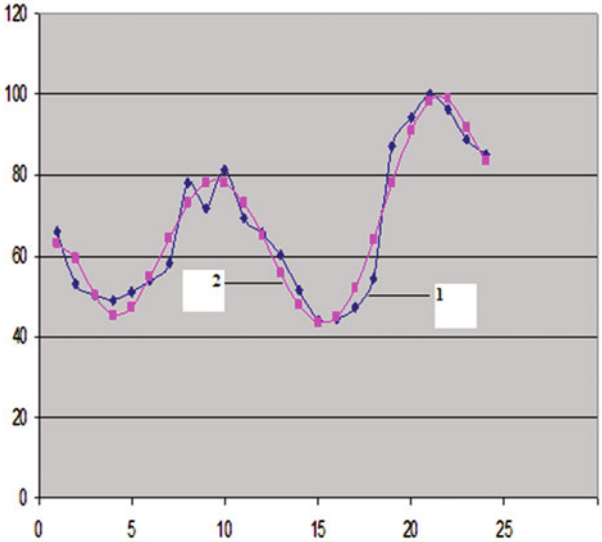

Fig. 3. The characteristic (typical) daily schedule of electric load of the shop manufactured goods: 1- constructed from experimental data, 2- built by Lagrange polynomial

where

$$
\begin{aligned}
a_0 &= \frac{M_i - M_{i-1}}{6h_i}, \\
a_1 &= \frac{1}{2h_i}(M_{i-1}x_i - M_i \cdot x_{i-1}), \\
a_2 &= \frac{1}{2h_i}(M_i \cdot {x^2}_{i-1} - M_{i-1} \cdot {x^2}_i + M_{i-1} \cdot {h^2}_i - M_i \cdot {h^2}_i - 2f_{i-1} + 2f_i), \\
a_3 &= \frac{1}{6h_i}(M_{i-1} \cdot {x^3}_i - M_i \cdot {x^3}_{i-1} + 6f_{i-1} \cdot x_i - 6f_i \cdot x_{i-1} \\
&\quad + M_i \cdot h_i^2 \cdot x_{i-1} - M_{i-1} \cdot h_i^2 \cdot x_i).
\end{aligned}
$$

On the base of this algorithm, substituting the values M_i, f_i, h_i, x_i from the table, we obtain a system from 24 equations in 3rd order.

As a result, for the curve of the daily schedule of electric load we obtain a system of equations, which has the following general form:

$$S_3\,(x) = a_{i0}x^3 + a_{i1}x^2 + a_{i2}x + a_{i3},$$

where a_{i0}, a_{i1}, a_{i2}, a_{i3}: coefficients of each equation.

Substituting the data from the daily schedule in these equations, we can obtain the curve segments of the daily schedule, and combining all of the 24 segments, as a result, get the curve of daily schedule, that is almost completely coinciding with the characteristic of daily schedule of consumer loads.

For each electrical consumer or appliances construct its equation of the curve and own formula for the maximum electrical load. As a result, the calculation is obtained precise and more authentic and closer to the actual load, taking into account the peculiarities of load conditions change, the time factor for each appliance and consumer included in the city's power system.

Example 1. The characteristic (typical) daily schedule of electric load of shop manufactured goods, built using the Lagrange polynomial for $x_0 = 1$, $x_1 = 10$, $x_2 = 16$, $x_3 = 22$; $y_0 = 10$, $y_1 = 54$, $98 = v_2$, $v_3 = 10$ is as follows (Fig. 3) [4]:

$$P\left(t\right) = 21.95057 - 15.91852t + 2.72962t^2 - 0.26084t^3.$$

5 Conclusions

The distributed generators of electricity integrated into Unified Energy System (UES), represent difficult system in which communication between observable parameters and a system condition has difficult and ambiguous character. Therefore, the approach to management in the automatic control systems, based on management on output parameters, is inadequate as a matter of fact. In this case formation of operating influence should be carried out on the basis of data about a current condition of object of management.

The daily schedules of electric load allow properly assess the mode of the work of electrical equipment and the enterprise as a whole, identify the bottlenecks and reserves, to set the optimal mode of the work.

This paper develops an improved method for determining the estimated electrical loads in residential and public buildings with using characteristic of daily load curves of the same type of consumers, constructed from experimental measurements of the characteristics of the typical power consumption of residential and public buildings consumers.

The use of the developed methods, models and algorithms allow more reliably determine the electrical loads in modern residential and public buildings taking into account peculiarities the load condition change each electrical consumer and load, included in the city's power supply system.

Abstract. The purpose of this paper is to study the effects of air pollution, especially the haze, on the stock returns of steel mills. This study collects data from air quality index, variables represent characteristic of the eleven steel mills in China and the stock returns ratio from the stock market etc. SPSS19.0 is utilized to conduct a descriptive analysis of the correlation between the principal air pollution(including $PM_{2.5}$, PM_{10}), the variables represent charactering(monetary funds, net assets, liabilities, operating margin, financial leverage, and total asset growth) of the elven steel mills in China and the stock returns ratio from the stock market etc. Hence, through the research on the air pollution index, analysis of the listed company's earnings and stock price, and by using the linear regression analysis method, research shows that the serious air pollution have a negative impact on the profitability of iron and steel enterprises through the emotion and expectations of investors. It is imperative for people to tackle air pollution urgently.

Keywords: Haze related air pollution · Stock return rate · Listed steel companies

1 Introduction

With the rapid economic development and fast expansion of productive enterprises, China is increasingly facing the large-scale severe air pollution. Air pollution with $PM_{2.5}$ and PM_{10} as the main pollutants troubles the people's life, threatening their health. According to a report released by the WHO in May, 2016, seven of the world's 10 cities with the most severe air pollution are in China (China Environmental Report 2016). $PM_{2.5}$ has an essential impact on air quality and visibility, and the haze may last longer based on the different geographical and meteorological conditions, impairing the people' health considerably. The report further shows that less than 1% of China's 500 largest cities

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_100

meet the air quality standards recommended by the WHO (China Environment Report 2016).

The severe air pollution is caused principally by the rapid growth of productive enterprises which use coal as the main raw material and highlight high energy consumption. To maximize the profits, these steel companies have ignored environmental protection, and even sacrificed the environment for a long time, causing serious environmental problems, threatening future health of the Chinese people and sustainable development of the ecosystem. As a resource-intensive industry, the iron and steel industry, using coal as the main source of energy, explores a variety of powdery and massive ferrous metals and non-metallic minerals through large-scale production and complex processes. The emissions of the iron and steel industry can be divided into three categories: The first is the exhaust gas caused in the production process, such as the smoke, sulfur dioxide and other harmful gases generated through the sintering, smelting, and steel rolling process. The second type is the dust and sulfur dioxide produced by burning fuels, for instance, coal and coal gas, in the furnace. The third category is the dust generated during the processes of transporting, loading and discharging and processing of raw materials and fuels.

The smog not only severely impairs people's health but limits their outdoor activities as well. It affects individual mental activities and emotional states, resulting in more negative emotions. This paper seeks to study whether air pollution, especially the smog, affects the steel plants' stock returns. Through examining the air pollution index, the paper analyzes the earnings and stock prices of listed steel companies, and uses the linear regression analysis to investigate whether the air pollution has relevance to the stock returns of these enterprises. The structure of this paper is as follows: Introduction comes the first, which is followed by a literature review–the second section. The third part is the research model, data and the method. Then, the paper presents the empirical research results and the corresponding analyses and discussions, which constitute the fourth section. Last, it draws conclusions and provides suggestions.

2 Literature Review

Studies have shown that air pollution directly or indirectly affects people's psychological conditions and emotions. Lepori [8], using different trading techniques in Italy and samples from major international stock exchanges, demonstrated the relationship between air pollution, people's emotions, as well as stock returns. Evans [5] find that exposure to polluted air increases the level of depression, anxiety, helplessness, and anger. Emotion affects people's assessment of both future prospects and risks [13]. Some studies reveal that air pollution is positively correlated with people's negative emotions. Levy [9] examined the relationship between air pollution and stock returns. Using air quality indices and stock return data from four US stock exchanges, they argue that air pollution is negatively correlated with stock returns. Mehra [11] observed, in their study, that small emotional volatility has significant impacts on the fluctuation of capital prices. Lucy [10] held that emotions, which are not caused by the investors' future decisions, may still affect the decision makers.

To address the deteriorating air quality and ease the increasing public concern, relevant government departments may reinforce stringent emission standards and formulate strict environmental policies to control the high pollution and high emissions behavior. The regulatory policies strengthening environmental protection will affect the stock returns of iron and steel companies with the such characteristics as high input, high pollution, and high energy consumption [12]. Taking China's steel mills as examples, considering the serious environmental protection attitudes and stringent environmental standards, steel mills will face greater pressure from environmental protection and environmental costs, and the stock returns of the listed steel companies will be affected accordingly. Meanwhile, air pollution may easily trigger industrial policy adjustments, which, in turn, lead to the re-allocation of resources. This may impact the listed companies' operating performances and growth prospects, resulting in stock price fluctuation [4]. In addition, other government policies, for instance, security regulations, energy prices, credit rationing, and international cooperation, which are closely related to air quality, also have a significant impact on the stock prices of the listed companies [6].

It is worth noting that air quality is regional and it largely affects the sentiment of local investors, especially individual investors. Likewise, air pollution may impact the stock market through influencing the stock traders' emotion. Currently, the two major stock exchanges and three futures exchanges in China adopt the command-driven system rather than the quotation-driven system, and all trading quotations should be input to the matching system by the investors with the help of the agent brokers (exchange members). As for the command trading system operators, when their emotions are affected by local air pollution, their rational judgment and selection ability may be reduced, resulting in irrational trading behavior and causing stock price fluctuation. In the information age, individual investors are still the largest fund providers and the main traders in the current stock market [3], among whom there is a "herd effect" [1,2,7]. In this context, when outside investors make trade decisions (of the listed companies) based on the air quality of the major cities (e.g. Beijing, Shanghai), the "herd effect" may further amplify the impact of air quality on the stock market of the steel industry.

3 Model and Assumption

3.1 Data

This paper studies 11 Chinese steel plants, which are Shanghai Baosteel (600019), Shougang Group (000959), Ansteel Group Corporation (000898), Wuhan Iron and Steel (Group) Company (600005), Jiangsu Shagang Group Co., Ltd. (0020), Taiyuan Iron & Steel (Group) Co., Ltd. (000825), Jinan Iron and

Steel Co., Ltd. (600022), Panzhihua Iron and Steel (Group) Co. (000629), Hesteel Group Tangsteel Company (000709), Benxi Iron and Steel (000761), and Nanjing Iron and Steel Group Co., Ltd. (600282). The paper gathers the stock returns and feature variables (monetary funds, net assets, liabilities, operating margin, financial leverage, and total asset growth) from the CSMAR database. Moreover, some data of financial leverage and total asset growth are collected from the WIND database and China Securities Depository and Clearing Corporation Limited (CSDC).

This paper uses six variables (monetary funds, net assets, liabilities, operating margin, financial leverage, and total asset growth), which are borrowed from Berger and Tuttle, to examine the stock information of the steel companies from different dimensions. The annual financial statements are released with a time lag. That is, the announcements are usually released in March of the next year. In order to ensure the relative effectiveness of the financial information, the paper uses the financial information (July, t, $\sim$ June, $t+1$) as the stock transaction data of the $t-1$ year.

Table 1. The definitions of explained variables

Explained variables	Comments
Monetary funds	Indicates the size of the company
Net profit assets	Indicates the company's ability to develop
Debt ratio	Indicates the company's ability to repay the debt
Operating margin	Indicates the company's growth characteristics
Financial leverage	Indicates the company's profitability
Total assets growth rate	To determine the stability of the stock return rate

The urban air quality data used in this study are gathered at the sites of the steel plants. Partly of the data are from the $PM_{2.5}$ hourly data monitored by the five US embassies and Consulates in China. The 2013–2015 air quality index data (such as SO_2, NO_2, CO, $PM_{2.5}$, PM_{10}, and AQI) are obtained from the Ministry of Environmental Protection of the People's Republic of China.

3.2 The Model

In order to investigate the impact of air pollution on the earnings of the steel mills, the paper uses an ordinary least squares (OLS) regression model, which is as follows:

$$\text{For Returns} = \alpha^{X_1} + \beta^{X_2} + e.$$

For Returns represents the dependent variable and refers to the monthly rate of return of the steel plant.

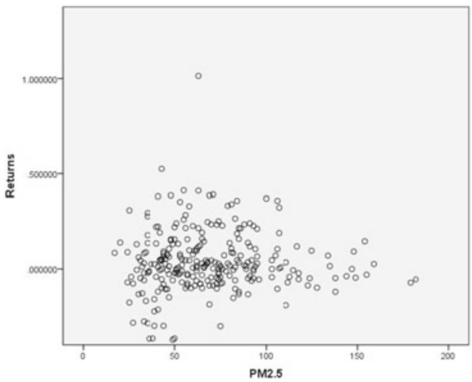

Fig. 1. A scatter plot of returns and $PM_{2.5}$

In the model, α denotes a constant term; e is the random error term; β signifies the weight associated with the explanatory variable; X_1 is $PM_{2.5}$ and X_2 represents PM_{10}.

The purpose of this paper is to explain whether and how air quality affects the profitability of the iron and steel plants. The explanatory variables involved are mainly the air quality indicators. The explained variables include data such as monetary funds, net profit assets, debt ratio, operating margin, financial leverage and total assets growth rate (Table 2).

The linear model: $Y = -0.179 \times X_1 + 0.233 \times X_2 + e$, where Y represents the returns, X_1 is $PM_{2.5}$, X_2 denotes PM_{10}, and e signifies the error.

In Table 3, the correlation coefficient R^2 is 0.015, which is very small and close to 0. Therefore, the returns are not significantly correlated to $PM_{2.5}$ and PM_{10}, and the e of the model is larger.

According to the analysis of the above theoretical background, in this paper, the assumption is as follows serious air pollution have a negative impact on the profitability of iron and steel enterprises.

Table 2. Model summary

Model	R	R Square	Adjusted R Square	Std. Error of the estimate	Change statistics				
					R Square change	Change F	df1	df2	Sig. F change

4 Empirical Results and Analysis

4.1 Descriptive Analysis

General descriptive statistical analysis & descriptive statistical analysis by company names (Table 4).

Table 4. The overall descriptive statistics are summarized

	N	Min	Max	Mean	Std. deviation	Variance	Skewness	Std. error of skewness	Kurtosis	Std. Error of kurtosis
Returns	263	−0.3729	1.0142	0.0392	0.1611	0.026	1.006	0.15	5.056	0.299
$PM_{2.5}$	275	17	182	67.95	30.103	906.212	1.072	0.147	1.311	0.293
PM_{10}	275	40	259	113.84	42.381	1796.152	0.729	0.147	0.241	0.293
Valid N (list wise)	263									

The population standard deviation of net profit is very large, indicating significant fluctuations of the net profit. The variance of $PM_{2.5}$ and PM_{10} is relatively small, but also they are over 30, reflecting obvious fluctuations of the air quality. The skewness of $PM_{2.5}$ and PM_{10} is greater than 0 and has a maximum, which should be removed, suggesting the right deviation. The skewness of the net profit is less than 0, showing left deviation. The skewness has a minimum, which should be removed (Table 5).

Table 5. The conclusion and analysis of the overall descriptive statistics

4.2 Descriptive Statistical Analysis by Companies

In terms of companies, the average net income of Panzhihua Iron and Steel (Group) Co. is negative, suffering loss, while the average $PM_{2.5}$ and PM_{10} of this enterprise are 35.72 and 74.56, respectively, considerably lower than the overall $PM_{2.5}$ and PM_{10} average, namely 67.95 and 113.84. It shows that the air quality of Panzhihua Iron and Steel (Group) Co. is better than the overall situation. The Shanghai Baosteel Group has the highest net income, the average $PM_{2.5}$ and PM_{10} of which are 55.56 and 75.64, lower than the overall $PM_{2.5}$ and PM_{10} average. As for other data, the net income fluctuates substantially, and the $PM_{2.5}$ and PM_{10} are close to the overall mean. Therefore, the relationship between $PM_{2.5}$ and PM_{10} and steel plants' net income cannot be analyzed directly (Table 6).

Table 6. Descriptive statistical test: Chi-Square tests

Test of $PM_{2.5}$	Value	df	Asymp. sig.(2-sided)
Pearson Chi-Square	23098.601[a]	23100	0.501
Likelihood ratio	2243.815	23100	1
Linear-by-linear association	0.109	1	0.741
N of valid cases	263		
Test of PM_{10}	Value	df	Asymp. Sig. (2-sided)
Pearson Chi-Square	30356.775[a]	30492	0.707
Likelihood ratio	2395.163	30492	1
Linear-by-linear association	1.666	1	0.197
N of valid cases	263		

[a] 30856 cells (100.0%) have expected count less than 5. The minimum expected count is .00.
[b] 23432 cells (100.0%) have expected count less than 5. The minimum expected count is .00.

The Table 1 is a chi-square test of $PM_{2.5}$, while the second is a chi-square test of PM_{10}. It can be seen from the tables that $sig < 0.05$, meaning that there are significant differences between $PM_{2.5}$, PM_{10} and the net income (Table 7).

The Table 1 is about $PM_{2.5}$ and the second is about PM_{10}. The values of the symmetric measures are both around 0.99, which is much larger than 0.1, indicating correlation between $PM_{2.5}$, PM_{10}, and the net income.

4.3 Correlation Analysis

As shown in the PM_{10} and net profit correlation Table 8, for most areas, the absolute value of the Pearson correlation coefficient between the net profit and PM_{10} is relatively low, suggesting an insignificant impact of PM_{10} on the net profit. Only a few areas are excepted: For instance, Jiangsu shows strong correlation.

Table 7. Symmetric measures

	Spearman correlation	0.083	0.062	1.341	.181[c]
Interval by interval	Pearson's R	0.08	0.053	1.292	.197[c]
N of valid cases		263			

[a]Not assuming the null hypothesis.
[b]Using the asymptotic standard error assuming the null hypothesis.
[c]Based on normal approximation.

This correlation varies from region to region. For example, Shanghai and Jiangsu show a positive correlation. That is, the net profit increases with the rise of PM_{10}. In contrast, Nanjing shows a strong negative correlation. In other words, the net profit reduces with an increase in PM. Overall, the majority of the cities show a negative correlation. That is, when the PM_{10} increases, the net profit decreases.

According to the correlation analysis of PM_{10} and the total assets growth, different from the net growth rate, most regions show strong positive correlations. That is, the total asset ratio will rise with the increase in PM_{10}. For example, Jinan, Panzhihua, Tangshan, and Benxi show a strong positive correlation. Jiangsu, however, shows a strong negative correlation.

The correlation coefficient between $PM_{2.5}$ and the return is less than 0.2, reflecting a weak correlation. Although some correlation coefficient of PM_{10} is over 0.2, but they are less than 0.5, indicating its weak correlation with the return. $PM_{2.5}$ and PM_{10}, hence, impact the return of the steel companies.

Table 8. Correlations

		Returns	$PM_{2.5}$	PM_{10}
Pearson correlation		1	0.02	0.08
	$PM_{2.5}$	0.02	1	0.856
	PM_{10}	0.08	0.856	1
Sig. (1-tailed)	Returns	.	0.371	0.099
	$PM_{2.5}$	0.371	.	0
	PM_{10}	0.099	0	.
N	Returns	263	263	263

PM_{10}	Pearson correlation	0.08	.857[a]	1
	Sig. (2-tailed)	0.197	0	
	N	263	275	275

[a] Correlation is significant at the 0.01 level (2-tailed).

5 Conclusion and Suggestion

This paper, based on a theoretical analysis, argues that air quality may affect stock market participants through emotions, policies, and expectations, ultimately impacting the steel companies' rate of return.

The results of this study show that severe air pollution has a negative effect on the profitability of the steel companies. The air pollution is not only an environmental problem, but also an economic and financial issue. Therefore, it is imperative for people to tackle air pollution urgently. The steel companies should increase the public transparency of information, enhance the development of corporate social responsibility activities, improve the corporate image. Air pollution event occurs, investors should keep rational judgment and choice ability, make relevant rational trading behavior. Relevant government departments should reinforce stringent emission standards and formulate strict environmental policies to control the high pollution and high emissions behavior to address the deteriorating air quality and ease the increasing public concern.

The research enriches the literature regarding the influence of investor sentiment on the capital market, and provides the empirical estimation of the impact of air pollution on the Chinese capital market. It has certain reference value for the relevant government departments in terms of policy evaluation and decision-making.

Abstract. Based on the perspective of low carbon and greenhouse gas emission reduction, this paper utilizes the synergy theory to analyze the coupling and coordination characteristics of China's energy investment and financing, and argues that energy investment and energy financing constitute a composite system and find that it has a stress effect on the climate environment, and the climate environment has a constraint effect on energy investment and financing. According to the analysis of the coupling relationship between the two, the energy industry investment and financing coupling coordination model and evaluation index system are established. By revealing the development law and evolution trend between the two, we will actively promote the coordinated and coordinated development of economic growth, energy supply and climate and environment, and provide new research ideas and analysis methods.

Keywords: Renewable energy · Investment and financing · Coupling mechanism · Coordination model

1 Introduction

In recent years, affected by the combined effects of resource endowment constraints and economic growth, China's energy production and energy consumption is dominated by coal, greenhouse gas emissions are rising rapidly has become the first emissions of global carbon dioxide and sulfur dioxide [5]. In recent years, China's atmospheric pollutant emissions continue to increase, the composite air pollution has become increasingly prominent, sulfur dioxide, nitrogen oxides and volatile organic compounds led to the second pollution was intensified, which include Fine particulate matter, ozone, acid rain and so on. The formation cause of air pollution is complex energy production and processing conversion is one of the important source. So it is imperative to realize energy saving and emission

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_101

reduction and low-carbon development in the energy industry. Energy industry investment and financing is to regulate and control the energy industry to improve the level of its clean production, “the total valve”, both the coupling coordinated development will help to accelerate the existing technology and equipment to upgrade and clean production projects and technology operation, to fundamentally reduce the energy consumption, reduce industrial emissions, to promote the coordinated development of energy, economy and environment, the purpose of climate. Investment in energy industry and energy industry financing interaction coupling relationship as follows: Energy industry investment through the production of investment and pollution control investment in two aspects of stimulating financing development, energy industry financing through the support of the above two aspects to promote investment expansion. When the energy industry investment expansion too fast and beyond the ecological environment carrying capacity limit, the government based on the reality of environmental degradation will significantly enhance the policy constraints of environmental protection and greenhouse gas emission reduction. Under the comprehensive control of industrial policy, credit policy and environmental protection policy, the energy industry financing will continue to shrink and restrict the energy industry investment. Instead, consistent with the national industrial policy, climate and environment protection policy of renewable energy projects in the production, energy production source pollution control and cleaner production projects will receive financing inclination, thereby stimulating investment in areas related to energy industry development. When the pollution control of energy production of excessive growth of investment, the economic principle of optimal use of funds is not consistent, the development of energy industry investment will be blocked due to the lack of funds, climate and ecological environment protection also lost the support of the construction. With the rapid growth of economy, the increasingly intensified climate environment has become an important bottleneck in the development of energy economy. This paper is based on the macro policy background of greenhouse gas emission reduction from the theory of synergetic and coupled coordination evaluation method the energy industry investment and energy industry financing can be considered as two subsystems, in the analysis of the two coupling based on the coordination of the relationship, the establishment of energy industry investment and financing coupled coordination model and the order parameter evaluation index system. By revealing the law of development and evolution trend of the two, to provide a new research ideas and analysis methods for the effective treatment of economic growth energy supply and climate environment deterioration of the prominent contradictions and actively promote the coordinated development of coupling.

Coupling coordination theory is mainly used to study economic management in technology innovation and technology management, industry cluster and industry chain and ecological environment and regional economic problems [1,3,6,7]. American scholar Weick [8] first used coupling theory to study economic and social problems, he explained the relationship between the school members contact each other but keep each other independent through loose coupling theory. Norgaad [4] put forward the theory of coordinated development, think through the feedback loop and can achieve the coordination and common development between social system and ecological system. Guneralp [2] constructed the important infrastructure and the national security, the ecological environment, the economical coupling effect model and so on. The domestic scholars based on the measure method of coupling coordination, researches on the problems of ecological environment and economic development coordination. Binding energy industry investment and financing characteristics, we believe that they may exist coupling interaction and coordinated operation mechanism and the coupling coordination theory and method shall also apply in the energy industry investment financing in the field of research on the coordination mechanism. In the plane of the sustainable development, if the interaction of investment in the energy industry and the energy industry financing has a higher level of coordination of the coupling of, there will be helping to improve the efficiency of the compound system, and ultimately the economy energy low carbonization and intensive development.

2 Key Problem Statement

Coupling as a physical concept, the extent to which two (or more than two) systems or forms of motion are affected by each other. For example, between two connected to a spring pendulum, they shake each other ups and downs, mutual influence, this interaction is called coupling pendulum. Similarly, you can put two sub investments in energy industry and energy industry financing system through their respective coupling elements produce interaction and mutual influence of the phenomenon is defined for the coupling of the investment in the energy industry and the energy industry financing, both of which constitute the energy industry investment and financing system. Energy industry investment subsystem as the guide and engine of energy economic development, determines the quality, scale and benefit of the energy industry financing subsystem, and at the same time, it is influenced by the movement of the order parameter of the financing of the energy industry. The mutual coupling situation of the investment and financing of the energy industry is decided by the investment and financing gap, which is equal to the time accumulation of investment minus the financing. Any investment factors that affect the investment and financing gap will contribute to the change of the financing. Under the background of greenhouse gas emissions reduction, investment in the energy industry in addition to the category of traditional energy industry investment should also cover for prevention and control of pollution source, newly started construction projects "three simultaneous" project, renewable energy development, carbon capture and sequestration (CCS) and integrated gasification combined cycle technology (IGCC) and other new production projects and processing technology of the investment. The productive capacity of these investments will contribute to a significant reduction in industrial emissions and greenhouse gases, and improve the quality of regional climate and environment. Information related to investment will continue to feedback to departments of environment and trade market, through policy intervention and price signals to attract financing support, and achieving the energy industry investment and financing coupling coordinated development goals.

In the energy industry investment subsystem, the long-term implementation of the energy industry investment government approval, corporate finance, bank loans investment and financing model, the lack of flexible, effective and clean investment and financing mechanism. This type of investment is the subject of the behavior of state-owned energy enterprises, national investment of this kind of enterprises lack of supervision method and risk control means, lack of supervision and evaluation mechanism of enterprise investment decision, enterprise project approval lack of benefit and risk evaluation mechanism. Especially in the oil and gas, electric power and other industries, to a large extent there are administrative intervention, unclear definition of the functions of the government, macro-control offside, resulting in energy companies are often blind investment behavior. In the energy industry financing subsystem, in recent years, the energy industry financing channels tend to be diversified, but still in the enterprise internal self financing and bank credit as the main. Commercial banks in the energy companies monopoly profits and national climate and environmental protection policies to make a difficult choice between. Leading to the ups and downs of the size of the finance. As shown in Fig. 1, the energy industry investment and financing gap has increased in recent years. At the same time, by stimulating the impact of energy production and consumption, energy industry investment growth rate increased year by year. Overall, the interaction between the two is weakened, and the coordinated development is facing challenge.

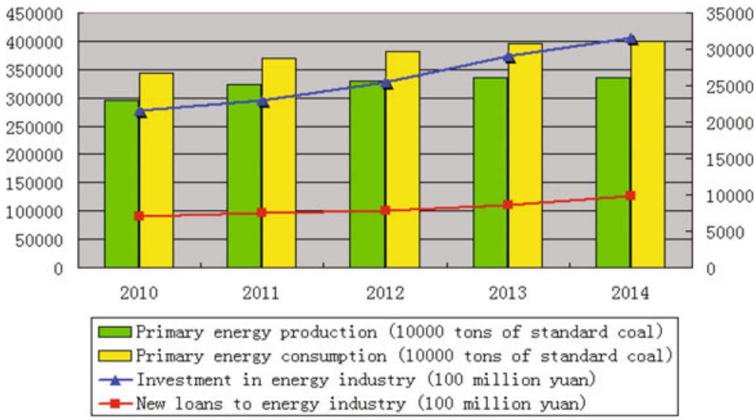

Fig. 1. Energy industry investment and financing, energy production and the evolution of energy consumption

The investments of oil and gas extraction, petrochemical, coking and nuclear fuel processing industry are unstable, lack of financing support. Overall, the energy industry internal financing coupling degree is not high.

3 The Coordination Model and Index System

According to the theory of synergetic, system always has a spontaneous irregular independence movement, while at the same time by the interaction of other subsystems, the connection between the seed system formed a cooperative movement. In the cooperative movement, there are many control parameters, which are divided into "fast variable" and "slow variable", that is, the order parameter is in the dominant position. With the constant change of the order parameter, the correlation between the subsystems is gradually increased before the critical point of the system; when the order parameter reaches the "threshold", plays a leading role in the association between subsystems system from disorder to order, from the chaos produced one kind of order structure. It can be said that the order parameter is the most prominent sign of the qualitative leap before and after the phase transition, which is about the characteristics and rules of the whole system transformation, find the order parameter of system is equivalent to find the observation of interaction between composite system movement and each subsystem of the key. Under the background of the greenhouse gas emission reduction and environmental protection policy, the energy industry investment subsystem has a multi-dimensional meaning, mainly including the existing production project pollution sources of investment, the new construction project "three simultaneous" investment, resource reserves and climate environmental protection policy, and so on four order parameters. Energy industry financing system is subject to monetary policy, energy industry financing and energy enterprise financial situation and so on three sequence parameters of the integrated drive. As a result, the coupling relationship of the energy industry investment and financing system is the sum of the various nonlinear relationships of the interaction between the order parameters. In order to eliminate the correlation between the subsystems within the control parameters, in this paper, the extraction and control parameter based, determine the order parameter estimated weight and measurement subsystem of order parameter, and then the composite system coupling coordination degree was evaluated.

3.1 The Theoretical Model of Investment and Financing in the Energy Industry

The coupling degree is used to describe the interaction degree of the energy industry investment and financing system, and to judge the degree of coordination and the stage of the coupling effect. First, establish the efficacy function. x_{ij} are the first I index of the control parameter of J, and x_{ij} is the function value of the function after the standardization. α_{ij} and β_{ij} are the upper and lower limit of the critical point order parameter of the system stability. Thus, "investment in the energy industry, energy industry financing coupled system orderly efficacy coefficient x_{ij} can be expressed as follows:

$$x_{ij} = \begin{cases} (x_{ij} - \beta_{ij})/(\alpha_{ij} - \beta_{ij}) \\ (\alpha_{ij} - x_{ij})/(\alpha_{ij} - \beta_{ij}), \end{cases} \tag{1}$$

where x_{ij} is the variable x_{ij} contribution to the system's function, which reflects the degree of satisfaction of the control parameters to achieve the goal, its range of values for [0, 1], 0 for the most dissatisfied, 1 for the most satisfactory. If $M(j = 1, 2, m)$ order parameter is extracted from the H control parameters in a subsystem $U(k = 1, 2)$, the order parameter matrix $(F_{ij})_{n\times m}$ with $n(i = 1, 2, \cdots, n)$ is formed. Because the investment in energy industry and energy industry financing are two different but interacting subsystems within the system, to achieve each order parameter of the order degree by the integrated method, the model is as follows:

$$u_k = \sum_{j=1}^{m} \theta_j \times F_{ij}, \quad \sum_{j=1}^{m} \theta_j = 1, \tag{2}$$

where θ_j are order parameter weights. Using the concept of capacity coupling and coefficient model for reference, the energy source is obtained, industrial investment and financing coupling degree function is:

$$C = \{(U_1 \times U_2)/\left[(U_1 + U_2) \times (U_1 + U_2)\right]\}^{\frac{1}{2}}, \tag{3}$$

where the letter C is the system interaction coupling degree, $C \in (0, 1)$; U_1 and U_2 represent energy industrial investment sub-system and the energy industry finance system on the system total contribution, namely investment in the energy industry comprehensive sequence parameters and energy industry financing order parameters.

For the energy investment and financing system, the significance of the coupling degree model is: quantitative description the interaction of between the two subsystems; reflect the order parameter of each subsystem in a certain period of time, the relationship between the number of regional interaction and adjustment process, in order to provide a basis for evaluation of the evolution trend of the interactive coupling of the composite system.

3.2 The Coordination Model of Investment and Financing in the Energy Industry

Coordination of each subsystem in the evolution process and factors of each part of the composition of different germplasm (order parameter), in which a unified whole showed mutual cooperation and harmony of property. If the order parameter of each subsystem is coordinated, it can promote the coordinated development of the whole complex system. In this paper, the difference of each subsystem in the composition of the composite system, the harmonious and consistent attribute is defined as the energy industry investment and financing Association scheduling. With respect to the coupling degree model, the coordination degree model considers the factors that influence the development speed of the overall order parameter of each subsystem, which makes up the coupling degree model only focusing on the horizontal coupling, and ignores the problem of the speed of development. It can be more comprehensive and accurate to judge the degree of coupling coordination between regional energy industry investment and financing system:

$$\begin{cases} D = \sqrt{C \times T} \\ T = \sqrt{\rho_1 U_1 \times \rho_2 U_2}, \end{cases} \tag{4}$$

where D is the coordination degree, $D \in (0, 1)$; C is the coupling degree; T is a comprehensive coordination index of energy industry investment and financing system, reflect the overall energy industry investment and financing synergy; ρ_1 and ρ_2 are undetermined coefficient; U_1 and U_2 are respectively the comprehensive order parameter of the energy industry investment and the order parameter of the energy industry financing. Coordination degree can be divided into 3 sections and 8 stages. As shown in Table 1 shows, through the comparison of the investment and financing system comprehensive order parameter, the sample can be roughly divided into three types: energy industrial investment excessive type, energy industry financing advanced type and investment and financing balanced development type, the following research will accordingly be identified and evaluated.

4 Summary

Based on the system theory and synergetic theory, this paper establishes a coupled coordination model based on low carbon sustainable development and greenhouse gas emission reduction to analyze their interactions. The main conclusions are obtained as follows: (1) The investment and financing of the energy industry has a stress effect on the climate environment, and the climate environment has a binding effect on the investment and financing of the energy industry. The energy industry investment and financing stress effects on climate and environment are mainly: the energy industry investment and financing of energy production capacity increase the emissions of air pollutants; the constraint effect of the climate environment on the investment and financing of the energy industry is mainly caused by the severe climate and environmental protection policy. (2) Under the conditions of the policy of reducing greenhouse gas emissions, the interaction between the energy investment and financing has weakened year by year. In considering the greenhouse gas reduction factors, energy industrial greenhouse gas emissions in areas of high energy investment and financing coupling is relatively low, relatively poor coordination; Energy development and construction may not be an important cause of regional complex atmospheric pollution; The climate and environment protection policy constraints on energy investment is not strong, but has an important impact on energy financing.

Abstract. This paper uses the DEA method to establish the evaluation model of water resources efficiency to make an empirical study on the urban agglomeration of Chengdu city in 2008–2014. The results show that the efficiency is increasing year by year, and the economic efficiency and environmental efficiency of the water resources utilization are improved. Meanwhile, under the control of the technology, education and transportation level to analyze of efficiency from the economic factors, this paper gets the conclusion that: (1) the city water use efficiency and the level of economic growth showed a significant linear correlation. (2) Technology shows no obvious linear relationship with the efficiency of water use. Traffic enhances the effect of openness on water efficiency. Education is negatively correlated to the efficiency. It indicates that the urban agglomeration should enhance the traffic infrastructure on its regional economic advantage, optimizing the industrial.

Keywords: DEA data envelopment · Water use efficiency · Urban agglomeration · Economic development · Econometric analysis

1 Introduction

With the economic development and population growth, water shortage is a severe problem. According to the National Bureau of statistics report, Sichuan water consumption for each industrial added value dropped from 135 m^3 per million yuan in 2008 to 46 m^3 per million yuan in 2014, a decline of 66%, achieving the requirements of the State Council in advance. However, compared with Beijing, Suzhou and other "national water-saving city" in recent years, which maintain the value of 16–19 m^3 per million yuan, the efficiency of water use needs improvement.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_102

The shortage of water resources is a global problem, and how to make efficient use of water to ease the supply and demand of resources is urgent. The coordinated development of economy and environment is the foundation of building a resource-saving society. On the one hand, the main branches of the economy have an impact on the efficiency of water use [2], on the other hand, the improvement of water use efficiency is conducive to the local food exports [7].

Therefore, the quantitative analysis of economic development with water use for sustainable development is particularly important. Previous studies had focused on the evaluation of the efficiency of water use on agriculture, industry and mixed model, or on the profound the model. The present studied the use of water in the economic output perspective, ignoring the ecological impact, this paper aims to evaluate the Chengdu city group water utilization through two aspects of economic and environmental efficiency. Few existing research attached quantitative analysis of factors affecting the efficiency of water use, this paper based on the empirical analysis study the efficiency of water use and its economic factors, prolonging sustainable development for the construction of water-saving.

2 Research Objectives

There are many ways to analyze the utilization of water resources, in view of the water potential of the unified understanding degree is not high. The range of fluctuation is difficult to quantitative analysis of the decoupling theory. This article based on the perspective of the utilization efficiency of water resources to study the water use in the city of Sichuan province. This article unfolds as follows. Primarily, In order to explore the relationship between water use efficiency and economic development, this article based on the Cobb-Douglas production function, to set the input-output model to measure the efficiency of water resources utilization. Secondly, according to the difference of water use in time and space, this paper divides the comprehensive utilization efficiency of water resources into economic efficiency and environmental efficiency. Thirdly, this article analyzes the impact of economic development on the efficiency of water use, to discover the relationship between economic development and water consumption in urban agglomeration. Lastly, In order to reflect the economic indicators in a better way, this paper under the control of the city of scientific technology, education and water transportation level, to do further analysis between economic level and efficiency of water use. It's of great importance to profoundly analyze economic development and resource allocation. Figure 1 shows the construction.

This paper chooses BBC model to analyze the relative efficiency of variable returns to scale. The BBC model increases the convexity assumptions on the basis of the CCR model, which will be helpful to analyze the environmental and economic output [4,8,9]. We add the curve measure to the BBC model. The curve measure is the environmental efficiency evaluation method of nonlinear analysis, analyze the output with radial infer, use reciprocal curve to measure the pollutants, in order to achieve efficiency evaluation in the process of increasing the output and reduce the pollution.

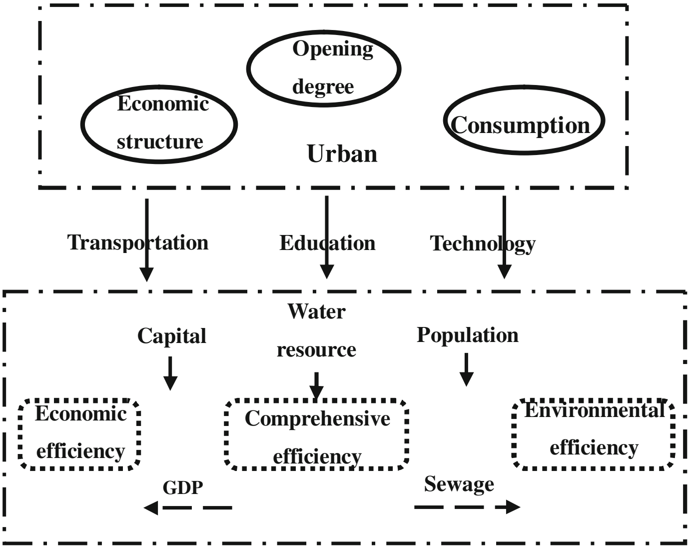

Fig. 1. The construction of the paper

In order to fully reflect the input and output of water resources in cities, the paper based on the Cobb-Douglas production function, constructed an input output analysis framework including water use and water pollutant emissions. The exact input-output index system followed in Table 1. The fixed assets investment of the whole society reflects the scale of capital investment of the whole society in a period. The local population, compared to the employment population, better expresses the contribution to the increase in water consumption and economic output. We use the annual water supply as the water consumption of each grade city. All the data comes from the Sichuan statistical yearbook. This paper adds city sewage emissions as undesirable outputs. In case of pollution and other undesirable products are produced, based on the previous [3,4] for pollutants treatment, this paper inserts the reciprocal evaluation which has comparative advantage to DEA model as the environmental impact.

Table 1. Input-output index system

Input	Water resource	Cities' water consumption
	Capital size	Social investment in fixed assets
	Population	Current population
Output	Economic output	Current GDP
	Environmental effects	Current sewage discharge

Table 2. The unit root test for panel data

	Structure	Export	Consumption
Statistic	−5.0904	−5.7898	−1.30E+02
Z	−4.5241	−3.7001	−4.9723
Prob.	0	0	0

3 Space-Time Analysis for Efficiency

The paper uses the DEAP 2.0 to set the model, lists the results in Table 3. It is obvious from Table 3 The water use efficiency of Chengdu urban agglomeration increased gradually in 2008 to 2014. The water utilization efficiency of Ziyang in 2008 to 2012 showed the optimal level 5 times, indicating that the capital investment, labor and water resources allocation in Ziyang city is in a good condition and take the best place among Chengdu urban agglomeration. We use ArcGIS to demonstrate the variation of the comprehensive efficiency.

Table 3. 2008–2014 Chengdu urban agglomeration water use comprehensive efficiency

	2008	2009	2010	2011	2012	2013	2014
Chengdu	0.76	0.69	0.81	0.87	0.9	0.92	1
Deyang	1	0.63	0.84	1	0.98	0.99	1
Mianyang	0.72	0.53	0.62	0.75	0.79	0.83	0.87
Leshan	0.81	0.73	0.76	0.9	0.89	0.86	0.9
Meishan	0.71	0.66	0.72	0.85	0.81	0.81	0.85
Yaan	0.65	0.73	0.64	0.8	1	1	1
Ziyang	1	0.86	0.67	1	1	1	1

On Fig. 2, these directly show the trend of water utilization efficiency. From the perspective of time series, the financial crisis in 2008 affected the economic development and water use of Chengdu urban agglomeration which led to the tendency of water utilization efficiency declined in 2009. In 2011, with economic recovery and city industrial construction, water utilization efficiency and the indirect influence gradually recovered to the level of 2008.

From the perspective of the spatial distribution of the industry, Chengdu urban agglomeration pillar industries (electronic information, water and electricity, pharmaceutical and chemical industry, machinery, metallurgy, food and beverage, etc.) of large enterprises were mainly distributed in Chengdu, Deyang, Mianyang, Ziyang, However, the development of industry in Meishan, Leshan lagged behind, which lacked the support for large enterprises and projects.

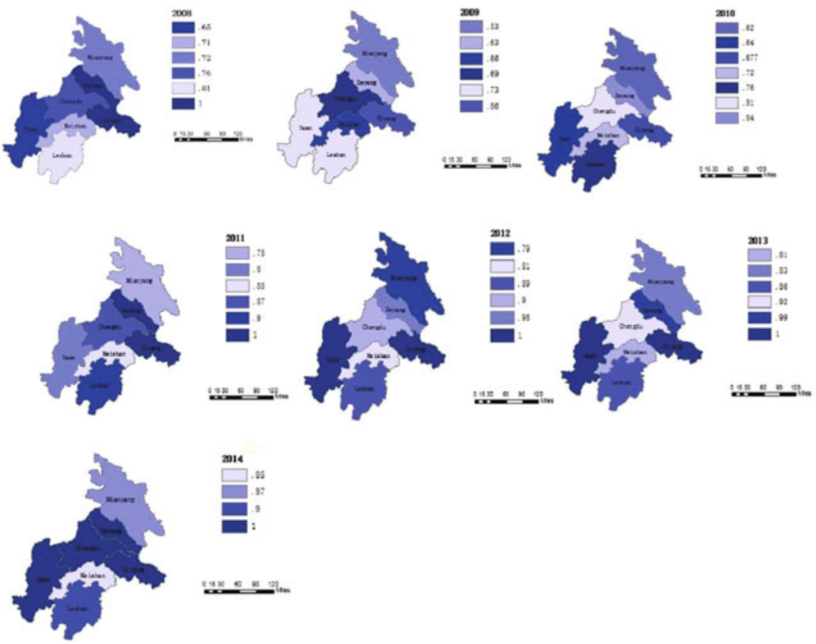

Fig. 2. Chengdu city group water use comprehensive efficiency from 2008–2014

This paper analyzes the comprehensive utilization efficiency of water resources from two aspects of economic efficiency and environmental efficiency. Environmental efficiency reflects the scale is insufficient or redundant. Based on the conventional expectations output, we adds the new sewage emissions as undesirable output. It not only reflects the moderation between water supply quantity and capital investment, but also reflects the reduction of potential pollutant emission under the same factor input and output conditions [6,10]. It is of great help for the various regions to establish future planning objectives in the existing economic and environmental conditions. Economic efficiency refers to the existing economic input, the best use of technology or the ability to deal with pollutants. It embodies the ability to achieve the maximum output under the conditions of a variety of input factors. In this paper the DEA-BBC input-output model, the economic efficiency reflects the investment of fixed assets and water resources social investment which leads to the ability to achieve the maximum economic output in the certain number consumption of a city. Analysis of the economic efficiency and environmental efficiency of water resources in Chengdu urban agglomeration by DEAP 2 is shown in Fig. 3. Based on the time series, it is obvious that 2009 was a turning point due to the financial crisis in 2008. In terms of the city's water efficiency, Yaan's economic efficiency had been maintained at a high level. The reason is that the economic development of Yaan lagged behind by the state in the Chengdu urban agglomeration. Its economic output and degree of industrialization were low, thus embodying water utilization efficiency good situation in the input and output. Ziyang and Deyang kept a stable efficiency at the high level in 2011. Deyang's pillar industry was mechanical, which accounted for nearly half share. Although the development of machinery industry was still in the extensive stage, under the atmosphere of 2011–2014, tap estates had a greater contribution to pull the local economic output. Ziyang on the location was the unique regional center city which connected Chengdu and Chongqing the "dual core". It's known as its automobile industry the same as Deyang, which drove the rapid economic development through increasing industrial output then indirectly improved the economic efficiency. Compared to Mianyang, the city manifested in industrialization as well, it existed an obvious gap. Mianyang played a relatively low ecoefficient role among Chengdu urban agglomeration with its electronic as pillar industry. The falling behind velocity of the increasing development restricted its economic efficiency to a higher level. Although Mianyang regarded as the second biggest city in Sichuan, the lowest water environmental effect dragged it at the bottom and pull down its water utilization comprehensive efficiency. Similarly, Chengdu, which was specialized in electronics, medicine and so on, because it was the urban agglomeration center city and the capital city of Sichuan Province, its economic development was much higher than that of other prefecture level cities which raised its water use efficiency. In terms of the environmental efficiency of water use, Chengdu urban agglomeration showed the effective in environmental efficiency but relatively low valid in eco-efficiency. The reason is that it didn't make the best use of factors. For illustration, Yaan and Meishan did not serve its turn. Meanwhile, the plenty of cities had already taken a big scale, such as Chengdu, Deyang, Leshan, Ziyang and Mianyang. In general, the input-output ratio was reasonable, and the combination of factors achieved a certain scale economy. Therefore, it is close to the optimal efficiency on the scale of the city but insufficient in eco-efficiency.

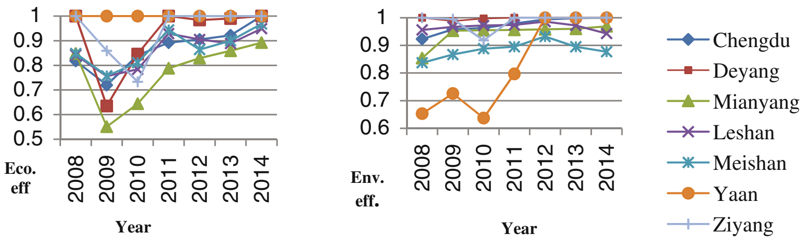

Fig. 3. 2008–2014 Chengdu urban agglomeration water use Economic and Environmental efficiency

4 Economic Effects

4.1 Hypothesis

Based on the above empirical, it is visible that economic output and its level of city development has close relationship with water utilization.

This paper assumes that the explanatory variables are: economic structure, opening degree, consumption level. At the same time, this paper selects the technology, transportation and education level as the control variables.

Hypothesis 1: economic structure has a negative impact on water use efficiency. The economic structure is the composition and structure of the national economy. The influence of economic structure on water resources utilization efficiency can be analyzed from two aspects. On the one hand, the industrial production have positive effects on the economy of a region, the economic structure in the industry tend to have higher economic output which shows high utilization efficiency of water. On the other hand, the increase in industrial investment will increase the impact of the ecological environment, resulting in a larger proportion of environmental output, thereby reducing the city's water use efficiency. Now the negative effect of the development of Chengdu city group is the ecological environment influence over its economic effects is unknown.

Hypothesis 2: the degree of opening to the outside world has a positive impact on the efficiency of water resources utilization.
The degree of opening effects the import of resources and the introduction of new technologies. Chengdu is located in China's western region, the western energy technology itself is relatively backward. The change in the degree of dependence on foreign trade has great influence on the west. Therefore, the study on the degree of opening to the outside world is of great significance to the utilization efficiency of water resources in Chengdu urban agglomeration.

Hypothesis 3: consumption level has a positive impact on water use efficiency.
To some extent, the consumption level reflects the scale of production and indirectly affects the efficiency of resource utilization. On the one hand, consumption is an important booster of economic growth. On the other hand, all kinds of garbage generated in the process of consumption also makes the decline in environmental quality [1]. Whether the ecological impact of rising consumption level is beyond its economic effects? This paper assumes that the consumption level is a positive impact on water use efficiency.

4.2 Analysis of Indicators

This paper will explain the following three aspects on the selection of economic factors and the setting of variables: As explained variable, utilization represents the regional comprehensive efficiency of water use. The data is calculated by the DEA-BBC model. Other data comes from the 2009–2015 Sichuan statistical yearbook. For Explanatory variables, structure refers to the economic structures, this paper uses the sum of the primary and secondary industries with the ratio of the service industries to express the economic structure. Set the ratio due to the water consumption of primary and the secondary industriesshare more, the service industrial (including commodity trade, catering and accommodation, transportation organizations and other services industry) accounted for only 3% (Sichuan water resources bulletin 2014). In terms of the gross national product structure, in the Chengdu urban agglomeration, the primary industry occupies less compared to the secondary, the service industries. Therefore, use the sum of primary and secondary industrial added value divided by the added value of the third industry to represent the economic structure and investment allocation direction. Consumption indicates the level of consumption, this paper selects the total retail sales of social consumer goods to express the transaction situation of various organs, enterprises and institutions, in order to reflect the domestic consumption level and demand of the city. Export is used to indicate the degree of opening up. In this paper, the ratio of total import and export to GDP is used to reflect the degree of opening up. The city's total import and export of goods better embodies the foreign trade level. Because of its joint venture, said the unit is million, taking into account other indicators to billions of units, the direct use of the total import and export data analysis model will have a certain deviation, and the change of exchange rate is floating, it is difficult to calculate by import and export the amount of US dollars into RMB. This paper selects the import and export volume and the current ratio of GDP to reflect the effect of the level of international trade.

Table 4. Definition and description of variables

Variables	Definition	Description	Effect
Utilization	Water utilization efficiency	Local comprehensive efficiency of water use	−
Structure	Economic structure	(Primary + Secondary)/(Service)	+/−
Consumption	Level of consumption	Total retail sales of social consumer goods	+/−
Export	Degree of opening up	(Import + Export)/(Current GDP)	+
Technology	Level of technology	The ratio of technology expenditure	+
Education	Level of education	The ratio of education expenditure	+
Transportation	Level of transportation	The ratio of transportation expenditure	+

For the control variables, this paper use the proportion of public finance expenditure to reflect the levels. The city's technology investment has positive effect on improving the efficiency of water resources utilization. The progress of technology can create more water-saving facilities, increase the circulating water, thereby increasing the utilization efficiency of water resources. The educational level of the city reflects a city's progress and the civilized degree. The level of urban transportation will affect the degree of opening up. At the same time, the improvement of the level of transport will also play a role in alleviating the imbalance of water resources distribution [5], so as to improve the utilization efficiency of water resources (Table 4).

4.3 Model Description

The econometric model of panel data includes fixed effect model, random effect model and least square regression method. The equitation is as followed.

$$\text{Utilization} = b_1 + b_2 \times \text{Structure} + b_3 \times \text{Export} + b_4 \times \text{Consumption} + \varepsilon, \quad (1)$$

where b_1 stands for the intercept, b_2, b_3, b_4 represent the coefficient of the economic structure, the degree of opening up and the social consumption. ε is the stochastic error. Because of the regional difference of the urban agglomeration is relatively small, the difference of the water resources utilization efficiency between different sections of the cross section can be ignored. The time span is small, and the variation of parameters can be ignored as well. In this paper, WLS regression is used to fit and analyze the influencing factors and weights, and the control variables are introduced gradually.

$$\begin{aligned} \text{Utilization} &= b_1 + b_2 \times \text{Structure} + b_3 \times \text{Export} + b_4 \times \text{Consumption} \\ &\quad + b_5 \times \text{Technology} + \varepsilon, \end{aligned} \quad (2)$$

$$\begin{aligned} \text{Utilization} &= b_1 + b_2 \times \text{Structure} + b_3 \times \text{Export} + b_4 \times \text{Consumption} \\ &\quad + b_5 \times \text{Technology} + b_6 \times \text{Transportation} + \varepsilon, \end{aligned} \quad (3)$$

$$\begin{aligned} \text{Utilization} &= b_1 + b_2 \times \text{Structure} + b_3 \times \text{Export} + b_4 \times \text{Consumption} \\ &\quad + b_5 \times \text{Technology} + b_6 \times \text{Transportation} \\ &\quad + b_7 \times \text{Education} + \varepsilon, \end{aligned} \quad (4)$$

where b_5, b_6, b_7 represent the effective coefficients of the technology, transportation and education towards the water use efficiency.

4.4 Empirical Analysis

(1) Test of stationary

In order to avoid spurious regression, and ensure the validity of the estimation results, we must check the stability of each panel sequence. We use Stata 11.0 to perform unit root test for short panel data. The sample capacity is small, the effect of the unit root test for single variable is weak, thus we use the LLC test to analyze the data. The original hypothesis H_0 has the same unit root. The test results are shown in Table 2, the data has a high degree of significance, so the result is to reject the original hypothesis. The perturbation terms of different individuals are independent of each other, and the data are stable.

(2) Results and analysis

According to the significance of the data, the mixed OLS model is better than the fixed effect and random effect by Stata 11, and the Table 5 is the regression fitting result of the three models. It was the primary and the secondary industry high proportion improve the utilization efficiency of water use. In addition, the further openness would introduce new energy, advanced technology and talents, and it could largely reduce economic output and has high impact on the ecological environment. The regression coefficient of the level of consumption is significantly positive. We use stepwise least squares regression, in the case of abandoning the constant, to analyze the standardized coefficient.

Table 5. Comparison of regression coefficients

	Before the insert of control variables				After the insert of control variables		
	Pooled OLS	Fixed effect	Random effects	WLS	+ Technology	+ Transportation	+ Education
b_2	0.217[a]	0.230[a]	0.2259[a]	1.041[a]	0.404	0.379	0.700[a]
b_3	4.162[b]	4.421	4.3012[b]	0.532[b]	0.671[a]	0.939[a]	1.253[a]
b_4	0.001[a]	0.001[b]	0.001[a]	0.637[b]	0.981[b]	0.607[a]	0.542[a]
b_5	–	–	–	–	−0.1	–	–
b_6	–	–	–	–	–	0.418[a]	0.471[a]
b_7	–	–	–	–	–	–	−0.338[a]
R^2	0.412	0.411	0.411	0.407	0.354	0.503	0.577
F	55.31	6.61	–	10.759	6.995	12.895	13.649

[a] Correlation is significant at the 0.01 level, [b] Correlation is significant at the 0.05 level.

From Table 5, it is obvious that the economic structure takes the greatest place among the economic indicators to demonstrate the trend of the water use efficiency. The reason is that the Chengdu urban agglomeration has a higher degree of industrialization. The domestic consumption promotes economic diversification of functions of the city through the sharing of resources among cities, which indirectly improve the utilization of water. Meanwhile, international trade will bring the inflow of technology and talent, and promote the development of economy.

In this paper, the coefficient of technology is negative as control, and it didn't pass the significance test. This doesn't mean that there is no linear relationship between the technology and the efficiency of water use. It is based on the technology proportion of public expenditure. In fact, many of the city's scientific development depend not only on the public finance expenditure, it depends on technological innovation in enterprises and large companies. The traffic level shows that increasing its proportion of public finance expenditure has a positive effect on improving the efficiency of water use. Under the influence of the traffic, the effect of the economic structure weakened, and the effects of opening up rise up. The coefficient of educational level is negative.

(3) Heteroscedastic test

In order to check the deviation between the fitting value and the real value of the model and to ensure the regression parameter estimation has good statistical properties, the paper makes use of the residual graph to illustrate the heteroscedasticity test. From the residual plot of heteroscedasticity test that, in general, the fitting degree of the model is good. The fit of economic structure is good, the scattered distribution is random and uniform (Fig. 4).

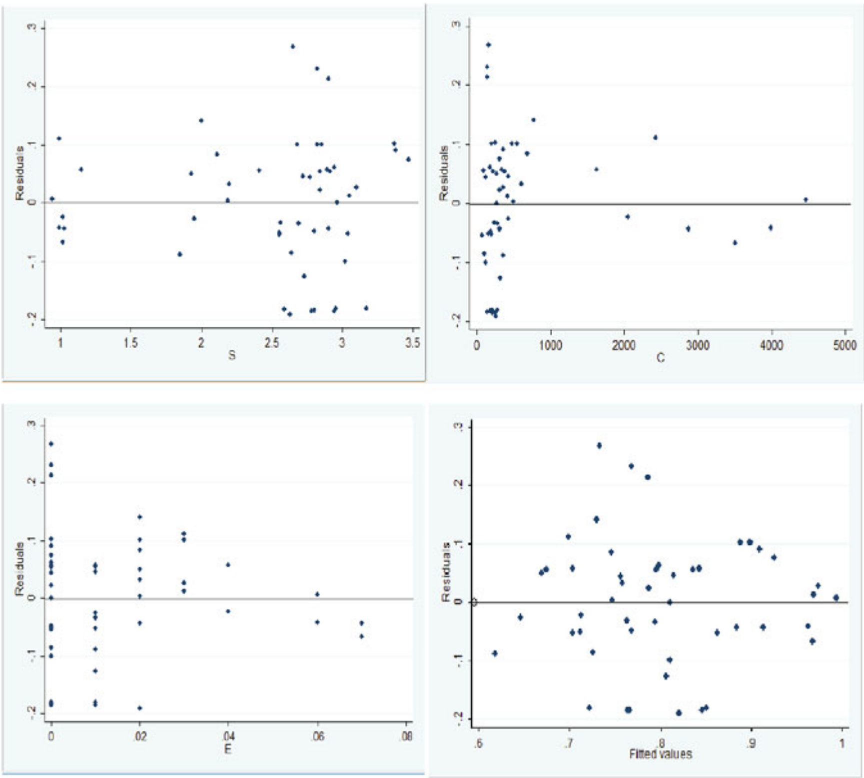

Fig. 4. The residue of structure, consumption, openness and fitted values

5 Conclusion

The water use efficiency of Chengdu urban agglomeration has difference in time and space. Attach the time series as the axis, since the financial crisis into the economic buffer period, the efficiency of water use was gradually increasing. From the perspective of spatial difference, because of its geographical advantages, in the electric, automotive and other industries as a pillar industry in the city, its water use efficiency was better. For some cities, although the marginal scale investment was higher, due to its serious environmental pollution and relatively weak economic growth, it shared the low utilization efficiency of water use. The data shows that the water use of Chengdu urban agglomerations still had some room to improve, the government departments should make efforts to increase sewage treatment.

The water utilization efficiency from the perspective of economic level analysis, found the water resource utilization and economic development is linear, the economic structure takes the most profound effect. Increasing the utilization rate of resources depends largely on the green industry output; the opening degree and city's consumption affected the input of technology and talent to indirectly affect the efficiency of water use. Meanwhile it directly affect the water use through the flow of resources among the agglomeration.

This paper makes a further analysis on the urban development, and finds that the level of urban transportation has a positive effect on the efficiency of water resources utilization and will increase the effective proportion of the degree of opening up. Raising the level of education in the short term is not conducive to the water use. Due to the long period of payback in the educational investment, it requires for a higher levels of openness to compensate the effect for extra education spending of the utilization efficiency of water resources.

Abstract. A new paradigm with a considerable influence on the industrial value creation is begun to evolve. Industry 4.0 represents the development to the fourth industrial revolution. A new shift in business and technology trends is confirmed. With this new paradigm of high-tech industry, supply chains will develop into highly adaptive networks. Lean and Green supply chain management should have better opportunities to be performed, becoming more efficient and competitive. The aim of this study is to link the lean and green supply chain characteristics to the Industry 4.0. This paper has twofold: first, presents an overview of the phenomenon Industry 4.0 and the lean and green supply chain management. Next, a conceptual model is developed which incorporates the Industry 4.0 topics to the well-known lean and green supply chain. This paper provides an understanding of the role of lean and green paradigms in the new era of industrialization.

Keywords: Industry 4.0 · Lean paradigm · Green paradigm · Supply chain

1 Introduction

Today we face a new paradigm introduced by Germany in 2011, the Industry 4.0. This represents the beginning of the fourth industrial revolution and is driven by modern information and communication technology (ICT) [21,26,27]. By Industry 4.0 intends the optimization of value chains by implementing an autonomously controlled and dynamic production [21], through a full automation and digitalization processes. This paradigm is based on the idea that communication via internet allows a continuous exchange of information applying cyber-physical systems (CPS) [27,30]. The CPS provides the source for the creation of internet of things and services and their combination makes possible the Industry 4.0 [15,27]. CPS integrates networking, computation and physical processes and take them together to create a global value chain networked [15,27,30].

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_103

According to [34] to establish the global value chain networks, the Industry 4.0 describes a production oriented CPS that integrates production facilities, warehousing and logistics systems and even social requirements. In addition, Germany Trade & Invest (GTAI) [15] mention that the industrial value chain, product life cycles and business information technology combination must integrate the processes from the product design to production, supply chain management, aftermarket service and training [15]. An intelligent factory is in development and is coined as smart factory. With this concept, others appear and are important for the establishment of implementation of Industry 4.0, as for example smart products, smart manufacturing and smart data.

The authors [27] mentioned that this implementation is still in progress. That's why it is important to understand the role of lean and green supply chain management in Industry 4.0. For example, the lean waste would be recognized with the smart factory implementation [28]. The resource efficiency which is a lean and green concept, are in the focus of the design of smart factories [27]. This study intends to understand if the Industry 4.0 allows the lean and green supply chains concepts become more important. That is, if it enables more easily the deployment of lean and green characteristics. A number of characteristics were presented on model, namely: (i) manufacturing, (ii) logistics and supply, (iii) product and process design, (iv) product, (v) customer, (vi) supplier, (vii) employee, (viii) information sharing and (ix) energy.

The remainder of this paper is organized as follows: in Sect. 2, a theoretical background on Industry 4.0 and lean and green supply chain are presented; in Sect. 3, a combination between lean and green supply chain and Industry 4.0 is developed; Finally, some concluding remarks are drawn.

2 Industry 4.0 Paradigm

The Industry 4.0 is considered the paradigm of the fourth stage of industrialization and describes a vision of future production [21,30]. The core idea of Industry 4.0 is the integration and application of information and communication technologies to implement Internet of Things and Services so that business process and engineering process are deeply integrated making an environment intelligent [28,34]. The concept of industry 4.0 which represents the integration of the virtual and physical worlds in a way that together create a truly networked environment and where intelligent objects communicate and interact with each other, is a Cyber-physical systems [15]. According to [19] the Industry 4.0 "will involve the technical integration of CPS into manufacturing and logistics and the use of the Internet of Things and Services in industrial processes. This will have implications for value creation, business models, downstream services and work organization."

The Industry 4.0 is represented by three features [19,30,34]: (i) horizontal integration across the entire value networks; (ii) vertical integration and networked manufacturing system; and (iii) end-to-end digital integration of engineering across the entire value chain or product life cycle.

The horizontal integration across the entire value network refers to the integration of the various systems used in the different stages of the manufacturing and business planning processes that involve an exchange of materials, energy and information both within a company as logistics, production, and marketing, and between several different companies; The idea is that information, material and money can flow easily among different companies creating new value networks as well as business models. This can result in an efficient ecosystem [19,30,34].

The vertical integration refers to the integration of the various information and physical systems at the different hierarchical levels, as for example the production management, manufacturing and execution, and corporate planning. This integration is inside a factory to create flexible and reconfigurable manufacturing system [19,30,34].

The goal of the horizontal and vertical integration is to deliver an end-to-end solution. The end-to-end solution refers to the digital integration of engineering across the entire value chain to support product customization: from the raw material acquisition to manufacturing product, and product in use and in the end of life [19,30,34].

Through these features, the Industry 4.0 expects to implement an environment more flexible, efficient, and sustainable. The idea is to individualize the customer requirements, as a customized product through a mass customization, improving productivity and achieving higher levels of quality with a manufactured profitably result [6,19]. Indeed, by applying advanced information and communication technologies and systems in the manufacturing and supply chain operations, the industry 4.0 addresses the smart factory [28]. Smart factory is designed according to sustainable and business practices, insisting upon, flexibility, adaptability and self-adaptability, learning characteristics, fault tolerance, and risk management [15]. Therefore, standards are essential to ensure the exchange of data between machines, systems and software and guarantee that product moves within a network value chain [6].

That is, high levels of automation come as standard [15]. Automation systems, manufacturing and product management are integrated and are the base of the smart factory [6]. Manufacturers can now add sensors and microchips to tools, materials, machines, vehicles and buildings to communicate with each other in real-time to make smart products [15].

According to [36], "products know their histories and their routes, and thereby not only greatly simplify the logistic chain but also form the basis for product life cycle data memories". Also, the products can be manufactured because smart factory is being supplied with energy from smart grids [30].

Not only smart factory and smart product were defined in this new industrialized era. Others concepts connected to them are considered in the literature. For their work development, Kolberg and Zuhlke [21] considered four different smart concepts to define the smart factory, namely, smart planned, smart product and smart machine, and smart operators. The authors [30] make mention of the smart grid, smart logistics and smart data. Sanders et al. [28] mention

Table 1. Concepts of Industry 4.0

Concepts	Description
Smart factory	Smart factory represents the key characteristic of Industry 4.0 [15]. The smart factory will be more flexible, dynamic and intelligent [27], where people, systems and objects communicate with each other [15]. The internet of things and services are the main enabler technology for a smart factory [15, 29]
Smart manufacturing	Manufacturing will be equipped with sensors and autonomous systems which allow that operations can be optimized with a minimum employee's intervention [27, 29]. It produces small-lot products of different types, more efficiently [34]
Smart product	A smart product is a product with sensors and microchips that allow communication via the internet of things with each other and with employees [27]. It holds the information about its requirements for the manufacturing processes and manufacturing machines [21, 30]
Smart logistics	It is one of sustainable mobility strategies [15]. Smart logistics will use CPS for carrying the material flow within the factory and in the supply chain (between factories, customers and other stakeholders) [30]. The transport equipment is a part of smart logistics that is able to react to unexpected and autonomously should be able to drive between the starting point and the destination [30]. Distribution and procurement will increasingly be individualized [27]
Smart engineering	Includes product design and development, production planning and engineering, production and after sales service [29]
Smart data	Smart data is structured information of data that can be used for decision-making [30]
Smart machine	Machines and equipment will have the ability to improve processes through an intelligent decision-making, instead of being directly instructed [27, 34]. The smart machines should have additional autonomy and sociality capabilities to adapt and reconfigure to different types of products [34]
Smart planner	Smart Planner optimizes processes in real-time [21]. Decentralized self-organization [27]
Smart operator	smart operator is an employee who supported by ICT, control and supervise ongoing activities [21]. Employees can be quickly directed to the right tool [6]
Smart customer	Customers' needs and behaviors are analyzed in real-time in way to provide them with new and more sustainable products and services [29]
Smart supplier	Based on factory needs it is possible to select the best supplier (which allows higher flexibility) and strengthen a sustainable relations with suppliers (by increase information sharing in real-time) [29]
Smart grid	Responsible to supply energy to a factory [30]. Energy management [15]
Smart energy	Monitor and provide feed-back on energy production and use [23]

others concepts as the smart systems, smart environment, smart machine and smart devices, and smart task. Table 1 compiles several concepts of Industry 4.0.

Through the integration of the industry concepts and technologies it should be possible provide a customized or individualized product or service and at the same time be highly adaptive to demand changes [15]. These changes must be made on all stages of product life cycle: design phase, raw material acquisition phase, manufacturing phase, logistics and supply phase, and the use and end of life phases [15,30]. Therefore, the requirements for design and operations of our factories become crucial for the success [36].

3 Lean and Green Supply Chain Paradigms

Nowadays, lean and green supply chain is an integrated approach; they have different objectives and principles but they complement each other [7,9,10,12–14,31]. Lean supply chain is about to increase value for customers by adding product or service features, with the elimination of waste or non-value steps along the value chain [11]. Green supply chain regards to reducing environmental impacts and risks while improve ecological efficiency of the organizations and their partners, and try to achieve corporate profit and market share objectives [35].

These two paradigms are often seen as compatible because of their joint focus on waste reduction [5]. Lean paradigm is concerning to the elimination of waste in every area of design, manufacturing, and supplier network and factory management [13]. The basic forms on the reduction and elimination of waste are [17]: production, waiting, transportation, unnecessary inventory, inappropriate processing, defects and unnecessary motions. One more waste is pointed by [31] as the unused employee creativity. Green considers ways to eliminate waste from the environment's perspective [11]. The waste generation have the form of [16]: Greenhouse gases, eutrophication, excessive resource usage, excessive water usage, excessive power usage, pollution, rubbish and poor health and safety. In their research [12] mention that the two paradigms have the same type of wastes: (i) inventory; (ii) transportation, and (iii) the production of by-product or non-product output. According to [5] the removal of non-value adding activities suggested by lean paradigm can provide substantial energy savings which integrates the principles of green paradigm.

The combination of lean and green supply chain practices have better results than the total from the implementation of each, but separately [12]. The two paradigms have similar characteristics. According to [4] both paradigm practice contribute for: (i) the increase of information frequency, (ii) the increase of the level of integration in supply chain, (iii) the decrease of production and transportation lead time, (iv) the reduction in the supply chain capacity buffers; (v) and the decrease of inventory levels. Another practice that contributes for the better employ and use of all tools is the involvement of the employees [12]. Both paradigms look into how to integrate product and process redesign in order to prolong product use, to allow easily the recycling or re-use of products, and to make processes with less wasteful [12]. In the supply chain both paradigms ask for a closed collaboration with partners [22]. In addition, waste reduction, lead time reduction, and use of techniques and approaches to manage people, organizations, and supply chain relations are synergies mention by [13].

Commitments must be made within factory, supplier network and customer, for the better deployment of lean and green practices in way to achieve the best supply chain efficiency. In the authors previous study [11] it was presented a table

Table 2. Lean and green paradigms characteristics in supply chain

Characteristics	Lean	Green
Philosophy focus	Long-term thinking [2]	Long-term thinking since environmental impacts affects the natural environment for many years [18]
Market focus	Serve only the current market segments with predictable demand [33]	Demands from at least some customer segments for more environmentally friendly practices [35]
Manufacturing focus	Lean manufacturing use Lean Automation [28]. Lean manufacturing focus on maximizing productivity by increasing output per unit of input, conserving resources, reducing waste, and minimizing costs [7]	Green manufacturing focuses on the environment and identifies waste as excessive use of resources or substances released to the air, water or land that could harm human health or the environment [24]
Product design focus	Product design sets the conditions for manufacturing: process and product development [18]; Eliminate waste, increase productivity and reduce cost [7]	Green design or Eco-design; Selection of low impact materials, reduction of materials usage, optimization of production techniques, improvement of distribution system, reduction of impact during usage, improvement of initial life time, and improvement of end of life system [18]
Inventory strategy	Minimizes inventory throughout the chain [4]	Reductions in inventory levels [4]
Supply focus	Inter-organizational involvement [22]. Close cooperation with all supply chain entities [18]	Inter-organizational collaboration involves activities to deploy green issues in supply chain entities [22]
Information sharing	Demand high levels of information sharing [22]	Information sharing is important for the successful implementation [22]
Employees	Employee involvement and empowerment [12]. The education and training of the employees to execute multiple tasks [2]	Involvement of employees [18]. The education of the employees concerning green issues [12]
Customer	Satisfying the customers by reducing costs and lead times [12]	Satisfying the customers by the implementation of green issues [12]
Processes	Focus on product [2]. Continuous improvement culture [24]	Focus on processes and products [18]. Process optimization through the implementation of green issues [31]

comparing the different characteristics between lean and green. Others important studies [3,4,12,18,22] were inspire for the development of a comparison between lean and green paradigms. Several lean and green supply chain characteristics are considered in Table 2.

4 Combining Industry 4.0 and Lean and Green Supply Chain

The future must become leaner in organization accurately in planning and technology [36]. The authors [21] mentioned that the paradigm Industry 4.0 solutions not only can be integrated in lean manufacturing but can be beyond that improve lean manufacturing. Also Sanders et al. [28] considered that industry 4.0 and lean manufacturing can be integrated to achieve a successful production management. However, they are not mutually exclusive [28].

Definitely, several researches mention the benefits of the integration of lean and green in different stages of the company or the supply chain [1,9,12,13,20]. Kainuma and Tawara [20] studied the lean and green supply chain incorporating there cycling or re-use during the life cycle of products and services. It represents the different phases of a product life cycle, consisting in [20]: (i) the acquisition of the raw material, (ii) the manufacturing, (iii) the distribution, (iv) the retailer, (v) the use, (vi) the collection, (vii) the transportation, (viii) the dismantling and (ix) the decomposition.

Stock and Seliger [30] presented the opportunities for the realization of a sustainable manufacturing in the Industry 4.0. For them the life cycle (in the end-to-end solution) consists in different phases [30]: (i) the raw material acquisition, (ii) the manufacturing, (iii) the transport (between all phases), (iv) the use and the service phase, and (v) the end-of-life phase (containing the reuse, remanufacturing, recycling, recovery and disposal). In addition, the environmental/green dimension of the sustainability is better considered because the allocation of resources as products, materials, energy and water can be realized in a more efficient way [30]. The adoption of smart energy systems facilitates the energy use [23].

In fact energy models would assist the analysis of green factory designs, especially for evaluating alternatives during early design stages [25]. The design of lean and green supply chain, special in the early design stages for the products and the processes is a very important issue for the elimination of waste. In a lean and green environment [7] mention that "eliminating the use of toxics through product or process re-design could mean reduced worker health and safety risks, reduced risks to consumers and lower risk of product safety recalls and reducing process wastes in manufacturing often find more opportunities to reduce waste throughout the life cycle of the product, thereby having a possible domino effect on the entire supply chain". Industry 4.0 is in line with these ideas. According to [27], Industry 4.0 processes will change the entire supply chains, from suppliers to logistics and to the life cycle management of a product. It helps to streamline the process, with more transparency and flexibility.

Lean and green supply chain requires manufacturing technologies to make processes and products more environmentally responsible [22]. In addition they ask for a flexible information system [17]. The technology is a driver of the Industry 4.0 [15,34]. With smart technologies which include the use of electronics and information technologies [27] will help the implementation of a more efficient lean and green supply chain.

Also the collaboration with suppliers which is a lean and green characteristic is considered by Industry 4.0. Through a better communication mechanisms, with a high compatibility issues of hardware and software which should required standardized interfaces, and synchronisation of data, allow that lean and green suppliers get better synchronisation with manufacturers [28,32].

The author [14] concludes that lean and green "is an effective tool to improve processes and reduce costs, by not only reducing non-value-added activities but also physical waste created by systems". Industry 4.0 is in line with this statement due this paradigm make all but in a better way, more sustainable, faster and efficient. According to [21] lean allows the organizations to be more standardized, transparent and having only the essential work which result in an organization less complex and support the installation of industry 4.0 processes and solutions. The green also support the implementation of the Industry 4.0 due it allows to reduce the negative environmental impacts.

The customer type is a concern in the lean and green supply chain. Of course that lean and green aim is to satisfy the customer needs, but this satisfaction is relative to: in the lean paradigm is based on cost and lead time reduction [9] and in the green paradigm is based on helping customers to being more environmentally friendly [13]. The Industry 4.0 will go to improve in this subject. It allows a better understanding of the customer needs and allows the immediate sharing of the demand data throughout complex supply chains [15]. According to [27] with the full automation and digitalization systems, it allows an individual customer-oriented adaptation of products that will increase the value added for organizations and customers. Customers instead of choose from a fixed product spectrum set by the manufacturer, they will be able to individually combine single functions and components and define their own product [15].

Another characteristic of lean and green supply chain is the employee involvement and empowerment [12]. According to [8] employee commitment and motivation, and employee empowerment and participation are elements of lean and green organization. Also [24] mention that connections between lean and green practices are shown through: (i) employee involvement, (ii) learning by doing, (iii) continuous improvement, and (iv) problem-solving tools. [36] mention that lean means reducing complexity, avoiding waste and strictly supporting the employees in their daily work. Also the reduction of environment impacts improves the health and safety of employees [31]. These aspects are in line of what is an employee in the four industrial revolution. Indeed, employees may find greater autonomy and more interesting or less arduous work [6]. Industry 4.0 needs employees not only with creativity and decision-making skills, encountered as a lean and green supply chain characteristic, as well as technical and ICT expertise [6].

There are in literature some studies that try to make the bridge between lean paradigm and green paradigm with Industry 4.0. [28] used 10 lean concepts in their research in way to validated for attainability through Industry 4.0 paradigm. Kolberg and Zühlke [21] described the lean automation and Industry 4.0 and give an overview of the links between them. [30] present an overview of sustainable manufacturing with the future requirements of Industry 4.0. Figure 1 illustrates an attempt to link lean and green supply chain characteristics to Industry 4.0 concepts.

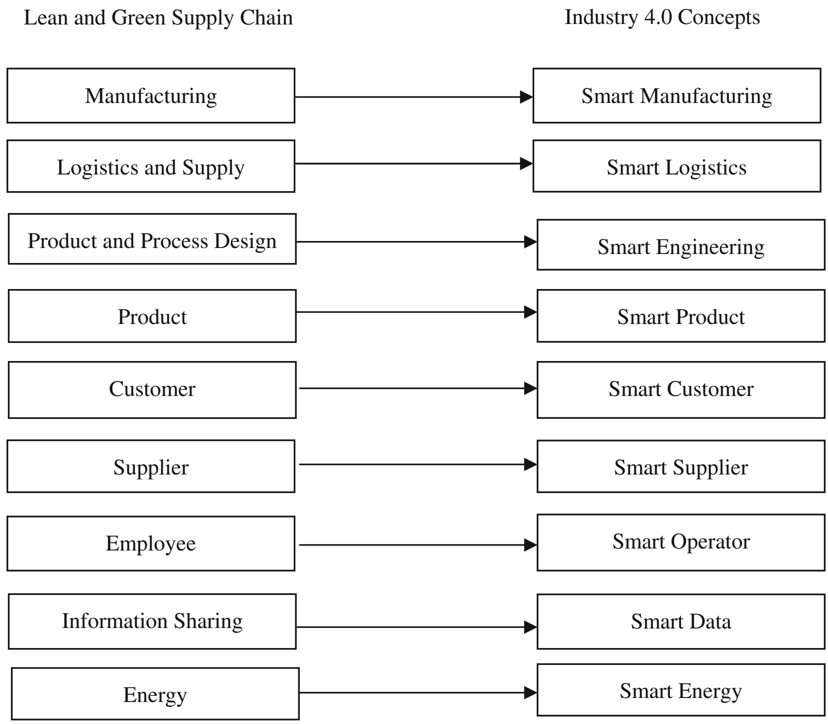

Fig. 1. Linking the lean and green supply chain characteristics to the Industry 4.0 concepts

5 Conclusion

Today, the term Industry 4.0 describes a vision of future of the supply chains. There is a strong conviction that the definition of lean and green supply chain will not disappear, it will be evolve and adapt to the new trends that the new industrial era will require. Lean and green supply chain is focussed on organization and in the flow of information, material and money between partners. That is, more directed to physical processes and less for virtual and technology. Even so there are in literature some examples that try to make the bridge between lean paradigm or green paradigm with Industry 4.0. This paper bridges the gap between the well-known lean and green supply chain management and the new era of industrial revolution.

A conceptual model was developed linking the lean and green supply chain characteristics to the Industry 4.0 concepts. Several characteristics were presented on model, namely: (i) manufacturing, (ii) logistics and supply, (iii) product and process design, (iv) product, (v) customer, (vi) supplier, (vii) employee, (viii) information sharing and (ix) energy. Those who understand the relationships between these two topics will have a greater chance of influencing their supply chains into a source of competitive advantage and help in a better way on the deployment of the Industry 4.0 paradigm.

Future research is needed. Understand which lean and green characteristics are more important for the development of Industry 4.0 is required. It would be also beneficial to understand the priority between characteristics on the implementation of this new paradigm and in different entities in the supply chain. Industry 4.0 will be a step forward for the effectiveness and competitiveness of the lean and green supply chains.

Abstract. Maker education is an important mission of Chinese universities for the entrepreneurship and innovation. However, current maker education failed to meet the makers' demands for real-time awareness of space, adaptive automatic resources, diverse innovation activities and tools with intelligent support in the makerspace. Therefore, the innovation ecosystem has emerged to be the best choice to solve those problems. This paper first reviews literatures on maker education, and then analyses fundamental principles and elements of the innovation ecosystem. After that, essentials and properties are discussed for innovation ecosystem-oriented maker (IEOM) education. At last, the model of IEOM education is developed, including innovation subject, innovation activity, and smart innovation environment.

Keywords: Maker education · Innovation ecosystem · Chinese universities

1 Introduction

Maker education is an important mission of Chinese universities for the entrepreneurship and innovation. However, current maker education in Chinese universities has the limitations of closed innovation, efficiency-driven, focal product, specialized organization, and so on. They use a hierarchical management team as the subject of innovation, and use virtual laboratories, heavyweight wearable devices and other technologies to build an intelligent and well-defined physical space. This failed to meet the makers' demands for real-time awareness of space, adaptive automatic resources, diverse innovation activities and tools with intelligent support in the makerspace. It also does not comply with their hopes of cooperative innovation, wisdom communications and results-sharing. Therefore, the innovation ecosystem has emerged to be the best choice to resolve

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_104

those problems. At the same time, it needs to construct a model of innovation ecosystem-oriented maker (IEOM) education as an important accelerator of the sustainable development of university makerspace. In IEOM education, any maker can be innovative as long as there are a true interest and consistency in establishing a favorable environment to support it [4].

In this paper, we first review literatures on maker education, and then analyses fundamental principles and elements of the innovation ecosystem. After that, essentials and properties are discussed for innovation ecosystem-oriented maker (IEOM) education. At last, the model of IEOM education is developed, including innovation subject, innovation activity, and smart innovation environment.

2 Literature Review

Maker education of universities arises from the maker movement with the learning by doing culture. The maker movement has provided a perspective on learning that differs from the traditional learning practices taking place in schools and universities [14]. Barrett, Pizzico, Levy and Nagel [1] discussed the benefits of university makerspaces that are primarily focused around building physical models and the inherent of informal learning environments and community. Physical models can increase the effectiveness and quality of the final design for the development of undergraduates by linking the material covered in the classroom to the real world. Informal learning environments are more open environment allows them to be used more freely and interwoven into the class structure for multiple classes without typical classroom scheduling constraints.

The best practices of university makerspace are investigated by several researchers. Wilczynski [23] explored academic maker spaces in universities, such as Arizona State University, Georgia Institute of Technology, Massachusetts Institute of Technology, Northwestern University, Rice University, Stanford University, and Yale University. He recommended the best practices as follows: The mission of the academic makerspace must be clearly defined; Ensure that the facility is properly staffed; Open environments promote collaboration; Aligning access times with the student work schedules; Providing user training is essential; Attention must be devoted to establish a maker community on campus. Katona, Tello, et al. [10] put forwards four best practices: flexible models for interdisciplinary faculty hiring and engagement, development of student entrepreneurs, integrating cross-campus curricula, and the development of cross-campus collaborations. Myers [12] encouraged interdisciplinary research and idea, which elements were student led engagement, access to the latest technology, and key partnerships. Bieraugel [2] found that the on-campus makerspace located outside the university library encouraged the most innovative behaviors and exploration of new ideas, and within the library, collaboration rooms were the best spaces for encouraging creativity.

As to Chinese researchers, their focuses are: relationships between maker education and innovation education [8,25]; Essentials and functions of maker education [27–29], double helix model [24] and design-based learning [9,30]; augmented virtual technology and Internet plus in maker education [19,20,27], development paths of maker education [18,21] and system framework [26].

Obviously, innovation ecosystem that can be aligned with university maker education currently seems to be not involved in the literatures. In fact, it is a good idea to solve problems that development of maker education faces in Chinese universities.

3 Theoretical Roots

The innovation ecosystem is a newer and mainstream concept discussed widely by scholars and practitioners. However, innovation ecosystem is often described in different ways, and thus understanding it remains a challenge. Luomaaho and Halonen [11] defined innovation ecosystem as a permanent or temporary system of interaction and exchange among an ecology of various actors that enable the cross-pollination of ideas and facilitates innovation. Nordfors [13] referred that innovation ecosystems embody technology and information flow between those needed to turn ideas into processes, products or services. Bulc [4] pointed out that an innovation ecosystem is a system made for innovation creation in an open, natural manner, which enables a holistic understanding of needs, solutions, and consequences related to innovation processes and innovation itself, and is an interaction between people, enterprises, and institution. Ritala [15] had a view that innovation ecosystem refers to clusters (physical or virtual) of innovation activities around specific themes (e.g., biotechnology, electronics and software). The complex innovation ecosystem where networks of innovations and communities of people and organizations interact to produce and use the innovations [22]. Taken all together, Innovation ecosystem is an interactive work environment which strengthens actors of different disciplines to co-create new ideas, and then to construct prototypes and commercialize them in a way of ongoing innovation.

An innovation ecosystem has several important elements. The basic components of the ecosystem must be a high quality (universities, funding possibilities, specialized services, talent pool and regional dynamics) [7]. Bulc [4] thought that key elements can be put into 4 major groups: participants, tools, content, and principles. Haines [6] identified the following key ingredients of an innovation ecosystem: culture, champion(s), network, stakeholder engagement, process, physical space and events. Obviously, the innovation ecosystem includes funds, material resources (equipment or facilities), and the innovative actors such as students, teachers, researchers, industry specialists, venture capitalists. They participate in the ecosystem to enable technology development and all kinds of innovations.

Creating an innovation ecosystem needs to think about some basic principles: getting rid of the box, core value, competences, dynamic structure, and constant change [4]. To make innovation, a suitable innovation ecosystem must meet different conditions such as natural, structural, organizational and cultural factors. Those factors can be grouped based on the following dimensions: resources, governance, strategy and leadership, organizational culture, human resources management, people, partners, technology and clustering [5]. A flow of technology and information is the key factor among the actors: the people, enterprises, and institutions [16].

4 Essentials and Properties of IEOM Education

4.1 Essentials of IEOM Education

IEOM education creates a new paradigm for a large-scale cooperative design, creation, invention, and innovation. It develops a novel way of intellectual association, transparent operation, and collaborative participation in the innovation. In this novel approach, creative ideas, services, and products can be implemented, and the greatest value can be achieved.

IEOM education takes innovative actors as a community and utilizes new technologies to create a real world of participatory innovation. These technologies are emotional computing, open source hardware, holographic environment, 3D printing, social media and adaptive technologies, etc. IEOM education is not only the emergence of new technologies but also the emergence of transformative innovation activities participated by makers. Firstly, due to the implementation of the open source hardware and open resources, IEOM education provides multiple paths involved in innovation activities for makers full of creative thinking and creativity. Secondly, makers can not only connect with people, machines and objects to the physical space, but also seamlessly connect all the information sources outside the space. Makers' creative partners are also just from members of a team to global actors in the project.

4.2 Properties of IEOM Education

(1) Wisdom circle
The wisdom circle is proposed to be a new concept in the development of the biosphere, emphasizing the powerful forces of human wisdom in modern evolution. Human beings give full play to collective wisdom to explore new methods, to create innovative technologies, and to develop new tools. They use created products to change the makerspace, further enhance the intelligence of the group, expand the scope of the role. Ultimately, the makerspace evolves into the human wisdom circle containing capacity for development and creativity. The wisdom circle relies on the rapid flow and superior connectivity of data, information and wisdom. The flow and connectivity produce great transformation power, and establish a fresh creative field of relating to wisdom individuals, enhancing group wisdom and activating participatory innovation experiences.

(2) Micro-innovation
While micro-innovation is characterized by a small team, it shares the common trait with macro innovation: creative thinking based on recurring actions, re-engineering an opportunity to make every thought new, and building creative solutions that bring true progress. Micro-innovation is a local action and a

global innovation. It is a decentralized, network-based innovation. Combinations of indigenous micro-innovation will have a direct impact on the overall innovation. Micro-innovation is not holistically planned and guided. In this sense, the innovation is a daily habit. Micro-innovation encourages new technologies and processes to be extended in IEOM education, and offers sustainable innovative results for any size of the makerspace.

(3) Cross-border
As a creative scene, the makerspace in IEOM education is cross-organizational, inter-spatial and interdisciplinary. It breaks the closed boundaries in order to truly achieve the integration of innovation. Firstly, the makerspace is not only beyond the visible border of physical space, but also is across the invisible boundary of the digital space. Secondly, the wisdom flow and the information flow continually mobilize among the enterprises, research groups, project groups, innovative communities and other organizations in IEOM education. Thirdly, the acquisition of innovation is not confined to a specific discipline. Therefore, the IEOM education emphasizes cross-border, connection and integration among the different disciplines and spaces.

(4) High value-added
There are ongoing associations, high circulation and self-enhancement in IEOM education. It is the circulation and re-creation of data and information, and environmental innovation that produces the most valuable knowledge. For those data and information of weak circulation and low re-creation, it is not able to create leapfrog development and high valued innovation. Therefore, data is needed to be reprocessed deeply, and the knowledge flow is needed to speed up. Further to this, individual wisdom and the power of group innovation are converged to achieve a high value-added and an upward spiral of innovation capabilities showing the development of creativity. For example, scientific knowledge and big data generated by activities, and deeper structure for mining methods, are combined with language understanding and image recognition to provide value-added services for makers.

(5) Strong lean
IEOM education of strong lean emphasizes scientific analysis of big data in the creative process, and optimizes decision-making. Strong lean can improve the performance and reduces the bias, with the aim of discovering potential problems, assessing the progress of creation, and predicting future performances. Among them, lean thinking is scientific and accurate, thereby being efficient and optimal. In strong lean, analysis technologies of data and information visualization can be used to present the results of complexity analysis such as charts or stereoscopic images. In doing so, relationships and patterns of things are identified quickly and easily.

(6) Multi-interactions
Multi-interactions include internal interactions between human-to-thing (H2T), human-to-machine (H2M), thing-to-machine (T2M), human-to-human (H2H),

thing-to-thing (T2T). They provide more maker-oriented services for IEOM education and meet the maker's strong demands of highly interactive experiences. The friendly multi-interactions are inseparable for designing human-thing communication devices, machine operation objects, and human-computer interaction. It provides natural, convenient and efficient interactions among makers, machine and things.

5 Design Principles of IEOM Education

IEOM education takes Web 4.0 as the basis and creation as being the engine to establish the innovative ecosystem of the overall situation. Its mission is to create an innovative ecosystem that integrates the various innovation activities into IEOM education. The core is to create synergies among the innovative collaborators, such as industries, educational institutions and research institutions. The paradigm is an innovative network which is composed of innovative actors.

IEOM education focuses on new technologies and innovation strategies. It also concentrates on innovators, new technology adoption, cross-cutting issues, learning organizations, forms of activity, and innovative business environments. IEOM education balances process innovation and creativity by establishing innovative space, and builds a network of innovative culture and a collaborative innovation model. Thus by strengthening the creative culture and interdisciplinary innovative solutions, IEOM education brings the integration of innovation strategy and digital technology to an unprecedented level.

IEOM education produces a combination of innovative technologies and provides better user experiences of contextualization and value-added, supported by digital technologies such as social media, mobile computing, big data, cloud computing, sensor networking, Internet and machine intelligence. For example, social media networks enhance coexistence; big data provides a unique analysis, targeting the recommendations and preferences in the situations; mobile technology creates location context services and awareness; cloud computing enlarges access to resources and services; sensors create real-time feedback and response; machine intelligence improves the quality of insight and decision-making.

The digital space is a new method to drive the innovative wisdom of individuals, organizations, and communities to establish a network of cross-industry and actors' innovation. It expands the ecosystem leading to innovation and creation. Digital space in IEOM education connects various things and the actors to enhance the relevance and importance of digital technology. Through newly connecting and integrating digital technologies aforementioned, the digital space can enhance collaboration, and access the results of high value-added.

With the integration of digital technologies, IEOM education takes Internet into the real-world, to form the human networking, things networking, and service networking. This integration can configure technology, media, market and actions of the actor altogether, and cross-links smart applications of real-world products, services, and location by Web 4.0.

6 Building a Model of IEOM Education

IEOM education consists of three elements of innovation subject, innovation activity, and innovation environment. Innovative subjects include experiencers, innovators, researchers and experts, namely, the inner creative knowledge space. Innovation activities are developed by the innovation subjects including interest, research, practice and smart creation, namely, external creative knowledge space. The innovation environment is a creative scenario of a whole new perspective, reflecting innovative subjects' rich creation in participating in innovation activities. The model of IEOM education is shown in Fig. 1.

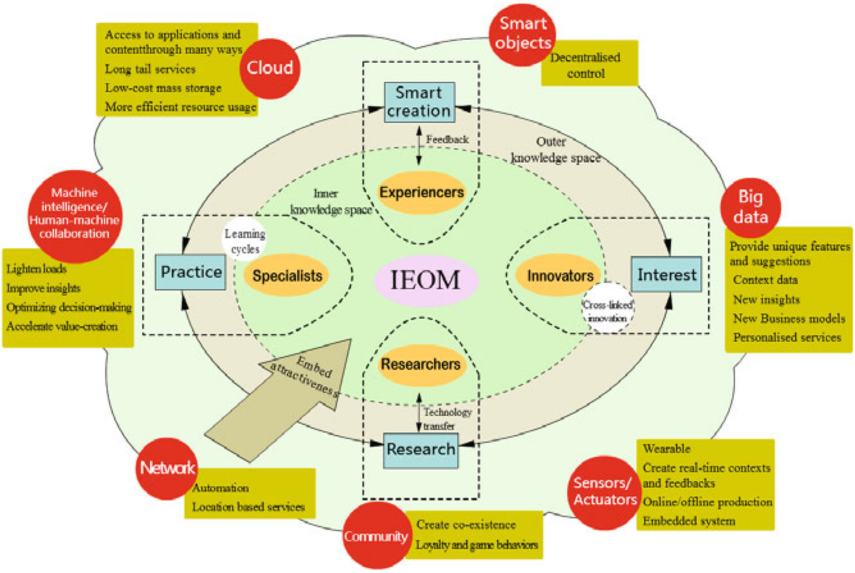

Fig. 1. Development model of IEOM education

6.1 Innovation Subjects

(1) Experiencers
The experiencers are the subjects of intellectual creation, are the explorers of the unknown world, and are the perceivers of facing the future. On the basis of light capital and low investment, numerous experimenters learn, experience and absorb in IEOM education, and then redesign and transform knowledge and activities. In IEOM education, experiencers affect the development of the real industry remodeling the physical world, to generate digital, open and popular desktop manufacturing industry. Experiencers take the dexterous participation and agile action to input new perceptions and ideas for the intellectual creation activities. At the same time, intellectual activities also provide feedback on innovative activities for the experiencers.

(2) Innovators
In IEOM education, innovators with the similar interests gather together to try unique combinations of multi-domain, multi-entity, multi-method and cross-linking innovations. They blur boundaries, continuously redefine, and constantly remodel works. Innovators connect IEOM education to nature and life in order to design a unique perspective of the new works, such as technology + nature + art, digitization + virtualization + audiovisual performances, and other new explorations.

(3) Researchers
Facing the unknown future, researchers use systematic thinking and scientific methods to deepen the essence of things and the main contradictions. They capture new knowledge, generate new ideas, utilize new technologies, and explore new approaches. Rather than the reality of unchanging model, researchers study the possibility of the future to help the development with the IEOM education. It is important for researchers to migrate and remix technologies, which are an evolution path of new technologies. Similarly, the study of innovative activities can also stimulate the creative thinking and technological innovation of the researchers.

(4) Experts
Experts emphasize the professionalism of their subject knowledge and the sensitivity to complex things. They are not to solve problems according to the steps, but to focus on asking questions, mining data, clarifying the relationship and finding a solution. In IEOM education, the experts transcend over-fitting (self-perceived vertexes) through cross-border connectivity and cyclic learning. At the same time, on the basis of strong information filtering, experts show innovative wisdom of research on product-updating, platform-upgrading, and entity-high-value-reusing.

6.2 Innovation Activities

(1) Interest
Interest is the engine of makerspace development. Innovators gather in the makerspace, generate creative ideas and innovative products in a more personalized and independent way, based on aspirations, visions and interests. In IEOM education, interest-based innovation activities, are not a clear bounded knowledge or experience passed to the creators, but a creative enthusiasm for innovation, social responsibility and other elements to affect makers. Innovation activities emphasize cross-border, connectivity, collaboration and sharing, to enhance the cohesion of makers' innovations. They highlight the motive of exploration and innovation, to encourage self-learning, decision-making and creativity. Innovative activities show the powerful forces of innovative self-development and co-creation through the de-centralization, peer organization. They offer high-yield innovations with substantial value-added.

(2) Research
Research is the foundation of the development of IEOM education. Through the unknown, undetermined, complex, chaotic and other advanced technology exploration and the transfer of key technologies, research achieves changes and technological breakthroughs. As for the entities, products, and services, a researcher can flexibly design, massively customizes and agilely develops. The aspects of design, construction, and testing may be updated or changed iteratively.

(3) Practice
Makerspaces are central resource spaces offering various making practices in different contexts. Practice is an acceleration power of innovation. Practice is the only way to produce knowledge creation and innovation. Creative activity in practice refers to the fact that the experts absorb, interact, reflect, criticize and recreate knowledge and products through the context-based collection, correlation and integration. It stresses the unity of theory and practice, and shows the great wisdom of innovation and creation. In IEOM education, cross-domain experts carry out innovative ideas and actions to the practice of product development. This practice appears in a circle of knowledge production and application transformation.

(4) Smart creation
In industry, smart creation means to quickly and adaptively fabricate products using automatic, networked and intelligent information technologies such as Internet of things. In IEOM education, smart creation can be all a matter of structural change, production optimization, efficiency enhancements and value-added. It is decided on core skills, intellectual capital and other top factors of the practitioners. Smart creation is the dexterous behavior, which the individual and the collective in the creative network culture focus on the tiny creativity, the agile product development, the custom individuality service, and the creative behavior reshaping. Smart creation demonstrates the interaction and collaboration between makers by enhancing their dexterity behavior and the creativity practice. With IEOM education, it increases the possibility of the creative exploration, scientific attempt and innovative practice for makers.

6.3 Innovation Environments

(1) Cloud services of IEOM education
Hyper-scale data gathered in a creative environment is inseparable from the bearing and calculation capacity provided by the cloud. Cloud supports the integration and sharing of large-scale resources and has a low requirement on equipment, multi-channel access to resources, low-cost storage of large-scale data, and efficient use of data resource to deliver long-tail stable service. Cloud has features of on-demand access, ubiquitous access, resource pooling, elasticity, measurable use, recoverability, high security and high scalability. These features of cloud computing are essential to the reality of demand for IEOM education.

(2) Smart objects of IEOM education
As the cognized smart objects, they empower objects or things corresponding cognitive abilities and reflect decentralized control features of the non-linearness, openness and flatness. As an entity embedded in the autonomously distributed intelligent system, smart objects can intelligently act on the human-machine-thing objects based on the sensor's perception in IEOM education. Multi-object cooperation is able to globally optimize, to percept real laws and to solve the major complexity of the problem by a distributed cooperative work.

(3) Big data of IEOM education
Big data in IEOM education aims at all the context data generated by the innovation subject in the innovation activity. Through batch data processing and unique perspective analysis of all the relational and non-relational data, it provides accurate forecast and personalized real-time suggestions for the innovation subject. It can be a keen insight into the quality of data, data-mining in the hidden information, and the true reflection of the state of activity. At the same time, weak related data floods with sparse value density can still be appropriately associated and deeply mined, in order to create a new situation and a new development stage of IEOM education.

(4) Sensors of IEOM education
Sensors provide large amounts of real metadata for big data by detecting objects, observing events, tracking targets, describing or quantifying activities and capturing information. In IEOM education, the main function of sensors is perception and cognition. The perception is the fact that the different sensing elements perceive the context to obtain the parameters of the quantized and non-quantized. Cognition is tantamount to acquire the state information or knowledge, such as subjective emotion, psychological state, and another individual implicit information. Cognition can abstract the relationship of information recorded in the communication, properties and location of devices and tools, and others. Sensors own the functions of self-capturing, self-tuning, self-identification, and logical judgments. They provide on-line or off-line production and establish real-time information feedback, moving towards the depth of miniaturization and high-level intelligence.

(5) Communities of IEOM education
Members of a community are technologically sophisticated do-it-yourself (DIY) enthusiasts interested in activities related to engineering, electronics, robotics, and desktop fabrication [3]. In the inter-connected times, the community reconstructs the circle of interaction, re-establishes the role of identity, reconstructs the cooperative relationship, and creates the group relationship of real and virtual coexistence. The community is connected. The connection is namely development. In IEOM education, the innovative subjects connected with interest will establish the creative community and is involved in the innovation activities. This community establishes a co-existence and co-construction, and shares in loyalty or game behaviors.

(6) Network of IEOM education
IEOM education networks provide links be-tween specific makerspace workshops and projects that permit forms of identities to flow and mobilize [17]. Innovation networks in IEOM education give innovation subjects insights into temporal and spatial contexts, in which to capture preferences, goals, paths, activities, and locations. They can automatically connect appropriate information, resources and nodes with humanized supports. Location-based networked services are not just based on the physical space of the subject, but also the mind and emotional states displayed by the subject of activities.

(7) Machine intelligence and human-machine collaboration in IEOM education
IEOM education can be inextricably linked to cyber-physical systems (CPS), which is the in-depth integration of computation, communication, and control technologies. CPS couples network and computing to the physical environment, and to achieve full autonomy, efficient collaboration, mobile control, dynamic adaptation, and human services. On the one hand, human-machine collaboration transforms the interaction between human and machine and object, and generates new methods. On the other hand, it associates individual objects or subsystems into a unified entity, setting up a fusion of the natural world, the virtual world, and the thought world. CPS emphasizes the communication between human and machine, and scientifically controls the movement of objects through precise calculation of data parameter. These communications and controls are woven into innovation activities and continuously facilitate innovative subjects sensing objects and knowing laws.

7 Conclusion

IEOM education not only drives the development of the world but also the progress of humanity. It transforms the external world, while at the same time shaping the inner world of mankind which conforms to the characteristics of the new era. IEOM education takes individual intelligence to be gathered into a powerful force, and to create a new situation of humanization, open-sources, and co-creation. It breaks the limitations of traditional innovation and closed research, to change people's ideas and thoughts in the traditional innovation environment, and promotes the development of the makerspace.

Pricing and Greening Policy for Manufacturer with Low Carbon Strategic Customers

Wen Jiang(✉)

College of Architecture and Urban-Rural Planning,
Sichuan Agricultural University, Chengdu 611830, People's Republic of China
xuezhongsha_wen@163.com

Abstract. Global warming is mainly caused by excessive emissions of greenhouse gases especially the carbon dioxide, which makes the carbon reduction become hot issues to businesses and consumers. This article considers a manufacturer produce one product and assumes the customers are of low carbon and consisting of myopic customers and strategic customers. The customer decision is affected by the price and unit carbon emissions of the product. The paper examines the optimal pricing and greening policies for the manufacturer with and without green technology investment. It shows that the optimal prices in two scenarios are decreasing in the ratio and patience of strategic customers. The presence of strategic customers is detrimental to the manufacturer and the negative impact increases as the ratio and patience of strategic customers increases. It also shows that with the addition of carbon sensitive degree, the manufacturer will improve the regular sale price and invest more in green technology when the customer number exceed a certain threshold. Finally, the article analyzes the effect of green technology investment on the optimal price and find that the optimal price with green technology investment is lower than that without green technology investment.

Keywords: Strategic customer · Carbon sensitive demand · Pricing decision · Green technology investment

1 Introduction

Global climate change is a serious threat to human survival and development. Global warming is mainly caused by excessive emissions of greenhouse gases especially the carbon dioxide [9], which makes the carbon reduction become hot issues to businesses and consumers [5,10]. In response to the Government's carbon reduction requirements and low carbon preference of customers, manufactures are considering whether invest in green technologies to reduce the carbon emissions of their products. With the implementation of the carbon footprint, it is becoming easier for customers to obtain the information on carbon emissions and to take this information into account in purchasing decisions. Therefore, it is very meaningful to study the optimal decisions of the manufacturer with carbon emissions sensitivity demand. Another phenomenon worthy

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_105

of study is the presence of strategic customer behavior [7]. With the development of e-commerce and the application of dynamic pricing strategies, customers are increasingly able to anticipate future price cuts and chose to delay the purchasing. Such "smart" customers are called strategic customer and customers who will not anticipate discounting are called myopic customer. The strategic and myopic customers are co-exist in real-life. Firms who ignore the presence of strategic customer will result in 20% losses of their total profit [1].

Two research streams are closely related to this article and will be reviewed to highlight our contributions. In the literature of models with carbon emissions demand or green technology investment, Bansal and Gangopadhyay [2] found that consumers were willing to pay a higher price for low-carbon products. Klingelhö [11] examined the effect of carbon emissions trading on green technology investment. The paper found that taking carbon emissions trading into consideration had impact on the investment, but this impact was not always positive incentives. Zhao et al. [17] investigated how did the manufacture in perfectly competitive market chose a technology when green technology was available. Yalabik and Fairchild [16] examined the manufacturer's optimal green technology investment of environment-friendly products with consumer choice was taken into consideration. Xia et al. [15] analyzed the interrelations among the carbon emission reduction, green technology investment choices and enterprise performance. These study provided a reference for the study of this paper, but they all assumed the customers were myopic and ignored the fact that myopic and strategic customers co-exists in real-life. In addition, Su [14] examined the pricing model of a monopolist who sold finite inventory to heterogeneous strategic customers in finite period. Jerath et al. [6] investigated the impact of two sales approach (through an opaque intermediary versus last-minute sales directly to consumers) on the service provider's profit when strategic customer behavior was considering. Lai et al. [12] investigated the effect of a posterior price matching policy on the customers' purchasing behavior, and seller's pricing decisions. They showed that strategic consumers' waiting incentive could be eliminated by this policy. Du et al. [4] examined the single-period joint inventory and pricing strategies with strategic customers and risk preference. Prasad [13] considering mix of myopic and strategic consumers and studied the choices of mixed bundling pricing and reserved product pricing for a firm who sold two products. Jiang and Chen [8] studied the optimal decision for a low carbon supply chain consists of one supplier constrained by cap-and-trade policy and one retailer facing homogeneous strategic customers. The literature above does not consider carbon emissions, or assumes that customers are homogeneous.

In order to fill the gap present above, this paper examine the manufacturer's pricing and green technology investment policy when the customer are carbon emissions sensitive and myopic and strategic hybrid. This paper aims to address following three questions:

- What is the optimal pricing policy for the manufacture without green technology investment? How does the presence of strategic customers affect the optimal pricing?
- What is the optimal pricing and greening policy for the manufacture with green technology investment? How does the presence of strategic customers affect the optimal pricing and greening policies?
- What effect does the green technology investment on the optimal policies?

2 Model Descriptions and Assumption

The paper considers one manufacturer who produce a product and direct sell it to the end users. The whole sales period is divided into two stage. At the first stage, the manufacturer sells the products at regular price p which is a decision variable. In the second stage, the manufacturer sells the products at lower price s which is an exogenous variable and decided by the market. The price in second stage is still greater than the cost of the product, i.e. $s > c$. The initial unit carbon emissions of the product is e_0. The manufacture can invest in green technology to reduce unit carbon emissions. The unit carbon emissions after green technology investment is $e(e < e_0)$. Referring to the expression of [16], the paper assumes the green technology investment function, denoted by $I(e)$, is:

$$I(e) = t(e_0 - e)^2, \tag{1}$$

where t represents the investment coefficient. So the manufacturer's decision variables is regular sales price p and unit carbon emissions e.

This paper characterizes customers as heterogeneous low carbon customers. The heterogeneity behavior in two aspects. On the one hand, the customers include myopic and strategic types. On the other hand, the customers have different valuation to the product. The customers can also observe the unit carbon emissions during the sales period and take it into consideration to make a buying decision. The paper assumes that the customer size are fixed and denoted by N. The ratio of strategic customers is θ and the ratio of myopic customers is $1-\theta$. The paper assumes that each customer purchases a product at most. The valuation of the two type customers (denoted by v) is follows uniform distribution in $[0, v^f]$. Strategic customers discount future consumption at δ, $(0 < \delta < 1)$. By delaying a purchase until the second stage, Strategic customers lose out on some consumptive value, and hence their future utility is reduced to reflect this loss [3]. δ can be see as patience of the strategic customer and higher δ implies more patient customers. The unit cost is c. The shortage cost and salvage value is not take into consideration.

In addition, $v^f > p + \eta e_0 > s + \eta e_0$, which indicates that the customers have positive margin when they buy the products. In order to express convenient, set $A = \frac{1-\delta+\theta\delta}{1-\delta}$.

3 The Base Model

3.1 Analysis of Decision Making Process

According to traditional study, the decision condition for myopic customers is $v - p > 0$. This paper extends it as $v - p - \eta e_0 > 0$ to depict the carbon sensitive characteristics of customers, where η represents the carbon sensitive degree. The extension of strategic customer decision rules is similar, that is $v - p - \eta e_0 > 0$ and $v - p - \eta e_0 > \delta(v - s - \eta e_0)$.

(1) The first stage

At the first stage, the manufacturer set p. Then the two type customers will response to these decisions according to themselves rules.

As to myopic customers. According to the decisions rules, myopic customers will buy products as long as $v-p-\eta e_0>0$, Otherwise, they will not buy products and leave the market. So the expected number of myopic customers who take the purchase action in the first stage is $(1-\theta)N\int_{p+\eta e_0}^{v^f} f(v)\,dv=(1-\theta)N\frac{v^f-p-\eta e_0}{v^f}$.

As to strategic customers. According to the decisions rules, strategic customers will buy products only if:

$$v-p-\eta e_0>0,\ v-p-\eta e_0>\delta(v-s-\eta e_0).$$

Then

$$0<\frac{p-\delta s+(1-\delta)\eta e_0}{1-\delta}<v<v^f.$$

So the expected number of strategic customers who take the purchase action in the first stage is:

$$\theta N\int_{\frac{p-\delta s+(1-\delta)\eta e_0}{1-\delta}}^{v^f} f(v)\,dv=\theta N\frac{v^f-\frac{p-\delta s}{1-\delta}-\eta e_0}{v^f}.$$

To sum up, the expected number of customers who take the purchase action in the first stage is $(1-\theta)N\int_{p+\eta e_0}^{v^f} f(v)\,dv=(1-\theta)N\frac{v^f-p-\eta e_0}{v^f}$.

(2) The second stage

At the second stage, the sales price reduces to s. Then the rest of the two type customers will response to this price according to themselves rules.

As to myopic customers. The expected number who take the purchase action in the second stage is $(1-\theta)N\int_{s+\eta e_0}^{p+\eta e_0} f(v)\,dv=(1-\theta)N\frac{p-s}{v^f}$.

As to strategic customers. The product will exit the market after the second stage. Waiting does not make sense for strategic customers now. As long as the valuation is greater than $s+\eta e$, the strategic customers will buy products. Therefore, the expected number of strategic customers who take the purchase action in the second stage is: $\theta N\int_{s+\eta e_0}^{\frac{p-\delta s+(1-\delta)\eta e_0}{1-\delta}} f(v)\,dv=\theta N\frac{\frac{p-s}{1-\delta}+\eta e_0}{v^f}$.

Based on the above analysis, the number of customers who purchase products can be obtained and listed in Table 1.

Table 1. The number of customers who purchased the product

	First stage	Second stage
Myopic customers	$(1-\theta)N\frac{v^f-p-\eta e_0}{v^f}$	$(1-\theta)N\frac{p-s}{v^f}$
Strategic customers	$\theta N\frac{v^f-\frac{p-\delta s}{1-\delta}-\eta e_0}{v^f}$	$\theta N\frac{\frac{p-s}{1-\delta}+\eta e_0}{v^f}$
Total	$\frac{N}{v^f}\left[v^f-(1-\theta)p-\frac{\theta(p-\delta s)}{1-\delta}-\eta e_0\right]$	$\frac{N}{v^f}\left[\frac{(1-\delta+\theta\delta)(p-s)}{1-\delta}+\eta e_0\right]$

3.2 Pricing Model Without Green Technology Investment

The manufacturers expected profit function without green technology investment, denoted by $\pi_n(p)$, is:

$$\begin{aligned}\pi_n(p) =& \frac{N}{v^f}\left[v^f-(1-\theta)\,p-\frac{\theta\,(p-\delta s)}{1-\delta}-\eta e_0\right](p-c)\\ &+\frac{N}{v^f}\left[\frac{(1-\delta+\theta\delta)\,(p-s)}{1-\delta}+\eta e_0\right](s-c)\,.\end{aligned} \tag{2}$$

Lemma 1. *$\pi_n(p)$ is a concave function of p.*

Proof. According to formula (2), I have $\frac{d\pi_n(p)}{dp}=\frac{N}{v^f}\left[v^f-\frac{2(1-\delta+\theta\delta)}{1-\delta}p-\eta e_0+\frac{1-\delta+2\theta\delta}{1-\delta}s\right]$, $\frac{d^2\pi_n(p)}{dp^2}=-\frac{N}{v^f}\frac{2(1-\delta+\theta\delta)}{1-\delta}<0$. So I can obtain that $\pi_n(p)$ is a concave function of p. This completes the proof. □

Proposition 1. *There exists an unique optimal pricing policy p_n, which maximizes $\pi_n(p)$, where $p_n=\frac{v^f}{2A}-\frac{\eta e_0}{2A}+\left(1-\frac{1}{2A}\right)s$.*

Proof. Set $\frac{d\pi_n(p)}{dp}=0$, I have $v^f-\frac{2(1-\delta+\theta\delta)}{1-\delta}p-\eta e_0+\frac{1-\delta+2\theta\delta}{1-\delta}s=0$. Assume $A=\frac{1-\delta+\theta\delta}{1-\delta}$, I can derive the optimal pricing policy $p_n=\frac{v^f}{2A}-\frac{\eta e_0}{2A}+\left(1-\frac{1}{2A}\right)s$ by solving the equation. This completes the proof. □

Proposition 1 shows that the manufacturer's optimal pricing policy without green technology investment is unique exist.

Proposition 2. *p_n is decreasing in θ.*

Proof. $\frac{dp_n}{d\theta}=\frac{dp_n}{dA}\frac{dA}{d\theta}=-\frac{v^f-\eta e_0-s}{2A^2}\frac{\delta}{1-\delta}$. I have $v^f-\eta e_0-s>0$, $1-\delta>0$. Then I can obtain $\frac{dp_n}{d\theta}<0$, i.e. p_n is decreasing in θ. This completes the proof. □

This conclusion is intuitive. θ represents the ratio of strategic customer. When the number of strategic customers is increasing, in order to enable more strategic customers buying at regular price, the manufacture will reduce the regular price in first stage.

Proposition 3. *p_n is decreasing in δ.*

Proof. $\frac{dp_n}{d\delta}=\frac{dp_n}{dA}\frac{dA}{d\delta}=-\frac{v^f-\eta e_0-s}{2A^2}\frac{\theta}{(1-\delta)^2}$. I have $v^f-\eta e_0-s>0$. Then I can obtain $\frac{dp_n}{d\delta}<0$, i.e. p_n is decreasing in δ. This completes the proof. □

Proposition 3 shows that the optimal pricing of the manufacturer decreases in consumer patience (i.e. δ). More patience means loss out less consumptive value and more willing to buy the product in second stage for the strategic customers. In order to stimulate strategic customers buy early, the manufacturer have to reduce the price.

Proposition 4. *p_n is decreasing in η.*

Proof. $\frac{dp_n}{d\eta} = -\frac{e_0}{2A^2} < 0$. So $\frac{dp_n}{d\eta} < 0$, i.e. p_n is decreasing in η. This completes the proof. □

Proposition 4 indicates that the optimal pricing of the manufacturer decreasing in the carbon sensitive degree (i.e. η). Without green technology investment, the unit carbon emissions is fixed and higher η means the customers less willing to buy the products. In order to stimulate more customers to buy products, the manufacturer will reduce the optimal price in first stage.

4 Pricing and Greening Model with Green Technology Investment

4.1 The Optimal Policy

The analysis of decision making process is similar to the base model and the difference is that the unit carbon emissions is no longer constant but a decision variable of the manufacturer. According to the analysis in Sect. 2, I can obtain the manufacturer's expected profit function, denoted by $\pi_g(p,e)$, with green technology investment.

$$\begin{aligned}\pi_g(p,e) =& \frac{N}{v^f}\left[v^f - (1-\theta)p - \frac{\theta(p-\delta s)}{1-\delta} - \eta e\right](p-c) \\ &+ \frac{N}{v^f}\left[\frac{(1-\delta+\theta\delta)(p-s)}{1-\delta} + \eta e\right](s-c) + t(e_0-e)^2.\end{aligned} \tag{3}$$

Lemma 2. *If $4tA - \eta^2 > 0$, $\pi_g(p,e)$ is a joint concave function of p and e.*

Proof. I can obtain the partial derivatives of profit function $\pi_g(p,e)$ with respect to p and e:

$$\frac{\partial \pi_g(p,e)}{\partial p} = \frac{N}{v^f}\left[v^f - \frac{2(1-\delta+\theta\delta)}{1-\delta}p - \eta e + \frac{1-\delta+2\theta\delta}{1-\delta}s\right], \tag{4}$$

$$\begin{aligned}\frac{\partial^2 \pi_g(p,e)}{\partial p^2} &= -\frac{2(1-\delta+\theta\delta)}{1-\delta} < 0, \\ \frac{\partial \pi_g(p,e)}{\partial e} &= -\frac{N}{v^f}(p-s) + 2t(e_0-e), \\ \frac{\partial^2 \pi_g(p,e)}{\partial e^2} &= -2t < 0, \\ \frac{\partial^2 \pi_g(p,e)}{\partial p \partial e} &= \frac{\partial^2 \pi_g(p,e)}{\partial e \partial p} = -\eta.\end{aligned} \tag{5}$$

I have $4tA - \eta^2 > 0$, then I can show that

$$\begin{vmatrix} \frac{\partial^2 \pi_g(p,e)}{\partial p^2} & \frac{\partial^2 \pi_g(p,e)}{\partial p \partial e} \\ \frac{\partial^2 \pi_g(p,e)}{\partial e \partial p} & \frac{\partial^2 \pi_g(p,e)}{\partial e^2} \end{vmatrix} = 4tA - \eta^2 > 0.$$

So $\pi_g(p,e)$ is a concave function of p and e. This complete the proof. □

Proposition 5. *The optimal pricing and greening policy (denoted by p_g and e_g) of the manufacturer are:*

$$p_g = \frac{2tv^f\left[v^f - e_0\eta + (2A-1)\,s\right] - N\eta s}{4Atv^f - N\eta},$$
$$e_g = \frac{4Ae_0tv^f - N\left(v^f - s\right)}{4Atv^f - N\eta}.$$

Proof. Let $\frac{\partial \pi_g(p,e)}{\partial p} = 0$ and $\frac{\partial \pi_g(p,e)}{\partial e} = 0$, from equation (4) and (5), I get $p_g = \frac{2tv^f[(2A-1)s - e_0\eta + 1] - N\eta s}{4Atv^f - N\eta}$ and $e_g = \frac{4Ae_0tv^f - N\left(v^f - s\right)}{4Atv^f - N\eta}$. This complete the proof. □

Proposition 5 show that the optimal pricing and greening policy for the manufacturer with green technology investment exist and are unique.

Proposition 6. *p_g is decreasing in θ; e_g is increasing in θ.*

Proof. From Proposition 5, I get the value of p_g and e_g, then I can show

$$\frac{dp_g}{d\theta} = \frac{dp_g}{dA}\frac{dA}{d\theta} = -\frac{8t^2{v^f}^2\left(v^f - \eta e_0 - s\right)}{\left(4Atv^f - N\eta\right)^2}\frac{\delta}{1-\delta},$$
$$\frac{de_g}{d\theta} = \frac{dp_g}{dA}\frac{dA}{d\theta} = \frac{4Ntv^f\left(v^f - \eta e_0 - s\right)}{\left(4Atv^f - N\eta\right)^2}\frac{\delta}{1-\delta}.$$

I have $v^f - \eta e_0 - s > 0$. Then I can obtain $\frac{dp_g}{d\theta} < 0$ and $\frac{de_g}{d\theta} > 0$. Therefore, p_g is decreasing in θ and e_g is increasing in θ. This complete the proof. □

Proposition 6 shows that the higher the ratio of strategic customers, the lower the manufacturer's optimal price. This conclusion is in line with the scenario without green technology investment.

Proposition 7. *p_g is decreasing in δ; e_g is increasing in δ.*

Proof. I can obtain

$$\frac{dp_g}{d\delta} = \frac{dp_g}{dA}\frac{dA}{d\delta} = -\frac{8t^2{v^f}^2\left(v^f - \eta e_0 - s\right)}{\left(4Atv^f - N\eta\right)^2}\frac{\theta}{(1-\delta)^2},$$
$$\frac{de_g}{d\theta} = \frac{dp_g}{dA}\frac{dA}{d\theta} = \frac{4Ntv^f\left(v^f - \eta e_0 - s\right)}{\left(4Atv^f - N\eta\right)^2}\frac{\delta}{1-\delta}.$$

I have $v^f - \eta e_0 - s > 0$. Then I can obtain $\frac{dp_g}{d\delta} < 0$ and $\frac{de_g}{d\delta} > 0$. Therefore I get p_g is decreasing in δ and e_g is increasing in δ. This complete the proof. □

Proposition 7 indicates that more patience the strategic customer have, lower the optimal pricing with green technology investment is and higher the optimal unit carbon emissions is with green technology investment. As to the impact of δ on the optimal unit carbon emissions, I find that more "strategic" customers will lead to less investment that the manufacturer do in carbon reduction.

Proposition 8. *If* $N > \frac{4Atv^f}{\eta}$, p_g *and* e_g *are decreasing in* η.

Proof. $N > \frac{4Atv^f}{\eta}$, then $4Atv^f < N\eta$. Recall $v^f - \eta e_0 - s > 0$, so

$$\frac{dp_g}{d\eta} = \frac{2Ntv^f\left(v^f - s\right) - 8Ae_0t^2v^{f^2}}{\left(4Atv^f - N\eta\right)^2} > \frac{2Ntv^f\left(v^f - \eta e_0 - s\right)}{\left(4Atv^f - N\eta\right)^2} > 0,$$

$$\frac{de_g}{d\eta} = -\frac{N^2\left(v^f - s\right) - 4NAe_0tv^f}{\left(4Atv^f - N\eta\right)^2} < -\frac{N^2\left(v^f - \eta e_0 - s\right)}{\left(4Atv^f - N\eta\right)^2} < 0.$$

□

Proposition 8 shows that with the addition of carbon sensitive degree (i.e. η), the manufacturer will improve the regular sale price and invest more in green technology investment to reduce carbon reduction when the customer number exceed a certain threshold.

4.2 Effect of Green Technology Investment

In order to analyze the effect of green technology investment on the manufacture's optimal pricing, I compare the manufacturer's optimal prices with and without green technology investment.

Proposition 9. *If* $N > \frac{4Atv^f}{\eta}$, $p_g < p_n$.

Proof. $p_g - p_n = \frac{2tv^f\left[v^f - e_0\eta + (2A-1)s\right] - N\eta s}{4Atv^f - N\eta} - \frac{v^f}{2A} - \frac{\eta e_0}{2A} + \left(1 - \frac{1}{2A}\right)s = \frac{N\eta\left(v^f - \eta e_0 - s\right)}{2A\left(4Atv^f - N\eta\right)}$. If $N > \frac{4Atv^f}{\eta}$, i.e. $4Atv^f - N\eta < 0$, then $p_g - p_n < 0$, i.e. $p_g < p_n$. This complete the proof. □

Proposition 9 indicates that the optimal price of the manufacturer with green technology investment is lower than that of without green technology investment when the number of customers exceed a certain threshold. Considering green technology investment, the manufacturer reduces the unit carbon emissions and then get the room for price reduction. In order to maximize the expected profit, the manufacturer need to reduce the optimal price to enable more customers to buy the products.

5 Conclusion and Future Research

This paper investigates the pricing and greening policy of a manufacturer and analyze the impact of green technology investment on the optimal price. The manufacture production a product and sells them to the mix myopic and strategic customers. Customers will be affected by unit carbon emissions of the product when making a purchase decision. The manufacture can invest in green technology to reduce unit carbon emissions. To the best of our knowledge, this is the first study on the model incorporate mix myopic and strategic customers and green technology investment together. This article provides several interesting observations.

(1) There is an unique optimal pricing policy for the manufacturer without green technology investment and there is also an unique optimal pricing and greening policy for the manufacture with green technology investment. Therefore, by deriving the optimal policies in different scenarios, the manufacturer can behave appropriately based on the findings to maximize its expected profit.
(2) I find that the optimal price without green technology investment is decreasing in the ratio of strategic customers, patience of strategic customers and carbon sensitive degree. This conclusion means that the presence of strategic customers is detrimental to the manufacturer and the negative impact increases as the ratio and patience of strategic customers increases.
(3) I find that the optimal price with green technology investment is also decreasing in the ratio and patience of strategic customers and carbon sensitive degree; the optimal unit carbon emissions is increasing in the ratio and patience of strategic customers but decreasing in carbon sensitive degree.
(4) The optimal price with green technology investment is lower than that without green technology investment when the number of customers exceed a certain threshold. This conclusion is interesting. The cost of the product is increasing when the manufacturer invest in green technology. According to the experience, the optimal price should be improved. However, the optimal pricing of the manufacturer not increased but reduced instead. This conclusion can guide firms make decisions scientific.

The paper formulates the model by considering only one manufacturer. But supply chain is more common in real-life. Extending this assumption will have a knock-on effect on supply chain decisions. So one key research direction is to consider a supply chain scenario. The manufacturer decide the wholesale price and green technology investment and the retailer decide selling price and order quantity. Second, this paper assume that the manufacturer only produces one product. While this simplified setting provides some interesting insights, we have to acknowledge that usually two or more products is produced by a manufacturer. These products will substitute or complement each other. So to assume that the manufacturer produces two or more products, which have different unit carbon emissions in production, is one important extension of this work.

Evolutionary Game Analysis of the Reservoir Immigrants' Joint Venture

Xiaofeng Liu(✉), Tingting Song, and Yanhua Liu

The Management Department in Northwest University for Nationalities, Gansu, People's Republic of China
liuxiaofengmdqk@126.com

Abstract. This paper combined the previous results with the actual situation of the immigrant area, proposed the main factors which would influence the joint venture, such as technology level, the familiar degree of both sides of cooperation, the costs and benefits of cooperation and coordination. To establish the evolutionary game model of immigrant joint venture, Finding the influence factors and the "free-rider" punish coefficient, the investment allocation coefficient, the income distribution coefficient how to affect the direction of the joint venture for immigrants according to payoff matrix and the Jacobi matrix.

Keywords: The reservoir immigrants · The joint venture · Evolutionary game

1 Introduction

With the time increase of reservoir immigrants living in the settlement, the possibility of its entrepreneurship. Many immigrants chose to entrepreneurship on some basis of technical in Yongjing county in Linxia Hui Autonomous Prefecture, Gansu province, such as tourism, fisheries and greenhouse cultivation. It still exists social employment problem now, the government vigorously encouraging entrepreneurship. There are many immigrants started the business in Yongjing county, but to reduce risk, choosing partners to joint venture will reduce the risk of entrepreneurship. Therefore, it is very necessary to study on the joint venture.

Yang [6] used the binary Logistic regression method to study the influence factors of immigrant entrepreneurs. Yang [7] re-examined the "bounded rationality" of venture capitalists. Su [3] argued that the policy of encouraging cooperation that government put forward to has not work, suggesting that the government should intensify the policy support and increasing investment. Chou [2] suggested when cooperating, both firms need to contribute sufficient and complementary efforts when they choose to cooperate partner. When entrepreneurs choosing a partner, relation network is the key variables to affect entrepreneurial decision [1]. Szolnoki [4] thouhgt that a carefully chosen threshold to establish a joint venture could efficiently improve the cooperation level. Wu and Wang [5] thought that the harder the joint venture is, the higher level of cooperation will be.

2 Evolutionary Game Model

Evolutionary game theory is the result of the evolution, which is a kind of dynamic equilibrium.

2.1 The Assumption of Model Variables

In this paper, the mode of entrepreneurship is individual, cooperation means people to do a project together. Assuming that the probability of individual A choose to cooperation is x, uncooperative probability is $1-x$, and the probability of individual B choose to cooperation is y, uncooperative probability is $1-y$. The rest of the variables are as follows: The technical level T_i, Resource utilization ability α_i, The cost of coordination C, the prior information Q_i, The credibility of the prior information β_i, the profit R, the free-rider penalty coefficient d. To make the following *Hypothesis* about the problem of the joint venture:

(1) This study involved two entrepreneurs, assuming that there are two individuals A and B, and the two individuals are in the same industry, they have their own worker sources and experience. In their cooperative game has two choices: cooperation and noncooperation.
(2) When the cooperative game beginning, both sides will take the degree of familiar with each other into account, a person's credit affects whether other people can choose to believe him. Both sides have some prior information about each other, which is the understanding of each other, but there is a credibility in prior information, and some of the information may be wrong. So it is important to put the prior information reliability coefficient as β_i. That is to say, A has the prior information with B, which is Q_B, The credibility of the information is β_A.
(3) Both the game sides have a certain technology. What's more, technical degree is one of the factors that both sides of game will consider in choosing cooperation. Assuming that technical level is T_i, there also is exists a certain degree of resource utilization while working together, assuming that resource utilization coefficient is α_i.
(4) Assuming that the investment apportion coefficient are a and $1-a$, which can get the income distribution coefficient b and $1-b$.
(5) When there is the phenomenon of "free-rider", it will have some punishment d, the punish coefficient is established on the basis of the technical level.

2.2 Evolutionary Game Model

According to the hypothesis and model variables, we can get the payoff matrix of A and B, as shown in Table 1.

In order to facilitate discussion, assuming that the value of x and y is invariable. To calculate the expectations of A and B in the case of cooperation and noncooperation respectively, and then get replicated dynamic equation of A and B:

Table 1. The payoff matrix

		B	
		Cooperation y	Noncooperation $1-y$
A	Cooperation x	$bR+\beta_A Q_B+\alpha_A T_B-aC$, $(1-b)R+\beta_B Q_A+\alpha_B T_A-(1-a)C$	$bR-aC-T_A$ $(1-b)R+\alpha_B T_A-(1-a)$ $C-dT_A$
	Noncooperation $1-x$	$bR+\alpha_A T_B-aC-dT_B$, $(1-b)R-(1-a)C-T_B$	0,0

$$\begin{aligned}
\text{A:}\quad F(x) = \frac{dx}{dt} &= x(U_{A1}-U_A) = x(1-x)[y(\beta_A Q_B + dT_B - bR + aC + T_A) \\
&\quad + (bR - aC - T_A)], \\
\text{B:}\quad F(y) = \frac{dy}{dt} &= y(1-y)\{x[(\beta_B Q_A + (1-a)C + dT_A + T_B - (1-b)R] \\
&\quad + (1-\mathrm{b})R - (1-a)C - T_B\}
\end{aligned}$$

To obtain the evolutionary stable strategy of the game, First of all, we need to get the stable point of replicated dynamic equation, namely it need to meet such conditions:

No. 1 $F(\mathrm{x}) = 0$; No. 2 Evolutionary stable strategy needs to have some anti-interference. For $\begin{cases} F(x)=0 \\ F(y)=0 \end{cases}$, we can get five stable points, O$(0,0)$, A$(0,1)$, B$(1,0)$, C$(1,1)$, D$(\mathrm{X_D},\mathrm{Y_D})$.

$$\begin{aligned}
X_D = x^* &= \frac{-(1-b)R + (1-a)C + T_B}{\beta_B Q_A + dT_A - (1-b)R + (1-a)C + T_B}, \\
Y_D = y^* &= \frac{-bR + aC + T_A}{\beta_A Q_B + dT_B - bR + aC + T_A}.
\end{aligned}$$

Assuming that $M = \beta_A Q_B + dT_B$ and $W = bR - aC - T_A$ in $F(x)$; $E = \beta_B Q_A + dT_A$ and $F = (1-b)R - (1-a)C - T_B$ in $F(y)$.

According to the methods put forward by Friedman, the dynamic equilibrium of participants' activities can be got according to the part of the system stability of the Jacobi matrix. We can get the Jacobi matrix based on the above. $J = \begin{bmatrix} X_{11} & X_{12} \\ X_{21} & X_{22} \end{bmatrix}$, Among them,

$$\begin{aligned}
X_{11} &= (1-2x)[y(M-W)+W], \\
X_{12} &= \mathrm{x}(1-x)(M-W), \\
X_{21} &= y(1-y)(E-F), \\
X_{22} &= (1-2y)[x(E-F)+F].
\end{aligned}$$

We use tr$J$ and det J to express the trace of matrices and determinant. When the stable points meet the conditions: tr$J > 0$ and det $J > 0$, The stable point is the evolutionary stable strategy of the system (ESS), the value of the Jacobi matrix and determinants are as follow:

$$tr J = X_{11} + X_{22},$$
$$\det J = X_{11}X_{22} - X_{12}X_{21}.$$

Based on the contents mentioned above we can get the local stability of equilibrium under different parameters:

(1) When $W < 0$, $F < 0$, $M < 0$, $E < 0$, the evolutionary stable strategy of the system is $\mathrm{O}(0,0)$.
(2) When $M < 0$, $E < 0$, $W > 0$, $F > 0$, the evolutionary stable strategy of the system is $\mathrm{A}(0,1)$, $\mathrm{B}(1,0)$.
(3) When $W > 0$, $E > 0$, $M > 0$, $F > 0$, the evolutionary stable strategy of the system is $\mathrm{C}(1,1)$.

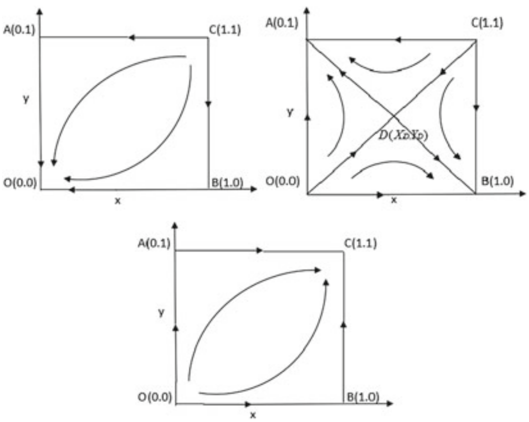

Fig. 1. System dynamic phase diagram of three different conditions

2.3 The Influence Factors Analysis of Evolution Path

Because of the coefficient set in the evolutionary game model that may influence the final result, the probability of system dynamic evolution reached to $\mathrm{O}(0,0)$, $\mathrm{A}(0,1)$, $\mathrm{B}(1,0)$, $\mathrm{C}(1,1)$. Probability of cooperation can be determined according to the area of the quadrilateral and quadrilateral. Therefore, for discussing the effect of various parameters on the dynamic evolution of the payoff matrix can be converted into the effects of various parameters on the area of the quadrilateral. The area of can be expressed as:

$$S_{ADBC} = \frac{(1-y^*)}{2} + \frac{(1-x^*)}{2} = \frac{E}{2(E-F)} + \frac{M}{2(M-W)},$$

(1) Request the first partial derivative and second derivative of S_{ADBC} about a, we can get $\frac{\partial^2 S_{ADBC}}{\partial a^2} = \frac{(E-F)C^2E}{(E-F)^4} + \frac{(M-W)C^2M}{(M-W)^4} > 0$.
  - If $E > M$, that is to say when investment apportion coefficient get greater, the both sides of game tend to be non-cooperative.
  - If $E < M$, that is to say when investment apportion coefficient get greater, the both sides of game tend to be cooperative.

(2) Request the first partial derivative and second derivative of S_{ADBC} about b, we can get $\frac{\partial^2 S_{ADBC}}{\partial b^2} = \frac{(E-F)R^2E}{(E-F)^4} + \frac{(M-W)M^2R}{(M-W)^4}$.
  - If $E > M$, that is to say when income distribution coefficient get greater, the both sides of game tend to be cooperative.
  - If $E < M$, that is to say when get income distribution coefficient greater, the both sides of game tend to be non-cooperative.

(3) Request the first partial derivative S_{ADBC} about C, then can get $\frac{\partial S_{\mathrm{ADBC}}}{\partial C} = \frac{1}{2}\left[\frac{(a-1)E}{(E-F)^2} + \frac{-aM}{(M-W)^2}\right] > 0$, that is to say when the coordination cost get greater, the evolutionary games tend to be non-cooperative.

(4) Request the first partial derivative S_{ADBC} about d, when the penalty coefficient get greater, the evolutionary game tends to be the cooperative.

(5) Request the first partial derivative S_{ADBC} about β_A and β_B, we can conclude that when the familiar degree between A and B is more higher, the more tendency for them to cooperate.

(6) Request the first partial derivative S_{ADBC} about α_{i}, the result is 0, so the ability to absorb and utilize resources in the cooperation is not the main factors.

2.4 The Analysis of Model Results

Based on the analysis above, we can conclude that:

(1) When the value of a and b equal to 0.5, it will reach the steady state, namely when both the investment allocation coefficient and income distribution coefficient are 0.5, the probability of cooperation is the largest.
(2) The less the coordination costs are, the more the probability of cooperation is.
(3) The bigger the "free-rider" punish coefficient is, the bigger the probability of cooperation is.
(4) The higher the credibility of a prior information is, the bigger the probability of cooperation is.
(5) The ability to absorb and utilize resources in the cooperation is not the main factors.

3 The Analysis of an Empirical Example

Through investigation and interview in Yongjing county in Linxia Hui Autonomous Prefecture, Gansu province, Some of immigrants are first to migrate, some are the second. Expert scoring method is used to evaluate several

Table 2. The value of the various factors

$Q_{\rm i}$	$Q_A = 2, Q_B = 3$
$\beta_{\rm i}$	$\beta_A = 0.2, \beta_B = 0.1$
R	5000
d	0.3

related aspects on some individuals according to the assumption. We found out two individual households at same level, The value of the various factors are as follows (Table 2):

According to the conclusion of evolutionary game model, assuming that $a = b = \frac{1}{2}$, and setting the value of the different factors according to the hypothesis, and then we can get the payoff matrix with different value:

Table 3. The No. 1 payoff matrix

		B	
		Cooperation y	Noncooperation $1 - y$
A	Cooperation x	2254.2, 2253.7	2245, 2252
	Noncooperation $1 - x$	2251.8, 2244	0, 0

It is the best choice for A and B to cooperate with each other. When $T_A = 1, T_B = 9$, other value isn't changed, the payoff matrix is as follow:

Table 4. The No. 2 payoff matrix

		B	
		Cooperation y	Noncooperation $1 - y$
A	Cooperation x	2256, 2250.9	2249, 2250.4
	Noncooperation $1 - x$	2252.7, 2241	0, 0

Comparing Table 3 with Table 4, it is not difficult to find that, in Table 4, the benefits is similar for B to choose cooperation or not, so the smaller technology differences between both sides of the game is, the more tendency to cooperation. It's easy to prove the other results from model analysis with this methods.

4 Conclusion

According to the example of Yongjing county in Linxia Hui Autonomous Prefecture, Gansu province, we can get the main factors which would influence the joint venture in this area, such as technology level, the familiar degree of both sides of cooperation, the costs and benefits of cooperation and coordination. we can also get the direction of every factors and the “free-rider” punish coefficient, the investment allocation coefficient, the income distribution coefficient influence on joint venture.

(1) When the both sides of the game have a big difference on technical level, the high level of technical would not choose joint venture.
(2) The most residents in settlement came from different areas, and some of them experienced two or more times of migration. When they familiar with each other, they will have a sense of security, and the higher the credibility of the information is, the more possibility the choice of the joint venture will be.
(3) The higher costs and benefits of cooperation is, the greater the risk will be, and the probability of joint venture will decline.
(4) The greater the benefits of joint venture is, the greater the probability of cooperation will be.
(5) The bigger the “free-rider” punish coefficient is, the bigger the probability of cooperation is.
(6) When both the investment allocation coefficient and income distribution coefficient are 0.5, the probability of cooperation is the largest.

Solid Waste Management in the Republic of Moldova

Gheorghe Duca(✉) and Aliona Mereuţa

Academy of Sciences of Moldova, Chisinau, Republic of Moldova
malvina.condratiuc@mail.ru

Abstract. Waste management refers to all operations implemented for the proper management of solid waste: methods of collecting, recycling and recovery, processing, treatment, storage, transportation, analysis and monitoring. The main topics in this paper are the following: institutional framework, national legislative and regulatory frameworks of waste management; Integrated management of municipal waste; Hazardous waste management; Secondary wine product management; Management of plastic waste; Infectious medical waste management. Thus, ASM in collaboration with a private company implemented two technologies for complex treatment of solid waste. The following goals were currently reached in RM: a sector of complex full processing of plastic waste was created at industrial scale, a pilot line was put into operation, for sorting, processing and obtaining of new products from secondary polymer raw materials and an authorized point was created for managing infectious waste resulting from medical activities in medical institutions and hospitals, by collecting, sorting, packing, transporting and neutralizing these wastes to prevent environmental contamination. The neutralization of infectious medical waste is performed by vacuum sterilization method using the STERISHRED 250, which is the most modern method of solving local problems of infectious medical waste processing without incineration.

Keywords: Waste management · Secondary wine product management · Integrated management of municipal waste · Management of plastic waste · Infectious medical waste management · Republic of Moldova

1 Introduction

Transforming waste management and recycling practices in Republic of Moldova is one of the most important challenges we face of the next decade. Inadequate waste management affects our communities, threatens our environment, and contributes to the global emissions of greenhouse gases. Thus, solid waste management and recycling is a local, national and international priority [1,3,5,6,9,10,12]. Government will establish the legal and institutional framework necessary to support the gradual alignment of our waste management prac-

tices to those of the European Union: Government Action Programme (2016–2018); National Strategy on Waste Management (2013–2023): Government Decision no. 428 of 10 April 2013; Strategy on Environment Protection: Government Decision no. 301 of 24 April 2014; National Plan on Implementation of the Association Agreement (2014–2016); Association Agreement between the European Union and the Republic of Moldova, ratified by Law no. 112 of 02.07.2014.

1.1 Waste Management Planning in Moldova

Municipal waste generation is influenced by many factors, the most significant being the income of the population, consumer behavior, appearance on the market of new packed products and the demographic evolution. A high level of the population's income and urbanization has resulted in the generation of large quantities of waste per capita, which is in the rural areas typically range from 0.3 to 0.4 kg/inhabitant/day, 0.9 kg/place/day or more in urban areas, according to the World Bank studies. The increasing number of supermarkets, along with increased GDP per capita has increased purchases of packaged products and hence the waste generated. Demographics also influence a waste generation, people in the urban areas producing much more waste than those in the rural areas. The most common method of treating household waste in Moldova is landfill, which often represents an important source of pollution of soil and groundwater. Annually through the sanitation services from urban localities are transported about 1144–2131 thousands m^3 of solid waste [2]. Another negative aspect of inadequate waste management is that many useful and recyclable materials are stored together with the non-recyclable thus is losing a large part of their useful potential (paper, glass, metals, plastics); being mixed, chemically and biologically contaminated, their recovery is very difficult. Effective waste management planning certainly is focused on the morphological composition of solid household waste [11]. The waste morphological analysis is imperative in recycling operations establishing and in generated waste eliminating. This data has been collected from newsletters, reports, publications, while in the national statistics such information is missing (Fig. 1).

Possible scenarios of development of the domain of reference in the Republic of Moldova were determined based on statistical data analyzes and the experts assumptions, taking into account the macro-economic indices, indicate the existing strategies for development of some sectors (industry, agriculture, etc.), and namely the Gross Domestic Product Value, demographic trends, trends of industry development, tendencies of the agricultural sector development and waste management system development. According to statistical data analysis, we can ascertain that the solid household waste tendencies increasing volumes for Chisinau city are 5–15% and in rural areas, there is a solid household waste volume increase by approximately 10%. These increases are explained by the fact that in localities, as well as in regional centers was improved the sanitation services activity. Currently, an increased attention is given to the creation of the solid household waste storage capacity and respective the annual growing trends

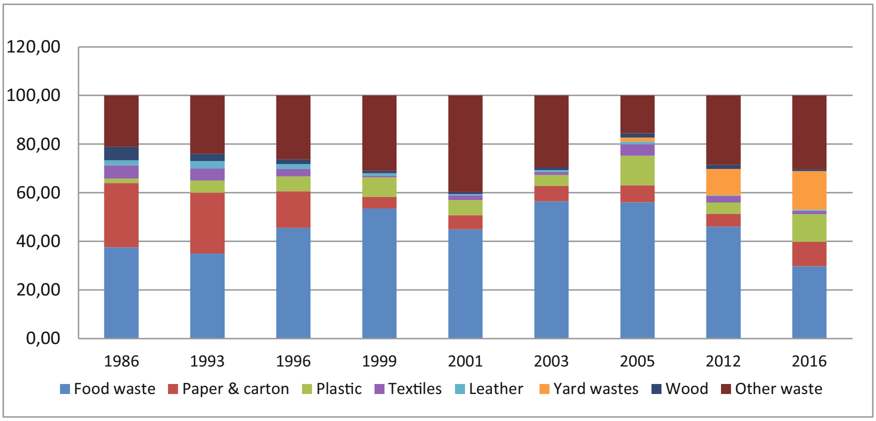

Fig. 1. Municipal waste composition

of 10% will be maintained in the 2011–2015, subsequently is expected a continued growth of 5% for both categories of localities. The solid waste generation trends are presented based on these assumptions (Fig. 2).

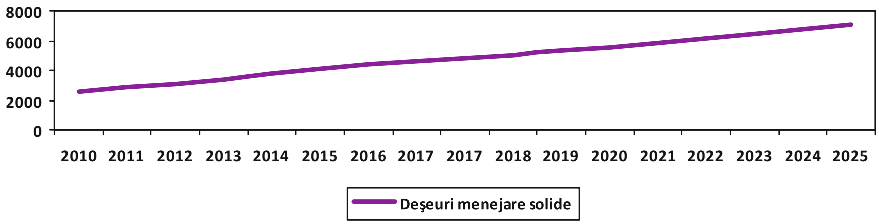

Fig. 2. The forecasts on the solid household waste generation, thousand m^3

The regional approach for waste management is essential for attracting necessary investment, as well as for the high-cost maintenance through realizing the implementation on the economical level. It is unacceptable and at the same time economically unjustified the enterprise's construction of recovery or waste disposal in every city, without taking into account the rural areas of the district, including the specific waste generated. The experience of neighboring countries shows that the object's financial sustainability of recovery and waste disposal is economically feasible when it has a territorial coverage of at least 200–300 thousand people. In this context, it is proposed the waste management regionalization by the territorial division of the country into 8 regions for waste management. The basic criteria for regional planning are the geographic position, economic development, the existence of access roads, soil, and hydrogeological conditions, the number of population, etc. (Fig. 3).

The local public authorities are expected to establish the waste management associations at a regional level, as recommended by the Ministry of Environment regarding the regional waste management planning. The role of associations is to establish and approve terms of reference for selecting the company that will manage waste in the region, as well as tariffs for the waste collection and disposal, etc.

Fig. 3. Regional waste management planning in the Republic of Moldova

Considering the country's economic development, morphological amount and composition of the generated waste, as well as pedological and geological conditions, were developed three alternatives for establishing integrated waste management system:

- Alternative 1 consists in the construction of eight solid household waste deposits for each region. The cost of implementation is approximately 293 million €.
- Alternative 2 envisions the building of 2 mechanical-biological waste treatment stations in Region 4 Chisinau and Region 7 Balti and 6 landfills for solid domestic waste for remaining regions. The cost of implementation is approximately 370 million €.
- Alternative 3 proposes the construction of 2 incinerators in Region 4 Chisinau and Region 7 Balti and 6 deposits for solid domestic waste for remaining regions. The cost of implementation is approximately 476 million €.

These options will be subject to public debate in order to select the optimal alternative from the perspective of environmental protection and cost–benefit analysis, to encourage the creation of partnerships at international, national and local level, and to attract the necessary investment that will allow the sustainable development of sector in accordance with the priority needs and at a rhythm accessible for society.

2 Advanced Treatment of Secondary Wine Products in the Republic of Moldova

For the Republic of Moldova, oenology is one of the most substantial key in the national economic sectors, thus this sector requires continuous implementation of new performances achieved in science and technology. The wine industry in the country has a potential of grape processing up to 1 million tons, located in over 100 companies. Recent years, Moldovan Wine industry attention is increasingly higher. As a result of the implementation of the State Program, the areas planted with vines have increased significantly, in the quantity of grapes processed rose as well. But it is known that about 20–25% of the processed grapes turns in are secondary wine products. If you calculate the amount of waste that result after processing 300 thousand tons of grapes, we get 60–75000 tones of products: the cake, yeast, vinasse, wastewater, etc. All these products are a source of environmental pollution and create major environmental problems. Therefore, it is important to use complex raw material (grapes), implementing technological processes with minimum waste, as well as processing products of wine in order to obtain a wide range of valuable products.

Products of vinification are an important source for obtaining special natural products with specific properties that cannot be obtained synthetically. Such products as tartaric acid, oil seed polyphones, colorings, tannins, etc. have a wide field of use in various industries.

Through the years 1980–1990, Moldova was the country that provides the raw tartar material (calcium tartrate, tirighia, calcareous sediments) for countries that produced directly tartaric acid (Ukraine, Odessa, Yerevan, Tbilisi, Italy, etc.). Prime cost of the product is quite high (100 g of tartaric acid (99.9%) used in the pharmaceutical industry costs 80–100 $, or 1 kg of natural tartaric acid used in food costs 30–40 $.

Tartaric acids are reductions that can be used in food, wine, bakery, pharmaceutical, photochemical, chemical, textile, construction, electro-technical industry, yet their production in the country is missing, although the country prevails large stocks of raw materials and annual it could produce 100 tons up to 350 tons of tartaric acid.

An effective stabilizer used in the wine industry is the met tartaric acid, which inhibits the process of submitting wine stone in wine and juice, do not change the taste of wine or juice qualities and is not toxic because it represents a modifying tartaric acid. Compared with the cold treating method, stabilization of the wines and juices with mesotartaric acid it has a much better economic effect. The local market is not assured, with this product, although it is requested on the domestic market than tartaric acid.

Grapes seed represents a precious waste for our national economy. The content of the seeds in one tone of grapes is 7% by weight. The process of obtaining seeds and their conditioning is a complicated technological process. In the years 1982–1986 in Moldova obtained to 10,000 tons seeds annually, which were transferred to processing in the Bender city (oil mill), Odessa, Armavir (Krasnodar region), Tbilisi (Georgia) and Cocand (Uzbekistan). Partly some seeds were exported to France with a price of $400 per ton.

Currently, grape dried seeds, oil seeds as well have high demand nationally and internationally and we are also having factories producing food seed oil.

Getting antimicrobial chemotherapeutic remedies, particularly in natural raw materials, is current and prospective permanent. Also of major importance is getting antifungal properties and antioxidative substances from plant raw materials. Research results on the activity of dissoluble etanon in water, allow production of preparations with pronounced biological activity, useful in medicine and veterinary use in combating bacterial diseases, fungal infections etc.

Currently, after processing the grapes are produced about 59 thousand tons of pomace. Marc contents of seeds make up 40–65%. So annually in the country, the grape processing plants can be harvested 20–25 thousand tons of seeds. Given the fact that enotatin content in grape seed makes up on average 8% annually could get about 2–2.5 thousand tons of enotanin. Prior research showed that leaching enotaninului yield is 65–70%. Thus, it may get about 1.2–1.3 thousand tons of active ingredient to changing them to produce medicinal preparations, veterinary, agricultural, etc.

Among all waste formed after the vinification process is the marc, which is the result of distilling alcohol from wine products. The perspective method of treating this waste concentrates worldwide is considered anaerobic digestion, which allows not only solve environmental challenges but also allows the conversion of organic pollutants into biogas, which can still be used as an alternative source of heat and electric.

The data presented above demonstrates that Moldova must build a complex factory for processing secondary wine products. An argument convincing enough to build such an enterprise serve the scientific data presented in the monograph [4].

2.1 Plastic Waste Management in the Republic of Moldova

The plastic materials represent about 10–12% of the amount of household generated waste in the country. Not all the categories of plastic materials are subject to recycling. The plastic materials in the majority of PVC degrade over several centuries, between 100 and 1000 years. Therefore we ascertain how great the pollution that they produce being persistent in time. The basic problems of recycling of plastics are in the variety of their frequencies, which are recycled separately and mixing them make it impossible to recover. The most often is considered optimal recovery separated from other plastic materials of the receptacles from PET by producers and consumers of soft drinks, which prevents mixing with other resins.

Beneficiaries dealing with plastics processing decide the categories of waste accepted for collection through specialized points.

For these reasons, it is necessary to organize the collection of differentiated plastics and training potential generators of waste plastic materials, including the general public. Concomitantly with the increasing amount of organic plastic materials in use, the problem of recycling is becoming more topical. Proceeding from the particularities of the composition of the waste polymers, plastics processing at low temperatures, which allowing us to obtain the polymer raw material (for example, construction materials, ramps, pillars, etc.) is the most promising.

Plastic deformation of solid bodies usually leads not only to changing its shape but also to the defects that change the physicochemical properties, including the reactivity. The accumulation of defects is used in chemistry to accelerate reactions involving the solid substances, for reducing the temperature processes and for other manipulations for increasing chemistry interaction in the solid-phase. The mechanical energy absorption initiates destruction of polymers, polymorphic transformations, and other reactions. In order to communicate the mechanical energy of plastic materials, the last are processed in extrusion reactors by using the crushers and conveyors. During of such a treatment, in addition to shredding polymers, are taking place the structural changes of substance, there are formed a lot of flaws and the material becomes reactive. In the simultaneous processing of several types of polymers, between them occur interactions–chemical reactions. However, analogous in the case of the thermal activation in the solid-phase reactions, for the initiation of mechanical-chemical reactions it is necessary to transmit the dust a sufficient quantity of mechanical energy. The energy can be communicated through the crusher and polymer screw reactor. The screws acting through the impulses on the polymer shredding. The strength and the result (the degree of transformation after the chemical reaction) of such actions depend on the acceleration of the movement of the screw within the reactor. Previously, the use of mechanical activation of substances in the production of new materials has been limited by the lack of reactors operating safely. Currently, such reactors exist and can be used in such a process harmless for the environment as a secondary plastic processing [7]. By a project of technology transfer, in the Republic of Moldova was implemented a complex process of waste plastics [8].

Waste of plastics separated from polyolefin (PE, PP), unwashed are introduced into the hammer mill where it is comminuted up to 50 mm parallel the polyolefin are crushing separately, and then they are crushing separately until the fraction 0.5 mm up to 10 mm (Fig. 4 and 5).

Comminuted and mixed waste in the proportion of 1/3 of the polyethylene and polypropylene: 3/4 of plastics waste with unidentified composition is loaded into the bunker with a speed of 0.2 m/s through the screw charger.

Fig. 4. Waste of plastics

Fig. 5. Waste of plastics comminuted by PP comminuted with containing unidentified

Thus, in the extruder (stainless reactor) the mixture is heated to a temperature of 180–2100 C. The speed of charging of comminuted waste of plastic materials are adjusted, for the temperature of self-heating of the mixture in the extruder (steel reactor) to vary in the range of 180–2100 C and no more.

At this temperature (polyethylene) (polypropylene) is liquidized and other compounds remain as viscous (polystyrene PS, polyvinyl chloride, PVC, polyethylene terephthalate, PET serve as compounds of liaison and polycarbonates, polyamides, etc. constitute the filler mixture. The obtained viscous mass is homogenized and transferred to the calibrator.

Calibrated mass of material is transported in the matrix pressing machine, where under the action of pressure from 3 bars is obtained the finite product: forms for plastic pallets (Fig. 6).

Respecting the same regularity of the technological process, but varying the report of homogenization of plastic waste comminuted in a proportion of 1/3 parts of polyethylene and polypropylene 3/4 of plastics waste with unidentified composition may be obtained new forms of the sidewalk (Fig. 6). To the

Fig. 6. New products obtained from waste of plastic mass

processing of 1,000 kg of the waste of plastics, may be obtained 950–970 kg of new products from plastics.

In the Republic of Moldova, in cooperation with the Academy of Sciences of Moldova for the first time, it was implemented a complex technology of processing from waste plastics with obtaining of new products. This technology creates no other waste and at the same time don't generate any wastewater (Fig. 7).

Fig. 7. The sector of complex processing of plastic waste

2.2 Infectious Medical Waste Management in Republic of Moldova

Medical wastes management activity is a part of nosocomial infection control in health facilities (IMS). Nosocomial infections are listed as special health issues (Regulation on the national epidemiological surveillance and control of communicable diseases and health events, Gov.Dir nr.951 of 25.11.2013).

According to the Statistical Yearbook of the health system for 2014 in Moldova (Right Bank) are 348 state medical institutions (legal entities) and 1029 are private.

There are 3 categories of infectious medical waste generators:

Large manufacturers: Republican, municipal, district and departmental hospitals; University of dispensary clinics, Medical Research Institute, Institute of

Forensic Medicine, Forensic Regional Services, Pre-Clinical Departments of the University of Medicine, Faculty of Medicine and Pharmacology, etc.

Medium manufacturers: Medical institutions of primary care clinics of hospitalization, blood transfusion centers, microbiological laboratories and clinics, nursing, medical and dental offices, private hospitals and clinics, etc.

Small producers: dental laboratories, rehabilitation centers, funeral services, vision care centers, acupuncture clinics, preventive medicine centers, private clinics, etc.

Among all categories of waste products of medical activity in medical institutions as a result of daily care activities, are the following categories of waste (Regulation of medical waste management no. 06.8.3.45 of 10.12.2001, approved by the Doctor Chief State Sanitary no. 05-00 of 14 December 2001 (Official Monitory of the Republic of Moldova, 2002, No. 13–15 art. No.:29).

"Hazardous waste" is the waste resulting from medical activities which present a real risk to human health and the environment, which are generated in the course of diagnosis, treatment, surveillance, disease prevention and rehabilitation, including medical research and production, testing, storage and distribution of medicines and biological products;

"Medical waste assimilated with domestic waste" are non-hazardous waste whose composition is similar to waste and no major risk to human health and the environment;

"Pathological waste and parts (parts) anatomical" these include tissues and organs, anatomical results of surgical instruments, the autopsy and other medical procedures; this category also includes animals used in laboratory diagnostic work, research and experimentation;

"Pathological waste and anatomical parts" are wastes include tissues and organs, anatomical results of surgical instruments, the autopsy and other medical procedures; this category also includes animals used in laboratory diagnostic work, research and experimentation;

"Infectious waste" are liquid and solid wastes containing or contaminated with blood or other body fluids and materials that contain or have come in contact with viruses, bacteria, parasites and/or toxins microorganisms;

"Chemicals and pharmaceutical waste" posed by chemicals are solid, liquid or gas that can be toxic, corrosive or flammable; expired drugs and chemotherapy residues of substances that can be cytotoxic, genotoxic, mutagenic, teratogenic or carcinogenic.

"stinging-cutting waste" is waste that can cause mechanical damage by puncturing or cutting; "Radioactive waste" is solid, liquid and gaseous waste resulting from nuclear activities medical diagnosis and treatment, containing radioactive material;

According to the World Health Organization, 80% of all waste resulted from medical activities are considered inoffensive and are managed as waste and other hazardous materials, 20% are infectious, toxic or radioactive.

The survey data conducted in 2004 with the support of the World Health Organization show that in Republic of Moldova the estimated amount of hazardous waste from medical activity is 0.05 kg/patient/day treated at home for hospitalized cases–average 0.44 kg/bed/day. Thus the total production of hazardous waste was estimated between 10 and 11 tons of waste per day 4000 tons per year.

Currently, the total amount of waste reported by medical institutions has increased, accounting for about 8.7 million tons per year, including infectious waste (syringes, infusion catheters, etc.).

In Chisinau daily it is accumulate about 3 tons per day of waste medical activity annually–about 1095 tons of wastes. At the same time, 120 million syringes annually and 6 million infusion systems are used throughout the country.

According to the World Health Organization, the estimated operational costs for treating 1 kg of infectious waste varies between 0.13–2.2 US $, depending on the applied method. The lowest costs for treating infectious waste is the method by autoclaving (0.13–0.36 US $/kg).

Academy of Sciences of Moldova and the Ministry of Health and Ministry of Environment in 2015 implemented a pilot project for treatment of infectious medical waste. It was developed an authorized treatment of infectious medical waste (Figs. 8 and 9).

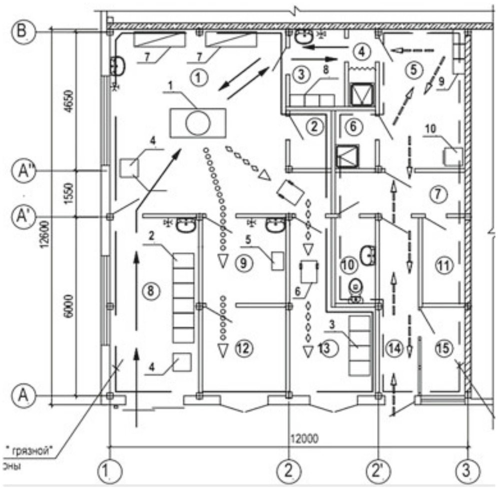

Fig. 8. Plan scheme of waste treatment point

In Fig. 8, 1 is working room of the plant; 2, 3, 4, 6, 7, 10, 11 are public spaces in the clean and dirty; 8 is room for receiving and temporary storage of waste (dirty area); 9 is room for washing and disinfecting bins; 12 is room for temporary storage of bins after washing and disinfection process; 13 is room for temporary storage of waste processed-disinfected; 5, 15 are rooms for personal and workplace.

Fig. 9. Authorized infectious medical waste processing point

STERISHRED technology and facility for treating hazardous waste from medical activities implemented at this enterprise, allows the obtaining of the final product environmentally friendly and health. Processing infectious waste takes place at low temperatures (136$\circ$C) with grinding, sterilization and destruction of confidential information storage units, in one compact space. The device converts waste "yellow bags" (biologically hazardous), including stinging and sharp objects in non-hazardous municipal waste-sterilized. Waste results, up to 70% can be processed at other companies for the obtaining of new products.

3 Conclusion

- Moldova has resources and scientific potential for capitalizing secondary wine products.
- Create a pilot plant for treating waste plastics complex served as an impetus for development of the field of waste recovery in Moldova.
- Academy of Sciences collaboration with the private sector has led to an authorized point of treating infectious medical waste, which resolved partially the pressing problem of neutralizing medical waste in Moldova.

How to Popularize Green Residential Buildings in China: A Survey Study from Sichuan

Jun Gang[1(✉)], Dirong Xu[2], and Ying Wei[1]

[1] Sichuan Institute of Building Research, Chengdu 610003, People's Republic of China
467488122@qq.com

[2] College of Architecture and Urban-Rural Planning, Sichuan Agricultural University, Chengdu 610003, People's Republic of China

Abstract. Green buildings have been ushered in a period of rapid development in China. For there are few researches on economic benefit analysis, a result that most of Chinese people don't want to purchase residential buildings because of misunderstanding that green buildings have a higher cost. This paper focuses on how to popularize green residential building in China. In order to achieve the goal, the field survey is carried out, qualitative and quantitative descriptive methods are used to analyze the statement of green residential building in Sichuan Province. There are two important conclusions. Firstly, the incremental cost control of green building in our province is relatively reasonable. However, the incremental selling price is much higher than the incremental cost. Secondly, ordinary people can accept is much lower than the selling price. Finally, in order to improve the popularization of green residential building, some suggestions are provided.

Keywords: Green residential buildings · Survey study · Statistical analysis · Popularization

1 Introduction

China has been the world's largest carbon emitter and the world's largest energy consumer country since 2011. Building is one of the main contributor of energy consumption and pollution emission. China's building energy consumption has more than industrial and transportation, as the first source of energy consumption. To reduce the energy consumption, China had proposed the concept of green buildings in 2004 [7], which aim to save resources (including: energy, land, water and materials) and reduce the environmental impact. In the past five years, China's green building ushered in a period of rapid development. Green Building has first stated explicitly in the Five-Year (from 2011 to 2015) Plan of China [3]. In 2013, China's Green Building Action Plan has been launched [5]. And in 2015, the new version of "assessment standard for green building" was formally

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_108

implemented [2]. All these have brought positive results to promotion of green building. And also, more and more scholars have paid their attention to the green building in China, not only involving technology [4], but also containing cost [1] and management [8].

Although more and more peoples are showing solicitude for green building, but most of them are architects, engineers, scholars, and others related to the construction industry. Green buildings are not yet popularized since most common peoples don't still understand its concept and value. In China, all evaluation standards on green buildings don't contain economic indexes. The new version of "green building evaluation criteria" explicitly proposed that green building evaluation should take the economic analysis into consideration, but it did not put the economic analysis into the comprehensive evaluation system. Researches on economic benefit analysis are also seldom found [6]. As a result, most of Chinese people believe that green buildings (especially residential buildings) always have higher cost, so they don't want to purchase residential buildings. That an important reason why residential buildings cannot be popularized in China.

In order to understand the common peoples' attitude to green residential buildings fully, we did carry out an investigation to 34 green residential buildings and 935 peoples in Sichan in January, 2016. The following several sections will show the investigation data and some statistical analysis in detailed.

2 Survey Statement

This investigation mainly includes three aspects: (1) the public foundation of green residential buildings; and (2) the incremental cost and incremental price of green residential buildings; and (3) the people's acceptability to the incremental price of green residential buildings. Among them, the first part mainly surveys local residents' cognitive level and purchase intention about Sichuan's Green Buildings; the second part mainly investigates the incremental cost and the incremental price of green residential buildings in Sichuan; the third part mainly researches the public acceptability to the price of green residential buildings, and analyzes the people's needs and purchase intentions to green buildings in different hierarchy.

The questionnaire method was used to the ordinary peoples who are chosen randomly. This sampling survey was issued 1000 questionnaires, which 935 were recovered, and 901 are valid. The effective recovery rate of the questionnaires was 90.1%. The basic information of the respondents is as follows Table 1.

In addition, we also generally investigated all the 34 green residential buildings in Sichuan, which information is showed as Table 2.

3 Popularization Degree

3.1 Knowledge Level About Green Residential Buildings

In order to find out the popularized degree of green residential buildings in Sichuan, three questions are designed: (1) Do you understand the conception of

Table 1. Basic information of the respondents

Statistical variables	Sampling	Percentage (%)	Statistical variables	Sampling	Percentage (%)
Sex			Education		
Male	599	66.48	High school or below	104	11.55
Female	302	33.52	College graduate or bachelor	632	70.14
Profession			Bachelor or above	165	18.31
Self-employed	101	11.21	Monthly income RMB		
White-collar	119	13.43	7000	417	46.28
Ordinary worker	338	37.51	7000 14000	303	33.63
Student	273	30.3	14000 21000	99	10.99
Other	68	7.55	21000	82	9.1

Total	25	6	3

green residential buildings? (2) Do you understand the functions of green residential buildings? (3) Do you know the policy of green building? The statistical results of the two questions are shown in Figs. 1, 2 and 3:

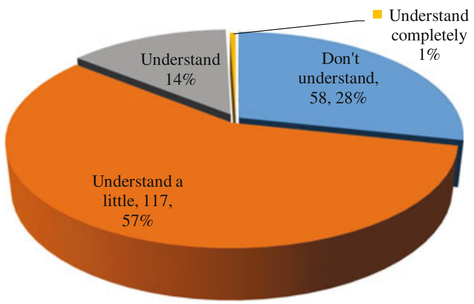

Fig. 1. People's understanding to the concept of green buildings

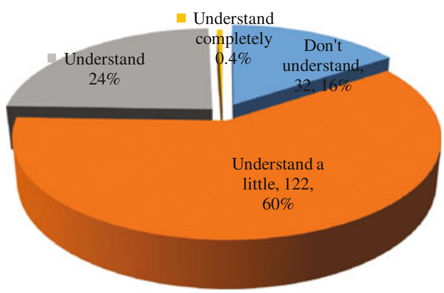

Fig. 2. People's understanding to the functions of green buildings

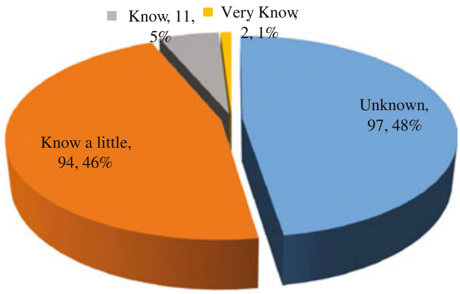

Fig. 3. People's understanding to the policies of green buildings

The survey results show that the people who know green buildings very clearly were accounted for only about 1%, some clearly only 14%; and understanding for the concept of green buildings, most people yet stayed in the "a little" and "a little more" dimensional level. Similar results are found about the functions and policies. 76% of the people don't understand or only understand a litter about the function of green residential buildings, while 94% of the people don't clearly understand the related policies about green buildings. However, in the process of investigation, we found that some people believe that the "green buildings" is the energy-saving buildings, and some people think "green buildings" is the buildings with many greenbelts. As a whole, the popularization of green residential buildings is serious shortage, although there is good policy support.

3.2 Purchase Intention to Green Residential Buildings

The purchaser of green residential buildings are the ordinary peoples, the government only plays a promotion role. Only when the public really understand what is the green building and how important to their live, it is possible to popularize green buildings. After analyzing the people's knowledge levels about green buildings, a question involving people's purchase intentions to the green buildings is designed, and survey results are showed in Figs. 3 and 4. It can be seen that 29.8% of the people think there is no necessary to develop green buildings in the first round of the investigation. However, after listening to the investigation team's explanation about the concept and functions of green buildings, 93.7% of people express their intentions to support the development of green buildings, which shows a good and extensive public foundation to popularize green residential buildings. Of course, it is necessary to enhance the publicity before popularization. Similarly, when investigated whether are willing to buy green residential buildings, after listening to the investigating group's carefully explanation, in the situation without considering incremental price, about 93.14% of respondents are willing to buy green residential buildings. In addition, nearly 7% of respondents are unwilling to buy green buildings, because of the worry about the incremental price. Indeed, the prices of green residential buildings will increase with the rise

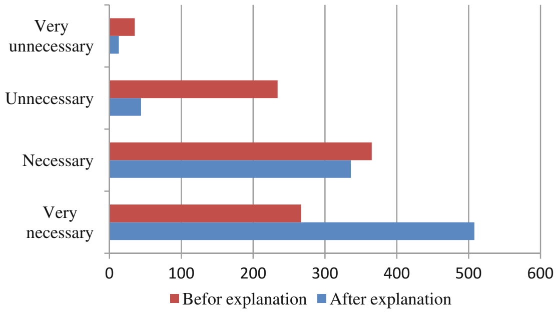

Fig. 4. Necessity of popularizing green residential buildings

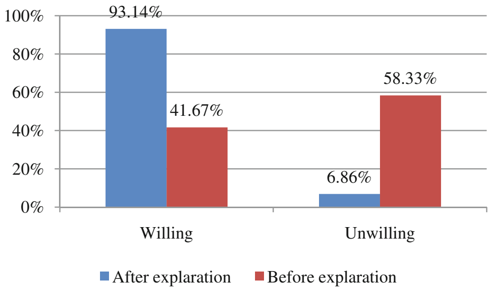

Fig. 5. People's willingness to buy green residential buildings

of design and construction cost. However, cost is not the unique factor which affects the selection to green buildings. It is found from existing literature that the main factors about the popularization of green residential buildings mainly include: government funding, comfort levels, crowding effects, cost factors and so on. Specifically, the survey found that most people give priority to benefit and comfort (36.82%). Followed by is the relevant government funding (29.1%). And 22.89% of the respondents tend to the benefit because of the diminishing cost in the operation phase. In addition, 10.2% of the respondents would buy green buildings if their relatives and friends have bought. In summary, the public has a high recognition for green residential buildings. They think it is necessary to vigorously promote and build the buildings, and also almost all are willing to buy this kind of building. This shows that the green buildings have a stable audience groups, there is a huge potential market to be tapped. But how to activate the vitality of the market, to stimulate people's actual purchase desire. The most important thing is that balance the relationship between the construction cost and the final benefit, that is, not only let people realize the bringing benefits of green residential buildings, and not simple to raise the price too much.

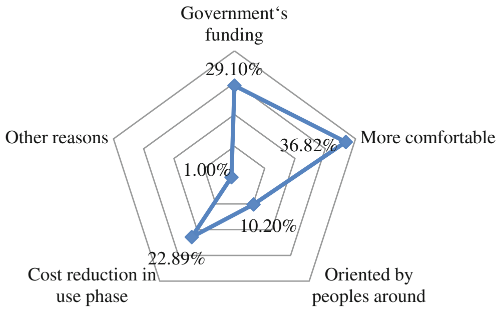

Fig. 6. Main factors affecting the purchase intention

4 Cost and Price

4.1 Incremental Cost and Incremental Price Statistics

From the statistics in Table 3, it can be seen that the incremental cost of green residential buildings in Sichuan is similar to that in China, which is controlled within 70 (CNY/m^2), the average incremental cost about 35 (CNY/m^2). It is less than 1% of total housing construction costs. It shows that the incremental cost of green buildings in Sichuan is reasonable.

Table 3. Incremental cost statistics

	One-star (CNY/m^2)		Two-star (CNY/m^2)		Three-star (CNY/m^2)	
	Average value	Scope	Average value	Scope	Average value	Scope
China	33	10 70	73	23 138	222	36 492
Sichuan	35	0–67	68	45–132	–	–

Notes: ① The nationwide data derives from the research results of "Post-assessment of green building in China", which is supported by the Ministry of Housing and Urban-Rural Development of China and led by of Chinese Society for Urban Studies; ② The data of Sichuan from the statistical results to 34 green residential projects from 2011 to 2015

At the same time, we also carried out statistics to the price of one-star green residential buildings in Sichuan, the results as shown in Table 4. It shows Sichuan Province's the average price of one-star green residential buildings is 7235 (CNY/m^2), and the average incremental price is 284 (CNY/m^2). Among them, the average price and average incremental price of the city of Chengdu are the highest. They are reached 9345 (CNY/m^2) and 385 (CNY/m^2), respectively. Compared the data in Tables 3 and 4, it can be found that the incremental price of green residential buildings in Sichuan is much higher than the incremental cost. The main reasons are as follows: (1) there is no a unified statistics standard to the incremental cost of green buildings in Sichuan, which leads the reported

Table 4. Incremental price statistics

	Actual selling price (CNY/m^2)		Incremental price (CNY/m^2)	
	Scope	Average value	Scope	Average value
Sichuan	4200–11500	7235	94–684	284
Chengdu	7800–11500	9345	136–684	385
Mianyang	4200–5100	4780	94–346	106
Nanchong	4900–5900	5360	115–526	218

incremental cost of some project seriously distorted; and (2) the current statistics to the incremental costs of green buildings only contain one-time investment cost, without considering the cost in the whole life cycle, such as cost in project planning, consulting, and operation stage. For example, although the consulting fees of green building must be produced for all the green buildings labeling programs, they are not counted in the reported incremental cost; and (3) for the same real estate, green buildings than other buildings often are occupied better natural resources (such as location, direction, greening, ventilation and etc.), and thus prices will be increased; and (4) housing prices than the cost of housing will usually retain a certain profit space, thus widening the direct gap between the price and the cost.

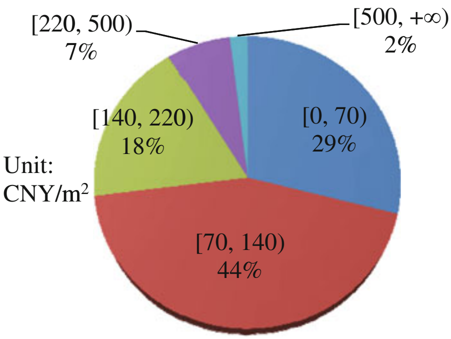

Fig. 7. People are willing to pay the proportion of the incremental price range

4.2 The Acceptability to the Incremental Price

In order to clarify the cost and efficiency of green residential buildings, a survey about public's acceptability to the incremental price is carried out. A question including five incremental price levels is set. The survey results are showed in Figs. 6–8. The results show that: (1) 73% of people are only willing to buy green residential buildings with increase price less than 140 (CNY/m^2); (2) only 8.8% of people can accept the increase price more than 220 (CNY/m^2). Thus, except

Mianyang, the incremental prices of green residential buildings are slightly high in Sichuan. Especially in Chengdu, the incremental prices of green buildings are much higher than the acceptable price of common people. Therefore, with enhancing the propaganda of green buildings, the price of green residential should also be reduced appropriately.

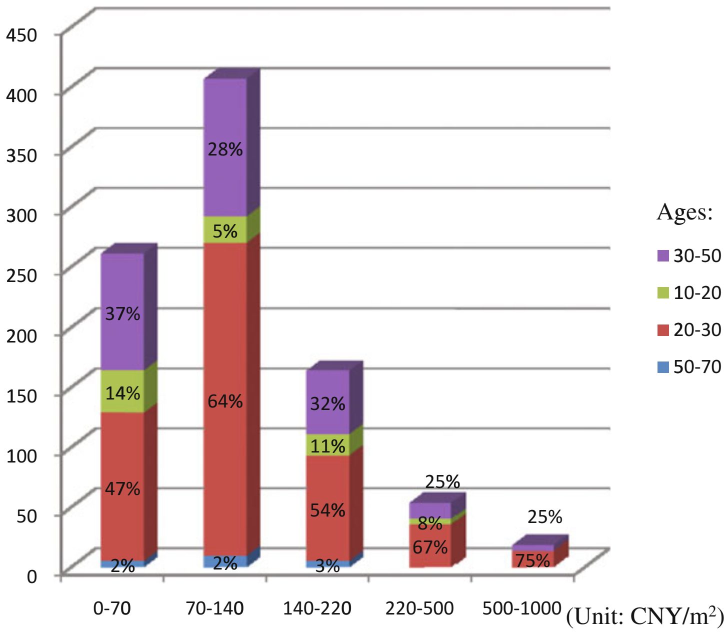

Fig. 8. Acceptability to incremental prices for different ages

5 Policy Proposals

In order to popularize green residential buildings, based on the survey results and statistic analysis above, the following policy recommendations are put forward.

5.1 Strengthen Publicity of Green Residential Buildings

From the above statistical analysis, it can be found that one of main reasons for hindering the development of green residential buildings in Sichuan is that the common people know too little about green buildings. The survey found that the vast majority of people are unclear about "what is a green building", "what can it bring what", "whether it increases the cost or not" and other core issues, which lead to a very low public acceptance for green buildings. At present, in China, only a small circle of people are working for green buildings. There are no specialized agencies or platform to popularize and propagate green buildings.

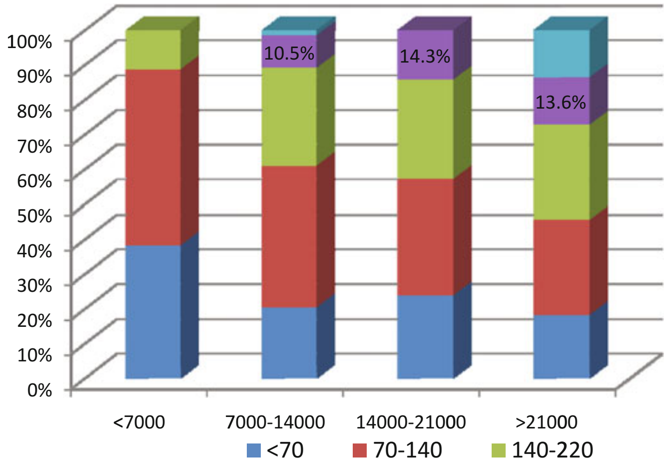

Fig. 9. Acceptability to incremental price for different income levels

Also, there is no corresponding funding support. Therefore, it is recommended that the government should increase budget to organize or guide some capable and responsible organizations or enterprises to give publicity to green buildings, including the conception, technology, production and benefit, to improve people's cognitive level for green buildings.

5.2 Build the Basic Database of Green Buildings

By the end of 2015, 3036 projects have obtained the identification of green buildings in China, and 56 in Sichuan. However, this information is only posted on few government websites, including the official website of ministry of housing and urban rural development of China, and some local official website. Moreover, these data are often published as public announcements, which are often too simple to understand. The project information in detail is always put in the attachment, and there is an open database to store them. As results, there are no channels to know and identify the green buildings' information, which hinder the further development of green building badly. So it is suggested that the government should establish official database on green buildings and open them to common people.

5.3 Drawing up Incremental Cost Statistical Standard

As describe above, the statistics on incremental cost of green buildings is variety in China. Unlike the German DGNB and Canada GBC, there is no strict requirements and uniform standard on the statistics of incremental cost in China. Some projects are counted rigorously, so reported relatively high incremental costs; however, some other projects are only counted minimal incremental cost items, some even no statistic, which lead to the unreasonable incremental cost. This brings serious difficult to correctly estimate the green buildings' costs and benefits, also to the management and service. In this situation, it is recommended that the unified standard about the incremental cost statistics of green buildings should be drawn up. In addition, the local government should require all green building projects must announce the data on incremental cost. Although this will increase cost slightly, it will pay an important role to popularize green buildings.

5.4 Enhance Cost and Price Control

From the above statistics analysis, it can be seen that the incremental price of green residential buildings in Sichuan was significantly higher than the affordable price of common people. Therefore, in order to promote the comprehensive development of green buildings, the price must be controlled. According to statistical data, the incremental price of green residential buildings should be controlled within 140 (CNY/m^2) as far as possible, especially for the one-star green residential buildings. In addition, the developers should also consider different demander according to the different price levels. For example, the projects which incremental prices are more than 140 (CNY/m^2) should focus on high-income groups. If the incremental price cannot be controlled to less than 500 (CNY/m^2), then the average monthly income of potential buyer should be more than 21000 CNY.

6 Conclusion

Although green residential buildings as the trend of the future development, many people still don't know exactly what's the green buildings. A green building not only means the vertical greening or roof garden, but also refers in the construction of the whole life cycle, to maximize the energy saving, land saving, water saving, material saving, environmental protection and pollution reduction. It is also called the sustainable development construction, ecological construction, energy saving and environmental protection construction etc. Looking around the property market in Sichuan, the green buildings are still very little. Three main reasons have been found according to the survey study in this paper. First, the common people know too little about green residential buildings. Second, the incremental prices of green residential buildings have exceeded the buyers' psychological expectations. Third, the environmental benefit and economic benefit for buyers are not widely accepted. Therefore, to popularize the green residential buildings, at the same time of improving the comfort, it is also necessary to strengthen the science propaganda and control the incremental price.

Abstract. Prognostics of lithium-ion batteries play an important role in the intelligent battery management systems. The State of health (SOH) estimation for batteries often needs to be implemented under uncertain situations for the complicated operating conditions. In this work, a novel integrated approach based on a mixture of Gaussian process (MGP) model is presented for lithium-ion battery SOH estimation under uncertain conditions, where the degradation process parameters distribution can be learnt from the multiple available capacity measurements. To capture the time-varying degradation behavior, the distribution information of the degradation model parameter is extracted by fusing the training data from different battery conditions with the MGP model. Moreover, by exploiting the degradation model parameter distribution information, the PF algorithm is employed to predict the battery SOH. The correlation case study and comparison analysis are provided to show the efficiency and effectiveness of the proposed prediction method.

Keywords: Prognostics · Lithium-ion batteries · State estimation · Uncertainty

1 Introduction

With the advantages of high energy density, high galvanic, low-temperature performance, and long lifetime, lithium-ion batteries play a more important role in electronics system energy supply, and therefore have been widely used in communication, aerospace avionics, portable devices and other industrial areas [5,8]. However, battery deterioration and battery failure commonly occur, which can lead to a reduction in systems performance, result in increased costs and catastrophic failure [14]. Therefore, for the electronics device, prognostics and health management (PHM) has received increased attention in battery management system to determine the advent of systems failure and to mitigate system

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_109

risk through the evaluation of system reliability in terms of the current life-cycle conditions [13,16].

In order to evaluate the current health situation, some indicators such as the state-of-charge (SOC), the state-of-health (SOH) and the state of life (SOL) are commonly used to quantify the degradation of lithium-ion batteries [17]. To provide useful prognostics information in the reliability monitoring for battery systems health management, current researches have focused on SOC and SOH estimation for batteries. The main measurements required to effectively measure battery SOH are impedance and capacity [7]. In this study, battery capacity percentages relative to the initial capacity are adopted to measure the SOH.

In recent years, there are many valuable research works on the battery degradation modeling and prognostics for battery SOH estimation [9,15]. For example, neural networks and artificial intelligent methods have been rapidly used to estimate the battery SOH and predict the remaining useful life [11]. Stochastic filtering approaches such as Kalman filtering [1], extended Kalman filtering [4,10], unscented filtering and Bayesian filtering [2] are widely adopted in the SOH estimation of battery, in which the empirical degradation models are often used to build the dynamical system equation. Usually, the stochastic filtering methods based on the parameter process or degradation model can show good performance only when the degradation model used represents the actual system's behavior effectively. However, in practical battery conditions such as operating conditions, environmental conditions, and other complicated inherent system, it is difficult to obtain accurate state process model or parameter description when the uncertainties are considered. To address this issue, many approaches have been proposed such as a prognostic algorithm based on a Bayesian Monte Carlo method and the Dempster-Shafer theory for battery SOH estimation and RUL prediction [3]. Liu et al. [7] used the Gaussian process regression (GPR) to perform SOH prediction for lithium-ion battery, where the degradation trends are learned from battery data sets with the combination of Gaussian process functions. It should be noticed that uncertainty representation of the degradation model has not yet been fully investigated.

As mentioned above, it is urgent to develop the battery prognostics under the uncertainties. In this work, a novel approach to lithium-ion battery SOH estimation is presented through the integration of the MGP model learning and particle filtering. The proposed method consists of two phases, and the first is the MGP is used to learn the statistical properties of the degradation model parameter combining training data sets from uncertain battery conditions. Secondly, based on the parameter distribution information for the degradation process, particle filtering is exploited to obtain the battery SOH estimation. In the training phases, the GPR is exploited to initialize the distribution parameters for each component. Then, the MGP learning and the PF updating are recursively implemented. Finally, a case example is provided based on the NASA battery data sets to show the performance of the new prognostics method. The contributions of this study can be summarized in two points: the first is a fusion prognostics framework for the lithium-ion battery SOH estimation is developed by combining the degradation conditions from different batteries, the second is the proposed algorithm implements distribution learning for the multimode process under uncertainty.

The rest sections of this paper are organized in the following order: the GPR and the MGP model are introduced in Sect. 2. Section 3 details the proposed SOH prediction method which incorporates MGP learning and PF. Experiments and analysis are given in Sect. 4 to show the performance of proposed prognostics algorithm. Finally, we make the conclusions in Sect. 5.

2 Related Work

2.1 Gaussian Process Regression

The degradation model parameter vectors need to be treated as a dynamic process which captures the time-varying situations in the battery degradation cycles. To represent the system degradation behavior, The Gaussian process is considered. A stochastic process $\{g(x) : x \in \mathcal{X}\}$, indexed by elements from some set $\mathcal{X}$, is a Gaussian process with mean function $m(x)$ and covariance function $k(x, x')$. It means for any finite set of elements $x_1, \cdots, x_m \in \mathcal{X}$, the associated finite set of random variables $g(x_1), \cdots, g(x_m)$ have a multivariate Gaussian distribution, i.e.,

$$\begin{bmatrix} g(x_1) \\ \vdots \\ g(x_m) \end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix} m(x_1) \\ \vdots \\ m(x_m) \end{bmatrix}, \begin{bmatrix} k(x_1, x_1) & \cdots & k(x_1, x_m) \\ \vdots & \ddots & \vdots \\ k(x_m, x_1) & \cdots & k(x_m, x_m) \end{bmatrix} \right).$$

It can be denote by $g(x) \sim GP(m(x), k(x, x'))$. Actually, the mean function and covariance function are defined as

$$\begin{aligned} m(x) &= E[g(x)], \\ k(x, x') &= E[(g(x) - m(x))(g(x') - m(x'))], \end{aligned}$$

for any $x, x' \in \mathcal{X}$.

Gaussian process represent distributions over functions, it provide a method for modeling probability distribution under multiple corruptions in complicated or uncertainty situations. When the accurately describe for the dynamical parameter process is hard to be obtained in advance, the Gaussian process regression (GPR) can be exploited to supply the approximation distribution of the parameter process through learning from the training data available [6].

Consider a set of training data $S = \{x_i, y_i\}_{i=1}^{N}$, the relationship between input x_i and output y_i can be modeled by $y_i = g(x_i) + \epsilon_i$, where ϵ_i is zero mean, Gaussian white noise with variance σ_n^2. From the GPR, if the prior distribution over $g(x_i)$ be assumed as Gaussian process, the posterior distribution over outputs conditioned on sample set S and the test input x_* is also a Gaussian process, and the mean and variance can be given by

$$\bar{g_*} = E[g_* | x_*, S] = k_*^T K^{-1} \mathrm{y}, \tag{1}$$

$$Cov(g_*) = k(x_*, x_*) - k_*^T K^{-1} k_*, \tag{2}$$

where, K is the covariance matrix whose entries is determined by the kernel function i.e. $K_{ij} = k(x_i, x_j)$. In order to capture the uncertainty of state process and the influence of noise, the kernel function can be expressed as $k(x_i, x_j) = k_g(x_i, x_j) + k_n(x_i, x_j)$, and the squared exponential kernel and constant kernel function are chosen as the covariance function of Gaussian process:

$$k_g(x_i, x_j) = \sigma_g^2 \exp\left[-\frac{(x_i - x_j)^2}{2}\right], \tag{3}$$

$$k_n(x_i, x_j) = \sigma_n^2 \delta_{ij}. \tag{4}$$

The parameters $\Theta = [\sigma_h, \sigma_n]$ are so-called hyper-parameters of the Gaussian process, which are actually the parameters of the covariance function. The hyper-parameters can be determined by exploiting numerical optimization techniques which is to maximize the log-likelihood function given by

$$\log p(y|X, \Theta) = -\frac{1}{2} y^T (K + \sigma_n^2 I)^{-1} y - \frac{1}{2} \log(|K + \sigma_n^2 I|) - \frac{N}{2} \log(2\pi),$$

where, I is the unit matrix of N dimensions, and N is the number of training data. Therefore, the learning process with GPR need to select the mean function and covariance firstly, then the hyper-parameters can be determined with the training data. After that, the prediction of the distribution parameter can be yielded with the new inputs.

2.2 Mixture of Gaussian Process Models

Consider the uncertainties in the degradation of different batteries, the available training data usually comes from several sources which may have different initial capacities or were collected from different measurement conditions. Therefore, to make full use of the various monitoring data, the MGP model is utilized to model the prediction distribution of the degradation model parameters by learning the mean and covariance from the multiple input space. With the obtained SOH measurements, the training set S is supposed to be composed of known K-components, $S_1, \cdots, S_K$, where $S_k = \{x_i, y_i\}_{i=1}^{N_k}$. For each training subset S_k, considering that there is a latent degradation model with uncertainty that can be used to describe the degradation trend for different battery components, the initial Gaussian processes are first used to learn the distribution parameters of the degradation process. Then, the MGP model which is obtained as a weighted combination of finite Gaussian process models can be exploited to fuse the distribution information from different components. Therefore, denote $p(z(x) = k)$ as the probability that sample x corresponds to the k component, then, with the mixture weights $\pi_i, i = 1, \cdots, K$, the posterior probability of the samples associated with the k^{th} component is given by:

$$p(z(x) = k|x) = \frac{\pi_k N(x|\mu_k, \Sigma_k)}{\sum_{i=1}^{K} \pi_i N(x|\mu_i, \Sigma_i)}. \tag{5}$$

Let $p(y_*|S_k, x_*)$ be the predictive pdf for the output variable y_* on the condition that the new sample x_* is obtained from the k^{th} component. Thus, the predictive pdf from the MGP models can be given as:

$$p(y_*|S, x_*) = \sum_{k=1}^{K} p(z(x_*) = k|x_*)p(y_*|S_k, x_*) \tag{6}$$

where, $p(z(x_*) = k|x_*)$ is the posterior probability that x_* belongs to k^{th} component, and it can also be denoted as $p(k|x_*)$.

Based on the structure of the MGP models, the state process for the battery degradation parameters can be given through the distribution learning which combines multiple possible degradation processes. It can be seen from Eq. (6), the predictive distributions from the MGP models can be determined from the posterior probability of the component the test sample belongs to and the associated distribution parameters update from the Gaussian process components when the new test sample is obtained. Commonly, the Expectation-Maximization algorithm, which is based on the maximization of the log-likelihood, is used for MGP model parameter optimization. To represent the time-varying process of the degradation model parameters in the training phase, recursive learning for the Gaussian mixture model can be exploited. In this way, denote the distribution learnt from k^{th} GPR component at time t as $\{\pi_k^{(t)}, \mu_k^{(t)}, \Sigma_k^{(t)}\}$, when the test sample $x^{(t+1)}$ arrives at time $t+1$, the mean and covariance of the k^{th} component, and its mixture weights can be updated as follows [18].

Step 1. Compute the posterior probability of the component:

$$p(k|x^{(t+1)}) = \frac{\pi_k^{(t)} N(x^{(t+1)}|\mu_k^{(t)}, \Sigma_k^{(t)})}{\sum_{i=1}^{K} \pi_i^{(t)} N(x^{(t+1)}|\mu_i^{(t)}, \Sigma_i^{(t)})}. \tag{7}$$

Step 2. Update the mixture weights:

$$\pi_k^{(t+1)} = \pi_k^{(t)} + \gamma(p(k|x^{t+1}) - \pi_k^{(t)}). \tag{8}$$

Step 3. Update the distribution parameters:

$$\mu_k^{(t+1)} = \mu_k^{(t)} + \gamma \frac{p(k|x^{t+1})}{\pi_k^{(t)}}(x^{t+1} - \mu_k^{(t)}), \tag{9}$$

$$\Sigma_k^{(t+1)} = \Sigma_k^{(t)} + \gamma \frac{p(k|x^{t+1})}{\pi_k^{(t)}}((x^{t+1} - \mu_k^{(t)})(x^{t+1} - \mu_k^{(t)})^T - \Sigma_k^{(t)}), \tag{10}$$

where, γ can be viewed as the control parameter which can be set as $1/N$ where N is the number of acquired samples.

3 The Proposed Method Based on MGP

The proposed method of SOH prediction has two phases. For the uncertainties in the battery capacity degradation, the MGP is able to combine the corresponding degradation process information under different conditions, thus, the MGP model is used to learn the appropriate distribution to represent the transition of the degradation model parameters in the training phase. In each mixture component, the nonlinear and time-varying parameter processes are treated as Gaussian process with associated means and covariance, which means the GPR is exploited for initialization. In the prediction phase, with the training data under the current condition, the trained MGP model is used to supply the importance density needed to produce the weighted samples in the Bayesian filtering implementation.

In fact, there are two parts in the training phase. Firstly, in order to capture the statistical properties for the degradation model parameters under uncertain state transition, the GPR is utilized to learn the distribution information from the different training sets. In each component, the training data can be given by $D_k = \{(x_i, y_i)\}_{i=1}^{N_k}$, where $y_i = \Delta x_i = x_{i+1} - x_i$, thus, the parameter at the next time instant can be expressed by adding the corresponding output to the current state, as the output with each input x_i is set as the change of the parameters. Then, for each component, the mean $\bar{g}_{N_k}$ and covariance $\mathrm{cov}(g_{N_k})$ are determined through the GPR Eqs. (1)–(2), and denoted $\mu_k^{(0)} = \bar{g}_{N_k}$ and $\Sigma_k^{(0)} = \mathrm{cov}(g_{N_k})$, which means that the initial mean and covariance are given in the Gaussian process components. Secondly, when the initial distribution parameters of MPG are given, the degradation model parameters pdf can be represented by using the recursive algorithm for MPG with the current training data. For the battery capacity data available from the current battery condition, denote the current training data $D_T = \{\Delta x^{(t)}\}_{t=1}^{T}$ as the parameter transition, where $\Delta x^{(t)} = x^{(t+1)} - x^{(t)}$, and $\Theta_k^{(t)} = \{p(k|\Delta x^{(t)}), \pi_k^{(t)}, \mu_k^{(t)}, \Sigma_k^{(t)}\}$ are the current distribution parameters for each component, then, the pdf of MGP can be computed from the MGP parameters updating using Eqs. (7)–(10). After that, the importance sampling and the resampling procedure are implemented from the standard particle filter algorithm. With the particles and associated weights, the battery capacity prediction $\mathrm{SOH}_{l+p}^{[i]}$ at p step after current cycle l can be computed by exploiting the degradation parameter samples $\tilde{x}_l^{[i]}$ for the i^{th} trajectory. Meanwhile, the SOH prediction at cycle l can be estimated by combining the N_s samples of capacity measurements with their corresponding weights. The steps of our proposed method are summarized as follows.

Step 1. Initialization:
Given the trained data set $S_L = \{(x_i, z_i)\}_{i=1}^{L}$ and the trained parameter set in different components $D_k = \{(x_i, y_i)\}_{i=1}^{N_k}$, $(k = 1, \cdots, K)$.

Step 2. Gaussian process regression-based learning in each component: For each component $k = 1, \cdots, K$, $\{\mu_k^{(0)}, \Sigma_k^{(0)}\}$=GPR$(D_k)$.

Step 3. Update the MGP parameters with current training data D_T:

Step 3.1 For each component$k = 1, \cdots, K$ $\Theta_k^{(t+1)} = \mathrm{MGP}(\Theta_k^{(t)}, \Delta x^{(t+1)})$

Step 3.2 Compute the density of MGP using Eq. (6)

Step 4. Denote $\mathrm{MGP}(\Delta x_{l-1}^{[i]}; \Theta^{(T)})$ as the MGP density with the parameters $\Theta^{(T)}$, and $N(z_l; GP_\mu(x_l^{[i]}, S_L), GP_\Sigma(x_l^{[i]}, S_L))$ represents the Gaussian pdf with the mean $GP_\mu(x_l^{[i]}, S_L)$ and the covariance $GP_\Sigma(x_l^{[i]}, S_L)$, then the importance sampling and resampling can be implemented:

Step 4.1 FOR $i = 1, \cdots, N_s$

$$\text{sample } x_l^{[i]} \sim x_{l-1}^{[i]} + MGP(\Delta x_{l-1}^{[i]}; \Theta^{(T)}),$$
$$\omega_l^{[i]} \propto \omega_{l-1}^{[i]} N(z_l; GP_\mu(x_l^{[i]}, S_L), GP_\Sigma(x_l^{[i]}, S_L)).$$

END FOR

Step 4.2 Calculate the normalization weights $\hat{\omega}_l^{[i]}$ and effective sample size N_{eff}

Step 4.3 IF $N_{eff} < N_{th}$

$$[\{\tilde{x}_l^{[i]}, \tilde{\omega}_l^{[i]}\}_{i=1}^N] = \text{resampling}[\{x_l^{[i]}, \hat{\omega}_l^{[i]}\}_{i=1}^N].$$

Step 4.4 IF $l < L$, let $l = l + 1$, turn to Step 4.1;

Step 5. Estimate the capacity with weighted samples $\tilde{x}_l^{[i]} = (a_l^{[i]}, b_l^{[i]}, c_l^{[i]}, d_l^{[i]})$:

$$\text{SOH}_{l+p}^{[i]} = a_l^{[i]} \times \exp[b_l^{[i]} \cdot (l+p)] + c_l^{[i]} \times \exp[d_l^{[i]} \times (l+p)],$$
$$\text{SOH}_{l+p} = \sum_{i=1}^{N_s} \tilde{\omega}_l^{[i]} \text{SOH}_{l+p}^{[i]}.$$

4 Case Example

4.1 Battery Data Set

In this section, a case study is conducted to validate the proposed approach. The battery capacity data used in this paper are collected by the NASA Ames' Prognostics Center of Excellence (PCoE) [12]. The lithium-ion batteries were run through different operational profiles, such as charge, discharge and impedance at room temperature. The battery capacity at cycles was adopted to measure the SOH, and the end-of-life criterion in the repeated charge and discharge cycles for the accelerated aging of the batteries was a 30% fade in rated capacity. Four batteries No. ~5, No. ~6, No. ~7, No. ~18 are acquired through the discharge with 2 A constant current level at an ambient temperature of 24 °C until the battery voltage fell to 2.7V, 2.5V, 2.2V and 2.5V, respectively.

To represent the empirical capacity degradation model, the conditional three-parameter capacity degradation model as follow was considered, where the constant variable κ was set at 2.

$$\text{SOH} = \tau \cdot \exp(\iota \cdot l) + \rho \cdot l^\kappa. \tag{11}$$

Using the Matlab curve fitting toolbox, the real degradation and the curve fitting for battery No. ~6 with the degradation model (11) are shown in Fig. 1. The empirical degradation model parameters are $(1.0263, 0.0037, 0)$, which were estimated by curve fitting with the capacity samples given from cycle 1 to cycle 100. It can be seen from Fig. 1 that the real SOH at prediction cycles are higher than the capacity degradation estimation. The root mean squared error is 2.8919 and the adjusted R^2 is 0.947, which are the goodness-of-fit statistics of the empirical model.

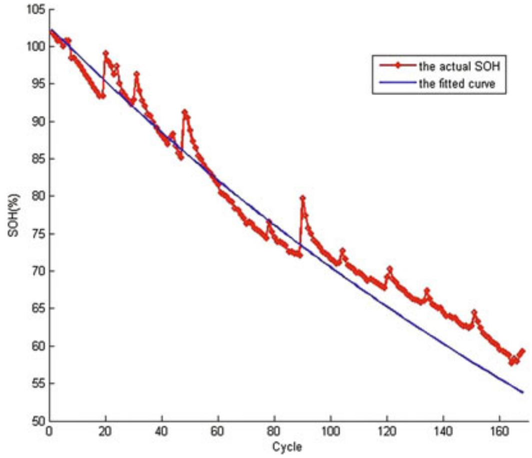

Fig. 1. The SOH of battery No. 6

4.2 The SOH Prediction

For the different operating profiles, the data from battery No. ~6 was assumed as the capacity samples under the current condition, and the data from other batteries, which represented the different operating conditions, were treated as the historical training data. In the training phase, there are two aspects. Firstly, with historical training data sets for different batteries, the GPR was exploited to learn the initial distribution parameters, where the mean function was chosen from the linear function $m(x) = ax + b$ and the covariance function was chosen as the exponential function expressed by Eqs. (3)–(4). Therefore, the hyper-parameters $\Theta = [a, b, \sigma_n, \sigma_g]$ were optimized with the maximization of the log-likelihood function. Secondly, the mixture density of MGP model is learnt by exploiting the current battery training set with the obtained distribution parameters from the different components. After that, the obtained distribution from data can be treated as the importance density, and then the particles and associated weights were updated using importance sampling and resampling procedure implemented as the standard particle filter algorithm.

In this study, the number of particles was set at 200. Consider the current battery No. ~6, the prediction began at cycle 100, which means the training data obtained from the cycle 1 to cycle 50 was used as the training set for the MGP learning, and the SOH measurements from cycle 51 to cycle 100 were used for the particles updating, and then the prediction results are shown in Fig. 2.

As shown in Fig. 2, the prediction combining three different training components can capture the degradation trends of SOH in most cycles. Therefore, from these results, the proposed method shows the effective prediction by fusing the multiple training data which represent the uncertain capacity degradation conditions.

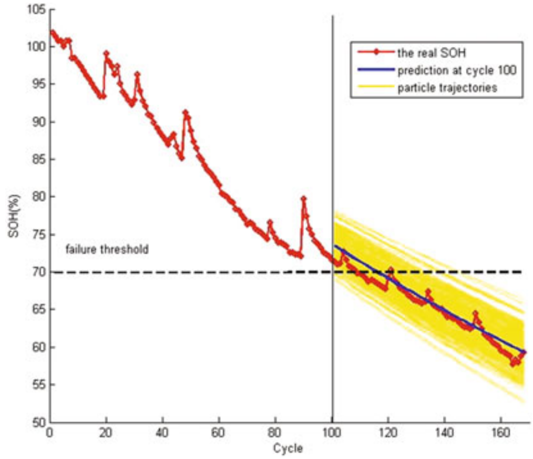

Fig. 2. Prediction results for battery No. 6 at cycle 100 with different training sets from batteries No. 5, No. 7 and No. 18

In addition, to further evaluate the proposed SOH prediction approach under uncertain condition, the method based on MGP learning and particle filtering (MGP–PF) was compared with the method which only considers the data from current battery. The GPR was used for parameter distribution learning, then the SOH estimation could also be implemented with the PF, thus the latter method denoted GPR–PF. Consider the current battery No. ~6, the prediction cycle was set at cycle 100, then the prediction results with two methods are shown in Fig. 3.

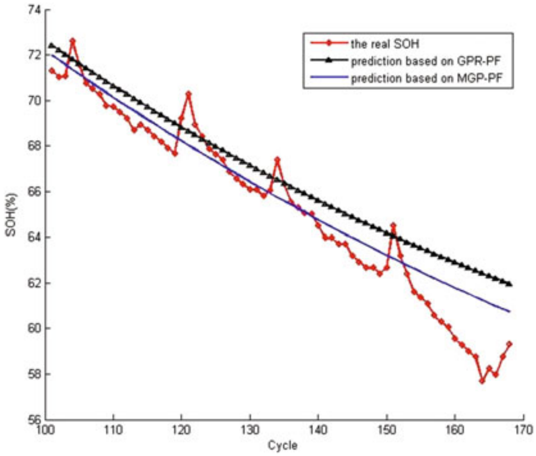

Fig. 3. Prediction results based on GPR-PF and MGP-PF for battery No. 6

For the battery No. 6, it can be seen from the Fig. 3 that the SOH prediction based on MGP and PF performed batter than the methods which only took the current capacity data into account. This indicates that the method which combines the priori information of capacity degradation process can improve the estimation performance in the current experiments. The reasons for this may lie in that distribution approximate which only considers the current measurements of battery ignores the useful fading information under different degradation conditions. Therefore, the method which fuses knowledge from multiple capacity degradation conditions is more suitable for lithium-ion battery SOH estimation with the uncertain battery degradation situations.

5 Conclusion

In this paper, a new model for the battery SOH estimation is presented based on the MGP model which was exploited to learn the distribution parameters from multiple training sets on the different degradation conditions. To represent the density of the degradation model parameters under uncertain conditions, the initialized distribution parameters can be updated recursively through MGP learning from the current capacity measurements of battery. Based on the degradation model parameter distribution information, importance sampling and resampling in the particle filtering framework was implemented. Our method is based on distribution learning from training data and does not assume any certain state model of degradation parameter, which is usually hard to be obtained in advance. Therefore, the proposed approach can also be applied to other estimation problems with unknown state space models under uncertain conditions.

Lithium-ion battery degradation under complicated conditions or working environments occurs in practice and different battery conditions can cause differences in the degradation. The prognostics for battery SOH estimation under uncertain conditions have many challenges, as different capacity degradation models with various degradation features cannot be obtained in advance. The uncertainties for the PHM of batteries is far more complex than the investigation in this paper, so further research on the implementation of fusion models under other uncertain conditions will be the focus of our future works.

Abstract. With increasing concern about $PM_{2.5}$, global warming, greenhouse gas emissions and the problem of the "last mile", the public bicycle system is gaining importance as viable mode in urban transportation worldwide. In order to more successfully promote the public bicycle to the residents, it is obviously necessary to understand in-depth what can affect the residents' usage of public bicycle. The study elicit the influence of demographic, attitude towards the behavior, subjective norm and perceived behavioral control on the usage of public bicycle. Based on the theory of planned behavior (TPB) and the binary logistic model, the paper conclude that the variable of gender, age, occupation and income are closely contacted with the usage of public bicycle. And the education qualification has a little effect on it. And there are significant relationship between usage public bicycle and environmental friendly, flexible, find-time, cleanness, the bicycle lanes, signals for cyclist, suitable weather.

Keywords: Public bicycle · Factor analysis · Low-carbon · Traffic behavior

1 Introduction

Though there are more and more convenient bus routes today in daily life, some back streets and new residential areas do not share public transport, and the residents often take more than 10 min to reach the bus station. To solve the public "last mile" problem, the community buses driving around the community entrance came into being in Chengdu in 2012. But because of the limitation of community buses, such as fixed lines and fewer bus stops, the residents were not satisfied with community buses, so the traffic pattern could not solve the problem perfectly. As the replacing for community buses, the public bicycles are more flexible and more popular.

Generally, the problem of traffic congestion and heavy emissions of CO_2 become more and more serious and people are increasingly worried about the $PM_{2.5}$ emissions and the smog problem in China. Therefore, low-carbon traffic

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_110

has been becoming increasingly popular in many cities. The local authorities have been paying more and more attention to public transport, and cycling in daily mobility is considered according to efficient means to reduce air pollution, traffic jams, and carbon emissions. Public bicycle systems (PBS) have turned out to be efficacious in promoting riding in many cities, particularly when contacted with public transportation.

Chengdu seems to be one of the most suitable cities for the development of shared bicycle in China due to flat terrain, mild weather, little sunshine and less wind as well as wide non-motor vehicle lanes. In addition, it is densely populated and there are about 238834 persons per square kilometers. Therefore, the public bicycle solve the Chengdu "last kilometers" of the problem effectively.

Despite public bicycle sharing system existing in many cities in China, cycling still does not become the habit of most residents, and researches for the influencing factors of PBS is not enough much and perfect. A study summed up the impact of spatio-temporal interactions on bicycle sharing system demand [10]. And a find pointed out bicycle sharing stations and greenness were motivators for bicycle commuting and public transport stations and elevation were deterrents for bicycle commuting by multinomial logistic regression models [6]. A research about public bicycle system in Beijing found that the bike-share choice is most sensitive comfort, user demographics, however, do not affect strongly on the bike-share choice, indicating the mode will draw users from across the social spectrum [4]. Firstly, this paper investigated the demographic factors related the usage of public bicycles. Then based on the theory of planned behavior the binary logistic model, this paper explored the factors that may affect the public bicycle selection of residents from the perspective of attitude towards the behavior, subjective norm and perceived behavioral control.

2 Literature Review

Attitudes and perception of an individual towards a particular mode would influence the behavior of that individual [8]. Commonly, the cycling requires a physical effort among the cyclist. The public bicycles are more and more popular today. The norm is also important for the usage of public bicycles. So it is necessary to understand which factors make a positive impact on the usage of public bicycles.

As the history of public bicycle system is not long, the researches on theory and practice of PBS are still immature. And most of the researches on public bicycle selection of residents concentrated on characters of public bicycle travel, the method or theory of travel choice and factors affecting public bicycle selection.

For the characters of public bicycle travel, a study found that the average travel distance of bicycle users is about 3.7 km, and the male users were 3.8 km, the female users are 3.6 Km through a survey towards the American travelers [1]. New findings unequivocally demonstrate that the mean journey length made by private bicycle is 700–800 m (0.44–0.5 miles) greater than those made by public bicycle [5]. And a survey found that the average distance traveled by bicycles for fitness was 14 km [9]. What's more, through the development of public bicycle planning in Hangzhou, Shi [16] pointed out that the public bicycle system facilities construction, the usage and operational mechanisms should be carried out to research from the perspective of public bicycle facilities. In addition, a paper that examines the tensions between the glamour of a global competitive city explained what roles might public bicycle paly and how might a public bicycle system business model operates if it were to serve the transport disadvantage [13].

For the method and theory of travel choice, based on the information theory, a selection procedure is proposed to select important variables in the logistic regression model, and the strong consistency of these programs is proved [2]. And Yang [17] built a structural equation model of resident's travel choice in the process of urbanization based on out chain. Sakari [12] put forward that public bicycle system should be viewed as part of public transport rather than as a separate cycling scheme. Furthermore, a study developed a methodology for categorizing bicycling environments defined by the bicyclist's perceived level of safety and comfort [14]. In addition, there is a research that develop an estimation method using sinusoidal model to fit the typical pattern of seasonal bicycle demand [11].

For the factors affecting public bicycle selection, it turned out that lower education and absence of docking stations within walking distance were associated with lower likelihood of awareness of the public bicycle system programs [3]. And a research explored the impact of specific weather conditions and calendar events on the spatio-temporal dynamics of the case study public bicycle sharing programs employing novel spatial analytical techniques [7]. Besides, there is the study agreed that residents' travel choices are mainly driven by environmental conditions and personal travel habits [4]. A survey outcomes in India revealed perceived benefits, physical barriers, safety hazards, social barriers, and road condition may be the major factor classes influencing bicycle mode choice used in exploratory factor analysis [15].

The current literature review reveals a dearth in studies that comprehensively elicit the influence of demographic, attitude towards the behavior, subjective norm and perceived behavioral control on the usage of public bicycle. Aptly, the current paper aims to identify the effect in those aspects. Moreover, the study also points out the determinants and correlates of public bicycle commuting.

3 Methodology

The factors were identified in the literature as influential in public bicycle system are numerous and diverse [15]. The study focuses on commuting trips in order to analysis the factors that influence people use the public bicycle based on theory of planned behavior (TPB). In this paper, the factors have been divided according to this rule that whether it is belong to "attitude towards the behavior", "subjective norm" and "perceived behavioral control", they are the three main variables that determine behavioral intentions. Where there is more positive attitude, the more support of important others, and the stronger the control of perceived behavior, there is more the behavior intentions about using public bicycle. And vice versa. The factors of personal, social and cultural (such as personality, intelligence, experience, age, gender, cultural background, etc.) indirectly affect attitude towards the behavior, subjective norms and perceived behavior control by influencing the behavioral beliefs, and ultimately affect behavioral intentions and behavior. Attitude towards the behavior, subjective norms, and perceived behavioral controls are conceptually distinct, but sometimes they may have a common basis of beliefs, so they are both independent and related.

We first investigated the factors of demographic by a simple distribution analysis specified for bicycle-shared and non-bicycle-shared commuters. Relevance analysis (e.g. Person's chi-square test) were applied to find the relationships between the factors of demographic and commuting by public bicycles or not.

After that, we investigated the determinants of public bicycle commuting with the model of binary logistic regression from the perspectives of attitude towards the behavior, subjective norms, and perceived behavioral controls.

4 Data Collection

4.1 Study Location

Chengdu is a large-size city of Sichuan province in the southwest of China with the resident population of 14.428 million. And it is about 604.1 square kilometers. Economic development is very rapid and it is one of the fastest growing cities in China. What's more, the environmental pollution is very serious, so it is important to develop low-carbon traffic in the city. The terrain of Chengdu is relatively flat so that the citizen develop riding habit is possible. And public bicycles became more and more popular in the city since 2016.

4.2 Questionnaire Survey

The questionnaire includes four sections. The first section focuses on the demographic variables, and the respondents were asked to report their gender, age, occupation, educational qualification and income. In the second, third and fourth section, the questions about attitude towards the behavior, subjective norms, and perceived behavioral controls are descripted in the questionnaire. Table 1 shows the characteristics about the questions.

The data for the study is collected usage face-to-face questionnaire survey by a sample collected using a random sampling method. And it was at subway station, university, attractions and business district we did this survey.

Table 1. Summary of questions

Attitude towards the behavior	Subjective norm	Perceived behavioral controls
(1) I think riding public bicycle is a cool choose to commute	(1) I do not use the public bicycle because I do not how it works	(1) I would not use the public bicycle because it is laborious
(2) I want to use the public bicycle because it is so flexible	(2) I would not use the public bicycle because the registration fee is too high(higher 300 yuan)	(2) I would not use the bicycle because there is not bicycle lane
(3) I want to use the public bicycle because it is time-saving	(3) I would not use the public bicycle because the unit price is too high(higher 2 yuan per hour)	(3) I would not use the bicycle because of heavy traffic
(4) I want to use the public bicycle because it is environmentally friendly	(4) I would not use the public bicycle if the destination is not near to my house(without 10 km)	(4) I would not use the bicycle because there is no signal for cyclist
(5) I want to use the public bicycle because it is entertaining	(5) I would not use the public bicycle if it takes too much time to find the bike.(beyond 5 min)	(5) I would not use the bicycle if it is night
(6) I want to use the public bicycle because it is good for health	(6) I would not use the public bicycle because the bicycle is not clean	(6) I would not use the bicycle if weather is not pleasant
(7) I would not use the public bicycle because it is not consistent with identity	(7) I would not use the public bicycle because the bicycle is not beautiful	
	(8) I would not use the public bicycle because I have private bicycle and e-bicycle	

4.3 Sample Characteristics

A total of 633 people are in the survey and 79% respondents have been used the public bicycle. Most of the respondents from various income classes use the public bicycle as transportation to school and to work. Before using the public bicycles, 73% of respondents used subway or bus as the main mode, 60% od them walked, 26% of them take a bike, 34% of them use car or taxi. In addition, it is at school and community sa well as subway and bus station where most respondents used the public bicycle.

5 Statistical Analysis

All data analysis were performed using SPSS. For the demographic data, we test whether it is independent between usage public bicycle and demographic character by Person's chi-square test (The significance level $\alpha = 0.05$).

Attitude towards the behavior that may affect propensity of using public bicycle were evaluated by using a binary logistic regression model (95% confidence). Participant characteristic were dichotomized before testing as potential confounders, including whether participants think it is cool, flexible, time-saving, environmentally friendly, entertaining, good for health, not consistent with identity. In addition, the potential confounders for subjective norm include the understanding about PBS, the registration fee, the unit price, the distance, the find-time, outward appearance, cleanliness, and whether the participants have private bicycle and e-bicycle. And the potential confounders for perceived behavioral controls include whether it is laborious, whether there is bicycle lanes, signals for cyclist, heavy traffic, visibility and weather. Final model fitness was checked with a (post-estimation) generalized Hosmer–Lemeshow goodness-of-fit test.

6 Results and Discussion

6.1 The Relationship Between Public Bicycle Selection and Demographic Factors by Chi-Square Test

When the demographic data was analyzed, Table 2 shows the sample distribution according to demographic factors. It reveals that the public bicycles are very popular among people. There are 503 respondents usage the public bicycle. The majority of cyclists who use public bicycle are women (65%). And for those who do not use public bicycle, it is equivalent between men and women. The Asymp.sig. (2-sided) is equal to 0.002, so it explain that the use of public bicycles is related to gender at the 99.5% confidence level.

For groups of aged 10–48, there is no significantly difference in column proportions between use and non-use. However, the proportion of the use aged 49–65 age (4%) is significantly lower than the non-use. What's more, among the use, the groups of aged 10–35 are significantly higher than the other age groups. The group mainly comprises students and the young worker who are more likely to take bikes to school or to work. In addition, the Asymp.sig. (2-sided) is equal to 0.006, so it explain that the use of public bicycles is related to age at the 99.5% confidence level.

For the group of students, it is obviously that the proportion of the use (78%) is higher than the non-use (49%). After all, the students are easier to accept new things, like public bicycle. And it is usually not too far from their home (dormitory) to school (classroom), so the bike is the best transportation for them. Besides, among the use, the groups of retirees (1%) are significantly lower than the other groups. The group mainly comprises elder who may feel more difficult to ride a bike. And the Asymp.sig. (2-sided) is equal to 0.003, so it explain that the use of public bicycles is related to occupation at the 99.5% confidence level.

For those whose income is less 3000, the proportion of the use is slightly higher than the non-use. But for those whose income is more than 3000, the proportion of the use is higher than the non-use. And for those who use the public bicycle, the groups whose income is less 1500 and between 1500 and 3000 are significantly higher than the other income groups. The group mainly prefer riding than driving in order to reduce the cost. What's more, the Asymp.sig. (2-sided) is equal to 0.005, so it explain that the use of public bicycles is related to income at the 99.5% confidence level.

For those whose educational qualification is at the same level, the proportion of the use and the non-use is equal on the whole. And the Asymp.sig. (2-sided) is equal to 0.345, so there is slight connection between educational qualification and the use of public bicycles at the 99.5% confidence level.

Table 2. Distribution of the sample according to demographic factors.

Variables	Total	Use	Non-use	Asymp.sig. (2-sided)
Gender	633(100%)	503(100%)	130(100%)	0.002
Male	241(61.9%)	176(35%)	65(50%)	
Female	392(38.1%)	327(65%)	65(50%)	
Age	633 (100%)			0.006
10–22	270 (42.7%)	227(45%)	43(33%)	
23–35	257(40.6%)	213(42%)	44 (34%)	
36–48	67(10.6%)	49(9%)	16 (5%)	
49–65	39(6.1%)	14(4%)	25(18%)	
Occupation	633(100%)			0.003
Student	444(70.1%)	391(78%)	63(49%)	
Office worker	138(21.8%)	93(18%)	45(36%)	
Self ?C employed	24(3.8%)	13 (3%)	11(8%)	
Retirees	13(2.1%)	4(1%)	9(7%)	
Income	633(100%)			0.005
≤1500	256(40.5%)	201(40%)	54(41%)	
1501–3000	184(29.1%)	155(31%)	29(22%)	
3001–6000	155(18.2%)	91(18%)	24(19%)	
≥6001	78(12.2%)	56(11%)	22(18%)	
Educational qualification	633(100%)			0.345
High school student	8(40.5%)	5(1%)	3(2%)	
College students	30(29.1%)	22(4%)	8(6%)	
Undergraduate	411(18.2%)	324(51%)	87(67%)	
Graduate or doctor	184(12.2%)	152(30%)	32(25%)	

Note: the Chi-square statistic is significant at 0.05 level

6.2 The Analysis of the Influencing Factors of Public Bicycle Selection by Binary Logistic Regression

The development of binary logistic model:

$$p = \frac{\exp(\beta_0 + \beta_1 x_1 + \cdots + \beta_k x_k)}{1 + \exp(\beta_0 + \beta_1 x_1 + \cdots + \beta_k x_k)} = \frac{1}{1 + \exp(-\beta_0 - \beta_1 x_1 - \cdots - \beta_k x_k)}.$$

In the model, p is the probability of selecting public bicycles, x_1, $x_2, \cdots$, x_k are explanatory variables, β_0, $\beta_1, \cdots$, β_k are the coefficients of the corresponding explanatory variables.

For the factors of attitude towards the behavior, a regression analysis were gone on according to whether the use of public bicycle as the dependent variable, whether participants think it is cool, flexible, time-saving, environmental friendly, entertaining, good for health, not consistent with identity as the independent variable. For the factors of subjective norms, according to whether the use of public bicycle as the dependent variable, the knowledge of PB, the registration fee, the unit price, distance, find-time, cleanness, appearance, and private bicycle and e-bicycle as the independent variable, a regression model get. For the factors of perceived behavioral controls, regressed according to whether the use of public bicycle as the dependent variable, laborious, the bicycle lane, the heavy traffic, signal for cyclist, visibility and weather as the independent variable. Then we develop binary selection model and select independent variable by “input” method to research what factors affect the choice of public bicycle.

Table 3 shows that the final chi-square statistics is 10.483 after iteration from Hosmer and Lemeshow Check and the critical value: $\text{CHINV}(0.05, 8) = 15.507$, so the chi-square statistics is lower than the critical value. From the perspective of significance, 0.233 is higher than 0.05. It indicates that the model can be a good fit and there is no significant difference.

Table 3. Hosmer and Lemeshow check (attitude towards the behavior)

Step	Chi-square	df	Sig
1	10.483	8	0.233

Table 4 elicits the factors of significant contribution for chose of public bicycles about attitude towards the behavior. Among the attitudinal characteristics, the characteristics of “environmental friendly” and “flexible” turned out to be the prominent variables with the Exp (B) value of 2.626 and 2.190 when compared with the others. From the perspective of significance, the significance of “environmental friendly” and “flexible” are lower than 0.05 and the significance of constant is 0.008 lower 0.005, so it explains that there are significant relationship between using public bicycle and environmental friendly as well as flexible. Therefore, a binary selection model can be shown below as following.

Table 4. Binary selection model regression results summary (attitude towards the behavior)

Independent variable	B	S.E	Wals	df	Sig	Exp (B)
Environmental friendly	0.816	0.237	11.881	1	0.001	2.262
Good for health	0.123	0.231	0.283	1	0.595	1.130
Entertaining	0.229	0.212	1.163	1	0.281	1.257
Cool	0.238	0.240	0.985	1	0.321	1.269
Flexible	0.737	0.215	11.733	1	0.001	2.090
Time-saving	0.002	0.217	0.000	1	0.993	1.002
Not matching identity	37.232	68459278.282	0.000	1	1.000	1.478E16
Constant	0.619	0.235	6.930	1	0.008	1.858

$$p = \frac{1}{1 + \exp(-0.619 - 0.816x_1 - 0.737x_2)}.$$

In the model, p is the probability of selecting public bicycles, x_1 is 1 when the participants use the public bicycle because it is environmentally friendly and is 0 when they do not. And x_2 is 1 when the participants use the public bicycle because it is flexible and is 0 when they do not.

Table 5 shows that the final chi-square statistics is 19.108 after iteration from Hosmer and Lemeshow Check and the critical value: $\mathrm{CHINV}(0.05, 8) = 15.507$, so the chi-square statistics is lower than the critical value. From the significant, 0.064 is higher than 0.05. It indicate that the model can be a good fit and there is no significant difference.

Table 5. Hosmer and Lemeshow Check (subjective norms)

Step	Chi-square	df	Sig
1	19.108	8	0.064

Table 6 shows the binary selection model regression results of subjective norms factors which can contribute to an increased public bicycle used. Obviously, the characteristics of “find-time” and “cleanness” are more important than other variables because the Exp (B) value (2.262 and 1.775) of them is higher than others. clearly, the significance of “find-time” and “cleanness” are lower than 0.05 and the significance of constant is 0.000 lower 0.005, so it explains that there are significant relationship between using public bicycle and find-time as well as cleanness. Therefore, a binary selection model can be shown below as following.

Table 6. Binary selection model regression results summary (subjective norms)

Independent variable	B	S.E	Wals	df	Sig	Exp (B)
The knowledge of PB	−1.146	0.218	27.554	1	0.172	0.318
The registration fee	0.252	0.230	1.203	1	0.273	1.287
The unit price	0.139	0.273	0.257	1	0.612	1.149
Distance	−0.27	0.213	0.016	1	0.899	0.973
Find-time	0.816	0.237	11.881	1	0.001	2.262
Cleanness	0.574	0.212	7.347	1	0.007	1.775
Appearance	0.307	0.246	1.564	1	0.211	1.359
private bicycle and e-bicycle	0.416	0.333	1.564	1	0.211	1.516
Constant	1.019	0.200	26.044	1	0.000	2.770

$$p = \frac{1}{1 + exp(-1.019 - 0.816x_1 - 0.574x_2)}.$$

In the model, p is the probability of selecting public bicycles, x_1 is 0 when the participants do not use the public bicycle if he (she) can't find public bicycles in 5 min and is 1 others. And x_2 is 0 when the participants do not use the public bicycle because it is not enough clean and is 1 when others.

Table 7 shows that the final chi-square statistics is 11.125 after iteration from Hosmer and Lemeshow Check and the critical value: $\text{CHINV}(0.05, 8) = 15.507$, so the chi-square statistics is lower than the critical value. From the perspective of significance, 0.195 is higher than 0.05. It indicates that the model can be a good fit and there is no significant difference.

Table 7. Hosmer and Lemeshow check (subjective norms)

Step	Chi-square	df	Sig
1	11.125	8	0.195

In summary, Table 8 highlights the determinant variable of perceived behavioral control that is closed linked with the use of public bicycles. As shown, whether there are the bicycle lanes, signals for cyclist or suitable weather contribute much for usage of the public bicycles according to the value (2.088, 1.861, 1.760) of Exp (B). And the significance of them (0.001, 0.006, 0.007) and constant (0.001) is lower than 0.005, so a binary selection model can get as following.

$$p = \frac{1}{1 + \exp(-0.609 - 0.736x_1 - 0.621x_2 - 0.566x_3)}.$$

Table 8. Binary selection model regression results summary (subjective norms)

Independent variable	B	S.E	Wals	df	Sig	Exp (B)
The bicycle lane	−0.736	0.225	10.700	1	0.001	2.088
The heavy traffic	−0.179	0.299	0.359	1	0.549	0.836
Laborious	0.533	0.336	2.522	1	0.112	1.704
Signal for cyclist	0.621	0.228	7.449	1	0.006	1.861
Weather	0.556	0.210	7.241	1	0.007	1.760
Visibility	−0.090	0.209	0.185	1	0.667	0.914
Constant	0.609	0.187	10.635	1	0.001	1.838

In the model, p is the probability of selecting public bicycles, x_1 is 0 when the participants use the public bicycle if there are not bicycle lanes and is 1 when others. x_2 is 0 when the participants use the public bicycle if there are not signals for cyclists and is 1 when others. x_3 is 0 when the participants use the public bicycle if the weather is not suitable to ride and is 1 when others.

7 Conclusion

This study investigated the demographic factors related the usage of public bicycles, and also explored the factors that affect the choice of using public bicycles from the perspective of attitude towards the behavior, subjective norm and perceived behavioral control according to TPB. The following are the conclusion obtained from the study.

For the demographic factors, the variable of gender, age, occupation and income are closely contacted with the usage of public bicycle. And the education qualification has a little effect to it.

As for attitude towards the behavior, people are more concerned about the convenience and low-carbon. Therefore, there are significant relationship between usage public bicycle and environmental friendly or flexible. From the perspective of subjective norm, people maybe care about the time-saving and comfort more than appearance of the public bicycles so that they are more particular about find-time or cleanness. What's more, for perceived behavioral control, people are more concerned about safety, and it is important for people to be competent to cycle in some particular environment, so people would have a more positive perception about cycling if there are the bicycle lanes, signals for cyclist or suitable weather.

Abstract. Vicious competition of tourism enterprises results from product homogeneity deeply manifested as homogeneity of tourism enterprise resource utilization, thus becoming the key impeding current tourism development. This paper uses niche theory as reference, illuminates the conception and connotation of niche overlap of tourism enterprise, and proposes its three-dimensional measurement model by interviews and questionnaire surveys of tourism enterprises, and this thesis also tests the data using methods such as EFA analysis and CFA analysis. On this basis, the influence mechanism of niche overlap of tourism enterprise on tourist satisfaction degree is analyzed by using structural equation. Verification result shows overlapping degree of space-time resource niche of tourism enterprises, niche overlap of market resource, niche overlap of ecology resource are all significantly negatively related to tourism satisfaction negatively.

Keywords: Tourism enterprises · Niche · Niche overlap · Measurement model

1 Introduction

Tourism industry is still in the initial phase of development at present, and the overall level of tourism enterprises' utilization efficiency of resources is relatively low, which leads to serious phenomena of product homogeneity and vicious competition affecting tourist experience. For tourism industry is a complex business ecology system which integrates many industries with blurred boundaries, problem of tourism enterprise competition cannot be explained if the competition is confined to traditional competition theory within the industry, thus many scholars have begun to use related theory of natural ecology system to research tourism phenomena, such as niche theory [8].

Niche theory, as basic theory of ecology, was widely applied in the research of related fields such as diversity of species, interspecies relation, etc. Niche refers

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_111

to a set of resources used in a community by a population or an individual, and is a "way of living" of itself [9]. Since the conception of niche is blurred, the theoretical cycle offers its measurement standard, namely niche measurements. And niche overlap is one of the most important indexes. Niche degree is used to measure the niche degree similarity of two (or more than two) populations, representing common use degree of them on a kind of resource to evaluate their level of competition [4].

In the application of the niche theory on tourism, foreign scholars prefer to use niche theory to study the tourism market segmentation. Lew and Duval [10] explained the Long Tail concept and proposed that the concept of the post-tourist, for example, is a Long Tail phenomenon. Pitts [12]'s study was to determine if there is a lesbian and gay sports tourism industry. Vanessa [15] used the Rocinha case, a favela in Rio de Janeiro, as a model for other communities to show the favela as a new niche market for tourism activity in Brazil.

Different from the foreign scholars, domestic scholars mainly discuss the definition and connotation of tourism niche, the construction of niche evaluation system and put forward niche optimization strategy from the perspective of tourism industry, tourism destination, tourism city and so on. Wang [18] firstly summarized the correlated theory research on the niche, and proposed that the industry cluster niche is its occupied resource space in the regional ecosystem through its own conditions, and further more brings forward the concept and features of the TIC niche based on its characteristics. And thus he held that the TIC niche consists of tourism resources, the cluster management and the cluster environmental niche. Wang et al. [16], by introducing the theory of ecological niche and based on the analysis of application, constructed the index system of the evaluation of theme parks in Pearl River Delta. Xiang [19] used Delphi method to choose and establish the tourism niche evaluation index, then evaluate the tourism niche of Zhangjiajie and Tianmenshan national forest park by means of on-the-spot investigation and questionnaire. Wang and Yu [17] proposed that the measurement system of the niche of regional tourism cities consists of 4 dimensions of tourism resources, market, socioeconomy and environment as well as 32 variables. Chen [3] explored how Taiwan could build a niche in Asia's cruise tourism industry.

The above researches mainly concentrated in the tourism industry, tourism market, tourism and regional tourism by using niche theory or thought. However, at present, the academic circle has little research on tourism enterprises, the core population in tourism business ecosystem. In fact, in the circumstance of explosive growth of tourism, vicious competition of tourism enterprises and product homogeneity have become the key impeding tourism's development. It is urgently needed to research the resource competition situation of tourism enterprises and resource utilization effect from the perspective of ecological system so as to optimize competition relationship.

The innovation of this paper is to applicate the niche theory to tourism enterprises, to construct a measuring index system of niche overlap degree of tourism enterprises, and to analyze the influence of niche overlap degree on tourist satisfaction by using SEM. This article mainly divides into the following several parts: the first part mainly introduces the research background and research progress, the second part mainly puts forward the theoretical model and research hypothesis, the third part constructs tourism enterprises measuring index system of niche overlap degree and tourist satisfaction, the fourth part is data collection and analysis which is based on the questionnaires and interview survey, the last part is the research conclusions and prospects.

2 Theory Model and Research Hypothesis

Scholars have identified niche factors from different aspects. People such as Hannan [6], Baum [1] elaborated the identification of niche from the aspects of enterprises' market resource demand and ability of providing products. They think enterprise niche, as the intersection of enterprise resource demand and enterprise producing ability, relies on the position where the enterprise is located and what it does. Yan A and Qing-Li DA proposed that enterprises' niche is formed by the interaction between other enterprises and themselves actively in special circumstances [21]. Shan M indicated that enterprise niche can be divided in three dimensions: human resources, tangible resources and intangible resources [13].

The above scholars' identification of niche can be summarized in two dimensions: market resource and human resource. However, tourism enterprises are service organizations satisfying tourists' tourism experience and demand by providing products in certain time and space, and the elements of tourism time and space of tourism enterprises are virtually tourism enterprises' resource. On this basis, this thesis proposes the research hypothesis as follows:

Hypothesis 1: Niche overlap of tourism enterprises can consist of three dimensions: space-time resource, market resource and productive resource.

Furthermore, in business ecosystem, competition within populations can not only affect their internal development, but also impact other populations' health. Tourists, as one of core populations in scenic business ecosystem, their health conditions are also certainly affected by the relationship of tourism enterprises. Presentation of tourist population health condition in the whole scenic business ecosystem is actually tourists' experience condition, which can be measured with the index of tourist satisfaction degree by us. Accordingly, this thesis proposes research hypothesis as follows:

Hypothesis 2: There is significantly negative influence of tourism enterprise niche degree on tourist satisfaction degree.

According to the above analysis, this thesis proposes theory study model and study hypothesis, as shown in Fig. 1.

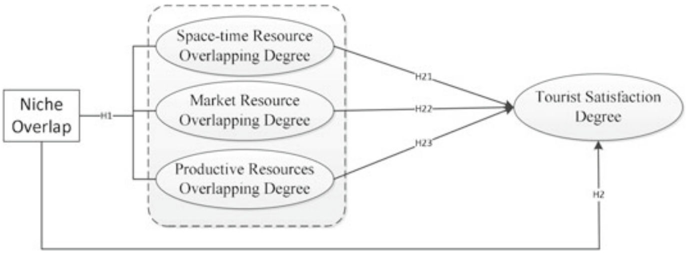

Fig. 1. Theory study model of "enterprise niche overlap-tourist satisfaction degree"

3 Variation Measurement

3.1 Measurement of Enterprise Niche Overlap

(1) Space-time Resource Overlapping Degree

Baum argued that enterprise niche, as the intersection of enterprise resource demand and enterprise producing ability, relies on the position where the enterprise is located and what it does [1]. Yan and Da [21] pointed out development opportunity and ecology strategy should be sought in time factor and social factor. Thus this thesis designs related measurement items to niche overlap, as shown in Table 1.

Table 1. Measurement items of space-time resource overlapping degree

Number	Measurement items	Sources
NO11	There are many enterprises of similar operation time-limit to your enterprise	Yan and Da [21]; Baum and Mezias [1];
NO12	There are many enterprises of similar life cycle phase to your enterprise	
NO13	There are many enterprises of same everyday business hours as your enterprise	
NO14	The enterprise is located in non-gold geographic area in the scenic spot	
NO15	There are many enterprises around your enterprise	

Data source: Arranged according to this research.

(2) Market resource overlapping degree

From the perspective of niche theory development, the influence of market resource dimension on enterprise niche has been emphasized more and more by scholars, and plenty of related research results have occurred in recent years. For example, scholars such as Dobrev [5], examined the effects of crowding in a market center on rates of change in organizational niche width and on organizational mortality. Hou et al. [7] considered that exorbitant overlapping between resources, abilities, markets, which populations need to exist and existing enterprises should be avoided to the greatest extent, for the niche overlapping will lead to competition of populations. Therefore, this thesis also adopts market resource dimension to measure the enterprise niche overlap (Table 2).

Table 2. Measurement items of market resource overlapping degree

Number	Measurement items	Resources
NO21	The enterprise is in bad situation in market competition	Hou et al. [7]; Dobrev and Hannan [5];
NO22	There are many enterprises of similar target customer groups to your enterprise	
NO23	Visitors think the product price of your enterprise is higher on equal basis of equality	
NO24	The sales method of the enterprise is similar to most enterprises	
NO25	The marketing channel of the enterprise is similar to most enterprises	

Data source: Prepared arranged according to this research.

(3) Overlapping degree of productive resources

Baum [1] considered that niche of enterprise relies on its location and functions, which is the intersection of enterprise resources and its productive capacity. Stuart and Podolny [14] proposed that niche of enterprises shall be identified by the number that the enterprise obtains in equivalent technical patents, while niche overlap in the enterprise shall be identified by the number of patents' relative references. According to the above analysis, the Thesis has extracted the dimensionality of productive resources to measure niche overlap in the enterprise as shown in Table 3.

Table 3. Measuring items of productive resources overlapping degree

No	Measuring items	Source
NO31	Staff's professional skills are better than other enterprises	Stuart and Podolny [14]; Hannan et al. [6];
NO32	Possessing similar techniques to most enterprises	Baum and Podolny [1]
NO33	Develop and launch new products and new services more often than other enterprises	
NO34	New products or services are quicker to be purchased by customers and seize the market	
NO35	The scale of manufactures is larger	

Data source: Sorted according to the research.

3.2 Tourist Satisfaction Degree

The research adopts a more mature SERVQUAL service quality scale to replace a simple tourist satisfaction evaluation. Proposed in 1990, SERVQUAL model included five dimensions, tangibles, reliability, responsiveness, assurance and empathy, and measured the distance of service quality by a questionnaire form [2]. At present, the model is considered as a most classic method to measure all kinds of service qualities appropriately and used in the relevant studies of all service industries [20]. In view of the particularity of different industries, the dimensionality and index of SERVQUAL model must be amended before it is applied to tourism industry [11]. Based on the previous studies, the paper has fine tuned the model and formed a tourist satisfaction evaluation system as shown in Table 4.

Table 4. Tourist satisfaction degree evaluation index system

Elements	Component items
Tangibles	1. Complete servicing facilities
	2. Modernized servicing facilities
	3. Staff in tidy clothes and appearances
	4. Comfortable and elegant decoration and environment
Reliability	5. Complete the things promised to the tourists without delay
	6. Show concerns and provide helps when the tourists encounter difficulties
	7. Provide products with reliable qualities
	8. Products safety can be trusted.
Responsiveness	9. Provide initiative and efficient products or service
	10. Provide prompt service
	11. Be always willing to help the tourists solve problems
	12. Provide service promptly and meet tourists' demands.
Assurance	13. Each staff is reliable
	14. Tourists will be at ease in service process
	15. The service attitude is passionate and polite
	16. Staff's communication skills
Empathy	17. Provide individual services for different customers
	18. Give an individual care for customers
	19. Pay attention to customer's demands
	20. Give priority to customer interests

Data source: Sorted according to the research.

4 Data Collection and Analysis

4.1 Data Collection

The research based on theoretical model and research hypothesis adopts one-to-one matching questionnaire method, chooses and designs each variable measurement scale and prepares and issues preliminary survey questionnaire. Due to indistinct tourism boundaries, it is difficult to define tourism enterprises. Thus, the selection of the research objects mainly focuses on the enterprises around scenic spots regarding tourism service as a main purpose. The research issues 450 questionnaires. Removing 38 questionnaires with incomplete data and obvious erring data, the research has recycled 402 valid questionnaires which indicate the recovery rate is 89.33%.

4.2 Testing of Validity and Reliability About Niche Overlap in the Enterprise

(1) Reliability test

The research adopts SPSS19.0 and AMOS17.0 software to test reliability and validity of scale. According to KMO value and Bartlett spherical test, the results show that KMO value is 0.917 and the significance probability of Bartlett spherical test's statistic is 0.000. The research adopts principal component analysis to leach factors, then extracts 3 factors in total with approximate 70.577% of gross number of variations according to the principle that characteristic root is greater than 1. The characteristic value of fourth factor is obviously less than 1, which indicates that the enterprise's niche overlap exists only 3 dimensionalities. Orthogonal rotation shall be used on factor reference axis and Varimax shall be used on the rotation. Loading coefficients of measuring items involved in all factors are basically greater than 0.7 after the rotation, which indicates that the scale has preferable discrimination validity and all measuring items are in line with the theorized expectations of factor structure. The above is shown in Table 5.

The Thesis adopts Cronbach's α coefficient to conduct a reliability test after the completion of factor analysis. Detailed analysis result is shown in Table 6.

It can be seen that internal consistency reliability of overall scale in official scale of the research is 0.917 and internal consistency reliabilities of all potential variable scales are all greater than 0.8 from reliability analysis. It indicates that consistency among all items of scales is comparatively high and official scale has a better internal consistency.

(2) Validity test

The research adopts SEM method to conduct construct validity test of all scales and the analytical model is shown in Fig. 2.

In 3 factors confirmatory factor analysis models of overlapping degree scale of niche, CMIN/DF value is less than 3, NFI, IFI and CFI values are all greater than 0.9, RMSEA value is less than 0.1 and fitting degree of all indexes is in better adaptation. The results have verified that niche overlap is formed by overlapping

Table 5. Rotating component matrix of niche overlap of tourism enterprise

Dimensionality	Measuring items	Factor loading		
		1	2	3
Space-time resources overlapping degree	NO11	0.198	0.186	0.798
	NO12	0.286	0.272	0.758
	NO13	0.284	0.217	0.795
	NO14	0.258	0.254	0.76
Productive resources overlapping degree	NO21	0.091	0.735	0.14
	NO22	0.132	0.765	0.103
	NO23	0.056	0.725	0.184
	NO24	0.165	0.729	0.27
	NO25	0.187	0.79	0.222
Market resources overlapping degree	NO31	0.84	0.133	0.23
	NO32	0.817	0.166	0.209
	NO33	0.851	0.151	0.2
	NO34	0.832	0.096	0.271
	NO35	0.867	0.141	0.194

Extraction method: Principal Component Analysis
Rotation method: Orthogonal rotation method with Kaiser standardization
The rotation is converged after 5 iterations.

Table 6. Official scale reliability

Scale (number of items)	Mean value	Variance of items	Internal consistency reliability
NO1 (4)	2.763	0.003	0.874
NO2 (5)	2.746	0.004	0.841
NO3 (5)	2.603	0.001	0.928
ST (4)	3.267	0.002	0.898
SRT (4)	3.18	0.002	0.867
SRS (4)	3.069	0.002	0.841

SE (4)	3.133	0.003	0.879
Total (34)	3.144	0.095	0.917

degree of space-time resource, overlapping degree of productive resource and overlapping degree of market resource.

Pearson's correlation coefficient is used in this study to calculate the relationship between niche overlap and tourist satisfaction. The empirical research indicates, there is no multi-collinearity between the variables, as shown in Table 7.

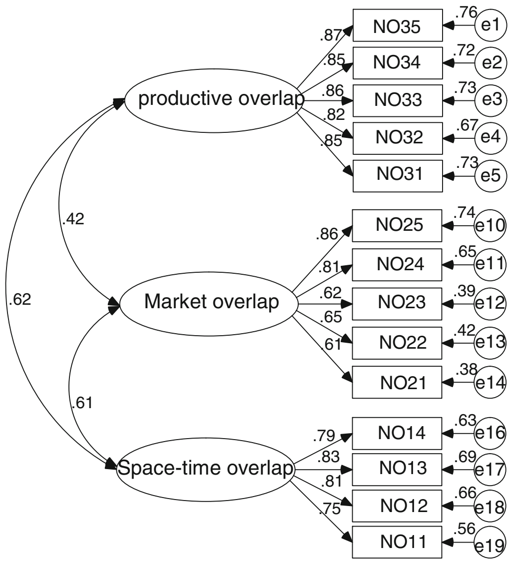

Fig. 2. Confirmatory factor analysis of niche overlap of tourism enterprise

Table 7. Pearson's correlation coefficient between niche overlap of tourism enterprise and tourist satisfaction degree

	Mean value	Standard deviation	NO1	NO2	NO3	TS

Note: ** $p < 0{:}01$, NO1 - space-time resource overlapping degree, NO2 - productive resource overlapping degree, NO3 - market resource overlapping degree, TS - tourist satisfaction degree.

Based on results above, structural equation model is presented in this thesis to analyze the influence of overlapping degree of corporate niche on tourist satisfaction degree, and as overlapping degree of space-time resource, overlapping degree of market resource, overlapping degree of productive resource and tourist satisfaction degree are incorporated into the structural equation model, model fitting is well completed, as shown in Fig. 3.

As shown in analysis results above, overlapping degree of space-time resource, overlapping degree of market resource, overlapping degree of productive resource all have obvious negative influence on tourist satisfaction degree, with their standardized regression coefficient being $\beta = -0.11^{***}, \beta = -0.07^{***}, \beta = -0.3753^{**}$ ($p < 0.001$), respectively. It is thus clear that overlapping degree of corporate niche has negative influence on tourist satisfaction degree, among which the

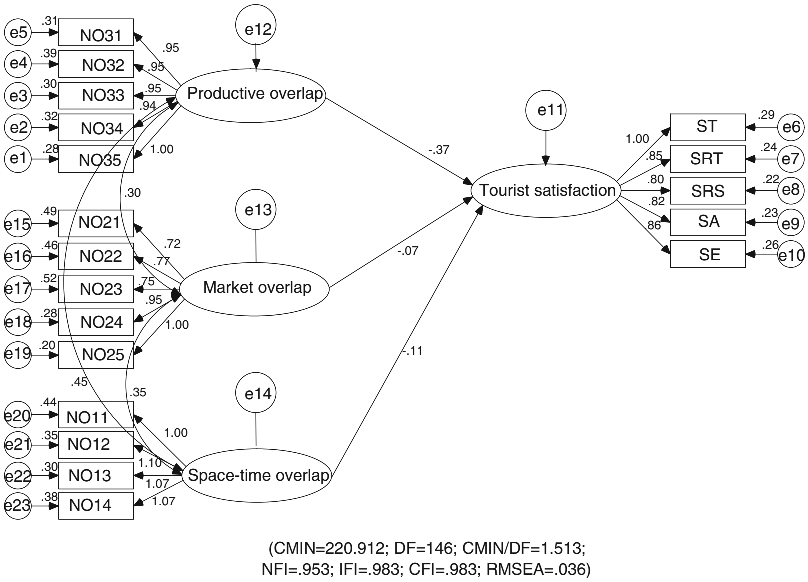

Fig. 3. The influence of niche overlap of tourism enterprise on tourist satisfaction degree

influence of overlapping degree of market resource is greater. Therefore, research Hypothesis *H2*, *H21*, *H22* and *H23* are all verified.

5 Research Conclusion and Prospect

The empirical research results indicate that overlapping degrees of corporate niche include overlapping degree of space-time resource, overlapping degree of productive resource and overlapping degree of market resource, and these three dimensionalities all have significant negative influence on tourist satisfaction degree. This is because: firstly, when business hours and location of corporations is the same as that of majority of corporations in business ecosystem of scenic spot, space-time resource overlap, as a result, competition in space-time resource of scenic spot between corporations is more intense, and in order to seek for more suitable time and space resource, the corporations will gradually consume their own resources in other aspects to survive in the competition.

Secondly, there are tourism enterprises of similar market niche inevitably in scenic business ecosystem, with different types of behavior occurring to fight for the same target customer group, such as price war, soliciting, etc., which will lead to decline of tourism satisfaction degree. Finally, tourists' experience of all products in the scenic area is actually experience of enterprise supply chains, so enterprises owning non-homogeneity technology are more likely to ally and integrate resources; and enterprises with homogenous technology tend to be subject to mutual repulsion, failing to provide better tourism experience for tourists.

In the future, research should be conducted further in combination with niche width of tourism enterprises, for niche overlap reflects the competition condition of resources used by tourism enterprises, while ecology width reflects the diversity degree of tourism enterprise resource utilization, and both of them interact with each other to influence tourists' tourism experience.

Abstract. Energy use is on the rise due to population increment and technology development. Generating electricity energy with fossil fuels causes environmental problems; moreover, their cost is high because of their depletion. For solving energy crisis and environmental problems, alternative methods for energy generation should be considered such as Renewable energy sources (RESs) which are considered as a promising alternative for fossil fuels. On the other hand, hospitals are one of the major consumers of energy. Energy costs consist a large amount of hospitals' costs; therefore, hospitals aim to minimize these costs owing to competition among health centers. The objective of this paper is to propose a long term scheduling model for the optimal sizing of the RESs among candidate technologies to meet the hospital's demand while minimizing the costs and maintaining reliability subject to economic and technical constraints. The model is run with real data from a hospital in Iran.

Keywords: Long term scheduling · Optimal sizing · Renewable energy sources · Hospitals

1 Introduction

Energy use has increased in last decades due to population and per capita usage increment. Due to fossil fuel sources depletion, importance of environmental issues and decrease in carbon emission, the energy crisis is on the rise. According to the energy crisis, most of the countries intend to generate energy with alternative sources and change their energy portfolio. Renewable energy sources (RESs) can reduce green gas emissions and environment pollution; therefore, they are proper alternatives for current generation method, and some researches focused on optimal sizing of RESs with different constraints. Moradi et al. [5] considered renewable energy sources as a reliable source of electricity. In this paper, they used Net Present Value (NPV) as an economic factor to determine type and capacity of sources. Sharafi and Tarek [8] presented a multi-objective model for determining the optimal size of renewable energy sources. They used ε-constraint

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_112

method to minimize total cost, fuel emission, and unmet load. Yamada and Raji [2] presented a model for determining the size of wind turbines, batteries, and solar panels. The goal of their paper was to minimize the costs in three years time horizon. Energy balance constraints, battery constraints, inverter model and load model constraints were considered in the paper. Abd-el-Motaleb and Bekdach [1] proposed stochastic model for optimizing size of wind turbines and energy storage units. They considered energy balance constraints, storage constraints, and also reliability constraints. Theo et al. [9] presented a linear optimization model for a hybrid power system in order to minimize net present value of costs. They chose wind turbines, solar panels and battery in an eco-industrial park as a case study.

Health centers and hospitals are one of the major consumers of electricity, where is necessary to generate energy in a continuous way and without blackouts. Health care forms a significant cost for governments; however, thanks to energy development, health care costs can be reduced [12]. Health care systems are evolving rapidly, and the number of patients is increasing due to emergence of new diseases and aging in society. Consequently, using modern medical equipment and patient increment cause to the rise in energy use. The number of health centers is increasing, and they evolved as a business industry because their competition increases. In competition market, patients have to pay parts of the costs, so health centers intend to decrease their costs as far as possible. Since hospitals consist 31% of health care costs, hospitals are considered in this paper. One way for reducing costs in hospitals is installation of RESs for energy generation [11]. Many countries allocate incentives to motivate investors for using RESs. Therefore, hospitals can use government's subsidy for supporting renewable energy sources. In this paper, hospitals are considered as energy consumers. Although supplying efficient energy is essential in hospitals, there are few researches on energy use in hospitals. Some scholars research about heating and cooling systems in hospitals [3,6]. Mavrotas et al. [4] developed a bi-objective model for minimizing costs and maximizing demand satisfaction. The technologies considered in their model were combined heat and power unit for providing power and heat, an absorption unit and/or a compression unit for providing a cooling load. Other papers focused on proper equipment selection in hospitals are [7,13].

The goal of this article is to determine optimal sizing of RESs in order to minimize the costs and conserve reliability. The paper is organized as follows. Section 2 proposes problem definition and mathematical model. Section 3 presents the numerical example, analyses results, and discusses sensitivity analysis. Finally, a conclusion is presented in Sect. 4.

2 Problem Definition

Since a significant amount of costs in a hospital is related to energy costs, careful energy planning is of a special importance in hospitals. In order to minimize the costs and reduce greenhouse gas emissions, hospitals can use renewable energy sources. Due to the importance of environmental issues, and consumer motivates for using RESs, governments consider some incentives for consumers producing renewable energies. Renewable energy sources are dependent on the natural situation for generation, and they are unpredictable; consequently, one way to increase their generation reliability is to use two or more renewable sources simultaneously [10]. For increasing generation reliability, wind turbines and solar panels are used in this paper, which means that hospital, according to its budget, can invest in solar panels and wind turbines for energy generation. Some part of required energy can be produced by RESs in this paper, and other parts are supplied by the grid. Moreover, the hospital can sell its extra produced energy to the grid. Economic factors such as inflation rate and interest rate affect decisions, so aforementioned factors are considered in this model by using NPV method for calculating objective function. The purpose of the model is to minimize investment costs in a specific period while maintaining RESs system's reliability. By solving the model, questions like the optimal size of wind turbines and solar panels and the optimum time for investment are answered.

Some assumptions are considered for the mathematical model as follows:

- The planning horizon is ten years which is divided into 120 months.
- According to geographic location, the hospital can invest in wind and solar energy.
- The hospital is connected to the main grid. Purchased energy price from the grid is varied in different time slots.
- Extra generated energy by RESs is sold to the grid with fixed price.
- Simultaneous buying energy from the grid and selling energy to the grid are not allowed.
- The investment cost of RESs is varied in time slots which is increased or decreased by the inflation rate.
- Interest rate and inflation rate are known and stable.
- The specific amount of money is considered as a budget for each time slot. The extra budget does not transfer to next time slot.
- Since the goal of the hospital is to focus on medical problems, the allocated area for installing RESs is limited.
- It is assumed that renewable energy sources use different rate of their capacity in each time slot $(\beta s, \beta w)$.
- In each time slot, minimum amount of energy has to be purchased from the grid to be used in emergency situations.
- For motivating hospitals to invest in renewable energy sources, government pays $a\%$ of sources investment cost.

To model the problem, the following notations are defined:
Indices:
t : Planning horizon (month) $t = 1, 2, \cdots, T$.

Parameters:

cap : Capacity of 1 kW of solar panels and wind turbines in a month;
βs_t : Utilization percentage of 1 kW of solar panels at time t;
βw_t : Utilization percentage of 1 kW of wind turbines at time t;
fs : Required area for installing 1 kW solar panel (Square meters);
fw : Required area for installing 1 kW wind turbine (Square meters);
F_s : Total area for solar panels (Square meters);
F_w : Total area for wind turbines (Square meters);
d_t : Energy demand of hospital at time t;
r_t : Reliability at time t;
$s_{\max}$: Maximum amount of allowable energy which can be bought from the grid;
$z_{\max}$: Maximum amount of allowable energy which can be sold to the grid;
p_s : Investment cost of 1 kW solar panel;
pm_s : Maintenance cost of 1 kW solar panel;
p_w : Investment cost of 1 kW wind turbine;
pm_w : Maintenance cost of 1 kW wind turbine;
c_t : Cost of buying energy from the grid at time (cent);
w : Price of selling energy to the grid (cent);
I_t : Budget at time t;
ss : Energy bought for emergency situations;
μ : Interest rate in a month;
α : Inflation rate in a month;
a : Government subsidy.

Decision Variables:

x_t : Installed capacity of solar panels at time t (kW);
y_t : Installed capacity of wind turbines at time t (kW);
z_t : Amount of energy bought from the grid at time t (kW);
s_t : Amount of energy sold to the grid at time t (kW);
u_t : Binary variable (1 if energy has sold to the grid).

Scheduling model intends to determine optimal sizing of RESs during 10 years time horizon as follows,

$$\min \sum_{t=1}^{T} \left[\frac{(p_s + pm_s)(1-a)(1+\alpha)^t x_t}{(1+\mu)^t} + \frac{(p_w + pm_w)(1-a)(1+\alpha)^t y_t}{(1+\mu)^t} + \frac{c_t(z_t + ss)}{(1+\mu)^t} - \frac{w s_t}{(1+\mu)^t} \right] \tag{1}$$

Subject to

$$\beta s_t \times \mathrm{cap} \times \sum_{j=1}^{t} x_j + \beta w_t \times \mathrm{cap} \times \sum_{j=1}^{t} y_j + z_t - s_t = d_t, \forall t \tag{2}$$

$$(p_s + pm_s)(1+\alpha)^t x_t + (p_w + pm_w)(1+\alpha)^t y_t + c_t(z_t + ss) - w \times s_t \leq I_t, \forall t \tag{3}$$

$$\sum_{t=1}^{T} fs \times x_t \leq F_s \tag{4}$$

$$\sum_{t=1}^{T} fw \times y_t \leq F_w \tag{5}$$

$$s_t \leq s_{\max} \times u_t, \forall t \tag{6}$$

$$z_t \leq z_{\max} \left(1 - u_t\right), \forall t \tag{7}$$

$$\frac{d_t - \beta s_t \times \text{cap} \times \sum_{j=1}^{t} x_j - \beta w_t \times \text{cap} \times \sum_{j=1}^{t} y_j + s_t}{d_t} \leq (1 - r_t), \forall t \tag{8}$$

$$x_t, y_t \geq 0, \text{ integer}, \forall t \tag{9}$$

$$z_t, s_t \geq 0, \forall t \tag{10}$$

$$u_t \in \{0, 1\}, \forall t. \tag{11}$$

The objective function is minimizing the cost of supplying energy from renewable sources and grid. The two first expressions calculate the investment and maintenance cost of the wind and solar energy sources by considering interest rate and inflation rate. The third expression shows the cost of buying energy from the grid, and the last one expresses hospital's income from selling energy to the grid.

Since supplying reliable energy is essential in hospitals, all the demand should be met which is presented in constraint (2). Constraint (3) represents the limitation of hospital's budget in each time slot. Area limitation for installing solar panels and wind turbines have been avouched by constraints (4) and (5), respectively. In each time slot, it is not possible to buy energy from the grid and sell energy to the grid simultaneously, which have been determined in constraints (6) and (7). Constraint (8) represents renewable energy sources' reliability. In this equation, the left expression shows the amount of energy which has been purchased from the grid which should be less than a specific amount. Constraints (9)–(11) indicates variable types.

3 Numerical Example

To show the performance of the model, it is solved for a hospital in Iran. The numerical example is carried out by using IBM ILOG CPLEX_Optimizer v12.3. As mentioned, the goal of this model is to find the optimal size of renewable energy sources (RESs) installed in the hospital during the ten years time horizon. For reducing forecasting errors, years are divided into months time slots (120 time slots). Hospital's monthly demand and budget are estimated during meetings with its experts. Some of the data used in the model are shown in Table 1.

The results are shown in Fig. 1. With scrutiny, it is obvious that investment is higher in first time slots. It is reasonable due to the positive inflation rate. Moreover, investments in solar panels are more than wind turbines owing to the fact that they have more productivity in the aforementioned hospital, and also they need fewer investment costs.

Table 1. Data related to time slots

Time	d(kW)	I (dollars)	βs	βw
1	12000	50000	0.5	0.23
2	12000	50000	0.6	0.3
⋮	⋮	⋮	⋮	⋮
120	15000	8750	0.25	0.3

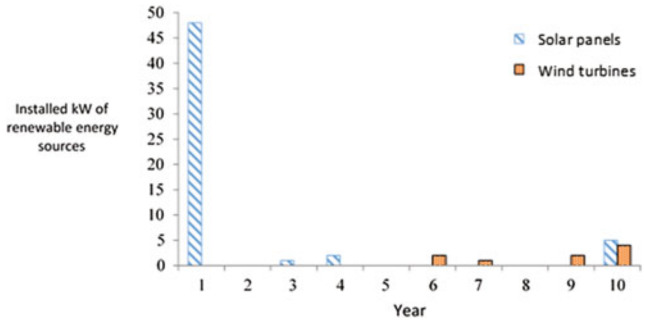

Fig. 1. Installed kW of wind turbines and solar panels in each year

Total solar panels which will be installed during ten years is 56 kW and installed wind turbines are 9 kW.

Sensitivity analysis is done for effective parameters on model such as inflation rate, interest rate, demand, reliability and etc. Some of them which are more important are elaborated in this paper.

In the aforementioned hospital, a high amount of budget is allocated to the first time slot because the decision for investment is given in this time slot. It is assumed that the budget is allocated to the hospital in the sixth time slot or at the beginning of the second year (13th time slot) with considering its interest. According to results, which is showed in Table 2, if the interest rate is between 15 and 20%, it is better to allocate budget in the first time slot. If the interest rate is between 20 and 24%, it is better to allocate budget in the 6th time slot.

Table 2. Inflation rate sensitivity analysis

Capital allocating method		Capital allocation in the first period	Capital allocation by considering its profit in the sixth month	Capital allocation by considering its profit in the second year
Objective function	Inflation rate = 15%	80226	82562	83379
	Inflation rate = 20%	67324	64824	67849

Table 3. Purchased price sensitivity analysis

	40% decrease in price	20% decrease in price	Current price	20% increase in price	40% increase in price	250% increase in price
Solar panels kW	56	56	56	56	56	56
Wind turbines kW	9	9	9	9	9	9
Amount of purchased energy from the grid	96460	90828	89744	88544	87416	53020

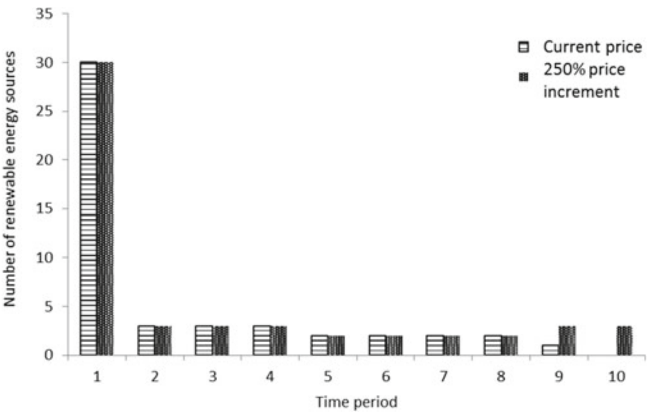

Fig. 2. Installed kW of wind turbines and solar panels in each year

When purchased price is increased, it is expected that investment in RESs is increased too. However, other scenarios can be happened due to other parameters. For example, it is possible that the number of RESs is decreased or even stay stable, but the time of investment is changing in these scenarios. According to results, shown in Table 3, with increment or decrease in purchased price, number of installed RESs is stable, and the time of investment is just changed. For understanding such changes, variations of investment time for current price and 250% price increment are shown in Fig. 2 for ten time slots. With current price, investment in wind turbines is started from 66th time slot; however, if purchased energy increases 250%, investment in wind turbines starts from 9th time slot, which causes to take advantage of wind generation in 57 more time slots.

Energy price is low in Iran; however, in developed countries such price is a significant amount. As a result, we compared current price in Iran with current price in United States, which is about 250% higher than energy price in Iran.

Table 4. Wind turbine utilization percentage sensitivity analysis

	30% increase in wind turbines utilization percentage	20% wind turbines utilization percentage	10% wind turbines utilization percentage	Current utilization percentage	10% wind turbines utilization percentage	20% wind turbines utilization percentage	30% wind turbines utilization percentage
Solar kW panels	48	48	51	56	57	60	61
Wind turbines kW	12	13	12	9	9	7	7

Table 5. Wind turbine utilization percentage sensitivity analysis

	20% increase in solar panels utilization percentage	10% increase in solar panels utilization percentage	Current utilization percentage	10% decrease in solar panels utilization percentage	20% decrease in solar panels utilization percentage
Solar panels kW	52	53	56	57	64
Wind turbines kW	4	7	9	13	13

Table 4 shows sensitivity analysis for wind turbine utilization percentage. When wind turbine utilization percentage increases, investment in solar panels decreases, and investment in wind turbines increases. Whatever the wind turbine utilization percentage increases, there is less need for wind turbines. With wind turbine utilization percentage reduction, the number of solar panels increases.

Table 5 presents sensitivity analysis for solar panels utilization percentage. By increment in solar panels utilization percentage, amount of installed kW of wind turbines decrease. Moreover, there is less need to install solar panels owing to the fact that more demand will be met by less solar panels with higher utilization percentage. On the other hand, by decrease in solar panels utilization percentage, the number of wind turbines increases as far as area constraint permits.

4 Conclusion

In this paper, long term scheduling model was presented for determining optimal sizing of renewable energy sources in hospitals. The model aimed at minimizing costs while maintaining reliability according to specific constraints in hospitals such as area limitation and budget constraint. By solving the model with real data of the hospital in Iran, the model can reduce 10% of costs comparing with the time when energy is only purchased from the grid. In presented model, planning horizon was divided into monthly time slots which caused an increment in forecasting errors. For further researches, authors can deal with daily or weekly data. Also in this model, the price of required field for installing wind turbines and solar panels was not considered. Authors can investigate the effect of field price on model outputs.

Life Cycle Assessment of Waste Mobile Phone Recycling–A Case Study in China

Tingting Liu, Moudi Mahdi, and Liming Yao(✉)

Uncertainty Decision-Making Laboratory, Sichuan University, Chengdu 610064, People's Republic of China
lmyao@scu.edu.cn

Abstract. With the rapid pace of technological development, electronic waste (e-waste) has become one of the fastest growing waste streams in the world. The exponential growth of e-waste, which is disposed of in landfills, incinerated, or dismantled, now significantly contributes to the massive increase in overall waste. This paper assesses the waste produced from recycling mobile phones in China and examines the influence of the waste that is released into the environment. The mobile phone recycling process at formal recycling facilities in China is investigated as a case study. The results highlight the toxicity of the waste and the influence such waste has had on the environment. Life cycle assessment (LCA) was employed to analyze the mobile phone recycling process and Gabi was used to quantitatively indicate the flows and environmental impacts. The results showed that resources recovery, human health, and ecosystem quality are the main effects of the mobile phone recycling waste produced. Based on this quantitative analysis, to reduce the environmental impact of mobile phone recycling, the demand for recycled materials, environmental awareness, law enforcement, and the e-waste recycling system were found to be significant drivers.

Keywords: Waste mobile phone · Life cycle assessment · Recycling

1 Introduction

Electronic waste, also known as e-waste, has been one of the major contributors to the waste stream since the rapid growth of advanced technological products [6]. E-waste includes waste electrical and electronic products such as televisions, desktop computers, microwaves and mobile phones. In recent years, economic and technological development in China has seen as massive growth in mobile phone penetration and a consequent rise in mobile phone waste.

Currently over 40 million tonnes of e-waste is generated annually in the world and is growing every year. Of all the kinds of e-waste, the growth in mobile phone waste has been three times faster than total annual waste [19]. Current mobile phone using data indicates that there are 7.2 billion active mobile phones in 2016, with over 1.305 billion of these being in China, a penetration rate of 93.1%

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_113

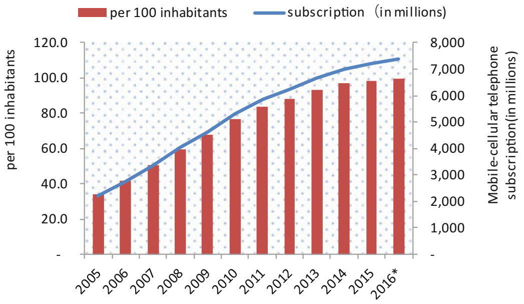

Fig. 1. Global mobile-cellular subscriptions, total and per 100 inhabitants, 2005–2016. Note: * Estimate

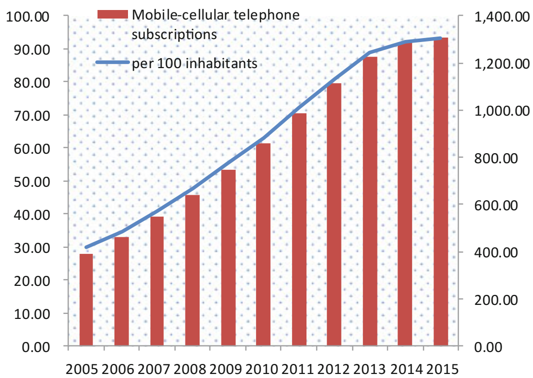

Fig. 2. China mobile-cellular subscriptions, total and per 100 inhabitants, 2005–2015

(see Figs. 1 and 2) [25]. About 77 million mobile phones are discarded every year in China, a figure the United Nations environmental program has predicted to be 7 times higher by 2020 [11].

The growing quantity of e-waste has begun to have a severe impact on the environment; especially in developing countries. As the leading manufacturing country of the world, China has become an "electronic waste treatment plant", with informal mobile phone recycling having become a major source of toxic pollution [13]. With rising climate change and water and land pollution concerns, mobile phone recycling waste has attracted increasing attention, forcing the mobile phone production industry to find solutions to decrease the environmental impact. In addition, various methods have been developed for mobile phone recycling to reduce the environmental damage. There has been a growing body of research into the recycling of waste mobile phones in China and the inherent problems. Wang et al. evaluated the potential yield of indium recycled from waste mobile phones in China [21], and Yi-Bo et al. and several others have examined the recovery and recycling of old mobile phones in China [23], and the other scholars did [4].

The main methods that have been applied to waste management analysis are data envelopment analysis(DEA) [2], the index decomposition analysis method(IDA) [12], and the structure decomposition analysis method (SDA) [1]. Life Cycle Assessment (LCA) was first used in 1969 when the Midwest Research Institute tracked and quantitatively analyzed the complete process of beverage containers from raw materials extraction to final disposal [3]. With development, the LCA has been included in the ISO14000 series of environmental management standards and has become an important support tool for international environmental management and product design [8]. LCA has been widely used in environmental assessments in such areas as food waste management [14], waste water [18], and plastic production as well as in waste electrical and electronic equipment (WEEE) management [10].

As an environmental management tool, LCA has expanded the boundaries of research systems, as it encompasses the entire life cycle of resource use, energy consumption and waste discharge and provides an evaluation of the potential environmental impact at each stage. This paper assesses the recycling of waste mobile phones in China using LCA. To date, analyses of the environmental impact of recycling waste mobile phones has lacked a systematic and scientific focus and has tended to ignore the management of discarded mobile phones [15]. In this paper, the life cycle assessment of the discarded mobile phone recycling process is quantitatively evaluated to identify the main factors influencing the environment and provide decision support for the waste management of other small electronic devices.

The remainder of this paper is structured as follows. In Sect. 2, the current recycling process in China is outlined, an abandoned mobile phone path analysis is conducted, and the latest recycling process explained. Section 3 applies the LCA to the mobile phone recycling process and gives the results. Section 4 gives suggestions and recommendations based on the analyses.

2 Mobile Phone Recycling in China

2.1 Recycling Status

China has had a rapid growth in e-waste streams over the past ten years [11], with mobile phone waste being the most rapidly growing. Because there has not been a regimented recycling system established in China, most waste mobile phones are kept, donated to others or discarded with other house-hold waste; the formal recovery rate has been only about 1% [25]. The recycling of batteries and other waste mobile phones parts has mainly been conducted through nonprofessional channels such as street vendors or small electronics shops or through recycling platforms on the internet. After recovery, refurbished mobile phones are generally sold in a second-hand market or sold at a low price in remote towns and villages. Mobile phones that cannot be refurbished often end up in illegal dismantling workshops, where workers extract the copper, gold, silver and other valuable metals using such processes such as acid leaching and open burning, processes which not only damage the health of workers but also severely pollute the surrounding environment.

From a product to waste, a mobile phone can change hands hundreds of times; they can be retained by consumers, returned to a retailer, sold to a second-hand shop or sent to recycling. The specific circulation paths are shown in Fig. 3.

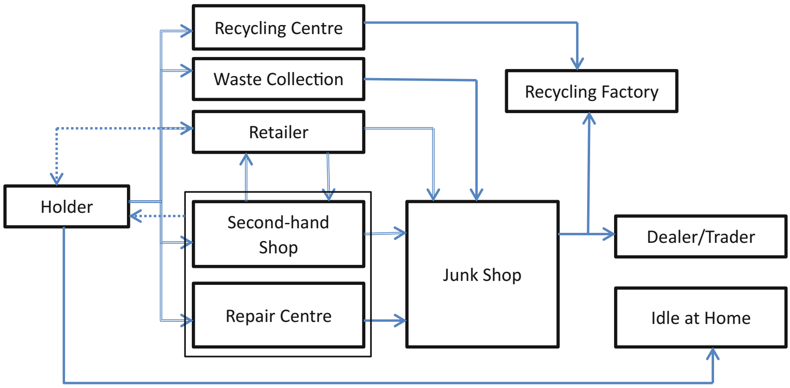

Fig. 3. The flow of waste mobile phones in China

2.2 Recycling Mode

This paper evaluates the pollution produced in the recycling phase from the perspective of material flows using the standard life cycle assessment method, examines the waste mobile phone recycling process in formal recycling facilities in China as a practical case study (see Fig. 4) and identifies the factors that adversely impact the environment in the recycling phase.

The brief description of the recycling process is as follows: after being transported to the waste treatment plant, the mobile phones are manually disassembled and the phone casings, printed circuit boards, lithium batteries, LCD screens and other main components extracted. Then, each of these components is processed separately. The ABS/PC plastic casings are crushed into plastic pellets then reused as raw materials, the stainless steel, copper and other metals are melted, with a further smelting processing step needed for the printed circuit boards and lithium ion batteries (recovery of electrolyte solvent) to recover the copper, gold, silver, palladium, cobalt, lithium, tin and other metals. LCD displays are generally incinerated to reduce environmental waste and the remaining residues are put into landfill.

Mentioned in the process: (1) the life cycle of the mobile phone at each stage from production, use, and disposal including the transportation of the various materials; however, the transportation and landfill residue stage after disassembly are not taken into account. (2) only lithium ion scrap mobile phone batteries and mobile phone LCD displays are considered.

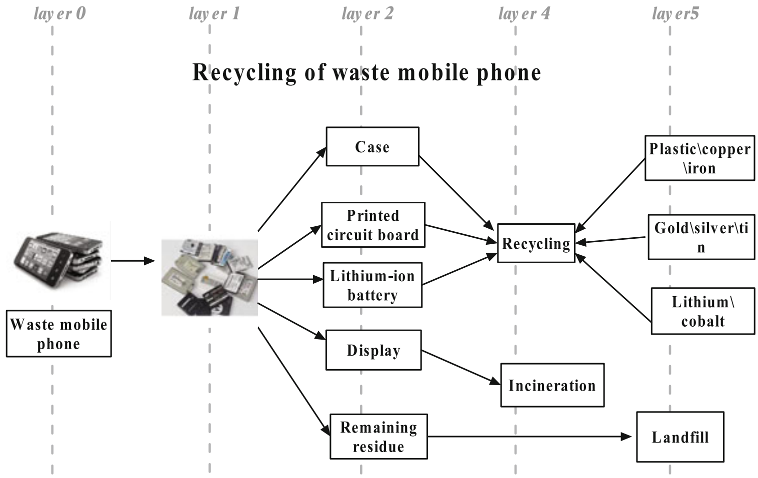

Fig. 4. Recycling process

3 LCA on Recycling Waste Mobile Phone

The LCA has four interrelated steps, which we applied to the mobile phone recycling process, the rough contents for which are shown in Fig. 5.

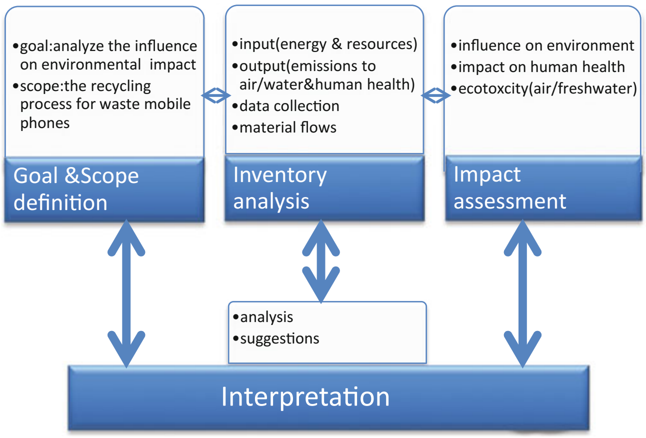

Fig. 5. Detailed content of the four steps

3.1 Goal and Scope Definition

The study object in this paper is the abandoned mobile phone. The functional unit is set to a tonne of phones of various brands and models, with the data for each component being set at an average value. The study scope for the system

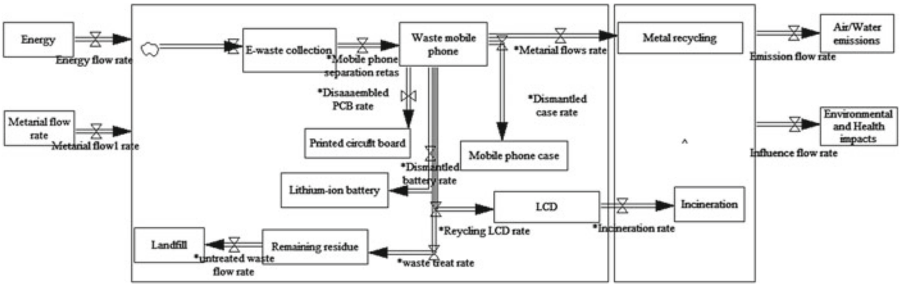

Fig. 6. Flows at a formal recycling facility

is set for disassembly, waste collection, sorting, processing and final disposal (Fig. 6) and an inventory analysis and impact assessment for the energy and resource consumption and pollutant emissions at each stage is established.

3.2 Inventory Analysis

From relevant research data regarding domestic and foreign waste mobile phone processing and combined with the Chinese current waste recycling, the main process inventory data related to the recycling process was determined (see Table 1). The data in this paper was taken from the ecoinvent database [7];

Table 1. Inventory analysis

Process flow	Inventory data
Disassembly	GLO: manual treatment plant, WEEE scrap [Recycling] = 2500 tone/yr. GLO: mechanical treatment plant, WEEE scrap [Recycling]/GIO/IU = 50,000 tone/yr
Plastic recycling	GLO: manual treatment plant, WEEE scrap [Recycling] = 2500 tone/yr
Iron metal	RER: steel, electric, un- and low-alloyed, at plant [Beneficiation]
Metal	SE: copper, secondary, from electronic and electric scrap recycling, at refinery [Beneficiation]
Printed Circuit Boards (PCBs)	GLO: disposal, treatment of printed wiring boards [Recycling] SE: gold, secondary, at precious metal refinery [Beneficiation] SE: silver, secondary, at precious metal refinery [Beneficiation] SE: palladium, secondary, at precious metal refinery [Beneficiation]
Tin	RER: tin, at regional storage [Beneficiation]
Li-ions batteries	GLO: disposal, Li-ions batteries, hydrometallurgical [Recycling] GLO: cobalt, at plant [Beneficiation] GLO: lithium hydroxide, at plant [inorganics]
LCD	CH: disposal, LCD module, to municipal waste incineration [municipal incineration]
Landfill	Disposal, municipal solid waste, 22.9% water, to sanitary landfill/CH U

as an overview and methodological framework for the LCA, the ecoinvent database is the most consistent and transparent life cycle inventory database in the world [22].

Inventory analysis involves the tracking of the input and output flows of a product system including the materials, water and energy used and the waste released to the air, land and water [17]. In the model developed in this paper, energy and raw materials consumption is taken into account and GaBi, a powerful life-cycle assessment tool, is used to generate the model from the inventory data to assess the sustainability solutions [24].

Fig. 7. Gabi built model

As shown in Fig. 7, the input for this model is 1000 kg of waste mobile phones.

3.3 Life Cycle Impact Assessment

LCIA is a qualitative and quantitative analysis of environmental impacts based on the elements listed in the inventory analysis (LCI) [20]. It is used to evaluate and interpret the environment impacts of a product system by assigning quantifiable measurements and connecting the input and output material inventories to obtain the damage points of a specified boundary system.

Generally speaking, the LCIA includes the following steps: classification of the elements listed in the inventory analysis process; a qualitative and quantitative analysis of the elements; identification of the major environmental factors in all aspects of the system; and analysis and judgment of the environmental factors. This paper identifies and analyzes the major environmental factors in the mobile phone recycling process. The environmental factors include ecotoxcity, cancer effects and human ecotoxicity [16].

3.4 Interpretation

In this section, the evaluation and improvements for the mobile phone recycling process are discussed, after which, with the aim of reducing the burden on the environment, suggestions are given to improve the current recycling mode of

China. In line with the goals and scope of the analysis, the recycling process results were evaluated, from which we were able to come to conclusions and develop recommendations.

The inventory results from the model focused on three main aspects. The first was the recovery of resources and materials. Valuable materials, such as copper, gold, and silver, which can be recycled and reused, were retrieved and the other materials treated as waste. The second aspect was human health concerns. Many related environmental issues such as carcinogenic materials, climate change, ozone depletion, radiation, and organic and inorganic respiratory irritants can cause various diseases, premature death and other non-normal deaths, reducing life expectancy. This aspect was measured in units of disability adjusted life years (DALY), which examined two kinds of health losses; disability and death; to determine the social impact of possible medical conditions on population health. This indicator has also been adopted by the World Bank and the World Health Organization. The third aspect focuses on ecosystem quality which refers to the ecological environmental biodiversity loss within a given time and space caused by environmental issues such as acidification/eutrophication of land and water bodies, toxicity, land-use changes [5], and air emission [9]. The measurement units for this aspect were the potentially disappeared fraction (PDF) m^2yr and the potentially affected fraction (PAF) m^2yr.

4 Discussion

The Chinese recycling waste mobile phone process was examined in this paper using LCA as the evaluation tool. A model was proposed and the possible three impact factors; resources, human health, and ecosystem quality; were analyzed to assess the environmental impact of the recycling process. In the model building procedure, resources consumption and material emissions were found to have a certain degree of impact on the environment, and further research can extract specific data to analyze the effects of specific substances such as heavy metals, CO_2 and NO_2. Because of the speed of mobile phone technological development, the rate of mobile phone disposal is expected to increase, further impacting the environment. If waste mobile phones can be effectively recycled, there will be less environmental and health effects, improving both the economy and the residents quality of life. This paper gave an assessment on the recycling process of waste mobile phone in China, identified the main factors affecting the environment. On the basis of this analysis, proposals were given to improve the eco-efficiency in recycling process. First, relevant policies should be presented to standardize the recycling behavior of citizens and market. Second, the recycling technology should be improved. Besides, a more eco-efficient recycling model is needed. The three main factors in this paper; resources, human health, and ecosystem quality; will be taken into account in the model.

A Malmquist Index-Based Dynamic Industrial Green Efficiency Evaluation in Sichuan Province

Xuhong Liu(✉) and Xiaowen Jie

Business School, Sichuan University, Chengdu 610064, People's Republic of China
liuxh_99@163.com

Abstract. In this paper, the DEA-Malmquist index is used to evaluate the industrial green efficiency of 18 cities in Sichuan province during 2008–2014. The study found that in the overall level, the industrial green efficiency of Sichuan prefecture level cities' is low, but it is growing year by year in recent years. The technical efficiency index grows rapidly, and the technological progress index weakened the role of technical efficiency. Industrial green efficiency of Chengdu Plain economic zone is the highest in the four economic zones, followed by the Panxi economic zone, South Sichuan economic zone, lowest in Northeast Sichuan economic zone. Industries need to increase the intensity of the green transformation in Sichuan province.

Keywords: Malmquist index · Dynamic evaluation · Industrial green efficiency · Sichuan province

1 Introduction

The industrial developments of China have received great achievement recent years, but the past extensive industrial mode was at the cost of environment pollution and excessive resources consumption, which results in the problems of resource constraint and environment pressure more visibly. And the resource utilization has also become one important factor to measure the competitiveness of a country's manufacturing industry, and the industrial green development is the necessary way to promote international competitiveness. In order to change the industrial mode of high involvement, high consumption and high pollution, to promote the region industrial economic development, the 13th Five Year Plan outline of national economic and social development had put forward higher requirement for industrial green development.

Sichuan province, as the most important economic area of China western, its industrial green development is in what level, whether the industrial green efficiency has improved. The deep research of these issues would be great theoretical and practical significance. So based on the urgent need of green development, the presented paper takes the prefecture-level city as research objects, by using DEA research method to dynamic evaluate the green efficiency of industrial inputs and its output. And propose countermeasures and suggestions to improve industrial green efficiency of Sichuan province.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_114

2 Literature Review

Industrial green development is the inner requirement and inevitable choice of new industrialization. United Nations Industrial Development Organization (UNID) definition that green development is a sustainable industrialization mode of the production and consumption by effective utilization energy resources, low carbon emission, low waste reduction, during the industrialization development process to expand in order to eliminate poverty and create employment opportunities. The proposed research consider that the industrial green development is under the theory guidance of sustainable development and circular economy, through green design, green production, green management and other aspects of the control, to realize the high utilization rate of energy resource, low environmental disruption, high comprehensive benefits development mode.

At present, the foreign scholars are focused to research the connotation of industrial green development and evaluation of its efficiency. Eiadat et al. [2] and Nagesha [11] selected patent number of green process and the carbon dioxide emissions to assess the industrial green efficiency, Honma and Hu [6] used the random front model to evaluate the industrial green efficiency. There are scholars had researched the influence factors of green development on the specific industry, Vasauskaite et al. [15] put forward R&D investment, energy saving technology or energy management system can promote the sustainable development of Lithuania furniture industry. Fleiter et al. [4] evaluated the 17 process technologies of the pulp and paper industry in Germany, and considered that the innovation of paper mills and paper drying technologies in heat recovery systems is the most influential technology for energy conservation and green development. Mukherjee et al. [9] proposed computer-aided process design can optimize the energy and material flow to minimize the impacts from other harmful emissions. Kanagaraj et al. [10] reviewed different cleaner technological methods of reducing the generation of solid and liquid wastes in leather industry.

Domestic scholars Chen et al. [1] researched the influencing factors of industrial green development. Wang and Huang [16] according to the five indexes of industrial and social development, recycling, resource reduction, pollution reduction, resource and environmental security, used AHP method to evaluate the development of industrial circular economy in Jiangsu province from 1985 to 2003. And they introduced the concept of "obstacle degree", to quantitatively diagnosis obstacle in different stages of industrial circular economy development in Jiangsu province quantitative. Tu and Xiao [14] established frontier function model of environmental by directional distance function, and calculated the green total factor productivity of industrial enterprises above designated size, with energy consumption and environmental pollution in 30 provinces of China in 1998–2005. As well the pollutants considered the emissions of industrial sulfur dioxide. It has found that the industrial development In the eastern coastal areas was more harmonious with the environment, and the environmental technology efficiency was generally low in the central and western regions. Mei et al. [8] established the evaluation index system of green development efficiency of coal industry by improved DEA. Wu [17] analyzed China's industrial total factor productivity (TFP) growth in 1998–2007 under environmental constraints through Malmquist-Luenberger index. The results showed that the TFP of western industry was growing fastest, eastern followed, while the central growth was the slowest. Zhang and Zhu [22] took the non-expected industrial exhaust emissions as input variables, and measured the efficiency of industrial innovation based on green growth. It was considered that there was a phenomenon of increasing returns to scale in the Western region. Yang [19] used DEA method to measure the efficiency of low carbon economy in Sichuan Province, based on the analysis of energy consumption and carbon emissions, and concluded that the efficiency of developing low-carbon economy was still not high in Sichuan Province, which was mainly restricted by technology shortage and scale bottleneck.

Therefore, the researches of industrial productivity considering of resource environmental factors are basically from the regional perspective. There are few studies on the efficiency of industrial development from the perspective of Economic Zone. Or mostly concentrated in the eastern region of China, such as the Pearl River Delta urban agglomeration, Shandong peninsula urban agglomerations and other places, the city of the western region was less discussed. So the presented paper based on the original data of prefecture level cities in Sichuan Province, evaluates the status of its industrial green development and lays the foundation for further research.

3 General Situation of Industrial Green Development in Sichuan

At present, industrial development in Sichuan Province is in the middle stage, but according to the environmental Kuznets curve, the negative impact on energy and the environment is still relatively large of the current industrial development in Sichuan [7]. Moreover, Sichuan is a traditional resource and energy province, in which has proven reserves of 132 kinds of mineral resources, accounting for 70% of the total resources in China. This will inevitably lead to its industrial development mainly resource oriented. From 2005 to 2015, the average annual growth of GDP in Sichuan province is 8.1%, but the average annual growth of total energy consumption is 3.5%, which put enormous pressure on Sichuan's resources.

It can be seen from Fig. 1 that, energy consumption per unit of industrial added value and energy consumption per unit of GDP in Sichuan continued to decline (2005–2013), decreased by 48.64% and 32.67% respectively. This shows that the efficiency of industrial energy utilization in Sichuan province has increased rapidly, and the industrial structure of its low-end has improved. But on the other hand, by the end of 2014, raw material resources traditional industry in Sichuan province accounted for up to 43%, and low-end manufacturing industry accounted for nearly 30%. It indicates that Sichuan province still needs to further increasing the green structure transformation, so as to improve the utilization efficiency of resources and energy. Figure 2 showed that the discharge of industrial waste water, waste gas and solid waste (hereinafter referred to as three wastes) per unit of GDP in Sichuan Province decreased year by year during the period of 2005–2013, with the decreasing rate of 38.96%, 32.07% and 85.19%. These were higher than the decreasing rate of national industrial three wastes emissions (30.63%, 21.85% and 72.89%). It indicates that in the process of industrial development, Sichuan Province compared to the national, the level of mitigation to environmental pollution is higher. In addition, although the industrial waste water, waste gas per unit of GDP in Sichuan province is lower than the national level after 2010, the industrial solid waste generated per unit of GDP is still higher than the national recently. It showed that the situation of environmental pollution in Sichuan province is still grim, and it is an important way of strengthening the industrial green transformation to ease the pressure of resources and the environment.

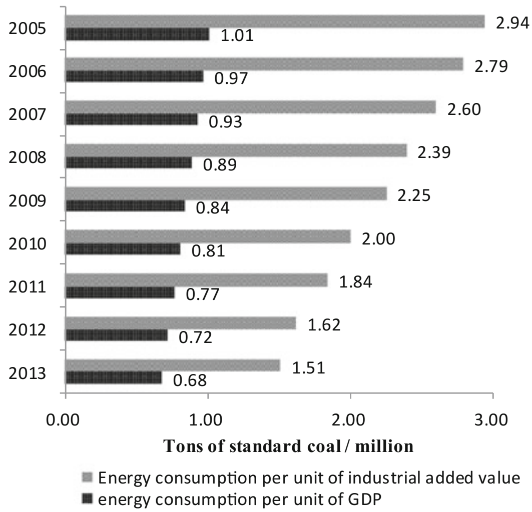

Fig. 1. Resource consumption situation of Sichuan province in 2005–2013 (Source: China Statistical Yearbook)

4 The Measurement of Industrial Green Efficiency

4.1 Malmquist Index Model

Malmquist index was proposed by the famous economist Malmquist in 1953, then Cavers et al. and Fare applied this index to estimate productivity. It can describe multiple input variables and multiple output variables of production technology, and is a method of measuring total factor productivity using panel data by

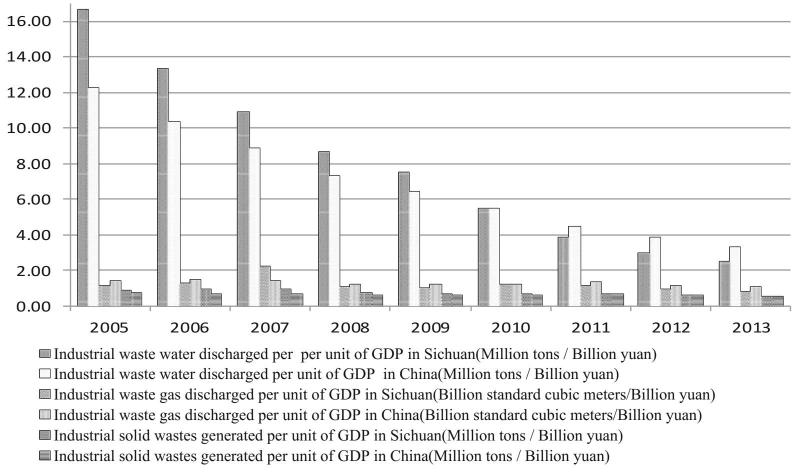

Fig. 2. Comparison of “three wastes” emissions in Sichuan province and China in 2005–2013 (Source: calculated according to the Chinese Statistical Yearbook 2006–2014)

nonparametric. In empirical analysis, researchers generally use Malmquist index based DEA by Fare et al. [3]. Its true value is approximately:

$$M_0{}^{t+1}\left(x^{t+1}, y^{t+1}, x^t, y^t\right) = \frac{D_0{}^{t+1}\left(x^{t+1}, y^{t+1}\right)}{D_0{}^{t}\left(x^{t}, y^{t}\right)} \times \sqrt{\frac{D_0{}^{t}\left(x^{t+1}, y^{t+1}\right)}{D_0{}^{t}\left(x^{t}, y^{t}\right)} \times \frac{D_0{}^{t+1}\left(x^{t+1}, y^{t+1}\right)}{D_0{}^{t+1}\left(x^{t}, y^{t}\right)}}. \tag{1}$$

In formula (1), M_0^{t+1} is the index for decision making unit DMU0 in t+1 period, $(x^t,\ y^t)$ and $(x^{t+1},\ y^{t+1})$ represent input-output vectors for period t to period $t+1$ respectively, D_0^t and D_0^{t+1} represent the distance function taking technology as a reference for period’s t and $t+1$ techniques. Further, under the assumption of variable returns to scale, formula (1) can be rewrited as follows:

$$\begin{aligned} M_0{}^{t+1}\left(x^{t+1}, y^{t+1}, x^t, y^t\right) = & \frac{D_0{}^{t+1}\left(x^{t+1}, y^{t+1}|V\right)}{D_0{}^{t}\left(x^{t}, y^{t}|V\right)} \\ & \times \left[\frac{D_0{}^{t+1}\left(x^{t+1}, y^{t+1}|C\right) D_0{}^{t}\left(x^{t}, y^{t}|V\right)}{D_0{}^{t}\left(x^{t}, y^{t}|C\right) D_0{}^{t+1}\left(x^{t+1}, y^{t+1}|V\right)}\right] \\ & \times \sqrt{\frac{D_0{}^{t}\left(x^{t+1}, y^{t+1}\right)}{D_0{}^{t+1}\left(x^{t+1}, y^{t+1}\right)} \times \frac{D_0{}^{t}\left(x^{t}, y^{t}\right)}{D_0{}^{t+1}\left(x^{t}, y^{t}\right)}}. \end{aligned} \tag{2}$$

In formula (2), V represents a variable size, C represents the same size. The first item represents the pure technical efficiency index (Pech), the second represents the scale efficiency index (Sech), and the third represents the technical progress index (Techch), that is Tfpch = Effch × Techch = Pech × Sech × Techch. Among them, the technical efficiency index measures the change degree to the production frontier of each decision unit from period t to period $t+1$, the technical progress index measures the moving degree of production frontier from period t to period $t+1$, the pure technical efficiency index reflects the technical efficiency when the scale returns unchanged, and the scale efficiency index reflects the optimal production scale of the decision unit. This paper uses directional output variables to measure the industrial green efficiency of prefectural-level cities in Sichuan. When the index is equal to 0, indicating it has no effect on the industrial green efficiency. If the index is greater than 1, indicating a promotion effect, or vice versa, showing there is a blocking effect.

4.2 Evaluation Indexes and Data Sources

The selection indexes in industrial green efficiency evaluation system are not only to meet the needs of industrial economic development, but also to meet the demands of environmental and social development. The presented paper selects evaluation index of industrial green efficiency combining with previous studies [13,18,21], and on the basis of following principles of scientific, systematic and operational. As shown in Table 1, input indicators select key elements of industrial development process. X1 and X2 represents human input and capital input of industrial development respectively. X3 reflects investment in energy application. Output indicators select total industrial output value (Y1) and total

Table 1. Evaluation index of industrial green efficiency

Indicator types	Index code and index name	Unit	Data sources
Input index	X1: employment number[a]	Ten thousand people	Statistical Yearbook of Sichuan Province
	X2: total investment in fixed assets[b]	Billion yuan	China City Statistical Yearbook
	X3: industrial added value of energy consumption	Tons of standard coal/million	
Output index	Y1: total industrial output value	Billion yuan	
	Y2: total discharge of industrial waste pollution[c]	Ton	

Notes Based on data availability. [a]Employment number selects the number of employed persons at the year-end in the mining, manufacturing and electricity, gas and water production and supply industries. [b]Total investment in fixed assets selects gross fixed assets of industrial enterprises above-scale on behalf of existing production and operation scale and technical level of industrial enterprises. [c]Because the comprehensive utilization rate of industrial solid waste in cities are all high and have no remarkable difference, so the output indicators mainly selects industrial emissions of waste water, waste gas (SO_2) and smoke (powder) dust.

discharge of industrial waste pollution (Y2) respectively reflects the industrial output and pollution emissions of each cities. In order to eliminate the influence of inflation, the total industrial output value of current year was converted to constant price in 2005, according to the ex-factory price index of industrial products. And the index unit of total discharge of industrial waste pollution was processed.

Each evaluation index data are from statistical yearbook of Sichuan and City Statistical Yearbook during 2005 to 2014. Some missing data has been processed accordingly to ensure the accuracy of indicators. Due to a large number of missing data in Ganzi, Aba, Liangshan area, this paper takes other 18 cities in Sichuan province as the research object.

Among them, total discharge of industrial waste pollution uses entropy weight method to calculate the index weight, and take reciprocal at last as a bad output. The process of calculating as follows:

(1) Standardizing the industrial emissions of waste water, waste gas (SO_2) and smoke (powder) dust. X_{ij} Indicates J index values in I area:

$$r_{ij} = \frac{(X_{j\,\max} - X_{ij})}{(X_{j\,\max} - X_{j\,\min})}.$$

(2) Calculating the entropy of each index, m is the number of evaluation units, n indicates the number of indicators:

$$H_i = -\frac{1}{\ln_m} \sum_{i=1}^{m} \frac{r_{ij}}{\sum_{i=1}^{m} r_{ij}} \times \ln \frac{r_{ij}}{\sum_{i=1}^{m} r_{ij}} \left(\text{while } \frac{r_{ij}}{\sum_{i=1}^{m} r_{ij}} = 0,\ \ln \frac{r_{ij}}{\sum_{i=1}^{m} r_{ij}} = 0. \right)$$

(3) Obtaining the entropy weight of every index. To keep the longitudinal comparability of the dynamic evaluation results, according to the method of Zhang and Zhou [23], the presented paper takes the average entropy weight as the final entropy weight to avoid the differences in each year:

$$W_j = \frac{1 - H_j}{n - \sum_{j=1}^{n} H_j}.$$

(4) Calculating the total discharge of industrial waste pollution (abbreviation to TIW):

$$TIW = \sum_{j=1}^{n} r_{ij} w_j.$$

5 Result

5.1 Overall Analysis of Industrial Green Efficiency in Sichuan

The paper using DEAP 2.1 software to calculate the Malmquist index of industrial green efficiency of Sichuan province and its decomposition during 2005–2014 as shown in Table 2. It can be seen that the level of Sichuan's industrial green efficiency is low, but the development trend is increasing year by year. This is consistent with Jia [7] results, which the Sichuan's green industrial development rate was still lagging behind, energy efficiency has gradually increased. But the energy pressure is still large, environmental pollution has been curbed but the situation is still grim. From the index decomposition terms, the impetus for growth of industrial green efficiency comes from technical efficiency, and its average annual growth rate is 2.1%. The improvement of technical efficiency is mainly due to pure technical efficiency and scale efficiency, which increased by 1.6% and 0.6% respectively. But the technical progress efficiency is low, far below the effective value of 1. It indicates that it should increase the R&D, introduction, digestion and absorption of green technology, to drive the green development of Sichuan industry. One of the highest levels of Sichuan industrial green development is in 2013–2014 with an increase of 16.6%, and mainly depends on the improvement of technological progress index. This may be due to the governments and enterprises had paid more attention to the green development of industry in recent years, as well as the lag effect of green technology has begun to produce.

Table 2. Average growth rate per annum and decomposition of TFP in Sichuan province (2005–2014)

Year	Effch	Techch	Pech	Sech	Tfpch
2008–2009	1.071	0.779	1.046	1.024	0.835
2009–2010	0.953	0.804	1.001	0.952	0.767
2010–2011	1.083	0.759	1.001	1.082	0.822

5.2 Analysis of Industrial Green Efficiency Among the Cities of Sichuan Province

According to the year data from 2005 to 2014, we further study the Malmquist index of industry green efficient and its decomposition terms item of Sichuan province; the results are shown in Table 3. It is easy inferred that there is big difference between different regions from the table date. The industry green efficient of Chengdu, Deyang, Mianyang, Yibin and Dazhou has increased, which accounts for 27.8%, Chengdu is 6% with maximal growth rate. The industry green efficient growth rate of rest of 13 regions is negative, Guangyuan is −20.5% with the lowest growth rate. This indicates that the industry prosperous of the latter is at the cost of taking up and consuming a large number of ecological resources. And the former is the beneficiary of development experience and mature technology learning.

Table 3. Average growth rate per annum and decomposition of TFP in cities (2005–2014)

Region		Effch	Techch	Pech	Sech	Tfpch
Chengdu Plain	Chengdu	1.054	1.006	1	1.054	1.06
	Deyang	1.055	0.974	1.081	0.976	1.028
	Mianyang	1.02	0.98	1.02	1	1
	Suining	1.025	0.864	1.056	0.971	0.886
	Leshan	1.055	0.829	1.011	1.044	0.875
	Meishan	1	0.822	1	1	0.822
	Yaan	1.042	0.843	1.054	0.989	0.879
	Ziyang	0.954	0.869	0.943	1.012	0.829
South Sichuan	Guangyuan	0.986	0.806	0.988	0.998	0.795
	Nanchong	1.064	0.868	1.056	1.008	0.924
	Guangan	1.009	0.842	1	1.009	0.85
	Dazhou	0.998	1.002	1	0.998	1
	Bazhong	0.987	0.807	0.987	1	0.797
Northeast Sichuan	Zigong	1.028	0.874	1.03	0.998	0.898
	Luzhou	1.005	0.867	1.003	1.002	0.871
	Neijiang	0.965	0.846	0.988	0.977	0.817
	Yibin	1.037	0.968	1.037	1	1.004
Panxi	Panzhihua	1.1	0.894	1.03	1.068	0.983
Sichuan	Mean	1.021	0.887	1.016	1.006	0.906

Note: Because of the missing statistical data of Liangshan state, Ganzi state and Aba state, this paper does not studied the West Sichuan Economic Zone. And considered the large industrial scale of Panzhihua, it was chosen to represent the overall level of Panxi Economic Zone.

Combined the Table 3 and Fig. 3, we analysis deeply the dynamic change trend and the distribute state of the Malmquist index resolution item in Sichuan province. Figure 3 reflects the growth pattern and characteristic of the industrial green efficiency. The cross-point of the horizontal-vertical coordinate is the equalization point of the technology efficient index and technology progress index, by which the 18 prefecture-level cities of Sichuan province are divided into 4 quartiles. In the first quartile, the Effch is higher and Techch is lower than the average. It indicates that these regions with lower technology contribution and simplex elements driven mode. The Effch and Techch are higher than equalization in the second quartile, these regions with reasonable element input scale, high technology import and absorption contribution rate. It promotes the growth of the

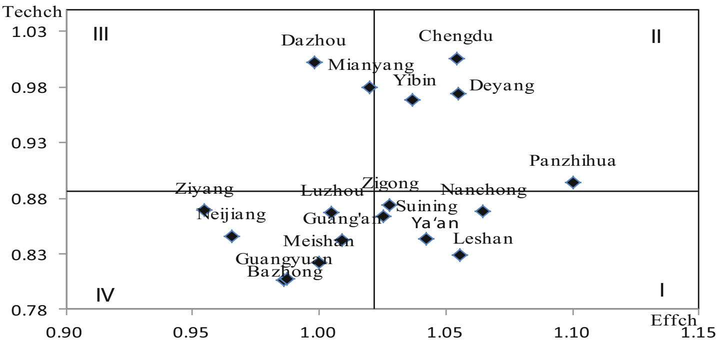

Fig. 3. The Techch and Effch distribution of the industrial green efficiency of 18 prefecture-level cities of Sichuan province

industrial green efficiency. The Techch is higher than Effch in the third quartile, it manifests that the technology level of these regions is above of production frontier. But it needs to improve the scale efficiency and pure technology efficiency. The Effch and Techch are lower than province equalization in the fourth quartile, these regions with low industrial green level and weak sustainable development due to the technical constraints and scale bottlenecks.

In the meantime, from the four major economic regions data of Chengdu Plain of Sichuan, Northeast Sichuan, South Sichuan, and Panxi (the presented paper have not studied the economic region of northwest of Sichuan due to the large missing data), it indicates that the industrial green efficiency is a gradual reduce step distribute from north to south, and from west to east, as show in Table 4.

The industrial green efficiency of Panxi head the list, secondly are Chengdu Plain of Sichuan and South Sichuan, the worst is Northeast Sichuan, its year equalization reduce is 12.7%. The technology progress indexes are inefficiency state of the four economic regions, from Malmquist index and its resolution items. Besides the south of Sichuan, the technology efficiency and its resolution items of the other three economic regions are progressing, which reveals that its resource allocation ability, resource utilization rate, and scale efficiency are valid.

The driving force of technical efficiency in Chengdu Plain Economic Zone is mainly pushed forward by pure technical efficiency. This also shows that the radiation driven role of Chengdu, as the capital of Sichuan Province, has significant advantages in terms of production factors, management level and system construction. The improvement of technical efficiency of Panxi Economic Zone mainly originates in its advantage of scale efficiency (an increase of 6.8%). It also shows that the resource input and its utilization efficiency have achieved scale benefit. Conversely, the scale efficiency of South Sichuan Economic Zone has decreased by 0.6%, which may be related to the unreasonable input structure of production factors.

Table 4. Average growth rate per annum and decomposition of TFP in economic zone (2005–2014)

Region	Effch	Techch	Pech	Sech	Tfpch
Chengdu Plain Economic Zone	1.022	0.883	1.023	1	0.903
Northeast Sichuan Economic Zone	1.009	0.865	1.006	1.003	0.873
South Sichuan Economic Zone	1.009	0.889	1.015	0.994	0.898
Panxi Economic Zone	1.1	0.894	1.03	1.068	0.983

6 Conclusions and Suggestion

Combined with the existing problems and deficiencies in the process of industrial green development in Sichuan province, there are several measures could be taken.

(1) Adjusting the industrial structure within industry.

To eliminate backward production capacity with high energy consumption and low added value, and reduce the industries proportion of high energy consumption and high pollution [8], such as steel, cement and others. Developing renewable energy sources actively, like wind, solar, bio-energy and others to improve coal-based industrial structure. Besides, it can expand the scale of environmental protection industry, for instance, solid waste treatment industry and sewage treatment industry.

(2) Promoting technological innovation.

It is beneficial to reform and upgrade traditional industries, to strengthen technological transformation, thus promoting the development of green recycling economy. Positively implementing environmentally friendly technologies and industrial process, such as industrial energy and water saving, clean production, recycling and others, to enhance green technology capability [12]. Encouraging university–industry collaboration to promote the industrialization of green technology. Protecting intellectual property is to enhance the enthusiasm of enterprises to develop green technology, and solve the market barriers. The government can set up innovation platform with the opportunities of the eastern industry transfer to the west, to enhance the ability of independent innovation.

(3) Adjusting scale structure to improve industrial green efficiency.

Using "incentive" environmental regulation tools based on market tools, and establish market based emission regulations and industry dynamics to promote industrial scale efficiency [5]. Increasing the environmental surveillance of medium-sized enterprises and implementing environmental measures with powerful binding. In the aspects of the industrial development policy, it's should play an exemplary role of leading enterprise, encourage the joint development of small and medium enterprises, enhance the linkage with large enterprises in the upstream and downstream industry chain. In addition, establishing green network supply chain to reduce the damage to ecological environment and achieve the goal of improving industrial green efficiency.

(4) Accelerating the construction of green manufacturing system.

Firstly is to improve “green performance” in product design, manufacturing, transportation, application and other product life cycle. Secondly is to create and promote green factories and green areas, with high technology content, high resource utilization and low environmental pollution. Thirdly is to establish green manufacturing standards and clean energy policies [20], which can evaluate the resource utilization and the cost of social environmental, thus to constraint and guide industrial green development.

The presented paper studies the industrial green efficiency in Sichuan province by DEA-Malmquist index method. The study results indicate that the overall level of industrial green efficiency in Sichuan province is not high, but with a gradually increase trend in recent years. The reason is mainly caused by technology efficiency, but the technology progress index retardants the promote effect of technology efficiency. In the four major economic regions, the industrial green efficiency of Panxi heads the list, next are Chengdu Plain of Sichuan and South Sichuan, the worst is Northeast Sichuan.

Risk Control

Machine Learning and Neural Network for Maintenance Management

Alfredo Arcos Jiménez(✉), Carlos Quiterio Gómez Muñoz, and Fausto Pedro García Márquez

Ingenium Research Group, Castilla-La Mancha University, Ciudad Real, Spain
Alfredo.Arcos@alu.uclm.es

Abstract. The paper presents a novel approach that allows to optimize the ultrasonic wave sensors for a condition monitoring system employing. It can detect and diagnosis different faults with a signal, such as delamination, mud or ice on blades of wind turbines. This methodology allows to avoid the redundancy of sensors, since a specific number of ultrasonic transducers can determine the structural condition using guided waves. The signal is pre-processed with the aim of removing the noise, then extracted and selected features to be later classified by Machine Learning and Neural Networks. Finally, for each damage or anomaly, the best classifier will be evaluated. The best classifier of each damage will act on a parallel network that will process the signal sent by the sensor.

Keywords: Non-destructive testing · Fault detection and diagnosis · Condition monitoring system · Wavelet transforms · Machine learning · Neuronal network

1 Introduction

The objective in the next decades is to obtain a competitive and sustainable energy to all countries, allowing to reduce dependence on fuels to households, industries and transportation. Wind power and Concentrated Solar Power (CSP) are being two of the main renewable energy sources. Its importance in the energy market is being essential, and the forecasts show it will continue in the near future.

Renewable energy industry requires significant improvements in reliability, lifetime or availability that it is done by an efficient maintenance based on Condition Monitoring Systems (CMS). CMS is the process of determining the condition of system [37,38,49], where one of the main proposes is to identify changes between two main states of the structure, damaged and undamaged [36,39,41]. They will provide different patterns that will be used in order to analyze the condition of the system [19].

A complex CMS contains numerous sensors that generates different type of signals with information and sampling frequencies [41]. It needs to be processed, preferable on-line, with a minimum computational cost and with high accuracy to reduce false alarms [39].

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_115

This paper present a novel approach to reduce the number of sensors, maximizing the signal processing analysis to detect different damages. The guided wave ultrasonic signals are employed for fault detection and classification.

Structural Health Monitoring (SHM) is a technology that combines advanced CMS, together with signal processing, to determine the condition of the structures on line or not [19,36,41]. SHM leads to increase the Reliability, Availability, Maintainability and Safety (RAMS) of the system [16,41]. SHM allows also to know the different levels of the defect severity. It will be useful for an optimal maintenance management to reduce costs and increase the profitability.

Farrar and Sohn [16] considered pattern recognition in SHM. This methodology consists in four stages shown in Fig. 1.

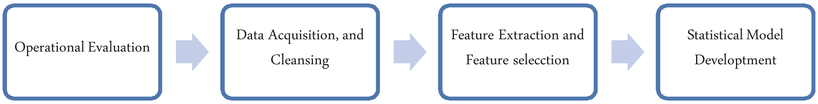

Fig. 1. Methodology SHM

The problems caused by the implementation of damage identification system is assessed in operational evaluation phase. Data acquisition and normalization involves the choice of sensors and their location, the normalization procedure of the data collected and the selection of the data to be used in the feature selection process. Dimensionality reduction techniques have been developed to remove irrelevant data (noise) and redundant features, and categorized mainly into Feature Extraction (FE) and Feature Selection (FS). FE contains information of the signal that distinguishes between a damaged or non-damaged structures [57]. FS selects the data that are better for the detection of damage and executes a condensation of the data [16,40]. Finally, classifiers, based on statistical models, calculate and cluster the dataset depending on the damage. These classifiers are grouped as: Supervised Learning (SL) and Unsupervised Learning [35].

This paper proposed patterns recognition of each damage by Machine Learning and Neural Network. Then approach minimize the number of sensors, where through an ultrasonic signal emitted by a sensor is able to classify different states of different damages or anomalies.

This process is complex because each damage must be analyzed individually. On the other hand, there is no generic classifier that provides the best results. Even the same classifier for the same signal depends on the methodology of FE and its subsequent FS.

2 Approach

Figure 2 shows the schematic approach for determining the level of damage or anomaly based on SHM employing ultrasonic guided waves.

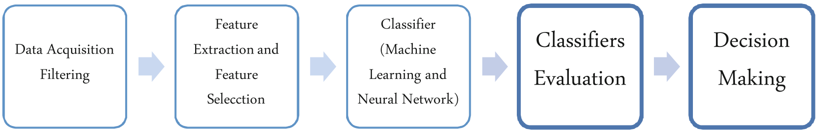

Fig. 2. Methodology schedule for determining the level of damage or anomaly

2.1 Signal Pre-Processing

Sensors generate noise from a variety of sources and therefore a signal pre-processing is necessary to eliminate/reduce the dataset that does not provide useful informatio [45]. Standard statistical techniques have been employed in references [10,53]. Yu et al. [64] were able to reduce global noise using averaging techniques and Daubechies Wavelet (DW) to eliminate local high-frequency perturbations. Denoising and compression signal in Guided Waves (GW) based on the Discrete Wavelet Transform (DWT) was employed by Rizzo and Scalea [55]. There are a large number of research and reviews articles on filtering in the treatment of ultrasonic guided waves [46]. Hamming [21] performs a review about low-pass filters available for data smoothing. This paper will consider Wavelet transforms for filtering the signals.

The denoising of the signal is performed employing a multilevel 1-D wavelet analysis using Daubechies family. The wavelet decomposition structure of the signal is extracted. The threshold for the de-noising is obtained by a wavelet coefficients selection rule using a penalization method provided by Birgé-Massart [47]. An overly aggressive filtering could eliminate data that should show, for example, small echoes that come from defects. Figure 3 shows the original signal and the de-noised signal when it is applied the wavelet de-noised filter. The Wavelet de-noising filter does not produce an unwanted signal delay in contrast to other digital filters.

It is observed that the filter removes noise significantly, and does not eliminate information that is related to different structural features.

2.2 FE Methods

FE affects the learning and classification process. FE and FS are capable of improving learning performance, presenting less computational complexity and historical dataset [58].

Classical dimensional reduction techniques such as Principal Component Analysis (PCA) [26] and Multidimensional Scale (MDS) [29] are extensively employed. However, the Linear and Nonlinear Regression systems are used when the signal type is complex and the first order interactions are not enough to derive good results [20].

Two autoregressive models have been applied in this paper for FE: Linear (AR) and nonlinear (NARX). AR is a lineal mathematical model commonly employed for FE because of its high computational performance. AR method

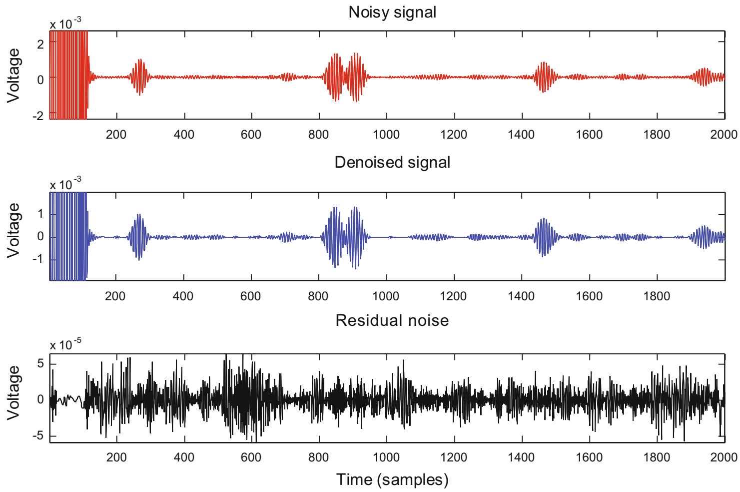

Fig. 3. Decomposition detail five (D5), De-noised D5 and extracted residual noise

is popular because estimation of AR parameters (features) is achieved easily by solving linear Yule-Walker equations [13]. NARX presents a better behavior in the most of the nonlinear systems. NARX was introduced by Leontaritis and Billings [30] and it has been widely used in the identification of nonlinear dynamic models and feature selection [6]. NARX presents a good generalization capability, as effective training algorithm, a fast convergence rate, and can represent a wide class on nonlinear systems [3,18,25].

Within the NARX model, the lineal-in-the-parameters structure is a method widely used in nonlinear dynamics models. It is a linear combination of model terms, or basis functions, that are some nonlinear-usually polynomial- functions of the system variables [32]. In this case, the monomials of the linear combination are the features. The linear-in-the-parameter models are well structured to adaptive learning, with learning conditions and demonstrable convergence and capacity parallel processing, in addition to numbers applications in signal processing and pattern recognition [24,36].

2.3 FS Methods

FS techniques can be categorized into three approaches: embedded, wrapper or filter [33]. The main methods for FS are Information Gain, Relief, Fisher Score and Lasso [27]. In this paper, the main objective to reduce dimensionality and it is not intended to select the best features.

SHM literature propose several methods to select the AR model order: AIC [2]; Akaike's Final Prediction Error [1] (FPE); Partial Autocorrelation Function (PAF) [60], and; Root Mean Square (RMS) [31]. AIC statistical technique has been used to reduce the dimensionality of the feature extraction. The AIC is one of the most efficient techniques for order optimization [35]. The AIC is a measure of the goodness-of-fit of an estimated statistical model, based on the trade-off between fitting accuracy and the number of estimated parameters.

2.4 Classifiers

(1) Machine Learning Approach

① Decision Trees

Decision Tree (DT)is a classifier used in many fields to study if the data contains different classes of objects that can be interpreted significantly in the context of a substantive theory [34,48,51,52].

DT generates a split of space from a labeled training set. The objective is to separate the elements of each class into different labeled regions (leaves) minimizing the local error. Each internal node in the tree is a question (decision) that determines which branch of the tree must be taken to reach a leaf. DT is determined for; (1) how to split the space (Splitting Rules); (2) stop condition of splitting; (3) labeling function of a region, and; (4) measurement of error.

The purpose of the Splitting Rule is to minimize the impurity of the node. The recursive splitting algorithm stops when it finds any of the following conditions: the node is pre-set maximum deep; all elements of the node are same class; there is no empty sub node or; SR does not reach a pre-set value.

To label a leaf or region once it is already considered as a terminal is considered to develop a DT. Equation (1) establishes the labeling function.

$$l' = \arg\min l' \left\{ \sum_{l=1}^{k} N_I \times c_{l,l'} \right\}, \tag{1}$$

where N_I is the number of elements of class l in the region, l' is the class to label and $c_(l, l')$ is the labeling cost.

$c_(l, l')$ with all classes is calculated and l' is selected, which minimizes the error. The label that minimizes the error of a region is the most populated class. In case of a tie, a random one is chosen. Equation (2) gives the classification average error

$$\varepsilon = \frac{1}{N} \sum_{l=1}^{N} \mathrm{err}(l, l'_i), \tag{2}$$

where $\mathrm{err}(l, l'_i)$ is the error of labeling a class l as l'. This error is solved by splitting the space and assigned to each split a label.

② Discriminant Analysis (DA)

The ultrasonic signals considered are homogeneous for the same frequency and, therefore, the classifier that provides better results is LDA [15]. This classifier is valid for ultrasonic signals obtained at different frequencies and used for speech recognition. This type of classifier is based on a geometrical approach. A linear function representing a decision limit divides a feature space into regions that have common properties. The aim of this method is to find the expression of linear discriminant functions that enable the objects classification in the considered classes.

③ Support Vector Machine (SVM)
SVM [9] is a supervised multivariate classification method. "Supervised" refers to a training step where the algorithm learns the differences between pre-specified groups to be classified [59]. SVM treats each feature as a point in a high-dimensional space, being the number of dimensions the same to the number of rating levels. Each feature is assigned to a group and the linear classification function (3) learns the characteristics to discriminate among five groups. A limit of decision, or hyperplane (a generalization of a plane of $n-1$ dimensions which divides an n-dimensional space), must be defined to separate the data based on class membership and to classify linearly the dataset. However, for a linearly separable problem, there are an infinite number hyperplanes correctly classified data. SVM algorithm finds the optimal one characterized by the largest margin between classes. The margin is defined as the distance of the closest training data points of the hyperplane. These points are the most difficult to classify and they are called support vectors. The hyperplane is defined by a weight vector, which is a linear combination of the support vectors, and specifies both a direction and a displacement which together define the maximum margin classifier. The decision function $D(x)$ is given by Eq. (3),

$$D(x) = w\emptyset(x) + b, \tag{3}$$

where w and b are the SVM parameters, and $\emptyset(x)$ is a kernel function

The hyperplane is defined by Eq. (3), and the distance between the hyperplane and pattern x can be written by Eq. (4).

$$\frac{D(x)}{\|w\|}. \tag{4}$$

A training classifier is designed to find the value of w that maximizes the margin between the class boundary and the training patterns. The objective function of the training algorithm is given by Eq. (5).

$$J = \frac{\|w\|^2}{2}. \tag{5}$$

In this case, the linear function Kernel and one vs one method have been employed [43].

④ k-Nearest Neighbors
k-Nearest Neighbors(k-NN) [11,12] is a high-performance classifier widely used in Machine Learning [42]. k-NN rule classification is an extension of the Nearest-Neighbor (NN) rule. Given a set x of the k samples, the rule assign to each sample is to label most frequently represented among the k nearest samples [15].

k-NN search technique and k-NN based algorithms are widely used as benchmark learning rules. The relative simplicity of the k-NN search technique makes it easy to compare the results from other classification techniques to k-NN results.

The accuracy of k-NN classification significantly depends on the metric used to compute distances between different samples [61]. In most cases, the best performing classifier is Fine k-NN [62], using metric Euclidean distance in Eq. (6).

$$d_{st}^2 = (x_s - y_t) \cdot (x_s - y_t)' \tag{6}$$

⑤ Ensemble Subspace Discriminant (ESD)
Ensemble methods are learning algorithms that construct a set of classifiers whose individual decisions are combined in some way (generally by weighted or unweighted voting) to classify the set of features of each pattern [14]. Bagging, boosting, and random subspaces are general techniques that can be used with any type of base classifier. Ensemble Bagged Tree (EBT) and Random Subspace Method (RSM) have been the most successful methods. EBT uses the Breiman's 'random forest' algorithm [7]. RSM is a parallel learning algorithm proposed by Ho [23].

(2) Artificial Neuronal Network (ANN)
ANN unidirectional supervised through a MLP with training by backpropagation algorithm [56] has been applied. Backpropagation with algorithm scaled conjugate gradient and performance Cross Entropy [28,44] with 'Early Stopping' to avoid overfitting [50] has been training mode. ANN is given by Eq. (7),

$$z_k = \sum_j w'_{kj} y_j - \theta'_i = \sum_j w'_{kj} f\left(\sum_i w_{ji} x_i - \theta_j\right) - \theta'_j, \tag{7}$$

where x_i is ANN input, y_i is hidden layer output, z_i is final layer output, t_k is targets output, $w_j i$ is hidden layer weight, w'_{kj} is final layer weight, θ_j is hidden layer bias, θ'_k is final layer bias and $f(.)$ is the activation function of sigmoid type, employed as the activation function of the ANN.

The MLP process tests initially with an ANN architecture and is trained with 70% of the total of the experiments and 30% of them to test the network. Then the ANN architecture is chosen according to the accuracy and performance. Finally, ANN is tested with different cases (30%) to know if the learning is right and to the accuracy.

Backpropagation (BP) is one of the simplest and most general methods for supervised training of multi-layer ANNs. Scaled, standardization, normalization that perform pre-processing inputs techniques have been employed to accelerate the BP training. Scaled conjugate gradient and performance Cross Entropy are employed to increase the computational learning cost of ANN.

2.5 Evaluation Classifier

Analysis Receiver Operating Characteristic (ROC), as Confusion Matrix (CM), is employed to evaluate of the classification. CM determines the accuracy of a classifier and measures its performance. The main parameters in CM are:

True Positive (TP) : corresponds to real successes of the classifier
False Positives(FP) : is the sum of the values of a class in the corresponding CM column, excluding the TP
False Negative(FN) : is the sum of the values of a class in the corresponding CM row, excluding the TP
True Negatives(TN) : is the sum of all columns and rows, excluding that class's column and row

Recall function, R, given by Eq. (8), provides the probability to be correctly classified, called true positive rate or hit rate:

$$R = \frac{TP}{TP + FN}. \tag{8}$$

Specificity, S, also called the true negative rate, measures the proportion of negatives that are correctly identified as negatives.

$$S = \frac{TN}{FP + FN}. \tag{9}$$

Precision, P:

$$P = \frac{TP}{FP + TP}. \tag{10}$$

F-score, F [54]

$$F = \frac{2 \times P \times R}{P + R}. \tag{11}$$

There are two conventional methods to establish the average performance in all categories: macro-averaging and micro-averaging [63]:

Macro-average: P^M, R^M and F^M is obtained are the mean of all P_i^M, R_i^M and F_i^M where M denotes Macro-average, and i is the scenario, then for each category they are calculated, i.e. they are valued are evaluated locally P_i^M, R_i^M and F_i^M, and then globally P^M, R^M and F^M.

Micro-average: P^M, R^M and F^M value is obtained as: i) TP_i, FP_i, FN_i values is calculated for each of the scenario; ii) the value of TP, FP and FN are calculated as the sum of TP_i, FP_i and FN_i, and; iii) to applying the equation of the measure that correspond.

There are several indices extracted from the ROC curve to evaluate the efficiency of a classifier. Area Under Curve (AUC) represents the area between the ROC curve and the negative diagonal [5,22], being between 0.5 and 1. Values ≤ 0.5 indicates that the classifier is invalid and a value of 1 indicates a perfect rating because there is a region in which, for any point cut, the values of R and Pare equal to unit. The statistical property of AUC is equivalent to the Wilcoxon test of ranks [22]. The AUC is also related to the Gini coefficient [8], which is twice the area between the diagonal and the ROC curve.

The recommendations by Demsar [4], and the extensions by Garcia and Herrera [17], have been employed to perform the comparative analysis of classifiers. Friedman Test will be used to test the null hypothesis that all classifiers achieve the same average. Bonferroni-Dunn Test is applied to determine significant differences between the top-ranked classifier and the following. Holm Test is used to contrast the results.

3 Approach Scheme

The methodological process is represented schematically in Fig. 4. Firstly, for each damage or anomaly, the best classifier is selected.

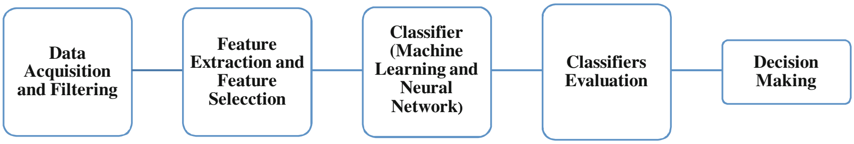

Fig. 4. Methodology flow for determining the classifier

The methodological process will follow the scheme given in Fig. 5 when the best classifier for each damage is set.

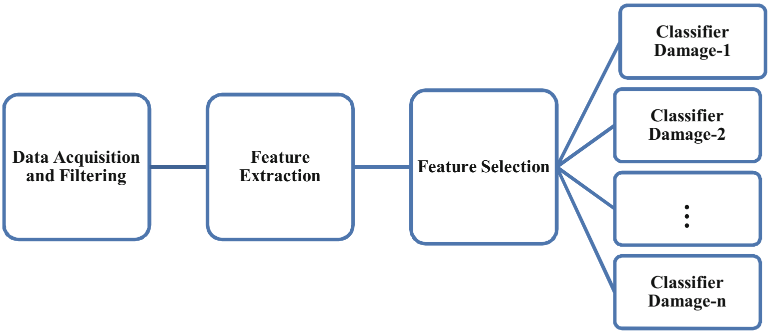

Fig. 5. Methodology flow for determining the damage

4 Conclusions

The paper presents a novel approach to optimize the sensors in a condition monitoring system employing ultrasonic waves. The approach can detect different potential faults with a single signal emitted by a sensor, such as delamination, mud or ice on blades of wind turbines. This methodology allows to avoid the redundancy of sensors, since a specific number of ultrasonic transducers can determine the structural condition using guided waves. The signal is pre-processed with the aim of removing the noise, then extracted and selected features to be then classified by Machine Learning and Neural Networks. Finally, for each damage or anomaly, the best classifier will be evaluated. The best classifier of each damage will work in a parallel network that will process the signal sent by the sensor.

Volatility Spillover Between Foreign Exchange Market and Stock Market in Bangladesh

Shibli Rubayat[1](✉) and Mohammad Tareq[2]

[1] Faculty of Business Studies, University of Dhaka, Dhaka 1000, Bangladesh
shibli@du.ac.bd

[2] Department of Accounting and Information Systems, University of Dhaka, Dhaka 1000, Bangladesh

Abstract. This paper investigates the link between foreign exchange market and stock market in Bangladesh through volatility spillover between the markets. It also examines the volatility persistence and asymmetric effect of information on the volatility of these two financial markets. Using data from January 1, 2009 to December 12, 2016 Taka/USD exchange rate's volatility and the stock return's volatility of CSE General Index this paper utilizes ARCH and GARCH models to investigate the spillover, persistence and asymmetry effect of volatility. The results reveal high level of presence of volatility of CSE General Index but not of the Taka/USD exchange rate. The result also finds asymmetric effect of information i.e. bad news is followed by higher volatility compared to that of after good news in the stock market. However, the result shows that volatility in the CSE General Index spillover that of the Taka/USD exchange rate but not vice versa. The meaning and significance of the study is also presented in the paper.

Keywords: Foreign exchange market · Stock market · Volatility · Spillover · Taka/USD (The local and United States Currency)

1 Background of the Study

Foreign exchange market and capital market are linked in many countries and show inter-dependence [1,7,11]. Among others, volatility of these markets links each other and spillover from one market to another. The volatility is a key factor that causes risk in these markets and thus influences economic activities in a country. Volatility information of these markets is used for risk management, portfolio allocation and stock trading strategies [12].

Bangladesh, a south Asian country struggling for poverty reduction and economic development, has a smaller and less equipped capital market than its neighboring countries [10]. A developed capital market can aid a country's economic development by turning savings into investment. Researchers have consistently found a positive relationship between a developed stock market with economic growth and capital accumulation [8,9]. As mentioned above, knowledge

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_116

about the volatility help investors in their risk management, portfolio allocation and stock trading strategies and is considered one of the ways of developing a capital market. However, there is no notable study in Bangladesh that has investigated the volatility of these financial markets, especially how these two markets are linked through volatility.

The contribution of the research lies in the fact that no notable study has been done so far that investigates the link between the volatility of the capital market and foreign exchange markets in Bangladesh. It is hoped that this study will inform policy-making decisions in relating to these two market and help investors in making investment decision.

1.1 Methodology

The study uses CSE General Index of Chittagong Stock Exchange (the 2^{nd} largest in the port city) from January 1, 2009 to December 1, 2016. The official exchange rate of Taka/USD of the same period was also used. These data were collected from Chittagong Stock Exchange and from the central bank of Bangladesh, 'Bangladesh Bank' respectively. The Taka/USD exchange rates and the CSE General Index for the sample period are shown in Figs. 1 and 2 respectively.

The return of the stock market was calculated as follows:

$$R_t = \ln\left(P_t/P_{t-1}\right) \times 100.$$

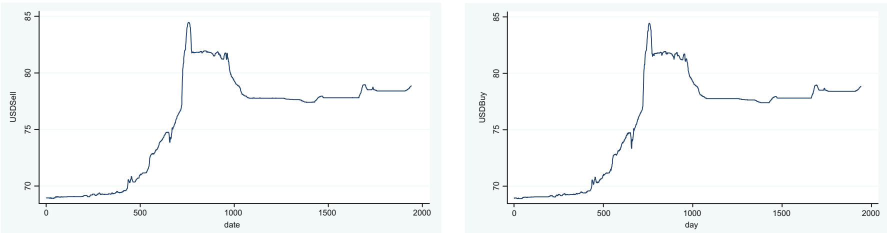

Fig. 1. Taka/USD exchange rate (From January 1 2009 to December 12, 2016)

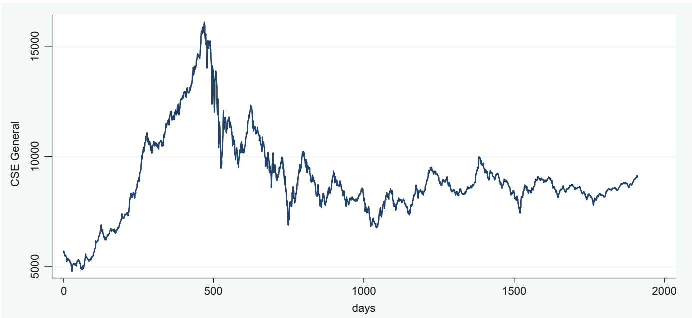

Fig. 2. CSE General (From January 1, 2009 to December 12, 2016)

Daily spread between buy and sell rate of Taka/USD was used to measure return on Taka/USD exchange rate. The Taka/USD exchange rates return and the CSE General Index daily return is for the sample period are shown in Figs. 3 and 4 respectively.

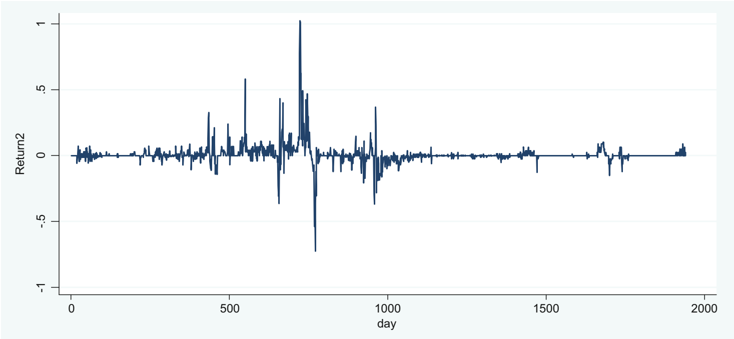

Fig. 3. USD/Taka exchange rate return (Dec 12, 16 to Jan 1 2009)

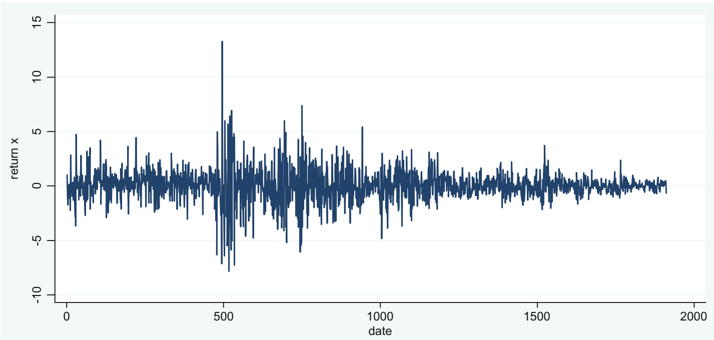

Fig. 4. CSE General Index stock return (Dec 12, 16 to Jan 1 2009)

To analyze volatility, asymmetric volatility and spillover effect, different variation of the Generalized Auto Regressive Conditional Heteroskedasticity (GARCH) were used in this study. Maximum Likelihood estimation method was used to estimate the parameters of the GARCH models of this study. Augmented Dickey–Fuller (ADF) unit root tests for the CSE General Index return and Taka/USD exchange rate return series were done and the results reject the hypothesis of unit root. GARCH is a model for time-series where volatility is clustered together. The autoregressive term in a GARCH model takes into account past values on the time-series. Heteroskedasticity means that data contains non-constant variance, which by running a standard OLS would result in erroneous standard errors and confidence intervals. GARCH models corrects these treat heteroskedasticity as a variance inside the model.

The ARCH model was the forerunner to the GARCH specifications. Before this, volatility used to be measured using rolling standard deviations over past time periods. However, the problem with this approach is that each time period receives equal weight in the estimation of the current period's variance. The ARCH process, proposed by Engle [5], solves this by letting these weights be parameters to be estimated. This allows the data to determine the best weight to be used on the present volatility [6]. An ARCH model is presented below:

$$r = \pi + \varepsilon_t,$$
$$\sigma_t^2 = c + \sum_i^q \alpha_i \varepsilon_{t-i}^2,$$

where $\varepsilon_t = \sigma_t z_t$; z_t is an i.i.d random variable with mean zero and variance one and σ^2 is the squared conditional variance in the model.

So the conditional variance is here described as a distributed lag of past squared innovation [3]. That means that the variance of the current error term is a function of the size of the previous period's squared error term. In order to avoid a very large number of coefficient in high order polynomial, Bollerslev [2] developed the GARCH-model as a generalization of Engle's [5] ARCH-model. This makes a declining weight that never reaches zero [6]. GARCH $(1,1)$ is the most common model to use in empirical research. A GARCH $(1,1)$ model is presented below:

$$r = \pi + \varepsilon_t,$$
$$\sigma_t^2 = c + \alpha\varepsilon_{t-1}^2 + \beta\sigma_{t-1}^2,$$

where, $\varepsilon_t = \sigma_t z_t$; z_t is an i.i.d random variable with mean zero.

2 Persistence and Asymmetry of Volatility

The study utilize a GARCH $(1,1)$ model for the CSE General Index return and Taka/USD exchange rate return. The result shows that the "$\alpha + \beta$" estimated from the CSE General Index is about .99. This means that volatility is highly persistent for the CSE General Index. It means that if there is volatility in the CSE stock market it decays slowly over a long period of time. However the study did not find the persistence of volatility in the Taka/USD rate (See Table 1).

In the world of financial market the reality is that negative news often has much bigger impact on volatility than good news has on relaxing these fluctuations i.e. negative shocks at time $t-1$ have a stronger impact on the variance at time t than positive shocks. The GARCH model is symmetrical, negative and positive shocks are given equal weight. The study also investigated the asymmetry effect of positive news and negative news on the market volatility using EGARCH-model. Result of the asymmetric GARCH shows that bad news causes

Table 1. Persistence and asymmetry of CSE General Index and Taka/USD exchange rate

	CSE General Index	CSE General Index	Taka/USD exchange rate
Con	.005*(.027)	.005*(.027)	0.00**(00)
α	.16***(.014)	.16***(.014)	1.23(1.15)
β	.83***(.011)	.83***(.011)	.34***(.03)
γ (asymmetric term)	-	$-$.02*(.011)	$-$.6(1.16)
n	1911	1911	1940

$^{*}p < .05$; $^{**}p < .01$; $^{***}p < .001$

higher volatility ($\gamma = -0.02^{*}$).compared to good news in the stock markets in Bangladesh (See Table 1).

Past studies have shown that volatility in one market can affect other markets [4,11]. The study also investigates whether the volatility crated in stock market spills over the other and vice versa. To study this, MGARCH is used. The result shows that volatility in the CSE General Index spillover that of the USD/Taka exchange rate but not vice versa. Table 2 shows the spillover effect of CSE General Index on the Taka/USD exchange rate market.

Table 2. Spillover effect of stock market on foreign exchange market

	CSE General Index	Taka/USD exchange rate

N	1911	1940

$^{*}p < .05$; $^{**}p < .01$; $^{***}p < .001$

3 Conclusion

This study investigates and analyses the link between the stock market and foreign currency (ForEx) market of Bangladesh. The study was done to get insight about on the volatility and its spillover effect between the stock and the foreign exchange markets, and consequently the degree of their integration to expand the information set available to international portfolio managers, multinational corporations and policymakers for decision-making and policy formulation.

It was found that the persistence of volatility in stock market in Bangladesh is very high which indicates that volatility clusters in stock market and decays slowly. This study is similar to studies to Wu [11] and Jebran and Iqbal [7]. However, the study found low persistence in Taka/USD currency market. The study also found that there is asymmetry in the volatility of in the stock market i.e. negative news causes higher volatility compared to good news in the market. The result shows that volatility in the CSE General Index spillover that of the Taka/USD exchange rate but not the opposite.

Cost/Efficiency Assessment of Alternative Maintenance Management Policies

Diego Ruiz-Hernández(✉) and Jesús María Pinar-Pérez

Department of Quantitative Methods, CUNEF-Ingenium, Madrid, Spain
d.ruiz@cunef.edu

Abstract. In this work we compare a number of maintenance scheduling policies for a collection of deteriorating machines. We consider a framework where a manager must allocate the effort of a small number of technicians for providing preventive maintenance to a larger number of machines. The aim is mitigating wear and preventing failures or breakdowns, guaranteeing the system's availability, reliability and safety. We evaluate different maintenance regimes that emerge in practice, distinguishing two main groups: time based and condition based policies. The comparisons are conducted by means of an intensive computational assessment of the performance of the different policies discussed.

Keywords: Machine maintenance management · Condition based maintenance · Time based maintenance · Index policies · Simulation

1 Introduction

Maintenance interventions in deteriorating equipment are aimed at guaranteeing its availability, reliability and safe performance whilst maximizing output and minimizing waste. Such interventions may be predictive, preventive, or corrective. Regarding the planning horizon, whereas corrective maintenance is reactive (interventions come as a response to a failure), predictive and preventative interventions are typically scheduled using either time-based or condition-based schemes. Time-based interventions are usually scheduled according to an age-based regime or following a pre-determined calendar (usually as indicated by the producer or by certain legal requirements). In this work we focus our attention on preventative maintenance interventions.

There is a vast amount of literature addressing the problem of scheduling preventative maintenance interventions in one single machine. Some recent references are [3–6, 12, 13]. Good reviews of earlier contributions please see [1, 8, 20]. However, it is hard to find references in literature addressing the problem of scheduling maintenance interventions to more than one machine, among them [10, 15, 21]. Moreover, in most of the work addressing single machine maintenance, the attention is focused on finding optimal intervention times given the information gathered about the current condition of the machine without taking

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_117

into consideration the costs associated with the machine operation, intervention and potential breakdowns. These values become particularly relevant when it comes to deal with the design of multiple machines maintenance schedules, as the trade-off intervention/operation-breakdown becomes more relevant.

Notwithstanding the shortage of academic work, technical literature shows that maintenance tasks are typically allocated following either calendar based programmes or, alternatively, regimes based on information about the current state of the equipment [2,7,11,14,18,22]. Based in this observation, in this work we compare the performance of a number of maintenance scheduling policies which broadly replicate the approaches taking in real life problems.

2 Problem Formulation

In this work we address the problem of scheduling preventive maintenance interventions in a collection of independent machines by a limited number of technicians. The aim is operating the system at the least operation/maintenance cost whilst minimizing the cost of failures or breakdowns. At each period the manager selects the number of machines that will be maintained during that period. If necessary, technicians are allowed to remain idle during certain period.

As discussed in [19], the manager's problem can be modeled a discrete-time infinite-horizon Markov Decision Problem, where each machine is modeled as a two action (operation/intervention) Markov Decision Chain that evolves over a discrete state space[1]. Roughly speaking, during the operation phase the machine deteriorates, operation costs increase and the probability of a failure or breakdown becomes larger. Maintenance interventions, which are conducted at a cost, aim at returning the machine to some pristine or as-good-as-new state. The objective of the manager is to minimize the discounted operation/intervention cost of equipment over an infinite horizon.

In order to characterize the decision maker's problem we introduce the following notation: let β, M and R represent the discount factor, and the number of machines and repairmen, respectively. The system's state space is represented by the set $\mathscr{S}$, with the state at any decision epoch t given by $\mathbf{S}(t) = \{s_m(t), m = 1, \cdots, M\} \in \mathscr{S}$. The actions available are represented by the set $\mathscr{A}$, whose elements $\mathbf{a} = \{a_m : a_m \in 0, 1, m = 1, \cdots, M\}$ represent the admissible actions at any given state $\mathbf{S}(t)$; where $a_m = 1$ indicates that machine m must be intervened during the current decision period, and $a_m = 0$ prescribes operation. Finally, $\mathscr{C}$ is the collection of all possible vectors $\mathbf{C}^{\mathbf{a}}(\mathbf{S})$, representing the costs incurred from taking action $\mathbf{a} \in \mathscr{A}$ when the system is in state $\mathbf{S} \in \mathscr{S}$.

With this elements we can now write down the objective of the decision maker as the one of choosing the stationary, deterministic policy σ that minimizes

[1] Please notice that, even if the machines' condition or level of wear may not necessarily be a discrete variable, if the deterioration of the machine occurs smoothly over a linear space, then the state space can be discretized or uniformised in order to obtain a discrete state space [17].

the expected discounted operation/maintenance cost incurred over an infinite horizon, namely $V^* = \min_\sigma\{E_\sigma[\sum_{t=0}^{\infty} \beta^t \mathbf{C}^{\mathbf{a}(t)}\mathbf{S}(t)]\}$.

Unfortunately, this problem suffers a dimensionality problem making standard dynamic programming techniques unavailable for finding an optimal solution. Instead, in real life, different approaches are taken (see [2,14,22]) in order to obtain the most efficient maintenance scheduling regime possible. Most of these approaches fall within the five broad categories described in the following section.

3 Maintenance Policies

In this section we briefly describe the five maintenance regimes that have been used in our work. All of them aim at minimizing the overall operation/maintenance cost of equipment. Three of them are condition based and presume the existence of a condition monitoring system that provides timely information about the system's state. Most of the condition based policies that are used in real life fit (with minimal adaptations) within the more general frameworks described below. However, because of the large investment costs involved, in some cases condition monitoring systems may not economically feasible (see, for example, [16]). In such cases time based regimes are particularly useful. For this reason, the fourth policy discussed in this work is a purely calendar based one. Finally, the last policy discussed below combines features of both, condition based and time based regimes.

(1) Threshold Policy

At each decision epoch, the manager observes the state of the system and assigns maintenance tasks to those machines whose state is equal to or above than certain threshold. If the number of candidate machines is larger than the number of technicians, then the effort is allocated to those machines with larger state of wear. Ties are broken randomly. More precisely, the action set of the threshold policy for a threshold T at time t is given by $\mathbf{a}(t) = \{a_m(t) : s_m(t) \leq T, \sum_{m=1}^{M} a_m(t) \leq R\}$.

(2) Pure Condition Based Policy

At each decision epoch, this policy prescribes to intervene those machines with larger observed state of wear. As in the previous case, ties are broken randomly. This kind of policies do not take into account other characteristics of the machines as age, deterioration rate, operation and intervention costs, etc. If we define an ordering $s_{m,(i)}$, $i = 1, \cdots, M$, where $s_{m,1}$ is the machine with largest state and so on, then we can build the following two sets $\bar{a} = \{s_{m,(i)}, i = 1 \cdots, R\}$ and $\underline{a} = \{s_{m,(i)}, i = R, \cdots, M\}$, therefore the condition based policy is represented by: $\mathbf{a}(t) = \{a_m | a_m = 1 \,\forall\, m : s_{m,(i)} \in \bar{a};\; a_m = 0 \;\forall\, m : s_{m,(i)} \in \underline{a}\}$.

(3) Index Policies

Index based families of maintenance scheduling policies have been proposed in order to address the deficiencies of purely condition based policies, [9,10]. These policies exploit all the information available for each machine at any time in order to compute a so-called activity or intervention index. The indices are calibrated for each machine/state pair and the policy prescribes to intervene those machines with larger indices. Typically, the indices will have negative values for early states of wear, when the machine is supposed to be in an as-good-as-new condition. Consequently, only machines with positive indices will be intervened. This result has been extended to all the other policies evaluated in this article, imposing that no machine must be intervened whenever it lies in a state whose index has negative value[2].

If we let Im, s_m represent the index of machine m at state s_m, and $\mathscr{I}$ is the R^{th} largest index, then the actions available at time t are given by $\mathbf{a}(t) = \{a_m | a_m = 1 \quad \forall\, m : Im, s_m > \mathscr{I}; \quad a_m = 0 \quad \forall\, m : Im, s_m \leq \mathscr{I}\}$.

(4) Calendar Based Policy

Periodical or calendar based policies follow a pre-defined intervention plan. In our setting, a periodical intervention time is fixed for all the machines, with the first intervention scheduled after certain sojourn time (when the machine is operated from new). Even though in practice this calendar is determined by the acquisition date and the periodical interventions prescribed by the maker, in our formulation the interventions calendar is determined as follows: Once the sojourn period is finished, at each period the decision-maker intervenes as many machines as technicians are available according to their level of wear (pristine machines are not intervened). Once a machine has been intervened, a new intervention is scheduled at certain time in future (the interval between interventions is the same for all machines and exogenously determined). Once all the machines have been scheduled and intervened, a new cycle begins. For the sake of results's comparability with the index and other pure condition-based regimes, a variant of this policy consisting of preventing the machine to be intervened in early states of wear, has been included. These states coincide with the minimal state for which all the indices computed for the index policy are non-negative.

(5) Dynamic Calendar Policy

When the collection of machines includes equipment from different versions, ages or makers, their deterioration rates may differ and a rigid calendar-based policies may not be completely appropriate. In order to address these cases, we propose an extension of the pure calendar-based policy which is an hybrid of calendar and condition based policies: at each decision epoch, the less deteriorated machines in the plan are substituted for other -more deteriorated ones- which are not in the current period's plan. The machines whose intervention is postponed join a queue or *buffer* of delayed machines that will be included in future plans.

This policy, depicted in Fig. 1, works as follows. First, all the machines are assigned an intervention period as in the *Calendar Based Policy.* Once the intervention stage has started, at each period the manager checks on the condition of

[2] Please notice that this condition has only been imposed for the sake of results' comparability and does not apply for more general cases.

all the machines. If any of the machines scheduled for intervention at the current period is still at the pristine state, the machine is dropped-off from the list and its identifier is included in the buffer. Simultaneously, if there are non-pristine machines in the buffer, they are immediately included, by order of wear, in one of the empty slots of the current plan. The decision maker then checks on the condition of all the other, non-scheduled, machines and identifies those units whose state of wear is worst than the best machine in the plan. If no machines are identified, the intervention stage starts and the maintenance tasks are deployed. If, otherwise, some machines are picked during the check, they are either allocated to any empty slot in the current plan (if any), or substitute any scheduled machines which are in a better condition. The machine (or machines if there are ties) with the largest state of wear in the current intervention plan is never substituted. The displaced machines are included in the buffer and the intervention actions are deployed. As it was done for the purely calendar based policy, a variant of this policy consisting of preventing the machine to be intervened in early states of wear, has also been considered.

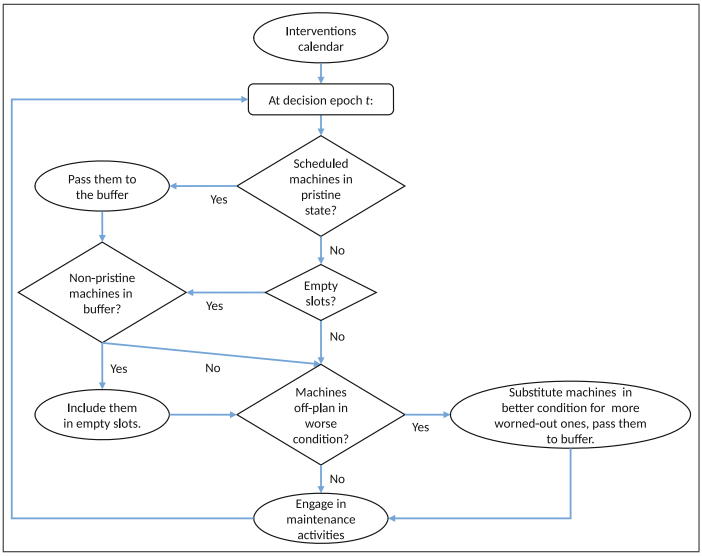

Fig. 1. Dynamic calendar policy

4 Numerical Experiments

A number of numerical experiments was conducted in order to compare the performance of each of the policies discussed in Sect. 3 under a collection of different scenarios characterized by the following variables: maintenance and operation costs; breakdown costs; transition rate; breakdown probability; and number of machines technicians.

The value of the objective function, V^* is computed by means of the simulation of 1040 decision periods. If we consider that interventions are conducted weekly, this accounts for a planning horizon of 20 years, which corresponds to the lifespan of a typical industrial equipment under normal conditions.

A total of 30 instances were simulated for each of 19440 possible scenarios. The scenarios were obtaining as combinations of the following parameter specifications. Instances consisted of 30, 60, 100 and 150 machines with the number of technicians given by ceiling of the 2%, 4% and 6% of the number of machines. The machines evolve over a 52 states deterioration space, visiting a new state every 4 to 6.67 weeks in one case, and every 2 to 4 weeks in another. Therefore, the deterioration probabilities are random extractions from $U(0.15, 0.25)$ and $U(0.25, 0.50)$ distributions, respectively. Additionally, the deterioration probabilities increase 0.5% in every transition. For the breakdown probabilities we considered five cases where each machine is first assigned a random value B_m obtained from one of the following distributions $U(0.05, 0.10,), U(0.10, 0.15), U(0.15, 0.20), U(0.20, 0.25)$ and $U(0.25, 0.30)$[3]; once this value is fixed, the breakdown probability of machine m at state s_m is computed as $B_m e^{0.025 s_m}$.

Regarding the costs, three possible values were considered for the breakdown costs: 500, 1500 and 3000. A random linear operation costs function was defined with three alternative intersects obtained from distributions $U(45, 55), U(135, 165)$ and $U(270, 330)$, and slope extracted from a $U(11.25, 18.75)$ distribution. Finally, twelve different configurations of the intervention costs where defined: three of them, constant random functions with support on $U(90, 110), U(225, 275)$ and $U(450, 550)$; and other nine quadratic configurations with the intersect following the same distribution as the constant cases and the quadratic term obtained from one of the following distributions: $U(0.0075, 0.0125), U(0.0225, 0.0375)$ and $U(0.0375, 0.0625)$.

In order to determine the states where intervention is allowed for all the policies, a parameter *Forbid* was introduced. This parameter takes the value of the minimal state for which all the indices in the index policy take non-negative values for each particular instance. In order to do so, the indices corresponding to the index policy are computed in the startup routine of each instance of the numerical experiments. These values were obtained based on [19] by means of the expression $I(m, s_m) = G(s)(1 - E[\beta^{\tau(0,s)}]) - K(0, \tau(0, s)) - E[\beta^{\tau(0,s)} C(\tilde{s})]$. In these expressions, with $G(s) = \frac{K(s,1)+E[\beta C(s^*)]-C(s)}{1-\beta}$. In these expressions, $E[\beta^{\tau(0,s)}]$ represents the accumulated discount during a transition from state 0 to state s, which takes an expected time given by $\tau(0, s)$; $K(0, \tau(0, s))$ represents the expected discounted intervention cost incurred in a transition between states 0 and s; $E[\beta^{\tau(0,s)} C(\tilde{s})]$ is the expected discounted cost of intervening a machine after $\tau(0, s)$ periods of operation ($\tilde{s}$ represents the expected arrival state after the operation sojourn); $K(s, 1)$ is the expected discounted cost of operating during one period when the initial state of the machine is s; $E[\beta C(s^*)]$ represents the expected discounted cost of intervening the machine at the expected arrival state

[3] Notice that in each case all the random values are extracted from the same distribution.

Table 1. Results of the illustrative example

† The benchmark example consists of a collection of 60 machines and three technicians. The operation costs are linear with constant parameter 150; the intervention costs are quadratic, with intersect 500 and quadratic coefficient 0.03. The breakdown costs are 1500, with breakdown parameter 0.10. Parameter *Forbid* takes value 3.

after one period operation (notice that $s^* \in (0, s, s+1)$); finally, $C(s)$ is the cost of intervention when the machine is in s.[4]

Once the indices are obtained, the threshold policy is computed fixing the threshold equal to the value *Forbid*; likewise, the pure condition based policy is only allowed to intervene machines with current state larger than *Forbid*. For the calendar based policies two alternatives approaches were taken: in the first one, the procedure was allowed to intervene any machine with state different than zero; in the second one, intervention was only admitted for states larger than *Forbid*.

A summary of the results obtained in a benchmark example is shown in Table 1. The columns represent the seven alternative policies, with the suffix $(-F)$ indicating that parameter *Forbid* has been used. The columns show, respectively, the average visited state and its variance, the maximum visited state, the number of breakdowns over 1040 periods, the average intervened state and it variance, the total operation/maintenance cost and the total number of interventions. The cost structure and the indices are illustrated in Fig. 2.

Figure 3 illustrates the evolution of an insulated machine under two of the most relevant policies: Index and Calendar. It can be seen that, under the index policy, the interventions tend to occur, in average, at state number 5, whereas the evolution under the calendar policy tends to be more erratic, as this policy does not take into consideration the state of the machine for scheduling interventions.

Given that the numerical values of the results of the experiments are not as important as the patterns detected during the numerical computations, we limit ourselves to presenting a graphical summary of our main findings. Firstly, we notice that the average cost of the operation/maintenance schedule over the

4 Closed form expressions for this equations, which have been omitted for the sake of briefness, are available from the authors upon request.

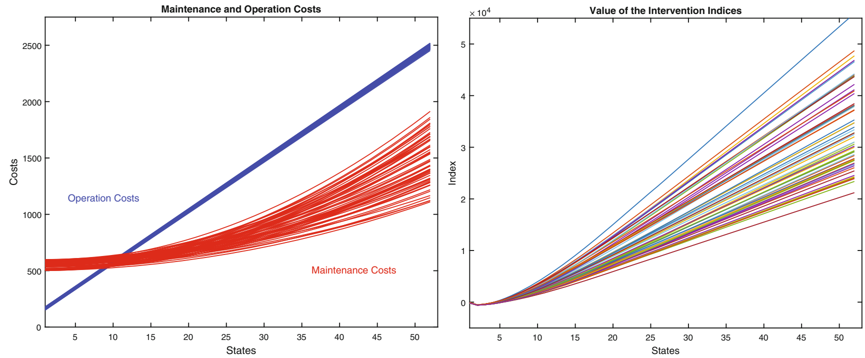

Fig. 2. Costs and Indices for 56 states in the illustrative example

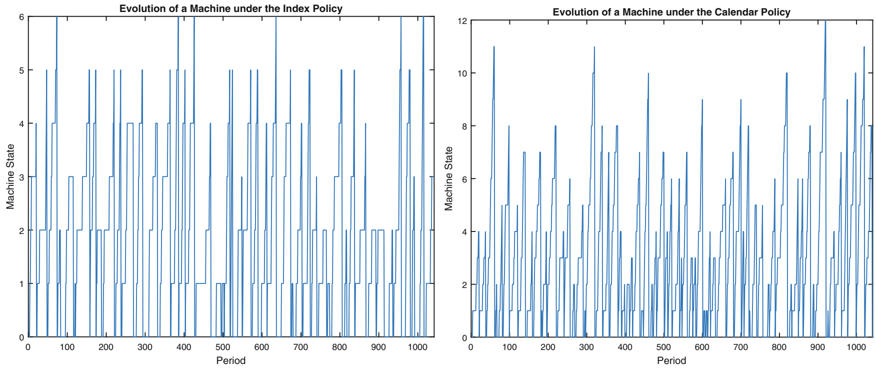

Fig. 3. Evolution of a random machine under index and calendar policies.

20 years planning horizon follows a very similar pattern for all policies, with the time dependent policies showing larger costs (in average) than the state dependent ones. This can be seen in panel (a) of Fig. 4, where the index (blue), Calendar-F (red) and the threshold policies (green) are compared[5]. This panel shows the total cost incurred by the seven policies over the 19440 scenarios and (the values are averages over 30 repetitions for each case)[6].

The sketch suggest the existence of four well defined blocks, corresponding to each of the four different specifications for the number of machines. Each of these main blocks is composed by three more or less differentiated segments, which

[5] For the sake of simplicity, the dynamic calendar policies and the simple version of the calendar policy have not been illustrated in this figure. However, their behavior does not present significant differences with respect to the results shown in the displays.

[6] Each point in the graph corresponds to the average cost, computed over 30 randomly generated problems, of a particular combination of operation, maintenance and breakdown costs, deterioration rates, breakdown probabilities and number of machines and repairmen.

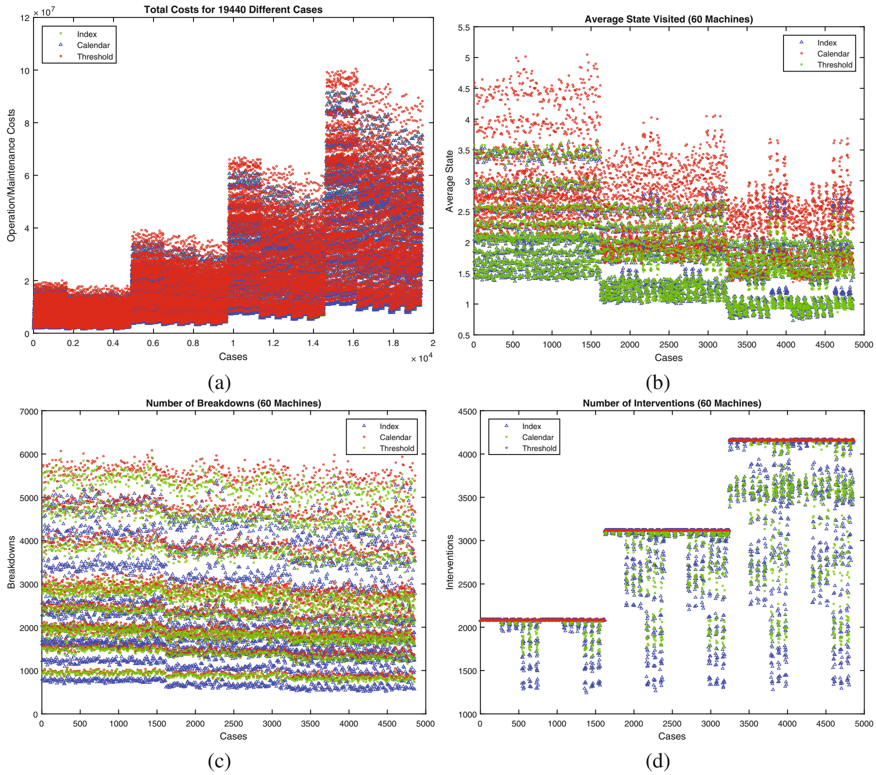

Fig. 4. Costs performance of the index, calendar-f and threshold policies over a 20 years planning horizon

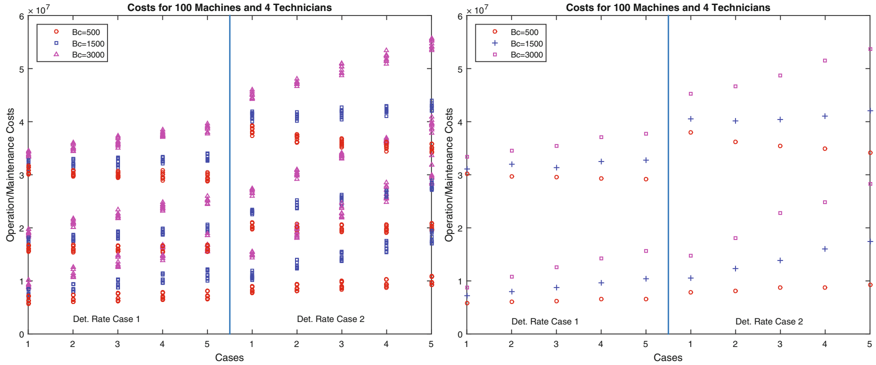
correspond to the three possible number of technicians used in our experiments. The figure clearly shows that the costs are increasing on the number of machines and decreasing on the number of technicians. In order to make our discussion simpler, and given the fact that the results observed in one group follow the same structure as the others (differing mainly in their absolute scale), in panels (b), (c) and (d) we limit our discussion to the results observed for the cases with 60 machines. Panel (b) shows the average visited state during the planning horizon. It can be appreciated that the time based regimes tend to visit larger states (i.e. machines deteriorate more) than state based policies. It can also be observed that the behavior of the threshold and the index policy is quite similar. This suggests that, even in the absence of a well grounded index heuristic, a decision maker will-in general-do better with a threshold policy than with a time based one. In panel (c) we show the number of breakdowns suffered by the system over the planning horizon. Again, the calendar policy shows a larger number of breakdowns, and the index policy shows a smaller number of failures than the other two. Finally, panel (d) depicts the number of interventions conducted by each policy over the 20 years horizon. It can be appreciated that condition based policies intervene much less than the time based ones. Moreover, the index policy clearly outperforms the threshold one. It is also interesting to see that the calendar policy intervenes a constant number of machines irrespectively of the specific cost structure of the particular scenario, with interventions depending only on the number of machines and technicians available.



(a) (b)

Fig. 5. Inner structure of the index policy results

We finally take a look inside of our plots in order to illustrate the inner structure of the results. In order to do so, we pick the case where there are 100 machines, four technicians and the costs are quadratic. Figure 5 illustrates the corresponding 810 results obtained for the index policy. Vertically, each panel is divided in two sections, corresponding to each of the two alternative deterioration rates proposed. Each section consists of five columns representing each of the possible configurations of the breakdown probabilities. Horizontally, it is possible to distinguish three blocks consisting of three groups of points (red, blue and magenta). Each of these groups is associated with a different value of the breakdown cost as illustrated by the legend. Additionally, each of the three main levels (consisting of three colors each) correspond to a different operation cost. For example, the southernmost red group corresponds to the smallest operation and breakdown costs; the next one (blue) corresponds to the lowest operation and the second breakdown cost, and so on. It can be seen that the colored points are grouped in small clusters. Each of these clusters correspond to the nine different combinations of the maintenance cost parameters. The second panel depicts the cases of a fixed maintenance cost and two alternative (high and low) operation costs, together with the three alternatives for the breakdown cost. This panel allows a more clear visualization of the behavior of our formulation. It can be seen, for example, that a larger deterioration rate implies larger costs for all the configurations (comparing the right and the left hand side sections). In general, the costs are larger as the likelihood of a breakdown increases, however, it is worth noticing that for low breakdown costs, this relationship may become negative. This may be reflecting an incentive to intervene less when the replacement cost of the equipment is small compared with the maintenance costs. This structure can be observed all over the set of experiments with only small variations between policies.

5 Conclusion

In this article presented a collection of general purpose machine maintenance scheduling policies that mimic the intervention strategies that are used in practice. These policies can be grouped in two broad categories: time and condition based policies. We additionally suggest a novel alternative consisting of a mixture of both. Our aim has been to obtain an assessment of their relative performance before different combinations of operation, intervention and failure costs, deterioration rates and breakdown probabilities.

With this aim, we conducted a large number of experiments. In general the results are according to what intuition will suggest: condition based policies in general perform better than time based ones. We also found that threshold policies in general outperform the pure condition based ones and are almost as efficient as the more sophisticated index policies. Our results show that when intervention and breakdown costs are low, time based policies may perform better than the index one, as this will try to postpone the intervention tasks, increasing the probabilities of breakdowns.

Our results are consistent with the trend that has been observed in the last few years in heavy equipment based industries: the use of time based policies has been gradually relegated in favor of more efficient condition based strategies. However, time based policies are still relevant because of both guarantee, safety and maintainability purposes, and the fact that in many cases condition monitoring systems require an important investment that cannot always be afforded by small firms.

Abstract. The environment of agricultural businesses in Japan is changing drastically due to decreasing self-sufficiency rate and the number of farmers, increasing average age of concerned workers, and competition with imported products. To cope with these trends, national government revised agricultural land law which came into effect in 2009 and some companies in this industry are implementing industrial management methods such as lean management for better performance. Besides the general common problems of manufacturing industry, agri-products have distinctive features such as production in natural environment, perishability of products, demand volatility although products are living necessaries. Based on the above cognition, this study discusses implementation of Heijunka (the method of level production and supply) operation, which is one important concept of lean management.

Keywords: Lean management · Supply chain · Agri-businesses · Heijunka production · Seeding schedule · Segmented farmland

1 Introduction

Because of the decreasing self-sufficiency rate and the number of farmers, increasing of the average age of farmers and limited agricultural land, the environment of agricultural business is in tough phase [6]. In addition, extreme narrowness of agricultural land area hinders production cost reduction, which leads to decline in price competitiveness of domestic agricultural products against imported goods. For this reason, in recent years the government has considered the ways of agricultural reform and promotion of more efficient production activities. As the result, the revised agricultural land law was implemented in 2009. So many companies try to adopt the management approach developed in manufacturing industries such as TPS (Toyota Production System) and aim for stable and efficient supply. However this scientific approach against hidden problem was

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_118

not satisfactory performed in the conventional agriculture, because of managers' leadership and employees' understanding, intuitions and skills [4].

Based on the above cognition, this study investigates and analyzes cases of farmers' efforts which incorporate industrial management methods and guide to effective management of agricultural production.

2 Related Study

Vassian [7] logically derived the periodic production ordering method that achieves the minimization of inventory fluctuation by using the demand forecast values, past production ordering and the term end stock amount. Based on this, Chiyoma et al. [1] proposed the production planning model for agricultural supply chain by the following mathematical Eqs. (1), (2), and (3), where consideration is given to varied harvest quantity that peculiarly happens on agricultural products.

$$P_t = \sum_{i=1}^{L} \hat{D}_{t,t+i} - \sum_{i=1}^{L-1} P_{t-i} - I_t + SS, \tag{1}$$

$$I_t = I_{t-1} + Q_t - D_t, \tag{2}$$

$$Q_t = P_{t-L} + \varepsilon_t. \tag{3}$$

Symbols

P_t : Production quantity planned at period t, completed at period $t + L$;
$\hat{D}_{t,t+i}$: Demand quantity of period $t + i$ predicted at the end of period t;
I_t : Inventory quantity at the end of period t;
SS : Safety stock level;
L : Production lead time $+ 1$;
D_t : Demand quantity at period t;
Q_t : The yield quantity at period t, where it does not always coincide with the planned quantity;
ε_t : The difference between Q_t and P_{t-L}.

3 Background and the Production Process of the Objective Products

In this study, research procedure includes case investigation of a company that aggressively adopts lean management, model building of manufacturing process focusing on loss structure, development of Heijunka contrivance for the objective system, of which idea is cropping scheduling based on segmented farmland. Actually, this study focuses on the baby leaf growing and supply process at the collaborating company H [2]. Among the people, who carefully consider their health, baby leaf are now booming foods and this business has been growing rapidly in Japan and many SMEs including this company were established. As a result, the competitiveness of this field becomes serious. On the other hand, there is a burden on production and delivery activities because of the lack of reliable workers and useful tools/weapons regarding agricultural management.

Companies trying to mitigate such obstacles have begun to learn from companies in other industrial field and introduce their management methods and techniques. For example, TPS is a typical lean management scheme born in Japan. Company H started the TPS learning project in 2006 with Toyota Motor headquarters under supervision of former Chairperson Mr. Cho and Senior Technical Executive Mr. Hayashi, who proposed how to introduce TPS during 2006–2008 [2]. This study focuses on reaching the next stage of lean, namely realizing level production and supply (that is called Heijunka) operations based on the historical approaches such as 5S, visualization, yield improvement etc.

The objective process consists of 4 major operations, i.e. seeding, germination, harvesting and shipping, and it is illustrated in Fig. 1. Note that there are some unknown mechanism creating losses in each sub-process, these losses are called germination yield rate, harvest rate and sorting rate where weight gain is increasing quantity of the baby leaf during the growing process. Models for parameter estimation of these losses and weight gain are given in the following 4 steps with Eqs. (4)–(10) and the result is given in Table 1 [5], where it is known that germination, harvest and sorting rates are stochastically fluctuated and weight gain rate stays constant which depends on climate (warmer or cooler terms).

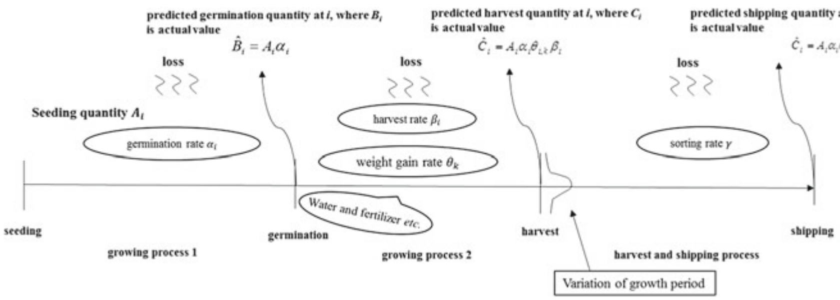

Fig. 1. Outline of the objective production process [5]

Step 1. Calculation formulas of $\hat{\delta}_i, \hat{\theta}_k$

Estimates $\hat{\delta}_i$ and $\hat{\theta}_k$ can be evaluated by least square method through minimizing the total difference between actual data of harvest and its estimated quantity as shown in Eqs. (4), (5), (6) and (7).

$$\min \sum_{i \in N} \left(\hat{C}_i - C_i\right)^2, \tag{4}$$

$$\hat{C}_i = A_i \times \hat{\delta}_i \times \hat{\theta}_k \, (k = 1, 2), \tag{5}$$

$$\text{s.t. } 0.64 \leq \hat{\delta}_i \leq 1, \tag{6}$$

$$50 \leq \hat{\theta}_k \leq 300. \tag{7}$$

Step 2. Calculation formulas of standard deviation

Estimating standard deviation of $\hat{\delta}_i$ is also important as this value represents the degree of internal turbulence that harms stable production.

$$\sigma_{\hat{\delta}} = S(\hat{\delta}_i), \tag{8}$$

where, sample data of $\hat{\delta}_i$ is obtained by the formula $\hat{\delta}_i = \frac{C_i}{A_i \hat{\theta}_k}$, which is deduced from formula (5) and S is the operator for standard deviation.

Step 3. Calculation formula of $\hat{\gamma}$

Point estimate of sorting rate $\hat{\gamma}$ can be obtained by the quotient of actual data of shipment and harvest quantities as shown in Eq. (9), where, E is the operator for mean value.

$$E(\hat{\gamma}) = E\left(\frac{D_i}{C_i}\right). \tag{9}$$

Step 4. Calculation formula of standard deviation

As the same meaning described in Step 3, standard deviation of $\hat{\gamma}$ is also important to estimate.

$$\sigma_{\hat{\gamma}} = S\left(\frac{D_i}{C_i}\right). \tag{10}$$

Symbols

A_i : Seeding quantity at planning term i [kg/a];
C_i : Harvest quantity at planning term i [kg/a];
$\hat{C}_i$: Estimated harvest at planning term i [kg/a];
D_i : Shipping quantity at planning term i [kg/a];
$\hat{D}_i$: Estimated shipping quantity at planning term i [kg/a];
N : Planning horizon [day];
α_i : Germination yield rate at planning term i;
β_i : Harvest yield rate at planning term i;
$\hat{\gamma}$: Estimated sorting yield rate;
$\hat{\theta}_k$: Estimated weight gain rate in k, ($k = 1$: warmer season, $k = 2$: cooler season)
$\hat{\delta}_i$: $\alpha_i \times \beta_i$ which is called estimated value of aggregated yield.

4 Concept of Heijunka and Its Realization

In this section, general approach and agri-specific production model for Heijunka are discussed.

Table 1. Estimated statistics of parameters [5]

	Germination rate × harvest rate	Weight gain (warmer term)	Weight gain (cooler term)	Sorting rate
Average	0.63	78.29	128.58	0.57
Standard deviation	0.14	N/A	N/A	0.21

4.1 General Approach for Heijunka

It is necessary that standard deviation and average of variable must be controlled in this order to realize continuous and stable production, which is called Heijunka production. General approach for Heijunka is illustrated in Fig. 2.

- Phase 1: Recognition of "Muri"; Firstly, current Muri must be recognized.
- Phase 2: Reduction of "Mura"; Secondly, variance reduction must be focused.
- Phase 3: Reduction of "Muda"; Finally, reduction of "Muda" must be conducted after reduction of "Mura", where level production and supply operations become much easier than before because internal turbulence was controlled in Phase 2.

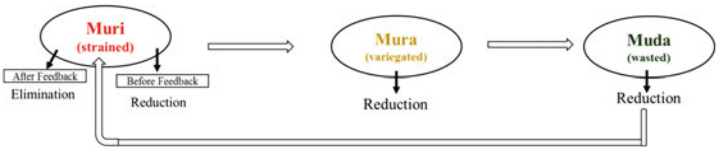

Fig. 2. General approach for Heijunka

4.2 Agri-Specific Production Model for Heijunka

For Heijunka of the objective operation, 3M ("Muri", "Mura", "Muda") are visualized and zero-tized, and seeding schedule based on segmented farmland are discussed respectively.
(1) Visualizing and zero-tizing the phenomena of 3M (Conventional lean approach)

Heijunka procedure regarding to Muri, Mura and Muda for the objective process is illustrated in Fig. 3 where target variable and its factors are shown. Stochastic simulation is a possible way to analyze the characteristics because variables and parameters in this system are fluctuated. In this study, firstly, current Muri is understood and assumed. In the second stage, variance control must be focused, which consists of 2 experiments. Factors affecting variation of harvest interval are considered as seeding interval and growth term, and that of

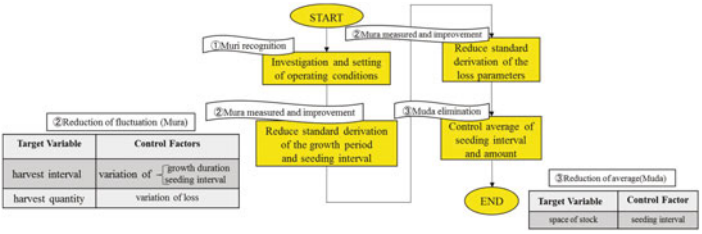

Fig. 3. Procedure of experiment

harvest quantity is considered as aggregated yield, and these standard deviation must be reduced. In the final stage, average of seeding interval is controlled under the idea of frequent small-lot production of industrial management method.
(2) Seeding schedule based on segmented farmland (Lean approach with case depending procedure)

It is essential to introduce a production system that can meet demand with limited field area because productivity improvement is indispensable in agricultural business in Japan. Therefore, seeding schedule on segmented farmland that can flexibly respond to demand quantity is considered. Design of seeding quantity, harvest quantity and harvest date is defined by Eqs. (11), (12) and (13).

$$A_i = T/N, \tag{11}$$

$$\hat{C}_i = A_i \hat{\delta}_i \theta, \tag{12}$$

$$\hat{d}_i = R_i + s_i. \tag{13}$$

Symbols
N : Number of segments of farmland;
T : Seeding capacity of entire farmland [kg];
A_i : Seeding quantity per segment at planning term i [kg/seg].
$\hat{C}_i$: Estimated harvest quantity at planning term i [kg/seg];
$\hat{\delta}_i$: Estimated value of aggregated yield of seeding quantity at planning term i;
θ : Supposed weight gain rate (percentage of weight increase);
$\hat{d}_i$: Estimated harvest date of seeded plants at term i;
R_i : Growth duration of seeds at planning term i;
S_i : Seeding date at planning term i.

In addition, an example of seeding schedule is shown in Fig. 4, and an example of input and output dates are shown in Fig. 5, where the number of segments is 9.

5 Result

In this Sect. 2 results derived from the model/procedure described in the previous chapter are summarized.

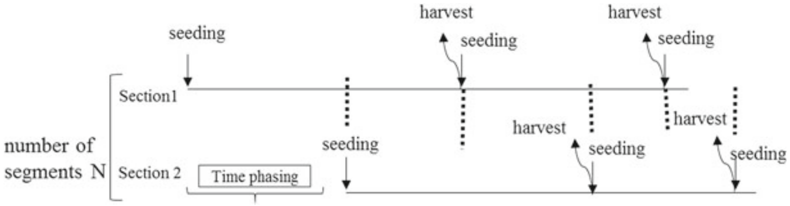

Fig. 4. Example of seeding schedule

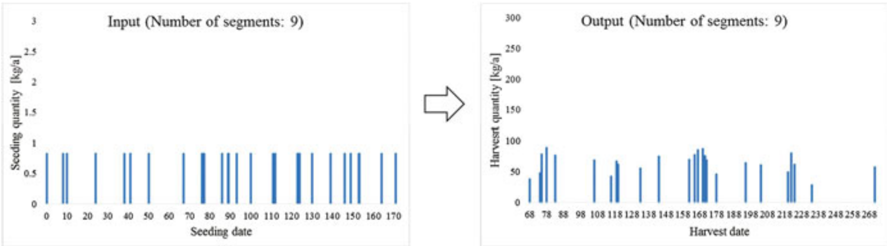

Fig. 5. Example of input and output time series

5.1 Performance of Conventional Lean Approach

(1) Phase 1: Quantification of "Muri" and its effects

The lack of human resources and skills throughout the whole process from seeding to shipment is recognized. Performance of current system is given in Table 2.

Table 2. Condition and performance of current system

	Variable			Aggregated yield	Result	
	Seeding quantity [kg/a]	Seeding interval [days]	Growth duration [days]		Harvest quantity [kg/a]	Harvest interval [days]
Average	0.85	7.12	63.26	0.63	71.27	8.28
Standard deviation	0.08	5.24	18.10	0.14	18.72	7.71

(2) Phase 2: Reduction of "Mura"

The purpose of the experiment is to evaluate the stability of harvest performance by improving fluctuation of variables. Firstly, standard deviation of the seeding interval and growth duration were reduced. Result is given in Table 3.

Secondly, in addition to the condition of the first experiment, standard deviation of the aggregated yield is reduced. Result is given in Table 4.

Table 3. Result of "Mura" reduction: first experiment (* is focused variable and performance)

	Variable			Aggregated yield	Result	
	Seeding quantity [kg/a]	Seeding interval [days]	Growth duration [days]		Harvest quantity [kg/a]	Harvest interval [days]
Average	0.89	7.05	63.26	0.63	73.35	7.06
Standard deviation	0	1.26^*	6.08^*	0.14	17.20	4.89^*

Table 4. Result of "Mura" reduction: second experiment (* is focused variable and performance)

	Variable			Aggregated yield	Result	
	Seeding quantity [kg/a]	Seeding interval [days]	Growth duration [days]		Harvest quantity [kg/a]	Harvest interval [days]
Average	0.89	7.05	63.26	0.63	72.27	7.06
Standard deviation	0	1.26	6.08	0.05^*	5.66^*	4.89

Table 5. Result of "Muda"reduction (* is focused variable and performance)

	Variable			Aggregated yield	Result	
	Seeding quantity [kg/a]	Seeding interval [days]	Growth duration [days]		Harvest quantity [kg/a]	Harvest interval [days]
Average	0.73^*	5.78^*	63.26	0.63	59.29^*	5.82^*
Standard deviation	0	1.26	6.07	0.05	4.89	4.32

(3) Phase 3: Reduction of "Muda"

The purpose of this experiment is to evaluate the influence of frequent small-lot production (Heijunka). For a pragmatic improvement point of view, a case that average seeding interval and quantity are 6/7 respectively is considered for analysis. Result is given in Table 5. Where, it is assumed that necessary farmland can be procured without any restriction but based on the contracts.

Changes in each value of standard deviation and average are described below.

- Before and after ratio of standard deviation of harvest interval is 0.56 approximately (from 7.71 to 4.32) and that of harvest quantity is 0.26 approximately (from 18.72 to 4.89).
- Before and after ratio of average of harvest interval is 0.7 approximately (from 8.28 to 5.82) and that of harvest quantity is 0.8 approximately (from 71.27 to 59.29).

Relationship of before and after improvement is given in Fig. 6. By the above procedure, harvest date and quantity can be predicted more accurately by reducing Mura which is general turbulent factor, and stock volume and space are expected to be improved by reducing both seeding interval and quantity as mentioned in Fig. 3. This procedure leads us to the Heijunka world. Worker's skill and the number of necessary workers can be encouraged to improve and then Muri of current system must be disappeared.

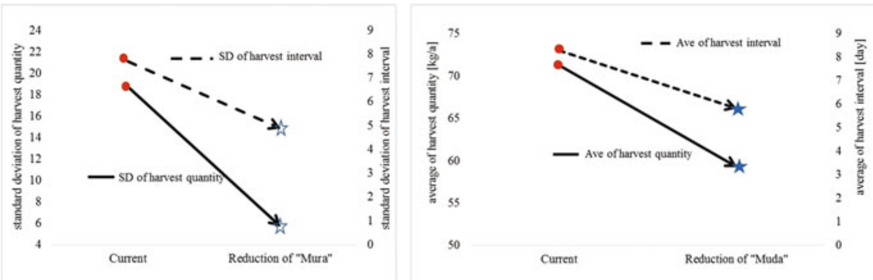

Fig. 6. Relationship on before and after improvement

5.2 Performance of Lean Approach with Case Depending Procedure

In Sect. 5.1, condition of farmland is not considered. In this section, performance of the proposed model is as described in Sect. 4.2, where farmland segmentation and its scheduling procedure [3] are added to the conventional lean approach, is evaluated by experiments. Relationship between number of segments and harvest interval and that of harvest quantity are given in Fig. 7. The star marks (★ and ☆) in these figures show the result of the model described in Sect. 5.1, where ★ and ☆ represent the performance described in Tables 3 and 4 respectively. Obtained performance of the proposed model indicates that average harvest interval and quantity are both decreasing along with increase of number of segments. Standard deviation of these variables has the same characteristics. And there are significant gaps in the characteristics between standard deviations of harvest interval obtained by Sects. 5.1 and 5.2. Namely, the proposed model discussed in this section seems to provide worse performance than conventional lean approach. Main reason will be consideration of the pragmatic restriction on segment rotation in the proposed model, which simply describes seeding is the precedence operation of harvesting in the same segment.

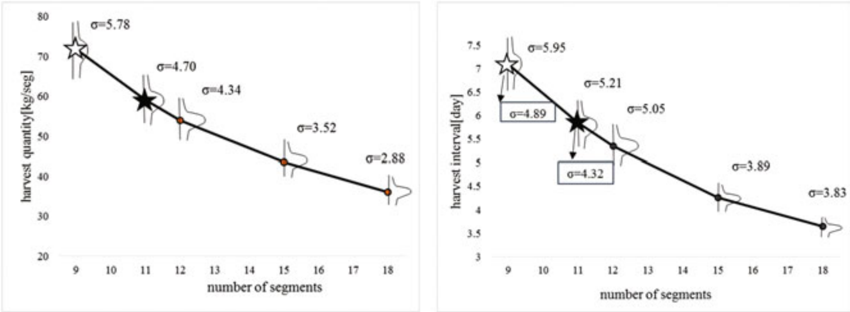

Fig. 7. Trial experiment results (five years)

6 Concluding Remarks

In this study, agricultural production management method is suggested for achieving Heijunka operation and applied to a production management division of collaborating agri-company. The turbulent factors in the agricultural production process were clarified and its performance is analyzed by simulation experiments by controlling levels of these factors. The obtained results revealed that elimination of turbulent elements such as seeding interval, growth duration and aggregated yield are critical for performance improvement. Furthermore seeding schedule on segmented farmland can respond flexibly to demand changes under restricted usability of farmland. Obtained result can be a fine example of lean management transfer to agriculture industry.

Optimizing Reserve Combination with Uncertain Parameters (Case Study: Football)

Masoud Amel Monirian(✉), Hamideh Razavi, and Shabnam Mahmoudzadeh Vaziri

Industrial Engineering Department, Ferdowsi University of Mashhad, Mashhad, Iran
masoudmonirian@yahoo.com

Abstract. Preventive maintenance is critical when non-stop operation with maximum efficiency and reliability is required. In such conditions, proper identification of reserve and spare parts in terms of types and models, order and stock sizes as well as replacement timings become highly important. Arranging reserve sets, many constraints such as costs, space, obsolescence and deterioration must be met. Therefore, an integrated model for appropriate selection of reserves and timing for substitution is needed. This model can be similarly used in multiplayer sports such as football games. In this paper we propose an uncertain mathematical model to solve reserve combination strategy.

Keywords: Reserve combination · Optimization · Uncertainty theory · Uncertain programming

1 Introduction

Selecting an optimum reserve set and implementing the best replacement strategy is a challenge for most industries. Likewise, in multiplayer sports, choosing the right combination of the reserve team and taking a proper replacement strategy needs an advance planning and optimization. Inaccurate arrangements can cause significant financial loss as well as reputations.

When a team enters a tough league to play against different opponents with different methods, these issues become even more critical. Success or failure of each team depends on member's ability and skills. Therefore, it is essential to arrange the best combination both in main and reserve team in order to obtain the optimum results [2,9]. A few structured models have addressed this problem. Most of the studies emphasis on combination of the main team [1]. Since decisions are made prior to the games, we face probability and uncertainty in the problem, for which we use uncertain programming. It is a powerful tool in modeling industrial, human, natural and peddling and probability systems.

Certainly in intensive games, it is impossible to use 11 players. Players due to fatigue, injury, disciplinary cases and other reasons aren't available in all

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_119

games, and coach should use all main and reserve players to reach victory and profitability. Importance of reserve players when they replaced in proper time with suitable person, is not hidden to anyone, because with their adequate energy and by using skills and power can be influential. For instance, in final game of world cup 2014 in extra times, substitution players led the German team won the game.

1.1 Football Overview

Players are divided to 5 posts: goal keeper, defender, midfielder, sides, forward. According to game's technique, number of players in each post (expect goal keeper) can be different. This classification is done according to each player's abilities. Players due to their skills can be suitable for several posts.

1.2 Problem Definition

Broadly speaking, in selecting reserve team we assume that we have a main team and according to its constraints, situation and game circumstances, a reserve team should be selected. Replacement strategy conforming the game process and player's situation, declares that which player in the pitch should replace with which player in reserve team, in best time in order to preserve quality of the team. A football team plays in diverse leagues. Sometimes the schedule becomes so compressed, even they may have 3 or 4 games in a week. This event causes player's exhaustion. Consequently, generally main combination are not considered fix, so reserve combination selection problem and also replacement planning are very important issues. The first and main step for selecting reserve team and replacement strategy is recognition and evaluation of main team and desired options for reserve so that able us to compare different players in each post with stable criteria. First, players evaluated with belief degrees and by using mathematical model, choose reserve team to maintain team quality at maximum state. For rating players we need to consider several number of quantitative and qualitative characteristics in player's selection, like individual skills, statistics data in previous matches, physical readiness, psychological factors, injury and also opponent's condition [8]. In average, each football team, in normal situation, has more than 24 players that 10 of them plays in main combination and 6 of them are in reserve team. In this problem, we do not consider goal keeper selection. Because they run less during the game so their fatigue is less, but for compulsive situations, injury or expulsion it is necessary to have a goalkeeper in reserve team [3,8]. For scoring and evaluating players, 18 indexes and criteria such as heading, jumping, dribbling, tackling and so on are defined, that these criteria are approved by football simulation's companies. We value these criteria according to coach's opinion. In Table 1 these criteria are presented.

Uncertainty theory was founded by Liu [5] in 2007 and studied by many researchers. Uncertainty theory is a new method for modeling undetermined phenomena based on normality, duality, subadditivity and product axioms.

Table 1. List of criteria

Criteria	Number	Criteria	Number
Heading, jumping	1	Create goal scoring position	10
Shoot	2	Tackling	11
Short passing	3	Both feet	12
Crossing	4	Great stamina	13
Ball control	5	Height	14
Dribbling	6	Providing through (long) pass	15
Finishing (composure)	7	Technical ability	16
Speed	8	Create attacking opportunities	17
Creativity	9	Read the game	18

Uncertain programming presented by Liu [3], is a type of mathematical programming which involves uncertain variables. This paper aims to model uncertainty in football decisions based on uncertainty theory.

The rest of this paper is organized as follows. In Sect. 2, we review some basic concepts about uncertainty theory. Then we introduce uncertain programming in Sect. 3. After that, we introduce determining the reserve combination problem and uncertain determining the reserve combination problem in Sects. 4 and 5, respectively. In Sect. 6, we propose experimental results and solve the model. At last, some remarks are made in Sect. 7.

2 Preliminary

Uncertainty theory is a branch of axiomatic mathematics based on normality, duality, subadditivity and product axioms. In this section, we introduce some concepts in uncertainty theory, which are used throughout this paper.

Definition 1 (Liu [7])**.** Let τ be a nonempty set, and $\mathcal{L}$ be a $\sigma-$ algebra on Γ. A set function M is called an uncertain measure if it satisfies the following axioms,

Axiom 1: (Normality Axiom) $M\{\Gamma\} = 1$;

Axiom 2: (Duality Axiom) $M\{\Lambda\} + M\{\Lambda^c\} = 1$ for any event Λ;

Axiom 3: (Subadditivity Axiom) For every sequence of, we have

$$M\left\{\bigcup_{i=1}^{\infty} \Lambda_i\right\} \leq \sum_{i=1}^{\infty} M\{\Lambda_i\}. \tag{1}$$

In this case, the triple $(\Gamma, \mathcal{L}, M)$ is called an uncertainty space.

In addition, a product axiom on the product of uncertainty spaces was defined by Liu [7], which is the fourth axiom of uncertainty theory.

Axiom 4: (Product Axiom) Let $(\Gamma_k, \pounds_k, M_k)$ be uncertainty spaces for Then the product uncertain measure M is an uncertain measure satisfying

$$M\left\{\prod_{k=1}^{\infty} \Lambda_k\right\} = \Lambda_{k=1}^{\infty} M_k \left\{\Lambda_k\right\}, \tag{2}$$

where Λ_k are arbitrarily chosen events from $\pounds_k$ for $k = 1, 2, \cdots$, respectively.

Definition 2 (Liu [7]). An uncertain variable ξ is a measurable function from an uncertainty space $(\Gamma, \pounds, M)$ to the set of real numbers, i.e., for any Borel set ξ of real numbers, the set

$$\{\xi \in B\} = \{\gamma \in \Gamma | \xi(\gamma) \in B\} \tag{3}$$

is an event.

Definition 3 (Liu [4]). The uncertain variables $\xi_1, \xi_2, \cdots, \xi_n$ are said to be independent if

$$M\left\{\bigcap_{i=1}^{n} (\xi_i \in B_i)\right\} = \Lambda_{i=1}^{n} M\left\{\xi_i \in B_i\right\} \tag{4}$$

for any Borel sets $B_1, B_2, \cdots, B_n$ of real numbers.

Definition 4 (Liu [7]). The uncertainty distribution ϕ of an uncertain variable ξ is defined by

$$\phi(x) = M\left\{\xi \leq x\right\} \tag{5}$$

for any real number x.

If the uncertainty distribution $\phi(x)$ has an inverse function $\phi^{-1}(\alpha)$ for each $\alpha \in (0, 1)$, then $\phi^{-1}(\alpha)$ is called the inverse uncertainty distribution of the uncertain variable ξ. In this case, the uncertainty distribution ϕ is said to be regular. An uncertain variable ξ is called linear if it has an uncertainty distribution

$$\phi(x) = \begin{cases} 0, & \text{if}\, x < a \\ \frac{(x-a)}{(b-a)}, & \text{if}\, a \leq x \leq b \\ 1, & \text{if}\, x > b \end{cases} \tag{6}$$

denoted by $\pounds(a, b)$.

Theorem 1 (Liu [6]). *Let $\xi_1, \xi_2, \cdots ., \xi_n$ be independent uncertain variables with regular uncertainty distributions $\phi_1, \phi_2, \cdots, \phi_n$, respectively. If the function $f(x_1, x_2, \cdots, x_n)$ is strictly increasing with respect to $x_1, x_2, \cdots, x_m$ and strictly decreasing with respect to $x_{m+1}, x_{m+2}, \cdots, x_n$, then $\xi = f(\xi_1, \xi_2, \cdots, \xi_n)$ is an uncertain variable with an inverse uncertainty distribution*

$$\phi^{-1}(\alpha) = f(\phi_1^{-1}(\alpha), \cdots, \phi_m^{-1}(\alpha), \phi_{m+1}^{-1}(1-\alpha), \cdots, \phi_n^{-1}(1-\alpha)). \tag{7}$$

Definition 5 (Liu [7]). The expected value of an uncertain variable ξ is defined by

$$E[\xi] = \int_0^{+\infty} M\{\xi \geq x\}\,\mathrm{d}x - \int_{-\infty}^{0} M\{\xi \leq x\}\,\mathrm{d}x, \tag{8}$$

provided that at least one of the two integrals is finite.

If an uncertain variable ξ has a regular uncertainty distribution ϕ, then

$$E[\xi] = \int_0^1 \phi^{-1}(\alpha)\mathrm{d}\alpha \tag{9}$$

provided that the expected value $E[\xi]$ exists. Lease acknowledge collaborators or anyone who has helped with the paper at the end of the text.

3 Uncertain Programming

Uncertain programming, which was first proposed by Liu [5], is a type of mathematical programming involving uncertain variables. Assume that x is a decision vector, and ξ is an uncertain vector. Since the uncertain programming model contains the uncertain objective function $f(x,\xi)$ and uncertain constraints $g_j(x,\xi) \leq 0$, $j = 1, 2, \cdots, p$, Liu [5] proposed the following uncertain programming model,

$$\begin{cases} \min_x & E[f(x,\xi)] \\ \text{s. t.} & M\{g_j(x,\xi) \leq 0\} \geq \alpha_j, \quad j = 1, 2, \cdots, p. \end{cases} \tag{10}$$

Definition 6 (Liu [6]). A vector is called a feasible solution to the uncertain programming model if

$$M\{g_j(x,\xi) \leq 0\} \geq \alpha_j \tag{11}$$

for $j = 1, 2, \cdots, p$.

Definition 7 (Liu [6]). A feasible solution x^* is called an optimal solution to the uncertain programming model if

$$E[f(x^*,\xi)] \leq E[f(x,\xi)] \tag{12}$$

for any feasible solution x.

Theorem 2 (Liu [6]). *Assume $f(x, \xi_1, \xi_2, \cdots, \xi_n)$ is strictly increasing with respect to $\xi_1, \xi_2, \cdots, \xi_m$ and strictly decreasing with respect to $\xi_{m+1}, \xi_{m+2}, \cdots, \xi_n$, and $g_j(x, \xi_1, \xi_2, \cdots, \xi_n)$ are strictly increasing with respect to $\xi_1, \xi_2, \cdots, \xi_k$ and strictly decreasing with respect to $\xi_{k+1}, \xi_{k+2}, \cdots, \xi_n$ for $j = 1, 2, \cdots, p$.*

If $\xi_1, \xi_2, \cdots, \xi_n$ *are independent uncertain variables with uncertainty distributions* $\phi_1, \phi_2, \cdots, \phi_n$*, respectively, then the uncertain programming*

$$\begin{cases} \min_x & E\left[f(x, \xi_1, \xi_2, \cdots, \xi_n)\right] \\ s.\ t. & M\left\{g_j(x, \xi_1, \xi_2, \cdots, \xi_n) \leq 0\right\} \geq \alpha_j, \quad j = 1, 2, \cdots, p. \end{cases} \tag{13}$$

is equivalent to the crisp mathematical programming

$$\begin{cases} \min_x & \int_0^1 f(x, \phi_1^{-1}(\alpha), \cdots, \phi_m^{-1}(\alpha), \phi_{m+1}^{-1}(1-\alpha), \cdots, \phi_n^{-1}(1-\alpha))\mathrm{d}\alpha \\ s.\ t. & g_j(x, \phi_1^{-1}(\alpha_j), \cdots, \phi_k^{-1}(\alpha_j), \phi_{k+1}^{-1}(1-\alpha_j), \cdots, \phi_n^{-1}(1-\alpha_j)) \leq 0, \\ & j = 1, 2, \cdots, p. \end{cases} \tag{14}$$

4 Mathematical Model for Determining the Reserve Combination

In this model, due to the evaluations from players on the pitch and reserve players and considering constraints, number of players are chosen to be in reserve team, aims to maximize the power of reserve team and minimize the reduction of team's weakness. The model is linear with binary variables.
Indices:

n: number of players (in football it is usually 22 players);
k: number of features $k = 1, 2, \cdots, 18$ (Table 2);
i: the number of fixed players $i = 1, 2, \cdots, 10$;
j: the number of reserve players $j = 1, \cdots, n - i$;
l: number of posts $l = 1, \cdots, 4$ (for values of l we have:
$l = 1$ defender, $l = 2$ midfielder, $l = 3$ sides, $l = 4$ forward).

Parameters:

c_{jk}: the value of criteria k of player;
$MinR$: minimum number of reserve players;
w_{kl}: the value of criteria k in post l;
$MaxR$: maximum number of reserve players;
L_i: the post of player i;
P_i: probability of need to replace player i;
R_j: player accessibility characteristic (if player j is available $R_j = 1$, otherwise $R_j = 0$).

Decision variable:

$$x_{ij} = \begin{cases} 1, \text{ if there is need to replace player } i \text{ with player } j \\ 0, \text{ otherwise.} \end{cases}$$

The model is defined as follows,

$$\max \sum_{k} \sum_{i} \sum_{j} w_{kL_i}\, c_{jk}\, p_i\, x_{ij} \tag{15}$$

$$\text{s.t} \sum_{i} \sum_{j} x_{ij} \leq \max R \tag{16}$$

$$\sum_{i} x_{ij} \leq R_j \quad \forall j \tag{17}$$

$$\sum_{j} x_{ij} \geq 1 \quad \forall i,\ \mathrm{L_i} = 1, \quad \forall i, \quad \mathrm{L_i} = 2, \quad \forall i, \quad \mathrm{L_i} = 3, \quad \forall i, \quad \mathrm{L_i} = 4 \tag{18}$$

$$x_{ij} \in \{0, 1\}. \tag{19}$$

The proposed model is linear. The objective function (15) targets to maximize the reserve team's quality, which obtains from multiplying each player's value in desired post in probability of the need to replacement in that post. Constraint (16) determines maximum number of allowable replacements. Constraint (17) indicates the availability of players because it is possible that the player is not in the team owing to Injury or deprivation of the game. Constraint (18) states that each post should not be vacant. Constraint (19) indicates decision variable type.

5 Uncertain Mathematical Model for Determining the Reserve Combination

The player's criteria are not constant always and they can change due to game situation, fatigue and so on. To use the criteria in mathematical model, we use belief degree and uncertain programming.

The parameters c_{jk}, w_{kL_i} and p_i are uncertain parameters with uncertain distributions $\varphi_{jk}, \phi_{kL_i}$ and ω_i, respectively. We define $f(x, C, W, P) = \sum_k \sum_i \sum_j C_{jk} W_{kL_i} P_i x_{ij}$, whose inverse uncertainty distribution is $\gamma^{-1}(x, \alpha) = \sum_k \sum_i \sum_j \varphi_{jk}^{-1} \phi_{kL_i}^{-1} \omega_i^{-1} x_{ij}$.

To use uncertain programming the model changes as follows, Since $\gamma^{-1}(x, \alpha)$ is the inverse uncertainty distribution of $f(x, C, W, P)$, the mathematical model is simplified as follows,

$$\max E\left[f(x, C, W, P)\right] \tag{20}$$

$$\text{s.t.} \sum_{i} \sum_{j} x_{ij} \leq MaxR \tag{21}$$

$$\sum_{i} x_{ij} \leq R_j \quad \forall j \tag{22}$$

$$\sum_{j} x_{ij} \geq 1 \quad \forall i,\ \mathrm{L_i} = 1, \forall i, \quad \mathrm{L_i} = 2, \quad \forall i, \quad \mathrm{L_i} = 3,\ \forall i, \quad \mathrm{L_i} = 4 \tag{23}$$

$$x_{ij} \in \{0, 1\}. \tag{24}$$

6 Experimental Results

The proposed model solved with IBM ILOG CPLEX-Optimizer v12. 3. We choose a team with 24 players and solve the problem with these players. Due to coach's opinion the belief degrees are obtained. The results are presented in appendix. In football games the maximum allowed replacements as 3 times. The results of solving models using these data are examined in this section. The main players' number, which is determined according to coach's opinion, is like follows. This will be an input for model. The reserve team will be chosen due to the input of model.

22	20	18	15	14	9	5	2	7	1

The reserve team, due to the model, is chosen as follows,

12	23	19	11	8	3

According to model suggested combination, average quality of the reserve will be 83%. When only the coach's opinion was important, and without using model, the average quality of the reserve was 55% that brings a significant increase for team. The reserve team, according to coach's opinion, shows as follows,

10	24	19	11	4	3

Table 2 shows the comparison of objective functions in two cases which indicates the model's efficiency.

Table 2. Comparison of the first model in simulation environment

Number of simulation runs	$\overline{f^*}$ without the model	$\overline{f^*}$ by the model	Improvement of simulation runs
80	63%	91%	28%

7 Conclusion

The purpose of this article is to propose a model for choosing reserve team, so the quality reduction will be minimum. We proposed a linear mathematical model. To obtain uncertain parameters we use belief degree and uncertain programming. For future works, authors can investigate main combination selection due to the future games and simultaneous select reserve team.

Abstract. In recent years, flexible scheduling attracted considerable attention, motivated by both important practical issues and interesting research problems, especially under stochastic environment. In this paper we discuss a stochastic scheduling problem whose scale arranges from small to large. The objective in the schedule is to minimize the processing time over all of the jobs. However, stochastic environment will bring more difficulty especially for large scale because the sudden change of processing time for each operation may break the current optimal solution and lose efficiency. So, we propose a Bayesian network based particle swarm optimization (BNPSO) for solving this stochastic scheduling problem. Firstly, we use new framework named co-cooperative (CC) evolutionary framework which decompose all decision variables into several small group containing part of decision variables to overcome large scale problems. And then, BNPSO adjust the group scene according to their interactive relationships based on Bayesian network structure. Meanwhile, importing self-adaptive mechanism for parameters in order to satisfy the stochastic environment. Some practical test instances will demonstrate the effectiveness and efficiency of the proposed algorithm.

1 Introduction

Over the past sixty years, a great number of researches have been conducted on the job shop scheduling problem (JSP), which is a branch of the scheduling problem and highly popular in the manufacturing industry. JSP is a classical combinatorial optimization problem, and it is recognized as NP-hard under the precedence and resource constraints [2,5]. The flexible job shop scheduling problem (FJSP) is a generalization of the classical JSP for flexible manufacturing systems (FMSs).

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_120

In real-world problem, most of the scheduling problems are the stochastic scheduling problems. As one of the newest issues, more and more attentions focused on the problem with random processing time. As a result, in the last several decades, a significant amount of results has been achieved on the stochastic scheduling problems [3]. Moghaddam et al. [13] proposed a hybrid method using a neural network approach and a simulated annealing algorithm in two stages, in order to produce the optimal/near-optimal solution. Liu, Wang and Jin [9] presented an approach named PSOSAHT that is hybrid with simulated annealing (SA) and hypothesis test (HT), for stochastic flow shop scheduling with uncertain processing time. Zhou, Nee and Lee [17] developed an ant colony optimization algorithm (ACO) with different levels of machine utilizations, processing time distributions, and performance measures. Lei [6] developed an efficient decomposition-integration genetic algorithm (DIGA) to minimize the maximum fuzzy completion time. For solving realistic scheduling problems, intelligent manufacturing planning and scheduling based on meta-heuristics, such as GAs and ACOs have become common techniques for finding satisfactory solutions within reasonable computational times. However, as the scale of problem increases, the search space will increase exponentially, consequently and the probability of obtaining optimal solution will be reduced. To overcome it, coevolution framework was proposed firstly in 1994, which represents and solves more complex problems by explicitly modeling the coevolution of cooperating species [11]. Up to now, there exist various typical grouping mechanisms. Bergh et al. [14] proposed a cooperative coevolutionary approach which used the fixed group size to solve function problems. Li, et al. [10] thought more frequent random grouping mechanism could have better performance and proposed a cooperative coevolutionary framework and employs a technique called random grouping in order to group interacting variables into one subcomponent for large scale continuous global function optimization. Yao et al. [8] balanced the random grouping with fixed grouping, and proposed a set-based grouping mechanism which group set was given in advanced. When the global optimal solution does not be optimized, to select a new group size randomly immediately. However, all of the grouping strategies described so far use a predefined and fixed group size. For example, random grouping decomposes an n-dimensional problem into k s-dimensional problems. A major drawback of these techniques is that the user needs to specify a value for either k or s or a set of potential s values and the given values will effect the performance directly. Another drawback of this multilevel scheme is that once an s value is chosen, the decision variables are divided into a set of equally sized subcomponents. It is unlikely that in most real-world problems the sizes of interacting groups will be not equal. Hence, it is desirable that a decomposition strategy can automatically determine the number of subcomponents and their sizes.

In recent years, probabilistic graphical models (PGMs), which are used to represent the relationship among the discrete variables, have attracted a growing attention. PGMs can be mainly categorized into two categories: Bayesian networks (directed) and Markov networks (undirected) [15]. In Bayesian network, nodes represent variables and arcs shows the relationship between two linked nodes. So, if we can use Bayesian network to shown the relationships among the variables, we will no longer need to determine the number of subcomponents and their sizes. In the application of Bayesian network, Bayesian optimization algorithm (BOA) is widely used in scheduling, such as, resource assignment, task scheduling and so on. In 2011, Yang et al. [15] present a novel scheduling algorithm based on BOA for heterogeneous computing environments. Li et al. [7] proposed a Bayesian optimization algorithm to solve task assignment problems in heterogeneous computing systems. Hao et al. [4] proposed a novel cooperative Bayesian optimization algorithm (CoBOA) to overcome the challenges mentioned in the field of multiple resources scheduling problem (MRSP). Inspired by BOA, in this paper, we proposed a learning-based grouping mechanism in which we apply BOA to get the optimal Bayesian network structure for finding the potential relationships among variables and then to divide the variables according to relationships (network structure).

The remainder of this paper is organized as follows: Sect. 2 gives the formulating process of S-fJSP and mathematical programming model; Sect. 3 describes the BNPSO combined BOA Particle swarm algorithm (PSO) with multiple subpopulations in detail; Sect. 4 gives kinds of detailed numerical experiments and computational results; finally, Sect. 5 comes to the conclusion of the paper.

2 Mathematical Formulation

In order to solve a stochastic flexible job-shop scheduling problem (S-fJSP), it assumes that the probability distribution of the processing time is known in advance. In this paper, we use a pure integer programming model to transmute the processing times in terms of stochastic variable. The S-JSP can be formulated as an extended version of fJSP. Difference to the conventional fJSP, each operation o_{ij} is carried out under uncertain random disturbance with pre-given expected valued $E\left[p_{ij}\right]$ and variance v_{ij}, where p_{ij} is the processing time of O_{ij} on the machines. The distribution of the variance can be predicted from the experimental data such as normal distribution, uniform distribution and exponential distribution etc. It may also consist of several assumptions as follows:

- A1. Each machine processes only one job at a time.
- A2. Each job is processed on one machine at a time.
- A3. For each operation, the probability distribution of processing time and machine assignment are known in advance, but the processing time is stochastic.
- A4. There are no precedence constraints among operations of different jobs.
- A5. Operations cannot be interrupted.
- A6. Neither release times nor due dates are specified.

The S-fJSP has already been confirmed as one of the NP-hard combinatorial problems. There are N jobs and M machines to be scheduled; furthermore, each job is composed of a set of operations and the operation order on machines is pre-specified. Each operation is characterized by the required machine and the processing time [5].

Index:

i,h: indices of tasks, $i, h = 1, 2, \cdots, n$;
j: indices of resources, index, $j = 1, 2, \cdots, m$;
k,g: indices of operations, $k, g = 1, 2, \cdots, n_i$.

Parameter:

n: number of total tasks;
m: number of total resources;
n_i: number of operations for task i;
n_{ik}: k^{th} operation of task i;
t_{ikj}: processing time of O_{ik} processed on j^{th} resource;
A_{ik}: the available resource set of O_{ik};
c_{ik}: the completed time of O_{ik}.

Decision variables:

$$x_{ikj} = \begin{cases} 1, \text{ if } o_{ik} \text{ is performed on machine } j \\ 0, \text{ otherwise.} \end{cases}$$

The objective function is minimizing the makespan, as follows:

$$\min E\left[C_M\right] = E\left[\max_i \left[\max_k\right] \left[\max_i \xi c_{ikj}\right]\right]. \tag{1}$$

For the process of scheduling, the operations are not allowed to terminate until it is completed and for each resource. The resource constraints are described as follows in Eq. (2):

$$s.t. \quad \xi c_{ik} - \xi c_{i(k-1)} \geq \xi t_{ikj} \times x_{ikj} \qquad k = 2, \cdots, n_i, \forall i, j. \tag{2}$$

For each task, it consists of several operations and each operation is allocated different machine, although each operation can be processed on different resources, the operation sequence within each task must be observed. Note that the two constraints (3) and (4) only one need to be satisfied at the same time.

$$(\xi c_{hg} - \xi c_{i(k-1)} - \xi t_{ikj}) \times x_{hgj} \geq 0 \quad \forall j, g, h, \tag{3}$$

$$(\xi c_{ik} - \xi c_{hg} - \xi t_{ikj}) x_{ikj} \geq 0 \quad \forall i, j, g, h. \tag{4}$$

Besides the constraints mentioned above, the constraint (5) guarantees machine allocation that for each operation can only process on one machine from machine set at one time.

$$\sum_{x_{ijk} \in A_{ik}} x_{ikj} = 1 \quad \forall i, k, j. \tag{5}$$

For each resource, it contains only two cases: chosen or not chosen. And The constraint (6) and the constraint (7) gives the restriction constraint of decision variables.

$$x_{ikj} \in \{0,1\} \quad \forall i,k,j, \tag{6}$$

$$\xi c_{ik} > 0 \quad \forall i,k. \tag{7}$$

3 Algorithm Design

BNPSO starts by random grouping all decision variables encoded by real numbers into several subcomponents, each subcomponent contains s variables shown in Fig. 1. Then, to optimize the global optimal solution based on the co-evolutionary framework. In the process of evolution, to record down the data set for BN learning according to the value variation of each decision variable. Each 50 iterations, update the structure of BN follows BOA and adjust the grouping scene. Meanwhile, self-adjust the parameters used in evolution algorithms. Several key parts of BNPSO listed in the following subsections in detail.

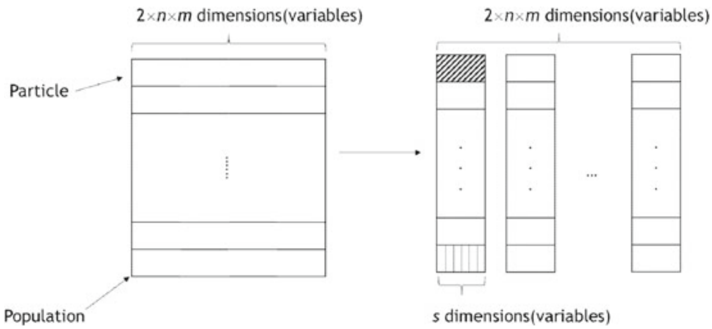

Fig. 1. The network based for decoding the operations

3.1 Encoding and Decoding

PSO is a typical met-heuristics algorithm in EAs, so the encoding and decoding methods will effect the performance partly. We choose two-section real priority encoding method in order to explore larger solution space. An example of representation and decoding network for one particle with 5 operations is shown Fig. 2.

The searching space is created in a $2 \times n \times m$ search space for n jobs on m machines. Each particle consists of $2 \times n \times m$ variables and is represented by real number. As mentioned above, S-fJSP can be considered as two subproblems: operation sequences and machine allocation. So the first section of particle presents the operations; the second part presents the machines allocation

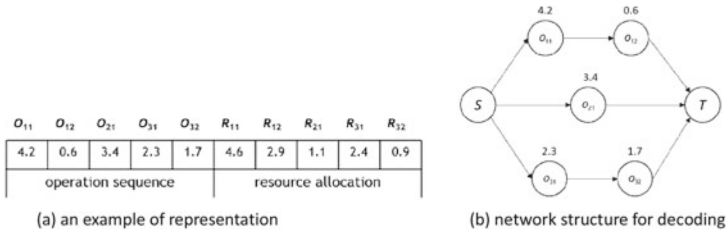

Fig. 2. An example of representation and decoding network for one particle

corresponding to each operation, we use the network based decoding method (shown in Fig. 3(b)) to get S-fJSP solution from the particle which can confirm the solutions are all feasible solutions.

PSO uses the following formulas to update velocity and position in each generation t, respectively. The initial values of velocity and position are set randomly with the lower bound and upon bound which are given in advance. The ω presents inertia weight, rand_1 and rand_2 are random value within [0,1]. The bigger ω means new velocity will mainly be effected by search history of particle itself; the smaller presents new velocity will mainly be effected by search history of the whole population. The parameters used in PSO is adapted according to the methods studied in the paper [10].

$$v_t(t+1) = \omega v_i(t) + c_1 \text{rand}_1[p_{\text{best}}(t) - x_{i\partial}(t)] + c_2 \text{rand}_2[l_{\text{best}}(t) - x_i(t)], \quad (8)$$

$$x_t(t+1) = x_t(t) + v_t(t+1). \quad (9)$$

In order to explore larger solution space, the velocity and position update model with both Cauchy and Gaussian distributions was proposed in [15]. This model updates the position directly through personal best: p_{best}, local best: l_{best}. p_{best} means the best particle in the searching history of each particle, l_{best} means the best one among the ith particle, $(i-1)^{th}$ particle and $(i+1)^{th}$ particle each iteration. rand and p are used for deciding which formula to be selected, rand is a random value within [0,1] and p is a given value at initial stage. $C(1)$ means the Cauchy distribution value with mean value 1; $N(0,1)$ means the normal distribution value with mean value 0 and the standard variance 1. The position updating formula is shown as follows, each time, generate rand, and compare rand with p to decide which equation to be chosen. If rand $\leq p$, the position will update follow the first formula, otherwise, follow the second formula.

$$x(t+1) = \begin{cases} p_{\text{best}}(t) + C(10\,|p_{\text{best}}(t) - l_{\text{best}}(t)|\,, & \text{if rand} \leq p \\ l_{\text{best}}(t) + N(0,1)\,|p_{\text{best}}(t) - l_{\text{best}}(t)|\,, & \text{otherwise.} \end{cases} \quad (10)$$

3.2 Bayesian-Based Grouping Mechanism

(1) Bayesian network structure learning
As mentioned above, BN structure learning is also a NP hard problem, if we use the traditional method to learn its structure, it will make our algorithm be too

heavy, so we use another evolutionary algorithm. Inspired by $K2$ which is the most classical and typical algorithm for learning BN structure, learning structure can be divided into two parts: the node sequence and the edges. Hence, we still use two-section encoding, in which the first section represents node sequence, and the second section represents the edge. We give an example with 4 variables in one group in Fig. 3(a). We can get variable sequence (descending order): $x_4- > x_2- > x_1- > x_3$, then get the edges by transferring the real values in the second part particle into binary value for the first 4 (equals to the number of variables s in current group) values, then to randomly select from the got binary values for other 2 (equals to $s \times (s-1)/2 - s$) binary values, shown in Fig. 3(b).

1	2	3	4	1	2	3	4
1.5	2.3	0.6	3.1	2.8	1.7	1.9	1.3
variable sequence				edge consideration			

(a) real number based encoding particle

x_4	x_2	x_1	x_3	1	0	0	1	0	0
variable sequence				edge consideration					

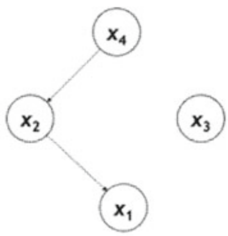
(b) particle after decoding

Fig. 3. The particle used for learning BN structure

Then, we decode particle into a BN by a strictly upper triangular matrix which means to put the binary sequence in the shadow position successively from the bottom to the end in Fig. 4. In which, 1 represents the variable in column is the parent of the variable in row. Each generation, we can get one network structure, after m generation, we can m candidate networks. A simple BN is shown in Fig. 4, it presents that the network constructed by particle in Fig. 3(a). Then, we adjust the grouping situation depends on BN structure, x_3 is a dependent variable, hence, we put it to another random group, after adjusting, this group only contain 3 variables temporary until other variables are put in.

	x_4	x_2	x_1	x_3
x_4		1	0	0
x_2			1	0
x_1				0
x_3				

(a) a strictly upper triangular matrix



(b) Bayesian network structure

Fig. 4. A simple BN structure example get from a particle

(2) Sampling train data
We record down the variance of each decision variable of particle between $(i+1)^{th}$ generation and the i^{th} generation. Because, the variance of each variable of global best particle shows the relationship when global best particle evaluates.

1	2	3	4
1.2	3.2	3.9	2.7
1.2	3.2	3.9	2.7
0.8	2.9	5.1	2.1
....			
1.0	2.7	3.0	2.3
1.2	2.5	2.9	2.7

(a) recorded global best particle

1	2	3	4
0	0	0	0
0	0	1	0
...			
1	0	0	1
1	0	0	1

(b) training data

Fig. 5. Sampling the training data

If the value of variable becomes bigger, then to record down 1, otherwise, if the value becomes smaller or keeps invariant, to record down 0. Then we can get the training data set for learning BN structure, shown in Fig. 5. After evaluating the network structure, we can find a optimal network with BDe score. Then, we adjust the group by putting the discrete variables into the other groups randomly. The whole process of BNPSO is shown as follows.

4 Experiment and Results

To prove the efficiency of our proposed algorithm logically, we do two kinds of experiments for S-fJSP on 4 scales of data: 5×5 (50 dims), 10×10 (200 dims), 15×15(450 dims) and 20×20 (800 dims). The dimensions are decided by encoding method mentioned in Sect. 3. For example, 5×5 means this benchmark has 5 jobs, 5 machines and 5 (the same to the number of machines) operations. These data instances can be accessed on OR-Library by Dirk et al. For the uncertainty processing time, the processing time of operation o_{ij} may equally take any real value from the uniform distribution U(lower, upon) where lower is 80% of static processing time and upon is 120% of static processing time. In order to ensure the reliability of the experiments and avoid the shock of results, all experiments are repeated 30 times to get the mean value and calculate variance. The machine environment of running experiments is Intel(R) Core(TM) i7-4770 CPU @ 2.2 GHz, 16 GB.

4.1 Experiment Settings

All compared algorithms contains: classical genetic algorithm (GA) [1], binary genetic algorithm (bGA) [1], differential evolution (DE) [12], classical particle swarm optimization (PSO) [16], self-adaptive neighbourhood search DE

(SaNSDE) [16] and cooperative coevolutionary particle swarm optimization (CCPSO) [8]. The values of the parameters c_1, c_2, and w used in PSO were selected based on [8]. The crossover and mutation probability are set to 0.5 [1]. The initial parameters of DE and SaNSDE were set based on [16].

Besides above parameters, there still exist common parameters such as population size, initial group size and the max iterations for all algorithms, they are shown in Table 1.

Table 1. Common parameters

Data	Pop size	Initial group size	Max iteration
5×5	100	10	1000
10×10	1000	10	5000
15×15	1000	50	5000
20×20	5000	100	10000

4.2 Results and Discussion

(1) Bayesian-based grouping mechanism
In order to prove the effectiveness of Bayesian-based grouping mechanism, we did experiments focus on fJSP and S-fJSP. And we used PSO as the basic algorithm, doing experiment on classic PSO (classical), PSO with fixed grouping (fixed), set-based grouping PSO (set) and Bayesian-based (Bayes) grouping PSO respectively. The objective is to minimize the mean value of makespan, the result are shown in Table 2. We can get the conclusion from the table that, Bayesian-based grouping mechanism has better performance no matter for fJSP or S-fJSP on mean value of makespan.

(2) Effectiveness of BNPSO
We compared BNPSO GA, bGA, PSO, DE, CCPSO and SaNSDE on the mean value and variance of makespan, the results are shown in Table 3. Firstly we can get the conclusion that, for encoding methods, real number encoding method (GA) performances better than the binary encoding method (bGA). The reason is that real number can use only one number to represent one variable, hence, for equal-length particle, real number encoding particle has larger search space. Secondly, for the basic algorithms which contains: GA, bGA, DE, PSO, we can find that GA performs better than PSO in most time, however, due to the characters of GA, co-evolution GA performs bad unfortunately. Compared to improved algorithms: CCPSO and SaNSDE, we get the conclusion that BNPSO performs better than them on most evaluation indexes.

5 Conclusion

This paper presents an effective BNPSO, which solves the S-fJSP with the uncertainty of processing time. It minimized the expected average makespan within reasonable time. With the framework of the proposed BNPSO, we construct BN structure according to the data showing the relationship among variables and adjust the group scene based on the independence shown by structure. We first proved the effectiveness of BN-based grouping mechanism, and then, we compared proposed algorithm with other compared famous algorithms, the results shown that, BNSPO performed better than other algorithms. In our future work, we will extend BNPSO to adapt to real case study based on multiobjective stochastic flexible job- shop models (moS-JSP).

Abstract. This paper explores the role of political environment (PE) and exchange rate (ER) movements in determining China's outward foreign direct investment (OFDI) for a period of 2003–2015. It includes 65 countries along "OBOR" (One Belt One Road) to build up a panel data base. ER level, ER volatility and Political Environment are examined in relation to Chinese OFDI in these "OBOR" countries. The empirical results show that RMB appreciation is associated with higher Chinese OFDI flow but Chinese OFDI is not sensitive to ER volatility and PE instability. Considering the growing importance of the "OBOR" initiative, we believe that our research results shed light on the trend of Chinese OFDI.

Keywords: Chinese outward foreign direct investment · "One Belt One Road" Initiative · Exchange rate · Political environment

1 Introduction

Since China adopted its "going out" policy in 2001, its OFDI flows have grown rapidly, reaching more than $100 billion in 2013. As an upgraded strategy for foreign investment, the "OBOR" was initiated in 2013 to better serve China's "going out" policy. In the area defined by this "OBOR" initiative, more than 60 countries have expressed their interest in cooperating with this program. In addition, the China-led Asian Infrastructure Investment Bank (AIIB) was created to provide professional, efficient financial support for the tremendous infrastructure needs under the "OBOR" initiative. At present, a total of 57 countries covering five continents have been approved as founding members of this international financial institution. As an Asian regional multilateral development agency, AIIB will play a constructive role in strengthening economic growth engine of infrastructure construction, improving the capital utilization efficiency and raising the regional development level.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_121

However, it is becoming increasingly clear that the global market is full of uncertainties that can undermine even carefully laid plans. The risks that Chinese firms are facing when they are encouraged to invest abroad should not be overlooked. According to Wang [26], the major risks that Chinese firms deal with during outward investment are political and financial risks, which accounted more than 60% of the total risks. The risks are mainly influenced by the political environment and exchange rate movements which in turn affect the volume and regional allocation of Chinese OFDI. Therefore, this paper examines these two major risks and their influences on Chinese OFDI. The panel dataset includes 65 countries along the "OBOR". This paper uses an index that is composed of 6 weighted indicators covering both political and social attributes to measure PE risk. The ER risks are calculated by measuring ER level and volatility.

The contribution of this paper is twofold. Firstly, little paper discussed China's OFDI in "OBOR" countries, let alone analyzed the impact of financial and political risks. Unlike the previous studies which are mainly focused on the Chinese FDI flows to developed countries or emerging economies, our study looks at the countries along the "OBOR" diversified in South and Central Asia, Central and Eastern Europe and Africa. Therefore, this paper contributes to the existing empirical literature on Chinese OFDI in a new region. Secondly, our result reveals that Chinese OFDI seems not to be affected by PE and ER volatility, which is not in line with the previous literature.

The remainder of this paper is organized as follows: Sect. 2 reviews the relevant theoretical and empirical literature. Section 3 provides a descriptive overview of Chinese OFDI in the "OBOR" countries. Section 4 describes the data. Section 5 presents the empirical specification and results. Section 6 concludes and relates policy implications.

2 Literature Review

Theoretical and empirical studies have looked at the foreign investment behavior of multinationals and have identified exchange rate movements and political environment as important determinants of outward FDI. We conclude these studies as follows.

2.1 The Impact of Exchange Rate Movements on FDI

The interest in the impacts of exchange rate and its volatility on international capital flows such as FDI is growing among policy makers. As for empirical research, quite a lot of scholars try to investigate the relationship between exchange rate and FDI by taking developed countries and newly emerging countries as sample, which is critical to the formulation of FDI polices.

With regard to the exchange rate level, one strand of the literature emphasizes the positive correlation between the appreciation of source country currency and FDI outflows based on the relative wealth effect, the expectation of future profitability and capital market imperfection. Schmidt and Broll [23] showed that the real exchange rate level has a positive effect on outward FDI flows in nine industries from the US. Takagi and Shi [24] used the panel data of Japanese FDI flows to nine dynamic Asian economics during 1978–2008 and found the current depreciation of host country currencies significantly increased FDI inflows from Japan. However, another strand emphasizes the ambiguous impact of currency appreciation. Pain and Welsum [21] provided no clear conclusions as to the impact of exchange rate movements on FDI due to the types of multinational activities undertaken in different countries. Lee and Min [17] took Korea's eight major FDI source countries in three different regions in the world as samples and tried to identify the changing behavior of foreign investors in Korea following the 1997 crisis. The change in FDI in response to exchange rate level is quite mixed, which is consistent with recently developed real option-based FDI theory.

There are contradictory conclusions of exchange rate volatility influences on FDI flows in theoretical and empirical literature. The risk averse multinationals consider the information-searching cost and may decide to put off investing overseas when faced with dramatic volatility of exchange rate. Udomkerdmongkol and Morrissey et al. [25] found evidence for a negative impact of exchange rate variation on FDI of US in emerging countries. However, another group of studies highlight the positive impact of exchange rate volatility on FDI. Cushman [6], in his theoretical models, concluded that the exchange rate uncertainty may positively affect FDI. In response to risk, the multinational firm reduces exports to the foreign country but offsets this somewhat by increasing foreign capital and stimulating direct investment. Goldberg and Kolstad [11] also came to a similar conclusion, namely, an increase of the uncertainty stimulates FDI. Deseatnicov and Akiba [8] employed a panel data analysis of 56 developed and developing countries (country and industry level) and found that exchange rate volatility positively affect Japanese FDI activities for all industry. The results showed that Japanese MNCs could tolerate a slight increase in the exchange rate volatility because the level of it may be far enough what is necessary.

Although Chinese OFDI has become a more interesting topic, relatively few empirical studies have been conducted. Some research has made contribution to the literature by examining the major determinants of Chinese OFDI including ER risks as well. But the results are controversial and apparently they did not include samples from enough counties. For example, Jin [14] found that the appreciation of RMB promotes FDI after the reforms in the ER regime in 2005. Hu [13] used a panel data including 49 countries from 2003 to 2010. They found that Chinese OFDI was positively related to ER level and negatively related to ER volatility. Liu and Deseatnicov [19] found out that Chinese MNCs tend to invest in locations with higher financial uncertainty because exchange rate volatility increases the competitive advantage of Chinese MNCs in developing countries with respect to MNCs from developed countries motivating an increase in Chinese OFDI.

2.2 The Impact of Political Risk on FDI

When entering foreign market, multinationals have to adapt their optimal investment strategy to the requirements of local political environment that may give rise to varying political risks. Different political environment and its impacts on economic activity have received substantial attention in the recent literature on FDI. There are a lot of scholars trying to prove that any form of political risk negatively affects the FDI profitability and incentive of an MNE as a whole. Busse and Hefeker [3] took 83 developing countries as samples and tried to prove the negative linkages among political risk, institutions, and FDI inflows. They also found out that political risk and institutional indicators matter the most when multinational corporations confront decisions about where to invest in developing countries. Hayakawa et al. [12] used the overall FDI inflows for 89 countries to empirically investigate the effects on inward FDI of various components of political risk. The results showed that internal conflict, corruption, military in politics, and bureaucracy quality are inversely related to inward FDI flows. Cezar and Escobar [4] tested their model using inward and outward FDI data on OECD countries and found that institutional distance reduces both the likelihood that a firm will invest in a foreign country and the volume of investment it will undertake. And they concluded that firms from developed economies adapt more easily to institutional distance than firms from developing economies.

Nevertheless, some previous studies implied that better political environment may not attract more FDI inflows. Kurul [16] constructed a composite institutional quality index to identify the overall impact of institutions on FDI inflows based on 126 countries over the period 2002–2012. The empirical results revealed that institutional quality affects FDI positively only after this measure exceeds a certain threshold value. In particular, Buckley et al. [2] found that Chinese foreign investment may be led by China's political and ideological heritage and be directed to ideologically similar countries which have higher records of political risk. Yeung and Liu [27] also supported this conclusion. They hold the view that Chinese state-owned transnational firms, to a great extent, played a crucial role in foreign investment. Partly due to China's unique and changing political-economic context, many state-owned transnationals are often involved in infrastructure projects and resource extraction industries in some developing economies with poor government institutions as a means of economic diplomacy.

3 The Background of Chinese OFDI in the Countries Along the "OBOR"

3.1 The Regional Distribution of the "OBOR" Initiative Area

The "OBOR" initiative focuses on bringing together China, Central Asia, Russia and Europe (the Baltic); linking China with the Persian Gulf and the Mediterranean Sea through Central Asia and West Asia; and connecting China with Southeast Asia, South Asia and the Indian Ocean (Table 1). In its largest definition, the "OBOR" initiative involves more than 60 countries, with a total

Table 1. The geographic distribution of countries along the "OBOR"

Region	Major countries
Northeast Asia	Mongolia, Russian Federation
Central and Eastern Europe	Bulgaria, Belarus, Austria, Belgium, Czech Republic, Romania, Poland, Ukraine, Hungary
Western Asia and the Middle East	Georgia, Turkey, United Arab Emirates, Israel, Egypt, Oman, Qatar, Iraq, Iran, Syrian Arab Republic, Saudi Arabia, Yemen, Rep.
Central Asia	Uzbekistan, Turkmenistan, Tajikistan, Kazakhstan, Kyrgyzstan
Southeast Asia	Vietnam, Malaysia, Myanmar, Cambodia, Thailand, Brunei Darussalam, Indonesia, Lao PDR, Philippines, Singapore
South Asia	Pakistan, India, Jordan, Bangladesh, Sri Lanka, Afghanistan

population of 3.08 billion, accounting for about 44% of the world's population. The total GDP of this area reaches $12.8 trillion, accounting for 17% of the global economy.

3.2 Chinese OFDI Along the "OBOR"

(1) The pattern of Chinese OFDI
In recent years, Chinese OFDI along the "OBOR" countries has increased rapidly as economic ties strengthened. Figure 1 describes the Chinese direct investment stock trends in the countries involved in the "OBOR" initiative from the period of 2003 to 2015. By the end of 2015, total flows of OFDI by Chinese enterprises to the countries covered by "OBOR" initiative reached $18.93 billion, with an increase of 38.6%, accounting for 13% of the total flows.

China's OFDI varies in different economic entities. Chinese direct investment along the OBOR concentrated on the developing countries from 2003 to 2015, accounting for 75% of the total share. Among these developing countries, ASEAN countries have absorbed more than 40% of China's OFDI and have become some of China's most important economic partners. In 2015, China's OFDI flows to ASEAN countries experienced rapid growth and reached US$ 14.604 billion. By the end of 2015, there had been six ASEAN countries included in China's top ten OFDI targets along the OBOR (Table 2). ASEAN economies have been at the forefront of the emerging markets success story of the past two decades. It is obvious that ASEAN countries occupy important positions in Chinese foreign investment. Additionally, Chinese overseas investing activities in the transition region have increased by 20% over the last couple of years. Rich natural resources and the expansion of markets in this region are and will continue to be a considerable attraction for foreign multinationals. Recent growth for this transition

Table 2. Top ten countries of Chinese OFDI stock along the "OBOR" by the end of 2015

Rank	Country	Chinese OFDI stock (million dollar)	Percentage (%)
1	Singapore	31984.91	27.65
2	Russia	14019.63	12.12
3	Indonesia	8125.14	7.02
4	Kazakhstan	5095.46	4.41
5	Laos	4841.71	4.19
6	United Arab Emirates	4602.84	3.98
7	Myanmar	4258.73	3.68
8	Pakistan	4035.93	3.49
9	India	3770.47	3.26
10	Cambodia	3675.86	3.18
Total	84410.68	72.98	

[a] Sources: Statistical Bulletin of China's Outward Foreign Direct Investment (2015)

region is highest among all regional groups. Kazakhstan, Mongolia and Russia are currently among the largest FDI recipients in the region. It is worth noting that the transitional region might become a new spotlight for Chinese foreign investment, especially motivated by the "OBOR" initiative.

(2) The industry structure and investment project of Chinese OFDI
There has been a trend of diversification in the industrial structure of Chinese OFDI along the "OBOR". In 2005, the Chinese large-scale project investment

along the "OBOR" only involved energy industry that was mainly dominated by oil and supplemented by natural gas and coal. Between 2006 and 2008, China's large-scale project investment extended to the metal ore industry, real estate, transportation and other industries. The Chinese enterprises further expanded their investment to high-tech, agriculture, finance, and chemical industries from 2009 to 2015. These changes in China's OFDI along the "OBOR" show it has experienced a steady process of ascension. In general, the focused industry is energy. Metal ore, real estate and transportation rank second to fourth. Agriculture, chemical and high-tech industries account for a smaller part of total shares.

The "OBOR" initiative makes the interconnection of infrastructure as a breakthrough in cooperation. Driven by this initiative, China actively develops high-speed railway networks, expressway networks, and regional aviation networks. In 2015, China plans to invest infrastructure construction along the "OBOR" for 1.04 trillion Yuan, especially in railways, water conservancy and port engineering, and airports, in that order (Fig. 2).

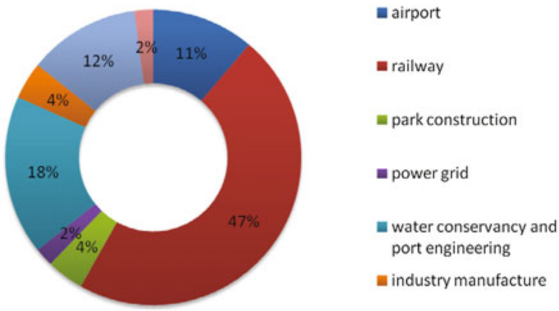

Fig. 2. China planed investment projects in "OBOR" countries (2015) (Sources: Minsheng Securities)

(3) The investment subject of Chinese OFDI

Under the "OBOR" initiative, government participation makes up the most important part while social capital participation remains a relatively small part. From the point of investment scale, central state-owned enterprises are the main force of China's OFDI along the "OBOR" while local private enterprises only play a supplementary role. By the end of the first half of 2014, the central enterprises' national large-scale projects investment stock in this "OBOR" area reached US $86.45 billion, accounting for 67.4% of the total share. Especially, the OFDI stock from state-owned enterprises belonging to SASAC was US $78.22 billion, making up 90.5% of the central enterprises' investment. In addition, local enterprises large-scale projects investment stock in this area was US $41.9 billion, accounting for 32.6% of the total share.

4 Data

4.1 Sample Selection

The aim of this paper is to examine the impact of exchange rate movements and political environment on Chinese OFDI along the "OBOR". Since the Ministry of Commerce, National Bureau of Statistics, and State Administration of Foreign Exchange started to publish a detailed Statistical Bulletin of China's Outward Foreign Direct Investment from 2003, our dataset contains the Chinese OFDI net flows to selected countries for a period of 2003–2015.

We realize that a large number of country samples are critical to our analysis. The Land and Maritime Silk Roads pass through over 60 countries with transmission of cultures, religion and trade. However, these vast networks cover so many developing and small countries, the detailed official FDI data of which cannot be found in Statistical Bulletin of China's Outward Foreign Direct Investment. As a result, our study met difficulties in collecting enough samples of countries along the "OBOR". So we include countries that are not geographically located on the "OBOR" but also belong to its coverage such as European countries, Africa and Far East. In this paper, the total sample consists of 65 countries on the basis of all available information (See Table 4 in Appendix).

4.2 Data Description

The dependent, independent and control variables are as follows. The summary statistics of the empirical variables is reported in Tables 5 and 6 in Appendix shows the sources of the data.

(1) Dependent variable

The dependent variable for our analysis is the outward FDI flows to the host country by Chinese multinationals during the sample period. We use LRFDI, the natural logarithm of real FDI flows from China to each recipient country expressed in ten thousand dollars (the CPI is used to deflate the nominal values, with 2010 as the base year), as a measure of FDI. To understand the details of China's OFDI, we downloaded an annual country-level data from Statistical Bulletin of China's Outward Foreign Direct Investment. This official government data repository for all Chinese firms (including Limited companies, Private enterprises, State-owned enterprises, Foreign-invested or Joint-Venture firms) and has rich information including the destination of OFDI, the various sectors, the name of the investor in China and regional origin of the investor. This is so far the most reliable information at country-level in long time-series.

(2) Independent variables
This paper mainly investigates the effect of the political environment and exchange rate movements on Chinese OFDI in the "OBOR" countries. The measurement of independent variables proceeded as follows.

(a) Exchange Rate variables
We also collect a set of observable monthly nominal exchange rates (RMB/local currency, using US dollars as the transformation instrument) from selected countries which can be obtained from the IMF International Financial Statistics database. In order to obtain the real exchange rates, we use host country's CPI index to deflate the nominal values, with 2010 as the base year. From this data, we study the level and volatility of exchange rate to explore their impacts on Chinese OFDI.

- LMEANR is the natural logarithm of the level of real exchange rates. We calculate the first moment (average) of monthly real exchange rates around year t (defined to include all monthly observations during year $t-1$ and year t) for host country.

$$\text{LMEANR} = \log\left(\sum_{\text{i}=1}^{24} {x_i}^2/24\right).$$

- LVARR is the natural logarithm of the volatility of real exchange rates. We calculate the second moment (standard deviation) of real exchange rate level around year t (defined to include all monthly observations during year $t-1$ and year t) for host country.

(b) Political Environment
Political environment, however, varies across countries and regions, which provides us an opportunity to test the impact of the severity of PE risks on outward FDI by Chinese multinationals. In this paper, we use PE to represent the evaluation of host country's political environment. As one of the most widely accepted system of completely independent political risk forecasting, the Political Risk Services Group (PRS) offers us a general risk model to translate political risk assessments into numbers and calculate risk ratings for its database of 140 developed, emerging, and frontier markets. The Political Risk Rating comprises 6 same weighted variables covering both political and social attributes in order to focus on the needs of the particular investing firm (see Appendix 1d). These

actions can result in threats or do harm to the business climate. Thus, we calculate the sum of PRS 6 indicators to capture the features of political environment in host country. An increasing value (from 0 to 6) represents lower political risk and better political environment.

(3) Control variables
We look at the macroeconomic determinants of outward FDI. The host country's CPI index is used to deflate the nominal values, with 2010 as the base year. Following previous research, we tested main factors as follows:

- LRGDP is the natural logarithm of host country's real GDP (Deflated by CPI) based on current US dollars in a given year, which reflects the host country's future market potential or absorptive capacity.
- NATURAL is the natural logarithm of total natural resources rents (% of GDP). The total natural resource rents are defined as the sum of oil rents, natural gas rents, coal rents (hard and soft), mineral rents, and forest rents. The estimates of natural resources rents are calculated as the difference between the price of a commodity and the average cost of producing it. This indicator could be used to measure the abundance of natural resource in the host country.
- LRW is the natural logarithm of real wage in host country. GDP per capita based on purchasing power parity (current US $) serves as a proxy for real wage due to the difficulties of getting average wage data for most of the "OBOR" countries. It weighs the labor cost in host country and is widely used to measure the advantage of human capital in attracting foreign manufacturing firms.
- LOPEN is the natural logarithm of the sum of annual imports and exports volume of goods and services (% of GDP). It stands for the degree of host country's openness in the FDI recipient economy, which is considered to be an important factor affecting FDI-related barriers.
- LTECH is the natural logarithm of host country's high-technology exports (% of real GDP). High-technology exports are products with high R&D intensity, such as in aerospace, computers, pharmaceuticals, scientific instruments, and electrical machinery. Data are in current U.S. dollars. This variable could measure the level of technology in host countries, which becomes the one of consideration in Chinese MNCs foreign investment activities.
- PLCY is a dummy variable that can be interpreted as the effect of the "OBOR" initiative. The PLCY dummy takes a value of zero if the time period is 2003–2013 and one otherwise. We splits the sample around 2013 because it is believed that Chinese OFDI activities in the countries along the OBOR are strongly driven by the "OBOR" initiative that was first launched by Chinese government in 2013.

5 Empirical Specification and Results

A linear dynamic panel-data model is used in this paper taking into consideration the lagged FDI effect on current FDI. We use the System GMM (SYS-GMM) estimator due to its capacity to deal with lagged values of the endogenous variables as poor instruments for first differences. With characteristics of missing observations for some countries and years, our dataset represents as an unbalanced panel data. Thus, we use "forward orthogonal deviations" variables transformation proposed by Arellano and Bond [7] in order to increase the number of observations used in the analysis.

As for instruments choosing, the independent variables were treated as strictly exogenous. So the system estimators use the first difference of all the exogenous variables as standard instruments, and the lags of the endogenous variables to generate GMM-type instruments. Finally, we added time dummies in order to increase the likelihood of no correlation across individuals in the idiosyncratic disturbances assumption to hold as suggested by Roodman [22].

As robustness check to our SYS-GMM regressions we report feasible generalized least squares (FGLS) estimation method with heteroscedastic error term. We include time dummies to the FGLS estimations as well and we exclude lagged FDI variable in order to avoid the autocorrelation problem in the FGLS method.

We estimate the equation:

$$y_{it} = \delta \times y_{it} - 1 + X'_{it}\beta + \varepsilon_{it}, \tag{1}$$

where y_{it} is the logarithm of annual outward FDI from China into a host 'country i' at time t and X'_{it} denote an (1xk) vector of exogenous variables which vary in the cross-section and in the time dimension. δ is a scalar. y_{it-1} is a lagged dependent variable. εit is a stochastic error term, which is assumed to be uncorrelated over all i and t. For FGLS estimation we omit δ y_{it-1} term.

All system GMM estimation results for Eq. (1) are shown in Table 3. In our specifications, the Hansen test of overidentifying restrictions indicates that the joint null hypothesis of valid instruments is not rejected. Besides, the FGLS results displayed in Table 3 show that the results of system GMM estimation are consistent and robust. Some interesting findings have been disclosed through the regression and we give some interpretations and evaluations for them.

5.1 RMB Appreciation Stimulates Chinese OFDI in "OBOR" Countries

ER level is found to be positive and statistically significant for the 65 selected countries. It is expected correctly signed and positively associated with Chinese OFDI. This suggests that Chinese multinationals are willing to invest abroad in these countries and areas when the Yuan appreciated with the host's currency. More specifically, ER level coefficient indicates that a 1% increase in the value of Yuan would promote an about 0.3% increase in Chinese OFDI. A considerable amount of OFDI is conducted through M&A, Yuan appreciation can systematically lower the cost of acquisitions of certain foreign assets [10] and increase the profitability of firms' foreign branches and subsidiaries [1]. Thus, an appreciation of home currency stimulates OFDI. Moreover, evidence found from the statistics suggests that there is a stable uprising trend for Yuan during the sample year.

Especially after 2005, Yuan appreciated over 30% [28]. In this case, the yuan's bias toward relatively large appreciation shocks is associated with expectation of the appreciation that leads to a lower cost of future reinvestment in the host country and stimulates the foreign investment.

5.2 Chinese OFDI Is Not Sensitive to the Exchange Rate Volatility in "OBOR" Countries

ER volatility coefficient shows a negative but insignificant relationship with OFDI, indicating that the influences of ER volatility on Chinese OFDI are ambiguous (Table 3). The possible explanation for this insignificant result is that firstly, the Chinese government is very cautious with respect to the pace of the

RMB appreciation. During our sample year, China's Central Bank intervened and managed the unexpected RMB exchange rate fluctuation. Also RMB is usually expected to appreciate gradually. Thus, Chinese multinationals pay less attention to the variance of ER than to the level of ER in managing financial risk. Secondly, unlike the multinationals in developed countries, the motivation for Chinese MNCs is not to substitute exports but to obtain higher values of assets or access natural resources in a host country. ER volatility is a sign of instability but at the same time it discourages potential investors from developed countries to involve in competition. Thus, Chinese MNCs may be indifferent to exchange rate volatility because of their motivation. Thirdly, less hedge tools and RMB investment instruments designed for safeguard the exchange risks are used in the international settlement practices for Chinese MNCs. They suffer large exchange loss due to a lack of awareness towards exchange rate volatility. This is a rather dangerous trait as China is going to make the RMB more flexible and the Chinese Central Bank will gradually quit the normal intervention.

5.3 Chinese OFDI Seems to Be Indifferent to Political Instability in "OBOR" Countries

The PE variable achieves a statistically insignificant result with a positive sign, which is not in line with previous studies from the perspective of risk premium and information asymmetries. This suggests that Chinese multinationals are not sensitive to the political instability when investing in "OBOR" countries. This result may be explained by three possible reasons. First, multinationals that are predominantly oriented toward seeking natural resource have a greater tolerance of political risk. Our empirical result shows that the abundance of fuel and ore resource in a host country has a positive impact on attracting Chinese OFDI. It indicates that Chinese OFDI in "OBOR" countries is motivated by the host's natural resources endowments. It is well known in the literature that countries rich in natural resources, on average, grow more slowly and have ineffective political institution than countries without such resources due to the "resource curse" [20]. The more Chinese OFDI a country attracts, the worse its government institution [15]. The "resource curse" effect can be confirmed by examples with extremely high political risk in our sample. There are some countries (such as Afghanistan, Iraq and Libya) in the Middle East, Central Asia and Africa, with large oil and other critical energy production. Therefore, it is inevitable that Chinese investors have to face and endure more political risk when conducting resource- seeking FDI in "OBOR" countries.

Second, in China, State-owned enterprises are the main force in foreign investment, whose investment behavior is affected by the government's willingness. Economics activities carried out by Chinese national firms are not only for their profit motive and economic efficiency, but also for distinctive political and diplomatic overtones in "economic diplomacy". Consequently, strongly supported by Chinese government, Chinese SOEs tend to be less averse to invest in countries with higher political risk compared to non-SOEs [9]. Government support may effectively compensate for the loss of the assets value and expected return due to the changes of political environment.

Third, China's political relations with potential hosts have significant influences on firms overseas investment decisions and patterns. Countries keeping better interstate relations with China tend to get more foreign investment from Chinese multinationals [18]. The "OBOR" initiative covers many countries that have developed good long-term relationships, supporting each other politically and co-operating economically. For instance, the members of SCO (Kazakhstan and Russia), some ASEAN countries and African countries have long-term strategic partnerships with China.

5.4 Natural Resources Abundance and Market Potential Attract Chinese OFDI in "OBOR" Countries

In preliminary regressions, we see that natural resource is the positive significant determinant of Chinese OFDI within the "OBOR" countries: that is, Chinese investors preferentially seek out the ownership advantage of natural resource in the "OBOR" countries. In the long term, Chinese resource-seeking foreign investment has been aimed at getting access to the scarce natural resource that China lacks to ensure the supply of domestic production and continue development. Especially, a great proportion of large acquisitions carried out by Chinese multinationals concentrates on the resource sector. Purchases of a 96.9% stake in the Russian oil company Udmurtneft by Sinopec, the equity M & A of Kazakhstan PK Petroleum Company by China National Petroleum Corporation (CNPC) and the strategic alliance between National Grid Corporation of the Philippines and State Grid Corporation of China are examples.

Moreover, according to our results, the two alternative measures of host market potential (real GDP and openness) attained significance. This finding reinforces the view that market potential and FDI outflow are associated positively [5]. Especially, new emerging economies or transition economies along the "OBOR" present more opportunities for generating profits than before. As an emerging hotspot, ASEAN is working towards regional integration aimed at one single market and free movement of goods, capital and services. It is becoming a rapidly developing destination for foreign investment. Besides, the transition economies have enjoyed the development dividend after their significant reforms of institutional and economic structures. Their increase has been well beyond that in Latin America and Africa in recent years.

5.5 A New Wave of Chinese OFDI in "OBOR" Countries Benefited from Favorable Policies

The estimated policy variable coefficient is positive and statistically significant in our specifications, which is intuitively plausible. The "OBOR" initiative proposed in 2013 is a centerpiece of China's foreign policy and domestic economic strategies, substantially giving boost to multilateral ties and economic co-operation that promote regional integration. Considering that "OBOR" initiative serves as a new engine to speed up investment facilitation, eliminate investment barriers, and push forward negotiations on bilateral investment protection agreements, it is not difficult to understand that the sizable increase of Chinese OFDI in "OBOR" countries. As the "OBOR" initiative has been put on the agenda, the spotlight falls on infrastructure construction, energy cooperation and advanced manufacturing sectors between China and the countries along the routes. For example, China has signed memorandum with 20 "OBOR" countries for institutional capacity cooperation, especially Indonesia, Kazakhstan, and Mongolia. There have been 52 projects with a total investment of $27 billion are being implemented under the "OBOR" initiative. Therefore, the increasing policy bonuses are encouraging Chinese investors to expand their presence overseas and explore new business opportunities (Table 7).

6 Conclusion and Policy Implications

The findings of our study have some policy implications for both the government and firms under the "OBOR" initiative. The empirical results reveal that ER level is a highly statistically significant determinant of Chinese OFDI while PE and ER volatility are not. Based on this result, the Chinese government should execute an active and strategy-focused diplomatic policy in the "OBOR" countries in order to better support and promote the Chinese multinationals' foreign investment. Research agencies and the Department of Commerce should cooperate to issue PE risk reference and precaution for the firms that have already invested or have the potential to invest. Industry associations should also play a role in guiding the firms to invest rationally at a steady pace.

Exchange rate risks should be taken into consideration as China is moving towards a more flexible exchange rate regime. Especially, China's Central Bank has taken further action on the RMB internationalization, by widening the RMB exchange rate's floating band within the inter-bank market from 0.5% to 1.0%. Becoming effective on April 16, 2012, this policy has been seen as a strong signal to the world that the RMB exchange rate regime is going to be driven more and more by market forces, than by government intervention. Thus, exchange rate volatility will increase as RMB exchange rate reforms are made. Financial institutions, like commercial banks, should provide more hedging tools for Chinese-outgoing-firms to reduce exchange rate risks. As for Chinese firms, it is vital to observe the ER indicators because these largely determine the safety of investment and the overall profitability calculated in home currency. In conclusion, a trend that direct investment in the "OBOR" countries will steadily increase can be foreseen. It is vital for Chinese Multinationals to be more aware of risks to conduct efficient investment abroad.

Abstract. To estimate the prevalence of post-traumatic stress disorder (PTSD) and assess determinants related to PTSD among survivors in areas after the 2013 Lushan earthquake in China. This study used the survey instruments included the PTSD Checklist-Civilian Version (PCL-C) and the Social Support Rating Scale (SSRS). We found that the prevalence rates of suspected post-traumatic stress disorder (PTSD) in hard-hit areas were 35.6% ($n = 500$). The incidence of PTSD was more prevalent among women (43.41%), compared with men (27.27%). Based on multivariate logistic regression analyses, female sex, Tibetan ethnicity, being injured, having family members injured and social support were significant risk factors in hard-hit areas.

Keywords: Prevalence · Risk factors · Post-traumatic stress disorder (PTSD) · Lushan earthquake

1 Introduction

On April 20, 2013 at 8:02 am, an earthquake measuring 7.0 on the Richter scale occurred in Lushan County, Sichuan Province, China. Its epicenter and focal depth were at latitude 30°308'N, longitude 102°888'E, and 14.0 km, according to the location of U.S. Geological Survey. Lushan earthquake occurred in the southwestern part of the Longmen Shan fault zone [5]. It was the strongest earthquake after the 12 May 2008, Ms 8.0 (China Earthquake Data Center) or Mw 7.9 (U.S. Geological Survey), Wenchuan earthquake in Sichuan province, China. Unlike other natural disasters, earthquakes usually occur without any warning and can cause widespread devastation and expose thousands of people to sudden bereavement, injury, loss of property, homelessness, and displacement [8]. Lushan earthquake still caused strong shaking for human society around its

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_122

epicenter. Since the source regions of the Lushan earthquake are highly populated, and with numerous mountainous, it resulted in more than 200 deaths or missing persons, more than 10,000 injuries, and huge economic losses according to the local government's official report. Besides deaths, physical injuries and economic losses, earthquakes can have serious psychological impacts for survivors as well as physical injuries and various mental health problems [1].

Many survivors of natural disasters experience post-traumatic stress disorder (PTSD) in their adjustment to the loss of resources (e.g. housing, belongings) or loved ones (e.g. family members) [1]. PTSD is the most frequently reported psychological sequelae among victims of natural disasters [15]. Numerous studies have documented the estimated the PTSD among other earthquake survivors. Through a longitudinal survey on the onset and development of DSM-IV Post-traumatic Stress Disorder (PTSD) after the Zhangbei earthquake in North China, Wang et al. reported the rate of onset of PTSD within 9 months in severely affected village (30.3%) was higher than that in lightly affected villages (19.8%) [13]. Another survey two and a half months following the earthquake in Beichuan and Langzhong Counties in Sichuan Province found that the prevalence rates of suspected PTSD in heavily (Beichuan County) and moderately (Langzhong County) damaged counties reached 45.5% and 9.4%, respectively [6].

To summarize the above studies, previous assessments among survivors of natural disasters have shown that PTSD are common, and the prevalence rates of PTSD among the hard-hit survivors were far higher than those of lightly hit survivors. Therefore, understanding PTSD is essential for identifying vulnerable populations and developing culturally specific mental health interventions [11]. For the purpose of public health emergency response, we conducted a rapid assessment of the prevalence of symptoms of PTSD and associated factors among random samples of survivors in the 5 countries of Lushan, Baoxing, Mingshan, Qionglai, and Tianquan, which were the most severely affected by the Lushan earthquake.

2 Methods

2.1 Subjects

According to the hard-hit counties list published by the Central People's Government of the People's Republic of China, we conducted a cross-sectional survey in heavily damaged counties. The hard-hit counties were Lushan, Baoxing, Mingshan, Tianquan, and Qionglai. These counties were selected because they had suffered more extensive damage than other counties in China. The inclusion criteria were as follows-having a high degree of exposure to the earthquake and experiencing the complete process of the earthquake-with a fair distribution of sex, age, and place.

The survey teams were temporarily established, consisted of well-trained master's level psychology students. They participated in a 6-day training program that included lectures describing the study protocol and instruments, role-play interviews, and mutual discussion. The survey comprised all assessments and was administered by senior staff psychiatrists and psychologists from Sichuan University's Medical School.

Before conducting the formal investigation, a pilot test was carried out in August and September 2013, with a group of randomly selected survivors participating. Minor modifications and adjustments were made according to the feedback from the pilot test. The final version of the questionnaire was used in the formal investigation. All assessment forms were translated from English to Chinese and back-translated by a bilingual team of professionals.

From December 2013 to January 2014, master's level psychology students working as research assistants approached the participants in their own homes or in temporary accommodation. To ensure privacy, interviewers and participants were encouraged to complete the questionnaires in private places. Supervision came out on a day-to-day basis throughout the survey.

2.2 Instruments

(1) PTSD Checklist-Civilian version

PTSD Checklist-Civilian version (PCL-C) is one of the most commonly used instruments for PTSD symptoms that result from disaster related psychiatric disorders [2]. The 17 items of the checklist is corresponding to each symptom in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) PDSD criteria B (re-experiencing), C (avoidance/numbing), and D (hyperarousal). With regard to the Lushan earthquake attacks, participants indicated the extent of each symptom correlated with the earthquake in a scale from 1 (not at all bothered) to 5 (extremely severely). Criteria B was re-experience of the earthquake (5 symptoms), criteria C was avoidance and emotional numbing (7 symptoms), and criteria D was increased arousal (5 symptoms). The score in each PTSD domain was simply added up, generating a total PTSD score ranging from 17 to 85. A score of 50 was found to be the optimally efficient cut-off score to predict the clinical diagnosis of PTSD [14]. The Chinese version of PCL-C has shown good diagnostic agreement and sound reliability and validity [7]. The coefficient of Cronbach's alphas for PTSD was 0.88.

(2) The Social Support Rating Scale

The Social Support Rating Scale (SSRS) evaluates subjective social supports from friends and family [12]. Numerous empirical studies have demonstrated the protective function of social support for post-disaster mental health [12]. The SSRS has been shown to have high reliability and validity on a wide range of Chinese populations. It contains 10 items, measuring three dimensions of social support: subjective support (SS, 4 items), objective support (OS, 3 items), and support-seeking behavior (SA, 3 items). The item scores of the SSRS were simply added up, generating a total support score ranging from 12 to 66 [12]. The subjective support score ranging from 8 to 32, the objective support score ranging from 1 to 22, and the support availability score ranging from 3 to 12, respectively. Higher scores indicate stronger social support. The Cronbach alpha coefficient for social support was 0.87.

2.3 Data Analysis

In the present study, statistical analyses were performed using SPSS Version 16.0 (SPSS Inc., Chicago, IL, USA). All presented data were adjusted for clustering and assigned a population-based weighting factor, based on the population size of each cluster in the final listing of all villages and settlements. Demographic data were analyzed using frequency. Chi-square test was used to compare PTSD total scores among male and female participants. One-way ANOVA was used to compare PTSD, total scores among different age groups. Multivariate logistic regression analyses were used to investigate the factors that affect PTSD.

3 Results

Characteristics of the entire study group in hard-hit areas of the Lushan earthquake were summarized. The demographic data of the 500 participants shows in Table 1. Males comprised 48.4% of the participant population compared with 51.6% for females. Of the participants, 489 (97.8%) were of Han nationality, and 11 (2.2%) were of Tibetan nationality. The average age was 38.0 years, with 44.6% of the participants in the 31–50 year age group; 71.8% of the participants were married. Only 4 participants (0.8%) had a graduate education, 144 (28.8%) had a bachelor education and 352 (70.4%) had an elementary school education or were illiterate. Among our subjects, 18.4% had a monthly income of over 2000 yuan, 38.2% had an income of 1000–2000 yuan and 38.4% earned less than 1000 yuan. With regard to the survivors' fear during the earthquake, 65.2% reported "yes". Of the survivors, 51.7% reported that their social support was high in the past year, whereas 28.6% reported low. One hundred and eight participants (21.6%) reported that they suffered from at least one physical disease, and no participants reported suffering from psychic diseases.

Percentages of PTSD status, as well as their scores, among males and females are shown in Table 2. Based on the PCL-C total scores, participants were classified as suffering from PTSD if the score was equal to or higher than 50. The overall percentage of PTSD was 35.6% ($n = 178$). The percentage of PTSD was significantly higher among females (43.4%) than among males (27.3%), as were PCL-C total scores (32.78 vs. 26.64, respectively).

Table 3 compares PTSD status among different age groups. Overall, there was a significant difference between the age groups with regard to PCL-C total scores and rates. The PCL-C total scores were significantly higher in the 41 to 50 year age group, and the prevalence rate was higher than other age group. The lowest prevalence rates and PCL-C total scores were found in the 15 to 30 year age group.

Table 4 shows the factors that affected post-traumatic stress disorder (PTSD) symptoms by multivariate logistic regression. Various demographic and loss variables were entered into the models. The prevalence rate of probable PTSD was 35.6% ($n = 178$) based on the PCL-C cut-off score of 50 (Table 4).

Results of the multivariate logistic regression analyses indicated that the prevalence of probable PTSD was significantly higher among individuals with

Table 1. Demographic data of the study population

Variables		n	%
Location	Rural	381	76.2

and over-51-year age group had higher PTSD symptoms and odds ratios (OR). PTSD was significantly higher among victims who sustained an injury or whose family member injured during the quake compared with noninjured survivors. OR for risk of PTSD among victims who sustained an injury or whose family member injured during the quake were 1.88 and 1.53 (compared with that of the noninjured survivors) (Table 4).

4 Discussion

4.1 Prevalence of Probable PTSD

PTSD is still common eight months after the earthquake. Compared with the prevalence of probable PTSD among hard-hit survivors soon after the earthquake, the prevalence after eight months has declined but remains significant. The elevated prevalence rates of psychological symptoms showed that PTSD is common mental health problems in the hard-hit areas after exposure to this natural disaster and remained alarmingly high.

The present study found that approximately more than one third of participants suffered from probable PTSD (35.6%) based on the PCL-C cut-off score of 50. PTSD among survivors in hard-hit areas of the Lushan earthquake were common in our subjects. Our findings indicated a steady decline in the prevalence of PTSD over time [4]. As time went by, the reduced mental health problems among survivors in hard-hit areas may be associated with relatively good living conditions and substantial social support given by the government and other aid organizations. The prevalence of PTSD in our sample were high, compared with rates of PTSD in previous studies after earthquakes. The prevalence rates of probable PTSD among the Wenchuan earthquake victims in hard-hit areas were 26.3% [15]. The prevalence rates of probable PTSD, among the survivors in the hard-hit areas of the Yushu earthquake were 33.7% [16].

4.2 Risk Factors Associated with Probable PTSD

Many studies found numerous associations between the demographics and PTSD. Among the demographic variables of interest, this study found that women were at a higher risk of suffering from PTSD than men. When exposed to

$*p < 0.05$, $**p < 0.01$.

earthquake trauma, females were nearly twice as likely as males to develop PTSD (OR = 1.84). This may be partly due to cultural factors, as women in traditional societies such as China tend to be more dependent, with such disasters causing their dependence object to encounter heavy loss. Initiatives should give priority to female, as they were more likely to develop mental health problems than men.

In our study, ethnicity was another significant predictor for PTSD in hard-hit areas, which agrees with the conclusions of many previous studies [3]. China has a myriad of ethnic minority groups, including the Tibetan. This study found that the odds of PTSD (OR = 1.87), in members of the Tibetan ethnic group were higher compared with the Han ethnic group. After the earthquake, the ethnic minorities should receive more support, care, and help from the government, aid organizations, and volunteers. However, a few studies were opposite to our study [10].

In present study, being injured or having family members injured was also a significant risk factor for the incidence of probable PTSD in the hard-hit areas. The findings are consistent with the conclusion of many empirical studies that the intensity of exposure to a disaster or loss is among the most robust predictive factors for mental disorders [9].

Many studies have documented the significant relationship between social support and PTSD in the aftermath of disaster [4]. Consistent with previous studies on post-traumatic psychological health, the present study confirmed that social support has a protective function [1].

4.3 Limitations

This study has some limitations. First, these participants belonged to an extremely hard-hit region. Thus, it may not be appropriate to generalize conclusions in the present study to other earthquake-affected regions. Second, self-report instrument is used, so the participants may be over reported or underreported. Third, in response to the question about history of physical or psychotic diseases, participants generally reported a history of physical disease, and few participants reported a history of psychotic disease.

5 Conclusion

Despite the limitations, to the authors' knowledge, this study has played an exploratory role in revealing the prevalence and risk factors of probable PTSD in the hard-hit areas among Lushan earthquake survivors. The findings revealed that PTSD (35.6%) are common mental health problems in hard-hit areas even eight months after the earthquake. Female sex, Tibetan ethnicity, being injured, having family members injured and social support were significant risk factors in heavily damaged areas. The findings were also one of a handful of studies on the psychological sequelae of catastrophic natural disasters among non-Western populations.

Abstract. Iraq is one of the most corrupt countries, as since it was part of TI's statistics occupy the last positions. The paper aims to analyze and understand the perceptions of corruption in Iraq and provide a general framework for anti-corruption by social tools. The education society has selected as study sample by questionnaires randomly at the University students reached (600) student and economics data from 1979 to 2015. The multiple regression analysis, percentages and charts are used to present the results. The findings indicate that corruption is a factor behind the deterioration of the country. The regression test show negative relationship between corruption and economic growth then, religious powers. In additional, the embezzlement and bribery are more common forms in state institutions appearances. The study value suggests answers out scope of government procedures in the fight against corruption that provide social tools relate with self-behavior for corruption problems.

Keywords: Corruption · Economic growth · Religious power · Education society

1 Introduction

The most common definition of corruption is the misuse of public office for private gain [15]. It has serious consequences in reducing the economic level and development [5]. As well as a reduction of per capita income [22,24], It hurts the poor more than the rich [10], to load the economic costs of institutions and social Large [18] and thus increases the levels poverty [3,9]. Corruption is not a problem of theft only but includes many forms such as bribery that may be in payments under the table and fraud, such as falsification of contract, assault,

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_123

for example, examination papers, or wasting time or selling state secrets and nepotism seeking the benefit of friends and relatives for, misappropriation of funds the public. What makes matters worse is the inability of the beneficiaries of recording information about the services received [21]. It is worth mentioning that there is corrupt behavior that considers a rate of return, including bribery of more than 11–15 times [12]. Some divides corruption into the first two types [8, 20, 21], a large corruption, which is intended to official corruption in the upper levels. Small corrupt practices which routinely incorrect practiced by the staff at the lower levels. Countries are trying, especially in developing countries to build effective strategies to fight corruption, in spite of the existence of other regulatory tools to take the fight against corruption in Iraq, such as the Integrity Commission and the Financial Inspection Office and the offices of the inspectors and the media, but discontent and still more from the Iraqi state institutions reached levels alarming. Show us that since the beginning of the Iraq enters Corruption Perception-wide and in 2003 for occupies ranked No. 133 and in spite of increased measures to combat it, but it kept growing, because occupies ranked No. 167 in 2015. As shown in Table 1. Also, the private sector is weak and the level of economic growth and income individuals wobbling for these reasons we focused on Iraq in our study. Here, the two puzzles: first, do you that the Iraqi economy negatively affected by corruption, or is it similar to the Chinese economy, which is growing with the increasing levels of corruption? Second, what motives corruption in the country under study?

In this paper, we investigate into the impact of corruption on both economic growth and capita income in Iraq. Second, provide estimates that relative

Table 1. Classification of Iraq, according to the Corruption Perceptions Index

Source: Transparency International publications efficiency of the procedures with the anti-corruption organizations in Iraq, the most important motives common forms of corrupt behavior. Moreover, we found that corruption is one of the most important reasons impeding economic growth in the country, economic hardship and poverty of the most important factors that drive an individual to exercise corrupt behavior. As well as the current government measures are ineffective in the fight against corruption, it may be the reason the ambiguity that is characteristic of the rules and procedures governing the functioning of the organizations. [16] refers to resort to innovation may contribute may raise overall performance. We believe that the focus on the ethical aspect may be the golden key that will end the problem or at least contributes to the minimization.

This paper has four parts, the Sect. 2 is research methodology. The Sect. 3 includes data analysis and discussion. Section 4 is conclusions.

2 Research Methodology

2.1 Subscribers Properties

The study analyzes the concept of citizens for corruption in Iraq for determination the actual behavior of society. A questionnaire was distributed to a sample of university students very (600), considering that young students are the heart and the leaders of the future. Distributing the questionnaire manually on (714) students returned them (637) have neglected them (37) to identify because of their health or for other reasons. It was the response rate (89%). We made this questioner basic on [20]. In addition, as well as data obtained (37) observations about corruption and economic growth variables from the organization of integrity and the Iraqi ministry of planning from 1979 to 2015. The method was used Multiple regression analysis, percentages, tables, and diagrams in the data analysis.

2.2 The Main Hypotheses

Bryant and Javalgi [4] found corruption affects economic growth and investment in each country. Particularly the impact on investment and promise a tax on profits in developing countries. But in South Korea found that more corruption leads to more economic growth, as it works on the development of economic strength [11]. In the same way, Ajao et al. [2] explained the impact of corruption on economics growth which emphasizes that corruption is the biggest inhibitor of growth in most countries of the world. The corrupt system gives contracts to dealers who paid the highest amount of bribes, regardless of the level of efficiency, as well as a tax in their pockets and not in the state treasury [13]. We summarize business literature about corruption by three hypotheses:

Hypothesis 1 (H1): The corruption variables negatively can decrease the growth rate of a gross domestic product.

Hypothesis 2 (H2): The corruption variables negatively can decrease the growth rate of capita income.
Hypothesis 3 (H3): The religious powers negatively can decrease corruption level.

2.3 Model Development

The Business literature suggests that corruption has a deleterious effect on economic growth through two main reasons: by directly decreasing the efficiency of administrative systems And generated an atmosphere of frustration, resentment, mistrust and Corrupt behavior carries additional financial costs for society [6,7,10]. In this section, we set up a statistical model of the relationships among corruption variables, economic growth and religious powers based on the model of Gyimah-Brempong [10] and Shadabi [23] as follow:

$$g = \gamma_0 + \gamma_1 gc + \gamma_2 ec + \gamma_3 tsc + \gamma_4 grc + \mu, \tag{1}$$

where g is growth rate of gross domestic product, gc is general corruption index, es is employees corruption index, tsc is Transaction speeding corruption index, grc is Governmental Unities regulations corruption index, γ_0 is a coefficient that estimates the growth rate of national income unassociated with corruption variables, γ_1 is a coefficient that estimates the association between growth rate of national income and general corruption, γ_2 is a coefficient that estimates the association between growth rate of gross domestic product and employees corruption, γ_3 is a coefficient that estimates the association between growth rate of gross domestic product and Transaction speeding corruption, γ_4 is a coefficient that estimates the association between growth rate of gross domestic product and Governmental Unities regulations corruption, μ is a GDP growth error term.

$$\mathrm{gcapi} = \gamma_0 + \gamma_1 gc + \gamma_2 ec + \gamma_3 tsc + \gamma_4 \mathrm{grc} + \omega, \tag{2}$$

where gcapi is the growth rate of capita income, and all other variables are as defined in the equation above, ω is a growth rate of capita income error term.

$$c = \beta_0 + \beta_1 \mathrm{drp} + \beta_2 \mathrm{irp} + \sigma, \tag{3}$$

where c is corruption index, irp is development religious power, irp is individual religion power, β_0 is a coefficient that estimates the corruption unassociated with religious powers, β_1 is a coefficient that estimates the association between corruption and development religious power, β_2 is a coefficient that estimates the association between corruption and individual religious power, σ is a corruption error term.

There is evidence that corruption negatively has affected both the growth rate of real income and income distribution [10]. We expect the coefficients of γ_1, γ_2, γ_3 and γ_4 to be positive on both the growth rate of gross domestic product and capita income, while in the third model, we expect the coefficients of β_1 and β_2 to be negative on the corruption.

3 Data Analysis and Discussion

The first and second models estimate of GDP and capita income growth rates presented in Table 2. Test statistics is consistent with our hypotheses. The coefficients of γ_1, γ_2, γ_3 and γ_4 are negative as expected and are statistically significant at $\alpha < 0.1$. The adjusted explanation coefficients are 0.57 and 0.47 respectively, where f-value greater than scheduled value. This indicates that the growth rate of GDP and capita income are negatively correlated with corruption variables. These results support *Hypotheses* 1 and 2 and agreement with [1,3,9,24].

The last model estimates of corruption level presented in Table 2 panel B. The coefficients of β_1 and β_2 are negative as expected, and are statistically significant at $\alpha < 0.1$. The adjusted explanation coefficients is 0.27. This indicates that the corruption level is negatively associated with development religious power and individual religious power by -0.39% and -0.43% respectively. This result is consistent with H3 and means the religious powers have affected corruption decrease that pushes to find new tools relate to ethics and spiritual behaviors these results fit with [26]. Shadabi [23] suggested but Contrasted with Paldam [17] Who pointed out that religious variables are not enough to predict corruption.

In Fig. 1, We noted the higher percentage of the sample about (90%) of their responses agree with the concept that argues corruption is a major problem in the country by selected always scale about (50%) and often scale about (40%). This is a very high percentage confirms the extent of realization of the corruption Appearances in the society.

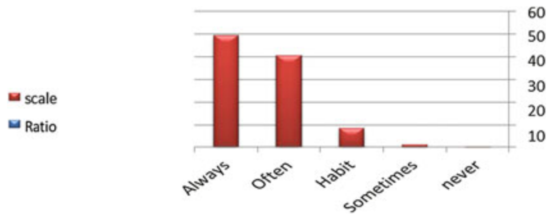

Fig. 1. The basic problem of corruption in Iraq

In comparison the impact of Corruption on economic growth. Figure 2 presents that (82%) of the participants stressed that corruption alters the level of the country and its development by selected always scale (50%) and often scale (32%). We prepared some questions to determine the level of corruption in country and to make evidence whether it contributes to change the country economics. The analytic result reports that most of the participants agreed that corruption and contributes significantly to the deterioration of the country. Lisciandra and Millemaci [14] provided evidence that corruption has negative impact on economic growth in Italian region and the relation between them is nonlinear when economic growth fall, corruption increase.

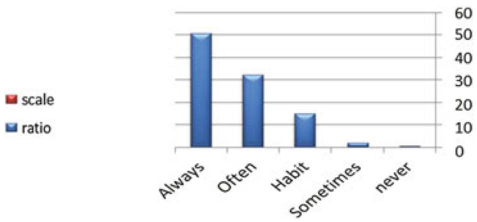

Fig. 2. The Corruption and country economics

In this study, Fig. 3 presents that the embezzlement is more famous common form to corruption phenomenon in Iraq by determined about (41.3%) of the sample. While the second form of corruption is bribery by 29.8% of their pointed, (16%) considered the third forms is favoritism, (8%) selected the extortion, and the last percentage about (4.7%) considered the information misuse is type of corruption there. Ajao et al. [2] confided that corruption forms of multiple and different gradient and conflict of interest, embezzlement, extortion, bribery and many others, which is a transfer or grab valuables and property to someone

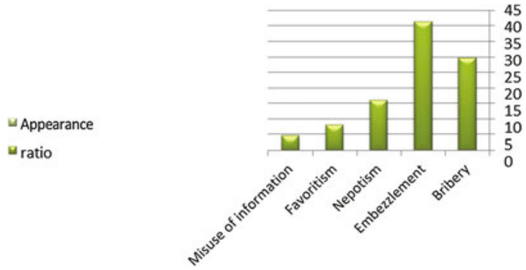

Fig. 3. The most common forms of corruption

who has no right to corruption, but used to do so by virtue of his position, and resorting to the use of misleading and erroneous information [21].

Wedeman [27] showed that widespread corruption at all levels and in the center of the large levels. This case is in our study sample consistent with studied confirmed the higher levels in the state were the most corrupt. Tabish and Jha [25] used anti-corruption strategies in Indian public sector, they are four latent constricts leadership, rules & regulations, training, and fear of punishment. The finding showed all of them are highlighted to help institutions for understanding the role of anti-corruption. Figure 4 describes the reasons of corruption based on education society. A large number of participants of the sample about) 30.5% (believes that the bribes paid based on the employee's request. Whereas about (25.2%) underlines the lack of receipt of services in the event of non-payment of a bribe, (17%) push for speeding up transactions, and (16.1%) in order to avoid problems, and finally (11.2%) pay because the treatment is not a fundamentalist.

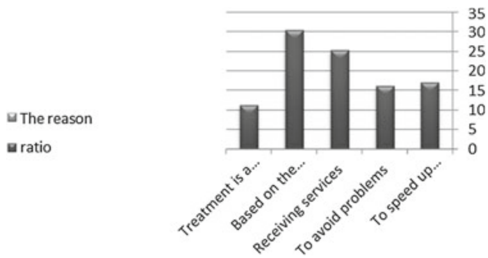

Fig. 4. Reasons for paying bribes to society situation

This study tried to know the rules and capabilities of government for anti-corruption by education society with five parts because that will make overview about the problem size and corruption effect. In Fig. 5, the higher percentage is confirmed that governmental anti-corruption measures have a low efficiency by (44.2) of the respondents, (31.7%) confirms that the measures originally inefficient and ineffective, (17.5%) considered the effect is mild, (5.2%) agreed with

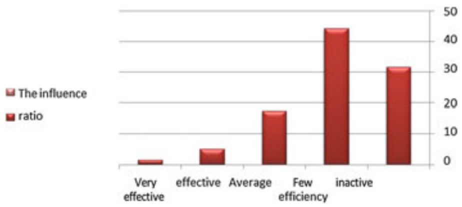

Fig. 5. The effectiveness of the procedures currently approved by government

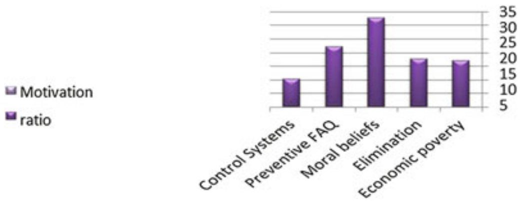

Fig. 6. The main motivations for corruption in Iraqi society

efficient and effective, and (1.3%) were a very effective and influential. Sampford, et al. [21] Delays in the implementation of judicial proceedings on the corrupt or non-implementation makes the work of that anti-corruption a few effectiveness. Lack of public confidence in the judiciary and the court and the police not to push them to give information about corruption, because they believed that the judge deal bribery or staff in court and this may be the result of the individual's personal experience in this regard. Corruption increases the uncertainty and skepticism in the judicial and legal system, the presence of authority has indisputable sovereignty opportunistic supports corruption. Also, the performance of organizations will decrease high levels of corruption, because corruption gives individuals a competitive advantage unfairly [19]. The reasons may include the failure of recent technology advances being on lower pollution emission intensity [28] (Fig. 6).

4 Conclusions

This analytic investigating aimed to expand the understanding of the impact of corruption on economic growth. Iraqi education society considers cultural focusing that has simulation key for anti-corruption. The major problem and barely missing from the country is Corruption. It also is inhibiting the development of the nation and the inhibitor of economic development and growth. Poverty or economic hardship of the individual may be the most important reasons driving for corruption for the average employee, which paid to bribe demands, on the other hand, the high cost of luxury, greed, panting behind excellence are paying the highest levels in the country to engage in corruption. We found evidence that the corruption levels are detrimental to long-run growth. This evidence is robust and persistent throughout different studies. The impact of corruption is negative with respect to economic growth at a high level for each Iraqi society.

FAQ mysterious and government actions ineffective staff gives a chance for corruption and thus the clear wording of government and striving may prevent the penetration of corruption in the institutions as well as provide the employee with a copy of the instructions when receiving the functional tasks. Accordingly, we can suggest a few considerations. A possible interpretation could be that anti-corruption by adoption non-financial measures such as moral beliefs, attitudes of safety and reliability. Finally, Corruption is not only economic but also far back in history far back in morality and must aim to change the functional ethics prevailing, and the laying of a plan put moral values purposeful organizations to clean up corruption and make it fairer, and cannot omission on the role of education society.

Procurement Risk Mitigation for Rebar Using Commodity Futures

Jian Ni, Wei Zhou(✉), and Dan Yang

School of Financial, Southwestern University of Finance and Economics, Chengdu 610074, People's Republic of China
zhouwei@swufe.edu.cn

Abstract. This paper presents a model to mitigate the risk of budget overruns during procurement of raw materials. A case example in rebar procurement fora typical metallurgical manufacturing company in China is used. The demand data was supplied by the company and the rebar price data was obtained from Shanghai Futures Exchanges. The novelty of this study lies in the incorporation of budgetary control into the objective function of the model. A multistage rebalancing strategy of the futures position is used to reduce the impact of unexpected changes in rebar supply price and finished product demand. The complex objective function is approximated by a quadratic expression, and suboptimal solutions are obtained for cases where raw the material price is independent of the customer demand. When compared with the company's spot buying approach without hedging, the results from the model show the proposed multistage futures balancing model can help reduce the budget overspending by as much as 32%. Further experiments are carried out to study the effects of changing price and demand volatilities, and the results confirm the usefulness of model in mitigating the underlying risk.

Keywords: Raw material procurement · Risk management · Budged control · Hedging with futures

1 Introduction and Background Literature

This paper is based on a case study in rebar procurement for a Chinese metallurgical machinery company that supplies iron and steel mills in China with drill pipe, drill head, steel making and refining equipment, and blast furnaces. The commodities markets in China are now mature and well established with a plentiful supply and fast delivery, and spot procurement is now widely used by many companies to try and avoid unnecessary inventory built-up. In recent years, however, the spot prices of steel materials have become much more volatile, and companies, if they want to remain competitive, cannot safeguard against such price volatility by raising the final product price or by imposing a contractual

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_124

surcharge on its customers. Added to this uncertainty of procurement price is the perennial problem of uncertain rebar requirements, resulting form uncertain customer demand for the finished products, especially in the prevailing worldwide economic uncertainties. This problem faced by the company in this study is not uncommon; it is faced by all manufacturers whose material procurement is exposed to severe risk arising from fluctuations in both material prices and demand for the final products.

In response to increasing raw materials price volatility caused by speculation, and to a lesser extent by volatility in material demand, many manufacturing companies are now looking at the use of financial hedging policies. Financial hedging is, of course, not an entirely new concept; much historical discussion can be found in Myers and Thompson [10], Mathews and Holthausen [8], Lence [7], McMillan [9], and Alizadeh, et al. [1]. However as suggested by Doege, et al. [5], financial hedging strategies developed for use in the world of finance are not directly applicable to risk mitigation in a manufacturing environment. With this in mind, this study is aimed at developing a dynamic multistage approach that can be used for budgetary control in material procurement under the specific business requirements of a manufacturing company. Starting with the futures contract as the instrument, the multistage hedging can be divided into two steps. First, a budget is set for a single procurement. Second, the multistage hedging is initialized and rebalanced at the end of several interim stages. The rebalancing makes use of updated information on material price and demand. With this type of dynamic rebalancing of the futures position, the financial hedge can respond fairly quickly to any unexpected changes in price and demand. At the end of the final stage, physical delivery takes place and the futures position is settled.

Another risk mitigation approach in material procurement, as reported in several studies, is the use of flexible supply contracts, such as back-up agreements [6], option contracts for physical delivery [19], and capacity reservation contracts [16,17]. It is also possible to use the flexible contracts in a synergic manner (e.g. by building portfolios) to achieve higher performance in procurement risk mitigation [18]. Generally, flexible supply contracts can alleviate the risk, but such contracts are difficult to price and may require the payment of a premium to the spot price. However, there are many situations where flexible supply contracts are not available, as is the case for the company in this study. In fact, Chod, et al. [3] employed an exponential utility to explore the relationship between operational flexibility and financial hedging opportunity. Using a similar exponential utility, Ni, et al. [12] then revealed that there can be a weak separation between the operations decision and financial hedging strategy of a firm. Other related studies on the interaction between financial hedging and operations management can be found in Okyay, et al. [20], Sayin, et al. [14], and Zhao and Huchzermeier [21].

It is only recently that researchers began to study the use of financial hedging as an approach to mitigate risk in procurement for manufacturing. In this context, Xu [20] obtained economical hedging strategies by developing an integrated framework model for procurement and inventory risk management using a financial hedge using the London Metal Exchange (LME) copper futures contracts. Another analytical framework was developed by Caldentey and Haugh [2] to investigate the appropriate hedging strategies for hedging against a possible drop in profit of a company when profit is correlated with certain returns in the financial markets. These two studies suggest that a financial hedging strategy, if carefully designed, can effectively mitigate the procurement risk. This was followed by Ni, et al. [11], who develop a multistage hedging strategy to mitigate procurement risk using a dynamic price and demand information updating process, and concluded that using appropriate information to update the hedging strategy can substantially improve the effectiveness of the hedge. Such updating makes an interim multistage rebalancing of the futures position possible, thereby providing a timely adjustment using up-to-date information. This study differs from that of Ni, et al. [11] in that it develops a hedging strategy that focuses on budgetary control. The management of the machinery company used in this study are very concerned with budgetary control and they emphasized the need to mitigate the risk of budget overruns, especially during the current economic uncertainties. With this in mind, a procurement budgetary control model (PBCM) is developed that aims at controlling the risk of excessive over budget. The PCBM model developed does not seem amenable to a direct solution, and therefore a heuristic approach had to be used to obtain efficient suboptimal solutions. Using the heuristic procedure, numerical experiments are conducted to determine the effectiveness of the multistage hedging strategy in controlling procurement spending.

In summary, this paper develops a financial hedging strategy for procurement risk mitigation in the form of an interim multistage rebalancing and dynamic information updating process, with the general objective to address the need to maintain adequate budgetary control.

2 The Dynamic Futures Rebalancing Model

2.1 Budget Control and Financial Hedging

Since the global financial turmoil that started towards the middle 2008, the management of the machinery company has been under increasing pressure to control the procurement risk arising from both volatile prices and uncertain demand. As considerable sums are being spent in procuring rebar steel required for production, the company management is also under pressure to maintain good budgetary control, and strives as much as possible to keep procurement spending in line with predetermined budgets. However, budgets can often be severely exceeded if both steel prices and product demand increase unexpectedly. When this occurs, the company may resort to banks loans to finance the overspending, but the availability of loans at reasonable interest rates is limited, mainly as a result of the current tight regulatory supervision of banks and higher Basel capital adequacy requirements. This is partly due to the economic slowdown in China over the past year or so, and perhaps also to the general downgrading of creditworthiness of private manufacturing companies as a result of this slowdown. In light of the scarcity of loans at reasonable or even unreasonable rates, the company and its peers in China need to maintain tight financial control over their procurement spending so as to reduce the type of risk that may lead to bankruptcy.

One existing approach to control procurement spending of a company is to sign long-term supply contracts with their suppliers and so to lock up the procurement price. However, this type of contract is restricted to fixed quantity deliveries, and limits the company's ability to quickly adjust to changing customer demand and will generally involve paying a premium to the spot price. China's commodity market is now quite mature and sophisticated, and commodity futures contracts are available on Shanghai Futures Exchange (SHFE) that can be used to hedge against the financial risk and to control procurement spending. As rebar is one of the raw materials that the company uses in very large quantities, the management is prepared to allow the authors to explore the use of rebar futures contracts in controlling the procurement risk that it faces. This case study is not unique, and highlights a general problem associated with commodity procurement risk management, viz., easy access to the commodity markets has encouraged many manufacturers to gradually shift to spot procurement to avoid excessive inventory built-up and achieve high flexibility in supply management. But excessive world-wide speculative activity in modern commodity markets has at the same time significantly increased price volatility. This is evidenced by the fact that only a small proportion (some 3% for copper) of futures contracts are actually settled through physical delivery, the rest can only be regarded as speculative and/or risk hedging and are settled in cash.

2.2 Risk Mitigation Model Development

The design of financial hedging strategies for commodity procurement is distinct in nature from their counterparts in the financial industry. It is not only the uncertainties in the underlying volume that arises from the changes or updates of customer orders that can extensively complicate the problem, but also the different hedging objectives (budgetary control in this paper) which require tailor-made hedging strategies to be developed. In addition, the transaction cost is usually negligible in hedging against the risk in procurement for a manufacturer [19], while this cost may be highly significant for hedging in the financial industry. This low transaction cost is mainly due to the fact that transaction costs involved in the futures contracts are very low (less than 0.02% in SHFE) in comparison to the value of the trade.

In the context of our model, the company that has to procure a certain commodity for future production (rebar for the company used in this study), where both commodity price and demand are expected to fluctuate. A multistage hedging approach is used with the aim of achieving a good overall hedge that can effectively reduce the possibility of budget overruns in procurement. Such a multistage hedging procedure is illustrated in Fig. 1. The time period or planning horizon in which we want to implement the financial hedge is T, which is divided into T stages $t = 0, 1, \cdots, T-1, T$. For the general class of problems that we are

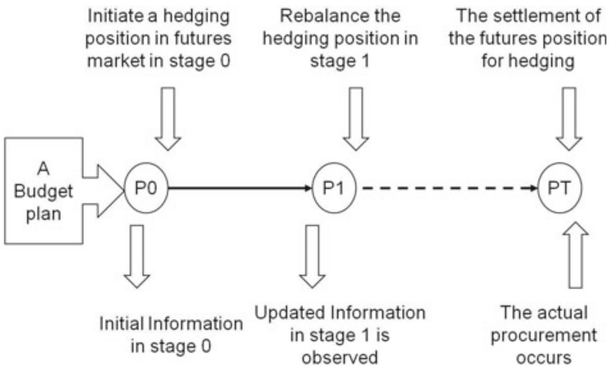

Fig. 1. The multistage hedging procedure

dealing with one stage can be a period of one week to one month, depending on the availability of updated information for both commodity price and customer demand. As shown in Fig. 1, at the beginning a budget plan is produced by the management that serves as a benchmark that the subsequent financial hedging strategy aims to meet. Using the price and demand information at stage 0, the multistage financial hedge is initialised by entering into a long position of the commodity futures that expire at the end of the final stage. At the subsequent stages, the futures position will be rebalanced to achieve the best hedge using the latest information available at each stage. At the end of the final stage, the actual procurement of the physical commodity takes place and the futures position is settled in cash. The cash settlement will completely or partially offset any overspending incurred because of the variability in both commodity price and customer demand.

The multistage hedging strategy is aimed at balancing the uncertainty of the unhedged procurement spending, C, which is defined as the product of the volatile commodity price P and the uncertain procurement quantity X, or $C = PX$. The hedge can generate a payoff from the cash settlement of the futures position, which leads to the hedged procurement spending as follows:

$$\bar{C} = C - H. \tag{1}$$

For the multistage hedging strategy, the payoff can be calculated by analyzing the stage-by-stage initialisation/rebalancing volumes y_t and the futures position z_t at each stage t $(1 \leq t \leq T-1)$. The variables y_t and z_t are related as follows:

$$z_t = \begin{cases} y_t, & t = 0 \\ z_{t-1} + y_t, & \forall\ 1 \leq t < T. \end{cases} \tag{2}$$

Given the price of the commodity futures $F_t (1 \leq t \leq T-1)$ at the beginning of stage t that will mature at the end of stage $T-1$, the payoff H can be calculated as follows:

$$H = P \times z_{T-1} - \sum_{t=0}^{T-1} F_t \times y_t. \tag{3}$$

Note that we do not consider the transaction cost. This is because of the low rebalancing frequency (weekly at most) and the low transaction cost relative to the settlement amount ratio (less than 0.02% in SHFE). From Eqs. 1 and 3, the hedged procurement spending will be:

$$\bar{C} = P\left(X - z_{T-1}\right) + \sum_{t=0}^{T-1} F_t \times y_t. \tag{4}$$

A hedging strategy is said to be effective when the hedged procurement expense $\bar{C}$ is less exposed to the volatilities of the commodity price and demand than the unhedged spending C. The design of an effective multistage hedging strategy needs to incorporate information updating processes for the material price and for the demand. These processes are used in deciding the initialisation/rebalancing volumes (y_t). In this study, the information updating process is modelled by filtration [2], a method often used to adequately model the timely availability of information. Generally, a filtration is an increasing family $\{\mathcal{F}_t\}_{t=0}^{T-1}$ of σ-algebra $\mathcal{F}_t$ [13]:

$$0 \le s < t < T \Rightarrow \mathcal{F}_s \subset \mathcal{F}_t \subset \mathcal{F}. \tag{5}$$

These σ-algebras $\{\mathcal{F}_t\}_{t=0}^{T-1}$ can be regarded as the available information set at each stage. Let $M_t\left(\Omega,\ \mathcal{F}_t\right)$ be the function space that is composed of all the $\mathcal{F}_t$-measurable random variables, i.e.,

$$M_t\left(\Omega,\ \mathcal{F}_t\right) = \left\{\xi \,|\xi \text{ is a random variable on } \Omega,\ \text{and } \mathcal{F}_t - \text{measurable}\right\}.$$

The hedging decisions are based on the available information at each stage, and any admissible adjusting volume y_t must satisfy the following constraint:

$$y_t \in M_t\left(\Omega,\ \mathcal{F}_t\right).$$

The multistage hedging strategy formulated below aims at keeping the procurement spending in line with an allocated budgeted. To achieve this aim, a procurement budgetary control model (PBCM) is developed which attempts minimise the expected budget overrun (EBO). The model can be stated as follows:

$$\min\nolimits_Y \text{ EBO} = E\left[\left|\bar{C} - K\right|^+\right]. \tag{6}$$

$$\text{s. t. } \bar{C} = P\left(X - z_{T-1}\right) + \sum_{t=0}^{T-1} F_t \cdot y_t, \tag{7}$$

$$z_t = z_{t-1} + y_t, \forall\ 1 \le t < T, \tag{8}$$

$$z_0 = y_0, \tag{9}$$

$$y_t \in M_t\left(\Omega, \mathcal{F}_t\right), \tag{10}$$

here the objective function $E\left[\left|\bar{C} - K\right|^+\right]$ is the EBO, which measures the average overspending with respect to the given budget K.

3 The Multistage Financial Hedging Strategy

3.1 Heuristic Solution

The discontinuity of $E\left[\left|\bar{C}-K\right|^{+}\right]$ in the objective function of the PBCM model developed above makes it difficult, if not impossible, to find a close-form solution that can be easily implemented. This inherent complexity in the PBCM model requires the use of some heuristic to generate suboptimal, though still effective and potentially useful, solutions. In this section, a heuristic is developed by first replacing the PBCM model by an α-PBCM model, where the value of α is set heuristically. The approximate model, α-PBCM, can then be solved using the closed-form results of Ni, et al. [11]; an exact solution to the approximate model. It is decided to approximate the objective function as:

$$E\left[\left|\bar{C}-K\right|^{+}\right] \cong \frac{1}{2}\left(E\left[\bar{C}\right]+\alpha\cdot E\left[\left(\bar{C}-K\right)^{2}\right]-K\right), \tag{11}$$

where

$$\alpha=\frac{E\left[\left|\bar{C}-K\right|\right]}{E\left[\left|\bar{C}-K\right|^{2}\right]}. \tag{12}$$

α needs not to be constant. However, it is expected that α will be relatively insensitive to changes in the hedging strategy used, suggesting that it should be possible to use a constant value for α in Eq. (11) and still produce a good quadratic approximation for $E\left[\left|\bar{C}-K\right|^{+}\right]$. In this study, α is determined heuristically using the following expression:

$$\hat{\alpha}=\frac{E\left[\left|\bar{C}(\hat{Y})-K\right|\right]}{E\left[\left|\bar{C}(\hat{Y})-K\right|^{2}\right]}, \tag{13}$$

where $\hat{Y}=\{\hat{y}_i\}_{i=0}^{T}$, $\hat{y}_0=E_0(X)$, and $\forall\ 1\leq t\leq T$, $\hat{y}_t=0$.

In the heuristic used, the value of $\hat{\alpha}$ is calculated on the assumption of a static hedge. It is in fact a simplified way to take into account the effect of financial hedging on the value of α. The effectiveness of $\hat{\alpha}$ is examined in Sect. 4.

When α is constant, the objective of the PBCM model can be approximated by an α-PBCM model as follows:

$$\min_{Y}\ E\left[\bar{C}+\alpha\left(\bar{C}-K\right)^{2}\right], \tag{14}$$

where Y is constrained by Eqs. (7), (8), (9), and (10).

In general, and also in the company used in this study, customer demand and material price are independent. Under this assumption the α-PBCM model can be further simplified as:

Assumption: if for every stage $t(0 \leq t < T)$ X and F_{t+1} are independent, then:

$$E_t\left[F_{t+1}X\right] = E_t\left[F_{t+1}\right] E_t\left[X\right], \forall\ 0 \leq t < T. \tag{15}$$

Under this Assumption, a close-form solution of the α-PBCM model can be obtained using the analytical results of Ni, et al. [11], because α-PBCM model has a similar quadratic objective function. While the α-PBCM and the model of Ni, et al. [11] do share a group of constraints in the multistage hedge, some modifications to two auxiliary variables are still required as follows:

$$\hat{X}_t = \begin{cases} E_{t+1}\left[X\right] - z_{t-1}, & 0 < t < T \\ E_1\left[X\right], & t = 0, \end{cases} \tag{16}$$

$$\hat{K}_s = \begin{cases} K - \sum\limits_{t=0}^{s-1} F_t \cdot y_t, & 0 < s < T \\ K, & s = 0. \end{cases} \tag{17}$$

Using the analytical results (specifically Theorem 3) in Ni, et al. [11], a closed-form solution to the α-PBCM can be obtained as:

$$y_t^* = -\frac{E\left[(F_t - F_{t+1})(F_{t+1}\hat{X}_t - \hat{K}_t + \frac{1}{2\alpha})\,|\mathcal{F}_t\right]}{E\left[(F_t - F_{t+1})^2\,|\mathcal{F}_t\right]}. \tag{18}$$

3.2 Information Updating of Price and Demand

The proposed multistage hedging strategy reacts to updates in the material price and the demand. The dynamic initialisation/rebalancing of the futures position from stage 0 to stage $T-1$ requires the predictions of the future material prices and demand levels, as well as some measure of their volatility. Such predictions are made at each stage of the planning horizon using the updating stochastic processes.

For the stochastic material price model, the long term/short term model of Schwartz and Smith [15] is employed to simulate the dynamics. When is the commodity spot price at time t, the process can be stated as:

$$\ln\left(S_t\right) = \chi_t + \xi_t, \tag{19}$$

$$d\chi_t = -\kappa\chi_t dt + \sigma_\chi dW_t, \tag{20}$$

$$d\xi_t = \mu_\xi dt + \sigma_\xi dB_t, \tag{21}$$

where dW_t and dB_t are correlated as $dW_t dB_t = \rho dt$. Equations (19), (20) and (21) produce the estimates, see Ni, et al. [11], as follows:

$$E_t\left(F_{t+1}\right) = F_t A(t), \tag{22}$$

$$E_t\left(F_{t+1}^2\right) = {F_t}^2 B(t), \tag{23}$$

where $A(t) = \exp\left\{\int_t^{t+1}\left(\lambda_\xi + \frac{\lambda_\chi}{\kappa}e^{-\kappa(T-s)}\right)ds\right\}$

$$B(t) = \exp\left\{2\int_t^{t+1}\left(\lambda_\xi + \frac{\lambda_\chi}{\kappa}e^{-\kappa(T-s)} + k(T-s)\right)ds\right\}. \tag{24}$$

In connection with the stochastic product demand, Choi, et al. [4] describe a Bayesian information update used in a two-stage application. However, for the machinery company used in this study, the Bayesian method needs to be extended to a multistage process. The raw material (rebar) required in this company for physical procurement is an aggregation of customer orders over τ stages. It is not unreasonable to assume that customer orders arrive randomly as a Poisson process. If λ is the average number of customer orders that are received in one stage, it follows that the number of orders $\tilde{N}$ arriving in τ stages is a random number from the Poisson distribution:

$$P\{\tilde{N} = k\} = (\lambda\tau)^k \frac{e^{-\lambda\tau}}{k!}. \tag{25}$$

The predictions of $\tilde{N}$ can be improved using the information on customer orders received at each stage. The expected value ($E_t[\tilde{N}]$ for $0 \le t \le T-\tau$) can be calculated using Eq. (25) as follows:

$$E_t[\tilde{N}] = \lambda\tau. \tag{26}$$

For the case when $T \ge t > T-\tau$, $E_t[\tilde{N}]$ can be calculated as follows:

$$E_t[\tilde{N}] = q + \lambda(T-t), \tag{27}$$

where q is the number of orders received in stage $T-\tau+1$ to t.

Customer orders are fulfilled by successful production of the specified end-products, which can only be done if the required amounts of various raw materials are in stock. The raw material required can be computed almost instantly (2 days) after customer orders are received. However customer orders often vary in size and due dates, and although the order size in the near future can be closely predicted by managers with good relationships with the customers, accurate long-term predictions are still difficult to make. So for certain raw materials, rebar being a good example, the amount needed to serve customer orders at a future point in time is variable, but the variability will reduce as that point in time approaches. If we let $\tilde{d}$ be the expected (average) amount of rebar needed to serve the orders of a single customer in stages $T-\tau+1$ to T, the reduction in variability can then be expressed as:

$$E_t[\tilde{d}] \sim N(d_t, \Sigma_t) \tag{28}$$

and

$$\Sigma_{t_1} \ge \Sigma_{t_2}, \text{ when } t_1 \le t_2 \tag{29}$$

Since the material demand can be computed almost instantly upon receiving customer orders, the planned rebar supply quantities, $\tilde{D}$, required in stages $T-\tau+1$ to T can be estimated as follows:

$$\tilde{D} = \tilde{N} \cdot \tilde{d}. \tag{30}$$

The value of $E_t[\tilde{D}]$ at stage t can then be calculated as:

$$E_t[\tilde{D}] = \begin{cases} d_t \lambda \tau, & 0 \leq t \leq T - \tau \\ d_t \left(q + \lambda(T-t)\right), & T - \tau < t \leq T. \end{cases} \tag{31}$$

4 Case Study Example

After analyzing the historical price data (weekly observations of prices for rebar futures contracts in Shanghai Futures Exchange from 03/2009 to 03/2011), the parameters of the Kalman filter [13] are estimated as shown in Table 1.

Table 1. Estimation of the price model parameters

Parameter	Description	Estimate	Standard Error
κ	Short-term mean-reversion rate	1.0837	0.0132
σ_χ	Short-term volatility	0.3241	0.0056
λ_χ	Short-term risk premium	0.121	0.0126
μ'	Equilibrium drift rate	0.0095	0.0005
μ	Equilibrium risk-neutral drift rate	0.0213	0.0024
σ_ω	Equilibrium volatility	0.2976	0.0112
ρ	Correlation in increment	0.6132	0.0466

There are 6 months in the planning horizon, corresponding to 6 stages in the model. The initial price of rebar is set at 4,500 RMB per tonne and the budgeted unit price is set at 5,000 RMB per tonne, which corresponds to a total procurement budget of $5000 \times E(\tilde{D})$ Yuan. According to the purchasing manager of the company, a customer order arrives every two weeks and raw material is procured every month, so $\lambda = 4.3$ per month and $\tau = 1$. The expected demand is assumed to take unit values, i.e., $d_0 = 1$. This assumption is acceptable because the purpose of the Monte Carlo simulation experiments is to analyse risk and volatility in relative terms, and no generality is lost by such an assumption as long as the volatility Σ_t applies equally to the two strategies that are being compared, i.e. hedged and unhedged. From the historical data for rebar quantities required by the company, it is estimated that $\Sigma_0 = 0.53^2$. It then follows that:

$$\Sigma_t = \frac{T-t}{T} \Sigma_0, \quad \forall\, 0 \leq t \leq T-1. \tag{32}$$

To obtain the heuristic solution, the parameter also needs to be estimated using Eq. (13); resulting in $\alpha = 1.21 \times 10^{-3}$.

Finally, with Eq. (18) together with the price and stochastic demand updating processes, the heuristic multistage hedging model is completely defined for the specific rebar case example. Monte Carlo simulation is used to generate a large sample (5,000) of the rebar price and of the demand. The performance of the proposed multistage hedging strategy is then evaluated in terms of the expected budget overrun (EBO, see Eq. (6) and the standard deviation (SD). The results are summarised in Table 2.

Table 2. Performance evaluation of different strategies (RMB)

	SD	EBO
No hedge	1,482.70	1,038.20
Multistage strategy	1,176.30	701.5

Table 2 shows that both the SD and EBO are significantly reduced by the multistage financial hedge. The significant reduction of SD (from 1,482.7 to 1,176.3) indicates that the stability of the overall procurement spending is improved by the multistage hedge. Further, the substantial reduction in EBO (from 1,038.2 to 701.5) suggests that the procurement budget is much less violated under the multistage hedge than that with no hedging. Therefore, it can be safely concluded that the multistage hedging strategy is effective in procurement risk mitigation from the procurement budget perspective. Moreover, the percentage reduction in EBO for the multistage hedge is larger than SD; EBO is reduced by 32.4% while SD is reduced by 20.6%, see Table 2. These reductions suggest that the proposed multistage hedging strategy is more effective in reducing overspending of the procurement budget than in reducing the uncertainty of the overall total procurement spending.

A sensitivity analysis is conducted to judge the effectiveness of the multistage hedging strategy when the price and demand become highly volatile, and also when their volatility can be regarded as low. The sensitivity analysis first examines the influence of changing volatility in demand. This is done by assessing the performance of the hedge with different levels of demand volatility, i.e., by increasing/decreasing the standard deviation Σ_0 through a *changing ratio*, such that:

$$SD_{\text{changed}} = SD_{\text{initial}} \times (1 + \text{changing ratio}). \tag{33}$$

The influence of changing price volatility, represented by both the short-term volatility σ_χ and the long-term equilibrium volatility σ_χ, is also investigated. Here these two volatilities are simultaneously increased or decreased by a ratio percentage. With either demand or price volatility changing by a ratio ranging from −70% to 70%, the effects of such changes on the hedging performance are shown in Fig. 2 (demand volatility) and Fig. 3 (price volatility).

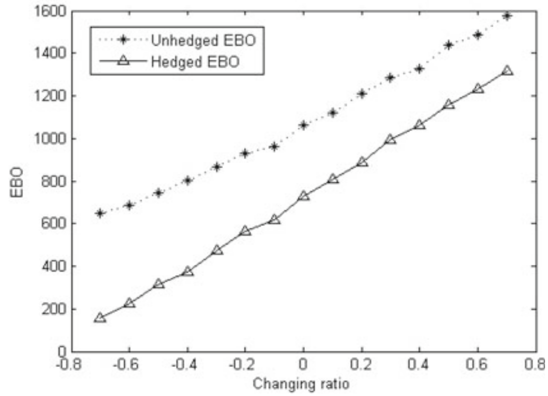

Fig. 2. Sensitivity analysis of demand volatility

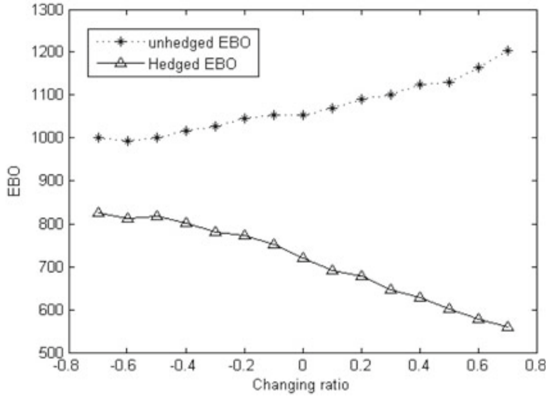

Fig. 3. Sensitivity analysis of price volatility

Figure 2 shows that changing the volatility of demand will affect the performance of the multistage strategy, an obvious result. However, the hedged EBO remains below the unhedged EBO for all changes in Σ_0, suggesting that the effectiveness of the multistage hedging strategy is always superior. When Σ_0 decreases, the hedged EBO is reduced by a larger ratio than the unhedged EBO, indicating that the procurement budget is less likely to be violated. This suggests that the multistage hedging strategy becomes relatively more powerful as Σ_0 decreases. On the other hand, the reduction ratio of the hedged EBO when compared to the unhedged EBO will decrease as Σ_0 increases. So, the multistage hedging strategy will be relatively less powerful as increases, an obvious result, since any procurement policy can be expected to deteriorate as volatility increases.

Figure 3 shows that the performance of the multistage strategy is affected by the price volatility, also an obvious result. On one hand, the multistage hedge will become relatively more powerful as σ_χ and σ_ω increase, as shown by the widening difference between the hedge and the unhedged EBO. While on the other, the multistage hedge becomes less powerful when σ_χ and σ_ω decreases, as shown by the narrowing difference between the hedged and unhedged EBO. Furthermore, Fig. 3 shows that the difference between the hedged and unhedged EBO will reduce sharply when the price volatility decreases significantly. This indicates that price volatility plays a major role in the performance of the multistage hedge model.

5 Concluding Comments

The financial hedging problem presented in this paper is modelled as a multistage strategy, and data from a machinery company is used to analyse the expected budget overrun risk in procuring rebar. A closed-form heuristic solution is obtained for the model when the raw material price is independent of customer demand. The novelty of the proposed multistage hedging strategy is that it addresses the importance of budget control, and hence the risk of possible overspending in commodity procurement is mitigated. Another distinctive feature of the model is the rebalancing of commodity futures position at the intermediate stages of the planning horizon. This rebalancing allows appropriate adjustments of the commodity futures position to be made at various stages, by taking into account new trends in the stochastic price movement, and up-to-date changes in the prediction of amount required.

The effectiveness of the model is tested via a case study in the supply of rebar for a machinery company. The results confirmed the usefulness of the proposed multistage hedging strategy in reducing procurement risk arising from variable finished product demand and raw material prices when using a predetermined level of budgetary control. This model developed in this study can be extended in several directions. First, it could be beneficial to investigate the use of other types of financial derivatives, such as options contracts, as the instrument of the hedge. Second, the multistage hedging approach could also be expanded to mitigate other types of operational risks, such as inventory risk and currency risk. Another possible extension is to use a penalty (cost) function for budgetary control, as under-spending by a certain amount is generally less serious than overspending by the same amount.

Ubiquitous Healthcare and Ubiquitousness of Chronic Disease Prevention and Control: Theory and Design

Zhihan Liu(✉)

School of Public Administration, Central South University,
Changsha 410083, People's Republic of China
liuzhihan@csu.edu.cn

Abstract. With the gradual maturing of technologies such as cloud computing, high-speed mobile Internet and Internet of things, to realize the Ubiquitous Healthcare in the health field is not only an irresistible trend, but also a realistic possibility. According to the chronic disease management theory and the service-oriented architecture, this study proposed the designing scheme and implementation methods of a mobile service platform for the big data collection and analysis of chronic disease based on cloud computing. With this platform, community residents can enjoy the convenient and quick health self-management services, while community healthcare staff can provide timely and efficient services to the patients with chronic diseases or those potentially high-risk individuals precisely. This paper is aimed to provide theoretical reference for the ubiquitous healthcare research specifically in chronic disease prevention and control, and also help in the practice of upgrading community health service and promoting a supply-side structural reform in chronic disease management.

Keywords: Big data · Chronic disease · Cloud computing · Health management · Ubiquitous healthcare

1 Introduction

Community healthcare service was identified by the World Health Organization (WHO) as an effective measure for chronic disease prevention and control. However, since China started the reform of urban healthcare system and the development of community healthcare service in 1997, the condition of suffering from chronic diseases has not been improved as much as expected and the medical expenses have also risen rapidly. Why is that the community healthcare service in China did not have satisfactory effects on residents' health? In addition to the service object factors (e.g., people's health consciousness, lifestyle and stereotype of treatment selection) and the policy factors (e.g., government investment and allocation of health resources), the traditional form of community healthcare service, the content homogenization with hospitalization service,

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_125

and the maladaptation to the needs of patients with chronic diseases are also worthy of consideration.

In fact, it is difficult to achieve the goal of building an integrated system of prevention and control towards the growing outbreak of chronic diseases just through the traditional medical information management. In 2002, Kirn [6] formally put forward the concept of Ubiquitous Healthcare (u-Healthcare or u-Health). It is a kind of information system configuration enabling individual consumers to access any types of health services through mobile computing devices whenever and wherever [1–3,5,8–13]. This concept actually originated from the idea of Ubiquitous Computing (ubicomp or Pervasive Computing) in the field of information science and technology. Transcending the traditional desktop computing, ubiquitous computing is a bran-new computing mode aimed at fusion of cyberspace and physical space, under which people could acquire the digital services freely and transparently [7].

For being humanistic, ubiquitous computing was doomed to accomplish great deeds in the fields of medicine and healthcare (especially in the health management area) which are closely related to human health and well-being, since the day of its birth. As the 10th International Conference on Ubiquitous Healthcare held in Yokohama, Japan in 2013 declared: “Enhancement in the welfare for future requires the change to the current healthcare system. Our concern for the healthcare is shifting from ‘recovery from illness’ to ‘maintaining wellness and improving quality of life’. For the care of daily health level we need special kinds of methods and technologies that we can be applied into our daily life smoothly” [10]. Many developed countries have established relatively complete u-Health systems with the following typical architecture [11] (see Fig. 1). Based on the development of Internet of Things (IoT) and cloud computing, the medical industry in Taiwan, China, has also witnessed the transition from “e-Health” to “m-Health” and eventually to “u-Health”, in a short span of ten years. However, due to the late start of ubiquitous computing research in mainland China, previous work on u-Health (especially for the chronic diseases management) is quite limited at this time [12,13]. To addresses the problem, this study is the first one in mainland China to explore the application of u-Health in the chronic disease scenario. Not only the theory and the functions were introduced, but also the technical route and the implementation methods were presented, aiming at helping the Chinese government implement its comprehensive strategy for chronic disease prevention and control.

2 Functional Requirements of Mobile Community Health Management Service Platform for Chronic Diseases Based on Cloud Computing

Chronic Disease Management (CDM) includes health information collection, health data storage, health risk assessment, chronic disease monitoring, health interventions, etc. All these tasks provides natural basis for the functional unit division of a mobile community health management service platform for chronic

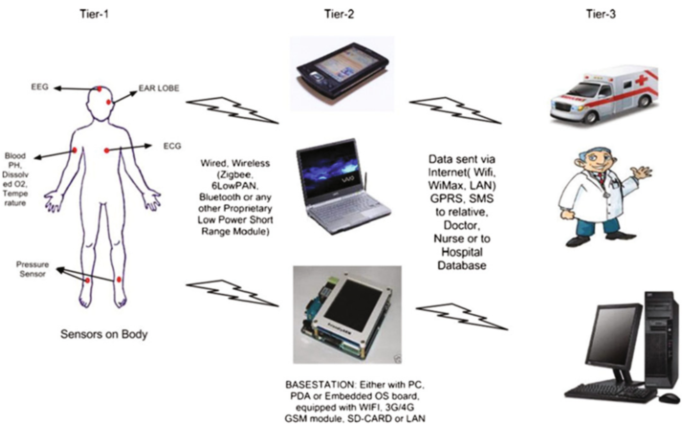

Fig. 1. Typical architecture of u-Health system

diseases. It is important to note that this study adopted the theory of Yang [14] which insists that the receptors of community prevention and control should not only include the patients with chronic diseases, but also the high-risk groups and even the healthy ones, from the perspective of community health management. Thus, the application system of this platform can be divided into two subsystems: community health service center and community residents (not just the patients). The main goal of the system is moving forward the "strategic pass" of CDM to help in cost control under the guidance of health data real-time acquisition, and carrying out a systematic, coordinated and integrated strategy on chronic disease prevention and control by in-depth health data exploring. The specific steps include: (a) collecting, managing and analyzing the personal health information used in health risk factors assessment, tracking, and health behavior guidance, for dynamical monitoring of community residents' state of health; (b) applying health interventions to the community residents based on the evaluation results; and (c) tracking and evaluating the effects of interventions (see Fig. 2).

3 Implementation Methods of Mobile Community Health Management Service Platform for Chronic Diseases Based on Cloud Computing

3.1 Technical Route

The system adopted the MySQL database for data storage, and used Java language for realizing the background management function and the apps development based on Android and IOS. Given the complexity of apps on the community health management service platform, the platform was designed in according to Service-Oriented Architecture (SOA), providing functions such as service definition, development, deployment, and running, etc. Logic reuse was implemented

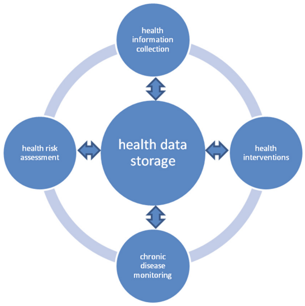

Fig. 2. System functional requirements of the service platform

through the loose coupling between the layers, while the loose coupling between modules on the same layer was implemented through the form of services. All of these equipped the platform with good ability of extension.

3.2 Overall Architecture

The technical implementation of the service platform function involved various kinds of data acquisition sensors, data transferring networks, storage databases, cloud computing services and apps for data processing, interaction with users, and many other complex factors. In order to improve the robustness of the program and make the design more reasonable, this study adopted a five-layer architecture (see Fig. 3).

Each layer has a clear job assignment as follows:

(1) Perception layer (PL): To be in charge of the perception, identification, collection and processing of residents' health data (under automatic control), and connecting data acquisition devices with network layer and application layer through communication module;
(2) Network layer (NL): To realize the function of information transmission (i.e., uploading collected data and downloading information from application layer), routing, and control. This layer is made up with core network and access network, and depend on the public telecommunication networks and the Internet;
(3) Support services layer (SSL): To set up a basic support service platform for the processing of CDM related information and operations. Specifically, it at least covers a SOA platform, an integration service platform for mass data, a cloud computing service platform, a communication service platform, and an IoT service platform;
(4) Application layer (AL): To carry and realize the various function of community health management, i.e., health risk assessing, chronic disease monitoring, health intervention and outcome evaluation;
(5) Interaction layer (IL): To provide users with a variety of interactive terminals (such as PC, mobile phones, etc.), realize the interaction of information and instructions between people and system.

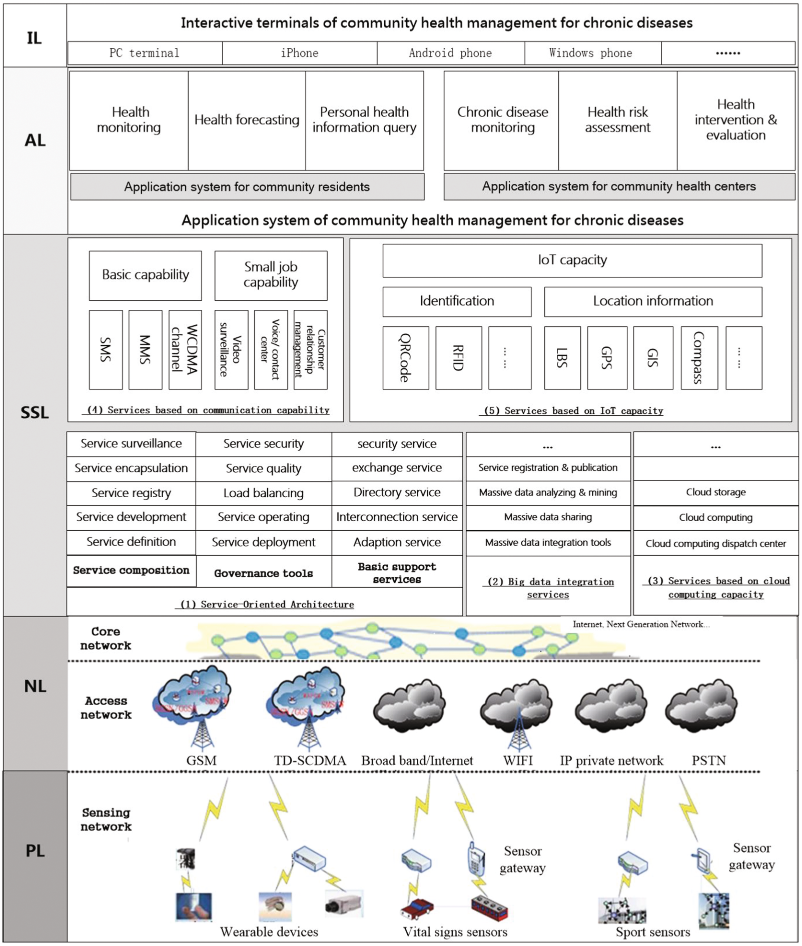

Fig. 3. Overall architecture of the mobile service platform for community health management of chronic disease

3.3 Public Service Modules

Four public service modules were designed uniformly as the system implementation process may require cloud computing, massive data, IoT, communication and other public services on many aspects.

(1) Big data integration services: According to the characteristics of massive structured data and unstructured data in the vast distributed network environment, the platform provided big data integration services based on SOA, including organization, storage, sharing, release, analysis and mining, etc.
(2) Cloud computing services: Considering ubiquitous healthcare are higher than current Internet several orders of magnitude on the amounts of data storage and operation, a cloud computing solution was needed to be integrated

into the platform design on the basis of traditional IT system, to improve the computing ability. For the community healthcare information centers, cloud computing could make full use of the great deal of idle computing and storage capacity, and provide important technical means for adaption to the flexibility of business growth and reduction of application deployment cost.

(3) Services based on IoT capacity: By accessing to a variety of IoT terminals and applications through standardized protocols and various adapter, the platform was provided with data acquisition and transmission capacity of IoT terminals, and finally realized the interaction and cooperation between machine and machine, and between machine and people.

(4) Services based on communication capacity: This module included the communication capacity required, such as SNS, WeChat, positioning, and call centers, etc. The platform may also need some other third-party services and resources.

4 Conclusion

Just as Dr. Robert M. Kaplan, who was Associate Director for Behavioral and Social Sciences in the National Institutes of Health of US at that time said in his paper: “Health-related information collected in psychological laboratories may not be representative of people’s everyday health. For at least 70 years, there has been a call for methods that sample experiences from everyday environments and circumstances” [4]. Ubiquitous healthcare not only provides us with this method, but also with the development direction of medical information construction. Under the u-Health theory and aiming at the key requirements and typical applications of CDM, this study is the first in mainland China to present a mobile service platform for the big data collection and analysis of chronic disease, on the comprehensive basis of cloud computing, intelligent sensing and perception technologies of IoT, data acquisition, storage and processing technologies, and computer decision support technology. The platform can be used in the health data acquisition, supervision and forecast for community residents, contributing to improve the community health services and lift the population health level. It is expected to help in realizing the humanistic self-health management of community residents, and providing community health centers with the ubiquitous, comprehensive prevention and control services of chronic diseases, so as to accelerate the supply-side structural health reform in the field of CDM. In consideration of the rapid progress in the international development of information technology, direction for future research would be getting the platform put into practice as soon as possible, and adjusting and improving the system in a timely manner according to the process of Chinese healthcare system reform.

Abstract. Using the sample of firms listed in China Growth Enterprise Market (GEM) from 2011 to 2015 we empirically test the effect of media coverage on the corporate internal control quality and the quality of internal control information disclosure. We found that the higher the degree of media coverage would lead to higher quality of internal control and information disclosure. The empirical results of this paper indicate that media can act as an important external supervision mechanism besides of state laws and regulations to regulate the behavior of corporate internal control, to protect the interests of investors, and to enhance investors' confidence.

Keywords: Media coverage · Internal control · Information disclosure

1 Introduction

With the development of information technology and the spread of internet, media's functions as supervision and governance are taking more and more significant roles in economy. Media, regarded as a forth power being independent of legislation, administration and judiciary, plays an essential role in disseminating information, restraining incompliant actions of government and businesses, and enhancing market's efficiency. Increasing number of scholars in economics and management have focused on studying the corporate governance role of media as well as its influence mechanism. Dyck and Zingales [8] found that the pressure from media supervision contributes drastically to reducing the personal interests of the controlling shareholders from their controlling rights. Dyck and Zingales [9] discovered that media supervision is able to effectively suppress or modify the corporate decisions that may harm external investors' interests. Miller [20] made a conclusion that through rebroadcasting investigation of information from information intermediary like securities analysts or original ones, media can disclose accounting frauds in advance. Joe et al. [15] claimed that an inefficient board would take actively measures to improve efficiency after exposed by

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_126

media. Maistriau and Bonardi [19] reported that media visibility has a positive effect on CSR performance of a sample of British firms, and Zyglidopoulos et al. [22] found that media coverage is positively associated with heightened levels of CSR performance of a sample of S&P 500 firms.

Using a large cross-country sample of firms, Ghoul et al. [10] further found strong evidence that firms engage in more CSR activities if located in countries where the media has more freedom. Dai et al. [5] investigated whether the media plays a role in corporate governance by disseminating news. Using a comprehensive data set of corporate and insider news coverage for the 2001–2012 period, they showed that the media reduces insiders' future trading profits by disseminating news on prior insiders' trades available from regulatory filings. Based on a sample of over two million newspaper articles, Kim et al. [17] found the media in China has an incremental impact on stock price efficiency, and a market-driven media can play the role of compensating for the underdeveloped governance institutions in transitional economies such as China.

Although prior studies accumulate evidence that supports the monitoring role of the media, they ignore an important issue: Can media supervision encourage firms to take precautions and initiate to improve the quality of internal controls and information disclosures? Previous literature regards media supervision as a substitute of internal controls in corporate governance, focuses on corporate inherent characteristics only when investigating determinants of corporate internal controls, and neglects the potential interaction between media's external supervision and corporate internal controls. Internal controls mean a series of restrictive organizing, planning, procedures and methods executed in entities, aiming to boost operating efficiency, acquire and use resources in an effective manner, and achieve given objectives. The setting-up, perfection and valid operation of business internal controls have direct impact on disclosures of financial information and investors' interests. Therefore, launching a research on the way media supervision influences corporate governance has theoretical and practical meanings. This article selects data of GEM firms in China's stock market from 2011 to 2015, and studies impacts of media coverage on internal controls and related information disclosures. The contributions of this paper mainly lie in the following two aspects.

Firstly, this paper enriches the literature on the corporate governance role of media. Existing studies on the corporate governance role of media mainly focus on the effect of media coverage on firms' socially beneficial behaviors such as CSR performance, or on firms' frauds and misconducts hurting the interests of the investors. This paper extends the scope of this research area by investigating the effect of media coverage on firms' internal control quality and internal control information disclosure.

Secondly, this paper also enriches the literature on the determinants of internal control quality and disclosure. Most prior studies on the determinants of internal control quality and disclosure mainly focus on corporate internal characteristics (e.g., [4,7,11]), while very few researches investigated the role of external factors, such as auditor expertise (e.g., [12,21]). In this paper, we find that media coverage, as another important external governance mechanism, also contributes significantly to the firms' internal control quality and disclosure.

2 Prior Literature and Hypotheses Development

As an important segment in corporate governance, the quality of internal controls plays a key role in business operation and development, as well as the protection of the interests of investors. Existing research indicated that good internal controls would suppress earning management [1], and reduce financing cost of firms effectively [16].

Most previous literature about the determinants of internal control quality mainly focused on corporate internal characteristics. Doyle et al. [7] examined determinants of weaknesses in internal control for 779 firms disclosing material weaknesses from August 2002 to 2005. They found that these firms tend to be smaller, younger, financially weaker, more complex, growing rapidly, or undergoing restructuring. Firms with more serious entity-wide control problems are smaller, younger and weaker financially, while firms with less severe, account-specific problems are healthy financially but have complex, diversified, and rapidly changing operations. Guo et al. [11] investigated the role of employment policies in reducing internal control ineffectiveness and financial restatements. They found that employee-friendly policies significantly reduce the propensity for employee-related material weaknesses. Moreover, they illustrated that financial restatements caused by unintentional errors are less likely to arise in firms that invest more in employee benefits. Chen et al. [4] documented a negative relation between board independence and the disclosure of internal control weaknesses. They also documented that the negative relation is stronger for firms with unitary leadership (combined positions of CEO and Chairman) than for firms with dual leadership.

Only a few studies studied the effects external factors on internal control, and these studies mainly focus on the role of audit expertise. Haislip et al. [12] argued that greater audit firm IT expertise promotes improved internal controls for their clients, especially those controls that are dependent on IT. Schroeder and Shepardson [21] found that internal control audits initially provided internal control quality benefits. However, after the 2007 auditing standards change, internal control quality deteriorated for ICFR audited versus unaudited firms.

An important external governance mechanism, media supervision, has been ignored by prior studies on the determinant of internal control quality. Most countries, particularly the transitional countries, are facing problems of imperfect legal system and inadequate protection of the investors' interests. Among the alternative governance mechanisms besides of legal system, media supervision is one of the most important. Most scholars hold an optimistic opinion towards the role of media supervision playing in corporate governance. Dyck and Zingales [8] found that media supervision could reduce the personal interests of the controlling shareholders on the sacrifice of other shareholders. Miller [20] showed that the media plays a positive role in the process of revealing accounting scandals.

Dyck and Zingales [9] further found that the media exposure could encourage enterprises to correct violations of the rights and interests of external investors. Zyglidopoulos et al. [22] found that media coverage is positively associated with heightened levels of CSR performance. Dai et al. [5] showed that media coverage can reduce insiders' future trading profits by disseminating news on prior insiders' trades available from regulatory filings.

We can conclude that existing researches have provided sufficient evidences for the corporate governance role of media supervising. Therefore, we ascertain that media coverage can urge firms to improve internal control quality, and reduce adverse actions to investors as far as possible, to avoid greater negative market response after exposed by media. At the same time, media coverage also encourages firms to build a good image in external stakeholders and enhance business values through improving internal controls. Hence, we can obtain the following hypothesis:

Hypothesis 1: Media coverage has a positive effect on the firms' quality of internal controls.

One important characteristic of internal controls is that they consist of internal managerial processes that are not directly observable for investors. Investors' judgment of the effectiveness of these internal controls is based on the information disclosed by managers.

From shareholders' perspective, higher levels of internal control disclosure reduce investors' information risk, lower down their required rate of return (e.g., [3,6]). At the same time, higher levels of disclosure enable shareholders to monitor managers more closely, resulting in fewer agency problems.

From the manager's perspective, the decision to voluntarily disclose information is based on a tradeoff between the expected benefits and costs of disclosing [14]. The main benefit of voluntarily disclosing information on the firm's internal controls is that it adds to managerial reputation building. Not having a reputation for credible reporting not only reduces the effectiveness of the manager's communication efforts, but also adversely affects her reputation in the managerial labor market [18]. Establishing a reputation for credible reporting requires disclosure of accurate and timely information as well as of information that is complete [14,20]. This means that career concerns incentivize a manager to voluntarily disclose information, even if the information is not favorable [3]. Hammersley et al. [13] find a significantly negative abnormal return following a firm's announcement that the firm's internal controls were not effective, but more importantly also document that the adverse effects on returns are more pronounced when the firm's managers claim that the internal controls are effective but the independent auditor report indicates that they were not.

An important cost of voluntarily disclosing information on the firm's internal controls is that it may have potential legal consequences. If a manager discloses inaccurate information or if a manager discloses incomplete information managers could be sued, face legal liability, and owe damages [3]. Moreover, once this matter is known to the public, it will also adversely influence the manager's reputation on the managerial labor market. To guarantee the accuracy and quality of the information disclosures on internal controls, the manager might need to pay extra efforts and related costs.

The above analysis and discussion on the benefits and costs of disclosing internal controls information implicate the importation role of the managers' reputation concerns. We can expect that the reputation mechanism will even be more important when a firm is in the spotlight of media coverage, since media can spread information to magnify the influence of signals and scope of audience, drawing more investors' attention [2]. When the media coverage is higher, the reputational benefit of disclosing high quality information of internal control will be larger, and the reputational cost of concealing information or disclosing poor information on internal controls will be greater. Therefore, higher media coverage can lead to higher quality of internal control information disclosure. We can conclude the second hypothesis as follows:

Hypothesis 2: Media coverage has a positive effect on the quality of internal control information disclosure.

3 Research Design

3.1 Data and Variables

This article selects GEM Growth Enterprise Market firms from 2011 to 2015 as initial sample, and eliminates observations with missing data on the key variables of this paper. The reason why we choose GEM firms is that these firms, which have small sizes and young ages in most cases, are opaque in information disclosure and have higher business risks in operation. In this case, the quality of internal controls and information disclosure of GEM firms are of great importance for investors to understand their business situations. Besides, this article uses balanced panel data, keeping only the firms with public financial data in each year from 2011 to 2015. The final sample of this paper includes 151 GEM firms, 755 observations in the period ranging from 2011 to 2015.

The corporate internal control quality index and its information disclosure quality index derive from the DIB Internal Control and Risk Management Database. Higher values of the two indexes represent higher qualities of the internal control and information disclosure respectively. The data of media coverage is from the News and Reports Database of WIND Info, which records the Chinese listed firms' daily news reported by more than 100 major financial newspapers and websites in China, covering nearly all the relevant news about public firms from major financial media in China. Using this database, we count the annual number of news reports for each GEM listed firm, and construct a media coverage indicator by taking the natural logarithm of one plus the number of new reports.

Referring to existing research results about determinants of internal control quality and information disclosure quality (e.g., [7]), our paper includes a set of basic financial characteristics and corporate governance variables as control variables. The basic financial characteristics variables include the firm size (natural logarithm of total assets), asset-liability ratio, return on assets, and sales growth.

The corporate governance variables include ownership concentration (the total share ratio of the top 10 major shareholders), executives' ratio of shareholding, equity separation degree (the quadratic sum of the share ratio of the top five major shareholders), and the separation of ownership and control. In addition, we also control the industry dummies. The data of these control variables is from CSMAR database. Continuous variables are censored at the 1st and 99th percentiles to mitigate the effect of extreme values. The descriptive statistics of variables are shown in Table 1.

Table 1. Descriptive statistics of variables

Na	Description	Mean	S.D.	Median	Min	Max
IC	Internal control quality index	6.833	0.405	6.891	5.165	7.524
Disclosure	Information disclosure of Internal control index	0.382	0.098	0.37	0.18	0.58
Media	Media concern extent	2.58	0.837	2.477	1.097	4.628
Size	Corporate size	20.785	0.528	20.77	19.65	22.25
LEV	Asset-liability ratio	0.171	0.123	0.142	0.028	0.619
ROA	Return on Assets	0.07	0.037	0.065	−0.003	0.164
Growth	Sales growth	0.317	0.307	0.263	−0.21	1.512
Ten	Ownership concentration	0.678	0.089	0.691	0.448	0.857
Mshare	Executives' shareholding	0.305	0.239	0.358	0	0.708
Herf_5	Equity separation degree	0.16	0.087	0.142	0.022	0.392
Separation	Separation of control and ownership	3.662	6.873	3.224	0	31.216

3.2 Empirical Modelling

Based on the preceding theoretical analysis, this paper established the following model (1) and (2) to analyze the effects of the media coverage on the qualities of internal control and information disclosure of internal control respectively:

$$\begin{aligned} IC_{i,t} = &\beta_0 + \beta_1 \text{Media}_{it} + \beta_2 \text{LEV}_{it} + \beta_3 \text{ROA}_{it} + \beta_5 \text{Growth}_{it} + \beta_6 \text{Ten}_{it} \\ &+ \beta_7 \text{Herl\_5}_{it} + \beta_8 \text{Mshare}_{i,t} + \beta_9 \text{Separation}_{i,t} \\ &+ \text{Industry and year fixed effects} + \varepsilon_{it}, \end{aligned} \tag{1}$$

$$\begin{aligned} \text{Disclosure}_{i,t} = &\beta_0 + \beta_1 \text{Media}_{it} + \beta_2 \text{LEV}_{it} + \beta_3 \text{ROA}_{it} + \beta_5 \text{Growth}_{it} \\ &+ \beta_6 \text{Ten}_{it} + \beta_7 \text{Herl\_5}_{it} + \beta_8 \text{Mshare}_{i,t} + \beta_9 \text{Separation}_{i,t} \\ &+ \text{Industry and year fixed effects} + \varepsilon_{it}, \end{aligned} \tag{2}$$

where IC represents the internal control quality index. Disclosure represents the quality of internal control information disclosure, and Media represents the extent of media coverage. The definitions and descriptions of other control variables are as shown in Table 1. Meanwhile, Industry and year fixed effects are also controlled in the above regressions. This article uses the OLS regression model, and clusters standard errors of the coefficients at firm level for more accurate statistical inference [18]. β_0 is the constant term in regression, while β_1 to β_9 represent the regression coefficients of the explanatory and control variables. We are mainly interested in the coefficient β_1, which indicates the effect of media coverage on internal control quality in model (1) or internal control disclosure in model (2).

4 Empirical Results and Analyses

4.1 Regression Results

Following the above regression models (1) and (2), this paper conducts regression analyses respectively with internal control quality (IC) and its information disclosure quality (Disclosure) as dependent variables. The regression results are shown in Table 2.

In the column 1 of Table 2, we used media coverage as the sole explanatory variable, without controlling other firm characteristic variables. The result shows that the regression coefficient of media coverage is positive and significant at 10% significance level, with a value of 0.099. This regression result indicates

		– 0.89	– 1.11		– 1.71	– 1.5
Ten			0.004			0.111
			– 0.04			– 0.96
Mshare			0.104			0.06
			– 1.14			– 0.65
Herf_5			– 0.086			0.039
			(– 0.91)			– 0.34
Separation			– 0.05			0.07
			(– 0.56)			– 0.89
constant	0.935^{***}	-0.755^{***}	0.549	1.116^{***}	-0.645^{***}	1.211^{***}
	– 18.4	(– 3.21)	– 1.39	– 23.32	(– 2.89)	– 2.71
Industry dummy	YES	YES	YES	YES	YES	YES
N	755	755	755	755	755	755
R_2	0.158	0.188	0.236	0.133	0.207	0.212

Note: ***, **, * represents significance at 1%, 5% and 10% level respectively.
The t-statistics reported in parentheses are based on standard errors clustered by firm.

that media coverage has a positive and significant effect on internal control quality. In column 2, we controlled the basic financial characteristics of the firms, including firm Size (Size), asset-liability ratio (LEV), return on assets (ROA), and the firms' sales growth (Growth). The positive regression coefficient of media coverage, with a value of 0.161, is significant at 5% level, indicating that the positive relationship between media coverage and internal control quality becomes more apparent after controlling the influences of these variables of firms' financial characteristics. In column 3, we further controlled the corporate governance characteristics, including ownership concentration (the total share ratio of the top 10 major shareholders), executives' share holding, equity separation degree, and the separation of ownership and control. The results show that after the control of the corporate governance, media coverage illustrates an even greater positive effect ($\beta_1 = 0.169$, $p < 0.1$) on the internal control quality. Thus, we can conclude that media coverage does help improve the quality of the firm's internal control, which is consistent with Hypothesis 1 above.

Column 4 to 6 use quality of internal control information disclosure as dependent variable. It could be found that whether using media coverage as an explanatory variable alone, or controlling the firm's basic financial characteristics and characteristics of corporate governance, there remains a positive effect of media coverage on the quality of internal control information disclosure. Thus, the media supervision not only helps to improve the quality of internal control of the company, but also help to improve the company's internal control information disclosure, thereby enhancing the company's transparency and self-restraint.

4.2 Robustness Test

In the above regressions, the measure of media coverage includes the news reports from the mainstream financial media channels in China, but excludes the Wind Info's own news reports. Although Wind Info is not a common source of information for retail investors, it is widely regarded by institutional investors and analysts as one of the important sources of information access. In order to test the reliability of the previous empirical results, this paper uses an alternative measure of media coverage, which includes Wind Info's own news reports, to do the robustness test. The regression results in Table 3 show that the main conclusions of the paper have not changed because of the replacement of media coverage measure. With the alternative measure of media coverage, denoted as *Media_A*, the regression results still show that media coverage has a positive effect on the quality of internal control and the quality of internal control information disclosure, and this conclusion remains the same regardless of whether we control the company's basic financial characteristics or corporate governance variables.

Table 3. The robustness test using alternative measure of media coverage

Note: ***, **, * represents significance at 1%, 5% and 10% level respectively. The t-statistics reported in parentheses are based on standard errors clustered by firm.

5 Conclusion

Based on the financial data of 151 listed companies in GEM from 2011 to 2013, this paper analyzes the impact of media coverage on the internal control quality and its information disclosure quality. The results show that media coverage positively relates to the quality of internal control and the quality of internal control information disclosure, and the conclusion is still valid after controlling corporate financial characteristics and corporate governance characteristics. This article provides new evidence for the corporate governance role of media supervision from the perspective of corporate internal control. The conclusion of this paper implicates that, under the imperfect Chinese legal system and market institutional environment, media, as an alternative form of supervision mechanism other than legal system, plays an important role in regulating the behavior of listed companies and protecting the interests of small and medium shareholders. In the current stage of China's market-oriented reform, strengthening the external supervision role of the media is of great significance to improving corporate governance of listed companies and protecting the interests of investors.

Abstract. In this paper, we propose a new fuzzy chance constrained twin support vector machine (FCC-TWSVM) via chance constrained programming formulation and fuzzy membership, which can deal data with measurement noise efficiently. This paper studies twin support vector machine classification when data points are uncertain statistically. With some properties known for the distribution, the FCC-TWSVM model is used to ensure the small probability of misclassification for the uncertain data. The FCC-TWSVM model can be transformed to second-order cone programming (SOCP) by the properties of moment information of uncertain data and the dual problem of SOCP model is introduced. In addition, we also show the performance of FCC-TWSVM model in artificial data and real data by numerical experiments.

1 Introduction

Nowadays, support vector machines (SVMs) are considered as one of the most effective learning methods for classification, which emerged from research of statistical learning theory [10,14]. The main idea of this classification technique is by mapping the data to the higher dimensional space with some kernel methods and then determining a hyperplane separating binary classes with maximal margin [9,19,26].

In recent years, SVM classification methods have made breakthrough progress and enjoyed great success in many fields. Binary data classification methods have made breakthrough progress in recent years. Mangasarian et al. [15] proposed generalized eigenvalue proximal support vector machine (GEPSVM). Jayadeva et al. [12] proposed a twin support vector machine (TWSVM) to solve the classification of binary data, motivated by GEPSVM. The main idea of TWSVM is generating two nonparallel planes, one of which is closest to one class and another plane is as far as possible from the other. At the same time, the ν-TWSVM [18] was proposed for handling outliers as an extension of TWSVM. Some extensions to the TWSVM can be founded in [8,13,20].

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_127

For the methods mentioned above, the parameters in the training sets are implicitly assumed to be known exactly. However, in real world application, the parameters have perturbations since they are estimated from the data subject to measurement and statistic errors [11]. When the data points are uncertain, different have been proposed to formulate the traditional SVM with uncertainties. Bi et al. [5] assumed the data points are subject to an additive noise which is bounded by the norm and proposed a very direct model. However, this model cannot guarantee a generally good performance on the uncertainty set. To guarantee an optimal performance when the worst case scenario constraints are still satisfied, robust optimization is utilized. Trafalis et al. [22,23,25] proposed a robust optimization model when the perturbation of the uncertain data is bounded by norm. Robust optimization [4,21] is also used when the constraint is chance constraint which is to ensure the small probability of misclassification for the uncertain data. Based on different bounding inequalities, Ben Tal et al. [1,2] employed moment information of uncertain training points to developing different chance-constrained SVM model. However, to our best knowledge, there is no researcher considering the chance-constrained optimization in TWSVM problem. Therefore, it is interesting and important to study the TWSVM with chance constraints for the uncertain data classification problem. The main purpose of this paper is to make an attempt in this direction.

Combining the capability of processing the uncertainty of chance constraints and the benefits of TWSVM, in this paper, we propose a fuzzy chance constrained twin support vector machine (FCC-TWSVM). The main method of this paper is to apply the moment information of uncertain data to transform into second order cone programming (SOCP). The rest of this paper is organized as follows. Section 2 recalls SVM and TWSVM briefly. In Sect. 3, we introduce the model of FCC-TWSVM. Experimental results on the uncertain data sets are presented in Sect. 4. Conclusions are provided in Sect. 5.

2 Preliminaries

In this section, we briefly recall some concepts of TWSVM and CC-TWSVM for binary classification problem.

2.1 TWSVM

Consider a binary classification problem of l_1 positive points and l_2 negative points ($l_1 + l_2 = l$). Suppose that data points belong to positive class are denoted by $A \in \mathbf{R}^{l_1 \times n}$, where each row $A_i \in \mathbf{R}^n$ $(i = 1, \cdots, l)$ represents a data point with label +1. Similarly, $B \in \mathbf{R}^{l_2 \times n}$ represents all the data points with the label −1. The TWSVM determines two nonparallel hyperplanes:

$$f_+(x) = w_+^T x + b_+ = 0 \quad and \quad f_-(x) = w_-^T x + b_- = 0, \tag{1}$$

where $w_+, w_- \in \mathbf{R}^n$, $b_+, b_- \in \mathbf{R}$. Here, each hyperplane is close to one of the two classes and is at least one distance from the other class points. The formulation of TWSVMis as follows:

$$\begin{aligned} \min_{w_+,b_+} \ & \tfrac{1}{2}\|Aw_+ + e_+b_+\|_2^2 + C_1 e_-^T \xi \\ \text{s.t.} \ & -(Bw_+ + e_-b_+) + \xi \geq e_-, \xi \geq 0 \end{aligned} \tag{2}$$

and

$$\begin{aligned} \min_{w_-,b_-} \ & \tfrac{1}{2}\|Bw_- + e_-b_-\|_2^2 + C_2 e_+^T \eta \\ \text{s.t.} \ & (Aw_+ + e_+b_+) + \eta \geq e_+, \eta \geq 0, \end{aligned} \tag{3}$$

where C_1, C_2 are positive numbers, e_+, e_- are vectors of ones of corresponding dimensions. The nonparallel hyperplanes Eq. (1) can be obtained by solving Eqs. (2) and (3). Then the new point is classified by following decision function

$$x^T w_r + b_r = \min_{r=+,-} \mid x^T w_r + b_r \mid . \tag{4}$$

2.2 Chance Constrained Twin Support Vector Machine

When uncertainties exists in the data points, the TWSVM model need to be modified to contain the uncertain information. Suppose there are l_1 and l_2 training data points in $\mathbf{R}^n$, use $\widetilde{A_i} = [A_{i1}, \cdots, A_{in}]$, $i = 1, \cdots, l_1$ to denote the uncertain data points and the label is positive $+1$. And let $\widetilde{B_i} = [B_{i1}, \cdots, B_{in}]$, $i = 1, \cdots, l_2$ to denote the uncertain data points and the label is negative -1 respectively. Then $\widetilde{A} = [\widetilde{A_1}, \cdots, \widetilde{A_{l_1}}]^T$ and $\widetilde{B} = [\widetilde{B_1}, \cdots, \widetilde{B_{l_2}}]^T$ represent two data sets. The chance-constrained program is to ensure the small probability of misclassification for the uncertain data. The chance-constrained TWSVM(CC-TWSVM) formulation is

$$\begin{aligned} \min_{w_+,b_+} \ & \tfrac{1}{2}\mathbb{E}\{\|\widetilde{A}w_+ + e_+b_+\|_2^2\} + C_1 \sum_{i=1}^{l_1} \xi_i \\ \text{s.t.} \ & \mathbb{P}\{-(\widetilde{B_i}w_+ + b_+) \leq 1 - \xi_i\} \leq \varepsilon \\ & \xi_i \geq 0, \quad i = 1, \cdots, l_1 \end{aligned} \tag{5}$$

and

$$\begin{aligned} \min_{w_-,b_-} \ & \tfrac{1}{2}\mathbb{E}\{\|\widetilde{B}w_- + e_-b_-\|_2^2\} + C_2 \sum_{i=1}^{l_2} \eta_i \\ \text{s.t.} \ & \mathbb{P}\{(\widetilde{A_i}w_- + b_-) \leq 1 - \eta_i\} \leq \varepsilon \\ & \eta_i \geq 0, \quad i = 1, \cdots, l_2. \end{aligned} \tag{6}$$

where $\mathbb{E}\{\cdot\}$ denote the expectation under corresponding distribution, C_1, C_2 are positive numbers, e_+, e_- are vectors of ones of corresponding dimensions, $0 < \varepsilon < 1$ is a parameter close to 0 and $\mathbb{P}\{\cdot\}$ is the probability distribution. The model ensures an upper bound on the misclassification probability.

3 Fuzzy Chance Constrained Twin Support Vector Machine

In this section, we propose a chance constrained twin support vector machine to process uncertain data points. When uncertainties exists in the data points, the TWSVM model need to be modified to contain the uncertain information. Like CC-TWSVM, suppose there are l_1 and l_2 training data points in $\mathbf{R}^n$, use $\widetilde{A_i} = [A_{i1}, \cdots, A_{in}]$, $i = 1, \cdots, l_1$ to denote the uncertain data points and the label is positive $+1$. And let $\widetilde{B_i} = [B_{i1}, \cdots, B_{in}]$, $i = 1, \cdots, l_2$ to denote the uncertain data points and the label is negative -1 respectively. Then $\widetilde{A} = [\widetilde{A_1}, \cdots, \widetilde{A_{l_1}}]^T$ and $\widetilde{B} = [\widetilde{B_1}, \cdots, \widetilde{B_{l_2}}]^T$ represent two data sets. By considering the contribution of different misclassified points, the chance-constrained program is to ensure the minimum misclassification rate for the uncertain data. The chance-constrained TWSVM(FCC-TWSVM) formulation is

$$\begin{aligned} \min_{w_+, b_+} \ & \tfrac{1}{2}\mathbb{E}\{\|\widetilde{A}w_+ + e_+b_+\|_2^2\} + C_1 \sum_{i=1}^{l_1} t_i\xi_i \\ \text{s.t.} \ & \mathbb{P}\{-(\widetilde{B_i}w_+ + b_+) \leq 1 - \xi_i\} \leq \varepsilon \\ & \xi_i \geq 0, \quad i = 1, \cdots, l_1 \end{aligned} \tag{7}$$

and

$$\begin{aligned} \min_{w_-, b_-} \ & \tfrac{1}{2}\mathbb{E}\{\|\widetilde{B}w_- + e_-b_-\|_2^2\} + C_2 \sum_{i=1}^{l_2} t_i\eta_i \\ \text{s.t.} \ & \mathbb{P}\{(\widetilde{A_i}w_- + b_-) \leq 1 - \eta_i\} \leq \varepsilon \\ & \eta_i \geq 0, \quad i = 1, \cdots, l_2. \end{aligned} \tag{8}$$

where $\mathbb{E}\{\cdot\}$ denote the expectation under corresponding distribution, C_1, C_2 are positive numbers, $t_i \in (1, 1]$ denotes the fuzzy membership of positive and negative samples, $0 < \varepsilon < 1$ is a parameter close to 0 and $\mathbb{P}\{\cdot\}$ is the probability distribution. The model ensures an upper bound on the misclassification probability, but two quadratic optimization problems (7) and (8) with chance constrained are typically non-convex, so the model is very hard to solve.

The work so far to deal with the chance constraint is to transfer them by different bounding inequalities. When the mean and covariance matrix of uncertain data points are known, then multivariate bound [3,16,17] by robust optimization can be used to express the chance constraints in special condition [4,21].

Lemma 1 [3,16]**.** *Let $X \sim (\mu, \Sigma)$ denote random vector X with mean μ and covariance matrix Σ, the multivariate Chebyshev inequality states that for any closed convex set S, the supremum of the probability that X take a value in S is*

$$\begin{aligned} \sup_{X \sim (\mu, \Sigma)} \ & \mathbb{P}\{X \in S\} = \tfrac{1}{1+d^2} \\ & d^2 = \inf_{X \in S} (X - \mu)^T \textstyle\sum^{-1} (X - \mu). \end{aligned} \tag{9}$$

Theorem 1. *Assume the first and second moment information of random variables $\widetilde{A_i}$ and $\widetilde{B_i}$ are known. Let $\mu_i^+ = \mathbb{E}[\widetilde{A_i}]$ and $\mu_i^- = \mathbb{E}[\widetilde{B_i}]$ be the mean* *vector seperately. And let* $\sum_i^+ = \mathbb{E}[(\widetilde{A_i} - \mu_i^+)^T(\widetilde{A_i} - \mu_i^+)]$ *and* $\sum_i^- = \mathbb{E}[(\widetilde{B_i} - \mu_i^-)^T(\widetilde{B_i} - \mu_i^-)]$ *be the covariance matrix of the two data set uncertain points respectively. Then the problems (7) and (8) could be reformulated respectively as:*

$$\begin{aligned} &\min_{w_+,b_+} \tfrac{1}{2} w_+^T G^+ w_+ + w_+^T {\mu^+}^T b_+ + \tfrac{1}{2} l_1 b_+^2 + C_1 \sum_{i=1}^{l_1} t_i \xi_i \\ &s.t. \ \ -(\mu_i^- w_+ + b_+) \geq 1 - \xi_i + k \| {\textstyle\sum_i^{-\frac{1}{2}}} w_+ \|, \quad \xi_i \geq 0 \end{aligned} \tag{10}$$

and

$$\begin{aligned} &\min_{w_-,b_-} \tfrac{1}{2} w_-^T G^- w_- + w_-^T \mu^{-T} b_- + \tfrac{1}{2} l_2 b_-^2 + C_2 \sum_{i=1}^{l_2} t_i \eta_i \\ &s.t. \ \ \mu_i^+ w_- + b_- \geq 1 - \eta_i + k \| {\textstyle\sum_i^{+\frac{1}{2}}} w_- \|, \quad \eta_i \geq 0, \end{aligned} \tag{11}$$

where $k = \sqrt{\frac{1-\varepsilon}{\varepsilon}}$ *and*

$$G^+ = \sum_{i=1}^{l_1} ({\mu_i^+}^T \mu_i^+ + \Sigma_i^+), \quad \mu^+ = \sum_{i=1}^{l_1} \mu_i^+$$

with

$$G^- = \sum_{i=1}^{l_2} ({\mu_i^-}^T \mu_i^- + \Sigma_i^-), \quad \mu^- = \sum_{i=1}^{l_2} \mu_i^-.$$

Proof. Now we prove that problem (7) can be reformulated to Eq. (10). In fact, it follows from Eq. (7) that

$$\begin{aligned} &\min_{w_+,b_+} \frac{1}{2} \mathbb{E}\{\|\widetilde{A} w_+ + e_+ b_+\|_2^2\} + C_1 \sum_{i=1}^{l_1} t_i \xi_i \\ &= \min_{w_+,b_+} \frac{1}{2} \mathbb{E}\{\sum_{i=1}^{l_1} (\widetilde{A_i} w_+)^2 + 2 \sum_{i=1}^{l_1} \widetilde{A_i} w_+ b_+ + l_1 b_+^2\} + C_1 \sum_{i=1}^{l_1} t_i \xi_i \\ &= \min_{w_+,b_+} \frac{1}{2} w_+^T \mathbb{E}\{\sum_{i=1}^{l_1} \widetilde{A_i}^T \widetilde{A_i}\} w_+ + \sum_{i=1}^{l_1} \mathbb{E}\{\widetilde{A_i}\} w_+ b_+ + \frac{1}{2} l_1 b_+^2 + C_1 \sum_{i=1}^{l_1} t_i \xi_i \\ &= \min_{w_+,b_+} \frac{1}{2} w_+^T \sum_{i=1}^{l_1} \mathbb{E}\{\widetilde{A_i}^T \widetilde{A_i}\} w_+ + \sum_{i=1}^{l_1} \mathbb{E}\{\widetilde{A_i}\} w_+ b_+ + \frac{1}{2} l_1 b_+^2 + C_1 \sum_{i=1}^{l_1} t_i \xi_i \\ &= \min_{w_+,b_+} \frac{1}{2} w_+^T \sum_{i=1}^{l_1} (\mathbb{E}^T\{\widetilde{A_i}\} \mathbb{E}\{\widetilde{A_i}\} + \Sigma_i^+) w_+ + \sum_{i=1}^{l_1} \mathbb{E}\{\widetilde{A_i}\} w_+ b_+ + \frac{1}{2} l_1 b_+^2 + C_1 \sum_{i=1}^{l_1} t_i \xi_i \\ &= \min_{w_+,b_+} \frac{1}{2} w_+^T \sum_{i=1}^{l_1} ({\mu_i^+}^T \mu_i^+ + \Sigma_i^+) w_+ + \sum_{i=1}^{l_1} \mu_i^+ w_+ b_+ + \frac{1}{2} l_1 b_+^2 + C_1 \sum_{i=1}^{l_1} t_i \xi_i \\ &= \min_{w_+,b_+} \frac{1}{2} w_+^T G^+ w_+ + w_+^T \mu^T b_+ + \frac{1}{2} l_1 b_+^2 + C_1 \sum_{i=1}^{l_1} t_i \xi_i, \end{aligned}$$

where

$$G^+ = \sum_{i=1}^{l_1}(\mu_i^{+^T}\mu_i^+ + \Sigma_i^+), \quad \mu^+ = \sum_{i=1}^{l_1}\mu_i^+.$$

Moreover, for the constraint of (7), we know that the set $\{-(\widetilde{B}w_+ + e_+b_+) \leq 1-\xi\}$ is a half-space produced by a hyperplane and so it is a closed convex set. Using Lemma 1, we obtain

$$\sup_{\widetilde{B}_i\sim(\mu_i^-,\Sigma_i^-)} \mathbb{P}\{-(\widetilde{B}_i w_+ + b_+) \leq 1-\xi_i\} = \tfrac{1}{1+d^2}$$
$$d^2 = \inf_{-(Xw_+ + b_+)\leq 1-\xi_i} (X-\mu_i^-)^T \Sigma_i^{+^{-1}}(X-\mu_i^-).$$

Now we claim that $-(\mu_i^+ w_+ + b_+) > 1-\xi_i$. Suppose that $-(\mu_i^+ w_+ + b_+) \leq 1-\xi_i$. Then by taking $X = \mu_i^-$, we can get $d^2 = 0$ and

$$\sup_{\widetilde{B}_i\sim(\mu_i^-,\Sigma_i^-)} \mathbb{P}\{-(\widetilde{B}_i w_+ + b_+) \leq 1-\xi_i\} = 1,$$

which is a contradiction to $0 < \varepsilon < 1$. Let

$$u_i = \Sigma_i^{-^{-\frac{1}{2}}}(X-\mu_i), \quad v_i = -\Sigma_i^{-^{\frac{1}{2}}} w_+, \quad \gamma_i = \mu_i^+ w_+ + b_+ + 1 - \xi_i.$$

Then $\gamma_i < 0$ and

$$d^2 = \inf_{v_i^T u_i \leq \gamma_i} u_i^T u_i.$$

Consider the Lagrangian

$$L(u_i,\lambda_i) = u_i^T u_i + \lambda_i(v_i^T u_i - \gamma_i), \quad \lambda_i \geq 0.$$

By taking the derivative to be zero, we have $2u_i = \lambda_i v_i$ and $v_i^T u_i = \gamma_i$. Thus,

$$\begin{aligned} d^2 &= \inf_{-(Xw_+ + b_+)\leq 1-\xi_i} (X-\mu_i^-)^T \Sigma_i^{-^{-1}}(X-\mu_i^-) \\ &= u_i^T u_i \\ &= \frac{\gamma_i^2}{v_i^T v_i} \\ &= \frac{(\mu_i^- w_+ + b_+ - 1 + \xi_i)^2}{w^{+^T}\Sigma_i^- w^+}. \end{aligned}$$

For the constraint (7), by

$$\sup_{X\sim(\mu_i^-,\Sigma_i^-)} \mathbb{P}\{-(Xw_+ + b_+) \leq 1-\xi_i\} < \varepsilon,$$

it is easy to see that $\frac{1}{1+d^2} \leq \varepsilon$ and so $d^2 \geq \frac{1-\varepsilon}{\varepsilon}$. Since $-(\mu_i^+ w_+ + b_+) - 1 + \xi_i > 0$, one has

$$-(\mu_i^- w_+ + b_+) \geq 1 - \xi_i + k\|\textstyle\sum_i^{-^{\frac{1}{2}}} w_+\|, \quad \xi_i \geq 0.$$

Similarly, we know that problem (8) can be expressed as (11). This completes the proof. □

For any non-zero vector (w_+, b_+), we have

$$\begin{aligned}
&\frac{1}{2}w_+^T G^+ w_+ + w_+^T {\mu^+}^T b_+ + \frac{1}{2} l_1 b_+^2 \\
&= (w_+, b_+)^T \begin{bmatrix} \frac{1}{2}G^+ & \frac{1}{2}{\mu^+}^T \\ \frac{1}{2}\mu^+ & \frac{1}{2}l_1 \end{bmatrix} (w_+, b_+) \\
&= \frac{1}{2}\mathbb{E}\{\|\widetilde{A}w_+ + e_+ b_+\|_2^2\} \\
&\geq 0.
\end{aligned}$$

On the other hand, it is easy to see that the constraint of problem (10) is a form of second cone.

Let

$$H^+ = \frac{1}{2}\begin{bmatrix} G^+ & {\mu^+}^T \\ \mu^+ & l_1 \end{bmatrix}. \tag{12}$$

Then the matrix H^+ is positive semi-define. To ensure the strict convexity of problem (10), we can always append a perturbation ϵI ($\epsilon > 0$, I is the identity matrix) such that the matrix $H^+ + \epsilon I$ is positive define. Without loss of generality, suppose that H^+ is positive define.

Theorem 2. *The dual problems of chance-constrained TWSVM models (10) and (11) can be formulated as the following models*

$$\begin{aligned}
&\max_{\lambda_i, \nu} \sum_{i=1}^{l_1} \lambda_i - \tfrac{1}{2}{s_i^+}^T {H_1^+}^T G^+ H_1^+ s_i^+ - \tfrac{1}{2} l_1 {s_i^+}^T {H_2^+}^T H_2^+ s_i^+ - \mu_i^+ H_1^+ s_i^+ H_2^+ s_i^+ \\
&s.t. \ -\left(\sum_{i=1}^{l_1} \lambda_i \left({\mu_i^-}^T + k{\Sigma_i^-}^{\frac{1}{2}} \nu\right), \sum_{i=1}^{l_1} \lambda_i\right) = s_i^+ \\
&\qquad 0 \leq \lambda_i \leq C_1 t_i, \quad \|\nu\| \leq 1
\end{aligned} \tag{13}$$

and

$$\begin{aligned}
&\max_{\gamma_i, \upsilon} \sum_{i=1}^{l_2} \gamma_i - \tfrac{1}{2}{s_i^-}^T {H_1^-}^T G^- H_1^- s_i^- - \tfrac{1}{2} l_2 {s_i^-}^T {H_2^-}^T H_2^- s_i^- - \mu_i^+ H_1^+ s_i^- H_2^+ s_i^- \\
&s.t. \ -\left(\sum_{i=1}^{l_2} \gamma_i \left({\mu_i^+}^T - k{\Sigma_i^+}^{\frac{1}{2}} \upsilon\right), \sum_{i=1}^{l_2} \gamma_i\right) = s_i^- \\
&\qquad 0 \leq \gamma_i \leq C_2 t_i, \quad \|\upsilon\| \leq 1,
\end{aligned} \tag{14}$$

where

$${H^+}^{-1} = [H_1^+, H_2^+], \quad {H^-}^{-1} = [H_1^-, H_2^-].$$

Proof. We only need to prove that the dual problem of Eq. (10) can be formulated as Eq. (13). The Lagrangian is given by

$$\begin{aligned}
L(w_+, b_+, \xi, \lambda, \beta) =& \frac{1}{2}w_+^T G^+ w_+ + w_+^T {\mu^+}^T b_+ + \frac{1}{2}l_1 b_+^2 + C_1 \sum_{i=1}^{l_1} t_i \xi_i \\
&- \sum_{i=1}^{l_1} \lambda_i \left(-(\mu_i^- w_+ + b_+) - 1 + \xi_i - k\|{\Sigma_i^-}^{\frac{1}{2}} w_+\|\right) - \sum_{i=1}^{l_1} \beta_i \xi_i,
\end{aligned} \tag{15}$$

where $\lambda_i, \beta_i \geq 0$.

Recall that for any $x \in \mathbf{R}^n$, we have the relationship $\|x\| = \max_{\|y\| \leq 1} x^T y$. Then the equivalent model of Eq. (15) are given as follows:

$$L_1(w_+, b_+, \xi, \lambda, \beta, \nu) = \frac{1}{2} w_+^T G^+ w_+ + w_+^T {\mu^+}^T b_+ + \frac{1}{2} l_1 b_+^2 + C_1 \sum_{i=1}^{l_1} t_i \xi_i \\ - \sum_{i=1}^{l_1} \lambda_i \left(-(\mu_i^- w_+ + b_+) - 1 + \xi_i - k(\Sigma_i^{-\frac{1}{2}} w_+)^T \nu \right) - \sum_{i=1}^{l_1} \beta_i \xi_i, \tag{16}$$

where $\lambda_i,\ \beta_i \geq 0$, $\|\nu\| \leq 1$. The Lagrangian L_1 has the same optimal value as L when maximized with respect to ν's subject to the constraint $\|\nu\| \leq 1$. Therefore,

$$L(w_+, b_+, \xi, \lambda, \beta) = \max_{\|\nu\| \leq 1} L_1(w_+, b_+, \xi, \lambda, \beta, \nu).$$

Similar to the discussion of Sect. 5 of [6], we know that solving Eq. (10) is equivalent to finding the saddle-point of the Lagrangian L_1. This fact combining the convexity implies

$$\begin{aligned} &\min_{w_+, b_+, \xi} \max_{\lambda_i, \beta_i} L(w_+, b_+, \xi, \lambda, \beta) \\ = &\min_{w_+, b_+, \xi} \max_{\lambda_i, \beta_i, \|\nu\| \leq 1} L_1(w_+, b_+, \xi, \lambda, \beta, \nu) \\ = &\max_{\lambda_i, \beta_i, \|\nu\| \leq 1} \min_{w_+, b_+, \xi} L_1(w_+, b_+, \xi, \lambda, \beta, \nu). \end{aligned} \tag{17}$$

By eliminating the primal variables in Eq. (17), we can obtain the dual problem. Taking partial derivatives of L_1 with respect to $w_+, b_+,$ and ξ, respectively, one has

$$\begin{cases} \frac{\partial L_1(w_+, b_+, \xi, \lambda, \beta)}{\partial w_+} = G^+ w_+ + {\mu^+}^T b_+ + \sum_{i=1}^{l_1} \lambda_i {\mu_i^-}^T + k \sum_{i=1}^{l_1} \lambda_i \Sigma_i^{-\frac{1}{2}} \nu, \\ \frac{\partial L_1(w_+, b_+, \xi, \lambda, \beta)}{\partial b_+} = w_+^T {\mu^+}^T + l_1 b_+ + \sum_{i=1}^{l_1} \lambda_i, \\ \frac{\partial L_1(w_+, b_+, \xi, \lambda, \beta)}{\partial \xi_i} = C_1 t_i - \lambda_i - \beta_i. \end{cases} \tag{18}$$

By equating the equations in Eq. (18) to zero, we can obtain following formulations

$$\begin{cases} G^+ w_+ + {\mu^+}^T b_+ + \sum_{i=1}^{l_1} \lambda_i {\mu_i^-}^T + k \sum_{i=1}^{l_1} \lambda_i \Sigma_i^{-\frac{1}{2}} \nu = 0, \\ w_+^T {\mu^+}^T + l_1 b_+ + \sum_{i=1}^{l_1} \lambda_i = 0, \\ C_1 t_i - \lambda_i - \beta_i = 0. \end{cases} \tag{19}$$

Thus, by solving Eq. (19) and considering (12), we can infer that

$$H^+[w_+, b_+] = -\left(\sum_{i=1}^{l_1} \lambda_i \left({\mu_i^-}^T + k \Sigma_i^{-\frac{1}{2}} \nu \right), \sum_{i=1}^{l_1} \lambda_i \right) = s_i^+. \tag{20}$$

Since H^+ is positive define, it is easy to see the solution of Eq. (20) can be obtained as

$$\begin{cases} w_+ = -H_1^+\left(\sum_{i=1}^{l_1}\lambda_i\left(\mu_i^{-^T} + k\Sigma_i^{-\frac{1}{2}}\nu\right), \sum_{i=1}^{l_1}\lambda_i\right) = H_1^+ s_i^+, \\ b_+ = -H_2^+\left(\sum_{i=1}^{l_1}\lambda_i\left(\mu_i^{-^T} + k\Sigma_i^{-\frac{1}{2}}\nu\right), \sum_{i=1}^{l_1}\lambda_i\right) = H_2^+ s_i^+, \end{cases} \tag{21}$$

where $H^{+^{-1}} = [H_1^+, H_2^+]$.

According to Eqs. (16), (19) and (21), we can obtain the dual problem of Eq. (10) as follows

$$\begin{aligned} &\min_{\lambda_i, u} \sum_{i=1}^{l_1}\lambda_i - \tfrac{1}{2}s_i^{+^T} H_1^{+^T} G^+ H_1^+ s_i^+ - \tfrac{1}{2} l_1 s_i^{+^T} H_2^{+^T} H_2^+ s_i^+ - \mu_i^+ H_1^+ s_i^+ H_2^+ s_i^+ \\ &\text{s.t.} -\left(\sum_{i=1}^{l_1}\lambda_i\left(\mu_i^{-^T} + k\Sigma_i^{-\frac{1}{2}}\nu\right), \sum_{i=1}^{l_1}\lambda_i\right) = s_i^+ \\ &\qquad 0 \le \lambda_i \le C_1 t_i, \quad \|\nu\| \le 1. \end{aligned}$$

Similarly, we know that the dual problem of Eq. (11) can be expressed as Eq. (14). This completes the proof. □

4 Numerical Experiments

In this section, our FCC-TWSVM model is illustrated by numerical test based on two types of data sets. The first test is implemented to certify the performance of our FCC-TWSVM by artificial data. And in second test, we also test the performance of FCC-TWSVM model on real-word classifying data sets from UCI Machine Learning Repository. All results were averaged on 10 train-test experiments and carried out by Matlab R2012a with 2.5GHz CPU, 2.5G usable RAM. The SeDuMi [1] software is employed to solve the SOCP problems of FCC-TWSVM.

4.1 Fuzzy Membership Function

The design of fuzzy membership function is the key to the fuzzy algorithm using fuzzy technology. In this paper, we use class center method to generate fuzzy membership. Firstly, we denote the mean of class +1 as class-center x_+ and the mean of class -1 as class center x_-, respectively. The radius of each class r+ and r- are the farthest distance between the each class training points and its class-center, respectively, namely $r_+ = \max_{x_i, y_i = 1} \|x_i - x_+\|$ and $r_- = \max_{x_i, y_i = -1} \|x_i - x_-\|$. Fuzzy membership t_i is a function of the mean and radius of each class

$$t_i = \begin{cases} 1 - \frac{\|x_i - x_+\|}{r_+ + \sigma} & \text{if } \ y_i = 1 \\ 1 - \frac{\|x_i - x_-\|}{r_- + \sigma} & \text{if } \ y_i = -1, \end{cases}$$

where $\sigma > 0$ is used to avoid the case $t_i = 0$.

(a) ε = 0.1 (b) ε = 0.01

Fig. 1. The performance of FCC-TWSVM in the first data set.

4.2 Artificial Data

To give an intuitive performance of FCC-TWSVM, we construct uncertain sets of 2-dimension data generated randomly from two normal distribution. The contribution of binary classes of the first data is

$$\mu^+ = \begin{bmatrix} 0 \\ 2 \end{bmatrix}, \quad \Sigma^+ = \begin{bmatrix} 1 & 0 \\ 0 & 4 \end{bmatrix}, \quad \mu^- = \begin{bmatrix} -1 \\ 0 \end{bmatrix}, \quad \Sigma^- = \begin{bmatrix} 7 & 0 \\ 0 & 3 \end{bmatrix}.$$

Figures 1 shows that the performance of FCC-TWSVM to two uncertain data set points. In numerical experiments, different data points are generated by respective distribution. In each data set, +1 class is generated by normal distribution (μ^+, Σ^+) and -1 class is generated by normal distribution (μ^-, Σ^-). Each class has 50 points, and 20 points are randomly picked as the training points, the other points are the test points. In Fig. 1, the blue stars are the points of +1 class, while -1 class with the red circles. The blue and red lines are the separating hyperplane (2-D) that we look for. In fact, the value of parameter ε also affects the determination of two hyperplanes. Figure 1(a) and (b) perform the effect of various parameters.

4.3 Application

China's VC [7] market is now in a substantial expansion of scale, while of the decline in return. The industry system is between preliminary cooperation and in-depth cooperation. The former is reflected in the VC firms, and the latter is reflected in the investment groups.

We call such structure a community which is closely related to each other and has far more links than other nodes in social network analysis method. From the sociology level, a community is a social network with strong relationships. The preference-dependent phenomenon in random network model has been widely accepted, but the condition of new VC firm's attachment is still unknown.

The formation of communities is determined by the attributes of VC firms. We select five basic attributes: capital scale, registration place, institution type, number of investments, age. Capital scale stands for the strength of VC firms. More capital controlled means stronger bargain power, which means the cooperative VC firms could make the advantage position in the equity pricing. If capital scale plays an important role in the decision tree, it means that big capital trends to cooperate with big capital as well as small capital, where there is a polarization. Registration place can be deemed to be the place where the headquarters or the institution with high administrative authority is, at least. It shows one of the most active areas in social and economic activities. Institution type indicates the main business type of VC firms. In addition to VC, PE, there are PIPE, strategic investment, angel investment, broker direct investment, which are classified as other categories. The number of investments represents the active level of VC firms. Although there is a certain correlation between capital scale, age, and the number of investments, taking these three indicators into consideration simultaneously could reduce the impact of relevance, to a certain extent.

In practice, the distribution properties are often unknown but need to be estimated from data. For example, if an uncertain data point $\widetilde{x_i} = [\widetilde{x_{i_1}}, \cdots, \widetilde{x_{i_n}}]^T$ has N samples x_{i_k}, $k = 1, \cdots, N$, then the sample mean $\overline{x_i} = \frac{1}{N}\sum_{i=1}^{N} x_{i_k}$ is used to estimate the mean vector $\mu_i = \mathbb{E}[\widetilde{x_i}]$, and the sample covariance

$$S_i = \frac{1}{N-1}\sum_{i=1}^{N}(x_{i_k} - \overline{x_i})(x_{i_k} - \overline{x_i})^T$$

is used to estimate the covariance matrix

$$\Sigma_i = \mathbb{E}[(\widetilde{x_i} - \mu_i)(\widetilde{x_i} - \mu_i)^T].$$

However, these could cause possible estimation errors. Some special cases were proposed when the mean vector μ_i and covariance matrix Σ_i may not exactly known. Panos M. Pardalos et al. [24] has discussed the way to processing these special cases. In our practical experiments, similar to Pardalos, we employ mentioned methods to modify the estimation and make the result easier to interpret.

Since the data sets are uncertain, the performance measures are worth discussed. Ben-Tal et al. [2] proposed using nominal error and optimal error to evaluate the performance. In our experiment, we choose these index to calculate the accuracy of our model.

The expression for NomErr is

$$\text{NomErr} = \frac{\sum_i \mathbf{1}_{y_i^{pre} \neq y_i}}{\text{the amount of training data}} \times 100\%.$$

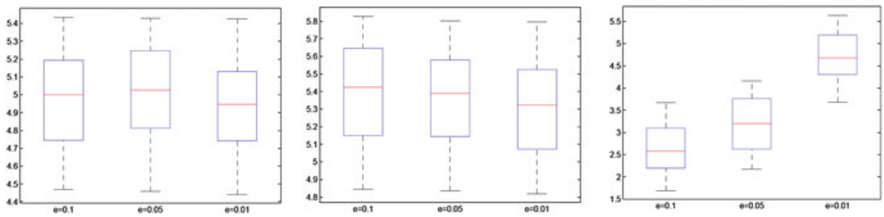
The optimal error is based on the probability of misclassification. The chance constraints in the model (7), (8) can be reformulated to Eqs. (10) and (11), then we can derive the least value of ε called ε_{opt}. Then the OptErr of data point x_i is

$$\text{OptErr} = \begin{cases} 1 & \text{if } \; y_i^{\text{pre}} \neq y_i \\ \varepsilon_{opt} & \text{if } \; y_i^{\text{pre}} = y_i. \end{cases}$$

And the OptErr of whole test set is

$$\text{OptErr} = \frac{\sum_i \text{OptErr}_i}{\text{the amount of training data}} \times 100\%.$$

We tested the from Qingke data set. Now each test data point x_i has 50 replicates x_{i_k}. The class label y_i^{pre} is decided by the majority label of the replicates based on Eq. 4. For the OptErr, the sample mean and sample covariance ε_{opt}. The real data sets have too many of the features to test the performance of FCC-TWSVM model. The results over 10 times experiments are shown in Fig. 2



(a) NomErr (b) OptErr (c) Training time

Fig. 2. The performance of FCC-TWSVM in the VC data set

The average results for VC data set and Ionosphere set are shown in Fig. 2. The boxplots of the results for two different sets show that the misclassification rate decreases when ε reduces. In addition, the OptErr is always bigger than NomErr. The experiment time is stable for different parameters ε. We can draw a conclusion that regional disparity is the biggest factor in the difference of community. There is a high information asymmetry between enterprises and VC firms, and the latter usually give more attention to local projects.

5 Conclusions

A new chance constrained twin support vector machine (FCC-TWSVM) via chance constrained programming formulation for classification was proposed, which can deal data with measurement noise efficiently. This paper studied twin support vector machine classification when data points are uncertain statistically. With some properties known for the distribution, the FCC-TWSVM model was used to ensure the small probability of misclassification for the uncertain data. The FCC-TWSVM model could be transformed to second-order cone programming (SOCP) by the properties of moment information of uncertain data and the dual problem of SOCP model was also introduced. Then we obtained the twin hyperplanes by calculating the dual problem. In addition, we also showed the performance of FCC-TWSVM model in artificial data and real data by numerical experiments. In the future work, how to further make the model more robust is under our consideration. In addition, dealing the situation of nonlinear classification with chance constrained is also interesting.

A Projection Pursuit Combined Method for PPP Risk Evaluation

Xinli Zhang(✉), Tianjin Wang, and Sihan Li

Business School, Sichuan University, Chengdu 610064, People's Republic of China
zhangxinli1231@163.com

Abstract. Risk assessment is very crucial to the building and operation of PPP (Public-Private-Partnership) project in its long-term cooperation during the long life circle. Based on the risk factors and their influences, the traditional risk assessment method of PPP project is achieved by the experts experience, Therefore, the evaluation result is subjective. Under the background of Big Data, the study proposed a projection pursuit combined method to model the PPP risk, which was called projection pursuit risk assessing model. Firstly, we use Monte Carlo simulation to get the data of the risks factors and their influence. Secondly, establish a multivariate regression function with projection pursuit method to research the relationship between the multivariable risk factors and the increment of internal return rate of PPP project. Thirdly, we offer the project risk level through the analysis of the regression results. The application in the specific project of this new method shows that the new model can accurately estimate the risk level of PPP project, and explain the trend of project risk.

Keywords: PPP (Public-Private-Partnership) · Risk assessment · Projection pursuit regression · Monte Carlo simulation

1 Introduction

In recent years, PPP (Private-Public-Partnership) pattern has been introduced to China as a new mode, aiming at attracting foreign capital to participate in infrastructure construction projects to make up for the financial lack of public sectors as well as improving the operational efficiency. Thus the mode is widely regarded as a new infrastructure project financing tool.

However, due to the long cooperation process, the wide investment scale, and the large number of participants, PPP projects have more potential and complex risk factors during the whole life cycle compared with average engineering project. Especially, risk assessment is a crucial link in the risk management process. However, currently few domestic cases have involved the implementation of the PPP project, thus the PPP risk assessment mostly depends on the expert's subjective judgment, such as the fuzzy mathematical evaluation method and decision tree method often used in related research and field [3].

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_128

In recent research, s the methods for PPP assessment are mainly quantitative assessment methods. For example, fuzzy-AHP-based risk assessment and fuzzy synthetic evaluation approach to PPP projects were established to assess risk factors in the PPP expressway project in China [8]. Another research identify the risk factors in PPP projects through a comprehensive literature review, and then introduce fuzzy logic in the pairwise comparison [12]. A few studies deal with uncertainty by presenting several estimates based on different values for the exogenous inputs using sensitivity analysis. Sensitivity analysis is a typical way to address uncertainty via variations in key inputs. It hence provides an insight into what happens if some variables values differ from the basic case [7].

As research shows, system dynamics (SD) modelling aims at developing a dynamic model to assess demand risk by evaluating how different variables jointly affect demand for services provided by PPP infrastructure projects. The research objectives thus involve identifying, understanding, mapping and measuring these variables and their complex interrelations [1].

FSE is a branch of fuzzy set theory (FST), a number of researchers have attempted to exploit FSE in the construction project risk management field. Yeung et al. present a model to assess the level of risk of PPP toll road projects in which experience knowledge based on linguistic variables were incorporated into the analysis using FSE [2].

In summary, the current PPP project risk assessment has a series of complex problems, for example, the original project data involves various risk factors which share no obvious function relationship between these factors. It is difficult to precisely describe the PPP risks with accurate mathematical model since most risk assessment methods are limited to subjective factors. The risk assessment is a high-dimensional problem, which the current assessing method is unable to solve. Thus the good risk management needs to establish a risk estimation model which can convert high-dimensional problem into low-dimensional problem.

Considering the deficiencies of existing evaluation methods, we present the projection pursuit regression method (PPR) based on the data analysis as an exploring method of risk assessment. The method can convert the high-dimensional risk variables into low-dimensional projection variables, meanwhile building up the relationship between the projection variables and the economic evaluation index variables [13].

The realization of the new method is further elaborated in four parts. Section 2 introduces a PPP risk assessment method with PPR; Sect. 3 offers the building and parameter optimization process of the new PPP risk assessing model, followed by a case study applying the model into assessing the risks of an ecological landscape PPP project in Sect. 4. We present our conclusions in Sect. 5.

2 Projection Pursuit Risk Assessing Method

2.1 Traditional PPP Risk Assessment Procedure

Among the existing PPP risks assessing methods, the fuzzy synthetic evaluation (FSE) method is the most prevalent, which is capable of effectively dealing with the imprecise non-numerical (linguistic) terms and accounting for the fuzziness in expert knowledge that typifies risk assessment [11]. As Fig. 1 shows, the hierarchical analysis approach utilized for assessing the risk level of principal risk factors.

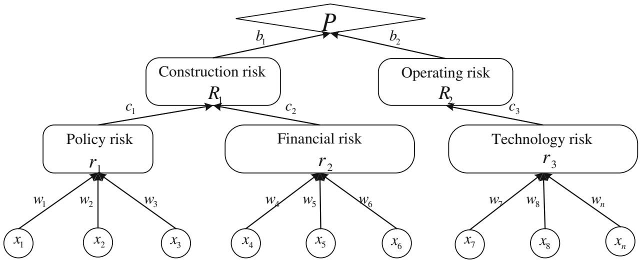

Fig. 1. FSE assessing procedure

where x_i represents the ith risk factor of the risk factor layer $(i = 1, 2 \cdots, n)$, r_i represents the sub factor layer, r_1, r_2, r_3 respectively represents the second-class risk factor layer, R_1,R_2 respectively represents the first-class risk factor layer. P represents the comprehensive risk membership of the project. w_i $(i = 1, 2, \cdots, n)$ respectively represents the i^{th} risk factor's weight in the second-class risk factor layer. c_1,c_2,c_3 respectively represents the second-class risk factor's weight in the first-class factor layer. b_1, b_2 respectively represents the first-class factor's weight in the comprehensive risk membership of the project. The relationships among these parameters can be presented as

$$X = \{x_1, x_2, x_3, \cdots, x_n\}, \tag{1}$$
$$R' = \{r_1, r_2, r_3\}, \tag{2}$$
$$R = \{R_1, R_2\}, \tag{3}$$
$$C = \{c_1, c_2, c_3\}, \tag{4}$$
$$B = \{b_1, b_2\}, \tag{5}$$
$$W = \{w_1, w_2, \cdots, w_n\}. \tag{6}$$

And then,

$$R' = W \times X, \tag{7}$$
$$R = R' \times C, \tag{8}$$
$$P = R \times B. \tag{9}$$

After several transformations of matrices, we get the value of the evaluation index. Though the FSE method has been widely used in the risk assessing field, it still has its limitations:

(1) The mechanism of how a risk factors exerts impact on the project objectives is unclear, so the actual process might be fuzzier.

(2) The interaction of various risk factors is ignored.
(3) Difficulty in accurately determining the membership.

Thus we need to discover a new method to optimize the traditional PPP assessing methodology.

2.2 Projection Pursuit Regression

Based on the analysis above, we need to find a method which can not only simplify the PPP risk assessment process compared with the traditional risk assessment process, but also improve the accuracy of risk assessment, to fulfill the purpose of redressing the defects of subjective evaluation. Thus the projection pursuit regression is introduced.

The projection pursuit regression is based on a regression method derived from projection pursuit thought [10]. Compared with the traditional methods focusing on exploring the relationship between the independent and dependent variables, this method projects multidimensional independent variables and determines the projection variables after obtaining a low dimensional projection of variables. The projection can reduce the number of variables which are used to establish the regression model, meanwhile transform the regression relationship between multiple variables and single variables into one solely between the single variables.

As for the PPP project risk assessment, it can be considered as a multi-input and single-output variable prediction problem. The ideology is, under different risk situations, we have data of set of risk values of 1 groups X_k $(k = 1, 2, \cdots, l)$ and these corresponding economic evaluation results(Y_k), then we can set up the relation between X_k and Y_k. Since X_k is a high-dimensional set of variables, we need to project these variables to low-dimensional space and find proper projecting directions z_j $(j = 1, 2, \cdots, m)$. After each projection, we'll get its corresponding residual value $\Delta y_j (\Delta y_j = y_{j'} - y_j$ where y_i is the actual value $y_{j'}$ is the fitting value) until the residual sum of squares meet certain accuracy requirement, then the parameter $j(j = 1, 2, \cdots, m)$ is optimal number of projection direction. And by minimizing a projection, finding out the projection can reflect the structural characteristics of high-dimensional data. The projection values of each direction are fitting by one-dimensional function. Then the regression function is approximated by one-dimensional fitting function [4]. The procedure of the projection pursuit method of risk assessment is shown in Fig. 2. The non-parametric regression $f(x)$ can be summed up as:

$$Y = \sum_{j=1}^{m} g_{(j)}(\sum_{i=1}^{n} \alpha_{ji}^T X), \tag{10}$$

$$\sum_{i=1}^{n} \alpha_{ji}^2 = 1, \tag{11}$$

where, X is n-dimensional independent variable x_i, Y is the response variable, g_j represents the j^{th} smooth ridge function. m is the number of approximation function, a_{ji} is the i^{th} component projection direction of the j^{th} smooth ridge function. The obtaining of big data needed in the function and algorithm of the calculation of PPR will be presented in Sect. 3.

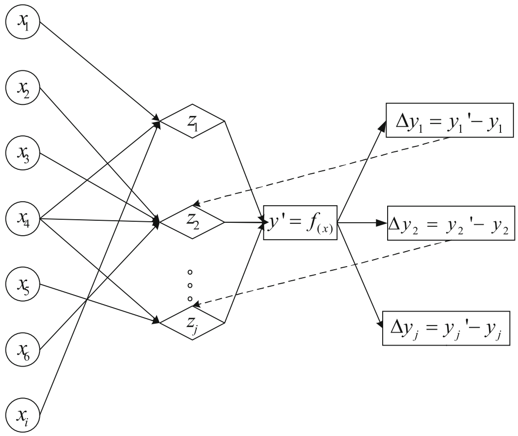

Fig. 2. The procedure of the projection pursuit method of risk assessment

3 PPP Risk Assessing Model Process and Its Parameter Optimization

3.1 The PPP Risk Assessing Model

Based on the analysis of the previous chapter, we are able to establish the relationship between the independent variable (risk variables) and the dependent variable (economic evaluation index) by the projection pursuit regression method. For every PPP project, multiple groups of risk values are not readily available to obtain. Instead they call for establishing and calculating after a large amount of data conversion and multiple model procedures. After that, the projection pursuit regression models can be summed up by Fig. 3 whose left column refers to the methods used to obtain the data, the middle column representing the specific form of the relevant data in the model, and the right column indicating the main mathematical model in the processes of data input and output.

In Fig. 3, I_k^i $(i = 1, 2 \cdots, n, \quad k = 1, 2 \cdots, s)$ represent the i^{th} risk's impact value according to s groups of historical data. $\sigma_{(I_i)}$, $\mu_{(I_i)}$ refer to the standard deviation and the mean value of the calculated values of the I_k^i. D_i represents the distribution of the i^{th} risk, I_k^i, $\mathrm{EEI}_{k'}$ respectively represents the $k'^{th}(k' = 1, 2 \cdots, l)$. Group of data of the project risk value and project economic evaluation index. α_j $(j = 1, 2, \cdots, m)$ represents the parameter in the j^{th} projection direction, $RE_{k'}$ $(k' = 1, 2 \cdots, l)$ refers to residual error. We can divide the model construction procedure into four specific steps as follows:

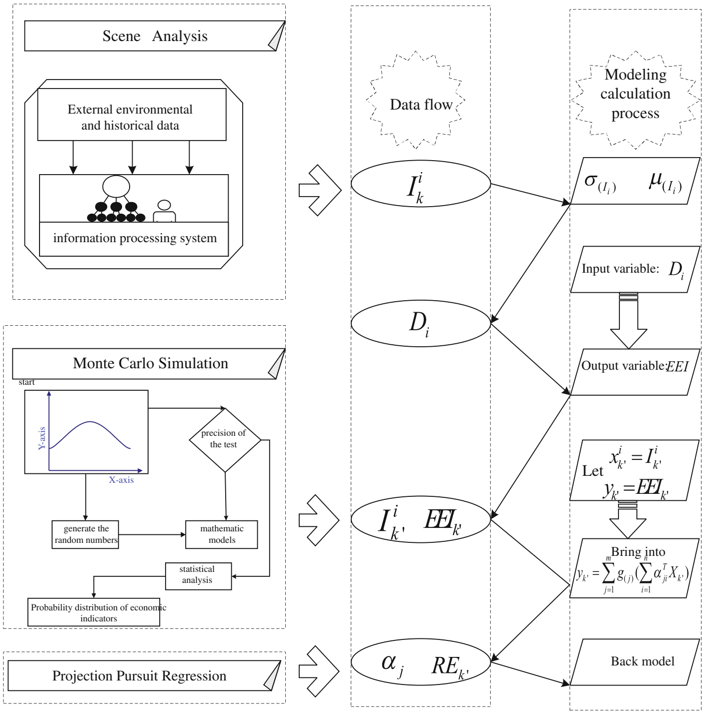

Fig. 3. The PPR risk assessing model for PPP project

Step 1. Determine the independent variables of the statistics, and fit distributions From historical data, we can obtain numerous data of different risk's impact value I_k^i of different tasks. After calculation, we can get the average value μ_i and standard deviation σ_i of the i^{th} risk's statistic value. Meanwhile, combining with experts' judgement, we can get the distributions of various risks.

$$\mu_i = \frac{\sum_{j=1}^{s} p_k^i I_k^i}{s}, \tag{12}$$

$$\sigma_i = \sqrt{\sum_{k=1}^{s} (p_k^i - \mu_i)^2 \times I_k^i}. \tag{13}$$

Step 2. Extract random number through Monte Carlo simulation and get the sample observation value.

We establish the project's economic evaluation model, and set the known variable as constant parameters variable of fixed value model. We set I_i as input random variable, which is followed by selecting economic evaluation index (EEI) according to the demand of project economic evaluation and setting it as an output variable. In order to obtain more groups of sample data, we extract random number through Monte Carlo Simulation and transform the probability distribution of random number as sampling values of input variables while repeating the experiment to meet a certain level of accuracy. At this time, we set the simulation iteration number is set as l, then we get l groups of input variables I_k^i and output variables $EEI_{k'}$ of the sample data. Now we let $x_{k'}^i = I_{k'}^i, y_{k'} = EEI_{k'}$, and establish a functional relationship between $y_{k'}$ and $x_{k'}^i$.

Step 3. Take the sample data to the projection pursuit regression model

$$y_{k'} = \sum_{j=1}^{m} g_{(j)} \left(\sum_{i=1}^{n} \alpha_{ji}^T X_{k'} \right), \tag{14}$$

$$X_{k'} = \left\{ x_{k'}^1, x_{k'}^2, \cdots, x_{k'}^i \right\} (k' = 1, 2, \cdots, l) \tag{15}$$

We send l groups of data to the PPR model, where $X_{k'}$ represents the k'^{th} set of the input variable $x_{k'}^i$ $(i = 1, 2, \cdots, n)$, $y_{k'}$ is the corresponding output variable. Other parameters mentioned in the Eq. (15) can refer to Sect. 2. Meanwhile, There are many forms to fit a variety of cell functions, such as the numerical function [13] and the polynomial function [11], a number of numerical functions, etc.

Step 4. Output the results

After the algorithm realization process, we get α_j and $RE_{k'}$ of the regression model. Generally, the smaller the $RE_{k'}$, the better the fitting effect. Then according to the distribution of *EEI*, we can arrive at some conclusions about the project's risk rank.

3.2 The Algorithm Realization Process

Since the numerical function involves an enormous numerical tables, it is not convenient to predict during the interpolation and extension [5]. Thus the paper uses multinomial to fit the unit function.

Take l groups of risk variables as input variables, and select economic evaluation index as output variables brought into Eq. (14) to determine the optimal output variables. Then optimize the number of unit functions and its corresponding projection direction parameters. In the model, the genetic algorithm is adopted to optimize the parameters as follows:

(1) Generate m projection directions randomly in the range of $[-1, 1]$, which is followed by selection, crossover and mutation of genetic algorithm to generate $3 \times n$ new projection directions [14].

(2) Respectively project m construction parameters of l sample projection on the projection direction, obtaining l projection variables for each projection direction.

(3) The polynomial is used to fit the corresponding relation between projection variables and the internal rate of return, resulting in $3 \times n$ fitting polynomials, then we can evaluate each fitting results according to the correlation coefficient d calculated through Eq. (16).

$$d = 1 - \sqrt{\frac{\sum (y' - \overline{y})^2}{\sum (y - \overline{y})^2}} (0 \leq d \leq 1). \tag{16}$$

In the Eq. (16), represents the actual value of the economical evaluation index. y' is the corresponding fitting value, and $\overline{y}$ stands for the average value of actual internal rate of return.

(4) In the $3 \times n$ projection direction, the coefficient d is calculated, and n projection directions with superior deterministic coefficient are chosen to enter the optimization process in the next round of genetic algorithm.

(5) After several times of optimization, when the deterministic coefficient's absolute value of difference between two calculations from start to finish come out less than some arbitrary positive number, the optimization of first unit function finishes.

(6) Output polynomial and its corresponding projection direction m, which lead to calculate the relative error between the fitting value and the actual value. According to the risk assessment, if the relative error is less than 10%, the model parameters are determined [6]. Otherwise, it is indicated that an arbitrary unit function can not meet the fitting requirements, and we should move to the next step.

(7) In the this step, we follow the same principle, which infers that the residual $\Delta y(y - y')$ completed in the fitting of the first step is to replace y to repeat the first step's work. We start the optimization aimed at second element function, until we have obtained fitting unit function and projection direction requirements which meet the requirements [9].

4 Case Study

4.1 Data Origin

The PPP risk assessment model based on projection pursuit regression method was validated through a case study, an ecological landscape PPP project case from Sichuan province. In this case, we identified 10 risk factors basing on the historical data, which respectively refers to cost overruns risk, construction duration extended risk, design risk, construction safety risk, operation risk, quality risk, policy changing risk, force majeure risk, tax increasing risk, and laws risk. In the PPP risk assessing model, we select (the impact value of the i^{th} risk) as independent variable, meanwhile ΔIRR as dependent variable, which can represent the increment of the internal rate of return, thus reflecting the economic viability of the project.

4.2 Input and Output Variables

We define xi as input variable, y as output variable. The distributions of each risk's impact value above can be seen in the Figs. 4 and 5, which are determined by numerous historical data Then we send the input variables and output variables into the Monte Carlo simulation model, resulting in 461 groups of sample data. The input and output variables' distributions are respectively shown in Figs. 4, 5 and 6.

4.3 Forcasting Results

With the 461 groups of sample data simulated above (436 groups are used for fitting, and 30 groups are used for testing), we can build up PPR. After experiencing algorithm realization process, the model's parameters are achieved. We can get two figures reflecting the fitting results. Figures 7 and 8 respectively shows the comparing results between the actual values and simulation values, the comparing results between the actual values and tested values, Figs. 9 and 10 respectively shows the percentage of residual error of the simulation variables and tested variables.

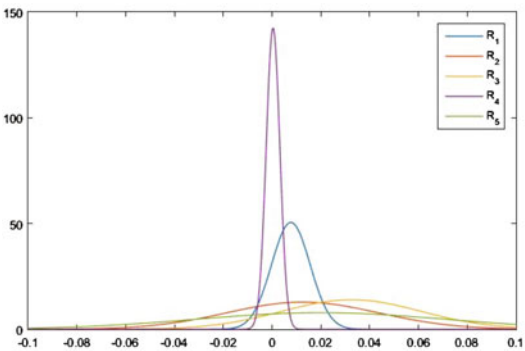

Fig. 4. The distribution of the first five risks

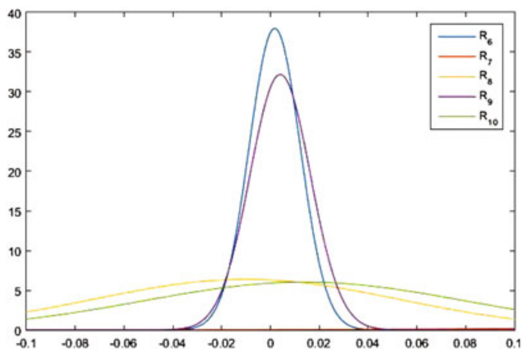

Fig. 5. The distribution of the post five risks

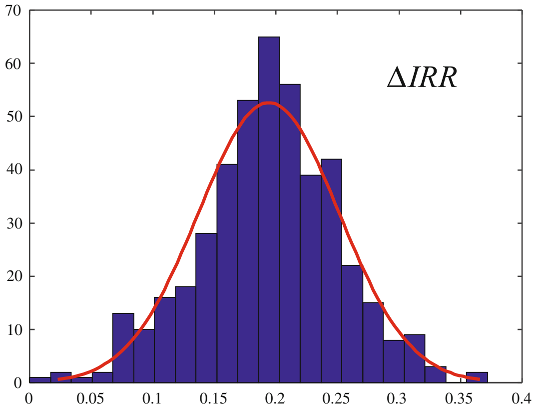

Fig. 6. The distribution of ΔIRR

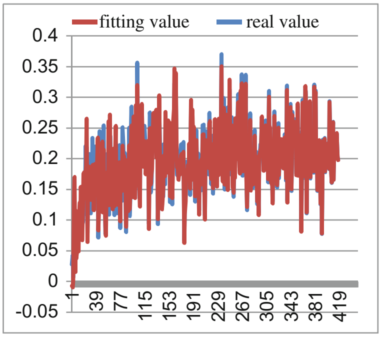

Fig. 7. The comparing results between the actual values and fitting values

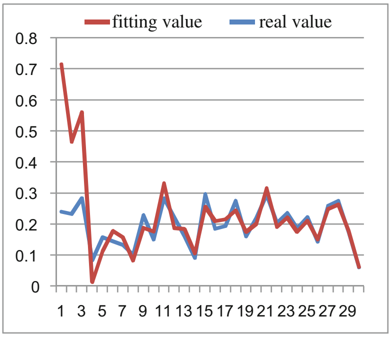

Fig. 8. The comparing results between the actual values and tested values

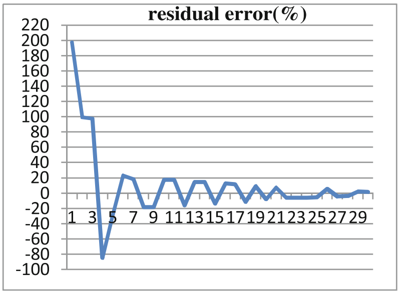

Fig. 9. The percentage of residual error of the fitting variables

Fig. 10. The percentage of residual error of the tested variables

According to the figures above, we can calculate some performance indexes in Tables 1 and 2.

Table 1. The fitting performance of PPR

The percentage of relative error	The sample size	The percentage of all samples
More than 20%	25	6%

Table 2. The tested performance of PPR

The percentage of relative error	The sample size	The percentage of all samples
More than 20%	6	20%

The results above show that PPR can get relatively accurate fitting performance for 88% sample. What's more, the majority of the relative errors are less than 10%, which indicates the variation range of the IRR is small. Namely, the anti-risk of this PPP project is good. Meanwhile, considering the risks, the investors can compare the IRR with the IRR of the benchmark yield to decide whether to invest the project.

5 Conclusion

This study introduces the projection pursuit regression method as a new risk assessment method, establishing a new risk assessment model related to the traditional risk assessment methods: Firstly we fit out the probability distribution of risk value based on historical data and expert's subjective opinions. Secondly we take the random numbers through the Monte Carlo simulation as input variables, and other economic indicators as output variables to obtain the sample data. Thirdly, we set up the interrelation between the two variables based on the data above. And then we establish a risk assessment model by projection pursuit regression method combined with the actual case, which is used to deal with the sample data regression to achieve a reasonable calculation effect. The results above shows that the model can reveal the change regulation of risk factors affecting PPP project economic evaluation index. The new assessment model can catch the risk features of PPP project influenced by many factors, to give an integrated results through dimension reduction.

The proposal of the evaluation model establishes direct interrelations between the risk factors and economic evaluation of PPP projects, reducing the intricacies of traditional risk assessment and making the risk assessment process more effective and rapid. At the same time, the evaluation model is also more accurate compared to its predecessors. However, some shortcomings also exist in this study: (1) the existing data is not sufficient enough to completely fit the probability distributions of all risks, which implies that the existing assessment of the risk still partly relies on expert assessment; (2) the evaluation model in normal circumstances is relatively stable, but part of the deviation still persists. Thus the accuracy of the algorithm calls to be improved in the optimization model in the future to improve the accuracy of risk assessment.

Abstract. Asymmetric information always creates conflict of interest between stakeholders. Purpose of this study is to discuss agency conflict from perspective of financiers, and suggesting its remedies as controlling mechanism. Monitoring role of different types of ownerships is studied. Study has investigated the impact of four different types of ownership structures namely; managerial ownership, family ownership, institutional ownership and ownership of block-holders on agency issue. Role of financial institutions is also discussed. To explore the agency problem from view point of both equity-holders and debt-holders, Agency cost is divided into agency cost of equity (ACE) and agency cost of debt (ACD). Study has also given empirical evidences to check the robustness of each monitoring mechanism. Using financial data of top capitalized 100 companies of Pakistan from 2010 to 2015; results are drawn by fix and random effect (GLS) model. Ownership of insiders, block-holders and institutions were found to be most effective monitoring devices for firms' growth. Study also contains recommendations for investors and debtors.

Keywords: Monitoring mechanism · Agency cost · Ownership structures · Manufacturing industry

1 Introduction

After the research stream on agency cost developed by Jensen [22] extensive empirical results can be found on evidence claiming that presence of agency conflicts has an adverse effect on business sustainability. Two types of agency cost are found: Agency cost of equity (ACE) and agency cost of debt (ACD). If alignment of interest of owners and managers is missing, this is hazardous

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_129

for the company by causing agency cost of equity. If debt-holders' interest is overlooked (due to conflict of interest between managers/shareholders and debt-holder), then agency problem of debt is created. To monitor the agent's action, incurs cost that is called the agency cost.

ACE arises when principal hires agent and delegates his authority. Problem originates when agent could not meet up with principal's expectations and don't utilize firm's resources efficiently to maximize shareholders' interest. ACD is created when more risk is transferred towards debt-holder. If capital structure has higher proportion of debt, managers have strong incentives to invest on the assertion of higher return in the extremely risky projects. If the project is successful, managers and shareholders will get benefit; if not, cost will be bear by debt-holders. Managers may expropriate wealth from debt-holders in order to increase shareholders wealth or increase their own luxuries. Similarly managers can expropriate wealth from debt-holders for shareholders by following actions: getting additional debt in the case where new issued debt has equal or higher claim than the previous debt (existing debt-holders hurt), Engaging in asset substitution (switch from relatively low risky assets to highly risky assets) and by underinvestment (managers may reject profitable projects if debt-holders get benefit from such projects) and by overinvestment (when success only benefits to shareholders and failure leads to financial distress).

Present study is focusing how both types of agency cost can be reduced by decisions regarding ownership structures. Present study is addressing four different ownership structures that are most common in Pakistan: family ownership, managerial ownership, institutional ownership and ownership of block-holders. Convergence of interest hypothesis (presented by Jensen) is also going to be checked in Pakistan through the ownership of managers and family (insiders). We will be also in a position to verify whether block-holders and institutions employ their greater monitoring ability in Pakistan.

Financial institutions may alleviate not only managers' moral hazards but also agency problems between managers and creditors through a grading function ex ante and a monitoring role for their firms ex post [28]. Banks grant loan only if they are satisfied with management performance and firm's financial strength. Concept of institutional debt financing has been driven from theory of agency cost [21]. Thus institutional debt financing is indirectly involved in reducing the agency costs due to efficient monitoring of firms' decisions. Banks monitor the activities of the firms to fulfil loans extension criteria. Monitoring forces the firm to utilize assets efficiently to repay loans. Present study is focusing to check the monitoring capability of financial institutions in case of Pakistan.

Literature does not have much more about agency problem in Pakistan, making our study a quite new topic for literature. Moreover, agency issues are particularly severe issues in emerging economies [20]. Secondly ownership structure is still a new topic for researchers and there is enough room to work on this topic. So combination of these two is expected to be very valuable for Pakistan and other developing countries. We hope that our working will prove a valuable initiative for researchers of our region. Our findings and recommendations will help Pakistani manufacturing sector to enhance its performance by identifying and reducing both types of agency problem.

2 Overview of Previous Studies

Literature does not answer that which type of ownership or set of different ownerships can be optimal ownership structure. It is because researchers have not included all equity ownership styles in their study. This section compiles prominent researches regarding agency cost with different ownership structure. However, some researchers have also concluded that agency cost is irrelevant of any type of ownership structure [11,29].

Convergence of interest hypothesis advocates that when ownership and management is in the same hands, then owner-agent interests are converged [21]. Agency conflict arises due to difference of interest between owners and agents and inability of the owners to monitor agents' action. If managers become part of the ownership then this might reduce agency cost [6]. These studies also report that there is better asset utilization with managerial ownership in the firms [32,44]. Proportion of insider ownership was found very low in firms with high agency cost [2,31,46]. Leverage, dividends, managerial ownership, the percentage of outside directors and executive compensation are effective in controlling the agency cost of insider trading [5]. But there is also reporting of contradictory results of convergence of interest hypothesis [9,50]. Managerial ownership cannot reduce the agency costs of ownership within family owned firms. Private ownership sets the firm free from external governance and capital market monitoring [42]. But majority of researchers are convincing that managerial ownership acts as an effective device in controlling agency cost. For example see [1,2,4–6,13,19,24,30–32,36,38,39,44,49].

Institutional ownership is considered to be an effective monitoring mechanism due to many reasons. Qualified analysts work for institutions to analyse a firm and its financial performance [13]. Institutions also have blocks of shares that strengthen its power and can control managers efficiently to work for the attainment of financial goals [48]. Institutional investors are found successful in reducing managerial overspending in the case of firms with low growth opportunities [49], family and institutional ownerships are found to be complementary devices in monitoring the CEOs [46]. There are also findings of some studies, which don't confirm the effective monitoring role of institutions to reduce agency problem [24,36]. As previous studies found significant evidence that institutional ownership reduce agency cost [1,4,5,13,41,46,49], our research also theorizes that there is inverse relationship between institutional ownership and agency cost. Study finds this argument more convincing that institutions have greater monitoring abilities and strong influential power on the managers to direct them to do actions that increase owners' wealth. Although some studies found no influential monitoring power of institutions in reducing ACD [24,36] but this result might be due to specific environment of their countries.

Almost all the previous studies are advocating the influential monitoring power of family ownership to overcome agency conflict [6,22]. Family ownership is more committed towards stability and continued existence of the firm due to their reputations [10]. Family firms perform better than nonfamily firms [4]. Due to higher proportion of insider ownership, founding family firms have lowest agency cost [41]. Founding family ownership is also associated with a significantly lower cost of debt financing [4]. Family firms control agency problem by delivering more amount of dividends to shareholders and by employing higher amount of debt in capital structure [43]. But in family owned firms, managers act for the controlling family, but not for shareholders in general [37]. Following [3,4,41], study also hypothesizes the inverse relationship between agency cost and family ownership.

Managers of a firm, whose ownership is held by blocks of shares, are less involved in utilization of firm resources for their discretionary activities [9,14,17]. More the outsider block holding of the firm, more is the monitoring of the managerial activities [44]. Recent research has proposed a signaling theory related with block-holding ownership, according to which an entrepreneur chooses to attract an outside blockholder in order to signal his low “propensity to expropriate [45]. Large board and small non-management block-holder ownership face severe agency problems and poor corporate governance [30]. But there is also evidence that high level of block holding is responsible for higher level of agency cost in firms [41]. If ownership is intense, it can also create agency conflict [16]. Some researchers found that block-holders are not expert enough in monitoring [24].

Bank debt is an effective device to control the agency problem. Bank credit shows the credit worthiness of borrower, reducing the information asymmetry, which affects ACD [19]. Agency cost decreases with the increase in the monitoring by the banks [6]. Bank debt reduces cash holdings [17]. Institutions monitor and evaluate the company regularly for extending credit [22].

3 Empirical Implementation

In this section, we present model used to examine the impact of ownership structures on agency cost of equity and agency cost of debt. We also describe the data used and firm level variables used in this study.

$$\begin{aligned} \mathrm{ACE}_{it} = & \partial_i + \beta_1 MO_{it} + \beta_2 FO_{it} + \beta_3 IO_{it} + \beta_4 BO_{it} + \beta_5 D_{it} \\ & + \beta_6 \mathrm{DIV}_{it} + \beta_7 \mathrm{Size}_{it} + \beta_9 Q_{it} + \varepsilon_{it}, \end{aligned} \tag{1}$$

where ACE_{it} is Agency cost of equity measured in terms of assets turnover ratio: MO_{it} is managerial ownership: FO_{it} is family ownership, IO_{it} is institutional ownership, BO_{it} is ownership of block-holders: D_{it} is debt ratio: DIV_{it} is dividend payout ratio: Size_{it} is size of firm: Q_{it} represents growth opportunities for the firms. Asset utilization ratio determines management aptitude to grasp growth opportunities by efficiently employing firm resources. If this ratio is significantly good as compared to industry average, it means that high level of sales and cash flows are generated from firm assets. Whereas a low ratio of turnover represents that the managers are using assets for unproductive purpose rather than utilizing them in the activities that generate cash flows [27]. However firm with low assets turnover ratio bears more agency conflicts relative to the firm with high turnover ratio. See also [6,19,36,44]. In addition, we also assess the effect of different types of ownership structures on agency cost of debt. This notion is examined substituting the agency cost of equity variable ACE by Agency cost of debt ACD variable. The new model is described in Eq. (2). Debt agency cost is defined as conflict between shareholders and bondholders [13]. Manso took the ACD as the difference between the total value of the all-equity and levered firms [34]. We obtained the proxy of agency cost of debt (ACD) from previous studies [13,26,40]. If major proportion of capital is invested in fixed assets, then managers have no more liquid resources to use it on their own luxuries. If firms has more liquid assets, managers may found it very easy to use these assets for their own requisites or transfer cash to shareholders in form of dividends, rather than keeping it for future payments of interest payments or principal amount to debt holders [25].

$$\begin{aligned}\mathrm{ACD}_{it} = {} & \partial_i + \beta_1 MO_{it} + \beta_2 FO_{it} + \beta_3 IO_{it} + \beta_4 BO_{it} + \beta_5 D_{it} \\ & + \beta_6 \mathrm{DIV}_{it} + \beta_7 \mathrm{Size}_{it} + \beta_9 Q_{it} + \varepsilon_{it}.\end{aligned} \tag{2}$$

Inclusion of variables of ownerships of management, family, institutions and block-holders in the model is to assess the optimal ownership pattern. Addition of debt variable in the model is to test Jensen's proposition of "debt as the remedy" of agency problem [22]. In case of agency cost of equity, when firm employs more debt, then it improves the efficiency of the firm to utilize assets to produce more sales and minimize its cost [18]. It is because mangers have responsibility to pay out installment and premium regularly. If they don't do so, then creditors may take firm to court to file bankruptcy. Mangers may lose their jobs in such scenarios. So debt disciplines the mangers. In case of ACD, managers are constrained to pay fix installments against debt. This constraint directs the managers to act in such a way that they don't waste firm resources. Debt serves as a monitoring device to mitigate agency problem between owner and principal [38,44]. Firms with more debt tend to have lower agency costs [9,12,36]. Family firms take up higher debt levels to resolve agency problem [43]. Firm's capital structure affects agency cost [47]. Some studies did not find relationship of debt with agency problem [23]. The amount of free cash flow was found increased with increased level of debt [17,35,49]. Addition of Dividend payout ratio in the model is to test whether Large incremental disbursements mitigate the agency problem associated with excess funds or not [33]. Money that is not given back to outside shareholders in the form of dividend that money can be invested in negative NPV projects or can be used for the perks of insiders [7,15]. But Byrd [9] found that Dividend is not influential in defining agency cost. ACD is more influential on dividend policy as compared to that of agency cost of equity [8]. Size variable is added in model to test the notion: "Greater the size of firm, more agency cost is expected" [17,44]. Larger firms bears higher agency costs because of greater complexity in their operations [13]. That's why present study also hypothesize that there is positive relationship between firm size and agency cost. Model also has variable of growth opportunities because literature directs that if there are growth opportunities for the firms, then more cash generation in the future is expected. When firms expect incremental growth opportunities, they hold extra cash in hands to invest in future projects. It leads towards the extra cash available to the manager to be used for wasteful expenditures. Thus chances of agency problem increases with increased level of growth opportunities [17,19]. Conflicts of interest between shareholders and managers vary with growth opportunities and free cash flow [49] (Fig. 1).

Out of 819 listed companies in Karachi Stock Exchange, which is largest stock exchange of Pakistan, we selected 100 top capitalized firms. Our sample contains only non financial firms. So we ignored 353 firms related with financial services in Pakistan. By this, study got 22% representation of all the non financial firms in Pakistan, present during the period of 2010 to 2015. Our sample got representation of all the manufacturing sectors listed in KSE for the stated time. Manufacturing sector is the largest sector of the Pakistan economy.

Estimation by FE, RE and Hausman test. Dependent variables are ACE and ACD in models 1&2 respectively. *, **, *** show significance at 1%, 5% and 10% respectively.

The contribution of manufacturing sector of Pakistan in GDP growth is slowly build up during the last three years from 18 percent to 19.2 percent. Data sources of Karachi Stock Exchange, State Bank of Pakistan, Bulletins of Statistical Bureau of Pakistan were used to collect the data (Table 1).

We checked our results by generalized least square method and Hausman Test. In models 1&2 relationship between agency cost and variables of our interest is explored. The purpose of this model is to find out the joint effect of all the variables (Table 2).

4 Results and Discussions

Managerial ownership was found influential in lowering agency cost of equity. Our results are supported by various researches [1,2,6,19,31,32,36,38,39,44,46]. Results tell that MNG is negative and significantly related with ACD. This means when managers are also owners of the firm, then they don't overlook debt-holders interests. Our results are convincing that in Pakistani firms, insiders don't create asset substitution or risk shifting problems. They don't add to the assets of owners on the expense of debt-holders. And they don't produce incentives to expropriate debt-holders' wealth as they maintain lower proportion of such assets which is not tied in fix plant and equipment or liquid assets. The motive behind this deed from managers might be because of the reason that when insiders own the firm, they want long-term performance and return from the firm, so they avoid increasing the price of debt.

Relationship between ownership of family and asset turnover of that firm is negative and significant. This means family has weak monitoring over managers. Our findings are also consistent with [37] which narrates that in family owned business, managers work for the welfare of controlling family, rather than for general shareholders. This is because Pakistan is among those emerging economies where minority rights are not well protected under any corporate law authority and due to these reason insiders with more concentration of shareholdings in companies have the capacity to misuse their rights for their personal benefits. Results are indicating that FML is negatively and significantly related with ACD i.e. increase in the ownership of family causes reduction in debt agency cost. Family owned firms have lesser proportion of such assets which are difficult to monitor by debt-holders [4].

Evidence supported that with the increase in ownership of institutions in a firm, managers make efficient utilization of assets and agency cost of equity is reduced. It can be inferred that institutions usually have strong monitoring power. Due to their monitoring and controlling power, managers are forced to make efficient utilization of assets and by this equity agency cost is reduced. Our results are consistent with majority of researchers like [1,5,6,13,46,49]. Regression results illustrate that INST is positive and significantly related with ACD. A firm which is more owned by institutions, have larger the proportion of such assets which are not tied in fixed plant and equipment, so debt-holders cannot monitor such assets easily.

With the increase in the ownership of block-holding, equity agency cost reduces. Block-holders have incentives to actively monitor agents because they have larger stake in the firm. Results tell that Pakistani block-holders have influential monitoring power. When firm is greater subjected to the monitoring of block-holders, then managers make efficient utilization of assets. So it mitigates the equity agency cost [6,42]. BLOCK is negative and significant related with debt agency cost. Higher cost of debt leads to additional cost of financing. Higher price of debt may result in the financial distress of the firm. As block-holders have large stake associated with the firm, they want to avoid such situations. So they try that there should be no debt agency cost [42,44].

Debt ratio (DR) was found to be effective in reducing both ACE and ACD. But Dividend pay out ratio came out to be insignificant in determining any type of agency cost. Size reduces ACE but on the other hand it increases the intensity of ACD. It is due to the reason that larger firms are difficult to be monitored by debt-holders. Assets of larger firms are diversified. Larger firms usually have enough free cash flows to cater future growth opportunities [13,17]. Firms having more growth, have better utilization of its assets. GROWTH is positive and highly significantly related with debt agency cost. A firm with good growth and investment opportunities is likely to have a relatively high quantity of cash and other short-term assets for future investment opportunities. The availability of more liquid assets increase the discretionary power of the manager hence increase the agency cost of debt (Table 3).

5 Conclusion

This research examines and provides further evidence on agency theory. Present study looks into the impact of ownership structures over equity agency cost (ACE) and debt agency cost (ACD). Equity agency cost is the disagreement of interest between shareholders and mangers whereas debt agency cost is the divergence of interest between shareholders and debt-holders or debt-holders and managers. Equity agency cost incurs when managers don't act in the best favor of shareholders and acquire perquisites for themselves. Agency cost of debt arises when managers, themselves or on behalf of shareholders, expropriate wealth from debt-holders and increase wealth of shareholders or do discretionary actions on the expense of debt-holders interest. Study incorporates four types of structures of ownership namely: managerial, general public, family, institutional and ownership of block-holders. We used different proxies for ACE and ACD. ACE is measured by asset turnover ratio. ACD is measured by amount of firm assets not invested in fixed plant and equipment and by liquidity of firm assets. Our sample is companies from KSE 100 index and study window is 2010–2015. We found no empirical study that has explored agency cost with set of hypotheses which present study has used.

Our research tested the convergence of interest hypothesis. In Pakistan, convergence of interest hypothesis is followed because ownership of managers' result in the reduction of agency cost. Ownership of family is causing reduction in efficient utilization of assets. However firms having managerial ownership and family ownership exhibit lower agency cost of debt. This conveys that insiders in Pakistan protect the interest of debt-holders. Due to greater monitoring abilities, institutions and block-holders have positive impact on firm performance by reducing agency cost of equity. In firms, which are more owned by institutions and block-holders, there is better protection of shareholders' interests in case of Pakistan. But institutions only take care of shareholders wealth and don't safeguard the interest of debt-holders; agency cost of debt is present in firms, which are more owned by institutions. But ownership of block-holders, not only reduces equity agency cost, but also mitigates debt agency cost by protecting debt-holders wealth and interests. So ownership of block-holders and managers are the structures of equity ownership, which reduce both types of agency costs. Pakistani firms which has greater debt ratio, also has efficient asset turnover and lower proportion of such assets which are difficult to monitor by debt-holders. Size worsens the both types of agency problems whereas growth opportunities for firm reduce agency cost of equity but exacerbates agency cost of debt.

Present study classified block-holders as all the shareholders that have more than 10% ownership of equity. Future researchers may expand this concept by classification of block-holders. For example, there are two major types of block-holders in Pakistan, family block-holders (more than 10% equity is owned by certain family) and institutional block-holders (more than 10% equity is owned by institutions). There are many types of institutions in Pakistan which have ownership in companies like NIT, pension fund managers, insurance companies etc. Future research should check individual monitoring impact of each type of institution in mitigating agency costs. The study employs five year data (2010–2015) from Pakistani economy. This period is recognized as unchecked inflation but stable or declining interest rate. Present study did not control variables for industry classification. No doubt asset utilization is different for different types of industries. Similarly other variables are different too for different industries. We were unfortunately enough that Pakistan has not codes for specific industries like SIC codes in other countries. If we use codes for different industries for control for industry specification, results might be better.

Appendix

Table 3. Variables and definitions

Variables	Formula
Asset Turnover Ratio	Net Income divided by Total Assets
Agency Cost of Debt	Proportion of firm assets not invested in fixed plant & equipment = One minus ratio of fixed assets to total assets
Managerial Ownership	The number of common shares own by insiders divided by total number of common shares outstanding. Insiders consist of officers, affiliated directors, beneficial owners and principal shareholders [26]
Institutional Ownership	Number of shares held by institutions as a proportion from total ordinary shares of the company [36]
Family Ownership	Ratio of shares held by family as a group to total shares [43]
Ownership of Block-holders	Total number of shares held by block-holders divided by total number of shares outstanding. Where block-holders are shareholders having more than 10% ownership in total equity outstanding
Size	Natural Logarithm of total assets
Debt Ratio	Book value of contractual long term debt/Book value of total assets
Dividend	Dividend per share divided by earnings per share
Growth	Ratio of (market value of equity + book value of debt) to Book value of total assets

The Impact of Institutional Investors on Stock Price Synchronicity: Evidence from the Shanghai Stock Market

Li Kun, Lei Yu(✉), and Xiaoxue Hu

Abstract. The article mainly consists of four sections, the first section is the basic introduction and literature review, the second is the background review of institutional investors and stock synchronization, the third is the empirical research and the last is the Conclusion. This paper use the basic literature review method, descriptive statistics and OLS models analysis to explore the Impact of institutional Investors on Stock Price Synchronicity. Using the data of 569 listed firms at Shanghai stock market from 2009 to 2012, this paper investigates the impact of institutional investors' behaviors on stock price synchronicity. We find that the institutional investors' long-term investments can reduce stock price synchronicity and increase the information efficiency of the stock market. However, the short-term trading of institutional investors does not necessarily reduce stock price synchronicity. Therefore, the Chinese policemakers should regulate institutional investors and encourage constructive long-term investment behaviors, to make it really rise to enhance the effectiveness of capital market information, and improve the efficiency of capital market resource allocation. The main contributions of this paper is that we investigate the stock price synchronicity from the perspective osf institutional investors' behaviors and A–share market.

Keywords: Stock price synchronicity · Institutional investors · Long-term investment · Investment activity

1 Introduction

The term "stock price synchronicity" refers to a phenomenon in which stock prices rise and fall in tandem. As a proxy for stock price informativeness, a higher degree of synchronization reflects more commonality regarding information on markets and industry; however, heightened synchronization suggests less detailed firm-specific information contained in stock prices, weakening the capacity to transfer signals of corporate value. In this circumstance, the pricing mechanism fails, thus reducing the efficiency of resource allocation in capital markets through prices.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_130

Morck and Yeung [12] examined the stock price synchronicity in the major stock markets around the world during the first 26 weeks of 1995. They found that the average stock price synchronicity was higher in less developed countries. In the Chinese stock markets, approximately 79% of stocks move in the same direction, only lower than Poland where all the stocks moved in the same direction. After a lapse of nearly two decades, what can be observed regarding stock price synchronicity in the Chinese stock markets? Figure 1 illustrates the price synchronicity of 1,218 stocks on the Shanghai Stock Market during the first 26 weeks of 2013. As Fig. 1 shows, averagely more than 70% of stocks were moving in the same direction, suggesting that price synchronicity still remained at a high level in China.

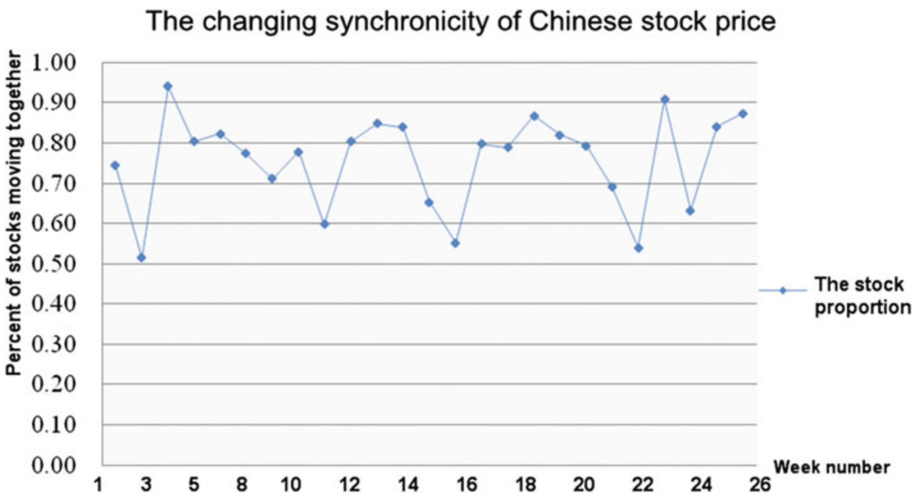

Fig. 1. The changing synchronicity of Chinese stock prices

Stock price movement is driven by investors, especially those who dominate the market. The Chinese stock market is dominated by individual investors with short-term vision. They tend to blindly follow trends without investigating the basic information of firms, thus exacerbating price synchronicity. In contrast, institutional investors are usually more professional and rational, and they engage in deeper and more fundamental research on firm-specific information. Just as Hasan and Song [6] argued, stock price synchronicity is lower when institutional investors dominate the market. However, Boubaker et al. [2] disagreed with this conclusion, they believe that the relation between institutional behavior and stock price synchronicity is not that straightforward. In recent years, institutional investors in China have been encouraged to expand for three main reasons: to return the markets to reasonable levels; to improve the pricing mechanism; and to heighten the effectiveness of market information. Therefore, it is important to clarify the influence of institutional investors on stock price synchronicity.

Since Roll, Richard [4] proposed as a proxy for stock price synchronicity, a growing body of literature has addressed this issue. Morck [12] found that the systematic component of returns variation is large in emerging markets, and lower firm-specific returns variation is associated with poorer corporate governance. Jin and Myers [3] noted that lack of transparency increases by shifting firm-specific risk to managers, and opaque stocks with high are also more likely to crash. Heng [1] found that both stock price synchronicity and crash risk are negatively related to the firm's ownership by dedicated institutional investors, which have strong incentive to monitor due to their large stake holdings and long investment horizons. However, Skaife et al. [9] argued that the zero-return metric is a better measure of firm-specific information impounded into share prices than the synchronicity measure internationally. In this paper, we use as the proxy for stock price synchronicity, because of its broad recognition and extensive applicability.

The stock price synchronicity in the Chinese stock market is significantly higher than in many other markets. Some researchers believe that this is related to the institutional development in China, e.g. Iftekhar [6] found that better institutions–respect for property rights and the rule of law - increase the value of private information which reduced synchronicity in the Chinese stock markets. However, most domestic researches tend to conclude that the high degree of speculation in the Chinese stock markets lead to high price synchronicity. This speculation is mainly caused by the composition of Chinese investors, which consists of many individuals but few institutions. This reinforces the view that institutional investors can reduce the price synchronicity. The institutional holdings can increase the quantity of firm-specific information, thus reducing stock price synchronicity and enhancing the efficiency of company signal-transmission mechanisms. However, some researchers disagree with this conclusion. Conversely, they claim that the institutional investors display "herd behavior" that can exacerbate stock price synchronicity [7].

In summary, scholars have not reached a consensus regarding the impact of institutional investors on stock price synchronicity, and more researches are required to confirm related findings, especially in the Chinese stock markets where stock price synchronicity is high. The contribution of this paper is reflected in two aspects. Firstly, this paper adds an index to demonstrate the investment activities of the institutional investors under examination. We refine institutional investor behaviors into shareholding level and examine both the effects of their long-term and short-term behaviors. This deepens the analysis of institutional investors' effect on stock price synchronicity. Secondly, this paper focuses on the study of Shanghai Stock Market, taking 569 listed companies from 2009 to 2012 as samples. The recent panel data illuminates the latest situation of stock price synchronicity in China, thus enriching the research on the effects of institutional investors on stock price synchronicity.

The remainder of this paper is organized as follows. Section 2 provides the theoretical background. Section 3 presents the research design and the main empirical results. Section 4 concludes the paper.

2 The Theoretical Background

2.1 Stock Price Synchronicity

In capital markets, the fluctuation of stock prices is driven by information shocks (unexpected or unpredictable events that affect perception of stock values). According to Roll [4], this information can be categorized into market-level and firm-level sources. The information at the market level refers to the external macro-level environment, including policies, regulations and important economic events. Firm-level information refers to the unique information of firms, including their changing financial indicators, executive turnover and other events. If the fluctuation of stock prices is caused by market-level information, then all stocks are vulnerable to the same systematic risk, and thus a significant correlation among different stock prices indicates a high degree of stock price synchronicity. As Song [10] finds, firms' stocks are less synchronized with the entire market and have less crash risk if firms have superior accounting disclosure policies. However, if the price fluctuation is based on a firms' specific information, then the entire market displays heterogeneity in terms of its stock price fluctuation. Therefore, significant stock price synchronicity in a specific market is due more to market information and due less to the firm-specific information in stock prices. On this occasion, a company's stock price cannot reflect the true quality of a company, which lowers the reference value of corporate information for investors. This damages the company signal transmission mechanism and lowers the efficiency of price-based market resource allocation.

2.2 Institutional Investors' Effects on Stock Price Synchronicity

Based on transaction incentives, traders can be classified into three categories: informed traders, noise traders, and liquidity traders. Informed traders conduct transactions based on a firm's value, and thus the related information can be conveyed into stock prices by their transactions.

Institutional investors are generally regarded as informed investors. They have access to information resources that individual investors do not have, and their teams include professional research staff. These advantages can make their evaluations of firms more accurate than those of individual investors, increasing the quantity of firm-level information contained in stock prices. Related studies have shown that the behaviors of institutional investors can affect the process of stock pricing and their information environment, and their transactions add firm-specific information into stock prices. This can help to reduce stock price synchronicity and improve the efficiency of capital markets.

The influence of institutional investor behaviors on stock price synchronicity also depends on their specific investment behaviors. On the one hand, if the institutional investors focus on short-term benefits and have high portfolio turnover rates, they will not have a strong incentive to collect firm-specific information related to corporate long-term benefits. In that case, they will not be able to decrease stock price synchronicity. On the contrary, the short-termism of institutional investors will make them more prone to herd behaviors, make them follow the trends to buy or sell stock and intensify stock price synchronicity. On the other hand, if institutional investors maintain a large stake in the firm for a long period, they may have a greater incentive to closely monitor their portfolios. To secure their investment, they may even take large positions with their shares and involve themselves in corporate governance. Therefore, the long-term investment of institutional investors is logically more likely to decrease the stock price synchronicity.

3 Empirical Design and Results

3.1 The Sample and Data

The sample consists of listed firms on the Shanghai Stock Market from 2009 to 2012, and we exclude the following firms from the sample: (1) firms without complete data; (2) financial institutions; (3) utility firms; (4) firms that conducted IPO or major assets restructuring in the current year; (5) and firms whose stocks were delisted or suspended. Finally we obtain 569 eligible companies, a total of 2276 sample points of panel data. All data are from China Stock Market & Accounting Research Database (CSMAR) and RESSET database. Table 2 shows the descriptive statistics.

3.2 Variables Construction

(1) The dependent variable: stock price synchronicity

To measure the synchronicity of stock price, we first calculate the for firm i in fiscal year t from the expanded market model regression in Eq. (1).

$$r_{i,w} = \alpha + \beta_i \times r_{m,w} + \varepsilon_{i,w}, \tag{1}$$

where $r_{i,w}$ is the return of firm i in week w, $r_{m,w}$ is the market return in week w.

Since R^2 is highly skewed and bounded between 0 and 1, we apply a logistic transformation to obtain a near formally distributed variable, SYNCH. A higher value of SYNCH indicates that the stock price is more synchronized.

$$\mathrm{SYNCH}_{i,t} = \ln\left(\frac{R^2_{i,t}}{1 - R^2_{i,t}}\right). \tag{2}$$

(2) The explanatory variables: institutional investor behavior

(a) The measurement of institutional investors' overall behaviors

We add up all the proportions of shares held by institutional investors in a listed firm to construct a proxy for the total stake of institutional investors.

$$LI_{i,t} = \frac{\sum_{j=1}^{n} \mathrm{INS}_{j,i,t}}{\mathrm{TOTAL}_{i,t}}. \tag{3}$$

The is the institutional investors' total proportion of firm i in the year t, $\mathrm{INS}_{j,i,t}$ is the shares of firm i held by institutional investor j in the year t, and $\mathrm{TOTAL}_{i,t}$ is the total shares of firm i in the year t.

(b) The measurement of institutional investors' investment liveness

According to Liu [8], 90% QFII (the Qualified Foreign Institutional Investors) hold the stocks for 1–4 quarters, and the QFII whose holding period are more than 5 quarters accounts for less than 10%. Therefore, we can deduce that the institutional investors are not necessarily long-term investors. In order to measure the short-termism of institutional investors, we construct an indicator.

$$SI_{i,t} = \frac{\mathrm{ABS}(IA_{i,t} - IA_{i,t-1})}{\mathrm{VOL}_{i,t}}, \tag{4}$$

where $IA_{i,t}$ is the total shares of firm i held by institutional investors in the year t, and $\mathrm{VOL}_{i,t}$ is the individual shareholders' trading volume of firm i in the year t. So $SI_{i,t}$ is the ratio of the absolute value of institutional investors' shares variation and stocks volume for firm i in the year t. The higher $SI_{i,t}$ means more active investment behavior of institutional investors, and short-termism is more significant.

(3) The control variables

In order to better examine the influence of institutional investors on stock price synchronicity in China, our control variables include the following: ROE, BM, SIZE, LEV, and CEN.

ROE is the contemporaneous income before extraordinary items divided by the book value of equity. ROE is a core indicator of corporate management performance, and when related to stock price synchronicity, ROE differs across models. Thus, we presently avoid making calculations on the regression coefficient.

BM is the ratio of the market value of equity to the book value of equity, and it is often used to measure the growth of a company. A lower BM ratio means stronger growth for a company. Many scholars agree that a company's growth and expanded demand for financing leads to more information disclosure; consequently more information will be contained in its stock price. In contrast, a blue-chip company with less demand for financing is reluctant to release information. Therefore, we expect that the company with a lower BM ratio will exhibit a less synchronous stock price.

SIZE is the natural log of the firms' market value of equity at the end of the fiscal year. Roll [3] held that a larger company is more vulnerable to the influence of macroeconomic or industrial events. Meanwhile, a larger company has a stronger ability to avoid risk, leading to less stock price volatility. Thus it can be concluded that the larger size of a company would bring about more significant stock price synchronicity. Others, however, hold that due to its greater scale, the company can garner more attention, which can add more information into its stock price and attenuate price synchronicity. Because of this controversy, we do not calculate a regression coefficient of the relation between SIZE and stock price synchronicity.

LEV is the book value of all liabilities scaled by total assets at the end of the fiscal year. LEV can reflect the level of a company's financial risk, and a higher LEV indicates a higher financial risk in a company. In this case, the company is more sensitive to credit risk, and thus the price fluctuation is mainly affected by the firm-specific financial risk. Thus, we expect a negative correlation between LEV and stock price synchronicity.

CEN is the concentration of corporate ownership, and a higher CEN means a stronger control held by large shareholders and more rights to internal information. These large shareholders can transfer firm-specific information into stock prices through their transactions, accordingly raising the firm-level information content in stock price [5]. However, some researchers found a concave functional relationship between stock price synchronization and CEN: CEN increases at a decreasing speed with a rising CEN until the maximum point, and then it starts to fall [11]. This suggests an unclear relationship, and any clarification would require further research.

3.3 Model Setup

We estimate the relation between institutional investors and the firms' stock price synchronicity in Shanghai A-stock market by the following model:

$$
\begin{aligned}
\text{Model (1):}\quad \mathrm{SYNCH}_{i,t} &= \alpha_t + \gamma_i + \beta_1 LI_{i,t} + \beta_3 \mathrm{ROE}_{i,t} + \beta_4 BM_{i,t} + \beta_5 \mathrm{SIZE}_{i,t} \\
&\quad + \beta_6 \mathrm{LEV}_{i,t} + \beta_7 \mathrm{CEN}_{i,t} + \varepsilon_{i,t}, \\
\text{Model (2):}\quad \mathrm{SYNCH}_{i,t} &= \alpha_t \alpha_t + \gamma_i + \beta_2 SI_{i,t} + \beta_3 \mathrm{ROE}_{i,t} + \beta_4 BM_{i,t} + \beta_5 \mathrm{SIZE}_{i,t} \\
&\quad + \beta_6 \mathrm{LEV}_{i,t} + \beta_7 \mathrm{CEN}_{i,t} + \varepsilon_{i,t}, \\
\text{Model (3):}\quad \mathrm{SYNCH}_{i,t} &= \alpha_t + \gamma_i + \beta_1 LI_{i,t} + \beta_2 SI_{i,t} + \beta_3 \mathrm{ROE}_{i,t} + \beta_4 BM_{i,t} + \beta_5 \mathrm{SIZE}_{i,t} \\
&\quad + \beta_6 \mathrm{LEV}_{i,t} + \beta_7 \mathrm{CEN}_{i,t} + \varepsilon_{i,t},
\end{aligned}
$$

where the explained variable $\mathrm{SYNCH}_{i,t}$ is the measurement of stock price synchronicity of firm i in the year t, $LI_{i,t}$ is the shares proportion held by institutional investors of firm i in the year t, and $SI_{i,t}$ is the transaction activity of firm i conducted by institutional investors during the fiscal year t, as a proxy for the short-term behavior of institutional investors.

3.4 Descriptive Statistics

Using the data of 569 listed firms at Shanghai stock market from 2009 to 2012, Table 1 provides the descriptive statistics of the sample. The mean and the max of Stock Price Synchronicity is 0.363 and 0.840 respectively. After applying a logistic transformation to obtain a near formally distributed variable, SYNCH, the mean, max and min of the SYNCH is $-0.673, 1.650$ and -5.790 respectively. The mean of LI which is the proportion of shares held by institutional investors in a listed firm is 0.155. The mean of SI which is the transaction activity conducted by institutional investors is 0.025. ROE, return on equity, show a large variation, with a mean of 4.815 and standard deviation of 17.517.

Table 1. Descriptive statistics

	N	Min	Max	Mean		Std.
	Statistic	Statistic	Statistic	Statistic	SE	Statistic
R^2	2276	.000	.840	.363	.0034	.162
SYNCH	2276	−5.790	1.650	−.673	.0188	.896

3.5 Empirical Analysis

In order to decide whether we should use fixed effect panel data model or random effects model on the panel data, we conduct a Hausman Test on the foregoing model.

Table 2. Hausman test result of investment behaviour

Test Summary	Chi-Sq. Statistic	Chi-Sq.d.f	Prob.
Cross-section random (long term)	38.597	6	0.000
Cross-section random (short term)	49.000	6	0.000
Cross-section random (overall)	46.736	7	0.000

This table shows the Hausman Test result of the institutional investors' overall investment behavior. The significant result encourages us to apply a fixed-effects model in the regression process.

Table 3. The empirical result

Variable	Mod (1)	Mod (2)	Mod (3)
C	-1.135 (0.000)	-1.156 (0.000)	-1.129 (0.000)
LI	-0.487^{**} (0.037)		-0.527^{**} (0.033)
SI		-0.055 (0.846)	0.149 (0.617)
ROE	-0.005^{***} (0.001)	-0.005^{***} (0.001)	-0.005^{***} (0.001)
BM	0.871^{***} (0.000)	0.888^{***} (0.000)	0.868^{***} (0.000)
SIZE	0.004^{**} (0.013)	0.004^{**} (0.023)	0.004^{**} (0.015)
LEV	-0.502^{*} (0.070)	-0.474^{*} (0.087)	-0.498^{*} (0.072)
CEN	0.889^{*} (0.051)	0.742^{*} (0.099)	0.882^{*} (0.053)
Adjusted R-squared	0.311	0.310	0.311

Note: $^{***}p < 0.01$, $^{**}p < 0.05$, $^{*}p < 0.1$.

Table 3 reports the estimated coefficients and associated p values. From this table we find the estimated coefficient of LI is −0.487 in Model (1) and −0.527 in Model (3), and both are significant at the 5% level. This demonstrates a significantly negative correlation between the proportion of institutional shareholding and stock price synchronicity, namely, the stock with a higher proportion of holding produces a less synchronous stock price. This supports the argument that institutional investors' behavior helps to convey firm-specific information to the market and facilitate a company's signal transmission mechanism, which can improve the efficiency of resource allocation with prices.

The other explained variable, SI, is a proxy variable for institutional short-term transactions. The empirical results show a negative correlation (−0.055) in Model (2) and a positive correlation (0.149) in Model (3), neither is significant, which is consistent with expectations earlier in this paper. This indicates the insignificant correlation between the institutional investor activity and stock price synchronicity.

In this paper, we believe this insignificant correlation is caused by the double effects of institutional investors' speculative behavior. On the one hand, frequent short-term trading transmits corporate-specific information to prices, which can raise the information content in stock prices and help relieve high stock price synchronicity. On the other hand, there herding is visible in the behavior of these informed investors, causing stock price to fluctuate in the same direction. Therefore, the offsetting dual functions lead to an insignificant effect on stock price synchronicity.

Empirical result shows that ROE and BM have significant influences on stock price synchronicity, and both of them are significant at the 1% level in all the three models. Firstly, the higher ROE, the less there is price synchronicity. The firm with a higher ROE suggests better corporate management; consequently, the firm gains more attention by institutional investors and the public, and thus the firm-specific information can be readily conveyed in the price. However, the absolute value of its estimated coefficient is small, which illustrates a limited influence on price synchronicity. Secondly, the estimated coefficient of BM is significantly positive, meaning that stronger growth companies are more likely to be tracked by investors, resulting in more information in the stock price. The coefficient of SIZE is significant at the level of 5% in all three models, and this positive correlation is consistent with our former expectation. Thus a larger company suffers from more synchronous prices. The estimated coefficient of LEV and CEN are significant at the 10% level in all three models, and the stock price is less synchronous in a company with higher LEV or lower CEN.

Overall, the adjusted of the model test is approximately 31%, which indicates our model's high explanatory capability. Therefore, our conclusion is highly credible.

4 Conclusion

The empirical results of this paper suggest that institutional investment can significantly decrease stock price synchronicity on the Shanghai Stock Market, and that this influence is achieved by long-term shareholding and not by frequent transactions. This paper provides empirical grounds for encouraging institutional investors to engage in long-term value investment, which can increase the efficiency of price-based resource allocation in our capital markets. For the policy - makers, it is necessary to improve the regulations of China's capital market in order to create a favorable external environment for institutional investors. They also should guide institutional investors to long-term value investment, enhance the confidence of long-term value investment and improve the quality of listed companies.

Research on Risk Allocation Model in PPP Projects: Perspectives from the SOEs

Chuan Chen, Tengteng Yan(✉), and Ping Chen

Business School, Sichuan University, Chengdu 610065, People's Republic of China
ytt19941128@foxmail.com

Abstract. PPP (Public-Private-Partnership), which is the cooperation between the government and private sector, is a major innovation in public service mechanism. Effective risk identification and reasonable risk allocation is not only a major challenge to each party, but also the key to manage projects efficiently, reduce the whole life cost and improve benefit. Under the influence of special economy, politics and culture, the state-owned enterprise accounts for absolute proportion of private sector in China. However, the systematic analysis of the state-owned enterprise participating in the PPP project is deficient. Given that the Chinese central governments have sped up the development of the PPP application in recent years, this paper provides a risk allocation model through the fuzzy comprehensive evaluation method, which is aiming at optimizing the allocation of risk, reducing transaction costs and enhancing comprehensive benefits from the perspective of state-owned enterprises (SOEs).

Keywords: PPP · SOEs · Risk allocation · Fuzzy comprehensive evaluation

1 Introduction

PPP (Public-Private-Partnership) model is an innovative financing tool for infrastructure projects procurement in China. After 2013, the 18th national congress of CPC proposed that the market should play a decisive role in resource allocation. In September 2014, the ministry of finance issued *Notice about promoting PPP Model* and devoted continuously to promoting PPP Model nationwide. In September 2015, The State Council issued *Guideline to Urge SOE Modernization through Mixed Ownership Reform*, which had further defined the overall requirements of the state-owned enterprises developing the mixed ownership economy [15]. According to the statistics of National PPP Integrated Information Platform, there were 9,285 projects that would be procured by PPP up to the end of June 20, 2016, and their total investment surged to ¥10.6 trillion [3]. Because of the national condition, the state-owned enterprises with large scale, strong capital power and rich experience have inherent advantage to participate in the PPP projects. As a result, the state-owned enterprises accounted for 80%

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_131

while the private enterprises only accounts for 20% of the private sector [14]. With a large amount of investment, long term cooperation, technical complexity, and uncertainty factors, appropriate risk allocation is not only a critical success factor (CSF) of PPP but also an important driving factor of meeting the Value for Money [4,6]. While the country issued relevant legal policies to standardize the operation and execution of PPP projects, the guidance of risk allocation is still relatively broad and vague [7].

At present, there is weak control force between government and SOEs, and government always has absolute competitive advantage. Initially, some risks would be allocated to SOEs with underperforming ability to control risk and no willingness to take risks. Once the risks occur, SOEs are unable to control the consequences of risk, thus the government need to bear losses, which inevitably causes most risks retransferred to the government at a higher cost. In addition, the complex contractual arrangements in PPP projects would lead to risk exposure, and inappropriate risk allocation only let the infrastructure debt simply transfer from the local government balance sheets to SOEs. However, it can't cut overall leverage utility of the public sector effectively. In terms of risk allocation, the government and SOEs always face severe challenge, strict requirements and high standards. However, there are few systematic analysis of the state-owned enterprises participating in the PPP project in Chinese journals. Therefore, this paper will establish risk allocation model combined with fuzzy comprehensive evaluation method and entropy coefficient method to optimize the allocation of risk perspectives from the SOEs.

This paper is organized as the following: Sect. 1 begins with an introduction, Sect. 2 makes a literature review about PPP risk allocation, Sect. 3 describes the modeling ideas and methods combined with fuzzy comprehensive evaluation method and entropy coefficient method, which optimizes multi-objective decision of risk allocation in PPP projects perspectives from the SOEs, Sect. 4 takes the case of *Mianzhu Integration of Water Supply and Drainage Project* to demonstrate the effectiveness of the model, Sect. 5 presents a brief conclusion .

2 Literature Review

Zhang put forward that the research topics of PPP papers in Chinese and International Journals mainly include PPP model's application, risk management, financing and economic issues, legal and procurement issues and government regulation [16]. The foundation of financing risk-sharing in PPP projects is the accurate identification of risk factors. Grimsey identified nine risks: financial risk, political risk, environment risk, construction risk, technology risk, operational risk of infrastructure, infrastructure recovering risks, force majeure and project default risk, introduced the risk evaluation index and evaluation method from the perspective of different project stakeholders [9]. Bing creatively carried out the dividing analysis of risk from the macro, medium and micro three levels [2]. Zou identified twenty-seven critical risk factors influencing the success of PPP projects from five dimensions: the owner, design, contractors, government institutions and the external environment [17].

The academic research for the risk-sharing mechanism in PPP project mainly concentrated on the risk-sharing principle, method and model. Abednego put forward the connotative meaning and conditions of risk sharing [1]. Deng analyzed and summarized nine principles in risk-sharing of PPP projects, such as the principle of responsibility, justice principle [8]. Bing put forward that the risk-bearer should be divided into the private sector, public sector, together undertaking, which is depended on the specific conditions of project [2]. Jin and Chang explained the risk allocation of PPP projects from the perspective of transaction cost theory (TCE) and resource-based view (RBV) [5,11]. At present, most studies tend to adopt quantitative methods to optimize the PPP project risk sharing mechanism and process. The questionnaire survey was the typical quantitative research method in risk allocation [16], such as Ke investigated the experienced practitioners to determine the preferences of PPP project risk allocation [13], Guo adopted the real option method to research the risk allocation strategy of highway PPP projects under the delay investment decisions [10], Jin selected the artificial neural network to realize the allocation [12].

In conclusion, with the perfection and development of theory and practice of risk-sharing in PPP projects, the scholars at home and abroad had a thorough study in risk allocation, which mostly confined to some specific risks that should be shared to specific stakeholders, government or private sector. However, there are few studies involved specific allocation strategies and proportions. Moreover, there is almost no study about the risk allocation whose perspective is from the SOEs.

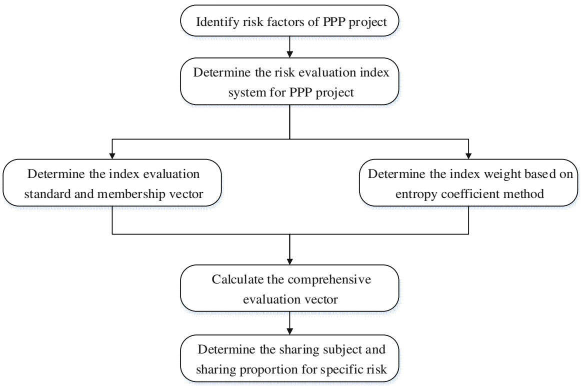

Fig. 1. The procedure of risk allocation whose perspective from the SOEs in PPP project

3 Method

The quantitative method adopted in optimizing risk allocation mainly include game theory, real option theory, artificial neural networks and fuzzy comprehensive evaluation theory. The game theory, option theory and artificial neural networks objectively reflect the actual negotiation process with complex model, which are difficult to apply in practice. In consideration of subjectivity and uncertainty in risk-decision mechanism, the fuzzy comprehensive evaluation (FCE) based on fuzzy mathematics will be reasonable in optimizing risk allocation. It can turn the qualitative questions into quantitative analysis based on membership degree theory. In addition, the method has the advantages of clear result, quite strong systematicness and can better solute the problems that are difficult to quantify, which has been widely applied in the field of engineering and applied science, such as water quality evaluation, clinical diagnosis, information technology, air quality assessment and product design. Some scholars also gradually attempt to apply fuzzy mathematics in the construction risk management. The paper establishes the PPP project risk allocation model to optimize the multi-objective decision-making in PPP project risk allocation perspectives from the SOEs. Figure 1 summarizes the procedure of PPP project risk allocation.

3.1 Identify Risk Factors of PPP Project

Risk identification further defined the risk factors and risk category, which is the foundation of risk allocation. In the practice of risk management in PPP project, there are several applicable methods, such as the *Delphi* method, Check list method and Brainstorming method. There are not many differences in risk factors and risk category between the SOEs and private enterprise, but there are considerable differences in the specific risk assessment. Moody's Investors Service said that China's state-owned enterprises were heavily involved in the PPP project, and it would reduce government leverage and debt at a certain extent. With the promoting of supply-side structural reform, Moody's said that the proportion of the debt in GDP in SOEs reaches to approximate 115%. Mostly SOEs faced systemic downgrade in credit rating, these factors would affect the risk assessment of PPP project.

3.2 Determine the Risk Evaluation Index System for PPP Project

This section discusses the risk evaluation index system based on allocation principle and influence factors. There are many factors and principles affecting the risk allocation of state-owned enterprises, the paper selects the basics of qualitative research to comb the influencing factors and principles. The influencing factors include project system properties, stakeholders' comprehending mistake for the PPP model, the risk-taking attitude and intention of stakeholders. Combined with the theoretical research and case study, the guiding principle of PPP project could be summarized as follows: equitable principle, criterion of liability, effective control principle, risk premium peer, upper limit principle and dynamic principle. Setting up the evaluation index system should be carried out in accordance with the principle: quantifiable, critical, objectivity, systematic, operability, independence, comparability and representative, which can full and accurately reflect the comprehensive management ability to control risk of the specific subject. Table 1 shows the evaluation index system.

Table 1. The evaluation index system in risk allocation

The evaluation index system			
Ability to control risk	U1	Foresee Risk	It can predict the probability and evaluate the consequences of risk occurrence (Degree of information symmetry)
	U2	Ability to monitor risk	The ability to avoid, reduce, supervise and control the likelihood of occurrence for the specific Risk
	U3	Ability to improve the risk management system	Construct management information system, improve the measures of dealing with risks
Ability to undertake risks	U4	The flexibility of dealing with risk	The ability to stabilize and control risk consequences, don't make it worse, take risks in the lowest price
	U5	Solid financial performance	Private capital (asset-liability ratio, risk reserve rate, profitability, etc.) the government (fiscal balances, GDP growth, debt levels)
	U6	The experience to cope with the risk	Rich experience and reputation of honoring agreements makes better coordinate various stakeholders, and then take risks at the lowest cost
Risk premium level	U7	Obtain direct premium level	The ability to get a reasonable and acceptable level for risk premium
	U8	Obtain indirect premium level	The ability to improve the credibility, reputation and efficiency of stakeholders
Risk preference	U9	Risk attitude	The tendency of the subject facing the specific risks, such as risk-averse, risk-neutral, risk-taking
	U10	Inclination of transfer risk	Transfer inclination based on the ownership and control power between the SOEs and the government

3.3 Determine the Index Evaluation Standard and Membership Vector

The fuzzy comprehensive evaluation model is based on the franchise agreement between the government and private sector. Combined with the risk evaluation index system in Table 1 and triangular fuzzy set theory, this paper set up the fuzzy reasoning rules. V includes five evaluation standards, $V =$ (Very low, Low, Medium, High, Very high).

The triangular fuzzy function $T = (f, g, h)$, Very low (0%, 15%, 30%), Low (15%, 25%, 35%), Medium (35%, 45%, 55%), High (55%, 65%, 75%), Very high (75%, 85%, 95%), Through the formula $V(T) = \frac{1}{3}(f + g + h)$ to calculate the fuzzy evaluation of value $V =$ (15%, 25%, 45%, 65%, 85%).

$$R = \begin{pmatrix} r_{11} & r_{12} & \cdots & r_{1m} \\ r_{21} & r_{22} & \cdots & r_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ r_{n1} & r_{n2} & \cdots & r_{nm} \end{pmatrix}.$$

We use *Delphi* method to determine the evaluation value. This paper establishes the subordinated matrix R based on the index system and evaluation standard to calculate the subordinated vector $r_i = (r_{i1}, r_{i2}, \cdots, r_{im})$ indicates the value of index i in the evaluation standard of j.

3.4 Determine the Index Weight Based on Entropy Coefficient Method

Considering the subjectivity of expert evaluation system, this paper adopts entropy coefficient method to determine the index weight, thus enhancing the reliability of the model and improving the accuracy and rationality of the evaluation results. The entropy concept derives from thermodynamics, which initially described the system disorder. Information entropy value is directly proportional to the disorder, which is inversely proportional to the information utility value. Entropy coefficient method is mainly according to the principle of $VarianceDrive$, which can largely avoid human factors to determine the index weights. The specific steps are as follows:

(1) Use the Stirling Formula to calculate the entropy value of each index utilizing Stirling Formula.

$$e_i = -\frac{1}{Inm}\sum_{j=1}^{m} R_{ij} InR_{ij}.$$

(2) Determine the weight value of each index.
- Utility value h_i is the difference between the entropy e_i and 1. $h_i = 1 - e_i$;
- The weight value of each index can be indicated as $W = (w_1, w_2, w_3 \cdots w_i)$;

$$w_i = \frac{h_i}{\sum_{i=1}^{n} h_i}.$$

3.5 Calculate the Comprehensive Evaluation Vector

According to subordinated vector and the index weight, we need to calculate the comprehensive evaluation vector $B = W \circ R$, $\circ$ represents fuzzy operator,

Table 2. Alternative fuzzy operators

Characteristic	Alternative fuzzy operators			
	$M(\wedge,\vee)$	$M(\bullet,\vee)$	$M(\wedge,\oplus)$	$M(\bullet,\oplus)$
Formula	$\max\limits_{1\le i\le n}\{\min(w_i,r_{ij})\}$	$\max\limits_{1\le i\le n}\{\min(w_i,r_{ij})\}$	$\min\left\{1,\sum\limits_{i=1}^{n}\min(w_i,r_{ij})\right\}$	$\min\left\{1,\sum\limits_{i=1}^{n}w_i r_{ij})\right\}$
Manifests the weighting function	Not obvious	obvious	Not obvious	obvious
Comprehensive degree	Weak	Weak	Strong	Strong
Using R information	Inadequate	Inadequate	More adequate	Adequate
Type	Dominant-factor Highlight	Dominant-factor Highlight	Weighted average model	Weighted average model

the commonly used fuzzy operators include $M(\wedge,\vee)$, $M(\bullet,\vee)$, $M(\wedge,\oplus)$, $M(\bullet,\oplus)$, $M(\bullet,\oplus)$ comprehensively consider the subordinated vector and weight of the index, and other fuzzy operator would lack some information $M(\wedge,\vee)$, $M(\bullet,\vee)$ are suitable for single constraints model, which only take the main indicators into account and ignore the other secondary index. The fuzzy operators' characteristics are shown in Table 2.

Based on the above analysis, this paper will choose $M(\bullet,\oplus)$to calculate the comprehensive evaluation vector $B = (b_1, b_2, b_3 \cdots b_m)$. The methods widely adopted to deal with the evaluation vector are weighted average method and the principle of maximum membership degree. However, the latter take the concept of optimal sorting in the evaluation scheme, and sometimes it would miss key information. So this section select the weighted average method to normalize the index system, which makes the comprehensive evaluation vector $B = (b_1, b_2, b_3, \cdots, b_m)$ converted to comprehensive score S. $S = B_K \times V$, V represent the weight of e index evaluation standard, $V = (0.150.250.450.650.85)$.

3.6 Determine the Sharing Subject and Sharing Proportion for Specific Risk

The government and SOEs respectively undertake a comprehensive assessment of specific risk, the government should bear the proportion $Q_1 = \frac{S_1}{S_1+S_2} \times 100\%$, SOEs should bear the proportion $Q_2 = \frac{S_2}{S_1+S_2} \times 100\%$.

4 Case Study

To further integrate the existing system of water supply and drainage, improve the systematicness, harmonization, sharing and economy of water supply and drainage, the government of Mianzhu, Sichuan province proposed to launch the Mianzhu Integration of Water Supply and Drainage project in November 2015. The project's investment is 680 million yuan, and its concession period is about 30 years, which includes the construction and reform period of 3 years. Mianzhu

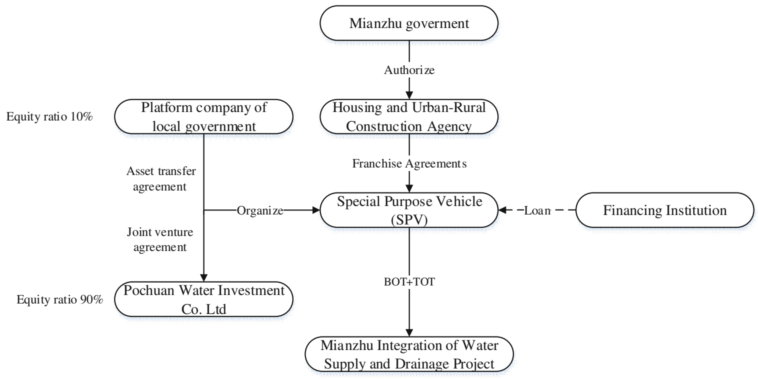

Fig. 2. The investment and financing structure

government authorized Housing and Urban-Rural Construction Agency as implementing agency to supervise and manage the implementation of project. The project intended to adopt BOT & TOT mode and complete government procurement through competitive consultation on February 5, 2016. Eventually, Pochuan Water (SOEs) was selected, and then the two sides formally signed on June 14, 2016. Pochuan Water is a joint-stock subsidiary companies of Sichuan Development Equity Investment and Fund Management Co. Ltd. and Poten Environment Group Co. Ltd. The investment and financing structure is shown in Fig. 2.

4.1 Risk Identification List Based on the VFM Evaluation

According to *Guidelines for VFM Evaluations of PPP (for Trial Implementation)* (Cai Jin [2015] No. 167), the VFM evaluation meeting was convened. The risk list identified by the participating experts is shown in Table 3.

Take the tax regulation change for example, this section will verify the application of fuzzy comprehensive evaluation method in the risk allocation decisions between Mianzhu government and Pochuan Water.

4.2 Determine the Subordinated Vectors of Mianzhu Government and Pochuan Water

According to the evaluation score from 30 experts (project management, engineering, finance, assets evaluation, industry, water industry, law, registered accounting field), the subordinated vectors of Mianzhu government and Pochuan Water are R_1, R_2. It shows that the comprehensive assessment about the ability to control and undertake risk, incentive mechanism, risk preference for Mianzhu government and Pochuan Water according to Mianzhu Integration of Water

Table 3. Risk identification list of Mianzhu Integration of Water Supply and Drainage project

Risk category	Major risks	Developing stage
Financial risk	Capital availability	Construction
	Credit risk in financial institutions	Construction
	Exchange rate risks	Construction and Operation
	Interest rate risk	Construction and Operation
	Inflation Risk	Operation
	Refinancing risk	Operation
	liquidity risk	Construction and Operation
Design risk	Design changeThe government put forward	Construction
	Design changeThe SOEs put forward	Construction
Construction risk	Geological exploration risk	Construction

Supply and Drainage project. R_1, R_2 are shown below.

$$R_1 = \begin{bmatrix} 0.50 & 0.23 & 0.20 & 0.04 & 0.03 \\ 0.15 & 0.42 & 0.24 & 0.13 & 0.06 \\ 0.01 & 0.03 & 0.26 & 0.40 & 0.31 \\ 0.59 & 0.32 & 0.03 & 0.03 & 0.03 \\ 0.01 & 0.01 & 0.22 & 0.50 & 0.26 \\ 0.08 & 0.04 & 0.53 & 0.26 & 0.09 \\ 0.02 & 0.14 & 0.37 & 0.34 & 0.14 \\ 0.02 & 0.01 & 0.53 & 0.40 & 0.04 \\ 0.06 & 0.13 & 0.52 & 0.23 & 0.06 \\ 0.33 & 0.27 & 0.14 & 0.17 & 0.09 \end{bmatrix}, \quad R_2 = \begin{bmatrix} 0.29 & 0.34 & 0.25 & 0.12 & 0.01 \\ 0.02 & 0.10 & 0.37 & 0.34 & 0.17 \\ 0.00 & 0.05 & 0.44 & 0.34 & 0.17 \\ 0.05 & 0.20 & 0.27 & 0.24 & 0.24 \\ 0.07 & 0.12 & 0.49 & 0.25 & 0.07 \\ 0.01 & 0.05 & 0.49 & 0.32 & 0.14 \\ 0.07 & 0.10 & 0.51 & 0.25 & 0.07 \\ 0.01 & 0.07 & 0.59 & 0.24 & 0.10 \\ 0.01 & 0.05 & 0.65 & 0.22 & 0.07 \\ 0.08 & 0.21 & 0.37 & 0.21 & 0.13 \end{bmatrix}.$$

4.3 Determine the Index Weight Based on Entropy Coefficient Method

According to the entropy coefficient method, the index weight is calculated following the step 4 in the above chapters.

(1) For Mianzhu government

$$InR_{ij} = \begin{bmatrix} -0.69 & -1.47 & -1.61 & -3.22 & -3.51 \\ -1.90 & -0.87 & -1.43 & -2.04 & -2.81 \\ -5.30 & -3.51 & -1.37 & -0.92 & -1.17 \\ -0.53 & -1.14 & -3.51 & -3.51 & -3.51 \\ -4.31 & -4.27 & -1.54 & -0.69 & -1.36 \\ -2.53 & -3.22 & -0.63 & -1.35 & -2.41 \\ -4.20 & -2.00 & -0.99 & -1.08 & -1.97 \\ -3.91 & -4.61 & -0.63 & -0.92 & -3.22 \\ -2.81 & -2.04 & -0.65 & -1.47 & -2.81 \\ -1.11 & -1.31 & -1.97 & -1.77 & -2.41 \end{bmatrix},$$

$$R_{ij} \bullet InR_{ij} = \begin{bmatrix} -0.35 & -0.34 & -0.32 & -0.13 & -0.11 \\ -0.28 & -0.36 & -0.34 & -0.27 & -0.17 \\ -0.03 & -0.11 & -0.35 & -0.37 & -0.36 \\ -0.31 & -0.36 & -0.11 & -0.11 & -0.11 \\ -0.06 & -0.06 & -0.33 & -0.35 & -0.35 \\ -0.20 & -0.13 & -0.34 & -0.35 & -0.22 \\ -0.06 & -0.27 & -0.37 & -0.37 & -0.28 \\ -0.08 & -0.05 & -0.34 & -0.37 & -0.13 \\ -0.17 & -0.27 & -0.34 & -0.34 & -0.17 \\ -0.37 & -0.35 & -0.28 & -0.30 & -0.22 \end{bmatrix},$$

$$e_i = -\frac{1}{Inm}\sum_{j=1}^{m} R_{ij}InR_{ij} = \begin{bmatrix} 0.77 & 0.89 & 0.75 & 0.62 & 0.71 & 0.77 & 0.83 & 0.59 & 0.80 & 0.94 \end{bmatrix},$$

$$h_i = 1 - e_i = \begin{bmatrix} 0.23 & 0.11 & 0.25 & 0.38 & 0.29 & 0.23 & 0.17 & 0.41 & 0.20 & 0.06 \end{bmatrix},$$

$$w_i = \frac{h_i}{\sum_{i=1}^{n} h_i} = \begin{bmatrix} 0.10 & 0.05 & 0.11 & 0.16 & 0.12 & 0.10 & 0.07 & 0.17 & 0.09 & 0.03 \end{bmatrix}.$$

(2) For Pochuan Water

$$InR_{ij} = \begin{bmatrix} -1.24 & -1.08 & -1.39 & -2.16 & -5.30 \\ -3.91 & -2.30 & -0.99 & -1.08 & -1.77 \\ -6.91 & -3.02 & -0.82 & -1.08 & -1.77 \\ -3.00 & -1.61 & -1.31 & -1.43 & -1.43 \\ -2.66 & -2.12 & -0.71 & -1.39 & -2.66 \\ -5.30 & -3.10 & -0.71 & -1.14 & -1.97 \\ -2.66 & -2.30 & -0.67 & -1.39 & -2.66 \\ -5.30 & -2.66 & -0.54 & -1.43 & -2.30 \\ -4.61 & -3.00 & -0.43 & -1.51 & -2.66 \\ -2.53 & -1.56 & -0.99 & -1.56 & -2.04 \end{bmatrix},$$

$$R_{ij}InR_{ij} = \begin{bmatrix} -0.36 & -0.37 & -0.35 & -0.25 & -0.03 \\ -0.08 & -0.23 & -0.37 & -0.37 & -0.30 \\ -0.01 & -0.15 & -0.36 & -0.37 & -0.30 \\ -0.15 & -0.32 & -0.35 & -0.34 & -0.34 \\ -0.19 & -0.25 & -0.35 & -0.35 & -0.19 \\ -0.03 & -0.14 & -0.35 & -0.36 & -0.28 \\ -0.19 & -0.23 & -0.34 & -0.35 & -0.19 \\ -0.03 & -0.19 & -0.31 & -0.34 & -0.23 \\ -0.05 & -0.15 & -0.28 & -0.33 & -0.19 \\ -0.20 & -0.33 & -0.37 & -0.33 & -0.27 \end{bmatrix},$$

$$e_i = -\frac{1}{Inm}\sum_{j=1}^{m} R_{ij}InR_{ij} = \left[0.84\ 0.84\ 0.74\ 0.94\ 0.82\ 0.72\ 0.80\ 0.68\ 0.62\ 0.93\right],$$

$$h_i = 1 - e_i = \left[0.16\ 0.16\ 0.26\ 0.06\ 0.18\ 0.28\ 0.20\ 0.32\ 0.38\ 0.07\right],$$

$$w_i = \frac{h_i}{\sum_{i=1}^{n} h_i} = \left[0.08\ 0.08\ 0.13\ 0.03\ 0.09\ 0.14\ 0.09\ 0.15\ 0.18\ 0.04\right].$$

Comprehensively considering the Mianzhu government and Pochuan Waters' information entropy evaluated by 30 experts, finally it is concluded that the weight of each index value are calculated. $W = [0.09\quad 0.06\quad 0.12\quad 0.10\quad 0.10\quad 0.12\quad 0.08\quad 0.16\quad 0.14\quad 0.03]$.

4.4 Calculate the Comprehensive Evaluation Vector (Comprehensive Membership)

Based on the above calculation, using fuzzy operator can calculate the comprehensive evaluation vector for the Mianzhu government and Pochuan Water, and the results are shown below.

$$
\begin{aligned}
B_1 &= W \circ R_1 \\
&= \begin{bmatrix} 0.09 & 0.06 & 0.12 & 0.10 & 0.10 & 0.12 & 0.08 & 0.16 & 0.14 & 0.03 \end{bmatrix} \circ \begin{bmatrix} 0.50 & 0.23 & 0.20 & 0.04 & 0.03 \\ 0.15 & 0.42 & 0.24 & 0.13 & 0.06 \\ 0.01 & 0.03 & 0.26 & 0.40 & 0.31 \\ 0.59 & 0.32 & 0.03 & 0.03 & 0.03 \\ 0.01 & 0.01 & 0.22 & 0.50 & 0.26 \\ 0.08 & 0.04 & 0.53 & 0.26 & 0.09 \\ 0.02 & 0.14 & 0.37 & 0.34 & 0.14 \\ 0.02 & 0.01 & 0.53 & 0.40 & 0.04 \\ 0.06 & 0.13 & 0.52 & 0.23 & 0.06 \\ 0.33 & 0.27 & 0.14 & 0.17 & 0.09 \end{bmatrix} \\
&= \begin{bmatrix} 0.15 & 0.13 & 0.34 & 0.27 & 0.11 \end{bmatrix}, \\
B_2 &= W \circ R_2 \\
&= \begin{bmatrix} 0.09 & 0.06 & 0.12 & 0.10 & 0.10 & 0.12 & 0.08 & 0.16 & 0.14 & 0.03 \end{bmatrix} \circ \begin{bmatrix} 0.29 & 0.34 & 0.25 & 0.12 & 0.01 \\ 0.02 & 0.10 & 0.37 & 0.34 & 0.17 \\ 0.00 & 0.05 & 0.44 & 0.34 & 0.17 \\ 0.05 & 0.20 & 0.27 & 0.24 & 0.24 \\ 0.07 & 0.12 & 0.49 & 0.25 & 0.07 \\ 0.01 & 0.05 & 0.49 & 0.32 & 0.14 \\ 0.07 & 0.10 & 0.51 & 0.25 & 0.07 \\ 0.01 & 0.07 & 0.59 & 0.24 & 0.10 \\ 0.01 & 0.05 & 0.65 & 0.22 & 0.07 \\ 0.08 & 0.21 & 0.37 & 0.21 & 0.13 \end{bmatrix} \\
&= \begin{bmatrix} 0.05 & 0.11 & 0.47 & 0.25 & 0.11 \end{bmatrix}.
\end{aligned}
$$

4.5 Determine the Sharing Subject and Sharing Proportion for Tax Regulation Change Risk

Then the section normalize the index system, which makes the comprehensive evaluation vector $B = (b_1, b_2, b_3, \cdots, b_m)$ converted to comprehensive score S.

$$
\begin{aligned}
S_1 &= B_1 \times V = \begin{bmatrix} 0.15 & 0.13 & 0.34 & 0.27 & 0.11 \end{bmatrix} \times \begin{bmatrix} 0.15 & 0.25 & 0.45 & 0.65 & 0.85 \end{bmatrix}^T = 0.48080, \\
S_2 &= B_2 \times V = \begin{bmatrix} 0.05 & 0.11 & 0.47 & 0.25 & 0.11 \end{bmatrix} \times \begin{bmatrix} 0.15 & 0.25 & 0.45 & 0.65 & 0.85 \end{bmatrix}^T = 0.50897.
\end{aligned}
$$

The Mianzhu government should bear the proportion:

$$Q_1 = \frac{S_1}{S_1 + S_2} \times 100\% = 48.577\%.$$

The Pochuan Water should bear the proportion:

$$Q_2 = \frac{S_2}{S_1 + S_2} \times 100\% = 51.423\%.$$

The example shows that the risk of tax regulation change should be shared by the Mianzhu government and Pochuan Water. The shared proportions were 48.577% and 51.423%. The Tax regulation change is belong to macroeconomic level risk, and the local government or superior government, central government can influence macroeconomic conditions. But the allocation is involved in local government and social capital, the local government is unable to fully control the occurrence and adverse consequences adverse consequences of tax risk, therefore the tax regulation risk should be shared.

5 Conclusion

Risk allocation is the key factor in the success of infrastructure PPP projects, and the reasonable risk allocation can effectively reduce the risk level. This paper explores the effective approach of risk allocation form the perspectives of the SOEs, and builds the allocation model based on fuzzy comprehensive evaluation and entropy coefficient method. In addition, the paper demonstrates the objectivity, rationality and feasibility of the allocation model, which provides the scientific methods and guidance for SOEs to participate in PPP projects, further deepening the reform of state-owned enterprises and gradually making the economic grows change from the factor-driven into the innovation-driven, promoting the transformation of public ownership economy.

An Exploratory Case Study of the Mature Enterprise's Corporate Brand Building Based on Strategic Perspective

Yuan Yuan, Jing Xu, Liming Zhang(✉), and Rui Zhou

Business School, Sichuan University, Chengdu 610064, People's Republic of China
zhangliming@scu.edu.cn

Abstract. Corporate brand plays an increasingly important role in intensive competition. Therefore, further research needs to be done on the relationship between strategic action and corporate brand. Particularly for mature enterprises, how to build corporate brand through strategic action is an important issue in this research field. Based on the case studies of Jinjiang Hotel Industrial Co., Ltd. and Luzhou Laojiao Co., Ltd., this paper analyzes the corporate brand management of mature manufacturing and service-oriented enterprises, giving the conclusion that strategic action will contribute to the corporate brand management and the brand construction of a mature enterprise is the consequence of its strategic action, since enterprises can manage corporate brand building by improving brand awareness, brand structure and the building path to construct their own corporate brands.

Keywords: Corporate brand · Strategic action · Mature enterprise

1 Introduction

Over the past two decades, corporate branding has been advocated by scholars as an effective way for companies to build competitive advantage [4], it has become a key strategic resource of enterprise [9]. In the contemporary global competitive environment, products and services typically become more similar, which makes it difficult for consumers to differentiate offerings coming from different enterprises. Consequently, promoting entire companies as a brand has become an efficient approach to create differentiation [8]. Corporate brand has significant value in consumers concern, product supporting, core communication, employee incentive [13]. And it is capable of helping enterprise to reduce cost, giving customers a sense of belonging, building consensus in stakeholders [11]. Therefore, the study on corporate brand from the perspective of strategy is significant.

To our knowledge, existing research about corporate brand mainly focuses on corporate brand itself [3,5,10,12,14], or on the marketing area, which explores

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_132

how corporate brand affects the consumers' reviews, attitudes or purchasing tendency [3,5,15,16]. Besides, the relationships among corporate brand and organization identity, image, reputation, etc. [7,12], the influence factors of corporate brand, and the effect of corporate brand on other aspects [7,8,16,17] are also research hotspots now. But there is little research on the inner relationship between corporate brand and enterprise strategy. Especially for mature enterprises, as to promote the corporate brand, the ways of facing the competition from start-ups and releasing from past traces become essential issues to be resolved.

So, this research plans to carry on an exploratory case study of two mature company cases, to analyze the role and impact of strategic actions taken in the enterprise development process on corporate brand rebuilding.

2 Literature Review

The research on corporate brand sprang up in 1930s'. To some extent, corporate brand is defined as an organization from the whole, which is the platform of all corporate brands and carrier used for promoting various differential services [1]. However, Knox and Bickerton [12] thought corporate brand is a manifestation of unique business mode of an organization in vision, diffusion and behavior. Harch and Schultz [11] defined corporate brand as brand umbrella covering all corporate products and plate brilliance for product.

2.1 Elements of Corporate Brand

Aaker [1] concluded the elements of corporate brand are historical foundation, corporate performance, employee performance, value view and priority item, local and global orientation, social resonance. Hatch and Schultz [9] proposed that corporate brand is made up of vision, culture and image. Vision comes from leadership consciousness of senior leaders, culture comes from employees, forming internal cognition and cohesion, and image is the evaluation of external public. Balmer [6,10] pointed out the components of corporate brand include brand vision, culture, location, personal feature, public relation and information.

2.2 Brand Building and Maintenance

Brand building and maintenance work need to design systematic and clear guidance plan from organizational strategic level. Philip Kolter [2] thought that enterprise should recognize advantages and disadvantages of brand regularly, maintain the development of brand constantly and propose four aspects of brand construction which are positioning, name selection, holder's decision and development strategy. With the gradual increasing of competition, corporation pays more attention to seek for differential competition of brand through unique emotional experience rather than function or characteristic in brand construction [10].

2.3 Management and Application of Corporate Brand

It's clear that theoretical research on definition, composition, role and feature, etc. of corporate brand at present has made some achievement, but corporate brand management research is somewhat lacking in guiding practice. Mukherjee and Balmer [14] clearly pointed out that the current articles about corporate brand are too ideal, they lack empirical data support and related measure description for possible conditions. The news shows that many scholars are developing related research on corporate branding, for example, Knox and Bickerton [12] pointed out corporate brand management is suggested to consider four aspects as vision management, culture management, image management and competition management. Hatch and Schultz [11] proposed corporate brand management is the process of eliminating the difference of corporate vision, culture and image.

In conclusion, not only does corporate brand has profound relationship with corporate strategic action, but it has close relation with corporate development stage and business type. Strategic action is strategic operation affecting future development direction of corporation and the result of executing corporate strategic plan, which reflects corporate strategic choice. However, strategic choice will promote the formation and change of corporate brand directly. Corporate brand can concentrate and abstract corporate vision, culture, value view, behavior and the expectation of stakeholders, etc. as a kind of contract relationship through certain strategic action so that corporation and stakeholders can establish stable 'emotion connection'. For many emerging enterprises, in order to obtain competitive advantage through corporate brand management in growing period, strategic actions with great influence on corporate brand must be adopted.

3 Research Design

Based on the current corporate brand theoretical achievement, this research adopts cross-case comparison research method to carry out exploratory research on brand management method of mature enterprises. After analyzing corporate brand management activities for mature enterprises with different business scope, the development circumstances of mature enterprises' corporate brand presented with related strategic actions can be drawn, and then exploring ways of mature enterprises' corporate brand.

3.1 Sample Selection

To make sure the representativeness and comparability of selected sample, sample enterprises should be in different industries with differentiated products and management operation mode, as a result, the mature manufacturing enterprise and service-oriented enterprise are selected as samples for exploratory cross-case comparison study.

One case is Luzhou Laojiao, a mature manufacturing enterprise founded in 1982, which is a large brewing backbone group that developed from 36 ancient workshops in Ming and Qing dynasties, has long been history of working on the brewing of organic liquor and commits to advocate healthy lifestyle. Luzhou Laojiao received various prizes from its establishment, and its 'Luzhou' registered trademark is one of ten most famous trademarks in first Chinese trademarks election. Past brilliant achievement usually makes the company lose the direction, however Luzhou Laojiao, through successful corporate brand management and continuous strategic revolution, broke through the dilemma and returned as the leader in Chinese wine industry.

Another case is Jinjiang Hotel, a mature Service-oriented enterprise founded in 1958, which was assigned personally "Jinjiang" as the name by Marshal Zhu De and Marshal Chen Yi when it was completed, honored as the first five-star business and tourist hotel in Southwest China. The enterprise's age sometimes is the constraint affecting its development. Jinjiang hotel adopted series of strategic actions like strategic alliance to build and cultivate corporate brand when facing the dilemma. And brand of Jinjiang Hotel eventually becomes the industry leader in Southwestern China.

Basic situation of sample enterprises is as shown in Table 1.

Table 1. Basic information of sample enterprises

Name of enterprises	Luzhou Laojiao Co., Ltd.	Jinjiang Hotel Co., Ltd.
Time of foundation	In 1982	In 1958
Main business	Wine products	Hotel services
Nature of ownership	State-owned enterprises	State-owned enterprises
Scale of enterprise	Owns more than 5000 employees and total assets of 3 billion RMB, annual output of Luzhou series of liquor 50,000 tons, brand valuation is 345.84 billion RMB	A five-star hotel, belongs to the Sichuan Tourism Development Group, owns more than 700 rooms
Business scope	Mainland China	Mainland China

3.2 Data Collection

This research explores dynamic interaction of corporate strategic action and corporate brand through longitudinal case study. Main data collection starts from 2013, and ends in October 2015. During this period, various mixed data collection methods were adopted by starting from the purpose of explorative research, including Personnel interview, secondary data collection and on-site observation.

1. Personnel interview. Adopting half structural interview manner; interviews are enterprise management.
2. Documents collection. Collection object are sample enterprises' brief report, internal management handbook, product menu etc.
3. On-site observation. Observation objects are sample enterprises' headquarters, manufacturing base, sales and service places etc.

4 Case Analysis and Discussion

4.1 Case Analysis

(1) Luzhou Laojiao Co., Ltd.
In the 1990s, rapid development of China's economy and improvement of people's material life level stimulated the consumer's brand awareness. Especially in liquor-making industry, the high-end brand is more profitable. Maotai, Wuliangye, Jiannanchun have Stopped selling goods in nationwide and raised product prices to develop in the high-end market, while Luzhou Laojiao persisted in the road of mass brand and missed the development opportunities.

When Luzhou Laojiao realized failures in the high-end market, it tried to sale its high-end liquor products, but the brand unlimited expansion followed let Luzhou Laojiao face bigger difficulties. For making up previous wrong doings, Luzhou Laojiao adopted series of strategic actions to manage its corporate brand. It cut down 49 sub-brands and reserved core brand through sliming brand, cleaning up the market sorting out product structure. After 2 years, Luzhou Laojiao finished long-term brand development plans, and formulated reasonable brand strategy architecture including two brands as well as three series, shown in Fig. 1. It improved brand identification and consumer recognition. After that, to establish brand image and improve brand value, Luzhou Laojiao decided to stop selling goods nationwide and raise price. Simultaneously, Luzhou Laojiao started stock reforming and coordinated the relationship between the stakeholders. Additionally, Luzhou Laojiao integrated channel strengths through rewarding retailers and established brand image through actively participating social campaign. Luzhou Laojiao rebecame a leading enterprise in Chinese liquor industry with series of strategic planning and actions.

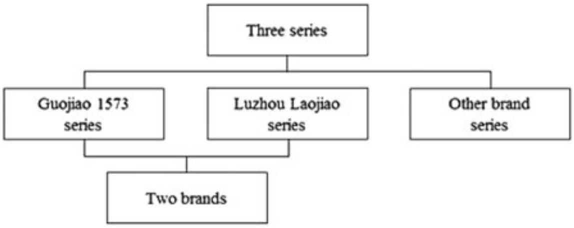

Fig. 1. Brand strategy architecture of Luzhou Laojiao

Corporate brand development process based on strategic actions for Luzhou Laojiao is as shown in Table 2.

Table 2. Corporate brand development process based on strategic actions for Luzhou Laojiao

Period and enterprise status	Important strategic actions affecting the corporate brand development	Corporate brand development situation
1980s Glorious history, high brand value and market acceptance	Establishment and development under the government's recognition and protection	1. Initially establishing corporate brand
		2. Strengthening brand value through old pits
1980s–1990s	Adhering to the mass brand Indulging in the past	Brand image was damaged
1997–2003 Inappropriate action under fear	1. Overstretched sub-brand	1. Brand excessive extension to destroy high-grade brand image of "Luzhou Laojiao"
	2. Taking the brand of "Luzhou Laojiao" as the intangible assets	2. Marketing model of paying money to OEM damaged the brand image
2002 - Brand renewal, value return	1. Sliming brand, cleaning up the market, sorting out product structure	1. Corporate brand achieving value return, Luzhou Laojiao embarking on the road of corporate brand management
	2. Stopping selling goods in nationwide	2. Rebuilding brand image in the minds of dealers and consumers
	3. Government approving listed companies to carry out tradable share reform	
	4. Non-public offering of no more than 3000 million shares	

(2) Jinjiang Hotel Co., Ltd.
1961–1979, as a hostel owned by government, Jinjiang Hotel didn't have authority or consciousness to manage its corporate brand. 1979–2001, because of the

reform and opening-up policy, Jinjiang Hotel went into modern enterprise administration phase of operating independence and self-financing. Since then, the time gave Jinjiang Hotel a great new identity. In 1995, Jinjiang Hotel, given the title of five-star hotel by National Tourism Administration, became the first five-star hotel in southeast of China. But with flourishing of Chengdu tourist market and increasing number of new hotels entering the market, fierce competition caused Jinjiang Hotel the development to receive the restriction again.

From 2001, the management team of Jinjiang Hotel decided to use advantage of carrying out the reshaping of the brand rebuilding work. It used "building a national top brand, being the best one of hotel industry" as vision, also offering services and products for high-end business market. And it redesigned brand logo, as well as inviting famous designer to redesign and redecoration the whole hotel. Then Jinjiang Hotel started building corporate culture and educational training system matched to corporate brand, and joined hands with strong brand enterprise. Through more than ten years of development, Jinjiang Hotel has successfully rebuilt its corporate brand through step-by-step strategic action.

Corporate brand development process based on strategic actions for Jinjiang Hotel is as shown in Table 3.

4.2 Case Discussion

According to the exploration of corporate brand management process regarding sample enterprises above, it can be found that the difference of business types can substantially make enterprises chose different strategic actions to build and manage corporate brand.

(1) Different extent of demand of corporate brand. Service-oriented enterprises possess more demand than manufacturing enterprises, since corporate brand is essential even only component of brand equity for service-oriented enterprises however, manufacturing enterprises have to concern product brand and related issues between product brand and corporate brand. Sample enterprises Jinjiang hotel relies on corporate brand to get involved in the competition, thus ways of adopting strategic actions to promote corporate brand are essential. Luzhou Laojiao has various product brand, it is significant to consider how to deal with the relationship between product brand and corporate brand through strategic actions.

(2) The difference of the essence of strategic choice. Service-oriented enterprises are keen on providing services with high quality to make success. However, manufacturing enterprises have to rely on innovation and R&D, high quality product and extraordinary manufacture to form strong corporate brand, which are implementation significance of strategic actions. Jinjiang hotel as sample enterprise has more concerns about services, and Luzhou Laojiao focuses more on product.

(3) Difference of implementation focus regarding organizational capability. Service-oriented enterprises tend to utilize intangible assets management to realize management goals of corporate brand. Manufacturing enterprises are suggested to improve tangible assets' operational capability to realize management

Table 3. Corporate brand development process based on strategic actions for Jinjiang Hotel

Period and enterprise status	Important strategic actions affecting development situation	Corporate brand the corporate brand development
1961–1979 Proud of "Yellow Vest"	Building and opening led by government	1. Initially establishing corporate brand
		2. Political overtonesbuilding strong brand image and basis
		3. Official hostel, lack of awareness of business operations
1979–2001 Develop-ment of new identity	1. Getting rid of government plans, becoming self-managed modern enterprise	1. Reforming corporate brand, laying the foundation of systematic brand management project
	2. Establishing enterprise management, system and reforming official human	2. Learning operation and management resource system
	3. Initiatingunion and establishing hotel management company	3. Becoming top1 hotel in southwestern China
	4. Carrying out hardware upgrading	4. Having some management infrastructure
	5. Regulating management	5. Difficult to resist external competition
	6. Awarded as the title of five-star hotel	
	7. Intense competition and inner defect	
2001 - Vigorous of brand develop-ment	1. Selecting brand development strategy	1. Carrying out series of ways to rebuild corporate brand
	2. Establishing vision, defining position, designing corporate logo	2. Discovering history heritage, increasing the essence of corporate brand
	3. Upgrading hardware facilities, improving product and service quality	3. Initially realizing the vision of "Nation's top and Industry leaders' brand"
	4. Embedding ideas through culture to prove service quality	4. Becoming the leading enterprise in Sichuan tourism and hotel industry
	5. Starting service personnel training system	5. Having ability to compete with international brands
	6. Focusing on opinions of leaders	
	7. Group expansion	
	8. Extending the brand network	
	9. Associating with strong brand enterprises	
	10. Rechanging management system	

goals of corporate brand. Sample enterprises Jinjiang hotel awakes consumers' memory through digging enterprises historical heritage and reforming image of corporate brand. Luzhou Laojiao improved the integrated value of corporate brand through re-positioning and forming product brand.

In the meantime, we found that from the points of strategic views, mature enterprises are suggested to consider tactics below to break through the dilemma of corporate brand management.

(1) Building the innovation expectation of corporate brand. And the construction of corporate brand has to be adjusted according to the changes of market conditions. At the first place, two sample enterprises immersed into the past distinctive achievement without improvement, which led corporate brand was lack of appropriate adjustment and revolution. Afterwards, in order to break through management delimma, Luzhou Laojiao conducted series of strategic actions to maintain its industry leading position.

(2) Knowing the methods of corporate brand system construction. Although sample enterprises were able to comprehend the significance of building corporate brand, but they still came across the crisis without adopted proper strategic actions. Luzhou Laojiao ignored the intrinsic connection between product brand and corporate brand in the process of exploring corporate brand management, so that the abuse of product brand weakened the value of corporate brand. However, through series of implementation, the corporate brand system was rebuilt. Therefore mature enterprises should clarify the position and role of corporate brand in the enterprise brand construction at the prior place. Designing the network structure of corporate brand, and adopting strategic actions, like putting the corporate brand as the core, to adjust brand structure is helpful for the strategy planning of corporate brand construction, which can the relationship and influence manner between corporate brand and product brand.

(3) Exploring the path of corporate brand rule development. Firstly, enterprises in different period of lifecycle, have different conditions of resources and capability and face different strategic choice, therefore management ways suiting corporate brand are different. And the difference of enterprise scale, the competition position, business type and operation ways can lead changes of corporate brand management ways. Enterprises are considered to constantly adjust corporate brand development path in accordance with development phases and strategic planning.

5 Conclusions

The research is based on strategic views, and integrates the strategic management and brand management theory. Besides, the research adopts the methods of vertical case study, and analyses ways of building corporate brand between mature manufacturing enterprises and service-oriented enterprises. From the process of building corporate brand for sample enterprises, implementing series of strategic actions which benefit prospects of future corporate brand development circumstance and direction, can boost the corporate brand construction of mature enterprises. Moreover, mature enterprises can adopt certain tactics to break through the dilemma of corporate brand management, thus realizing the corporate brand construction. It can be concluded that corporate brand construction and enterprises' strategic actions are correlated, mature enterprises brand construction is the consequence of related strategic actions, in the contrast, corporate brand construction has the certain impact on enterprises' strategic actions. The further discussion is placed regarding detailed roles, influence ways and path on enterprises' strategic actions from corporate brand.

Case Study: Packing and Distribution Logistics Optimization of Fashion Goods

Young Jae Jang(✉) and Shin Woong Sung

Industrial and Systems Engineering, KAIST, Daejeon, Korea
yjang@kaist.ac.kr

Abstract. In this short paper, we describe the development and implementation of the optimal packing and distribution of fashion products applied to a leading outdoor fashion brand in South Korea, Kolon Sport (K/S), through the academic-industry Business Analytics project with KAIST. We explain the framework of Business Analytics defined for the project and how modeling and analysis were performed under the framework. The packing and distribution decision involves how to determine a set of different box configurations and how to distribute these boxes to stores to meet store demand. The packing and distribution problem was formulated as a mixed-integer linear program, and a solution approach was developed to efficiently solve the industry-size problem in a timely manner. The modeling and analysis were performed with SAS packages. In particular, the optimization model was implemented with SAS/OR. The proposed approach was validated with simulation and on-site pilot test. The simulation showed an improvement in the packing and distribution process of around 15% in terms of meeting the demand in the stores, and it projected a $5 \sim 10\%$ improvement in revenue. After the successful pilot test, the approach was implemented in the internal IT system of K/S in July 2015. Consequently, the mass-produced items for the fall/winter season of 2015 were distributed by the system.

1 Introduction

1.1 Kolon Sport

Kolon Sport (K/S) is the signature brand of Kolon Industries, Inc., which was founded in 1957 in South Korea and operates more than 10 different fashion brands under its business unit. The total revenue of the Kolon Industries was around US $5 billion in 2014 [3]. The K/S brand was first established in 1973 and is now one of the top three outdoor fashion brands in Korea, a country with the world's second-largest market share in the global outdoor fashion industry, as of 2014, after the United States. K/S operates more than 250 stores over the country and designs, manufactures, and distributes more than 4,000 different types of products in all sales seasons. More information about the brand can be found at its website (http://us.kolonsport.com/). Note here that K/S refers to both the brand name and the department unit in Kolon Industries responsible for K/S operations. We use the term K/S interchangeably for the two definitions.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_133

1.2 Kolon-KAIST Business Analytics Project

The Kolon-KAIST Business Analytics project was first initiated in February 2014. The Big Data Analytics Team at Kolon Industries, an internal business analysis unit in the company that was established in 2013 to analyze massive amounts of data with advanced algorithms to support business operations and strategic decisions, was primarily responsible for the operation and management of the project. The team from the Korea Advanced Institute of Science and Technology (KAIST), the top science and technological university in South Korea, was responsible for guidance and for providing the technology for the project. The authors of this paper are the primary investigators of the project in the KAIST team.

The project goal was to improve the efficiency of the packing and distribution operation at K/S with Business Analytics. We defined Business Analytics as the process of delivering a specific tangible effect on the business operation by analyzing the data, developing scientific decision-making methods, and implementing methods with advanced IT solutions. Compared with conventional business analysis in which the final deliverables are forms of reports or documents of as-is analysis, the defined Business Analytics tried to provide a way to deliver specific actions and results. In contrast to the conventional business analysis or data-driven approach, which starts with collecting data and analyzing data first, we tried a problem-centric top-down approach. We first ask, "What is the problem?" and then ask, "Can this problem be solved with data and advanced algorithms and computation?" If the answer is yes to the preceding question, we try to collect data or create a system to collect the required data. Moreover, we emphasize an algorithm-based decision. To drive an action, "specific" action should be made. Therefore, optimization modeling and algorithm development are emphasized. We also include IT implementation in the definition of Business Analytics. To deliver sustainable results rather than a one-time as-is report, implementation of the analysis procedures and algorithm into the company's existing IT system is mandatory. This definition of Business Analytics clearly outlines the job scope of the project. It includes problem identification, data analysis to find the insight, development of an optimization model and algorithm to solve the complex problem, and then implementation of the system to derive the action.

Figure 1 shows the framework of Business Analytics that we constructed for the project. The framework describes the required techniques and corresponding departments or organization necessary to support the techniques. As shown, the framework consists of three different technical layers. The bottom layer comprises data collection and data management. The fact-based and data-oriented approach is the core concept of Business Analytics. Identifying the required data and effectively managing them were the fundamentals of the project. The IT department at K/S was responsible for this layer. The next layer addresses knowledge discovery through the analysis of data. Using data mining and statistical analysis, we tried to find new insights and knowledge or validate the existing knowledge. This function was done in cooperation with the

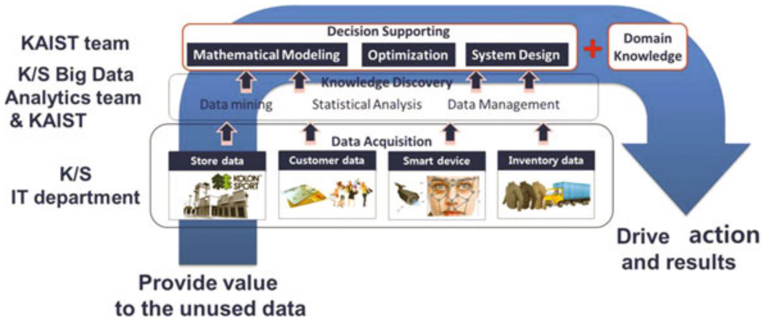

Fig. 1. Business analytics framework for the project

marketing team, business operation team, and various analytics-centric teams at K/S under the guidance of both the K/S Big Data Analytics and KAIST teams. The top layer concerns decision making. With the knowledge and insight gained from the underlying layers, this top layer attempts to support the decision for a complex problem. Mathematical optimization techniques were used in this layer. Because K/S did not have an internal team or organization using such optimization, this layer was the primary responsibility of the KAIST team.

2 Packing and Distribution Problem

To expedite the shipping process and reduce the operational costs of the distribution, K/S has been using direct delivery of their apparel products from the manufacturers, which are the third-party OEM supplier to K/S, to the K/S stores for the last several years. In the past before direct delivery was used, all of the manufactured products were shipped to the K/S warehouse, unpacked, sorted, and repacked for distribution to the stores. Given the fact that K/S distributes more than 1.6 million items in 1,000 different styles during each selling season, this repacking process required significant time and effort. Moreover, due to long delays in the repacking process, some stores did not receive products even after a sales season had already started. Direct delivery provided a significant benefit to the process. Each manufacturer packs the product with different sizes based on the size configurations given by K/S and ships their goods direct to each store. For example, K/S requests the manufacturers to provide two different types of box configuration such that for product WJ0001, Box 1 should contain 10 small, 30 medium, and 20 large sizes, and Box 2 should contain 3 small, 5 medium, and 4 large sizes. Also, K/S informs the manufacturer of which stores get how many boxes of each box configuration.

Although direct delivery significantly eliminated inefficiency in terms of delivery speed, it generated another problem. Because packing is done by third-party manufacturers, it was not realistic to make different box configurations for every store for each product, which would cause significant operational costs particularly when the numbers of products and stores are large. Therefore, the number of different box configurations was restricted to less than 10. Consequently, K/S should decide how to design the box configurations and determine which configuration and how many boxes are distributed to a store. These decisions are collectively called packing and distribution in K/S. Tables 1 and 2 show an example of packing and distribution decisions. The decisions on the configuration for each box type and the number of boxes for each type should be made in the packing and distribution process. In addition, which types and how many boxes of each type should be sent to each store must also be determined.

Table 1. An example of the packing decision

Configuration type	Configuration	Number of boxes
Type 1 Box	XS: 20, S: 25, M: 40, L: 15, XL: 10	10
Type 2 Box	XS: 10, S: 15, M: 20, L: 12, XL: 5	50
...	...	...
Type n Box	XS: 5, S: 10, M: 12, L: 8, XL: 3	30

Table 2. An example of the distribution decision

Store	1st box		...	m^{th} box	
	Configuration type	Number of boxes	...	Configuration type	Number of boxes
Store 1	Type 3 Box	1	...	Type 4 Box	1
Store 2	Type 4 Box	3	...	-	-
...	...	...	...	...	...
Store s	Type 2 Box	2	...	Type 3 Box	1

Because the OEM manufacturers charge packing fees based on the number of configuration types and the number of boxes shipped to the stores, appropriate packing and distribution can significantly reduce costs. However, due to the complexity of the configuration, decisions had been made on an ad-hoc basis that had caused inefficiency - some stores received more items than needed and some received less than needed.

3 Project Goal and Scope

The goal of the project was to develop a decision support system to optimally determine packing and distribution. The project was broken down into the following tasks:

- Demand analysis for each product style and size using the past sales data;
- Optimization modeling and algorithm development;
- Validation of the model and algorithm with simulation;
- Validation of the overall approach with pilot tests;

- Implementation of the approach in K/S's internal IT system.

The K/S Big Data team took the leading role of managing the overall project. The KAIST team took a leadership role for the first, second, and third tasks. The Sales and Operation Team at K/S was responsible for the fourth task, and the IT Department at K/S was responsible for the final task. The KAIST team also worked as the technical advisor for tasks four and five.

Note that demand forecasting or evaluation of the quantity of each product type was not within the scope of the project because of the following reason. The packing and distribution decisions were needed about one to two months before each sales season starts. However, decisions on production quantity had to be made one year before the target sales season. That is, by the time they were ready for packing and distribution, all of the products would have been ready for shipment at the manufacturers. Therefore, the product quantities for the items were given as the input parameters for the box assortment.

Although the product quantities to be distributed were known, the number of each item to be distributed to each store still needed to be evaluated. For instance, given that there are 100 medium-size winter jackets (item number WJ000111) available for the season, the number to distribute to each store must be determined. We evaluated this quantity based on the past sales data. Specifically, for each product style, we evaluated the percent of sales made by each store. This sales contribution value from the past data was used to estimate the distribution quantity for each product. For statistical analysis, we used multiple regression analysis and a standard method to estimate the future demand.

4 Packing and Distribution Optimization

The core part of the project was the development of the optimization model in the second task. As mentioned above, in this model, we determine the number and contents of the box configurations and their allocation to the stores to minimize the difference between store demand and the actual distribution quantity as depicted in Fig. 2. As indicated in the figure, the decision variables in the optimization model are the configuration of each box and the number of boxes to be distributed to each store. The demand for each store is evaluated from Task 1.

The constraints for the model are as follows. First, the types of configuration are limited. The manufacturers do not want to have more than 7 different types of configurations for each product. Second, the maximum number of boxes is restricted, as is the capacity of the box. Of course, the maximum capacity depends on the type of product. A $50 \times 50 \times 50\,\text{cm}^3$ box can hold 10 puffy winter down jackets at maximum, whereas it can hold 50 summer T-shirts. K/S has data mapping on the size of each box type and its maximum capacity for each product type. In addition, the maximum and minimum number of boxes a store receives are constrained. The last constraint is the upper limit of overstocking for each store. Note that due to the discrete nature of the problem, it may be impossible to meet the exact demand for each store. Therefore, some levels of over-shipping or under-shipping are unavoidable. However, K/S is more concerned with over-shipping. As a result, we added an over-shipping constraint, which specifies the upper limit of the allowable over-shipping to each store. The details of the general mathematical model are provided in the Appendix. The solution algorithm was also developed but is not presented in this document. For readers interested in the specifics of the algorithm, please contact the corresponding author.

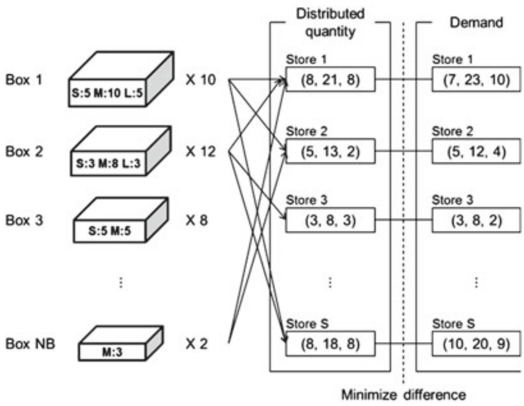

Fig. 2. Concept of the box assortment and allocation optimization problem

Similar formulations and optimization models are available in the academic literature, including [1,2]. However, the details of the models and the scales of the problem these optimization problems are trying to solve are different. To the best knowledge of the authors, this is the first work to develop an optimization model and solution algorithm at an industry-level scale and apply them to an actual business operation. Note that this paper is not intended for the academic community, and therefore the academic value of the work and scholarly implications are not discussed.

5 Validations

We conducted a simulation-based validation of the packing and distribution process in one sales season to compare the performance of the proposed method to that of the legacy procedure at K/S. The sales volume, i.e., number of sales, from the proposed method was approximately 10.16% better than that with the legacy method. We also conducted a pilot test of our approach by distributing a number of actual products for the summer season of 2015, and the result shows that compared to the legacy method of K/S, the inventory was distributed well by our method in accordance with store demand. Finally, the proposed method has now been completely implemented in the K/S's internal system for use in the upcoming packing and distribution season. The details of the validation results can be found in [5].

6 Conclusion

In this document, we describe the Business Analytics project jointly conducted by K/S and KAIST. The project has successfully developed a decision support system to assist the packing and distribution procedure at K/S. Throughout the project, the framework of the Business Analytics was first defined, and the roles and responsibilities of each team were clearly identified based on the framework. Then, multiple tasks were listed and performed by the joint team. The proposed packing and distribution approach includes a statistical data analysis that estimates the demand of stores for each product, the optimization of the box configurations and their distribution, and the IT implementation for sustainable use. The core technologies developed in the project were the optimization modeling and algorithm development. The box configuration of each box and the distribution quantity for the boxes to the stores were optimized by mixed integer programming. The proposed method was validated with simulation and actual tests in the stores. As a result, the proposed method showed significant effect, and K/S decided to implement it within their internal IT system.

The financial benefit delivered by the project is still under investigation. Based on the simulation result and on-site tests, we project that the proposed packing and distribution will improve sales by 5% 10% in terms of revenue. From the cost-saving viewpoint, we estimate that costs related to the man-hour working time for determining the configuration, the boxes, and shipping and handling will be significantly reduced. The unquantifiable contribution of this project is also very significant. The project demonstrates how advanced data-driven methods and algorithms can be incorporated into a traditional retail fashion business. It proves that in the modern data-driven society, a high-technology company is not defined by its product but rather by how it handles its operations. Mr. J.H. Jang, the Lead Manager of the Big Data Analytics Team, stated that "this project showed how the scientific method can improve the operation and provided the direction of the Big Data Analytics Team".

Moreover, this project has been an example of successful academic-industry collaboration deriving actual tangible results. Often, academic researchers find topics for research from other academic literature or come up with hypothetical imaginary topics in the hope that these kinds of problems will be valuable to industry. However, the KAIST researchers identify multiple topics that are not known to academia but which are worthy of further investigation. The authors are also currently working on an academic paper presenting the optimization algorithm they developed for this project.

Finally, this packing and distribution problem is common across the retail fashion industry. To our best knowledge, few retail fashion companies use logical methods for the process. The process, model, and algorithm developed in this project can be further developed as a service or software solution. We discovered three patents (two applications and one awarded patent) for solution algorithms of the optimization problem similar to what we constructed [4,6,7]. Among these patents, two are from the Oracle Corporation [6,7] and one is from the SAS

Institute [4]. However, we found that there is still room for improvement in the algorithms presented in these patents.

Appendix

Box assortment optimization model

The optimization model determines the number and contents of the box configurations and their allocation to the stores to minimize overstocking and understocking. The demand for items in each store is given by a multiple regression model. Because we know the maximum demand for each item among all stores and the capacity of the box is finite, it is theoretically feasible to generate a pool of all possible box configurations by selecting numbers between zero and the maximum demand for each item and making a combination of them as a box configuration, only if the sum of the number of items in a combination satisfies the capacity. In this way, a set of possible box configuration is given.

When the box configurations and their assignments are established in K/S, several managerial and operational requirements need to be met. First, a box only contains items with an identical product type, style, and color, but different sizes. For example, for such an item with five different sizes, a box can contain two "Small"-sized items, five "Medium"-sized items, and three "Large"-sized items because the manufacturer prefers to pack items of the same product type, style, and color at one time unless the finished products are waiting until changes in production setup and raw materials are needed. Additionally, the manufacturers of the items might be different even if their product types and styles are the same but their colors are different. Second, the following are constrained: the number of different box configurations, the maximum and minimum quantities of items in a box, i.e. capacity, the maximum and minimum number of boxes a store receives, the maximum number of boxes, and the upper bound on overstocking.

Indices

S : set of stores ($s \in S$);
I : set of items ($i \in I$);
C : set of possible box configurations ($c \in C$)

Parameters

d_{is} : demand of item i in store s;
c_{bi} : integer number of item i in box configuration b;
α_{is} : understocking penalty of item i in store s;
β_{is} : overstocking penalty of item i in store s;
δ_{is} : upper bound on overstocking of item i in store s;
NB : number of different box configurations;
N_s : minimum number of boxes store s receives;
M_s : maximum number of boxes store s receives;
T : maximum number of boxes

Decision Variables
x_{bs} : number of box configuration b allocated to store s;
y_b : binary variable, which is 1 if box configuration b is used and 0 otherwise;
u_{is} : understocking of item i in store s;
o_{is} : overstocking of item i in store s

Objective
$$\sum_{s\in S}\sum_{i\in I}(\alpha_{is}u_{is}+\beta_{is}o_{is})$$
Constraints
$$\sum_{b\in B} c_{bi}x_{bs}-o_{is}+u_{is}=d_{is}\quad \forall i\in I, s\in S$$
$$\sum_{b\in B} x_{bs}\geq N_s\quad \forall s\in S$$
$$\sum_{b\in B} x_{bs}\leq M_s\quad \forall s\in S$$
$$\sum_{b\in B} y_b\leq NB$$
$$\sum_{b\in B}\sum_{s\in S} x_{bs}\leq T$$
$$\sum_{s\in S} x_{bs}\leq \sum_{s\in S} M_s y_b\quad \forall b\in B$$
$$\sum_{s\in S} x_{bs}\geq y_b\quad \forall b\in B$$
$$x_{bs}\geq 0, \text{integer}\quad \forall b\in B, s\in S$$
$$y_b\in\{0,1\}\quad \forall b\in B.$$

Integrated Project Management

Algorithmical and Program Functions of Innovation Project Management in Technoloji Park

Elchan Ghuseynov, Javanshir Mammadov, and Shafahat Rahim Rahimov(✉)

Sumgait State University, Sumqayit, Azerbaijan
shafahat_61@mail.ru

Abstract. It was analyzed the present status of the innovation projects management problem in many technology parks of European, Asian and American countries. On the base of some of exists methods of option and creation process of innovation projects, there were defined the basis directions by innovation project management in technology park, also scientific problems of subject area and option of the best projects by means of flexible complex program system. In depend on the defined scientific problems in the paper, the process of managing an innovation project on the beginning stage of working in the departments of the technology park at higher educational school in Azerbaijan was considered. On the basis of the priority scientific directions and the scientific profiles of scientific technology park in the Sumgait State University (SSU) have been defined ways of decision a problem of an innovation project management from its registration till its option and input to the data base by an expert. On the base of the structural scheme of technology park in SSU, its scientific profiles, infrastructure and specialists, a new conception managing innovation projects in the technology park of SSU in Azerbaijan by means of complex flexible interface was offered. For executing all procedures of innovation project management on the stages its creation, experimental research, manufacture and business, special algorithm was worked out. By means of this algorithm, the block-scheme of managing functions, the program tool for development of new innovation project in the technology park beginning from the registration of the project till its assessment was created.

Keywords: Technology park · Flexible manufacture · Innovation project · Management · Higher educational school · Project assessment

1 Introduction

As known, creation of new innovation projects in the many science technology parks, Zouain [13] and Lamperti [7] considered the problems of science technology parks from its laboratory investigation, manufacture till economical process

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_134

in Brasilia organization is complex, difficult scientific-research, engineering, manufacturing and economical managing process. Traditional technology parks in of European, Asian and American countries solve own problem of innovation project management by means of the corporative connections between different departments of the technology park Volkonitskaia [12], Kirchberger and Pohl [6] considered the ways of decision of functions innovation project development in technology parks of different countries "without application of special software systems what do not enough provide efficiency of planning process of creation of innovation project. Application of such program will allow to realize some science-technical, collection of necessary information about the new project, its storage, choosing, expert analyzing and assessment. Analyze of the existed methods and ways of new innovation projects development Murzina [8] and Díez-Vial [4] considered international practice of innovation structure creation with economical knowledge for technology parks" shown that, there is not identify methodology for optimal choosing innovation project, its algorithmically and program providing, which would be allowed to support high economical efficiency and get great financial results for the budget of technology park.

Analyze of the problem by innovation projects option for them scientific research, manufacture and commercial process shown that the date problem solved without complex system application on a level of some experts solution after presentation of projects. In this connection, for effective solution of the best innovation project option under the complex system there were determined problems of researching by the following directions:

- Determination of the basic scientific profiles in the technology park at Sumgait State University (SSU) which can provide option of the necessary innovation projects for development them in the parts of science, manufacture and business of technology park;
- Creation of new conception of managing innovation projects in the technology park of SSU in Azerbaijan which can provide realization of option the best innovation project in the complex system for efficiency development of technology park for short time;
- Development of algorithmically and program tools for providing management of innovation projects in the scientific technology park of SSU which can provide executive menu procedures in corporative network system of technology park "Rafael Avila Faraco [9] considered a problem of creation and using social networks and knowledge transfer in technological park companies in Brazil, what is solved only forming data base in the internal system and therefore procedure of the best innovation project is done intuitive".

In depended on the determined scientific problems, the purpose of the paper defined as follows: it is necessary to work out universal algorithm and program which would be allowed to create innovation projects in technology parks with different scientific profiles.

This material was written by means of the executed sciences researches at the department of "Information technology and programming" of Sumgait State University, Azerbaijan Republic.

2 Determination of the Basic Scientific Profiles in the Technology Park at SSU

At present in Azerbaijan Republic, different innovations programs in many application areas are realized. Specially, in many high educational schools of Azerbaijan, as product of innovation technology, new technology parks are created. Traditionally at first stage of technology park creation, a basic problem is option of the necessary scientific profiles in the universities, as they have different specifies of education and different balance of scientific potentials-experts "Correia and Gomes [3] considered a problem of forming potentialities and limits for the local economic and innovative development of technology parks located in the Northeast region of Brazil, where the problems of scientific directions are limited owing to little application of intellectual information systems in different areas".

As an object of investigation is SSU, where scientific technology park must be created, then considering specifics of specialties of this universities and more development scientific directions of SSU, the basics profiles of technology park had been chosen:

- Application of intelligence information systems in different area of sciences (practically in medicine, biology, physic and other areas);
- Investigation of physical and chemical process and theirs application in manufacture;
- Application of modern commercial methods and systems for efficiency realization of technology park.

The first scientific profile of SSU technology park is one of priorities directions in technology park, as application of progressive information technology, intelligence systems and program tools provide computing functions of many medical, biology, engineering and others important technical problems for citizen. Option of this scientific profile was justified by means of the formed scientific base which organized scientists of SSU, their scientific works which they conduct about 50 years. Under scientific leader of Rafik Aliyev, a famous in world scientific circles by development of fuzzy logic theory, was organized the scientific school of scientists of SSU and theirs works had been implemented in flexible manufacture systems in the metallurgy enterprise of Sumgait city. At present the scientists as doctorates and professors work in SSU by own specialty. At present 4 the laboratories of the departments of faculty "Engineering" provide all education and sciences works of students and teachers.

The second scientific profile of SSU scientific technology park is multi-scientific area which is connected theoretical and experimental investigations, also implementation of results in manufacture process. Investigation on this directions conduct scientists of physical and chemical faculties which have 4 the scientific laboratories and some special devices for experiments, are founded in the scientific part of SSU.

The third scientific profile of SSU scientific technology park (SSU STP) is one of the basis profile, as that profile must provide economical realization of two profiles of SSU scientific technology park in whole. Application of modern commercial methods and systems of management and marketing provide all way economical control of innovation project beginning from an idea appearance, its including to the technology park system, presentation, theoretical and practical researching in laboratory, optimal option, embedding in the flexible manufacture and sale an innovation product in the internal or external market.

On the base of the explained scientific profiles of the technology park, we can mark that the existed laboratories for experimental researching in the first and second profiles are science C research part of the technology park, and in future they will have to be able to work by connection with business incubator and flexible manufacture.

3 Managing Innovation Projects in the Technology Park of SSU

Efficiency of working the experimental laboratories by 3 scientific profiles depends on conception of managing innovation projects in the technology park, as some of this projects have not the necessary text, graphical, animation and video information for expert analyze, high technical and economical characteristics, and also possibility of them making in the flexible manufacture system owing to lack of some equipments and materials "Prencipe [10] considered a problem of realization of innovation process in University Spin-offs" what is shown only some innovation operation by economical management and marketing. In this connection, solution of the problem of new conception creation of managing innovation projects in the technology park of SSU in Azerbaijan is important, scientific-actuality researching problem.

In accordance with the offered conception of managing innovation project in technology park, using principals of flexibleness and openness of working the automation system, the way of managing innovation project is represented by means of the following scheme:

- Input and presentation of scientist user idea with the necessary data of own user;
- Expert analyze of project annotation;
- Experimental investigation in the laboratory and making a laboratory exemplar of the project;
- The project embedding in flexible manufacture and its output Elchan Ghuseynov, Javanshir Mammadov, Gulnara Genjeliyeva [5] considered a problem of application of flexible industrial park in the scientific technology park of Sumgait State University of Azerbaijan where the problems of innovation project option and embedding in the manufacture are not considered.

4 Algorithmically and Program Tools for Providing Management of Innovation Projects in the Technology Park of SSU

Functions of management departments of SSU STP and development, commercial way of innovation project are provided by means of the algorithm scheme shown in the Fig. 1. The Procedures of innovation project management from the beginning registration to its embedding into manufacture are represented on the base of the following stages:

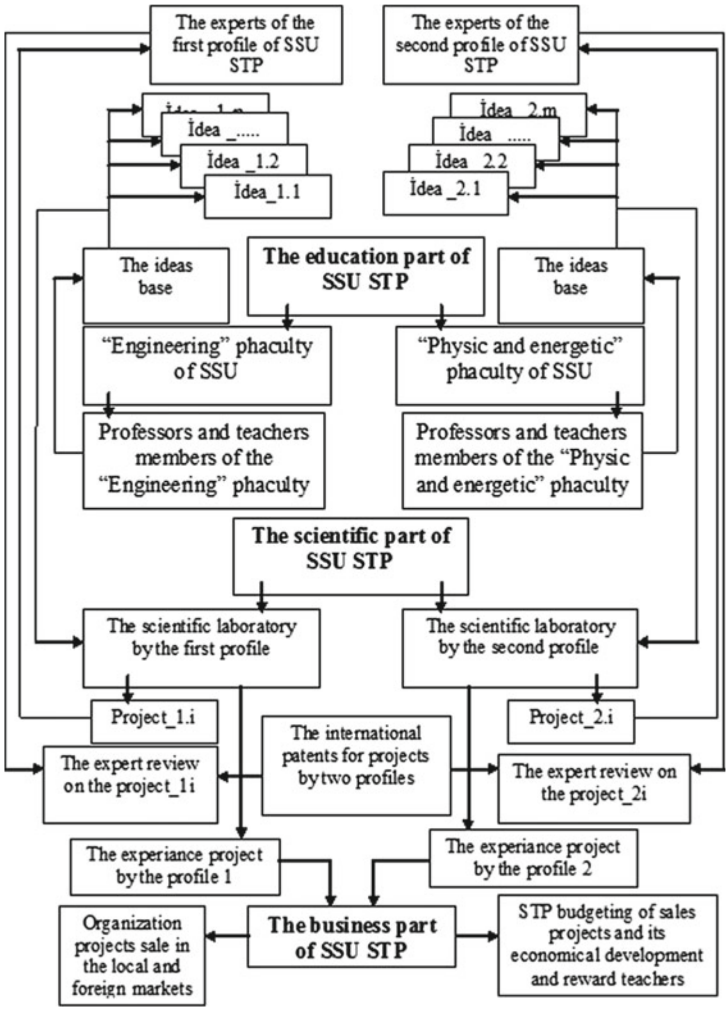

Fig. 1. The structural scheme of SSU STP with innovation project relocation

(1) The professors and teachers, also students of SSU present own ideas in the global level of the system of registration. At first they input the registration information to two the panels “Teacher registration” or “Student registration”. An User of the system inputs his data and information about himself project (name, purpose of the project, short idea of the project-annotation) which is saved in the “Annotation” panel for future familiarization of this project by an expert. Also on the first stage for careful analysis in this part of the system, the panel of “Prototipe of a project” is used.
(2) During a week, different experts in autonomy form control the registration and annotation informations. On the base of standart form of the new project receiving, a decision about acceptance or rejection of the project are given. Procedures of an expert are executed and saved in the panel “Expert review”.
(3) For carefully presentation of the projects, the projects are represented to the experts in the determined time. Actuality, newness, modernity, high engineering decision and economical efficiency of the projects are the basis of choosing the project for its first making as an experimental form in the laboratory condition in accordance of the scientific profiles.
(4) In the experimental laboratory the best project is given for its constructor design, material option, working out the first experience form of the project and control of its mechanical, automation and others functions. At this stage the basics technology characteristics of the project are defined and then its quality level, the better data in difference of the prototypes ones. The documents must be official formed by the status leader of the laboratory.
(5) All information of the designer is saved in his data base (in the part of “Project data base”).
(6) The commercial department determines the basis of rules and the demanded in the external and internal market and economical efficiency of the project is computed. Čirjevskis [11] presented dynamically “signature business model” which can provide durable competitive advantage at commercial procedures of business incubator of technology park. “For presentation of the project to the local and international markets Amit and Zott [1] worked out the model for application in business process of innovation project by science and technology connection” in “Presentation of the new project” department, the view of the 2, 3-measure pictures, animations, video and technical characteristics are saved in the data base. The managers by the scientific profiles chooses the clients and some information about them saves in the “Client firm”. Between the scientific technology park and the firm, official meeting is executed by means of this department. Therefore the official documents are prepared.
(7) The procedures of project documents presentation are realized for the experts in reality. On that stage all the documents registered by the expert are sent to the flexible manufacture where a process of the project making is executed.

The structural scheme of SSU STP with innovation project management is given in Fig. 1. Also the functional connections between the jobs departments of SSU STP are shown.

The represented text and block-scheme algorithms allow to develop a program for checking, choosing a project way in the scientific technology park at the Sumgait State University. In this connection, structural scheme of an innovation project management is proffered on the base of this algorithms (Fig. 2). The offered scheme consists of three blocks where each one works in different rooms, beginning from the room of projects registration, the room of the saved data base and the experts center.

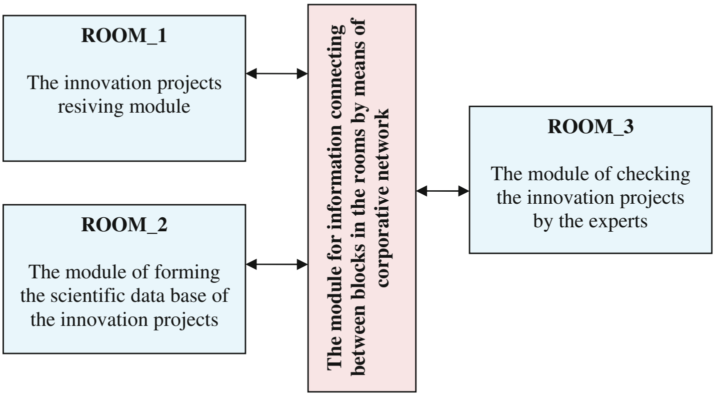

Fig. 2. Structural scheme of an innovation project management under corporative network of technology park

The innovation projects receiving module provides presentation of the basis data about authors, title and aim of a project, receiving date and time of project in the system, annotations of the project and its figure. The module of forming the scientific data base of the innovation projects provides automatically saving all data about a innovation project in the data base. Also in this database like table form, the certification by application area is executed. For assessment of every project which was marked in the system, an expert by corresponding application area checks his innovation project and gives a mark by the development project.

Checking one project can exist by some experts in this application area. Information about assessment of a project is sent to an author of the project. In this message answer can be by some versions: accepted; accepted, but must be corrected; rejected.

5 Development of Program Tool for Expert Assessment of Innovation Project in Scientific-Technoloji Park

In corresponding to functions of each the module, the program for expert assessment of innovation project (EAIP) Carver et al. [2] considered the problem of development of special Issue on software engineering technology and its applications corporative system of manufacture what is shown some program procedures of designing innovation project in corporative network is worked out (Fig. 3). The program for EAIP is worked by the following stages:

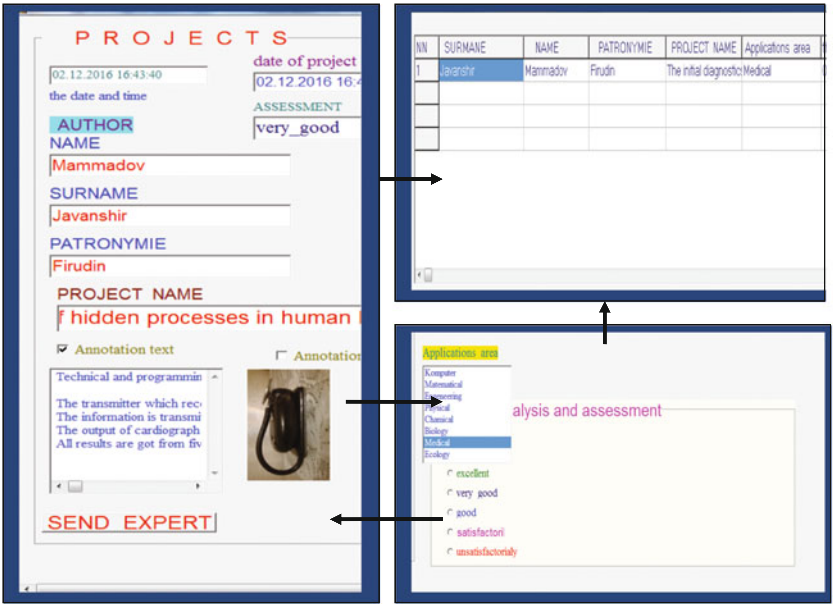

Fig. 3. The scheme of program functions in the EAIP

(1) At first stage a designer inputs his the data of authors names, title and aim of a project, annotations of the project, the reciving date and time of project into the system.
(2) On second stage all the data by the project are saved in the data base management system as a table view.
(3) In third stage an expert checks information about the designer of a project and begins to read and looking annotation of the project. After checking the project, an expert assessment of this project gives by marks where a result outputs in the system of EAIP and sends to the designer.

6 Conclusions

On the base of the made investigation by innovation project management, the following results were got:

(1) In corresponding to the aim of the investigation problem, the algorithm procedure for management and assessment of an innovation project in scientific-technopark was offered.

(2) The block-scheme of innovation management project, forming data base of projects and assessment of a project by an expert was worked out.
(3) On the base of algorithm procedures of innovation project management, the program operations with project registration; its author and text names; text and graphical annotations; sending all information to expert by different scientific areas; saving the neccessary data in the data base; expert assessment of innovation project were developed.

Abstract. In this paper, we propose two stage fuzzy DEA models with undesirable outputs to evaluate banking system. The banking system is divided to two subsystems: production stage and profit stage. In the model, two kinds of assumptions (constant returns to scale and variable returns to scale) are considered, and fuzzy parameters are adopted to describe the uncertain factors. Chance constrained operator is used to handle the proposed model and equivalent transformations are given to make the models solvable. We illustrate and validate the proposed models by evaluating 16 Chinese commercial banks. Some discussions are also presented to show the differences and advantages of the models.

Keywords: Two-stage DEA · Banking system · Undesirable outputs · Constant returns to scale · Variable returns to scale

1 Introduction

Efficiency is particularly illustrated in the comprehensive competitiveness of commercial banks. In terms of investment, supervision or independent operation, it is of great significance to evaluate the efficiency of commercial banks. Data Envelopment Analysis (DEA), a non-parametric mathematical programming approach to evaluate group of Decision Making Units (DMUs) with comparative efficiency, is widely applied to analyze the efficiency in the process of banking operation [1,4,5,12,13,17].

It seems like the traditional DEA model treats DMU as "black box", which is unable to explain the internal structure inside the "black box". In a banking system, taking deposits and making loans are the main activities. Some banks may have greater advantage in taking deposits, but perform not as well in making loans to realize profit. Hence, it is better to consider the banking system as a two-stage process. We should evaluate not only each stage, but also the whole system.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_135

In the banking system, there are desirable outputs, like the total deposit during the first stage, and the profit during the second stage. But in the operational process, banks want to get rid of the risk exposure and non-performing loans/assets, which are undesirable outputs. Scheele [15] concluded that the undesirable outputs could be handled by direct and indirect approaches. In indirect approaches, the values of the undesirable outputs are converted to a monotone decreasing function, and then we can treat the undesirable outputs as the other normal desirable outputs. Direct approaches avoid data transformation and incorporate the undesirable outputs as the inputs directly into the DEA models. In Hu's work [20], undesirable outputs were treated as the inputs, and the less of the undesirable outputs (inputs), the better. A new two-stage DEA model with the undesirable outputs to measure the slacks-based efficiency of Chinese commercial banks during years 2008–2012 was developed in [2], where the banking operation process of each bank was divided into a deposit generation stage and a deposit utilization stage. However, they neglected the undesirable outputs of the deposit generation stage.

In recent years, scholars have already realized that some inputs and outputs are imprecise in real life cases. Conventional DEA models used the accurate inputs and outputs data, which may not fit in the real world cases. To deal with the imprecise data, the fuzzy theory was introduced in DEA to become fuzzy DEA.

According to Hatami-Marbini [7], the methods of handling the fuzzy DEA can be divided into four types: (i) The tolerance approach [16]; (ii) The α-level based approach [8,11]; (iii) The fuzzy ranking approach [6]; and (iv) The possibility approach [9,10,19]. Puri [14] presented a fuzzy DEA model with undesirable fuzzy outputs, giving a numerical illustration of the banking sector in India using fuzzy input/output data for the period 2009–2011, but the internal structure of banking operation system was not taken into account. Wanke [18] developed new Fuzzy-DEA models to measure the impact of each model on the efficiency scores and to identify the most relevant contextual variables of efficiency by using bootstrap truncated regressions with fixed factors.

In this paper, we propose a two stage fuzzy DEA model with undesirable outputs to evaluate 16 China's commercial banks. The remainder of this study is organized as follows. Section 2 presents problem statement. Section 3 develops three kinds of two-stage DEA models with undesirable outputs. Section 4 discusses the solution method. Section 5 gives a case study with 16 banks in China. Finally, conclusions are given in the last section.

2 Problem Statement

The efficiencies of several banking systems (DMUs) are under evaluation, and each DMU, indexed by $j = 1, \cdots, J$, has two sub-stages: production stage and profit stage. During the production stage, funds are collected from depositors while consuming resources such as number of employees x_j^{NE}, fixed assets x_j^{FA}, operating expenses x_j^{OE} and number of institutions x_j^{NI}. Total deposits Z_j^{TD} is not only the desirable output of the production stage but also the input to

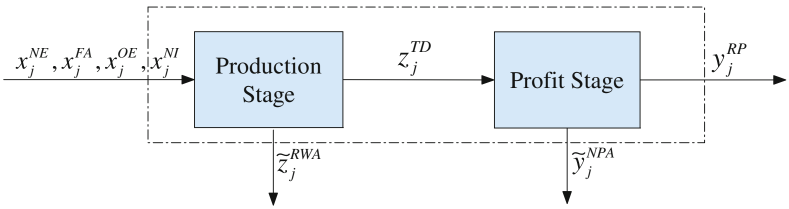

Fig. 1. Two-stage banking system

the profit stage. Total risk-weighted asset $\tilde{z}_j^{\mathrm{RWA}}$ is the undesirable output during the production stage. In the profit stage, deposits Z_j^{TD} are used to invest into other activities to get profits y_j^{RP}, but the undesirable output non-performing loans/assets $\tilde{y}_j^{\mathrm{NPA}}$ will also be produced. Because deposits collected during the production stage determines the investment decision in the profit stage, we model this banking system as a two-stage problem, which is shown in Fig. 1.

In practice, some data could be imprecise. Total risk-weighted assets refer to the sum of In-Balance-Sheet assets and Off-Balance-Sheet exposures, weighted according to different risk coefficients, respectively. The risk coefficients are affected by macroeconomic environment, current risk coefficient, exposure of bank, etc., which is difficult to ascertain. The non-performing loans/assets are loans with signs of difficulties to repay the loans principal and interest. It is different to ascertain whether the borrowers can repay the loans on time, which are affected by public policy, credit of the clients, actual situation of the clients, etc. Due to the variability of risk coefficients and the repayment ability of borrowers, we employ fuzzy numbers to describe the total risk-weighted assets and non-performing loans/assets.

Definition 1. [21] Let L(·), R(·) be two reference functions. If the membership function of fuzzy variable ξ has the following form:

$$\mu_\xi(x) = \begin{cases} L(\frac{m-x}{\alpha}), & x \le m, \alpha > 0 \\ R(\frac{x-m}{\beta}), & x \ge m, \beta > 0. \end{cases}$$

Then ξ is called an LR fuzzy variable denoted by $(m, \alpha, \beta)_{LR}$, where m is the central value of ξ, α, β are the left and right spreads respectively of ξ. And the $\gamma - cut(0 \le \gamma \le 1)$ for the LR fuzzy variable is:

$$\xi_\gamma = (m - L^{-1}(\gamma)\,\alpha, m + R^{-1}(\gamma)\,\beta), \gamma \in [0, 1].$$

3 Models

Charnes-Cooper-Rhodes (CCR) model assumes all the DMUs are Constant Returns to Scale (CRS) [3]. In some cases we also have Variable Returns to Scale (VRS). In this section, three kinds of DEA fuzzy models are developed for commercial banking system evaluation.

3.1 Fuzzy CCR DEA Model with Undesirable Outputs

When the banking system is considered as a "black box", then we formulate the CCR model as follows.

$$
\begin{aligned}
&\max\ h_0^{\mathrm{CCR}} = \frac{u_d y_0^{RP}}{\sum_{i=1}^{4} v_i x_{i0} + w_u \tilde{z}_0^{\mathrm{RWA}} + u_u \tilde{y}_0^{\mathrm{NPA}}} \\
&s.t. \begin{cases} \dfrac{u_d y_j^{RP}}{\sum_{i=1}^{4} v_i x_{ij} + w_u \tilde{z}_j^{\mathrm{RWA}} + u_u \tilde{y}_j^{\mathrm{NPA}}} \leq 1, \quad j = 1, \cdots, J \\ v_i, w_u, u_d, u_u \geq \varepsilon > 0, \end{cases}
\end{aligned} \tag{1}
$$

where v_i, w_u, u_d, and u_u are non-negative weights. ε is a small non-Archimedean number imposed for avoiding ignorance of any factor. $x_{ij}(i = 1, 2, 3, 4)$ represent $x_j^{NE}, x_j^{FA}, x_j^{OE}, x_j^{NI}$, respectively.

3.2 Two-Stage Fuzzy CRS DEA Model with Undesirable Outputs

Next we discuss the case when the banking system is divided into two stages. Suppose all the DMUs are CRS, we develop models (2) and models (3) to calculate the efficiencies of the first stage and the second stage.

$$
\begin{aligned}
&\max h_0^{\mathrm{CRS}^1} = \frac{w_d z_0^{TD}}{\sum_{i=1}^{4} v_i x_{i0} + w_u \tilde{z}_0^{\mathrm{RWA}}} \\
&s.t. \begin{cases} \dfrac{w_d z_j^{TD}}{\sum_{i=1}^{4} v_i x_{ij} + w_u \tilde{z}_j^{\mathrm{RWA}}} \leq 1, j = 1, \cdots, J \\ v_i, w_d, w_u \geq \varepsilon > 0, \end{cases}
\end{aligned} \tag{2}
$$

and

$$
\begin{aligned}
&\max h_0^{\mathrm{CRS}^2} = \frac{u_d y_0^{RP}}{w_d z_0^{TD} + u_u \tilde{y}_0^{\mathrm{NPA}}} \\
&s.t. \begin{cases} \dfrac{u_d y_j^{RP}}{w_d z_j^{TD} + u_u \tilde{y}_j^{\mathrm{NPA}}} \leq 1, j = 1, \cdots, J \\ w_d, u_d, u_u \geq \varepsilon > 0. \end{cases}
\end{aligned} \tag{3}
$$

Then we use ω_1 and ω_2 to represent the weights of the first stage and the second stage, and the formulations are as follows.

$$
\omega_1 = \frac{\sum_{i=1}^{4} v_i x_{ij} + w_u \tilde{z}_j^{\mathrm{RWA}}}{\sum_{i=1}^{4} v_i x_{ij} + w_u \tilde{z}_j^{\mathrm{RWA}} + w_d z_j^{TD} + u_u \tilde{y}_j^{\mathrm{NPA}}}, \tag{4}
$$

and

$$
\omega_2 = \frac{w_d z_j^{TD} + u_u \tilde{y}_j^{\mathrm{NPA}}}{\sum_{i=1}^{4} v_i x_{ij} + w_u \tilde{z}_j^{\mathrm{RWA}} + w_d z_j^{TD} + u_u \tilde{y}_j^{\mathrm{NPA}}}. \tag{5}
$$

Then the two-stage fuzzy CRS DEA model with undesirable can be proposed as Eq. (6).

$$\max\ h_0^{\mathrm{CRS}} = \omega_1 h_0^{\mathrm{CRS}^1} + \omega_2 h_0^{\mathrm{CRS}^2} = \frac{w_d z_0^{TD} + u_d y_0^{RP}}{\sum_{i=1}^{4} v_i x_{i0} + w_u \tilde{z}_0^{\mathrm{RWA}} + w_d z_0^{TD} + u_u \tilde{y}_0^{\mathrm{NPA}}}$$
$$s.t. \begin{cases} \dfrac{w_d z_j^{TD}}{\sum_{i=1}^{4} v_i x_{ij} + w_u \tilde{z}_j^{\mathrm{RWA}}} \le 1, \quad j = 1, \cdots, J \\ \dfrac{u_d y_j^{RP}}{w_d z_j^{TD} + u_u \tilde{y}_j^{\mathrm{NPA}}} \le 1, \quad j = 1, \cdots, J \\ v_i, w_d, w_u, u_d, u_u \ge \varepsilon > 0. \end{cases} \tag{6}$$

3.3 Two-Stage Fuzzy VRS DEA Model with Undesirable Outputs

Often, we also face VRS. In order to consider the efficiency of the banks in the case of VRS, we propose the two-stage fuzzy VRS model as follows.

$$\max\ h_0^{VRS} = \frac{w_d z_0^{TD} + \mu_1 + u_d y_0^{RP} + \mu_2}{\sum_{i=1}^{4} v_i x_{i0} + w_u \tilde{z}_0^{RWA} + w_d z_0^{TD} + u_u \tilde{y}_0^{NPA}}$$
$$s.t. \begin{cases} \dfrac{w_d z_j^{TD} + \mu_1}{\sum_{i=1}^{4} v_i x_{ij} + w_u \tilde{z}_j^{RWA}} \le 1, \quad j = 1, \cdots, J \\ \dfrac{u_d y_j^{RP} + \mu_2}{w_d z_j^{TD} + u_u \tilde{y}_j^{NPA}} \le 1, \quad j = 1, \cdots, J \\ v_i, w_d, w_u, u_d, u_u \ge \varepsilon > 0 \end{cases} \tag{7}$$

If $\mu > 0$, then the DMU has increasing returns to scale; if $\mu = 0$, then the DMU has constant returns to scale; if $\mu < 0$, then the DMU has decreasing returns to scale.

4 Solution Method

In this section, we propose a solution to the two-stage DEA models with fuzzy parameters.

4.1 Solution Method Equivalent Two-Stage CCR DEA Model

First, applying the Charnes-Cooper transformation (C-C transformation), the two-stage model (8) can be converted into the following linear program, and the efficiency of DMU_0 can be calculated. The optimal efficiency g_j^{CCR} is equal to the optimal efficiency h_j^{CRS}.

$$\max\ g_0^{CCR} = u_d y_0^{RP}$$
$$s.t. \begin{cases} u_d y_j^{RP} - \sum_{i=1}^{4} v_i x_{ij} - w_u \tilde{z}_j^{RWA} - u_u \tilde{y}_j^{NPA} \le 0, \quad j = 1, \cdots, J \\ \sum_{i=1}^{4} v_i x_{i0} + w_u \tilde{z}_0^{RWA} + u_u \tilde{y}_0^{NPA} = 1 \\ v_i, w_u, u_d, u_u \ge \varepsilon > 0. \end{cases} \tag{8}$$

Because of the fuzzy parameters, we use chance constrained operator to handle model (8), and we get model. (9).

$$\max\ g_0^{\mathrm{CCR}} = u_d y_0^{RP}$$
$$s.t.\begin{cases} \mathrm{Pos}\left\{u_d y_j^{RP} - \sum_{i=1}^{4} v_i x_{ij} - w_u \tilde{z}_j^{\mathrm{RWA}} - u_u \tilde{y}_j^{\mathrm{NPA}} \le 0\right\} \ge \gamma, \quad j = 1, \cdots, J \\ \mathrm{Pos}\left\{\sum_{i=1}^{4} v_i x_{i0} + w_u \tilde{z}_0^{\mathrm{RWA}} + u_u \tilde{y}_0^{\mathrm{NPA}} \ge 1\right\} \ge \gamma \\ \mathrm{Pos}\left\{\sum_{i=1}^{4} v_i x_{i0} + w_u \tilde{z}_0^{\mathrm{RWA}} + u_u \tilde{y}_0^{\mathrm{NPA}} \le 1\right\} \ge \gamma \\ v_i, w_u, u_d, u_u \ge \varepsilon > 0 \end{cases} \tag{9}$$

Theorem 1. *[21] Given two LR fuzzy variables* $\xi_1 = (m_1, \alpha_1, \beta_1)$, $\xi_2 = (m_2, \alpha_2, \beta_2)$, *where* m *are the central values; and* α *and* β *are the left and the right spreads respectively. Then we have:*

$$k\xi_1 = (km_1, k\alpha_1, k\beta_1), k > 0$$
$$\begin{cases} \xi_1 + \xi_2 = (m_1 + m_2, \alpha_1 + \alpha_2, \beta_1 + \beta_2) \\ \xi_1 - \xi_2 = (m_1 - m_2, \alpha_1 + \beta_2, \beta_1 + \alpha_2) \end{cases}$$
$$Pos\{\xi_1 \ge \xi_2\} \ge \gamma \Leftrightarrow m_{1\gamma}^R \ge m_{2\gamma}^L,$$

where k *is a real number,* $\gamma(0 \le \gamma \le 1)$ *are the possibility values,* $m_{1\gamma}^R$ *is the right end point of* $\gamma - cut$ *of* ξ_1*, and* $m_{2\gamma}^L$ *is the left end point of* $\gamma - cut$ *of* ξ_2*.*

According to Theorem 1, model. (9) can be transformed into model. (10).

$$\max\ g_0^{CCR} = u_d y_0^{RP}$$
$$s.t.\begin{cases} u_d y_j^{RP} - \sum_{i=1}^{4} v_i x_{ij} - (w_u (z_j^{RWA})_m + u_u (y_j^{NPA})_m) - (1-\gamma)(w_u (z_j^{RWA})_\beta + u_u (y_j^{NPA})_\beta) \le 0, \\ j = 1, \cdots, J \\ \sum_{i=1}^{4} v_i x_{i0} + w_u (z_0^{RWA})_m + u_u (y_0^{NPA})_m + (1-\gamma)(w_u (z_0^{RWA})_\beta + u_u (y_0^{NPA})_\beta) \ge 1 \\ \sum_{i=1}^{4} v_i x_{i0} + w_u (z_0^{RWA})_m + u_u (y_0^{NPA})_m - (1-\gamma)(w_u (z_0^{RWA})_\alpha + u_u (y_0^{NPA})_\alpha) \le 1 \\ v_i, w_u, u_d, u_u \ge \varepsilon > 0 \end{cases} \tag{10}$$

After getting the optimal solutions $\mathrm{v}_r^*, \mathrm{w}_u^*, u_d^*$ *and* u_u^**, the CCR DEA efficiency* g_0^{CCR} *of the evaluated whole system can be obtained.*

4.2 Equivalent Two-Stage CRS and VRS DEA Models

Similarly, models (6) and (7) can be converted into models (11) and (12):

$$\max\ \mathrm{g}_0^{\mathrm{CRS}} = w_d z_0^{TD} + u_d y_0^{RP}$$
$$s.t. \begin{cases} w_d z_j^{TD} - \sum_{i=1}^{4} v_i x_{ij} - w_u (z_j^{\mathrm{RWA}})_m - (1-\gamma) w_u (z_j^{\mathrm{RWA}})_\beta \leq 0, j = 1, \cdots, J \\ u_d y_j^{RP} - w_d z_j^{TD} - u_u (y_j^{\mathrm{NPA}})_m - (1-\gamma) u_u (y_j^{\mathrm{NPA}})_\beta \leq 0, j = 1, \cdots, J \\ \sum_{i=1}^{4} v_i x_{i0} + w_d z_0^{TD} + w_u (z_0^{\mathrm{RWA}})_m + u_u (y_0^{\mathrm{NPA}})_m + (1-\gamma)(w_u (z_0^{\mathrm{RWA}})_\beta + u_u (y_0^{\mathrm{NPA}})_\beta) \geq 1 \\ \sum_{i=1}^{4} v_i x_{i0} + w_d z_0^{TD} + w_u (z_0^{\mathrm{RWA}})_m + u_u (y_0^{\mathrm{NPA}})_m - (1-\gamma)(w_u (z_0^{\mathrm{RWA}})_\alpha + u_u (y_0^{\mathrm{NPA}})_\alpha) \leq 1 \\ v_i, w_d, w_u, u_d, u_u \geq \varepsilon > 0, \end{cases} \tag{11}$$

$$\max\ \mathrm{g}_0^{VRS} = w_d z_0^{TD} + \mu_1 + u_d y_0^{RP} + \mu_2$$
$$s.t. \begin{cases} w_d z_j^{TD} - \sum_{i=1}^{4} v_i x_{ij} - w_u (z_j^{\mathrm{RWA}})_m - (1-\gamma) w_u (z_j^{\mathrm{RWA}})_\beta + \mu_1 \leq 0, j = 1, \cdots, J \\ u_d y_j^{RP} - w_d z_j^{TD} - u_u (y_j^{\mathrm{NPA}})_m - (1-\gamma) u_u (y_j^{\mathrm{NPA}})_\beta + \mu_2 \leq 0, j = 1, \cdots, J \\ \sum_{i=1}^{4} v_i x_{i0} + w_d z_0^{TD} + w_u (z_0^{\mathrm{RWA}})_m + u_u (y_0^{\mathrm{NPA}})_m + (1-\gamma)(w_u (z_0^{\mathrm{RWA}})_\beta + u_u (y_0^{\mathrm{NPA}})_\beta) \geq 1 \\ \sum_{i=1}^{4} v_i x_{i0} + w_d z_0^{TD} + w_u (z_0^{\mathrm{RWA}})_m + u_u (y_0^{\mathrm{NPA}})_m - (1-\gamma)(w_u (z_0^{\mathrm{RWA}})_\alpha + u_u (y_0^{\mathrm{NPA}})_\alpha) \leq 1 \\ v_i, w_d, w_u, u_d, u_u \geq \varepsilon > 0. \end{cases} \tag{12}$$

By solving models (11) and (12), the CRS and VRS DEA efficiencies of the evaluated whole system, $\mathrm{g}_0^{\mathrm{CRS}}$ and $\mathrm{g}_0^{\mathrm{VRS}}$, can be obtained. Also the efficiencies of each sub-stage $\mathrm{g}_0^{\mathrm{CRS}^1}$ ($\mathrm{g}_0^{\mathrm{VRS}^1}$) and $\mathrm{g}_0^{\mathrm{CRS}^2}$ ($\mathrm{g}_0^{\mathrm{VRS}^2}$) can be obtained.

5 Case Study

In this section, we evaluate the efficiencies of the top 16 Chinese banks: Bank Of China (BOC), Agricultural Bank of China (ABC), Industrial and Commercial Bank of China (ICBC), China Construction Bank (CCB), Bank of Communications (BCM), China Citic Bank (CNCB), Ping An Bank (PAB), Hua Xia Bank (HXB), China Everbright Bank (CEB), China Industrial Bank (CIB), China Merchants Bank (CMB), Bank Of Ningbo (NBB), Bank of Nanjing (NJB), Bank of Beijing (BJB), Shanghai Pudong Development Bank (SPDB), and China Minsheng Banking (CMSB).

5.1 Data

Table 1 presents the data of the inputs and outputs of the selected 16 Chinese commercial banks in 2015.

5.2 Results

Based on the data in Table 1, first we set the decision-makers' confidence levels for the two stages as $\gamma = 0.9$, then the efficiencies of each bank in different circumstances can be produced after solving two-stage fuzzy CCR, CRS, and VRS DEA models by LINGO, respectively. The results are shown in Tables 2 and 3. And Fig. 2 compares the system efficiencies of 16 commercial banks based on the proposed three kinds of models.

Table 1. Data

Bank	Number of employees (×100)	Fixed assets (100 million RMB)	Operating expenses (100 million RMB)	Number of institutions (×10)	Total deposits (10 billion RMB)	Total risk-weighted assets (10 billion RMB)	Retained profits (100 million RMB)	Non-Performing loans/Assets (100 million RMB)

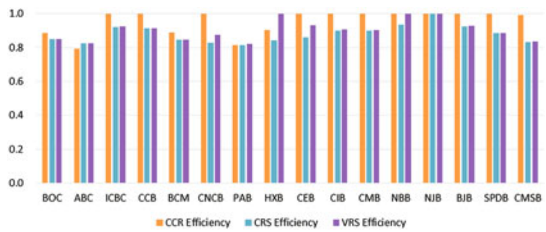

Fig. 2. Efficiencies based on CCR, CRS and VRS models

5.3 Comparison and Discussion

According to Table 2, ICBC, CCB, CNCB, CEB, CIB, CMB, NBB, BJB, SPDB, and CMSB are at the frontier when using traditional CCR DEA model evaluation, but the advantages are not maintained when using CRS DEA model. At the same time, the efficiencies of BOC, BCM, HXB, CMSB also decline in varying amounts. We conclude that often the CCR model may get high efficiency scores when the system is considered as a "black box" by using four inputs (Employees, Fixed assets, Operating expenses and Institutions) to produce three outputs (Total Risk-Weighted Assets, Retained profits and Non-Performing loans/Assets). However, the efficiencies may be not that high any more when the intermediates are taken into account. In other words, the traditional CCR model can only find weak effective system, but it is different to distinguish which banks are truly more efficient.

Table 2. Efficiencies based on two-stage CCR and CRS models

Bank	CCR DEA efficiency	CRS two-stage DEA efficiency			Bank	CCR DEA efficiency	CRS two-stage DEA efficiency		
		System	Stage 1	Stage 2			System	Stage 1	Stage 2
BOC	0.89	0.85	0.95	0.75	CEB	1	0.86	0.99	0.73
ABC	0.79	0.82	0.99	0.66	CIB	1	0.9	0.78	1
ICBC	1	0.92	1	0.84	CMB	1	0.9	1	0.8
CCB	1	0.91	1	0.82	NBB	1	0.94	0.75	1
BCM	0.89	0.85	0.96	0.73	NJB	1	1	1	1
CNCB	1	0.83	1	0.64	BJB	1	0.93	1	0.86
PAB	0.81	0.81	1	0.62	SPDB	1	0.89	0.92	0.85
HXB	0.9	0.84	1	0.69	CMSB	0.99	0.83	0.82	0.84

Table 3. Efficiencies under 2 return scale assumptions

Bank	CRS two-stage DEA efficiency	VRS two-stage DEA efficiency			Bank	CRS two-stage DEA efficiency	VRS two-stage DEA efficiency		
		System	Stage 1	Stage 2			System	Stage 1	Stage 2
BOC	0.85	0.85	0.95	0.75	CEB	0.86	0.93	1	0.74
ABC	0.82	0.82	0.99	0.66	CIB	0.9	0.91	0.8	1
ICBC	0.923	0.924	1	0.84	CMB	0.9	0.91	1	0.8
CCB	0.914	0.915	1	0.82	NBB	0.94	1	1	1
BCM	0.85	0.85	0.96	0.73	NJB	1	1	1	1
CNCB	0.83	0.88	1	0.65	BJB	0.926	0.93	1	0.86
PAB	0.81	0.82	0.97	0.63	SPDB	0.89	0.89	0.92	0.85
HXB	0.84	1	1	1	CMSB	0.834	0.835	0.82	0.85

By using two stage DEA model, we can further find out more discriminating DEA efficiencies for DMUs because of the stronger restriction on the production possible set. Although ICBC, CCB, CNCB, PAB, HXB, CMB and BJB are DEA efficient at the production stage, all the efficiencies of them at the profit stage are below 1. Similarly, CIB and NBB are inefficient at the profit stage while both of them are DEA efficient at the production stage. That is due to CCR DEA model neglects the internal interaction between the two stages. It also proves that model (6) reflects not only the efficiency of each stage, but also the efficiency of the banking system considering the relationship of two sub-stages.

Interestingly, the efficiency of ABC is improved by using model (6), which manifests ABC have a great advantage of the internal operational process. We find that the ratio of risk-weighted asset and inputs of the NJB is relatively small, the ratio of deposit and input is relatively high, and the input/output ratio of the NJB is at a reasonable level. Further analysis shows that both efficiency values of NJB in model (1) and model (6) are 1, i.e. they are both located in the frontier. This is consistent with our analysis, and policy makers can consider them as the industry benchmark.

If all the inputs of the bank have changed in the same proportion, this change will have an impact on the total outputs of the system. That is, the banking system will have VRS in the actual operation process. Based on above, we propose two kinds of models under the CRS and VRS assumptions. According to the model (7), the corresponding DEA efficiency can be obtained in Table 3. In Table 3, column 2 and column 3 are the two-stage banking system overall efficiency values obtained under the two assumptions, respectively.

It is found that HXB, NBB and NJB are DEA efficient not only in the whole bank system, but also in both of the two sub-stages. Compared with two-stage CRS DEA model, the efficiencies of two-stage VRS DEA increase slightly, and the number of points on the frontier also increases. Accordingly, we can draw a conclusion that commercial banks will have better performance in the VRS conditions. Therefore, in order to obtain a reasonable input/output combination to improve the performance of the system, the decision-makers can improve the scale of return by some actions (such as training staff to improve business efficiency, upgrading of banking equipment, improve its business throughput, and so on). In general, the difference between DEA efficiencies under the assumption of different scale returns is in a small range, which proves that the models we proposed have certain stability.

6 Conclusion

This paper explores a problem of efficiency evaluation of banking system under an uncertain environment. We consider the bank operating process consists of production stage and profit stage, and the two sub-stages of system are connected with each other by intermediate factor. Funds are collected from depositors in the production stage, which are used to invest into other activities to get profits in the profit stage. The undesirable outputs of both two sub-stages are treated as inputs. On this basis, we present two-stage fuzzy DEA models with undesirable outputs based on two different returns to scale.

In this paper, we have three main contributions as follows: First, based on two assumptions of returns to scale, we present the two-stage fuzzy CRS and VRS DEA models with undesirable output. The efficiency of the whole system is defined as the weighted sum of the efficiencies of two sub-stages, where the weights depend on the importance of the two stages. Second, considering the variability of risk coefficients and the repayment ability of borrowers, we apply fuzzy numbers to describe the total risk-weighted assets and non-performing loans/assets, which is closer to practice. Then we apply chance constrained operator to handle the fuzzy factors, and the objective is optimized subject to the chance constraints under certain confidence levels. Third, a case study and detailed comparison discussion are given by examining the top 16 China's commercial banks in 2015.

This paper focuses on the actual operation of commercial banks, considering the internal operational structure of commercial banks and its undesirable output in the process of operation. Through the application of the model, it is found that the model can better evaluate the input/output structure of the bank and has the ability of pointing out the direction to be improved.

Increasing Effect in Lodger Number of Hot Spring Hotel According to the Started Operation of Hokuriku Shinkansen

Takashi Oyabu[1](✉) and Junko Nakamura[2]

[1] Kokusai Business Gakuin College, Kanazawa, Japan
oyabu24@gmail.com
[2] Kanazawa Seiryo University, Kanazawa, Japan

Abstract. In Hokuriku district, economic efficiency is improved according to the stated operation of Hokuriku Shinkansen. However, there are some variations in the effect each area. It is necessary to utilize the effect into a future tourism strategy by indicating the effects. In this experiment, the effect is evaluated using the characteristics of the lodger number in nine spa areas of Hokuriku district. As a result, there is a larger effect as an area is near to a Shinkansen station and the increasing rate is over 30%. Other areas except Wajima area have the rates of 15 to 20%. The one for Wajima area is 33%. It keeps at a distance from Kanazawa which is the nearby station of Wajima area. Popular NHK television-drama (title is "Mare") was televised for end of March to September 2015 (half-year). Wajima area was the filming site. It is estimated that there is an effect over 10% as the filmed site. There is a large effect by connecting Hokuriku with Tokyo area by Shinkansen (high speed railway).

Keywords: Hokuriku Shinkansen · Hot spring · Lodger number · Economic effect

1 Introduction

Japan's population has entered into a decreasing phase due to the decreasing birthrate and aging population. Productive population also decreases remarkably, therefore a measure to put on the brake for the phenomenon is required. National budget is also tight due to the increasing of the cost of social security including medical expense as the society ages [2]. It is essential to build a policy which could create a new industry and put the brakes on the depopulation in a rural area. One of the regional-revitalization measures is "tourism industry". Human exchange is a basic policy to develop the tourism industry. The following measures are important in the exchange, namely information and transportation infrastructures [4].

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_136

Comfortable and express railway system (e.g. Shinkansen) had been desired in Hokuriku district (Fukui, Ishikawa and Toyama Prefectures) for 50 years. The newest section of the Hokuriku Shinkansen Line, between Nagano and Kanazawa, opened on March 14, 2015. The line was opened about fifty years after Tokaido Shinkansen Line started operations. The number of visitors was increased considerably due to the operation in Kanazawa City (Shinkansen effect), which was the prefectural capital of Ishikawa. The occupancy rate for hotels was over 85%. There are nine main spa areas mainly in Hokuriku district, namely Awara, Yamanaka, Yamashiro, Katayamatsu, Awazu, Yuwaku, Wakura, Wajima and Unazuki. The number of lodgers has increased nearly 15 to 30% in the areas. The areas except for Unazuki (Toyama Prefecture) and Yuwaku (Kanazawa City) take one hour and half by bus from each Shinkansen station. Unazuki and Yuwaku take within thirty minutes by car or train. The nearby station of Unazuki is Kurobe-Unazuki-Onsen and the one for Yuwaku is Kanazawa. The number of visitors for both spa areas increased about 30% and the start of the operation significantly affected the number for both areas. It is desirable for the ripple effect to affect whole areas. The mass media reported that the number increased in whole spa areas. It is necessary to investigate the effect and apply the survey result to the future strategy.

Outline of ripple effect can be known by examining the monthly variability of lodger number in each spa area and it is possible to determine the date of various kinds of providing events [1,3,11]. Moreover, it is helpful to construct the effective strategy that increases the guest number. The variability of lodger number in nine spa areas of Hokuriku District for three years is summarized as Shinkansen effect in this study. The data for December 2015 are estimated by the authors.

2 Hokuriku Shinkansen

Hokuriku Shinkansen is a railway rout to connect Tokyo and Osaka via Hokuriku District at the entire line available. When the entire rail line of Hokuriku Shinkansen is opened, it can assume the bypath function of Tokaido Shinkansen. A part of the line (from Tokyo to Nagano) opened in ahead of schedule in 1997 due to Nagano Olympics (1998 Winter Olympics). It took 18 years until Kanazawa opening of business. It was fifty years late than the opening of Tokaido Shinkansen (opened in 1964, Tokyo to Shin-Osaka). The line was the world's first high speed railway. The operation of Shinkansen line connected to Tokyo was desired earnestly for the tourism promotion and economic development in the district. The passenger number increased triple than the previous one. However, airplane passenger decreased sharply (more than 30%) and the number of the flights (including number of seats) was decreasing after the start of the Hokuriku Shinkansen Line. There are three airports in Hokuriku, namely Komatsu (Ishikawa Pref.), Noto (Ishikawa) and Toyama (Toyama). The maximum speed of the line is restricted to 260 km/hour for noise reduction and it is investigated to speed up (300 km/hour) in consideration of noise environment.

The maximum speed of each Shinkansen Line is indicated in Table 1. The speed of Tohoku Shinkansen is the fastest (320 km/hour). Speedup is important in future. Photograph of Hokuriku Shinkansen is shown in Fig. 1. Sky blue and copper color of the body provide a calm atmosphere.

Table 1. Maximum speed for each Shinkansen in Japan

Shinkansen	km/hour
Tokaido	285
Sanyo	300
Tohoku	320
Jyoetsu	240
Kyushu	260
Hokuriku	260
Hokaido	260

Fig. 1. Hokuriku Shinkansen

The route of Hokuriku Shinkansen is indicated in Fig. 2. The line will be expanded to Shin-Osaka and connected to Tokaido Shinkansen via Koto.

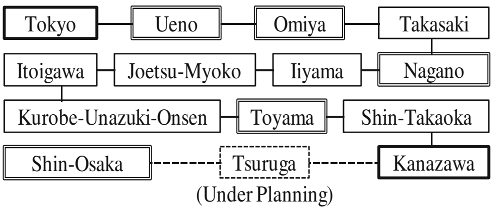

Fig. 2. The route of Hokuriku Shinkansen

It will take about twenty years [5]. The Linear Chuo Shinkansen will be able to run between Tokyo and Nagoya in just 40 min in 2027. The line will be expanded to Osaka from Nagoya in 2045 and it will take 67 min between Tokyo and Osaka. Strategy to take the interchange of the person is necessary, but it is also necessary to remark the comfortability, safety and security besides speed. Japan developed firstly a rapid transit railway in the world. Moreover, noise and environmental assessment should be remarked. Hokuriku Shinkansen is a pivot of the regional revitalization.

About 8.15 million passengers used Hokuriku Shinkansen in total since started operation (for Mar. 14, 2015 to Jan. 20, 2016; about 10 months). The number was about 3 times than heretofore and the handling incomes increased by 33%, which was released by JR West. The change of passengers for Mar. 14 to Sep. 13 (six months) is indicated in Fig. 3. The data was measured for Jyoetsu-Myoko to Itoigawa (working area of JR west). The values in March and September are very small because they are in half month. The average for April to August is about 0.8 million and the number of passengers a day each station is represented in Table 2. The one for Kanazawa is less than twice the one for Toyama.

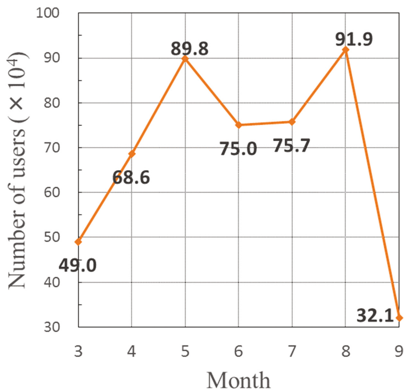

Fig. 3. Number of passenger of Hokuriku Shinkansen (Jyoetsu-Myoko to Itoigawa), which is measured for Mar. 14 to Sep. 13, 2015)

Table 2. Number of passengers a day in five stations

Station	Baoding number/day
Kanazama	8930
Toyama	4860
Shin-Takaoka	1600
Unazuki	840
Itoigawa	400

3 Number of Guest in Hokuriku Spa Areas

Hot spring is an important tourism resource and the economic effect by the guests is especially large in Hokuriku District. There are nine spa areas as main hot spring resorts in the district (Fukui, Ishikawa and Toyama Prefectures). In this study, Shinkansen effect was evaluated using the number of hotel guest in the areas. The number is introduced by the guests of the facilities which are joining Ryokan association (inn association). Only a few facilities do not join the association and the unjointed number is less than 10%. The data is not correspond to the local overall hotel guests. The nine survey target areas are as follows:

Awara (Awara, Fukui Pref.), Awazu (Komatsu, Ishikawa Pref.),
Yamanaka, Yamashiro and Katayamazu (Kaga, Ishikawa Pref.)
Wajima (Wajima, Ishikawa Pref.), Wakura (Nanao, Ishikawa Pref.)
Yuwaku (Kanazawa, Ishikawa Pref.), Unazuki (Kurobe, Toyama Pref.)

Yamanaka, Yamashiro and Katayamazu are collectively called Kaga Onsen-Kyo (Kaga three major spas). Unazuki (15 km) and Yuwaku (20 km) are close to a Shinkansen station and it takes less than half hour from each station to these spa areas by bus or car. It takes over one and half hours form each near station for other areas by train or bus.

3.1 Kaga Four Major Spa Areas

Kaga three major spas (Kaga Onsen-Kyo) and Awazu spa are collectively called 'Kaga Four Onsen'. Awazu is located in Komatsu city which is neighbor of Kaga city. There are many visitors from Kansai area in the four spa areas. Osaka is the center of Kansai area in which the area population is about 20 million. There are also many visitors from Chukyo area (Nagoya) in which the area population is about 15 million. The number of visitor is decreasing gradually due to the slump of the Japanese economy in the areas and some hot-spring hotels discontinue their business. A cheap hotel chain is also expanding. Kaga three major spas (Kaga Onsen-Kyo; Yamanaka, Yamashiro and Katayamazu) had over 4 million visitors in about 1990. It was the maximum value. The number increased a little in 2015 than the one in 2014. It had about 2 million in 2015 due to the Shinkansen effect. Awazu had 0.17 million visitors in 2015 and the number was about 10% of the total of Kaga three major spas. These four spa areas (Kaga four major spa areas) are developing a tourism strategy comprehensively. The capacity of the four areas is about 15 thousands and there is a loop bus (named CANBUS) which connects the four areas. The area is unlimited ride by showing the ticket for the tourist. The ratio of departure area of the visitor to the areas was as follows before the opening of the Hokuriku Shinkansen Line (in February 2015), namely Kansai area is 32% and Kanto area is 4%. The one for Kanto approximately quadrupled and the one for Kansai was 23.5% in June 2015. There was the Shinkansen effects obviously [8]. The effect is high in Yamashiro spa area especially.

The characteristics of lodger number for three years (2013–2015) in the area are shown in Fig. 4. The values in 2013 and 2014 are 1.73 and 1.74 million. They are nearly equal. The percentages in the areas are as follows, Yamanaka: 25, Yamashiro: 39, Katayamazu: 27 and Awazu: 9%. The value for Yamashiro is maximum. The mean total visitors for April to November in 2013 and 2014 were derived and compared with the one for the same term in 2015 after the Shinkansen opening of business. It increased by 16% after the opening. The percentage is thought as the Shinkansen effect. The total lodger number for 2015 in the area is about 2 million. The characteristic of the lodger in number in the spa areas of Hokuriku District has a peak in August. The tendency is the same as the characteristic in Japan. However, there are also small peaks in March and November and the characteristics resemble each other depending on tourism resources. The visitors from Kanto area (area population: 42 million) increased to double after the start of the Hokuriku Shinkansen Line but the tendency was the same.

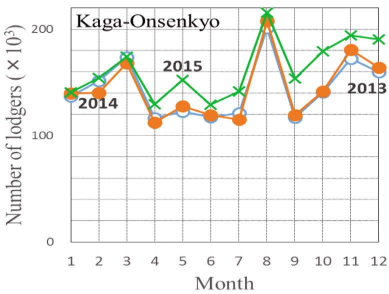

Fig. 4. Characteristic of lodger number for Kaga four major spa areas

3.2 Awara Spa Area

Awara spa area is located in Awara City (population: about 30 thousand) of Fukui prefecture and is called as a spa-resort of Kansai region. The city adjoins Kaga City. Therefore, a unified tourism strategy is sometimes built as the area of Kaga Onsen-Kyo altogether (including Yamashiro, Ymanaka, Katayamazu, Awazu and Awara). There are few tourism resources except the hot spring in Awara. The characteristics of lodger number for three years (2013–2015) in Awara spa area is shown in Fig. 5. The increasing percentage for April to November 2015 was 18%. The same deriving process was mentioned in the last section. The percentage is larger than the one for Kaga four major spa areas. The numbers in 2013 and 2014 were 0.61 and 0.69 million. It took a peak value (87 thousand) in August. The characteristics for Figs. 4 and 5 closely resemble to each other and it is a feature in Kaga Onsen-Kyo. The correlation diagram for both figures is shown in Fig. 6. The correlation coefficient R is 0.91 and the data

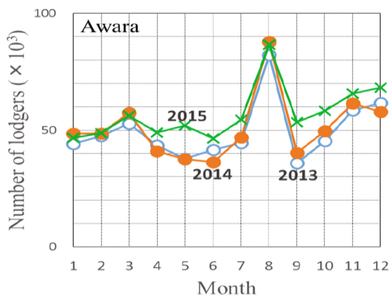

Fig. 5. Lodger characteristics in Awara spa area for 2013–2015

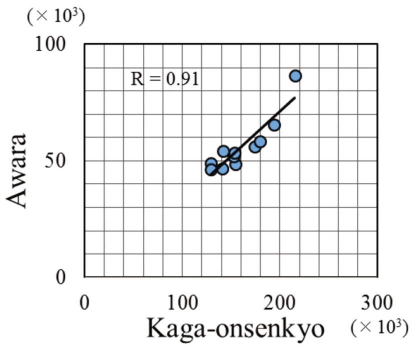

Fig. 6. Correlation diagram of lodger number between Kaga four major spa areas and Awara spa area

has a very high correlational relationship. If the coefficient is small, it can supplement the seasonal food and hotel guest mutually in the region. It is desirable for each facilities to have a specific tourism resources. And it is desirable that R is small. Lodger characteristics in five major spa areas of Kaga Onsen-Kyo should be varied due to a proposed strategy.

3.3 Yuwaku Spa Area

Yuwaku spa is located in Kanazawa city (population; 0.46 million) and is called as an inner room of Kanazawa. Business firms often give parties there to entertain their customers. There is Yumeji Takehisa Kan (a kind of museum) and many Yumeji-fans visit there. There is Lake Gyokusenko which is suited in the inner part of the hot-spring street. There is Himuro House (icehouse) by the lake and the winter snow is stored in the house. The stored operation is carried out in June every year. The snow ice was offered to Tokugawa family by Kaga Domain in the Edo Period. The many citizens have the habit of eating Himuro manju (steamed bun) to pray for good health at July 1. The area was the location of Hanasaku-iroha (an anime drama) broadcast on TV in 2011 and there were many visitors as the place of pilgrimage. Characteristic of lodger number in Yuwaku spa area is indicated in Fig. 7. The fluctuation for Yuwaku area is smaller than the ones for Kaga Onsen-Kyo spa areas which have a marked peak in August. The Shinkansen effect of 38% is derived, which is the biggest growth rate in this investigation. It is thought that Yuwaku is relatively near Kanazawa station as the reason for the high growth rate. The guests drift to the area because the occupancy rate for hotels near Kanazawa station is sometimes over 90%.

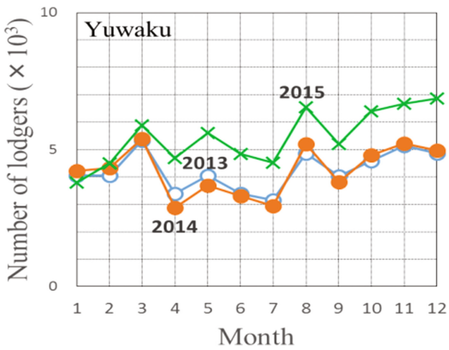

Fig. 7. Characteristic of lodger number in Yuwaku spa area

3.4 Wakura Spa Area

Wakura spa area is an entrance of the Noto sightseeing. It was said that the opening of the hot spring or bath house was about 1,200 years ago. A fisherman found a damaged white heron healing the wound in the hot spring. It was the origin. And there is a traditional Japanese inn "Kagaya" in the area. Kagaya was receiving repeatedly the best award as the most evaluated inn in Japan for 36 years until 2016. The award "100 selections of the best Japanese hotels and inns" is recognized by Ryoko-shinbun (a trip newspaper publisher). It is said that the hospitality (Omotenashi in Japanese) of Kagaya is number one in Japan, and the inn is also a place of corporate training by many companies. A picture of sending guest off is shown in Fig. 8. Wakura spa area is developing centered on Kagaya. Characteristic of lodger-number transition is presented in Fig. 9. It has the same trend as the one for Kaga Onsen Kyo, which is indicated in the figure and the increase of 20% is derived as Shinkansen effect. The decrease in number of the guests is relatively small in winter.

3.5 Wajima Spa Area

There are some Japanese inns and Minshukus (private home that runs inn providing room and board) in Wajima area but the capacity of guests is small. The number of guests was about 0.13 million in a year before the Hokuriku

Fig. 8. Hospitality of Kagaya (send-off)

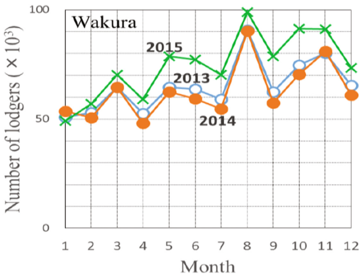

Fig. 9. Lodger number as a function of month in Wakura spa area

Shinkansen Line started operation. It became 0.17 million in 2015 and the increase of 30% is recognized. The increase rate of lodger number for April to November in 2015 was 33%. The number of visitors for Wajima morning market increased by 30%. The influence of the serial TV drama "Mare" produced by NHK is also thought. Wajima was used as a location for making the drama. It was broadcasted for March to September in 2015. There were really many visitors to Osawa area in Wajima City. Magaki (board fence) which is made up of bamboos, is famous in the area. Magaki protects a house from a strong winter wind (sea breeze). Lodger-number characteristic for Wajima spa area is presented in Fig. 10. The number increased after the broadcasted TV drama (May). The details for the increased number (30%) are as follows. Shinkansen effect for Wakura spa nearby Wajima is 20%. So Shinkansen effect is estimated by 20%, TV drama effect is 10%. It is difficult to judge the effect clearly because there is a synergistic effect.

3.6 Unazuku Spa Area

Unazuki is located to the east of Toyama prefecture and is the biggest hot spring resort in the prefecture. The name of the closest Shinkansen station to Unazuki is 'Kurobe-Unazuki Onsen'. There are a private railway from the station to Unazuki spa resort and it takes about 20 min by the train. There are a truck

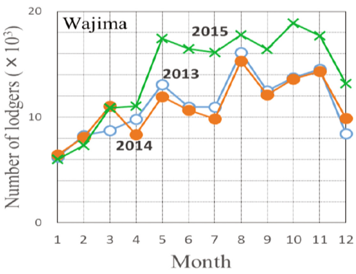

Fig. 10. Lodger-number characteristic for Wajima area

train in Unazuki to visit Kurobekeikoku (canyon). Hundreds of thousands of people visit the canyon annually. The scenery is wonderful especially for the autumn leaves. As for the result, the increasing rate of lodger number for April to November (after the Shinkansen opening of business) is over 30% and the shortage of human resources for some inns are remarkable in the area due to the increase of the room occupancy rate. The transition of lodger number is presented in Fig. 11. The increase after April is remarkable because the area is near from the Shinkansen station as well as Yuwaku. It is necessary to hold an attractive event in June and equalize the lodger number over whole year.

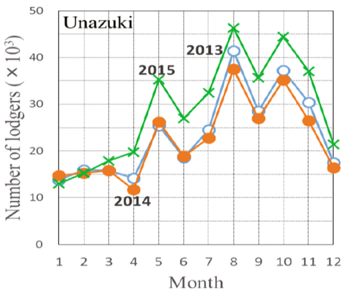

Fig. 11. Lodger number for Unazuki spa resort

3.7 Trend of Lodger Number Due to Shinkansen Started Operation

There were various kinds of advantages and disadvantages due to the Hokuriku Shinkansen started operation. The start of the operation spreads to over the entire area of Hokuriku (three prefectures) but there are the light and shade of the effect [8]. The movement of person is sucked into an area where an attractive event is held. This phenomenon is called "straw effect". Some points to be improved were listed by visitors to the area. The points are as follows.

- It is hard to make the reservation of the hotel.
- Hospitality is light due to the labor shortage.
- Rising of the meal price.

The increasing rates of lodger number for six hot spring areas as described above, is indicated altogether in Table 3. The rates of three areas (Yuwaku, Wajima and Unazuki) are over 30%. Yuwaku and Unazuki are near the Shinkansen stations, and Wajima is the filmed place for the drama (Mare). Consequently, the one for Wajima will decrease gradually. The correlation diagram for the lodger number between Yuwaku and Unazuki is derived and indicated in Fig. 12. The correlation coefficient R is 0.75 and the value is high. It is thought that there are some different types of tourism resources for the visitors in the area, for example autumn color of canyon, ski slope and cheap accommodation fee.

It was thought that the visitor number to Wajima increased by 10% due to the place for the TV drama "Mare". There was a synergistic effect with Shinkansen began the operation (increased by about 20%) and many persons visited Wajima to see the scene sites of the drama. Tokyo where the area population is 42 million, is the starting station of the Hokuriku Shinkansen. There is high potential to increase the number when the access becomes easy. The increasing rates of the five spa resorts (Kaga three major spa areas, Awazu and Awara) were almost 20%. The one for Wakura was 21%. The access for Wakura is relatively good because Wakura is connected directly to Kanazawa by JR railway and there is also a bus route. The rate is higher than the ones for the above mentioned five areas.

Coefficients of variation (cv: standard deviation/the mean value) for six spa resorts are summarized in Table 4. The values in 2014 and 2015 are represented. The ones for Wajima and Unazuki are exceed 0.3, namely the fluctuations for the lodger number of every month are larger than the other areas. A variation of the occupancy rate for each hotel is large, namely maintenance cost for the facilities including labor cost becomes higher. The coefficient for Wajima becomes large.

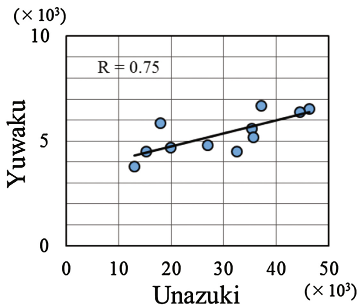

Fig. 12. Correlation diagram for the lodger number between Yuwaku and Unazuki

Table 3. Increasing rates for six hot spring areas in Hokuriku district

Hot spring	Kaga	Awara	Yuwaku	Wakura	Wajima	Unazuki
Rate	0.16	0.18	0.38	0.21	0.33	0.30

Table 4. Coefficients of variation for six spa resorts in 2014 and 2015

	Kaga	Awara	Yuwaku	Wakura	Wajima	Unazuki
2014	0.20	0.26	0.20	0.19	0.23	0.36
2015	0.16	0.20	0.17	0.20	0.31	0.38

4 Visitor Number for Other Main Facilities

There was a tourism spot in which the visitor number increased remarkably. It is Asakura remains in Ichijodani and located in Fukui prefecture. A CM movie was filmed in the spot and about 1.1 million persons visited the spot [7]. It is necessary to construct some facilities for visitors, namely parking place, rest house and souvenir shop. The elderly interested in history are also visiting. The service introducing the situation in ancient or olden times using a tablet is carried out.

Kenrokuen (one of the three largest gardens in Japan) is the spot which has the most visitors in Ishikawa prefecture and the number is 2.9 million in 2015 (increased by 45.5% than the one in 2014). There was 2.25 million visitors (increased by 81% compared with the previous year) in Kanazawa Castle Park which is adjacent to Kenrokuen. The number of foreign people visited Kenrokuen was 0.292 million (increased by 24.4% compared with the previous year). The visitors from Taiwan occupied by 46.5%. The one from Hong Kong was 10% and the one from USA was 5.3% (China was 5%). The rate of the one from Korea was few [6].

There is the Noto Railway Corporation in Noto area where Wajima and Wakura (in Nanao city) are located. It is a third sector railway company. The service is operating between Wakura and Anamizu (about 40 min by train), and JR operates a train between Nanao and Wakura. Many group tourists use the Noto Railway Corporation after the Hokuriku Shinkansen line started its operation. Some events were hold in the train, for example famous sweets-service and special guide by a conductor in the train. The events and TV drama "Mare" affected to the increase of the visitor number. The number was 61 thousand in 2015 (increased by 73% compared with the previous year). The visitor number form Kanto area were 42 thousand (70%). It is very large percentage compared with the ones for other areas [10]. The number for Tateyama Kurobe Alpine Route was 0.997 million in 2015 (increased by 10% compared with the previous year). There was a big snow wall (named Yuki-no-Otani in Japanese) in the route. One million visitors were expected as a goal in 2015. It was slightly few. As the details, the number of Japanese was 0.782 million and the one for foreign visitors was 0.215 million (increased by 12%). The number of visitors from Taiwan

(132 thousand) is the biggest and the second is Hong Kong (25 thousand) followed with Thailand (17 thousand) and Korea (16 thousand). Higher two countries are the same as Kenrokuen [9].

5 Conclusion

It is necessary to examine the visitor number after the Hokuriku Shinkansen line started its operation and to apply the result to a future strategy in the district. It is said that the number increases remarkably in the first year after the opening. However, it is also said that the effect does not continue after the second year. This phenomenon is called “Shinkansen jinx”. Some proper and attractive events are required to break the jinx every season and to secure the repeaters. Peculiar local hospitality (“Omotenashi” in Japanese) is also necessary to secure the repeaters. Some travel agents say that the traffic infrastructure and the accommodation cost (lodging and transportation expenses) are more important for repeaters. Some regional inhabitants have the objection against the increasing the number of visitors sharply because the community is in disorder. It is necessary to constitute the area in which the habitants and visitors can live together. The action of “Civic Pride” is also effective.

In this study, the fluctuation of the visitor number in spa resort areas is examined as a Shinkansen effect. It is important to understand the fluctuation and is also necessary for forming the social environment of the area in future. The visitor number of nine spa areas in Hokuriku district were investigated. As a result, it becomes obvious that the effect of visitors spreads to Hokuriku district whole. Especially, the lodger number of the areas near the two Shinkansen stations increased by about 30%. The Noto area was over 20% and Kaga area was less than 20%. The lodger number of the spa area near the station remarkably increased due to the beginning of the operation. It is necessary to review the comfortable Omotenshi (hospitality) to the guests and the staffing management in the high increasing areas. It is also necessary to level the fluctuation on the characteristic of the lodger number by holding events. There are the dispersion in the lodger number every month. The leveling leads to the effective utilization of the resources, especially capacity and the meal supply.

In future, it needs to be examined on foreign visitors (inbounds) who have an enhanced economic effect. It will also contribute Japanese globalization. Increasing the inbounds is one of Japanese strategies.

Charging Infrastructure Allocation for Wireless Charging Transportation System

Min Seok Lee and Young Jae Jang(✉)

Korea Advanced Institute of Science and Technology,
Daejeon, Republic of Korea
yjang@kaist.edu

Abstract. The dynamic wireless charging electric vehicle (DWC-EV) is the most developed form of EVs which use wireless power transfer (WPT) technology. The vehicle can be charged using a wireless charger embedded under the road, and an extremely competitive advantage of DWC-EV is that it can be charged while on the move. Thus, this system allows EVs to overcome the range limitation, long charging time, and heavy battery weights. In DWC-EV system, the battery and charging infrastructures called power tracks are major elements to operate vehicles, and these factors occupy large portion of initial investment cost for establishing the system. This paper suggests a mathematical model to optimally find the battery capacity and the allocation of power tracks in a multiple-route public transportation system. In addition, genetic algorithm (GA), which is one of widely used metaheuristics, is proposed as a solution approach to solve large and complex problems. Since chromosome design determines the format and information of chromosomes, it is crucial to the quality of the solutions and the performance of GA. We suggest two chromosome design methods and the methods to deal with infeasible chromosomes. A number of numerical experiments for comparing solutions and computation time are conducted, and we use the optimal solutions suggested by CPLEX solver as criteria. We also show that the proposed GA design method can be useful and effective compared to the exact solution approach based on the mixed integer programming (MIP).

Keywords: Dynamic wireless charging · Electric vehicle · System optimization · Genetic algorithm

1 Introduction

Electric vehicles (EVs) have attracted international attention as an alternative to internal combustion engine (ICE) vehicles, with the aim of reducing the dependence on petroleum and adverse environmental effects. Many countries and authorities have devoted much research and development to EVs, and numerous policies have also been suggested with respect to electric transportation systems

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_137

[15]. The number of EV users has grown in accordance with the global change, and in particular, the market share of plug-in EVs (PEVs) becomes larger. In addition, wireless power transfer (WPT) technology for EVs has recently been introduced to overcome the disadvantages of the existing PEVs, for example short travel distance and range anxiety.

The dynamic wireless charging electric vehicle (DWC-EV) is the most advanced form of EV, and uses a wireless charger embedded under the road, which charges the vehicle when it moves or stays on it. As it is possible to charge during operation, the driver does not need to stop for a long time to recharge the battery. The battery size can be reduced as the charging infrastructure can supplement the electric power throughout the operation. The online electric vehicle (OLEV) is a DWC-EV developed by the Korea Advanced Institute of Science and Technology (KAIST). In DWC-EV system, however, the charging infrastructure and the battery account for the largest proportion of the initial investment cost. InGumi city, about 80% of the total cost was allocated to these two key factors for setting the system [3,12]. In other words, the investment cost is mainly determined by battery capacity and the allocation of the charging infrastructure, so we focus on these factors in this study. To install a DWC-EV system at a reasonable cost, an optimum level of charging infrastructure and an estimation of battery capacity are required.

The purpose of this study is to identify the optimal allocation of charging infrastructure and battery capacities for the stable and economic operation of the DWC-EV system which is applied to public transportation buses. We focus on the minimization of the initial investment cost, not the operational cost. In this study, we suggest a mixed integer programming (MIP) model considering a multiple-route public transportation system. To find optimal solutions for the MIP model, specific algorithms would typically be used, but obtaining optimal solutions to the complex problems with these algorithms is difficult. In this case, genetic algorithm (GA), a widely used metaheuristic, can be useful for finding optimal or near-optimal solutions within a short time. Therefore, we design a GA procedure to solve the multiple-route problem. We analyze the overall performance of the solutions suggested by GA and also compare it with the optimal solutions obtained by solving MIP problem.

Several studies have been conducted on the system design for EVs, and some focus specifically on infrastructure planning and economic analysis of hybrid EVs or PEVs [4–6,9,14]. These studies generally focus on the deployment of charging stations or determination for the capacity of the charging stations. Also, recent studies related to the system design of DWC-EVs have dealt with the minimization of total cost by determining the battery size and the positions of power transmitters [7,8,8,10,11,13]. These studies have considered single route cases or do not suggest practical methods to solve large and complex problem. In actual, the optimization approach for these cases is not appropriate if the DWC-EV application is planned at the city or multiple district scale.

The remainder of this paper is organized as follows. Section 2 presents the basic characteristics of a DWC-EV system, optimization issues, and several main assumptions used in the optimization model. Section 3 describes the optimization modeling of the DWC-EV system, and Sect. 4 introduces the GA process and chromosome design methods used to suggest solutions for our model. Section 5 solves example problems using GA, and the quality of the solutions are verified by comparing them with the optimal solutions suggested by the CPLEX solver. Section 6 concludes and suggests directions for future study.

2 Description of the DWC-EV System

2.1 The Characteristics of the DWC-EV System

The DWC-EV system has two main parts: the vehicles and the charging infrastructure. The vehicle part mainly consists of a pick-up device for charging, a battery, and a motor for moving vehicles. The charging infrastructure is composed of an inverter and an inductive power cable, which is installed beneath the road. In this paper, we refer to the charging infrastructure as the power track. When a DWC-EV operates on the inductive cable, the power is delivered to the motor or the battery through the regulator. Figure 1 illustrates the main components of the DWC-EV system. The wireless power transfer system is described in detail by Ko and Jang [10] and Ahn et al. [2].

The battery and power tracks are essential elements of the DWC-EV system and constitute most of the total initial investment. It is important to find an appropriate balance between the battery capacity and the allocation of power tracks, but it is not economically viable to install power tracks under whole routes or to equip vehicles with excessively large battery capacity. Two extreme examples can help to explain the relationship between battery and power track. If a vehicle has a large battery that is adequate for operation over the whole route, it does not need to collect electric power during operation, and if it is charged at the base station just before operation there is no problem. The battery will here constitute most of the investment cost. If power tracks are installed under the whole route, the vehicle can travel with a very small battery, and the cost of the power track would be much higher than the battery cost. From the examples, we know that the battery cost and the power track cost have a trade-off relation. Therefore, determining the battery capacity and the allocation of the power tracks should be verified precisely in the commercialization of the DWC-EV system. The purpose of the optimization is to minimize the initial investment cost of the DWC-EV system.

2.2 Assumptions of the DWC-EV System

In this study, we focus on the DWC-EV system applied to public transportation buses. Buses must stop at several stations on each route during operation, and begin and terminate their service at the base station. Before modeling the optimization problems, we set several assumptions, which reduce the complexity of the problems and reflect the practical issues.

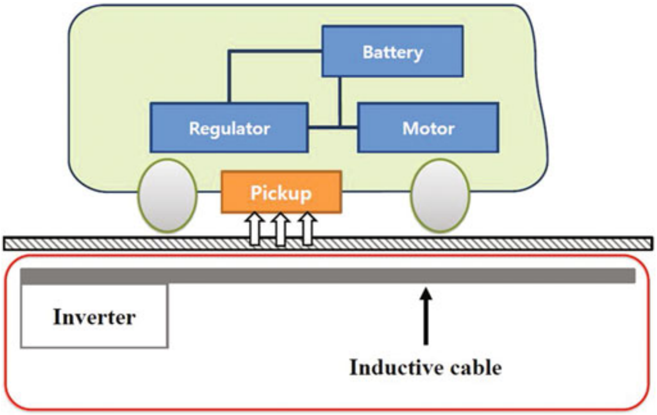

Fig. 1. Major components of DWC-EV

First, the energy consumption between two stations is given. We approximate the consumption is linearly proportional to the distance. The second assumption is that power tracks can be installed only at station areas. In the DWC-EV system, the level of battery charging depends on how long the bus stays on the road where the power track is installed, so clearly installing power tracks at locations where buses stay for a long time is advantageous. Another assumption is that the amount of charging at stations is linearly proportional to the length of power tracks.

The DWC-EV system also includes operational assumptions. First, if several buses travel on an identical route their battery capacities will the same, but battery capacity can differ according to the route. Buses are also assumed to be fully charged at the base station during resting time. We do not consider the installation cost of charging facilities at the base station in the optimization modeling. We will consider only the cost of facilities used during operation.

3 Optimization Modeling

3.1 Decision Variables

We consider multiple routes for public transportation systems in our study. The investment cost will change according to the number and the length of power tracks, so we must identify the number, length, and location of power tracks. Suppose that there are a total of N stations and M routes in the system. We define the integer decision variable X_s as the length of the power track installed at station s $(s = 1, \cdots, N)$. Also, let y_s be the binary variable for whether the power track is installed at station s or not. The battery capacity of a vehicle in route r $(r = 1, \cdots, M)$ is denoted by E_r^c. Figure 2 describes decision variables for a multiple-route optimization model.

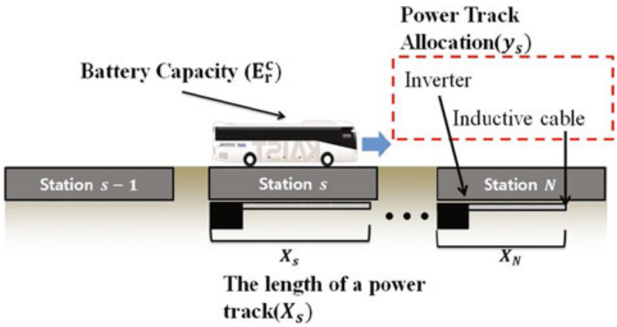

Fig. 2. Decision variables for a multiple-route optimization model

3.2 Objective Function

The objective function is composed of the battery cost and the infrastructure cost. Let c_b be the battery cost per unit capacity. Thus, we can represent the battery cost of a vehicle on route r as $c_b E_r^c$. The power track related cost is composed of a fixed cost and a cable cost. The fixed cost includes inverter installation and setup costs. The length of power tracks has a direct influence on cable cost. The longer the power track is, the more cost is incurred. We define c_f and c_v as the fixed cost and the cable cost, respectively. The power track installation cost at station s is represented by $\sum_{s=1}^{N} c_f \times y_s + \sum_{s=1}^{N} c_v \times X_s$. If there are k_r vehicles on route r, the objective function of the multi-route system is expressed as follows:

$$\sum_{r \in R} c_b \times k_r \times E_r^c + \sum_{s=1}^{N} c_f \times y_s + \sum_{s=1}^{N} c_v \times X_s.$$

3.3 Constraints

In most cases, battery manufacturers set maximum and minimum energy levels for battery stability, so the energy level is recommended to remain within a fixed range. The maximum and minimum levels are represented by multiplying a constant and the battery capacity. These equations are as follows:

$$E_r^u = n^u \times E_r^c,$$
$$E_r^l = n^l \times E_r^c,$$
$$0 \leq n^l \leq n^u \leq 1.$$

The number of stations on route r is denoted by $N(r)$, and k^{th} station on route r is represented by $I(r,k)$. Let $E_{r,k}$ be the energy level of the battery at the moment when the bus leaves k^{th} station on the route r. The battery will not have a higher energy level than E_r^u even if charged for a very long time. Surplus energy will then result, which cannot be stored in the battery. We call this remaining energy excess energy. The excess energy quantity at k^{th} station of route r is denoted by variable $q_{r,k}$. The energy level $E_{r,k}$ is written in the following form:

$$E_{r,k} = E_{r,k-1} - d_{r,k-1} + p \times X_{I(r,k)} - q_{r,k} \quad r \in R, \quad k = 1, \cdots N(r),$$

where $d_{r,k}$ means the energy consumption between k^{th} station and $k + 1^{th}$ station on route r, and p is the amount of energy charge per unit length of the power track.

The system must maintain the battery level within the upper and lower bounds while in operation.

$$\begin{aligned} &E_{r,k} \leq E_r^u \quad r \in R, \quad k = 1, \cdots N(r), \\ &E_{r,k} - d_{I(r,k)} \geq E_r^l \quad r \in R, \quad k = 1, \cdots N(r). \end{aligned}$$

The DWC-EV bus is fully charged when it leaves a base station.

$$E_{r,1} = E_r^c \quad r \in R.$$

The length of the power track cannot exceed the length of the station area. Installing very short power tracks is not economically viable. The following inequality constraint states the upper and lower bounds of the length of the power track.

$$y_s \times X^{\min} \leq X_s \leq y_s \times X^{\max} s \in S,$$

where $X^{\min}$ and $X^{\max}$ are the minimum and the maximum length of the power track.

We develop the following mathematical model for the optimization problem using the objective function and constraints explained above.

$$\min \sum_{r \in R} k_r \times c_b \times E_r^c + \sum_{s \in S} c_v \times X_s + \sum_{s \in S} c_f \times y_s \tag{1}$$

$$\text{s. t. } E_{r,k} = E_{r,k-1} - d_{r,k-1} + p \times X_{I(r,k)} - q_{r,k} \quad r \in R, \quad k = 2, \cdots N(r) \tag{2}$$

$$E_{r,k} \leq E_r^u \quad r \in R, \quad k = 1, \cdots N(r) \tag{3}$$

$$E_{r,k} - d_{I(r,k)} \geq E_r^l \quad r \in R, \quad k = 1, \cdots N(r) \tag{4}$$

$$E_{r,1} = E_r^u \quad r \in R \tag{5}$$

$$y_s \times X^{\min} \leq X_s \leq y_s \times X^{\max} s \in S \tag{6}$$

$$y_s \in \{0, 1\} \quad s \in S \tag{7}$$

$$X_s \text{ and } E_r^c \text{ are zeros or positive intergers } s \in S. \tag{8}$$

4 Genetic Algorithm

Several algorithms are used to solve MIP problems, such as the branch and bound algorithms. However, these algorithms cannot suggest optimal solutions for large-scale problems in a timely manner. In this case, heuristic methods or metaheuristics are more useful for solving the problems. The genetic algorithm (GA) is a widely used metaheuristic, and we use it as our main solution approach in this study. Chromosome design determines the format of chromosomes, and the chromosome's information is crucial to the quality of the solutions and the performance of GA. We suggest two chromosome design methods for our problem.

4.1 Chromosome Design with Battery Capacity

(1) Format of chromosome

The first chromosome is divided into two parts. Figure 3 describes the format of the chromosome, and the first part represents the battery capacities. The value of each gene represents the battery capacity corresponding to each route. The second part of the chromosome expresses the length of the power track at each station. Therefore, this chromosome format contains information about the decision variables E_r^c and X_s.

However, infeasible chromosomes can be produced with this format. Specifically, several chromosomes created during generation will not satisfy the energy dynamics constraint introduced in Eqs. (3) and (4). The infeasibility of the chromosome can be dealt with in two ways; either by giving a large penalty to the chromosome, such as very bad fitness value, or by applying repair mechanism to make it feasible [1]. We deal with these two methods in numerical experiments.

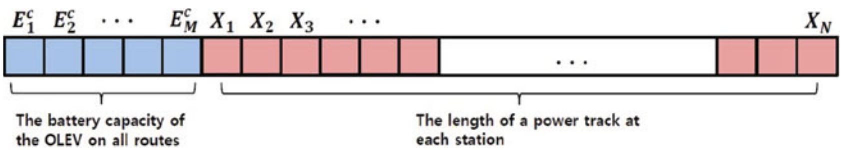

Fig. 3. The structure of a chromosome with genes of battery capacity

(2) Repair mechanism

From a generated chromosome, we calculate the energy level of the battery using Eqs. (2) and (5) at all stations on multiple routes. We suppose that we start the investigation from kth station of route r. We calculate $E_{r,k} - d_{r,k}$, which is defined as remaining energy. From now on, we assume that the lower bound of energy level E_r^l is zero for convenience. If the remaining energy is greater than or equal to zero, we go to the $k+1^{th}$ station and calculate the remaining energy at the $k+2^{th}$ station again. If k^{th} station is the last station of route r, the mechanism starts from the first station of route $r+1$. The mechanism will terminate after the investigation of the last station on the last route.

However, the remaining energy $E_{r,k} - d_{r,k}$ may result, which is less than zero. In this case, we calculate the additional battery capacity and the length of power tracks, respectively, to supplement the shortage of energy. The additional battery capacity or the length of the power track can replenish the energy amount $d_{r,k} - E_{r,k}$, and then we calculate the corresponding cost for each additional element. If the additional battery cost is cheaper than the additional power track cost, we add the battery capacity to the existing battery capacity of route r instead of the power track. In the opposite case, we attach the additional power track to the existing power track. However, if the length after adding the additional power track is longer than the upper bound, the rest of the additional power track is converted to battery capacity. This generated battery capacity is then added to the existing capacity. When the length after adding the additional power track is shorter than the lower bound, we choose additional battery capacity instead of power track.

Next, we modify the energy level $E_{r,k}$, and go to the $k+1^{th}$ station and calculate the remaining energy at the station again. The mechanism should start from the first station of the first route and finish after the process of the last station on the last route. The new chromosome created by the repair mechanism will satisfy all constraints in the MIP model.

4.2 Chromosome Design Without Battery Capacity

(1) Format of chromosome

In this format, we allocate only the power track part of the previous format to a chromosome. Each gene of a chromosome expresses the length of the power track at each station. Therefore, the decision variable X_i in the MIP model corresponds to the i^{th} gene of the chromosome. Figure 4 describes the structure of the chromosome. Although the chromosome does not have information about battery capacity, it is possible to calculate the minimum battery capacity to operate the DWC-EV without depletion of energy based on the gene values of power tracks. Here, there is no infeasible chromosome in terms of energy dynamics constraints, so the repair mechanism is not needed in this format, and we can reduce the waste of battery capacity as we calculate the minimum battery capacity for each chromosome. However, we must calculate the battery capacities for all chromosomes created until the last generation, so more calculation time will be spent on the GA procedure than the previous format.

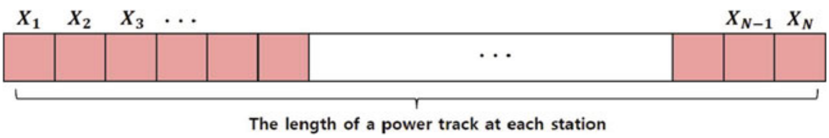

Fig. 4. The structure of a chromosome without genes of battery capacity

(2) Calculation of battery capacity

Let $W_{r,k}$ be the required energy level of the battery at the moment when the bus arrives at k^{th} station on route r. We assume that $W_{r,N(r)+1}$ is zero, which is the lower bound of the energy level, because station N(r)+1 represents the base station of route r. When the bus departs from $N(r)^{th}$ station on route r, it needs at least $d_{r,N(r)} + W_{r,N(r)+1}$. If a power track of $X_{I(r,N(r))}$ in length is installed at $N(r)^{th}$ station, $W_{r,N(r)}$ would be max $0, d_{r,k} + W_{r,k+1} - p \times X_{I(r,k)}$. In this manner, it is possible to explain other $W_{r,k}$. Therefore, $W_{r,k}$ can be expressed as follows:

$$W_{r,k} = \max\left(0, d_{r,k} + W_{r,k+1} - p \times X_{I(r,k)}\right), r \in R, k = 1, \cdots N(r) \tag{9}$$

To calculate the battery capacity E_r^c on route r, we define $bat(k)$ as the required battery capacity to move from k^{th} station to $k+1^{th}$ station on route r. The battery will consume $d_{r,k}$ until arriving the next station, and the energy state at $k+1^{th}$ station should be $W_{r,k+1}$. Thus, $bat_r(k)$ is the sum of $d_{r,k}$ and $W_{r,k+1}$.

$$bat_r(k) = d_{r,k} + W_{r,k=1}, r \in R, k = 1, \cdots N(r). \tag{10}$$

The battery capacity E_r^c is the maximum value among all $bat_r(k)$ to cover all movements between two stations. Therefore, E_r^c is represented as follows:

$$E_r^c = \max_{k=1,\cdots N(r)} (bat_r(k)), r \in R. \tag{11}$$

4.3 GA Settings and Procedures

Fitness function is an indicator of the quality of the solutions in GA. The objective function of the mathematical model is the fitness function of our problem. The purpose of the GA procedure is to find a solution that minimizes the fitness value. Before starting GA procedure, we generate the initial population to enhance the GA performance. The chromosome in the initial population is generated using the optimization results of each single-route problem. Most single route solutions are easily obtained using the algorithm for MIP model.

Selection function finds parents for the reproduction of new chromosomes using the fitness value. In our case, the selection function is based on the roulette wheel selection. After that, a portion of offspring is reproduced by the crossover function, which generates a new chromosome by combining a part of each parent. First, the crossover function creates a random binary vector that has a length identical to a chromosome. From the first parent, genes placed at the location 1 in the binary vector are selected. Those placed at the location 0 are selected from the second parent. The selected genes from the two parents generate a new chromosome.

The mutation function prevents the solution from converging to a local optimum, and is used to find various solutions in the searching space. In our case, it generates a random vector with length the same as that of the chromosome, and the random vector is added to a selected chromosome. If the new chromosome satisfies the bounds and constraints, it enters the next generation, and we can call it a mutated chromosome. We also set the elite reproduction which means that some of outstanding chromosomes in terms of fitness value must survive to the next generation.

In general, GA stops the procedure when several conditions satisfy the stopping criteria. In our case, the number of generations is selected as a stopping criterion. When the algorithm carries out the last generation, GA will find and suggest the best solution in that final generation.

5 Numerical Experiments for a Multiple-Route DWC-EV System

In this section, numerical experiments for a multiple-route model are handled, and solution approaches introduced in the previous sections are used to solve the problem. We consider 120 stations in Gumi city, which are used for three real routes, 1-1, 8, and 17, in the public transportation system. We add three hypothetical routes to these existing routes, which also use some parts of the 120 stations. Thus, there are 6 routes in the example problem. We assume that the energy consumption between two stations is constant, and the data is already given. Several numerical experiments are conducted as the number of the routes increases from 1 to 6. From routes 1 to 6, there are 47, 32, 46, 36, 36, and 36 stations, respectively, and some of those routes share the same stations.

Table 1. The comparison of average computational time (in seconds)

Description	Values
Unit battery cost (c_b)	800
Fixed cost (c_f)	20,000
Unit cable cost (c_v)	100
Charging rate (p)	0.5
The number of buses on each route (k_r)	5
The maximum length of the power track ($X^{\max}$)	30
The minimum length of the power track ($X^{\min}$)	10

The MIP model for the DWC-EV system is solved using CPLEX 12.5 embedded in a JAVA environment, and the GA coded with the MATLAB Global Optimization Toolbox is used to solve the problems. There are three approaches in the GA. First, we apply the chromosome format with battery capacity, which does not conduct a repair mechanism. This approach is defined as GA method 1. In this method, infeasible chromosomes should have infinite fitness values. The second approach is GA method 2, and carries out the repair mechanism to the same format. The last approach, GA method 3, uses the chromosome format without the battery capacity. Other GA procedures are applied identically to all approaches. The constant values for the numerical experiments are summarized

Table 2. Parameter settings for GA

Description	Values
Population size	1,000
The number of generations	1,000
Crossover fraction	0.84
Mutation fraction	0.01
Elite fraction	0.15

in Table 1. In this example, the maximum and the minimum energy level of the battery are the battery capacity E_r^c and 0, respectively. Several parameter settings for the GA procedures are defined in Table 2. These values are determined from a number of test experiments to find the better solutions.

We select the routes in a regular sequence starting from route 1; for example, if we select 3 routes, we choose route 1, 2, and 3. The total cost obtained from CPLEX and three GA approaches is listed in Table 3 according to the number of routes.

Table 3. The comparison of total cost between solution approaches

Algorithm	CPLEX	GA method 1		GA method 2		GA method 3	
Description	Obj. value	Best	Average	Best	Average	Best	Average
One route	325,100	325,100	357,139	325,100	345,759	325,100	326,934
Two routes	611,900	623,300	680,141	614,900	640,350	611,900	612,215
Three routes	967,400	1,031,200	1,098,603	982,900	1,032,737	975,100	977,649
Four routes	1,074,000	1,161,500	1,225,973	1,117,300	1,154,917	1,105,200	1,108,030
Five routes	1,266,600	1,476,900	1,554,957	1,373,500	1,446,741	1,314,500	1,321,851
Six routes	1,366,000	1,595,400	1,684,494	1,471,400	1,535,578	1,416,400	1,438,070

The GA results of Table 3 are obtained from 100 experiments for each case. The results of CPLEX are objective values, which are calculated by optimal solutions, so it is impossible to have costs lower than the results. These values can be used as criteria to assess the performance of the GA results. In the case of one route, the best value for each GA method is identical to the objective value, but average values are different from each other. GA method 3 suggests the smallest average value of all GA methods, while GA method 1 has the worst average value. In the case of two routes, the best value of GA method 3 also has the same value as the objective value, but GA methods 1 and 2 do not suggest the objective value, and GA method 3 still draws the best values between the three methods in both the best and average values. From the case of three to six routes, no GA methods suggest optimal results, and the performance of solutions in GA method 3 is always better than the others, in the same manner.

GA method 2 takes second place in every case, and GA method 1 proposes the worst results.

Though methods 1 and 2 use the same format of chromosome in the GA procedure, there are huge differences in the results, depending on whether the repair mechanism is used or not. In GA method 1, many infeasible chromosomes can be created during the 1,000 generations, so feasible chromosomes that do not have good fitness value in comparison with the optimal results will easily survive. In addition, the speed of improvement in the chromosomes slows, as the population generally consists of poor chromosomes. The quality of the best chromosome in the final generation will consequently be worse than in other methods. However, if the repair mechanism is applied to GA, it is impossible to have infeasible chromosomes, so all chromosomes can have specific fitness values that are not infinite. Unlike GA method 1, in which feasible chromosomes compete with many infeasible chromosomes, GA method 2 creates competition between comparable chromosomes, and the outstanding chromosomes will survive. Some infeasible chromosomes may also be changed to remarkable chromosomes during the repair mechanism. Therefore, we claim that GA method 2 can suggest better solutions than GA method 1.

GA method 3 provides the best solutions among all GA methods because of the format of chromosomes, and the fact that battery capacity plays an important role in the total cost. Figure 5 represents the total battery cost of the best chromosomes in all GA methods. GA method 3 suggests the smallest battery cost in all cases except for the one route case. GA method 3 can have an advantage in the battery cost as the battery capacities in the chromosome format are calculated to have the minimum values without depletion when it is driving. In contrast, other methods randomly allocate battery capacities, regardless of the gene values in the power track part.

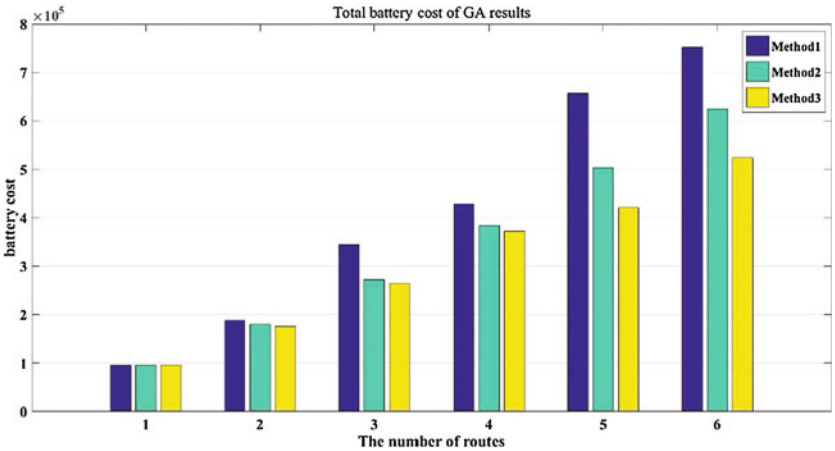

Fig. 5. A comparison of total battery cost in the GA methods

The power track costs of the best chromosomes in all GA methods are shown in Fig. 6. In contrast with the battery cost, the power track cost has the biggest value in GA method 3. The power track costs are identical in the different methods for the one route case, in the fourth case GA method 3 has a slightly smaller value, but for the other cases method 3 has the largest. From the perspective of a trade-off relationship, the results are reasonable as a small amount of power track is allocated to the solution with large battery capacity, and a large amount of power track is provided to the solution with small battery capacity. By comparing battery and power track costs, we confirm that the difference in the battery cost has a huge effect on the trend of the total cost.

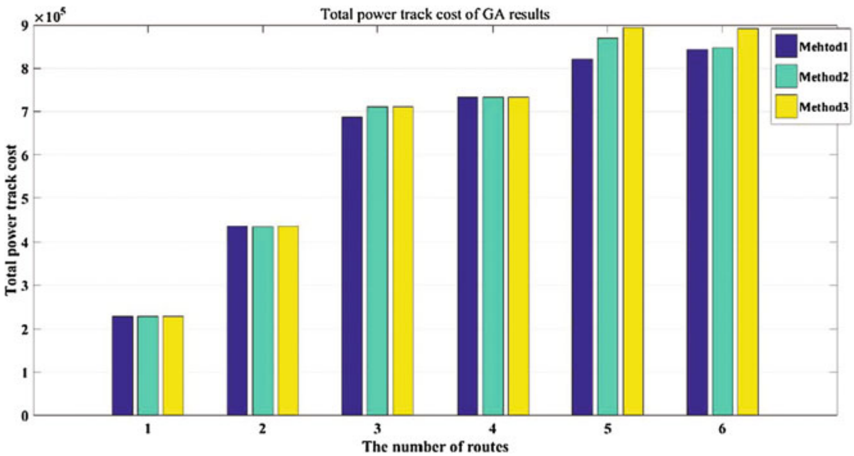

Fig. 6. The comparison of total track cost in GA methods

A comparison of the average calculation time in CPLEX and all GA methods is given in Table 4. The calculation time of GA method 1 and GA method 2 very slightly increases as the number of routes increases. The results of GA method 2 are slightly higher than those of GA method 1 because of the repair mechanism. The repair mechanism does not take up much time during the GA procedure as not all chromosomes are infeasible, and the modification is carried out for only for several genes in the infeasible chromosome. However, the results of GA method 3 indicate that the calculation time for each case is longer than for methods 1 and 2. The slope of the graph is also the steepest of the three methods. In the case of six routes, GA method 3 takes 381.15 seconds to suggest a solution, a calculation time about 5 times that of methods 1 and 2, as it must calculate the minimum battery capacity for all chromosomes in every generation, and the tasks for calculating the battery capacity also increase with the increase in the number of routes.

In the first and second cases, CPLEX is faster than all GA methods, but the time then increases exponentially from the third case, and for the six routes it

Table 4. The comparison of average computational time (in seconds)

Algorithm	CPLEX	GA method 1	GA method 2	GA method 3
One route	0.74	70.62	70.96	110.78
Two routes	1.26	71.4	72.14	156.05
Three routes	409.89	72.21	75.21	227.67
Four routes	619.68	77.13	80.36	274.96
Five routes	902.86	78.98	81.13	321.9
Six routes	40828.58	80.96	83.86	381.15

takes over 11 hours. This trend shows the characteristics of the exact algorithm, such as the Branch and Bound algorithm, which means that the exact algorithm is more sensitive to the size of problems compared to the GA. From the numerical experiments, we identify that GA methods 1 and 2 have an advantage in calculation time compared to GA method 3, but the quality of solutions from method 3 outperforms the other two. The GA can suggest reasonable solutions in a timely manner, but does not always guarantee optimal solutions. Therefore, the GA can be useful for large scale problems.

6 Conclusion

This study has introduced a new kind of dynamic wireless charging electric vehicle (DWC-EV) system. A mixed integer programming (MIP) model, which reflects multiple-route public transportation systems, was suggested to identify the economic allocations of the charging infrastructure and the battery capacity of the vehicle. A GA was introduced as a solution approach, and two approaches for chromosome design were suggested. Numerical experiments for an exact algorithm and a GA were conducted, and we analyzed the performance of three GA methods by comparing the optimal results of CPLEX. We checked that the repair mechanism for infeasible chromosomes improved the algorithm performance. A chromosome design without battery capacity was found to provide better solutions than other GA methods, though its calculation time was slow. These solutions are thus almost optimal solutions.

In this study, several assumptions were applied to develop the mathematical model. The assumption that the energy consumption between two stations is linearly proportional to the distance is particularly impractical, as this does not reflect the uncertainties of traffic or unpredictable situations. The assumption that the amount of charging is linearly proportional to the length of the power track was used to simplify the model. These assumptions should be proved quantitatively, and robust optimization can be used to consider uncertainties. The procedure of the GA must be established to solve the problem efficiently and effectively. After extending the limits of this study, we plan to apply our approach to broader multiple-route systems on a city or national scale. The GA is a simple approach and can be useful for discovering solution properties, and the solutions obtained can be reference points for heuristics and other algorithms, which will be examined in future research.

The Research of Incentive Model Based on Principal-Agent for R&D Personnel in System-Transformed Institutes

Ying Wei(✉) and Jun Gang

Sichuan Institute of Building Research, Chengdu, People's Republic of China
452758107@qq.com

Abstract. The lack of innovation and vitality from R&D personnel is a major problem to system -transformed institutes' innovation activities, and the short of rational and effective incentive mechanism is the source. Based on the analysis of present compensation and motivation, this paper established an incentive model of income distribution and a bonus incentive model by principal-agent theory, and then discussed the advantages and disadvantages of the two incentive models. The result shows that the incentive model of income distribution is more conducive to stimulate the enthusiasm of R&D personnel for system-transformed institutes.

Keywords: System-transformed institutes · R&D personnel · Incentive mechanism · Principal-agent

1 Introduction

Over 10 years' reform, some scientific research institutes have been transformed into enterprises. In this process, the system-transformed institutes actively cultivated the ability of technological innovation with excellent talent teams, and obtained advanced scientific and technological innovation constantly, those are inseparable with the creation and contribution of scientific and technological innovation talents. R&D personnel as the key power of the system-transformed institutes, is irreplaceable in the development and growth of enterprises. Therefore, how to provide maximize innovative space and their creative enthusiasm has become the most important issue for the institutes. But due to historical and practical reasons, there are still some problems such as the inflexible incentive mechanism, the single incentive means and so on, which restrict the innovation ability and enthusiasm seriously. Consequently, whether from the development of institutes itself or from the realization of the personnel value, it is very necessary to study the motivation of R&D personnel in system-transformed institutes.

Although some institutes have already developed incentive policies, but most of them are one-time awards, and usually pay attention to the number of achievements while ignore the quality and the efficiency, which are not conducive to

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_138

long-term enthusiasm for the R&D personnel. Many scholars at home and abroad have carried out a lot of research work about the motivation. Ou [5] researched on incentive of science and technology plan project by principal agent, analyzing the incentive factors and expound the design ideas of project incentive mechanism. Dikolli and Kulp [1] studied the impact of interaction between performance indicators of each task with multitask principal agent model. From the perspective of creating core competence, Gao [3] focused on human resources management problems and disadvantages about system-transformed institutes. Guo and Zhang [4] summarized the policies and regulations of the income distribution of personnel achievements, and proposed suggestions to improve the incentive mechanism. Ding and Chen [2] analyzed the Chinese S&T personnel motivation legal laws and regulations, and put forward policy recommendations to break the barriers to strengthen the transformation achievements motivation.

In summary, the current researches mainly concentrate on the demand characteristic, incentive factors and other aspects of R&D personnel, having certain referential significance to solve the motivation problem. On the basis of above researches, combining with the actual situation of system-transformed institutes, this paper took use of the principal-agent theory, optimizing the incentive mechanism design, discussed the incentive model of income distribution and bonus incentive model respectively though the balance of benefits and risks among the R&D personnel.

2 Background

2.1 The Connotation of the Collaborative Governance

A questionnaire survey for 18 system-transformed institutes in Sichuan has been carried out. As we can see in Fig. 1 that R&D personnel are always with high degree and different titles, showing that knowledge talents are the backbone of personnel team. Speaking of the salary system and incentive mechanism, we find that there are two main problems in current R&D personnel innovation. One is how to combine the performance appraisal with income, the other is the relationship between achievements and income. Each institute is actively exploring or thinking to solve the innovation problems. About 63.6% of institutes have a preliminary study on how to establish the performance evaluation and incentive mechanism, while others do not give a complete management advice on scientific and technological performance appraisal, still in a state of wait and see on the issue of income distribution about achievements.

The composition of R&D personnel income includes intrinsic compensation and extrinsic compensation, which can be seen in Fig. 2. Further, the intrinsic compensation is closely related to incentives, containing basic salary, merit pay, research prize and others. And the R&D personnel's income is mainly dependent on the basic salary and merit pay, taking 81.4% of the whole income, while less incentive income in Fig. 3. Most system-transformed institutes have not established a performance evaluation system different from the business production personnel, especially the case of performance appraisal system is not well sound.

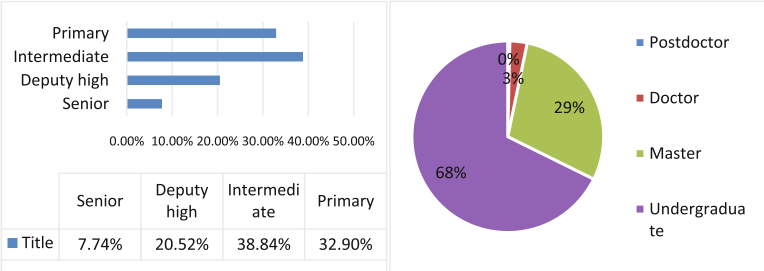

Fig. 1. The composition of R&D personnel in 18 institutes

Even though some institutes set up a merit pay, but not link to the performance of scientific research, so the income systems are still egalitarianism with small incentive income, especially lack of long-term incentive mechanism.

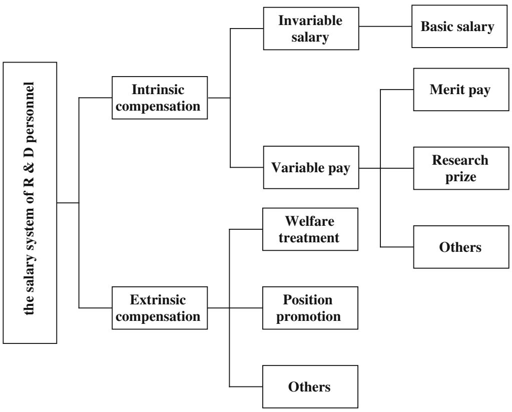

Fig. 2. The salary system of R&D personnel

3 Incentive Modeling

3.1 Income Distribution Incentive Model

Through the investigation and analysis above, it is not difficult to find that even there are four parts of R&D personnel income, the first two are actually relatively fixed, which can be seen as fixed income. And the other two are more fluctuant and associate with the degree of effort, can be regarded as incentive income. Assuming that the effort degree is proportional to the output, so the output of R&D personnel can be shown as:

$$X = W_0 + a + \varepsilon \quad \varepsilon \sim N(0, \sigma). \tag{1}$$

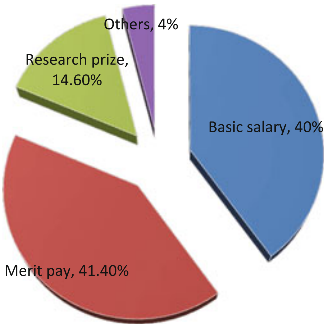

Fig. 3. The composition of intrinsic compensation

At the same degree of effort, the output embodied in two levels, the single value of scientific and technological achievement and the number of achievement. For the labor of R&D personnel is the knowledge labor, long term on a small number of achievements will get more value than those focus on numbers of achievements. For example, a patent will be specialized or in 10 patents be invented in one year. Obviously, the 10 patents tend not to produce too much real value. Therefore, hypothesis that and satisfy the following relations:

$$a = qv^{1/n}. \tag{2}$$

So, the actual benefits from R&D personnel to the institutes can be expressed as:

$$S = vq = v^{\frac{n-1}{n}}a. \tag{3}$$

Assume that R&D personnel share the results of income in accordance with a certain proportion k_1, so the personal income can be expressed as:

$$I = W_0 + v^{\frac{n-1}{n}}a. \tag{4}$$

In addition, R&D personnel have to pay a certain cost as well as the effort. Taking use of the common quadratic model in principal-agent theory, use to represent the effort cost, which is the relationship between effort and cost, so the cost can be expressed as:

$$c_1 = \frac{1}{2}ba^2. \tag{5}$$

Otherwise, comparing with the scientific research institutes, R&D personnel usually take risk aversion which needs to pay a certain risk costs. Set c_2 on behalf of the risk aversion, using Arrow-Pratt measure of absolute risk aversion to construct the risk cost function as follows:

$$c_2 = \frac{1}{2}\rho k_1^2 v^{\frac{2n-2}{n}}\sigma^2. \tag{6}$$

So the actual expected income can be expressed as:

$$\mathrm{E[I]} = W_0 + k_1 v^{\frac{n-1}{n}} a - \frac{1}{2} b a^2 - \frac{1}{2} \rho k_1^2 v^{\frac{2n-2}{n}} \sigma^2. \tag{7}$$

Certainly, most of the institutes usually demand the minimum number of achievements, which record as $\underline{v}$. And set $\underline{q}$ as the lower limit of the single value, so the value of a single scientific and technological achievement shall meet the following constraints:

$$\underline{v} \leq v \leq a/\underline{q}. \tag{8}$$

In summary, the R&D personnel decision-making model is:

$$\begin{aligned} &\max_{a,q} \quad \mathrm{E[I]} = W_0 + k_1 v^{\frac{n-1}{n}} a - \tfrac{1}{2} b a^2 - \tfrac{1}{2} \rho k_1^2 v^{\frac{2n-2}{n}} \sigma^2 \\ &\text{s.t.} \quad \underline{v} \leq v \leq a/\underline{q}. \end{aligned} \tag{9}$$

Similarly, the income of institutes is $(1-k_1)v^{\frac{n-1}{n}} a - W_0$. The risk of institutes is often neutral relative to R&D personnel, pursue the maximization of expected return usually. In addition, R&D personnel usually set a psychological bottom line of personal income, which institutes must take it into consideration. So the decision model of institutes is:

$$\begin{aligned} &\max_{k} \quad \mathrm{E[V]} = (1-k_1) v^{\frac{n-1}{n}} a - W_0 \\ &\text{s.t.} \quad W_0 + k_1 v^{\frac{n-1}{n}} a - \tfrac{1}{2} b a^2 - \tfrac{1}{2} \rho k_1^2 v^{\frac{2n-2}{n}} \sigma^2 \geq I_{\min}. \end{aligned} \tag{10}$$

To sum up, the incentive model under the income distribution model for R&D personnel, the decision model can be shown as:

$$\begin{aligned} &\max_{k} \quad \mathrm{E[V]} = (1-k_1) v^{\frac{n-1}{n}} a - W_0 \\ &\text{s.t.} \quad \begin{cases} W_0 + k_1 v^{\frac{n-1}{n}} a - \tfrac{1}{2} b a^2 - \tfrac{1}{2} \rho k_1^2 v^{\frac{2n-2}{n}} \sigma^2 \geq I_{\min}, \\ \max\limits_{a,q} \mathrm{E[I]} = W_0 + k_1 v^{\frac{n-1}{n}} a - \tfrac{1}{2} b a^2 - \tfrac{1}{2} \rho k_1^2 v^{\frac{2n-2}{n}} \sigma^2, \\ \text{s.t.} \quad \underline{v} \leq v \leq a/\underline{q}. \end{cases} \end{aligned} \tag{11}$$

For the income is directly linked to the transfer profit, so the R&D personnel will try to create the greatest value of achievements under the premise of the minimum completion number. The effort level of R&D personnel is positively correlated with the income coefficient, the greater proportion of income distribution, the more initiative from R&D personnel. Strives for the partial derivatives can get the following results:

$$\frac{\partial k_1}{\partial \rho} < 0, \frac{\partial a}{\partial \rho} < 0, \frac{\partial E[V]}{\partial \rho} < 0, \frac{\partial k_1}{\partial b} < 0, \frac{\partial a}{\partial b} < 0, \frac{\partial E[V]}{\partial b} < 0, \frac{\partial k_1}{\partial \underline{q}} < 0, \frac{\partial a}{\partial \underline{q}} < 0, \frac{\partial E[V]}{\partial \underline{q}} < 0.$$

Thus it can be seen that, in the optimal state, the income coefficient, the effort level and the income of institutes are negatively correlated with the risk aversion, the effort cost and the minimum number of achievements. This suggests that under the incentive model of income distribution, the system-transformed institutes should reduce the limit number of achievements can not only encourage R&D personnel in a greater extent, but also improve the actual income of institutes.

3.2 Bonus Incentive Model

This part will discuss the incentive problem of R&D personnel under the bonus incentive model. Hypothesis that the bonus is positively with the number of achievements, and the achievement bonus of the institute is k_2. Still, the single value v and the number q satisfy the following relations at the same level of effort:

$$a = qv^{1/n}. \tag{12}$$

Then, the income of R&D personnel can be expressed as:

$$I = W_0 + k_2 q = W_0 + k_2 v^{\frac{1}{n}} a. \tag{13}$$

For the bonus is positively with the achievement number, so under the same level of effort, R&D personnel must ignore the quality of the results, and pay more attention to the number of results. Set $\underline{v}$ as the lower limit of the single value of achievements, and the upper limit is $a/\underline{q}$ when meet the minimum number of results, so taking the cost and risk into account, the expected return model of R&D personnel is:

$$\begin{aligned} &\max_{a,v}\ \mathrm{E[I]} = \mathrm{W}_0 + k_2 v^{-\frac{1}{n}} \mathrm{a} - \tfrac{1}{2} b a^2 - \tfrac{1}{2} \rho k_2^2 \mathrm{v}^{-\frac{2}{\mathrm{n}}} \sigma^2 \\ &\text{s.t. } \underline{v} \le v \le a/\underline{q}. \end{aligned} \tag{14}$$

The expected return of institute is:

$$E[V] = S - W_0 - k_2 q = vq - k_2 v^{\frac{1}{n}} a - W_0 = v^{\frac{n+1}{n}} a - k_2 v^{\frac{1}{n}} a - W_0. \tag{15}$$

So, under the bonus incentive model the incentive model can be shown as follows:

$$\begin{aligned} &\max_{k_2}\ \mathrm{E[V]} = v^{\frac{n+1}{n}} a - k_2 v^{\frac{1}{n}} a - W_0 \\ &\text{s.t.}\quad \begin{cases} \mathrm{W}_0 + k_2 v^{-\frac{1}{n}} \mathrm{a} - \tfrac{1}{2} b a^2 - \tfrac{1}{2} \rho k_2^2 \mathrm{v}^{-\frac{2}{\mathrm{n}}} \sigma^2 \ge I_{\min}, \\ \max\limits_{a,v}\ \mathrm{E[I]} = \mathrm{W}_0 + k_2 v^{-\frac{1}{n}} \mathrm{a} - \tfrac{1}{2} b a^2 - \tfrac{1}{2} \rho k_2^2 \mathrm{v}^{-\frac{2}{\mathrm{n}}} \sigma^2, \\ \text{s.t. } \underline{v} \le v \le a/\underline{q}. \end{cases} \end{aligned} \tag{16}$$

There we can get the following conclusions, (1) under the bonus incentive model, in order to maximize the personal interests, R&D personnel will ignore the actual value of the research results and blindly pursue the numbers. As a principal, institutes can set the appropriate technology bonus by assessing the lowest value of achievements. (2) For the bonus amount is proportional to the lowest value, so the lower value of achievements, the more achievements R&D personnel create in the same level of effort, so as to obtain more revenue. (3) Stand in the perspective of the institutes, to avoid the emergence of low value achievements, they should set a threshold of achievements, and strictly evaluate them.

4 Comparison Analysis

Compare the income distribution incentive model with the bonus incentive model (see in Table 1), we can find that: (1) R&D personnel have different pursuit in the two models. R&D personnel pay more attention on the value of achievement under the income distribution incentive model, while pursue to create a great number of achievements in the bonus incentive model. For the system-transformed institutes take profit as the goal, thus using income distribution incentive model more. And the colleges use bonus incentive model frequently when facing with a large number of assessment indicators. (2) In the income distribution incentive model, the revenue sharing factor of R&D personnel is relative with effort cost, risk aversion coefficient and output random error, but has nothing to do with the result itself. While the bonus factor in addition to the impact above, also related to the lowest value of scientific and technological achievements.

Table 1. The comparison of two models

Parameter	Income distribution incentive model	Bonus incentive model
k	$\frac{1}{1+\rho b\sigma^2}$	$\frac{\underline{v}^{\frac{n+2}{n}}}{1+b\rho\sigma^2}$
v	$\frac{1}{b^n \underline{q}^n (1+\rho b\sigma^2)}$	$\underline{v}$
a	$\frac{\underline{q}^{1-n}}{b^n (1+\rho b\sigma^2)^n}$	$\frac{\underline{v}^{\frac{n+1}{n}}}{b+\rho b^2\sigma^2}$
$E[V]$	$\frac{\underline{q}^{2-2n}}{2b^{2n-1}(1+\rho b\sigma^2)^{2n-1}} - I_{\min}$	$\frac{\underline{v}^{\frac{2n+2}{n}}}{2b(1+\rho b\sigma^2)} - I_{\min}$

5 Conclusion

Scientific incentives can attract and retain excellent researchers for scientific research institutes, meeting the ultimate needs of beneficiaries constantly. And salary is the prerequisite to ensure the material needs of R&D personnel, also is the prerequisite and basis for the scientific and technological talents to pursue higher level needs. Even though China's policies and regulations for the allocation of R&D personnel incentive requirements are put forward, most of the institutes only pay fixed income when they can observe the effort level from personnel. Normally, it is difficult to observe the effort level, still let researchers share part of the output share, otherwise R&D personnel will not work hard with basic salaries, which is detrimental to the development of enterprises, also the country. From the analysis, R&D personnel focus on the value is applied to the system-transformed institutes, while a great number of achievements will be made to the colleges. The revenue sharing factor of R&D personnel is relative with effort cost, risk aversion coefficient and output random error, but has nothing to do with the result itself. Therefore, the greater effort cost, the smaller share of output, and the smaller risk for those who fear of hard work. Conversely, the stronger ability, the lower effort cost.

Abstract. In the crisis, the biggest psychological threat to the public is the loss of public sense of security. Through the related research, it is hypothesized that critical events, countermeasures of the government and the media, emergency response capability of the individual and the emergency psychological behavior of the group are the four main factors influencing public sense of security in the emergencies. A total of 330 samples were randomly selected from those people who had experienced the explosion in Tianjin. By exploratory factor analysis and the structural equation model examination, the fourfactors all have different degrees of explanation towards the loss of public sense of security. According to the conclusion, we can see that it is the key for the government to construct the governance mechanism by enhancing the emergency response capability of the group improve their certain sense of crisis and their sense of control of the situation.

Keywords: Public sense of security · Critical events · Countermeasures of the government and the media · Emergency response of the individual and the group · Structural equation model

1 Introduction

A crisis is often caused by both the "objective crisis of the events" and "subjective crisis of the individual", but the negative impact of the subjective crisis of individual is often greater than that of the events. Just as the attack on September 11 has happened for 15 years while its impact and psychological fears left to people have a long-term influence on American society. In 2011, Fukushima nuclear accident caused "salt-buying panic" in China, the reason of which is

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_139

people's fear for the crisis. When the crisis comes, the biggest threat to the public is the loss of their sense of security which is a prominent feature of public emergency psychology after the crisis. But why a few events that are actually less harmful are more influential on the public than those that have fatal consequences? Why do crisis of the same types have different effects on the public sense of security in a different time and place? This series of events have shown that the formation of public sense of security requires both objective conditions and also subjective factors.

Based on the existing research on the public sense of security, this paper designs a model of the influencing factors of public sense of security and also analyzes the data through questionnaire and the relationship between data and their characteristics based on SPAA as well as the influencing factors of the public sense of security based on the structural equation of AMOS. Besides, it measure how these factors influence the public sense of security, which contributes to the design of the emergency psychological governance mechanism in the emergency.

2 Conceptual Definition and Literature Review

2.1 Definition of the Public Sense of Security

According to scholars at home and abroad, sense of security is referred to the sense of belonging in a community and the sense of self [3]. The "public sense of security" in this article involves the sense of belonging, the certain sense of control and the satisfaction of security needs that the public experience in a certain public environment. Among them, the sense of belonging refers to the warm and the reliable subjective experience of the cares and comfort from other members in the community. The certain sense of control refers to the certain cognitive and controlled experience for the causes, processes and trends of the public crisis based on the timely, adequate and consistent information attained from the main information channels. Satisfaction of security needs refers to the effective sense attained from effectively coping with the crisis and safe subjective experience, which is formed on the basis of the full understanding of the development of the public crisis and the assessment of the social assistance system and the public emergency capability.

2.2 Overview of Domestic and Foreign Research

Foreign research has gone through two stages: the first stage is the public sense of security in the perspective of "crisis management". "Bounded Rationality" of Simon [7] thinks that due to the limitation of the individual in memory, thinking, computing power and other aspects, individual rationality is just bounded rationality in constrained conditions. The second one is to introduce the theory of "risk perception" with the public sense of security examined by "crisis communication" model. Industrial pollution happening in 1984 in Union Carbide Corporation triggered panics due to slow release of information, which then urged the scholars to reflect. Covello finds that the risk assessment by the authorities is very different from the risk perception by the public and also the public show great distrust in the authority of risk management, which weakened their sense of security and even lead to fear [1]. Sun Ding and Matthew, the American scholars, thinks that the public sense of security is "the degree of anxiety and concern of those who are becoming victims", so the potential victims is selected as the objects in their research. However, they also agree that the public sense of security is a psychological phenomenon, which is characterized by anxiety or concern. Lois Mok, an American scholar, put more focus on the power of control in the sense of security and think it is the reflection on the normal order and the weakened social control from of the public [9].

In recent years, we have conducted deeper research on the public sense of security in the crisis, and the theoretical circle has shown a basic trend of multidisciplinary research and innovation. In terms of the social and psychological impact from critical events, Zhang Yan, in her study of the critical events, divided the psychological impact on the victims from critical events into three stages: the first stage is the formation of risk experience; the second is psychological cognition of risk; the third one is the implementation of mental decision and the spread of psychological influences [10]. The most important empirical investigations of the public sense of security was the sample survey conducted by Institute of public sense of security in the Ministry of public sense of security in 1988 in 15 provinces and urban areas with its results published in the book–"Do you feel safe?". The group defined the public sense of security as: the subjective feelings and evaluation of the public for the social security are the comprehensive psychological reflection of the infringement that the personal rights, property rights and other lawful rights and interests of citizens have suffered or will suffer and the protection they expect in a certain period of the social life [4]. Based on the theory of prospect, Sun Doyong constructed the research model to study the personal perception of fears in the crisis from three aspects: the features of the event itself, the characteristics of the individual and the social factors [8].

3 The Hypothesis in the Research

3.1 Build a Model of the Influencing Factors of Public Sense of Security

The critical events, the countermeasures of the government and the media, the emergency response capacity of the individual and the psychological behavior of the group in the natural disasters are described as four main factors that influence the public sense of security in "Research on the Influencing Factors of public sense of security and Countermeasures in Major Emergencies–An Empirical Analysis Based on the public sense of security of Ya'an Earthquake on April 20". Based on it, we assume that, in the disaster of security incidents, the critical events, the countermeasures of the government and the media, the emergency response capacity of the individual and the psychological behavior of the group are still the most important factors that influence the public sense of security.

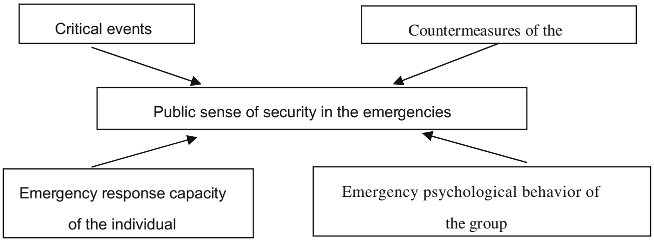

Fig. 1. Model of the influencing factors the public sense of security in the emergent events

Thus, we construct a conceptual model that affects public sense of security in the disaster of security incidents, which is shown as in Fig. 1.

3.2 The Hypothesis in the Research

Caplan and Edward assumed that each person is basically in a state of dynamic balance with the environment. When a person is facing a huge disaster in his life, he will have a high degree of tension, anxiety, pessimism and disappointment and a series of psychological problems if the disaster goes beyond his psychological endurance [2]. Thus, we assume that:

Hypothesis 1: In an emergency, the severity of the crisis, the extent of the impact and the number of casualties are negatively related to the level of the public sense of security. The more serious the crisis are, the more insecure the public will feel.

"The media dependence theory" put forward by Melvin Devler, a prominent American communication expert, points out that people are often anxious to get to know the truth through the government and the media, and the dependence will be enhanced obviously when the society is undergoing major changes but the situation is not clear. Therefore, the timely warning and the objective and fair reports from the government and the media is helpful to reassure the public and prevent further deterioration of the situation [6].

Hypothesis 2: In the emergencies, the countermeasures of government and the media to the emergencies is positively related to the public sense of security. The more timely and effective the countermeasures of the government and the media are, the safer the public will feel.

Robert Hiss put forward the FPC model and thought that the individual's ability and familiarity constituted the core variables of effective response to the crisis. The stronger the individual' ability and the higher the familiarity with the crisis are, the better the effect of dealing with the crisis will be [5].

Hypothesis 3: In the emergencies, the individual's knowledge of crisis, risk preferences, psychological quality are positively correlated to the public sense of security. The stronger the individual' emergency capacity are, the safer he will feel.

According to the theory of “Herd Behavior” which has been widely verified, individual in the crisis, often affected by others’ behavioral strategies, will often adopt the same behavioral strategy. That is to say, instead of being based on their own information, their behavior choice is the imitation of others or over-reliance on the public opinion, which tends to lead to the herd behavior. Thus, we assume that:

Hypothesis 4: In the emergencies, the psychology and behavior of the surrounding people are positively related to the public sense of security. The more stable the emergency psychological behavior of the group is, the safer the public will feel [8].

4 Research Methods and Tools

4.1 Scale

The paper collects data from the victims suffering from in the “explosion that happened in October 12 in Binhai New Area in Tianjin” by questionnaire survey which is divided into three parts. The first part is about the measurement of public sense of security and it makes the subjects score their sense of security; the second part is the measurement of public sense of security in emergencies; the third part is involved in the investigation of the five factors that influence hypothesis to finally form the questionnaire for formal study which is consisted of 25 items by the analysis of the factor and project.

4.2 Descriptive Statistical Analysis

A total of 330 questionnaires were distributed and 320 of them were collected with a recovery rate at 96.9%. After removing the unqualified questionnaire, 305 valid questionnaire were collected with the effective rate at 95.3%.

4.3 Examination of the Internal Consistency

According to the third part of the questionnaire, SPSS was used to analyze the internal consistency of the samples, which is shown as in Table 1. The results show that the alpha coefficient is 0.839, which proves that the designed questionnaires have good internal consistency and also indicate that the design of the questionnaire is scientific and reasonable.

Table 1. Analysis results of the internal consistency

Alpha of Cronbach	Alpha of Cronbach that is based on standardized project	Number of the projects
0.839	0.837	20

5 Results

5.1 Analysis of the Impact of Gender on the Public Sense of Security

In this questionnaire, we conducted survey on the demographic characteristics of respondents from the perspective of gender.

Using Independent-samples T test of the SPSS, we analyzed the impact of gender on sense of security with its results shown in Table 2. In the first part, we tested Levene' variance homogeneity with $F = 0.041$, $p = 0.084 > 0.05$, which meant that the variance was homogeneous while in the second part, the tested $t = 2.585$, $p = 0.010 < 0.05$, symbolized that the mean difference of the two samples is significant.

Table 2. Results of T test about gender

	Levene test in variance equation			T test in mean equation					
	F	Sig.	T	df	Sig. (in two sides)	Difference between the means	Standard margin of error	Min.	Max.
Index of the sense of security construct the equal variances	0.041	0.841	2.585	314	0.01	0.609	0.236	0.146	1.073
Construct the unequal variances	0	0	2.569	298,915	0.011	0.609	0.237	0.143	1.076

The results of T test show that the public sense of security is significantly affected by the gender after the explosion and the sense of security of men is distinctly higher than that of women, which may be explained by the environment where men and women grew up or their physical differences and also shows that in the post-disaster relief, we need to put more focus on women to rescue them.

5.2 Exploratory Factor Analysis

SPSS was used to carry out exploratory factor analysis on the samples with its results shown in Fig. 3. v13 to v32 are the corresponding items of the four influencing factors in the questionnaire. Among them, v13 to v15 correspond to critical events, v16 to v23 to the countermeasures of the government and the media, v24 to v27 to the emergency response capabilities of the individual, and v28 to v32 to the emergency psychological behavior of the group.

The results of exploratory factor analysis showed that the influencing factors mainly concentrate on four aspects, which was consistent with the hypothesis of the paper. Because of the dispersion of the concentration of the emergency psychological ability of the group in exploratory analysis, after analyzing and interpreting the corresponding items, we deleted two of them to conduct the exploratory factor analysis once again, which showed that the polymerizing effect of the four factors was good.

As shown in Table 3

5.3 Examination of the Model of the Influencing Factors of the Public Sense of Security

Based on the above four factors, this paper uses Amos to test the structural equation model, the indicators of which all meet expectation, as shown in Fig. 2. It can be seen that the four factors have a better explanation towards their impact on the public sense of security. Among them, only the impact of the critical events on the public sense of security is negative, indicating that they are negatively correlated, while the other three factors have positive impacts. Compared with the five hypotheses originally designed, the trust in the government and the countermeasures of the media are combined as one influencing factor. At the same time, according to the value of how these factors influence the public sense of security, we can see that the emergency psychological behavior of the group has the greatest impact, followed by the emergency capacity of the individual, the countermeasures of the government and the media and the severity of the critical events.

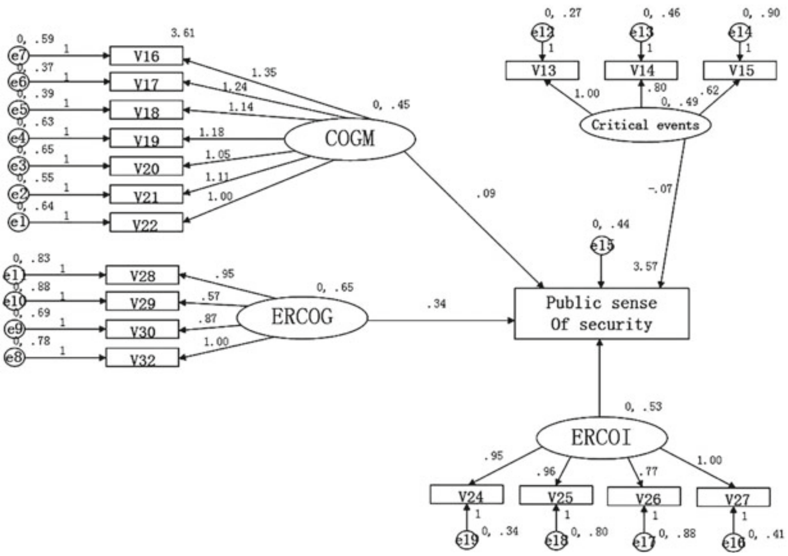

Fig. 2. Model of the influencing factors of the public sense of security. (ERCOG-Emergency response capacity of the group, COGM-Countermeasures of the government and the media, ERCOI-Emergency response capacity of the individual)

5.4 Examination on the Exploratory Factor Analysis of the Structural Dimension of the Public Sense of Security

We divided the structural dimension of the public sense of security, examined by SPSS, into sense of belonging, certain sense of control and sense of security with its results shown in Table 4: We can see that 10 items of the questionnaire are better aggregated into three categories, the coefficient of which statistically meet the requirements. We can see that V3, V4, V5, V6 come together as the first dimension while V7, V8, V9 as the second and V10, V11 and V12 as the third, which is consistent with the idea of how questionnaire is designed, but the structure of the questionnaire is more clear. According to the design of the questionnaire, we reduced the first dimension to a sense of belonging and the second dimension to a sense of security and the third to certain sense of control.

5.5 How the Influencing Factors of the Public Sense of Security Affect the Sense of Security

On the basis of determining the model of the influencing factors of the public sense of security and how each factor affects the public sense of security, we explored the mechanism of how the influencing factors affect the structural factors of the sense of security.

(1) How the influencing factors of the public sense of security affect the sense of belonging

First of all, we tested the structural equation model based on how the influencing factors of the public sense of security affect its first structural factors–"sense of belonging" with its results shown in Fig. 3. The results that may be affected by the characteristics of the security incidents showed that the emergency psychological behavior of the group had the strongest effect on the sense of belonging of the individual while the emergency response capacity of the individual comes second, followed by the countermeasures of the government and the media. When accidents and disasters that human error should be to blame for occurs, the credibility of the government and the media in the public mind will somewhat decline. The public will be more dependent on how the surrounding people deal with disasters, the rational behavior and effective countermeasures of whom will give the public a "sense of belonging." With the development of the newly emerging net media, the knowledge of how to effectively deal with the disaster has been more and more universal, at the same time the overall emergency response capacity of the group is also improved, which is consistent with the reality.

(2) How the influencing factors of the public sense of security affect the security needs

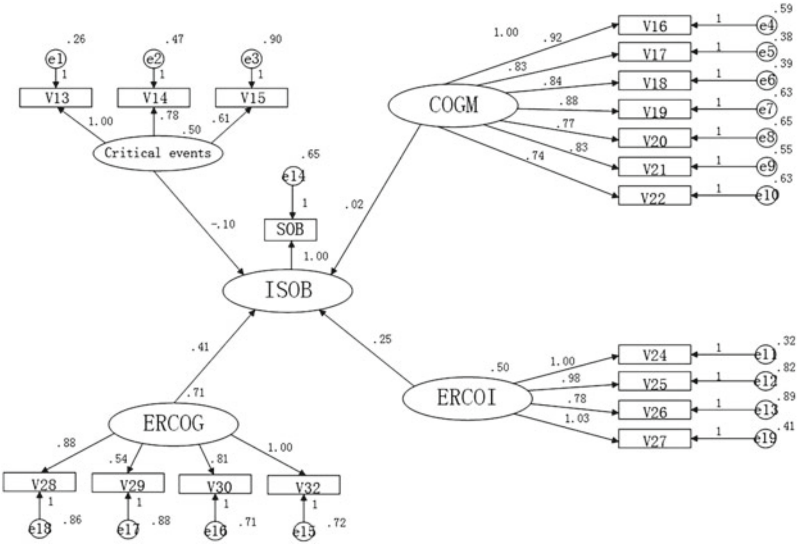

Fig. 3. Model of how the influencing factors of the public sense of security affect the sense of belonging. (ERCOG-Emergency response capacity of the group, COGM-Countermeasures of the government and the media, SOB-Sense of belonging, ISOB-Individual's sense of belonging, ERCOI-Emergency response capacity of the individual)

First of all, we tested the structural equation model based on how the influencing factors of the public sense of security affect its second structural factors–"security needs" with its results shown in Fig. 4. The results showed that the emergency response capacity of the individual was the most important factor that affects the sense of security of life, followed by the emergency response capability of the group and the countermeasures of the government and the media. Although personal characteristics, knowledge of emergency response and reactions on the spot are vastly different in the individuals, the security needs, for us, is the most essential experience of our safe lives and our emergency response capacity can directly affect our sense of security. In spite of the fact that the personal characteristics are difficult to control, it is possible to maximize the rationality by improving the personal crisis knowledge and his emergency response capacity in the face of major emergencies and minimize the casualty through effective emergency response. Once the individual has the clear understanding of that he should take immediate effective emergency measures, he will maximize the index of his sense of security. At the same time, the results also showed that in the crisis the emergency psychological behavior of the surrounding people will have great effect on the security experience of the individual.

(3) How the influencing factors of the public sense of security affect the certain sense of control

First of all, we test the structural equation model based on how the influencing factors of the public sense of security affect its third structural factors–the

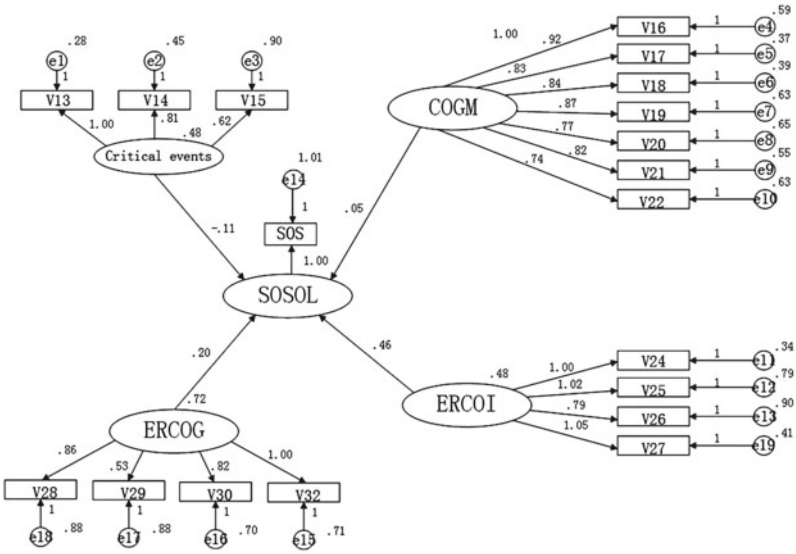

Fig. 4. Model of how the influencing factors of the public sense of security affect the security needs. (ERCOG-Emergency response capacity of the group, COGM-Countermeasures of the government and the media, SOS-Sense of security, SOSOL-Sense of security of life, ERCOI-Emergency response capacity of the individual)

"certain sense of control" with its results shown in Fig. 5. The results showed that the emergency psychological behavior of the group is the most important factor which can affect the certain sense of control of the public with the countermeasures of the government and the media coming second and the emergency response capacity of the individual third. The emergency behavior of the group can offer the demonstration and guidance to personal behavior, therefore, in the security incidents, their rational and effective emergency behavior can enhance the sense of control of the individual. In this mutual action model, the countermeasures of the government and the media also have greater influence, because it is a key to obtain the adequate, accurate and timely information for enhancing the sense of control. In China, our government and media have the ability to grasp the information of the emergencies and delivery them to the public adequately, timely and accurately to help themata in the whole information and improve their certain sense of control.

6 Countermeasures

In the major emergencies, the biggest problem that the public face is the loss of their sense of security, which, as a concept of subjective cognition, is to a large extent affected by self psychology. Thus, we can by certain means and ways affect our sense of security so as to enhance the effectiveness of disaster aid.

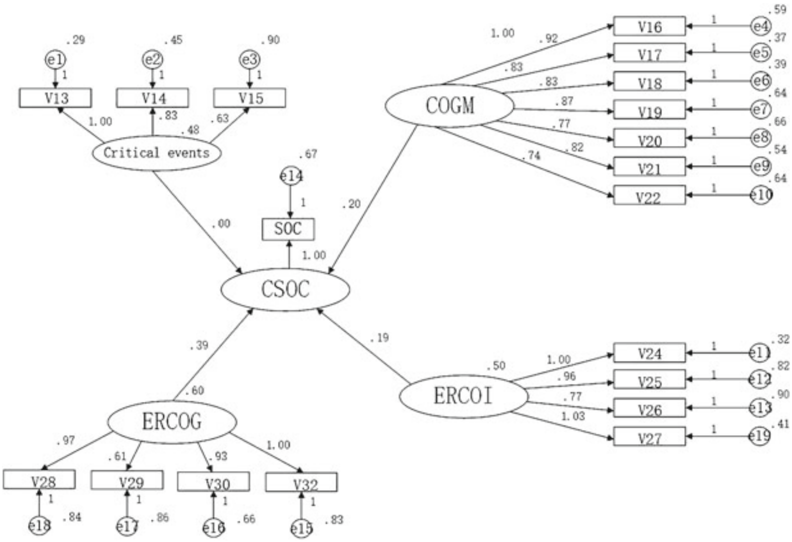

Fig. 5. Model of how the influencing factors of the public sense of security affect the certain sense of control. (ERCOG-Emergency response capacity of the group, COGM-Countermeasures of the government and the media, SOC-Sense of control, CSOC-Certain sense of control, ERCOI-Emergency response capacity of the individual)

When the crisis happens, it is a starting point of emergency psychological governance to create the public sense of security and the measurement of its influencing factors and how it is affected provide the evidence and direction for us to create a countermeasure system of social emergency psychological governance, which will be introduced in terms of the following three aspects.

6.1 Enhance the Countermeasures of the Emergency Response Capacity of the Group

In the measurement of the influencing factors of the public sense of security, the emergency response capacity of the group has the greatest impact. Personal behavior, influenced both by the external factors and group action, is easy to imitate the group action. In critical events, whether the emergency behavior of the group is effective or not will directly affect the sense of security of the individual. Therefore, it is necessary to enhance emergency response capacity of the group by regularly relevant knowledge and disaster drills.

6.2 Improve the Countermeasures of Certain Sense of the Crisis

In light of the countermeasures of the government and media as the key influencing factors of the public sense of security, unscientific reports on critical events from medias and the delay of the emergency measures from the government will lead to a serious decrease of the public sense of security and also fuel their fears. In the case of asymmetric information, government and the media should play their role of "delivering information timely" to enhance the sense of certainty of the public. The emergency measures taken by the government departments should be combined with the information distributed by the media and the view of the media to keep the information timely, adequate and accurate so that they can enhance the certain sense of crisis of the public.

6.3 Put More Importance to the Countermeasure of the Sense of Control of the Situation

This study also validate the assumptions that the nature and severity and other aspects of the critical events have impact on the emergency psychology of the public. Public fear in the face of crisis is an important reason for the loss of the sense of security. A sense of control of the situation should be created to help the public know how to deal with the crisis. They have become the important topics of emergency psychological governance to strengthen crisis education of the whole society so that people in the face of crisis can keep rational and orderly in the risk society. We should create a four-in-one crisis education system of the government, media, social organization and the public and design diagnostic measures, publicity measures and mentoring approach of the effective emergency measures in all kinds of situations for the public.

Abstract. The objective of this paper is to investigate the effect of free tissue flap colorimetric card in the postoperative flap management for tumors of oral and maxilla-facial region. Through observing 42 patients who used free tissue flap colorimetric card after operation, it was found that twelve patients had vascular disease, three had insufficient arterial infusion, and nine had venous return obstruction. Among them, one patient who had insufficient arterial infusion and two had venous return obstruction received re-anastomosis of vascular surgery and hemostasis surgery, and then all patients recovered well. The paper conclude that the free tissue flap colorimetric card is a simple, timely, accurate and effective tool for the observation of flaps, and it is suitable for clinical application.

Keywords: Free tissue flap colorimetric card · Tumors of oral and maxilla-facial region · Skin flap care · Crisis of blood-circulation

1 Introduction

Radical surgery for malignant tumors of oral and maxilla-facial region involves a wide range of injury, resulting in soft and hard tissue defects, seriously affecting the appearance and function of patients. Using their own tissue flap free graft to the mouth for large area of tissue defects repair has become a common method to improve the quality of life of patients [11]. It is the most important care content after free skin flap transplantation surgery to timely detect and actively deal with crisis of blood-circulation, as well as to promote the survival of the flap. In order to improve the success rate of free tissue flap, reduce the occurrence of crisis of blood-circulation and improve the success rate of the crisis tissue flap rescue, the branch designed the colorimetric card for free tissue flap in 2011 and applied the national utility model patent certificate (Certificate No. 3767860). Whats more, it has been used in has been in clinical application for more than

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_140

3 years, and the reflecting is very good. In this paper, the effect of free tissue flap colorimetric card in the postoperative flap management for tumors of oral and maxilla-facial region was concluded.

2 Materials and Methods

2.1 Normal Information

From September 2013 to November 2016, 42 cases of free flap repair were performed in our department, including 35 males and 7 females with an average age of 46.2 years (range, 17–74 years), including 17 cases of tongue cancer, 9 cases of buccal cancer, 7 cases of oral bottom cancer, 5 cases of gum cancer, 4 cases of soft palate cancer.

The information of surgery: there were 27 forearm radial free skin flap in repairing of oral cavity defect, 6 anterolateral thigh flap in repairing of oral cavity defect, 4 free pectoralis major myocutaneous flap in repairing of oral defect, 3 fibula myocutaneous flap in repairing of oral and maxillofacial defect, 2 osseo myocutaneous iliac flap in repairing of oral and maxillofacial defect.

2.2 Observation and Nursing of Skin Flap

Free flap is mainly observed blood flow of the skin flap, such as the color of the flap, temperature, degree of swelling and Shiatsu back to the blood reaction so as not to crisis of blood-circulation. Observer should avoid flashlight and other light interference, while maintaining the correct posture, to prevent the flap tension is too large or distorted [12]. The flap was observed by free tissue flap colorimetric card immediately after the patient was returned to the ward, and the results were recorded on the free tissue flap monitor. The observation was recorded every 30 min within 24 h after surgery, every 2 h within 24–72 h after surgery, every 4 h within 72 h–7 d after surgery. Abnormal flaps were observed every 15 min to record, and observe the records as usual since removing crisis of blood-circulation.

2.3 The Design of Free Tissue Flap Colorimetric Card

There are 10 colorimetric card for free tissue flap grafting made of silicone, its four corners rounded. The color areas of the ten cards are selected according to Table 1 and are different from each other, like Fig. 1.

The connecting shaft 6 has at least three elongated cards 1 whose one end is provided with a connecting hole 2, and the other end is provided with a colored area 3, and all the cards 1 are mounted on the connecting shaft through the connecting hole 2 in a manner similar to the fan structure, which is rotatable about the connecting shaft 6. The side edge of the card is also provided with a graduation zone 4 (accurate to millimeters) adjacent to the color zone 3 to accommodate various sizes within the oral cavity of the patient. In addition, the card is also provided with a text description area 5, with the color area 3 (seen Table 1).

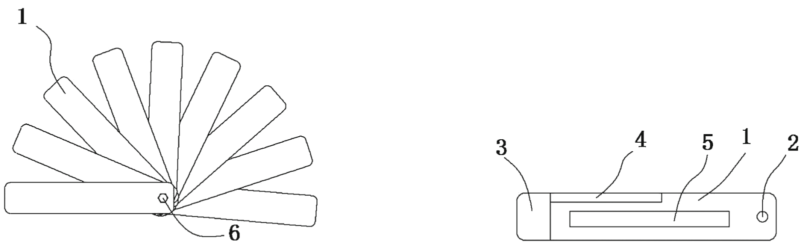

Fig. 1. The design of free tissue flap colorimetric card

Table 1. Description of color about free tissue flap colorimetric card

Parameter	Pale 1	Pale 2	Pale 3	Rosy 1	Rosy 2	Rosy 3	Violaceous 1	Violaceous 2	Violaceous 3	Atropurpureus
Tonal	20	20	20	20	9	9	234	235	225	225
Saturation	240	240	240	240	231	232	80	79	75	75
Brightness	226	216	204	195	166	152	169	146	126	45
Red R	225	225	205	255	252	252	205	188	172	63
Green G	240	230	217	207	136	113	155	122	96	33
Blue B	225	205	179	159	100	70	162	131	125	44

Note: the form of parameters are computer palette.

Pale1: arterial of flap flood inadequacy severally.
Pale2: arterial of flap flood inadequacy generally.
Pale3: arterial of flap flood inadequacy lightly.
Rosy1: the flaps grew well and the blood circulation was smooth relatively.
Rosy2: the flaps grew well and the blood circulation was smooth.
Rosy3: the flaps grew well and the blood circulation was very smooth.
Violaceous1: venous return is blocked lightly.
Violaceous2: venous return is blocked generally.
Violaceous2: venous return is blocked severally.
Atropurpureus: flaps is dead.

2.4 Detailed Description of Free Tissue Flap Colorimetric Card

The patient opened his mouth as fully as possible in order to expose the flaps in the irradiation conditions of natural light or fluorescent white light. At first, let the colorimetric card range by fan-out, compared and estimated flap color belongs to which card 1 color area 3. Then in order to improve the accuracy, the card 1 of the color region 3 is further inserted into the oral cavity of the patient, and the contrast is confirmed in close proximity. If colorimetric card was contaminated by the patient's oral secretions, blood, etc. in the usage of the card, it is necessary to be disinfected with alcohol or chlorine preparations after cleaning with water, and to prepare a set of colorimetric cards for every patients with specific infections. Colorimetric cards can also be set into a PVC gloves, discarded after every used. Generally, each card 1 is provided with a color region 3, and the number of the cards 1 can be determined according to the circumstances. When more accurate conditions are required, more cards 1 are required to make the whole structure have more color areas 3, in order to obtain more accurate flap discoloration.

2.5 Beneficial Effect of Free Tissue Flap Colorimetric Card

As the color areas were set in the card, the color of color area can be set by color in different conditions of flap, then the medical staff can objectively compare the transplanted flap color with the card on the color area in order to determine t whether there is a problem in the growth of the flap and to solve timely. This judgment of same standard reduces the judgment error caused by different subjective consciousness or lack of experience, which makes the flap observation simpler and more accurate.

3 Results

The 42 flaps were all live. Twelve patients had vascular disease, three arterial insufficiency, and nine venous return obstruction. Among them, 2 cases of mild arterial insufficiency maintain the correct position to release the pressure around the wound and the symptom relief after strengthening the local negative pressure drainage. 6 cases of mild venous return disorder were light by roasted lights. Among them, 2 cases relief after plus acupuncture flap bleeding, heparin sodium coated. 1 case of severe hypoperfusion of the arteries and 2 cases of severe venous return obstructed patients received re-anastomosis underwent vascular surgery and bleeding debridement surgery. 1 case of venous return to the middle and severe blocked, skin flap dead. All the patients recovered well after phlebotomy, and all the patients recovered well in phonation, chewing and swallowing (seen Table 2).

Table 2. The status about 42 cases of flaps after surgery

Situation of flap	# of cases	Vascular crisis time/h				Interventions measures			TFBBI	
		≤12	12–24	24–48	48–72	Lamp illumination	Needle bleeding of flap	Surgical debridement	≤6	≥6
Arterial insufficiency	3	1	1	1	0	0	0	1	1	2
Venous reflux disorder	9	0	2	6	1	9	2	2	2	7
Good growth of skin flap	30	0	0	0	0	0	0	0	0	0
Total	42	1	3	7	1	9	2	3	3	9

Note: TFBBI, Time of flap becoming better after intervention

4 Discuss

Large area of soft and hard tissue defects after the radical surgery for malignant tumors of oral and maxilla-facial region, often resulting in severe postoperative facial deformity and dysfunction. Although the survival rate of various free tissue flap has reached more than 90% [1,2,7,9], there are still a small number of patients whose tissue flap dead due to various reasons. The rate of crisis of blood-circulation is about to 3.5%–9.1% [8,10,14,15] according to domestic and foreign literature. Once the free tissue flap dead, it will give patients a disastrous blow, not only to extend the length of stay, increasing medical costs, more likely to make the mortality rate increased. The success of flap repair surgery, in addition to surgical techniques and equipment, but also thanks to good observation and nursing measures.

4.1 Routine Care of Flap After Surgery for Tumors of Oral and Maxilla-Facial Region

(1) Respiratory management

It is easy to lead to edema of Tongue and mouth bottom after surgery for tumors of oral and maxilla-facial region. The establishment and maintenance of airway patency is an important link, if necessary, preventable tracheostomy. There are a group of 19 patients with prophylactic tracheotomy. Strictly according to tracheotomy care routine, the use of saline and chymotrypsin atomization inhalation, 3 times a day, timely suction, no case of pulmonary infection occurred in patients. 1 case of buccal cancer free forearm flap transplantation, body fat, short neck, dyspnea occurred on postoperative day 3, and lift the respiratory distress after emergency tracheotomy.

(2) Position of care

Tissue flap transplantation area position nursing: Maintain the patient's head in the median or slightly biased side of surgery, non-distortions, effectively reducing the flap microvascular anastomosis tension. Raising bed 15°–30° after patients wake up is conducive to wound drainage and tissue valve venous return in order to reduce the surgical area and head and face edema. Attention to night patrol, and timely correct the patient is not correct position, to avoid the flap vascular pedicle compression, traction, discount.

Tissue flap for the position of care: Raising the donor limb elevation in order to facilitate venous return, and pay attention to finger blood supply and swelling. At the same time observe the wound bleeding situation, keep the dressing clean and Bandage intact. 1 patient of the group complaint the tissue flap for side limb numbness after 6 h, and the acral skin is pale by physical examination, skin temperature decreased, then immediately notify the physician to relieve decompression, symptom relief after rewrapping, to ensure the donor limb of the blood circulation.

(3) Ward management

Temperature of ward room is in 22–26° C, humidity 50% to 70%, and ward disinfect with ultraviolet every day 2 times. Attention to keep warm, to prevent crisis of blood-circulation due to vascular spasm by cold stimulation. Publicize non-smoking to family members and visiting staff, so that small artery spasm due to nicotine in tobacco, affecting the flap blood supply and induced arterial crisis.

(4) Medication care

It is important to attention to vital signs of observation, in particular changes in blood pressure which should be in 130/70 mmHg above, to ensure adequate blood volume. At the same time the usage of anticoagulation, anti-spasm, anti-infective drugs, routine use of low molecular weight heparin sodium, papaverine, dextran, Xiangdan should be as prescribed. In addition, observe the effect of medication and anticoagulant treatment side effects.

Strengthening nutrition promote incision growth. All patients underwent PG-SGA score, according to the results of the nutritionist to intervene, to provide patients with high-calorie, high protein and vitamin-rich diet plan, to prepare specialized nutrient solution if necessary. 42 patients retain the stomach tube to contact vacuum suction device, fasting on the day of surgery, to be drained liquid light green for nasal feeding which done 200 mL/time, interval 2 h 1 time. After the incision healed, the patient was instructed to practice swallowing. Nasogastric tube could be remove when oral feeding is without exception, instead of gold-type tube feeding (Using 50 mL syringe, a section of about 15–20 cm of the infusion tube, the tube set in the syringe, the injection of food when the skin placed in the mouth between the second and third molar). Diet from the liquid gradually transition to semi-liquid and solid food, avoiding cold, sharp, hard, with bone, barbed food.

(5) Nursing care of the irradiation of roasted lamps

This method can improve the local temperature of the flap, reduce arteriovenous vasospasm, as well as maintain microvascular smooth blood supply. With 40–60 W roasted lamp irradiation anastomosis, the use of distance 30–45 cm avoid baking lamp close-up flap, to prevent local temperature too high. There were nine cases of vascular crisis in this group, in the emergence of flap color darkening, flap tension increased to give roasted lights irradiation, with the use of vasodilator drugs in 2 cases after 6 h, 7 cases the flap color improved after 6 h.

(6) Nursing of wound drainage

Maintain the drainage area smooth, to prevent blood clots oppression arteriovenous effects of blood circulation and venous return. A one-time high vacuum drainage bottle contacting the end of drainage tube continued to attract, properly fixed drainage tube, regular squeeze, to avoid pipe distortion, compression, clogging, shedding, close observation of drainage fluid color, and measure the amount of drainage fluid and make a record 1 time/1 h within 24 h after surgery. If the drainage beyond 400 ml/d, bright red color, solidification, bleeding may be considered. If the amount is small, dark red, then alert subcutaneous congestion, and report to the doctor timely. If the drainage lower 10–15 ml/d, estuation can be considered after 48–72 h.

(7) Oral care

It was necessary to do oral management and to keep the flap area clean, if there were oral bleeding, more exudate after surgery. Routine oral care should be three times a day. Cotton balls should be along the line of blood vessels and pay attention to grasp the intensity when scrubbing. If necessary, to do oral cleaning. With 20 ml syringe aspiration of 3% hydrogen peroxide and saline as well as compound chlorine has been mixed, it was repeatedly washed, companying with a negative pressure. Note that suction should be on the contralateral, so as not to damage the flap and incision.

4.2 The Care of the Usage Free Tissue Flap Colorimetric Card in the Postoperative Flap Management for Tumors of Oral and Maxilla-Facial Region

After free flap anastomosis, a common complication is crisis of blood-circulation, divided into venous crisis and arterial crisis, usually occurring after 24–48 h [4]. The main monitoring indicators is the color, acupres sure and flap temperature difference [5]. The change of the flap color is the main basis for recognition and treatment. Early period of flap reconstruction, targeted nursing monitoring measures can help find vascular complications, providing first-hand information for clinical treatment. Weng [13] reported that flaps generally tolerate up to 6 h of ischemia without severe necrosis, 75% of the flaps would be necrosis after venous thrombosis continued 6 h and Flap necrosis rate would be 100% if beyond 8 h. Therefore, there some studies [6,13] pointed out that occurrence of flap ischemia and the timely monitoring of care is to determine the success of the key to the success of flap transplantation.

(1) Content of flap observation

Skin color changes and capillary reflow measurement, is the early minimum two indicators of reflection of blood circulation status of the most direct and rapid, subject to outside interference, and receiving repeat verification. Where both the skin color and capillary reflow abnormalities or more than two abnormal monitoring indicators, there is the crisis of blood-circulation. Venous crisis is usually manifested as red flap color, capillary response, and gradually become dark red, dark red, late black, acupuncturing out of dark red or black liquid when swollen hardened. Arterial crisis showed that the flap color is pale, lack of elasticity, acupuncturing without blood flow. However, the clinical description of the flap color and elastic temperature difference is often subjective, and the evaluation result is limited by the professional skill and nursing condition. First-line duty personnel for flap blood flow status judgment may be insufficient. If the flap color change with not knowing whether abnormal and the person do not have enough judgment experience, it may delay the flap vascular crisis rescue. We set up a free tissue flap management team, the department head deputy head appointed director and deputy director and head nurse as deputy head.

The backbone experts in the organization department access to a large number of domestic and foreign literature and review past patients pictures and case information, referred to the skin Flap vascular crisis indicators, combined with 20 years of clinical experience, to design the free tissue flap colorimetric card. In the flap color, degree of pale, ruddy, cyanotic were distinguished carefully to help clinicians to determine the extent of vascular crisis. At the same time, the observation of flap vision and abnormal changes in the scope of color flap provide accurate information for clinical care analysis, diagnosis and treatment according to the actual data. For 1 case of buccal cancer patients in the group after surgery 3 h, at 1:00 at night the flap color is pale 1 and skin temperature is slightly lower, as well as the examination body find no swelling of the neck, with plasma drainage tube patency and drainage of 15 ml dark red liquid. Doctor asked to record once every 15 min. The flap color transact pale 2 close to the pale 3 after 1 h and the neck was swollen with the drainage of the blood of the liquid drainage tube bright red liquid 50 ml. Then immediately report the surgeon, decisively send the patient to the operating room emergency line of neck incision debridement and vascular crisis exploration as well as small vessel anastomosis. After that, no longer found bleeding by observing 1 h, with the wound closed and a smooth period of 72 h risk period, the patients was back to the ward and at the latter part, voice, chewing, swallowing function of the patient recovered well.

(2) Observation field and time of flap

Defects in the postoperative flap management for tumors of oral and maxilla-facial region are generally located in the mouth. Especially the flap near the tongue observed inconveniently, so it need to increase the patient mouth opening, so that the full exposure of the flap. For 1 patient of the group within surgery 12 h, the wound edge bleed too much, the edge was dark purple and the area continue to expand to the center. It observed color change is not obvious within 2 s by sterile cotton swab compression capillary filling degree. And with 1ml syringe needle piercing the center of the flap, there were 0.5 cm dark red liquid outflow. Then we immediately notify the surgeon back to the operating room emergency treatment within 6 h after the flap color improved. There was another cases of oral bottom free radical repair, whose flap color was purple bark 1 and slightly faster response of the capillaries when back to the ward. Nurses found visible spots at mouth flap near the tongue 1/5 and increased speckle area with time in 13 h after surgery. When roasted lamp irradiation treatment is invalid, we immediately notify the doctor back to the operating room line exploration, and it found to be venous cramps combined embolism. Finally, the flap survived after the embolization vein re-anastomosis.

(3) The rule of crisis of blood-circulation

Flap crisis often occurs at night, which is linked with nocturnal high vagal tone, vascular intimal injury caused by hemodynamic changes, the role of nerve on the blood vessels and hormone secretion [3]. Nurses should strengthen the night patrol and attention to patient complaints as well as strict shift. There was 1 patients with left squamous cell carcinoma resection and left cervical lymph node dissection and thoracic duct ligation as well as common carotid artery epineurium and sublingual resection and free forearm flap excision repair and small vascular anastomosis and abdominal free skin graft repair complained neck pressure, pain, physical examination after 17 h. And physical examination only saw the flap suture and tongue bruising. But shift officers have not attracted great attention, so that the white skin flap color deepening, the area expanded to 1/2 or more when the shift after 6 h. It found negative pressure drainage tube shift, subcutaneous hemorrhage obvious, vascular anastomotic pressure and venous return blocked when sent to the operating room exploration. However, there was no obvious improvement in the flap condition at 6 h after operation, and the capillary reflex was not obvious. The elasticity also was poor and the skin temperature was low. Then the doctor surgery to trim the skin flap, to strengthen drainage, with local iodoformize gauze dressing and intravenous anti-infection as well as blood circulation and other treatment, so the flap survived.

5 Summary

Crisis of blood-circulation is one of the main complications of vascular anastomosis after vascular tissue transplantation. It is an important factor to timely find problems and take appropriate measures to ensure the survival of the flap. By using free tissue flap colorimetric card, it describe the flap color, capillary filling and the scope of flap color changes with the objective data as well as text, which makes the observation of free tissue flap more Simple and accurate. Therefore, it is worthy to promote in clinic.

The Impact of Intellectual Capital on High-Tech Enterprise Performance: Applied Study in China's Second-Board Market

Hongchang Mei(✉) and Kunling Wang

School of Administration, Chongqing Technology and Business University, Chongqing 400067, People's Republic of China
1426315339@qq.com

Abstract. This paper chooses high tech enterprises listed on China's Second-board Market as research objects. The aims of this thesis are to find out the impact of intellectual capital on the performance of high-tech enterprises. This study has carried out an empirical analysis with the method of multiple linear regression. The empirical findings indicate a trend that for high-tech industries on the GEM, the improvement of their performance efficiency depends more on the human capital compared to structural capital and physical capital. Both human capital and structural capital significantly influence the performance efficiency of enterprises in the high-tech industry, while physical capital practically doesn't impact it significantly. According to the empirical findings, this paper has put forward some advices on capital allocation for Chinese high-tech enterprises.

Keywords: Intellectual capital (IC) · Performance · High-tech enterprises

1 Introduction

In the industrial age, human capital is the driving force of economic growth, but in the age of knowledge economy, intellectual capital has become the power source of economic growth, which is also changing the rules of business and national competitiveness. Also, nowadays intangibles are almost universally considered as the main value drivers for companies [12].

China as a rapidly developing country, has strongly encouraged entrepreneurial activities especially in high-tech fields. Similarly, intellectual capital seems more important than any other factor in the fields of high-tech, that intellectual capital management have become the domain of the so-called Chief Knowledge Officer [1], there is a great need to study the impact of intellectual capital in Chinese high-tech enterprises. The result will not only aid in selection for managing intangibles, but also accelerate the pace of growing of high-tech companies.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_141

This research aims to investigate the impact of intellectual capital on the performance of selected enterprises in the high-tech sector on the Second-board market in China. The first section deals with the introduction of intellectual capital and related researches. This follows with research methodology and design. In the third section, the research empirical findings are presented. Finally, the conclusion outlines the limitations and implication of this study.

2 Literature Review

2.1 Intellectual Capital and Sub-Components of Intellectual Capital

The word Intellectual capital was first proposed by Senior as a synonym for human capital in 1836, which he believes is a combination of knowledge and skills of human beings. John Galbraith extended the concept of intellectual capital, noting that intellectual capital was not just knowledge or pure intellect, but also the process of making use of knowledge effectively. Guenther, Beyer [11] argued that intellectual capital represents the sum of all the intangible assets of the company. Also Intangible assets are defined as the company's non-material and non-financial resources, including technology, customer information, brand name, honor and corporate culture. The intellectual capital of an enterprise can improve the performance of an enterprise by relying on the dynamic interaction of IC components [4].

IC is also considered as the sum of following three categories: (1) Human capital, which refers to the people in an organization and describes their cumulative tacit knowledge skills. (2) Structural capital, which consists of supportive infrastructure, processes, and databases of corporation that enable human capital to function [8]. (3) Relational capital.

Another definition is that IC is derived insights about head value, future earnings capabilities, based on human capital, as well as organizational, structural and relational capital [5]. Some scholars hold the view that intellectual capital can be classified into human capital and structural capital, divides intellectual capital into human capital and structural capital, which is accepted by author of this article.

2.2 Relation Between IC and Firm Performance

Firer did an empirical research on the relationship between the three components of value added intellectual coefficient (VAIC) in South Africa. He concluded that, if the decision makers focus more on exploiting the physical capital reward, it would lead to the neglect of the use of human capital.

The human capital is very important to the enterprise performance, that companies should value it while managing their IC. Bontis [2] conducted a study on the efficiency of IC to enterprise value in service industry and other industry in Malaysian. The results show that human capital in various industries is an important role as structural capital and is positively correlated with the performance of enterprises. Fengetal [6] proposed that it was necessary to clarify the relationship between corporate performance and human capital with more attention to human capital.

They also have mentioned that performance of enterprises should be considered by combining the characteristics and degree of competition of specific industry. Zhu et al. [13] assumed that human capital is the key factor to determine enterprise performance.

2.3 IC Measurement Models

IC is difficult to measure as an intangible asset. So far there is no unified view on the measurement method for intellectual capital. The current measurement models are as follows.

(1) Difference between market value and book value, which assumes that the intellectual capital of enterprises could be the difference between their market value and book value.
(2) Tobin'sq, which refers to the ratio between a physical asset's market value and its replacement value. It was proposed in 1968 by James Tobin and William Brainard [3]. If the replacement cost of the company's assets is lower than the company's market value, the company's investment behaviors would have obtained excess profits, which are generated from IC [10].
(3) VAICAnte Public proposed Value Added Intellectual Coefficient (VAIC) in 1998 to measure the intellectual capital value of an enterprise. According to this method corporate capital consists of physical capital and intellectual capital, and corporate performance depends on the efficiency of value added by a firm from its physical capital and intellectual capital resources. This method assumed that the enterprise's intellectual value-added efficiency represented its performance.

Lentjušenkova and Lapina [7] proposed that, in a modern organization, its managerial approaches and investment facilities are changing along with the growing importance of IC and the changes of its components, thereby changing the managerial approaches and focusing on value creation.

The paper chooses the VAIC method to analyze impacts of intellectual capital on the performance of high-tech enterprises in China. In this sector, business in the following specific industries are preferred, like high-growth, high-tech, high value-added and new economy, new services, new agriculture, new energy and new materials, that possess high growth potential with high risk [9]. In these industries, the value and function of intellectual capital seems have exceeded financial capital.

3 Research Methodology and Design

This study is a longitudinal research in a time-span 2013–2015 and refers to China. Based on the developed VAIC model by Firer, this paper analyzes the correlation and regression between value-added coefficients of IC components and high-tech enterprise performance. And then explains the relationship between intellectual capital components and enterprise performance based on the analysis results. In this model, it is assumed that value creation of enterprise mainly comes from physical capital resources and intellectual capital resources.

3.1 Research Hypotheses

Economic growth mainly depends on physical capital and intellectual capital. For the composition of intellectual capital in this paper, it is assumed that IC includes human capital and structural capital. Human capital is the sum of knowledge, skills, experience of people in the corporate. IC can be performed in the products and services, knowledge level and education level of corporate members. This paper uses the index of human capital value-added coefficient to represent its intensity. Structural capital is an organizational asset that is embedded in organizational structure, management system standard and corporate culture. In this paper, the structural capital intensity will be represented by its value-added coefficient.

Hypothesis 1: The intellectual capital and physical capital of an enterprise cause the performance of an enterprise.
Hypothesis 2: Intellectual capital consists of human capital and structural capital.
Hypothesis 3: For high-tech enterprises, the impact of intellectual capital on corporate performance is significant.

3.2 Sample Selection and Data Sources

The sample of this article comes from the financial statements of 80 companies listed on the GEM from 2013 to 2015. Research samples in this paper are all certified as high-tech by related government agency and listed on China's second-board market in Shenzhen stock exchange from 2013 to 2015. In order to ensure the validity of the data, the criteria for screening the original samples are as follows:

(1) Selecting the samples of the listed GEM companies, which are in continuous operation during this period to ensure the necessary continuity of the sample set.
(2) Financial services listed companies are eliminated because of their large total share capital, which may cause deviation of the regression results.
(3) Excluding listed companies of which annual financial statement data are incomplete, or not continuously operating in the time-span 2013–2015.
(4) Elimination of abnormal operating listed companies (e.g. Debt ratio surpassing 100%) and companies with deteriorating financial condition to ensure the validity of the sample data.

(5) Listed companies who have changed their main business because of mergers and acquisitions or other acts will not be included in the sample set. The final sample set includes 80 high-tech enterprises. This article used EXCEL and EVIEWS9.0 in the processing of sample data.

3.3 Research Model

Enterprise's ability to creating value by using physical capital and intellectual capital is called "intellectual ability", which is expressed by VAIC model. This model consists of capital employed efficiency (CEE), human capital efficiency (HCE) and structural capital efficiency (SCE). Relation between them is that, $\mathrm{VAIC}_i = \mathrm{CEE}_i + \mathrm{HCE}_i + \mathrm{SCE}_i$.

The main purpose of this article is to study the impact of intellectual capital on the performance of high-tech enterprises. By establishing the multiple linear regression model and doing a statistical hypothesis test, we obtained the estimation for the regression coefficient. Based on all the above conditions, we will interpret the impact of IC on performance of Chinese high-tech Enterprises.

The basic model used to estimate the binomial logistic regression models is:

$$\mathrm{ROA} = \alpha + \beta_1 \mathrm{CEE} + \beta_2 \mathrm{HCE} + \beta_3 \mathrm{SCE} + \beta_4 \mathrm{Leverage} + \beta_5 \mathrm{LNSIZE} + \varepsilon.$$

4 Research and Discussion

4.1 Variable Selection

(1) Selection of dependent variable
Interpretations of selected variables in this paper are as follows:

Table 1. Dependent variable

	Variable symbol	Variable explanation	Variable expression
Dependent Variable	ROA	Return on Assets	Net Income after Taxes/Assets

ROA shows the percentage of how profitable a company's assets are in generating revenue. In the following analysis we use ROA to express the performance of a company (Table 1).

(2) Selection of independent variables
(See Table 2)

① CE is for the book value of total assets of an enterprise.
② HC represents human capital of an enterprise which is measured by total wage cost of an enterprise. The total wage cost in this article is indicated by cash paid to employees as salary and other payments in cash flow statement of a listed company.

Table 2. Independent variables

	Variables symbol	Variables explanation	Variable expression
Independent variables	CEE	Capital Employed Efficiency	CEE = VA/CE
	HCE	Human Capital Efficiency	HCE = VA/HC
	SCE	Structural Capital Efficiency	SCE = SC/VA

③ VA expresses the value added of enterprise, which is a sum of net income, income tax and total wage cost.
④ Income taxes cost is used in place of income tax in this thesis.
⑤ With income tax cost as a approximation of income tax.

(3) Selection of control variables
(See Table 3)

Table 3. Control variables.

	Variables symbol	Variables explanation	Variable expression
Control variables	LNSIZE	Logarithm of Main Business Income	SIZE = LN (Total assets)
	Leverage	Debt ratio	Leverage = Total debt/Total assets

① The size of the assets impacts on the value of enterprises. IT is usually expressed by the total assets of enterprises. In order to reflect the size of the assets of enterprises accurately, this paper selects the logarithm of main business income as a control variable.
② Debt Ratio is a financial ratio that indicates the percentage of a company's assets that are provided via debt. It can be used to measure the ability of a firm to operate. Therefore, we use the Debt Ratio together as the second control variable.

4.2 Model Construction

On the basis of previous theoretical analysis, this paper constructs a multiple regression model between physical capital efficiency, human capital efficiency, structural capital efficiency and firm performance. The model is set as follows:

$$\mathrm{ROA} = \alpha + \beta_1 \mathrm{CEE} + \beta_2 \mathrm{HCE} + \beta_3 \mathrm{SCE} + \beta_4 \mathrm{Leverage} + \beta_5 \mathrm{LNSIZE} + \varepsilon.$$

Here: α is for the constant, $\beta_1 - \beta_5$ are corresponding coefficients. ε represents the random disturbance.

Table 4. Descriptive statistics of variables.

Observations	2013		2014		2015	
	Mean	Std. dev	Mean	Std. dev	Mean	Std. dev
ROA	0.061608	0.070561	0.065428	0.097572	0.068864	0.063246
LNSIZE	20.20134	0.855858	20.38727	0.888847	20.59145	0.8757
Leverage	0.27982	0.329841	0.224613	0.227157	0.304221	0.320626
CEE	0.174146	0.155064	0.213168	0.232301	0.196046	0.250991
HCE	2.095241	1.147357	2.430141	3.53092	2.484896	4.281109
SCE	0.309643	0.658739	0.41756	0.340202	0.343141	0.790112

4.3 Empirical Analysis

(1) Sample description statistics
We have described statistical relationships between variables in the model, that empirical results are as Table 4.

From results of descriptive statistics, we can see that the three-year average of ROA of high-tech enterprises on the China's second-board market are 0.061608, 0.065428 and 0.068864, which show that the performance of the high-tech enterprises listed on the China's second-board market is increasing year by year. The means of CEE in the sample period respectively are: 0.174146, 0.213168 and 0.196046, which means the change of physical capital is not very stable. But their standard deviations are: 0.155064, 0.232301 and 0.250991, which shows an increasing trend with time. It indicates that the difference between impacts of physical capital on each enterprise's performance is widening per year. The mean 2.095241, 2.430141 and 2.4484896 of HCE over sample period, which is showing an increasing trend, indicates that the influence of human capital on high-tech firms' performance listed on Chinese Second-board market is gradually increasing. The mean 0.309643, 0.417560 and 0.3343141 of SCE in these three years is showing an unstable trend without regularity.

We can also see from the above figure that mean of HCE is obviously greater than the mean of CEE and SCE during the period from 2013 to 2015, which tells that human capital of high-tech enterprises contribute more to the corporate performance than physical capital and structural capital.

(2) Partial correlation analysis for variables
In order to make the multiple regression analysis meaningful, we have analyzed the correlation between selected variables. The analysis results are as follows (Table 5):

It can be seen from the above analysis, that, there is a positive correlation between HCE, SCE, CEE and ROA. However, the correlation coefficient between ROA and CEE in 2014 is 0.0638, with the concomitant probability of T test 0.5712, which hasn't passed the confidence level of 1% test. This indicates that the impact of physical capital on firm performance is only a little in this year, The correlation coefficients of the other two years both correspond the 1% confidence

Table 5. Partial correlation analysis for selected variables.

			ROA	CEE	HCE	SCE	Leverage	LNSIZE
2013	ROA	Correlation	1	0.478	0.6902	0.4722	0.4403	0.6734

		Probability	0	0	0	-	0	0
	Leverage	Correlation	0.342	0.6802	0.3954	0.5557	1	0.6984
		Probability	0.0018	0	0.0003	0	-	0
	LNSIZE	Correlation	0.5711	0.6705	0.5731	0.7725	0.6984	1
		Probability	0	0	0	0	0	-
2015	ROA	Correlation	1	0.4335	0.4596	0.3742	0.4386	0.7515
		Probability	-	0.0001	0	0.0006	0	0
	CEE	Correlation	0.4335	1	0.418	0.3674	0.8234	0.6076
		Probability	0.0001	-	0.0001	0.0007	0	0
	HCE	Correlation	0.4596	0.418	1	0.3517	0.456	0.508
		Probability	0	0.0001	-	0.0013	0	0
	SCE	Correlation	0.3742	0.3674	0.3517	1	0.3422	0.3996
		Probability	0.0006	0.0007	0.0013	-	0.0018	0.0002
	Leverage	Correlation	0.4386	0.8234	0.456	0.3422	1	0.6803
		Probability	0	0	0	0.0018	-	0
	LNSIZE	Correlation	0.7515	0.6076	0.508	0.3996	0.6803	1
		Probability	0	0	0	0.0002	0	-

level of T test. At the same time, there are positive correlations between HCE, SCE and CEE, and all of them have passed T test with confidence level of 1%. This result tells that influencing factors of business performance are not independent of each other, but interacting with each other.

(3) Multiple regression

The regression results have shown that the results are not very ideal. Only the value of the intercept term in there gression equations passed the T test for linear regression (here 5%), with CEE, HCE, SCE coefficients did not. This result tells that the coefficients are not very credible. However, the F-test values 6.107650, 9.607723 and 5.317085 of each model have passed the F-test for linear regression (here 5%), which indicates explained variables in the model could be explained by explanatory variables (Table 6).

Table 6. Multiple regression model.

Time		2013		2014		2015	
Dependent variable		ROA		ROA		ROA	
		Coefficient	t-Statistic	Coefficient	t-Statistic	Coefficient	t-Statistic
Constant		−0.6637	−3.7726 (0.0003)	−0.476358	−2.175358 (0.0328)	−0.645427	−3.986521 (0.0002)
Independent variables	CEE	−0.0602	−1.1093 (0.2709)	−0.237977	−5.567514 (0.0000)	0.04047	1.134204 (0.2604)
	HCE	0.0177	2.3107 (0.0236)	0.004414	1.623358 (0.1088)	0.001087	0.703479 (0.484)
	SCE	0.005	0.3683 (0.7137)	0.03222	1.119615 (0.2665)	0.008388	1.020737 (0.3107)
Control variables	Leverage	0.034184	1.427739 (0.1576)	0.077395	1.812786 (0.0739)	−0.025991	−0.927511 (0.3567)
	LNSIZE	0.034031	3.966973 (0.0002)	0.027024	2.563172 (0.0124)	0.034416	4.429544 (0.0000)
Adjusted R-squared		0.244296		0.352664		0.214598	
F-statistic		6.10765		9.607723		5.317085	
Durbin-Watson stat		1.626685		2.100722		1.85182	

Besides, we can see that the coefficients of CEE in 2013 and 2014 respectively are −0.0602 and −0.237977, with 0.040470 in 2015, which indicates that CEE has a negative effect on ROA. Coefficients of other explanatory variables to ROA are positive, which tells that human capital and structural capital drive performance of high-tech enterprises. DW 1.626685, 2.100722, 1.851820 in the time-span are all close to 2, indicating that the regression equation does not have strong autocorrelation.

5 Conclusion

5.1 Limitations

The results seem to be achieved, but there are some limitations of the research. The first concerns the fact that the sample set limited to listed high-tech companies, because their financial data are available, while financial data of non-listed high-tech companies are not. Accordingly, carrying out further research linking IC and non-listed high-tech enterprises could develop this research field.

Another limitation concerns that some indicators of basic data used substitutions due to the availability of fundamental data on each company's financial report. So it needs more in-depth, exhaustive analysis to be carried out. A further limitation is, this analysis considers only the time-span 2013–2015 without consideration of environmental differences.

5.2 Implications for High-Tech Enterprises in China

From the above empirical research, we find that human capital and structural capital have significant positive correlation with the performance of listed high-tech enterprises, while physical not significant. For the high-tech enterprises listed on China's GEM, human capital of intellectual capital has greater impact on the corporate performance than structural capital and physical capital does. Structural capital has relatively less effect compared to other human capital on high-tech firms' performance. However, high-tech enterprises still need to pay attention to structural capital, and strengthen enterprise management. The average value-added efficiency of intellectual capital is bigger than that of physical capital, which reflects that the dependence of enterprise performance on intellectual capital is increasing in high-tech field. The author puts forward based on this empirical research following suggestions:

(1) High-tech enterprises should devote more efforts to the development and management of the intellectual resources of employees, and give full play to the intelligence of them.
(2) The focus of high-tech enterprises should be transferred from physical capital to intellectual capital.
(3) Designing enterprise size according to IC of a company will help to operate structural capital and physical capital more reasonable, and thus enhance their efficiency of creating corporate value.

Abstract. As an important solution to reduce the dependency on crude oil and minimize transportation-related carbon dioxide emissions along with other pollutants, electric vehicles (EVs) are broadly promoted by government. As the energy provider of EVs, electric vehicle charging stations (EVCSs) play important roles in electric vehicle popularization. The effective site selection of EVCS is in favour of promoting the willing of consumer to use EVs. In this paper, we apply multi-criteria group decision-making (MCGDM) method to site the public fast electric vehicle charging stations. To avoid the information lost in aggregation process, we use an intuitionistic fuzzy projection-based approach. The proposed method is applied into a numerical example, and the results show that the proposed MCGDM is feasible and efficient for EVCS site selection.

Keywords: Intuitionistic fuzzy set · Electric vehicle · Fast charging station · Multi-criteria decision making algorithm

1 Introduction

Electric vehicles (EVs) are considered as a significant solution to reduce the dependency on crude oil and minimize transportation-related carbon dioxide emissions along with other pollutants [7]. As the energy provider of EVs, electric vehicle charging station (EVCS) is the foundation of electric vehicle industry development [4]. Efficient, convenient and economic EVCS is in favour of promoting willingness of consumers and also the industry development. As the preliminary work of EVCSs constructions, the EVCS site selection is quite important in the whole life cycle, which has significant impacts on the service quality and operational efficiency of EVCS. Therefore, it is necessary to employ proper methods to determine the optimal EVCS site.

Li et al. [6] considered dynamic origin-destination trip satisfaction and public electric vehicle (EV) charging network expansion to develop a multi-period

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_142

refueling location model. Sheppard et al. [8] applied an agent-based simulation modeling platform to site EVCSs in Delhi. Antunes et al. [3] used a maximal coverage model to determine the optimal location, quantity and capacity for EVCSs. Although many models have been proposed to site EVCS, few papers have considered multi-criteria group decision making (MCGDM) techniques.

In classical decision-making problems, the preference value for each alternative expressed by each decision maker is precise [2]. Due to the fuzziness and uncertainty of decision-making problems and the inherent vagueness of human preferences, however, the best way for decision-makers to give their opinion is using natural language [11]. For that reason, linguistic variables [18], the value of which are expressed using words and sentences from natural language, have been widely used to indicate the preference values for each attribute. Aggregating linguistic information has generally been discussed under four main schemes [10].

The purpose of this paper is to apply the intuitionistic fuzzy projection-based approach to determine the optimal site for public fast electric vehicle charging station to promote the popularization of EVs in Chengdu. This framework differs from the traditional method as the weights of decision makers are undetermined and the complete process is conducted in an intuitionistic fuzzy environment. The remainder of this paper is organized as follows. In Sect. 2, we briefly review the basic concepts of intuitionistic fuzzy sets. The proposed fuzzy multi-criteria group decision making framework is presented in Sect. 3. Then, in Sect. 4, the proposed MCGDM is applied to determine the site for PFEVCSs. Finally, conclusions are drawn in Sect. 5.

2 Preliminaries

In this section, we briefly review the basic concepts of IFSs.

Definition 1. [17] Let X be a universe of discourse, then a fuzzy set A is defined as

$$A = \{\langle x, \mu_A(x)\rangle | x \in X, \mu_A(x) \in [0, 1]\}, \tag{1}$$

where $\mu_A(x)$ denotes the membership degree of the element x to the set A.

Definition 2. [1] Let X be a universe of discourse, then an intuitionistic fuzzy set A is shown as follows:

$$A = \{\langle x, \mu_A(x), \nu_{A(x)}\rangle | x \in X, \mu_A(x) \in [0, 1], \nu_A(x) \in [0, 1]\}, \tag{2}$$

where $\mu_A(x)$ and $\nu_A(x)$ respectively represent the membership degree and non membership degree of the element x to the set A with the condition $0 \leq \mu_A(x) + \nu_A(x) \leq 1$.

Definition 3. [1] For each intuitionistic fuzzy set A, if

$$\pi_A(x) = 1 - \mu_A(x) - \nu_A(x), \forall x \in X, \tag{3}$$

then, $\pi_A(x)$ is called the indeterminacy degree or hesitant degree of x to the set A. The bigger the $\pi_A(x)$, the more the indeterminacy degree of knowledge about x [15]. Especially, when $\mu_A(x) + \nu_A(x) = 1$, for $\forall x \in X$, the intuitionistic fuzzy set A is reduced to an ordinary fuzzy set [9].

Definition 4. [14] Suppose there are two intuitionistic fuzzy numbers $\alpha = (\mu_\alpha, \nu_\alpha)$ and $\beta = (\mu_\beta, \nu_\beta)$, in which $\mu \in [0,1]$, $\nu \in [0,1]$, $\mu + \nu \leq 1$ and $\pi = 1 - \mu - \nu$. Let λ be a real number, then the arithmetic operations are defined as follows:

(1) Addition operation

$$\alpha + \beta = (\mu_\alpha + \mu_\beta - \mu_\alpha \mu_\beta, \nu_\alpha \nu_\beta); \tag{4}$$

(2) Multiplication by a real number operation

$$\lambda\alpha = (1 - (1 - \mu_\alpha)^\lambda, \nu_\alpha^\lambda), \lambda > 0. \tag{5}$$

Definition 5. [15] Let $\alpha = (\mu_\alpha, \nu_\alpha)$ and $\beta = (\mu_\beta, \nu_\beta)$ be two intuitionistic fuzzy numbers, then projection of the α on β is defined as follow:

$$Proj_\beta(\alpha) = \frac{\alpha \cdot \beta}{|\beta|} = \frac{\mu_\alpha \mu_\beta + \nu_\alpha \nu_\beta + \pi_\alpha \pi_\beta}{\sqrt{\mu_\beta^2 + \nu_\beta^2 + \pi_\beta^2}}. \tag{6}$$

In general, the larger the value of $Proj_\beta(\alpha)$, the more the degree of the α approaching the β.

Definition 6. [15] Let $A = (\alpha_{ij})_{mn}$ and $B = (\beta_{ij})_{mn}$ are two intuitionistic fuzzy matrices. Then the projection of A on B is defined as follows:

$$Proj_B(A) = \frac{\sum_{i=1}^m \sum_{j=1}^n (\mu_{ij}^\alpha \mu_{ij}^\beta + \nu_{ij}^\alpha \nu_{ij}^\beta + \pi_{ij}^\alpha \pi_{ij}^\beta)}{\sqrt{\sum_{i=1}^m \sum_{j=1}^n \left((\mu_{ij}^\beta)^2 + (\nu_{ij}^\beta)^2 + (\pi_{ij}^\beta)^2\right)}}. \tag{7}$$

3 A Framework for MCGDM

The MCGDM problems have some common characteristics: multiple alternatives, multiple criteria and multiple decision makers. The aim of this kind of decision is to screen and rank the alternatives based on the preferences expressed by decision makers. Due to different education background and subjective perception, different decision makers have difference importance during decision-making process. Besides, it is quite common that there is no decision makers' weights information for the MCGDM, even decision makers' weights are decisive. Therefore, we construct a new framework to deal with MCGDM problems without any decision makers' weights information, as shown in Fig. 1.

Suppose that there are m alternatives $A_i, i \in \{1, 2, \cdots, m\}$ to be ranked. The performances of n criteria $C_j, j \in \{1, 2, \cdots, n\}$ are defined in linguistic terms which are obtained from t decision makers $D_k, k \in \{1, 2, \cdots, t\}$. Each decision

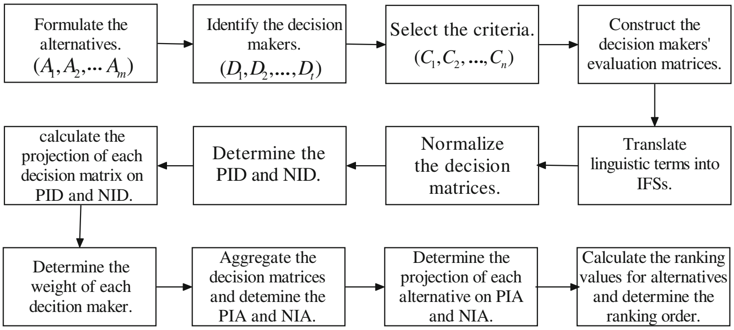

Fig. 1. The framework of proposed method

maker expresses his preference to each alternative regarding to each criterion using linguistic terms. Then decision matrices are constructed based on the all preferences, shown as follows:

$$D^k = \begin{pmatrix} r_{11}^k & r_{12}^k & \cdots & r_{1n}^k \\ r_{21}^k & r_{22}^k & \cdots & r_{2n}^k \\ \vdots & \vdots & \ddots & \vdots \\ r_{m1}^k & r_{m2}^k & \cdots & r_{mn}^k \end{pmatrix}. \tag{8}$$

3.1 Decision Makers' Weights Determination

TOPSIS, which was first developed by Hwang and Yoon [5], is a technique for establishing the order of preference by its similarity to the ideal point [13]. Inspired by [13,16], we present an extended TOPSIS method for the decision makers' weight determination under an intuitionistic fuzzy environment.

First, we construct the positive ideal decision (PID) matrix D^+ based on the average of all decision matrices, which is treated as a cursory group consensus of decision-making group. The equation is as follows:

$$D^+ = \begin{pmatrix} r_{11}^+ & r_{12}^+ & \cdots & r_{1n}^+ \\ r_{21}^+ & r_{22}^+ & \cdots & r_{2n}^+ \\ \vdots & \vdots & & \vdots \\ r_{m1}^+ & r_{m2}^+ & \cdots & r_{mn}^+ \end{pmatrix}, \tag{9}$$

where

$$r_{ij}^+ = \frac{1}{t} \sum_{k=1}^{t} r_{ij}^k. \tag{10}$$

Then, the negative ideal decision (NID) matrix D^- is determined as the most indeterminate decision matrix, which means that the indeterminacy degree of worst decision matrix possesses is the highest in all decision matrices. The equation is as follows:

$$D^- = \begin{pmatrix} r_{11}^- & r_{12}^- & \cdots & r_{1n}^- \\ r_{21}^- & r_{22}^- & \cdots & r_{2n}^- \\ \vdots & \vdots & \ddots & \vdots \\ r_{m1}^- & r_{m2}^- & \cdots & r_{mn}^- \end{pmatrix}, \tag{11}$$

where

$$r_{ij}^- = (\min_t \mu_{ij}^k, \max_t \nu_{ij}^k). \tag{12}$$

Since PID and NID have been determined, we consider the projection of each decision matrix on the ideal decision matrices. According to Eq. (7), the projection of D^k on D^+ can be calculated as follows:

$$\mathrm{Proj}_{D^+}(D^k) = \frac{\sum_{i=1}^m \sum_{j=1}^n (\mu_{ij}^{H^k} \mu_{ij}^{H^+} + \nu_{ij}^{H^k} \nu_{ij}^{H^+} + \pi_{ij}^{H^k} \pi_{ij}^{H^+})}{\sqrt{\sum_{i=1}^m \sum_{j=1}^n \left((\mu_{ij}^{H^+})^2 + (\nu_{ij}^{H^+})^2 + (\pi_{ij}^{H^+})^2\right)}}. \tag{13}$$

The projection of D^k on D^- can be calculated as follows:

$$\mathrm{Proj}_{D^-}(D^k) = \frac{\sum_{i=1}^m \sum_{j=1}^n (\mu_{ij}^{H^k} \mu_{ij}^{H^-} + \nu_{ij}^{H^k} \nu_{ij}^{H^-} + \pi_{ij}^{H^k} \pi_{ij}^{H^-})}{\sqrt{\sum_{i=1}^m \sum_{j=1}^n \left((\mu_{ij}^{H^-})^2 + (\nu_{ij}^{H^-})^2 + (\pi_{ij}^{H^-})^2\right)}}. \tag{14}$$

After that, the relative closeness of each individual decision matrix is determined as follows:

$$RC^k = \frac{\mathrm{Proj}_{D^-}(D^k)}{\mathrm{Proj}_{D^-}(D^k) + \mathrm{Proj}_{D^+}(D^k)}. \tag{15}$$

The relative closeness is used to determine the rank order for all decision makers. Obviously, the closer to the best decision result, the larger the value of RC^k is. Therefore, based on the relative closeness, the weight of each decision maker is obtained as follows:

$$\varpi_k = \frac{RC^k}{\sum_{k=1}^t RC^k} \tag{16}$$

where ϖ_k represents the wight of the kth decision maker, and $\varpi_k \geq 0$, $\sum_{k=1}^t \varpi_k = 1$. We use the vector $\varpi = (\varpi_1, \varpi_2, \cdots, \varpi_t)$ to represent the decision maker's weight vector.

3.2 Alternatives Ranking Order Determination

As the weights for decision makers are determined, the aggregated decision matrix can be calculated as follows:

$$D = (D^1, D^2, \cdots, D^t) \cdot (\varpi_1, \varpi_2, \cdots, \varpi_t)^T$$
$$= \begin{pmatrix} r_{11} & r_{12} & \cdots & r_{1n} \\ r_{21} & r_{22} & \cdots & r_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ r_{m1} & r_{m2} & \cdots & r_{mn} \end{pmatrix}, \tag{17}$$

where r_{ij} is the group preference IFS of alternative A_i respect to attribute C_j and

$$r_{ij} = \sum_{k=1}^{t} \varpi_k \cdot r_{ij}^k. \tag{18}$$

Then, the positive ideal alternative is determined as follows:

$$A^+ = (r_{11}^+, r_{12}^+, \cdots, r_{1n}^+), \tag{19}$$

where

$$r_{ij}^+ = (\max_m \mu_{ij}, \min_m \nu_{ij}). \tag{20}$$

The positive ideal alternative (PIA) should has the maximal separation from the PIA A^+. It is a very natural idea that we consider following decision:

$$A^- = (r_{11}^-, r_{12}^-, \cdots, r_{1n}^-), \tag{21}$$

where

$$r_{ij}^- = (\min_m \mu_{ij}, \max_m \nu_{ij}). \tag{22}$$

Then, the projection of each alternative on the ideal alternatives are calculated as follows:

$$\mathrm{Proj}_{A^+}(A^i) = \frac{\sum_{j=1}^n (\mu_{ij}^{A^i}\mu_{ij}^{A^+} + \nu_{ij}^{A^i}\nu_{ij}^{A^+} + \pi_{ij}^{A^i}\pi_{ij}^{A^+})}{\sqrt{\sum_{j=1}^n \left((\mu_{ij}^{A^+})^2 + (\nu_{ij}^{A^+})^2 + (\pi_{ij}^{A^+})^2\right)}}, \tag{23}$$

$$\mathrm{Proj}_{A^-}(A^i) = \frac{\sum_{j=1}^n (\mu_{ij}^{A^i}\mu_{ij}^{A^-} + \nu_{ij}^{A^i}\nu_{ij}^{A^-} + \pi_{ij}^{A^i}\pi_{ij}^{A^-})}{\sqrt{\sum_{j=1}^n \left((\mu_{ij}^{A^-})^2 + (\nu_{ij}^{A^-})^2 + (\pi_{ij}^{A^-})^2\right)}}. \tag{24}$$

Finally, the relative closeness is defined to determine the rank order for all alternatives. We have

$$RV_i = \frac{\mathrm{Proj}_{A^-}(A^i)}{\mathrm{Proj}_{A^+}(A^i) + \mathrm{Proj}_{A^-}(A^i)} \tag{25}$$

It is obvious that the bigger RV_i, the better alternative A^i is.

4 Site Selection for PFEVCS

PFEVCS site selection, as the preliminary work of EVCS construction, is quite important in the whole life cycle, which has significant impacts on the service quality and operational efficiency of EVCS. In this section, the proposed method is employed to select the optimal EVCS site from all the alternatives. In order to determine the possible alternatives and obtain the linguistic preference ratings, three groups of expert panels ($k = 1, 2, 3$) with expertise in the fields of environment, economy, society were formed. After reviewing the project feasibility research reports, the expert panels finally selected four EVCS sites as alternatives A_1, A_2, A_3 and A_4. EVCS sites alternatives A_1, A_2, A_3 and A_4 are respectively located at Wuhou district, Qingyang district, Jinniu district and Chenghua district in Chengdu.

The MCDM problem related to EVCS site selection includes three criteria (environment, economy and society) and eight sub-criteria ($j = 1, 2, \cdots, 8$). After reviewing the general information of all the alternatives, each expert group gave the linguistic ratings judgments for the sub-criteria performance of each alternative, and the results are listed in Table 1. According to the transform rules in Table 2, we transform the linguistic terms into intuitionistic fuzzy sets.

Step 1. We transform the decision matrices into intuitionistic fuzzy sets, and then determine the PID and NID respectively based on Eqs. (9)–(12). The projection of each decision matrix on PID and NID are calculated using Eqs. (13), (14). Then, according to Eq. (15), (16), the weights for decision makers are calculated as $\varpi = (0.3351, 0.3317, 0.3332)$.

Table 1. The decision matrix of decision makers

Decision makers	Alternatives	Criteria							
		C_1	C_2	C_3	C_4	C_5	C_6	C_7	C_8
D_1	A_1	MH	ML	H	VH	H	VH	ML	L
	A_2	ML	VL	M	M	MH	M	VL	M
	A_3	M	L	M	L	M	H	L	MH
	A_4	ML	MH	VL	MH	L	VL	MH	VL
D_2	A_1	H	L	VH	H	H	H	L	L
	A_2	M	M	ML	L	VH	H	L	ML
	A_3	MH	L	M	H	M	MH	ML	MH
	A_4	L	VH	L	H	ML	L	H	VL
D_3	A_1	H	L	H	MH	VH	H	ML	L
	A_2	ML	ML	MH	ML	MH	VH	M	H
	A_3	M	L	L	L	M	M	M	MH
	A_4	L	VH	ML	H	MH	VL	L	VL

Table 2. The relationship between IFSs and linguistic terms [12]

Linguistic terms	Corresponding IFNs
Very low (VL)	[0.15,0.80]
Low (L)	[0.25,0.65]
Medium low (ML)	[0.35,0.55]
Medium (M)	[0.5.0.4]
Medium high(MH)	[0.65,0.25]
High (H)	[0.75,0.15]
Very high (VH)	[0.85,0.10]

Step 2. Based on the weights for decision makers and Eq. (17), the aggregated decision matrix is calculated. Besides, the PIA and NIA are determined, respectively, using Eqs. (19)–(22).

Step 3. The projection of each alternative on PIA and NIA are calculated based on Eqs. (23), (24). Then the ranking value for each alternative is calculated as $RV = (0.9583, 0.9445, 0.9344, 0.8973)$. Therefore, the ranking order for alternatives is $A_1 > A_2 > A_3 > A_4$.

As a result, site A_1 is the best site for public fast electric vehicle charging station.

5 Conclusion

In MAGDM problems, it is quite common that decision makers' weight information is partly or completely unknown because of such problems as decision makers lack of knowledge, the complexity of the decision-making environment, and scientific development limitations. Therefore, it is important to research a solution to MAGDM problems when no weight information is available. In this paper, we applied the intuitionistic fuzzy projection-based approach to determine the optimal site for public fast electric vehicle charging station to promote the popularization of EVs in Chengdu. In our model, the extended TOPSIS method under an intuitionistic fuzzy environment was developed to determine the attributes weights. With the weight determination method proposed in this paper, we effectively reduced the subjective effects to a minimum, so, because less information was required to make a decision using the proposed method, we demonstrated how MCGDM problems may become easier based on our approach. Finally, under an intuitionistic fuzzy environment, the proposed approach was shown to be able to handle MCGDM problems effectively, thus guaranteeing that there is less deviation in the decision making.

Abstract. We exploit a fixed effect model to examine if the uncertain medical expenses of rural residents reduce their total consume using the provincial-level panel data from 2000–2013. To obtain a robust results, we then add the model with the time fixed effect. The results show that, rural residents' medical expenses share raise will reduce the share of rural residents' total consume in GDP by more than 6%, and this effect is more obvious than the rural residents' education expenses which is less than 6%. We also find that if the government increase the funds proportion of health care, the medical demand of rural residents will raise which may reduce the percentage of rural residents' total consume in GDP by more than 6%. By the way, liquidity constrains may also enhanced the rural residents' precautionary saving motives based on the medical expenses. So we can conclude that the medical expenses of rural residents do effect the consume demand of rural households significantly. And the government need to control the rural residents' medical expenses if they attempt to expand the consumption of rural residents.

1 Introduction

As the uncertainty of global economic recovery increases, the major economic growth engines of investment and export are facing the constraints of environmental protection and trade barriers. In order to keep economic growth at a reasonable rate China must pay more attention to the role of consumption in stimulating the economy.

Figure 1 illustrates the change in consumption and investment rates between 1978 and 2013 in the gross domestic product of the expenditure approach. Where S represents the consumption rate, and I represents the investment rate. It is clearly that from 1978 to 2013 the rate of consumption in our country shows a general downward trend, especially after 2000, it shows a steep downward

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_143

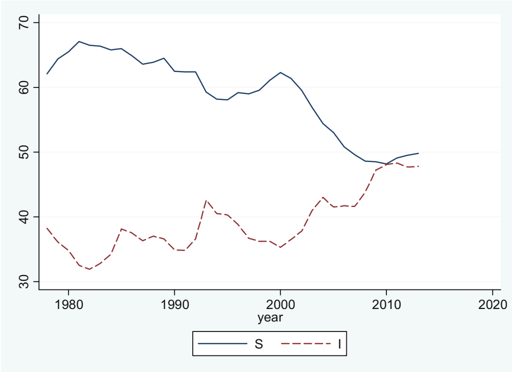

Fig. 1. Trends of consumption and investment rates in 1978–2013

trend, and it does not start to stabilize until 2010, and rises slightly. In sharp contrast to this is that since 1978, China's economic growth into the fast-rising channel, which indicated that China's consumption rate is not with China's rapid economic growth and increase.

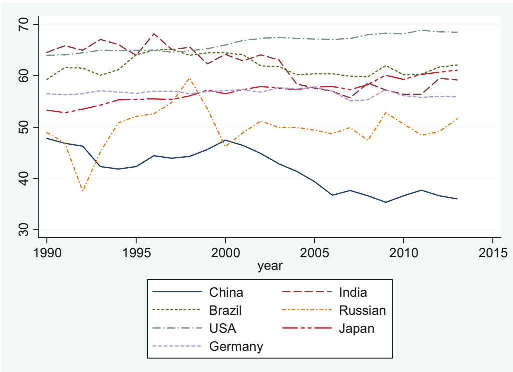

Fig. 2. International comparison of final consumption proportion of residents in GDP

From the international comparison point of view, we can also get the same conclusion. Figure 2 shows the trend of final consumption among main countries in GDP. Can be seen from Fig. 2, China's consumption rate is not only lower than developed countries such as European countries and the United States, with India, Brazil and other emerging countries, which were also significantly lower. Developed countries from Europe and the United States, its consumption rate is generally high, and long-term stable operation. From the Fig. 2, The US consumption rate has maintained a high level of smooth operation (basically remained above 64), and in a steady rise with a slight trend; Germany and Japan, similar to the situation, although the final consumption rate ate not as high as the United States, but can also maintained at a high level (basically remained around 55) and with a more stable trend. While the emerging market countries, the final consumption rate of residents compared with the developed countries is characterized by the fluctuations are generally large, including China. Whether China, India, Brazil or Russia, the consumption rate of its residents in the 1990–2013 years have experienced a more vibration. It is obvious that the final consumption rate of Chinese residents is still very low compared with that of emerging market countries.

When looking at the household consumption which play a decisive role of consumption, we can find that the rural residents' consumption as a share of household consumption has not increased with the urban residents', and it makes rural consumption become a short board of China's strategy of expanding domestic demand.

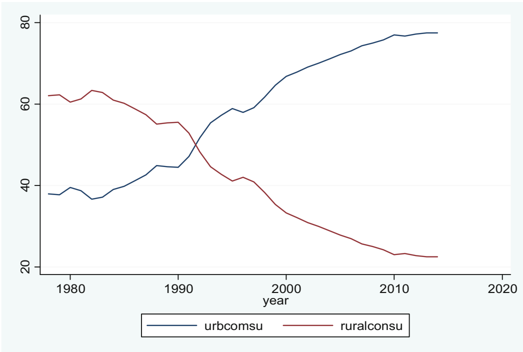

Fig. 3. The share of urban and rural household consumption in 1978–2013

Figure 3 shows the proportion of urban residents' consumption and rural residents' consumption in China's household consumption during 1978–1930, where urbcomsu' represents urban residents consumption in the proportion of consumption, 'ruralconsu' represents rural residents consumption in the proportion of consumption. As can be seen from the figure, before 1992, the proportion of consumption of rural residents in China's household consumption in a dominant position, but the early 90s of last century, the proportion of rural residents began to decline sharply and the urban residents began to dominate the proportion of consumer demand. The consumption gap between urban and rural residents has been widening year by year, until 2010, the gap widening trend has slowed down.

Generally, there are many factor which constrain China' rural consumption, but the imperfect medical security system and the uncertainty of medical expenditure of rural resident cannot be ignored. As the medical consumption has the characteristics of uncertainty and urgency, the impact of medical consumption on rural residents' overall consumption may be significant. This paper using the provincial-level panel data from 2000–2013 to test if the uncertain medical expenses of rural residents reduce their total consume by adopting fixed effect model. Through the empirical research, we expecting find out the relationship between medical expenses of rural residents and rural residents' total consumption. And based on the conclusion, we may provide some reference for the policy of rural residents' consumption.

2 Literature Review

Scholars have studied the reasons for the downturn in rural consumption and how to start rural consumption from different aspects: Wang's research [14] indicated that the uncertainty expectations of rural residents are one important reason that restricts the consumption in rural areas in China. Similar views also include Tan [11]. Qu [13] found that the pessimistic expectations on future expenditure of rural residents will place greater emphasis on deposit but not expenditure. Therefore to start rural consumption China's policy makers should improve the rural consumption environment and reduce the burden on farmers. Sun and Zhu' research [9] also emphasized the importance of optimizing the rural consumption environment to improve the consumption of rural residents. Cai [1] had point that in addition to income levels, rural social security system construction is also an important factor affection rural consumption. Clearly, as a important part of social security system, medical security system are closely related to medical expenditure, which indicate that the medical expenditure of rural residents may play an important role in consumer decision making.

There are also scholars' studies focused on the consumer environment and the expectations of rural residents. Liu [7] found that insufficient financial support limited the development of rural residents' consumption. Yang and Chen's research [16] based on the view of rural public goods supply, proposed that increasing rural public goods supply can reduce the uncertainty of expenditure expectations of rural residents which may benefit the rural consumption. Zhou and Yang analyzed the consumption both urban and rural areas and pointed out that, precautionary saving motive may also effect rural residents as well as urban residents.

Furthermore, some scholars studied about rural medical expenditure and the existing literature mainly focuses on two aspects: first, the impact factors of rural residents' medical expenditure such as Tan and Zhang et al. [10] whose study explores the influencing factors of rural households' medical consumption spending and its demand elasticity based on QUAIDS model and the cross-section; And Huang and Liu [6] provided a similar study, which state that the income level, government health investment and other factors do affect the medical consumption of rural residents; Zhao [17] used the 1993–2012 panel data to analysis the regional differences of rural residents' health care consumption, and state that the income, education, economic development and other factors on the impact of rural resident's medical spending are significant regional differences. Second, the function of rural medical security system such as Bai and Li et al. [3] found that the insurance coverage increases non-health care consumption by more than 5% and the insurance effect exists even for households with medical spending, by exploiting a quasi-natural experiment; Ding and Ying et al. [2]

also stated that the propensity to consume of rural households is universally low in China, and the medical insurance do increased rural durables consumption significantly, base on the analysis of China Health and Nutrition Survey panel data from 1991 to 2009. Tan and Qin [12] used IV-TOBIT model to test the crowding out effect of China's households' medical expenses and conclude that the medical expenses do reduce the households' expenses on food and clothing, whose research also used the China Health and Nutrition Survey data (2013). Although the above study about rural medical expenditure focused on difference aspects, they provided us with the method of reference.

In general, although many studies focused on the rural residents' consumption expansion directly or indirectly mentioned factors such as rural residents' expectation, consumption environment, and precautionary saving motive. But there are few research put rural residents' medical expenses as an independent factor which effect the rural residents' consumption behavior. For this reason, we develop an empirical model that includes both residents' medical expenses and a set of factors that may affect the rural residents' medical expenses. This model also contain standard economic variables. Our study adds to the current literature by utilizing pooled time series and provincial cross-sectional data over a longer period than the household survey data cover. In addition, by utilizing medical expenses variable, we are looking for if the medical expenses of rural residents do effect the rural consume.

3 Investigation of if Medical Expenses Affect Rural Residents' Aggregate Consumption

The equation to be estimated for (i) provinces and (t) time periods is as follows:

$$\left(\frac{C}{Y}\right)_{it} = \beta_0 + \beta_1 \mathrm{medratio}_{it_{it}} + \beta_2 \mathrm{goeratio}_{it} + \beta_3 \mathrm{loandep}_{it} + \gamma_1 P_1 + \cdots + \gamma_{i-1} P_{i-1} + \lambda_1 D_1 + \cdots + \lambda_{t-1} D_{t-1} + \sum \sigma_i Z_{it} + \mu_{it},$$

where

$\left(\frac{C}{Y}\right)_{it}$: rural residents' consumption as ashare of provincial domestic product;

$\mathrm{medratio}_{it}$: the share of rural household medical expense in rural household consumption per capita;

$\mathrm{goeratio}_{it}$: local government expenditure on health as a share of total local government expenditure;

$\mathrm{loandep}_{it}$: the share of loans plus deposits in provincial domestic product;

P_i, D_t : provincial and time dummies;

Z_{it} : vectors of economic system variables;

growth_{it} : the annual growth in provincial domestic product;

dinco_{it} : tprovincial net income of rural residents per capita;

$\mathrm{depratio}_{it}$: dependency ratios;

$\mathrm{eduratio}_{it}$: the share of rural household education expense in rural household consumption per capita.

This empirical model used here combines standard consumption determinants relating to income, government expenditure and family structure which expected to influence households' consumption decisions. While this model also concentrated to rural residents' medical expenses and the medical expenses expectation. We use the share of rural residents' consumption in domestic product $\left(\frac{C}{Y}\right)_{it}$ as our dependent variable. This is the share that appears to behave differently compared to urban. Our panel data set includes provincial data for 31 provinces between 2000 and 2013. The variation across provinces allows us to explore possible factors in addition to the standard consumption variables.

The impact of medical expenses on household's consumption is manifest in two aspects: First, medical spending will be squeezed the share of other consumption under the total budget constraints. Second, medical expenditure will increase people's cautious motivations, which will increase precautionary savings. In addition, as the medical treatment has high uncertainty, residents could not predict the medical expenses in the time and amount, which may strengthen residents' saving motive. To test if this impact do affected China's rural consumption we applied the share of rural household medical expense in rural household consumption per capita as a key variable ($\mathrm{medratio}_{it}$). A reasonable hypothesis is that the increase in the share of rural household medical expenses in rural household consumption per capita will lead rural residents to reduce consumption.

A second factor that might influence rural residents' consumption relating to medical expenses is government expenditure on health ($\mathrm{goeratio}_{it}$). If the government is taking care of residents' health care needs, households would not need to save for the possible expenditures or may save less. So we can hypothesis that the government health expenditure variable is positively correlated with the dependent variable.

The third factor we concerned relating to the household medical expenses and the rural residents' consumption is the ability of rural residents to use the financial system to smooth consumption over time. So we adopt financial development indicators as the third variable which can lessened liquidity constraints of rural residents. The standard financial development indicators are the percentage of total financial assets to GDP [4] or money supply measures such as M2 as a share of GDP [8]. But we do not have access to financial assets data for all provinces for the period of time we study, and the money supply measures do not vary by province but only vary by country. Therefore we follow [18] and use the total deposits and loans issued by all financial institutions as a percent of GDP reported by each province ($\mathrm{loandep}_{it}$) as a proxy variable for liquidity constraint.

For the control variables in the Z vector, we include a number of factors raised by the literature: (growth_{it}) is the annual growth in provincial domestic product to interpret the economic development of the provinces; (dinco_{it}) is provincial net income of rural residents per capita; ($\mathrm{depratio}_{it}$) is the provincial dependency ratios, in principle, higher dependency ratio will lead to higher consumer spending. In the empirical model we also adopt the share of rural household education expense in rural household consumption per capita as a control variable

($eduratio_{it}$) because it has been pointed out by the literature that education expenses is an important factor that affected residents saving motions. By the way, adopting the education expenses variable can make a comparison with the medical expenses variable.

4 Estimation and Results

Table 1 reports our descriptive statistics as well as the between-province standard deviation and within-province standard deviation (over the entire time period) of our main variables in our model. This table confirms the considerable variations of the dependent and independent variables of interest in our data set.

We begin our estimation with a pooled OLS model. The result reported in Table 2 model 1. This model is estimated with pooled ordinary least squares using

The most data used in this paper are from China Statistical Yearbook. The provincial net income of rural residents per capita data were adjusted based on 1999 CPI. The government expenditure on health and education data are budgetary data from both China Statistical Yearbook and China Fiscal Yearbook.

the full data set from 2000–2013. The share of rural household medical expense variable (medratio$_{it}$) is significant and negative. Which met our hypothesis that the increase in the share of rural household medical expenses in rural household consumption will lead rural residents to reduce consumption. While the government expenditure on health variable (rugeoratio$_{it}$) is significant and positive which met our hypothesis too that the government health expenditure variable is positively correlated with the dependent variable.

There after we add cross-provincial fixed effect to controls for omitted variables that vary across provinces but do not change over time. Furthermore, vast differences in economic, industrial and fiscal structures across provinces are likely to influence household consumption. So the intercepts generated for each province in this model should absorb the influences of these omitted

Sequence correlation	Wooldridge test for autocorrelation in panel data	H0: no first order autocorrelation	$Prob > F = 0.0000$

variables that differ for each province but are constant over time. Model 2 is also estimated with ordinary least squares, but with provincial fixed effects reported in Table 2. The F-statistics of the test on the significance of provincial fixed effects show that there are significant variations among provinces ($F(30, 396) = 11.18, \Pr ob > F = 0.0$). In model 2 the government expenditure on health variable (rugeoratio$_{it}$) is significant but negative, reflecting that government expenditure on health increasing would not stimulate the rural residents' consumption. Although the share of rural household medical expense variable (medratio$_{it}$) is also significant and negative.

Table 3 presents a series of robustness checks on model 2 including heteroskedasticity, cross-section correlation, and sequence correlation. As the test results shown in Table 3. The result estimated in model 2 is not robustness. So we re-estimates model 2 using Daniel Hoechle's [5] method to get stronger results in model 3. Compared with model 2, the estimate result in model 3 are fairly similar, only the significant level of the coefficients has changed. But our main independent variables are still significant.

Based on model 3, we then add time-fixed effects to control for variables that are constant across provinces but evolve over time, such as the introduction of new healthcare regime "Xinnong he" (New Cooperative Medical Scheme), the nationwide economic reforms deepen in China rural area, etc. Model 4 replicates model 3 except that these estimates include the time fixed effects as well as the provincial fixed effects. We included dummy variables chosen for several time periods to capture the trend of the introduction of new healthcare regime. As the New Cooperative Medical Scheme start the pilot at 2003 and realized full coverage at 2009, considering the lag of policy, our first time dummy starts from 2000 and ends in 2004. The next time dummy covers the period of 2005 to 2009. The last dummy variable covers the time period between 2010 and 2013. In model 4, at least one newly generated time dummy variables is statistically significant and produce coefficients with a trend: over time the coefficient increase each year. The basic findings of model 3 remain robust in model 4, although some coefficient changed in magnitude. So we can draw our conclusion based on model 4.

In model 4, our main dependency variable were all significant although we added the time-fixed effects. The share of rural household medical expense is negative, which is consistent with our assumption. The government expenditure on health is negative, implying that government expenditure on health do not release rural residents' saving motive, which doesn't met our hypothesis. The financial development is negative in model 1–model 4, which indicated that the financial development did not lessened rural households' liquidity constraint. In Table 2 we also found that the shares of rural household education expense in rural household consumption, which we adopted to make a comparison with the medical expenses as a control variable, were significant and positive in model 1–model 4. So we can conclude that the impacts of medical expenditure and education expenditure on rural residents' consumption are not consistent.

As the government expenditure on health and the financial development's estimated results did not consistent with our expectations and the general theory, we re-estimated model 4 by alternative measures of these two variables as a further robustness check, presented in model 5.

In model 5 we used the number of beds in township health institutions to replace the government expenditure on health. Simultaneously, we adopted the net saving rate of rural residents [15] per capita to replace the financial developments as the proxy variable of liquidity constraint of rural residents. Since the statistical agency is no longer announced the number of beds in township health institutions of Shanghai and Beijing after 2009, our estimation in model 5 did not include the two sections of Shanghai and Beijing. Also because we adopted the panel data contain 31 sections, so there is no substantial impact on the estimation from the elimination of the two sections.

In model 5, although there are some changes in the estimation results compared with model 4, but the share of rural household medical expense remain significant and negative, by the way the shares of rural household education expense are also significant and positive, which are corresponded with model 4. Furthermore, the number of beds in township health institutions is significant and negative too, as a part of government expenditure on health, which indicated that the result of government expenditure on health estimated in model 4 has quite robustness. As the net saving rate of rural residents is significant and negative, we can conclude that the rural residents faced obvious liquidity constraints. In addition, as the model 5 adopt the net saving rate of rural residents, the coefficient of the share of rural household medical expense becomes smaller, indicated that medical expense always accompanied with liquidity constraint, which is associated with the amount of medical expenditure relatively large.

5 Discussion and Conclusion

We use various models and estimation techniques to examine if and how the medical expenses affect the variation in rural residents' consumption as a share of GDP. As our expectation the medical expenses do lessened the rural residents' consumption as a share of GDP. In our study, the most significant and robust discovery is that reducing rural residents' motivations for precautionary savings through government's expenditure at the local level have the opposite effect in increasing rural residents' consumption. While this result contrary to our expectation and the general theory, the alternative measure that captures the role of the government expenditure through the number of beds in township health institutions was also significant. From the direct meaning of this estimation result, we can conclude that the increasing of government spending on health has stimulated the rural household saving motive. But this is by no means a justification for reducing the fiscal responsibility of the government. On the contrary, the result implied, to some extent, that the government expenditure on rural health is not enough, and there is a heavy responsibility on the government to improve the rural medical and health environment. Because at the pooled medical and health environment level, the rural household's medical consumption demand has been repressed.

The financial development and its alternative measurer always robust regressors in all the models, while the measurements are small and negative, which means the liquidity constraints is a factor that do not bode well for the rural consumption. The shares of rural household education expense are always significant and positive, while the coefficient absolute value is large. As demonstrated in this study, this means that, the impacts of medical expenditure and education expenditure on rural residents' consumption are not consistent, so we need different options to develop the medical and education in rural areas.

For the control variables in the Z vector, although the annual growth in provincial domestic product is significant influenced the independent variable but the coefficient absolute value is too small, while the provincial net income of rural residents and the provincial dependency ratios suffer from the same problem.

These results point to several suggestions that the increasing medical expenses is the obstacle of boosting domestic consumption especially in rural areas. So the policy makers need to formulate policies to optimize the consumer environment in rural areas, just like increase investment in rural health care, although the government expenditure on health is negative in this paper. The cautious motive which lead rural household to increase their savings has been proved indirectly by the estimated result in this paper as the share of rural household medical expense in rural household consumption is significant and negative. In addition, as the liquidity constraint has also been found in the rural are as from the estimated results. To enhance the rural consumption, the government needs to not only lift the burden of rural households medical expenditure but lessen the liquidity constraint also. In our opinion, to increasing the coverage and funding levels of NRCMS is an effective method. Furthermore, increasing the accessibility and convenience of rural health care facilities may also a effective way.

Abstract. Stronger environmental protection regulations and innovative contracting methods focused on reducing environmental impact through new incentives have placed increasing pressure on decision makers, especially those on large-scale construction projects. This increase has led to a need to identify optimal decision and select the most efficient construction modes for each activity to minimize not only the project's time and penalty costs but also its environmental impact. To address this need, this paper applies a mathematical model based on a hybrid genetic algorithm with fuzzy logic controller (flc-hGA) to the time-cost-environmental trade-off problem with multiple projects under a fuzzy environment. Applying the proposed method to the case study of the Jinping-I Hydropower Station, a large-scale project in Southwest China, clearly demonstrates its economic, technological, and social ecological effectiveness.

Keywords: Time-cost-environment · Trade-off · Multiple project · Fuzzyt · Hybrid genetic algorithm

1 Introduction

Two of the most crucial aspects of any such construction project are time and project cost, both of which have received considerable research attention [9,12]. One particularly important element of effective project scheduling theory and applications is the discrete time-cost trade-off problem (DTCTP) introduced by Harvey and Patterson [6]. Of more recent concern, however, are accusations that the construction industry is causing environmental problems that range from excessive consumption of global resources-both in terms of construction and operation-to pollution of the surrounding environment. Hydroelectric projects, particularly, contribute significantly to changes in river environments

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_144

[2,17]. Yet previous studies have paid more attention to evaluating the environmental impact at later stages of reservoirs and hydraulic electricity rather than considering it from the construction stage. Recently, however, a tightening of environmental protection regulations, especially for hydroelectric projects, has increased pressure on project managers to reduce the environmental impact through the selection of optimal construction modes. There is an imminent need, therefore, to study management decisions on selection methods to ensure more environmentally friendly means of construction during the project planning stage when the environmental impact can best be incorporated into other project objectives. For hydroelectric projects such as the JHS-I, this planning stage should include the optimization of construction and subsequent operations for environmental impact as well as time and cost.

The expanding scale of such construction projects worldwide, however, makes effective project management extremely complex. To deal with this complexity while still achieving management objectives, construction managers must employ a project management decision system that effectively controls total project duration, penalty costs, and environmental impact. One effective method for such control is the discrete time-cost-environment trade-off problem with multiple projects (DTCETP-mP), which is an extension of the original DTCTP. This analysis thus applies DTCETP-mP to solve the three main objectives of the JHS-I problem: (1) minimization of the total project duration, (2) minimization of the total project penalty cost, and (3) minimization of the environmental impact.

In non-routine projects such as the new construction at JHS-I [10], the duration of each activity and completion time may be uncertain, so the project manager must handle multiple conflicting goals in an uncertain environment in which information may be incomplete or unavailable. In this context, activity duration uncertainty can be modeled using either probability-based methods [12] or fuzzy set-based methods [18,19] depending on the situation and the project manager's preference. When a project manager has difficulty characterizing the random variables, as in the current scenario of a new construction project with unique activities and a lack of historical data, the fuzzy method is the most effective approach.

Because the DTCETP-mP is an extension of the DTCTP, it is an NP-hard problem that is difficult to solve [15]. Yet even the most exact of currently available methods can only solve small projects with under 60 activities, a far cry from the numerous activities and modes per activity involved in the large-scale, complex JHS-I project, whose optimal solutions are beyond the capabilities of traditional production scheduling methods like PERT (Program Evaluation and Review Technique) and CPM (Critical Path Method) [3]. More suitable heuristic solution procedures for solving the DTCETP-mP are thus needed, several of which have been suggested in the literature. For example, Franck et al. [4] demonstrated that a genetic algorithm (GA) performed slightly better than a tabu search (TS) procedure but required more computing. In earlier work, Wang et al. [16] addressed larger, more complex problems by introducing an improved hybrid genetic algorithm (hGA) that uses a fuzzy logic controller (flc) to adaptively regulate the GA parameters (including generation number, population size, crossover ratio, mutation ratio) and automate mutation ratio fine tuning. The effectiveness and efficiency of the proposed flc-hGA is evaluated through comparison with other methods.

This present application of the DTCETP-mP to identify optimal solutions for the JHS-I large-scale deeply buried tunnel group project amends the GA first introduced by Holland [7] to an flc-hGA. The analytic results indicate that this optimization method is both practical and highly efficient in solving the JHS-II problem and achieving minimization of the project's total duration, penalty costs, and environmental impact.

2 Problem Description and Mathematical Model

2.1 Problem Description

Because the JHS-I project is unique, lacking in historical data, technically difficult to construct, structurally complex, and subject to strict requirements and many construction uncertainties, it is difficult to estimate the exact duration of each activity or assign each a strict function [8,11]. Duration is thus characterized by fuzziness and subjective uncertainty [18,19]. In such a situation, not only the duration but also the cost and environmental impact of each activity depends on construction mode selection, which is in turn related to the assignment of construction materials and machines, crew formation, and overtime policies. In this case, therefore, a DTCETP-mP discrete mode selection for these variables is more practical than a continuous mode selection.

In the DTCETP-mP analysis, each subproject activity is assigned certain discrete well-defined construction methods so that the analysis can determine the best combination(s) of duration, cost, and environmental impact for all activities. The start time for each subproject activity is optimized by the flc-hGA, and all activities are executed in a certain order to achieve completion under budgetary, environmental, and cash flow constraints in any time period. The project completion date is as estimated by project experts and lies between the earliest start time for the first activity and the latest finish time for the last activity. The total project penalty costs, also assessed by these experts, comprise penalty costs for delays in all subprojects and for the environmental impact. Project planning involves the selection of proper methods, crew sizes, equipment, and technologies to ensure efficient activity completion.

Despite such careful planning, however, project completion inherently involves a trade-off between time, cost, and environmental impact. For example, using more productive resources or technologies (e.g., more efficient equipment, more workers, increased overtime) may save time but raise costs. Conversely, a reduction in time may lower environmental impact, while a reduction in cost may increase both time and environmental impact. These three important considerations of time, cost, and environmental impact are thus the criteria used to determine the best scheduling and combination for the DTCETP-mP, thereby pinpointing the optimal construction mode combination for all activities.

2.2 Assumptions

The DTCETP-mP model for the JHS-I makes the following assumptions:

(1) The DTCETP-mP comprises multiple projects, each containing several activities;
(2) The start time of each activity is dependent upon the completion of its predecessor;
(3) The capital used by all activities does not exceed the limited quantities in any time period, and the total project budget is within a predetermined limit;
(4) The environmental impact caused by the activities does not exceed the limited quantities in any time period, and the total project environmental impact is within a predetermined limit;
(5) When an activity begins, it cannot be interrupted;
(6) The managerial objective is to minimize the total project time, total tardiness penalty, and total environmental impact for all subprojects.

2.3 Model Formulation

The problem is represented on an activity-on-node (AON) network with a single starting and a single ending node, each of which corresponds to dummy activities. The analysis uses the following notation:

Index:
i : index of subproject in a project, where $i = 0, 1, 2, \cdots, I, S$ and T are dummy projects;
j : activity index in each subproject, $j = 0, 1, 2, \cdots, J$, and are dummy activity.

Parameters:
$\tilde{d}_{ij}$: processing time for activity j in subproject i;
$\tilde{t}_i^D$: specified project completion time for subproject i;
l_{ijc} : cost of activity j in subproject i per unit of time;
l_{ije} : environmental impact of activity j in subproject i per unit of time;
c_i^p : total penalty cost of subproject i per unit of time;
b_c : maximum cost allowable per unit of time for the subproject;
b_e : maximum environmental impact allowable per unit of time for the subproject;
B_c : maximum cost allowable per unit of time for the project;
B_e : maximum environmental impact allowable per unit of time for the project;
$\tilde{t}_{ij}^F$: finish time of activity j in subproject i;
V_{ij} : environmental impact of activity j in subproject i;
w_{ij} : weight of the environmental impact of activity j in subproject i;
S_p : set of activities in progress in period p
$S_p = \left\{ j \left| t_{ij}^S \leq p \leq t_{ij}^S + t_{ij}, i = 1, 2, \cdots I+1; j = 1, 2, \cdots J+1 \right. \right\}$;
$\Pr e(i)$: set of the immediate predecessors of subproject i;
$\Pr e(j)$: set of the immediate predecessors of activity j

Decision variables:
$\tilde{t}_{ij}^{S}$: start time for activity j in subproject i

Functions:
z_1 : total duration of the project;
z_2 : total penalty costs of the project;
z_3 : total environmental impact of the project

2.4 Multiobjective Model

The solution proposed by the multiobjective optimization model is based on managerial objectives and project constraints, which for clarity are discussed separately in the subsections below.
(1) Objective Functions

The first objective is to minimize total project time; that is, the sum of the completion times for all subprojects, which can be expressed as follows:

$$\min z_1 = \sum_{i=1}^{I} E(\tilde{t}_{iJ}^{F}). \tag{1}$$

The second objective is to measure and minimize the total cost by minimizing the total penalty costs of multiple projects:

$$\min z_2 = \sum_{i=1}^{I} c_i^p (E(\tilde{t}_{iJ}^{F}) - E(\tilde{t}_i^{D})). \tag{2}$$

The third and final objective is to minimize total environmental impact:

$$\min z_3 = \sum_{i=1}^{I} \frac{\sum_{j=1}^{J} V_{ij} \times w_{ij}(E(\tilde{t}_{iJ}^{F}) - E(\tilde{t}_i^{D}))}{E(\tilde{t}_{iJ}^{F})}. \tag{3}$$

(2) Constraints

Because a specific subproject must be completed before another subproject can be initiated (the precedence constraint of multiple projects), the model includes the following constraint:

$$E(\tilde{t}_{eJ}^{S}) \leq E(\tilde{t}_{i,1}^{S}) - E(\tilde{d}_{eJ}), \quad e \in \Pr e(i). \tag{4}$$

Likewise, because the start time of each activity is dependent upon the completion of some other activities (the precedence constraint of activities), the next activity must be started after a specific activity is completed:

$$E(\tilde{t}_{il}^{S}) \leq E(\tilde{t}_{ij}^{S}) - E(\tilde{d}_{il}), \quad l \in \Pr e(j). \tag{5}$$

The project is also subject to a limitation on the total capital and capital per time period,

$$\sum_{j \in S_p} l_{ijc} \leq b_c i = 1, 2, \cdots, I, \tag{6}$$

as well as on the total environmental impact and the environmental impact per time period:

$$\sum_{i \in S_p} \sum_{j \in S_p} l_{ijc} \leq B_c, \tag{7}$$

$$\sum_{j \in S_p} l_{ije} \times w_{ij} \leq b_e, \quad i = 1, 2, \cdots, I, \tag{8}$$

$$\sum_{i \in S_p} \sum_{j \in S_p} l_{ije} \times w_{ij} \leq B_e, \quad l_{ije} = \frac{V_{ij}}{d_{ij}}. \tag{9}$$

The nonnegative variables are described in the model by the following equation:

$$E(\tilde{t}_{ij}^S), E(\tilde{t}_{ij}^F), E(\tilde{d}_{ij}) \geq 0, \quad \forall i \in I, \quad \forall j \in J. \tag{10}$$

3 Hybrid Genetic Algorithm with Fuzzy Controller

Although mathematically, several Pareto optimal solutions are possible for the multiobjective model formulated above, in real-world construction, only one optimized solution is needed in each time-constrained decision-making situation. Hence, the multiobjective model is transformed into a single-objective model using a weighting method. Additionally, because accurately determining the GA parameters is especially important in solving large-scale problems like the JHS-I project, GA effectiveness is improved by adaptively regulating the crossover and mutation rate during the genetic search process using the fuzzy logic controller (flc) [16]. This regulation reduces CPU time and enhances optimization quality and stability by regulating the increasing and decreasing crossover and mutation rate ranges [1,5,13,14,20].

3.1 Overall Procedure for the Proposed Method

Solving the problem with the flc-hGA involves the following steps:

Step 1. Concentration of multiple objectives using the weight-sum procedure.
Step 2. Setting of the genetic algorithm parameters: population size, crossover rate, mutation rate, and maximum generation.
Step 3. Generation of an initial set of individuals.
Step 4. Choosing of the selection and hybrid genetic operators: crossover and mutation.
Step 5. Evaluation of the fitness value of the chromosome.
Step 6. Selection of the best total penalty for the minimized total project time and minimized environmental impact and storage of an alternative schedule for the minimized total project time.

Step 7. Check of the termination: If one individual has achieved the predefined fitness value, the process stops: otherwise, it goes on to step 8.

Step 8. Regulation of the mutation rate through adaptive use of the fuzzy logic controller; otherwise, the process returns to step 4.

The model uses two hybrid genetic operators, a position-based crossover and a swap mutation (SM) operator. The crossover operator randomly takes some genes from one parent and fills any vacuum with genes from the other parent by scanning from left to right, while the SM operator selects two projects at random and swaps their contents.

3.2 Hybrid Genetic Operators

The model uses two hybrid genetic operators, a position-based crossover and a swap mutation (SM) operator. The crossover operator randomly takes some genes from one parent and fills any vacuum with genes from the other parent by scanning from left to right, while the SM operator selects two projects at random and swaps their contents.

3.3 Fuzzy Logic Controller

The fuzzy logic controller (flc) is used to automatically tune the GA parameters whose determination is so important in large-scale problems. Here, only a mutation flc is used because in the proposed hGA, the effects of the crossover and crossover flc are almost the same. The main difference between the hGA and the flc-hGA is that a mutation flc based on the flc is implemented independently to adaptively regulate the mutation ratio during the genetic search process by considering the changes in average fitness in each parent and offspring population over two continuous generations. Mathematically, this procedure can be expressed as follows: letting $f(t)$ be the difference in the average fitness function between the t^{th} and $(t-1)^{th}$ generation, ε is a small positive number near to zero (in this paper, $\varepsilon = 0.1$), allowing the mutation ratio for the next generation to be derived using an if-then procedure:

(1) If $|f(t) - f(t-1)| < \varepsilon$, then the mutation ratio p_m for the next generation should be rapidly increased;
(2) If $f(t) - f(t-1) < \varepsilon$, then the mutation ratio p_m for the next generation should be decreased;
(3) If $f(t) - f(t-1) > \varepsilon$, then the mutation ratio p_m is selected for the next generation.

When $f(t)$ and $f(t-1)$ are the flc's inputs and the change in mutation ratio $m(t)$ is its outputs. $m(t)$ Once the input values are assigned, the scaling value $Z(a,b)$ can be determined by setting $\lambda \in [-1.0, 1.0]$ as the given values for regulating an increasing and decreasing range for the mutation ratio. The changes in the mutation ratios are then determined by $\Delta m(t) = \lambda Z(a,b)$ and the mutation ratio values for the next generation by $p_m(t+1) = p_m(t) + \Delta m(t)$, where $p_m(t)$ is the mutation ratio at generation t.

4 Case Study: The Jinping-I Hydropower Station

The Jinping-I (JHS-I) and Jinping-II Hydropower Stations, which epitomize the large-scale constructions of China's West-East Electric Transmission Project, have a combined capacity of 8,400 MW and were planned for Jingping River Bend, a major artery 150 Km in length whose downstream river section is separated from the opposite bank by only 16 km. Along that length, the elevation drops 310 m, creating an excellent site for hydroelectric production. Whereas JHS-I will rely on its high dam and reservoir to supply water, JHS-II, located 7.5 Km downstream (at coordinates $28°07'42''N101°14'27''E$) is diverted by a much smaller dam and will rely on the world's four largest and longest (16.7 km) diversion tunnels. This latter has a total installed capacity of 4,800 MW (8×600 MW), for a multiyear average annual generation of 24.23 TWh.

Because such scale and complexity presents computational challenges, our model includes only the elements typical of constructions, making it generalizable to similar projects. As previously emphasized, the study goal is to identify the most effective strategies and thus the most effective and viable project management methods for JHS-I, so that these may be implemented in future large-scale projects (Table 1).

Table 1. Subprojects and activities

A_1 Spillway project	A_{11} Earth-rock excavation A_{12} Concreting A_{13} Gates hoist equipment installation A_{14} Clearing up and finishing work
A_2 River diversion during construction	A_{21} Import and export hole dug A_{22} Concrete lining and check-gate installation A_{23} Lockup A_{24} Gen set installation A_{25} Substation construction and equipment installation
A_3 Dam construction	A_{31} Concrete cut-off wall A_{32} Dam foundation lock cut A_{33} Dam filled A_{34} Asphalt concrete watertight diaphragm
A_4 Power capacity of stream	A_{41} Diversion opening A_{42} Air pressure system A_{43} Second-stage cofferdam A_{44} Bore-hole A_{45} Concrete lining
A_5 Transport and power system	A_{51} Road clear A_{52} Warehouse and factory construction A_{53} Water supply A_{54} Power transmission project

4.1 Data Collection

The data for the JHS-I project, obtained primarily from the Ertan Hydropower Development Company, includes observations of managerial practice and interviews with designers, consultants, contractors, subcontractors, and a city government officer at the station. This data set is supplemented by information from prior research. The construction manager's project experience, in particular, was invaluable for researcher comprehension of the projects' specific nature and configuration. In addition to two dummy (start and end) projects, JHS-I has five subprojects: a transport and power system, river diversion during construction, dam construction, a stream power capacity project, and a spillway project (see Table 2).

Table 2. Detailed information for each activity

	Activity	DA	C	EI and W	PA	DP	PP
S	Dummy project			$S < 1, 2, 3$			
1	s (dummy activity)				s < 1,2	11	1<4,5
	1	2	2	20.0,0.05	1 < 3,4		
	2	5	2	32.6,0.055	2 < 4,t		
	3	5	2	16.7,0.03	3 < t		
	4	3	4	37.5,0.08	4 < t		
2	s (dummy activity)				s < 1,2	11	2 < 4,5
	1	4	2	23.5,0.037	1 < 3		
	2	2	3	24,2,0.048	2 < 3		
	3	4	2	23.8,0.038	3 < 4,5		
	4	3	1	19.8,0.053	4 < t		
	5	2	3	15.7,0.027	5 < t		
3	s (dummy activity)				s < 1	11	3 < 4,5
	1	2	3	25.0,0.027	1 < 2,3		
	2	5	3	23.6,0.019	2 < 4		
	3	3	3	21.3,0.033	3 < 4		
	4	3	1	21.6,0.041	4 < t		
4	s (dummy activity)				s < 1,2	11	4 < T
	1	2	1	11.6,0.027	1 < 3,4		
	2	5	2	16.3,0.047	2 < 4,5		
	3	4	3	11.4,0.028	3 < t		
	4	2	3	13.5,0.059	4 < t		
	5	4	1	11.5,0.037	5 < t		
5	s (dummy activity)				s < 1,2,3	11	5 < T
	1	1	1	21.6,0.031	1 < 4		
	2	2	2	26.7,0.0122	2 < 4		
	3	5	1	17.2,0.018	3 < 4		
	4	3	2	22.0,0.03	4 < t		
T	Dummy project						

Note: DA = expected value for activity duration (month), C = cost (million RMB), PA = activity predecessors, DP = expected value for project duration, PP = project predecessors, EI and W = environmental impact and weight.

Each activity must be performed in one of m_i possible modes, each with a corresponding duration, cost, environmental impact, and budget and cash flow limit (see Tables 3 and 4). Hence, each activity has a certain maximal cost and environmental impact unit requirement. Other relevant data for the analysis are as follows: The maximum capital (units: million RMB) and environmental impact for each time period are 14 and 10 units, $(B_c, B_e) = (12, 10)$, respectively, while the maximum capital (units: million RMB) and environmental impact for each subproject time period are 6 and 6 units, $(b_c, b_e) = (8, 6)$. The penalty cost for each subproject in each time period is $c_i^p = 12$ (units: million RMB). The evolutionary parameters are a population size of 20, maximal generation of 200, an optimistic-pessimistic index of $\lambda = 0.5$, and a weight for each objective of $\eta_1 = 0.5, \eta_2 = 0.2, \eta_3 = 0.3$. The remaining variables are activity duration, cost, activity predecessors, project duration, and project predecessors.

4.2 Case Study Results

To achieve managerial objectives, all project aspects must be optimized through the best possible arrangement of start times and construction modes for each subproject activity. According to the proposed model, for optimal scheduling, the JHS-I activities should be arranged in the order below and corresponding construction modes chosen to fulfil the decision maker's requirements:

$$S = \{P_2(1,2,3,5,4) \to P_3(1,2,3,4) \to P_1(1,3,2,4) \to P_4(2,1,3,5,4) \to P_5(2,1,3,4)\}.$$

Table 3. Optimal solution for the JHS-I case study

Optimal schedule	$S = \{P_2(1,2,3,5,4) \to P_3(1,2,3,4) \to P_1(1,3,2,4)$ $\to P_4(2,1,3,5,4) \to P_5(2,1,3,4)\}$
Sum of completion times for all subprojects	54 (month)
Total penalty cost	−18 (million RMB)
Total environmental impact	−6.88
Fitness value	0.871

Table 4. Contrast between the optimal solution and actual data

	z_1	z_2	z_3	Optimal order and executed mode
Actual project data	56	32	7.76	$S = \{P_1(2,1,4,3) \to P_2(2,1,3,4,5) \to P_3(1,3,2,4) \to P_4(2,5,1,4,3) \to P_5(3,2,1,4)\}$
Optimal result	54	−18	14.64	$S = \{P_2(1,2,3,5,4) \to P_3(1,2,3,4) \to P_1(1,3,2,4)$ $\to P_4(2,1,3,5,4) \to P_5(2,1,3,4)\}$
Net decrease in project value	2	50	15.5	
Rate of decrease	3.57%	156%	200%	

It should also be noted, however, that, because of cost and environmental impact constraints, certain noncritical activities in subproject 1 (2), executable between the 4^{th} and 9^{th} month, are flexible but other noncritical activities in subproject 3 (2), executable between the 3^{rd} and 8^{th} month, are not. The model thus defines the critical path meaningfully enough to be used in practical (rather than simply theoretical) scheduling. In particular, it enables the project manager to schedule activities according to the situation, which can be affected by such factors as available manpower, equipment, holidays and the need to harmonize with other parallel projects or activities. Moreover, even though a comparison of the actual project data with the optimal result generated by the flc-hGA reveals differences, these differences move in a positive direction. For example, the net decrease from plus to minus in each objective, when considered specifically for the changes in penalty costs and environmental impact, signals a shift from penalty to reward. Overall, the rate of this decrease for each objective, which ranges from 9.56% to 200%, signals an improvement in construction efficiency that could bring considerable economic benefit to any construction project, but especially to one that is large scale.

Admittedly, because the assumptions on which the mathematical model is based may generate certain modeling errors, the results do not represent a 100% optimal DTCETP-mP solution. Nevertheless, they can still serve as a useful optimal scheduling guideline for decision makers in current construction projects.

5 Conclusions and Implications for Future Research

The multiple objective optimization model developed in this paper extends a traditional single project model to an advanced multiple project trade-off model able to determine optimal scheduling and construction mode selection for the project at Jinping-I Hydropower Station. The model is designed to not only minimize duration and penalty costs but also reduce the DTCETP-mP's environmental impact. It thus controls for the project constraints of duration, cost, and environmental impact.

Because the DTCETP-mP is an NP-hard problem, the optimization method employs an flc-hGA to solve it. The analytical results for the JHS-I case study indicate that the trade-off between competing incommensurate objectives is actually dominated by the project manager's determination of the weight for each objective. Hence, decision makers can use the importance of project objectives to determine the optimum trends for time, cost, and environmental impact. One major advantage of the proposed method is that it enables decision makers to systematically and feasibly control the schedule according to an optimistic-pessimistic index. In addition, the flc-hGA developed for the study can be used to enhance optimization quality and stability.

The findings reported here suggest three important areas for future research, all of which warrant equal concern. Firstly, a more holistic measurement should be developed for environmental impact to ensure a more reasonable and effective model. Secondly, future studies should address more complex practical problems, such as those involving resource constraints, and uncertainties. Lastly, more efficient heuristic methods need to be developed to solve NP-hard problems with a greater number of constraints. The method and model proposed here offer a useful foundation for all such investigations.

Research on Equalization of Public Services Based on Changes of Urban and Rural Population Structure

Qian Fang(✉) and Yi Sheng

Sichuan Academy of Social Sciences,
Chengdu 610072, Sichuan, People's Republic of China
lily_lily009@163.com

Abstract. This paper starts the discussion from five aspects population distribution, age structure, employment characteristics, family characteristics and flow population, and conducts qualitative and quantitative analysis on the changes of urban and rural population of new period of China, so as to master the basic situation and development trend of urban and rural population. On this basis, the paper proposes suggestion and countermeasures on equalization of public services in urban and rural areas in our country, basically from three aspects-"increasing the flexibility of the urban and rural public service supply mode", "promoting the urban and rural service supply balance and accessibility" and "strengthening the effective supply to important groups and regions".

Keywords: Equalization of public services · Urban and rural areas · Population structure · Public service supply

1 Research Background

The problem of urban and rural areas is always a hot issue during the process of China's development. In November 2013, in the "Decision on Several Significant Problems on Comprehensively Deepening Reform by the Central Committee of the Communist Party of China" issued by the Third Plenary Session of the 18^{th} PCP Central Committee, it is clearly proposed to "propel the equalization of basic public services in urban and rural areas." There is no doubt that in the new period, the government has taken the perfection of urban and rural development integration mechanism as the main path for solving the problem of the unbalanced development between urban and rural areas, and has taken the equalization of public services as the main measure for relieving the conflict on development between urban and rural areas.

On the premise of the given orientation, it is urgent to conduct reasonable allocation on the public service resources of urban and rural areas and ensure the balance. In order to solve this problem, three aspects shall be taken into consideration: Firstly, what is the current situation of urban and rural population

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_145

structure? Secondly, how to define the equalization of urban and rural public services? Thirdly, how to realize the equalization of urban and rural public services? Domestic and foreign scholars have given some answers to the above questions, but not sufficient. Take the urban and rural population structure as an example. In 2011, the proportion of urban residents in our country exceeded that of the rural residents for the first time, which is called by media as “the reversal of urban and rural population structure since thousands of years in China” [3]; China has turned to the urban civilization stage with characteristics of industry and service industry from the giant agricultural country and agricultural civilization. It is noted in the “Social Blue Book” by Chinese Academy of Social Sciences that: “this is not only a change in the urban population percentage, but means the extremely profound change on the production method, occupational structure, consumption behavior, living method and value system of people” [12]. Is 2011 the time-point for the qualitative change of the urban and rural structure of China? If we narrow the scope to four major economic regions east region, middle region, west region and northeast region, we can find that such a so-called reversal has already appeared in Jiangsu, Zhejiang and Fujian as early as 2005. In the west region, the rural population in many regions is still more than that of the urban population (such as Guangxi, Sichuan, Guizhou, Yunnan, etc.), and no reversal has happened. The conclusion obtained from the average value of the statistical data is both scientific and some bit of biased, which shall not be taken too much consideration. Besides, the urban and rural population structure often discussed by some scholars is actually the urban and rural registered population structure, i.e., the personal status relationship of urban and rural residents, which is greatly different from the actual distribution of urban and rural population. In 2014, the population of separation of registered and actual residence in our country was 298 million, and the floating population was 253 million. It means that the era judging the population distribution according to family register has passed in our country. In brief, the urban and rural population structure in our country has come to a complex stage; from now on, equalization of public service will step into a period of overall promotion, accurate definition and courageous attempt. On the basis of accurate mastering of the change of urban and rural population structure, we will propose reform ideas and suggestion aiming at the new problem on urban and rural public service, which is an interesting topic, and also the original intension of this research.

2 Research Review

When conducting retrieval by taking CNKI as the retrieval source, “public service” and “public product” as the title and key word, and “urban and rural” as the title, more than 1800 results are obtained, in which there are 189 master and doctoral thesis, 149 conference papers, more than 570 papers on newspaper and 940 journal literatures.

There are 344 literatures with high quality, which are published on SCI, EI, Chinese core periodicals and CSSCI source periodicals. The following conclusion is obtained after conducting analysis on literatures by utilizing Citespace software.

Firstly, the high quality periodical achievements are concentrated during 2003–2016, mainly after 2010. Secondly, the top three authors in terms of the number of publishing are Wu Yemiao, Liu Chengkui and Yu Yaguai. No preferable cooperative relationship is formed between the authors, and most literatures are researched independently. Thirdly, the top three research institutions are the Institute of Public Administration of Sichuan University, the School of Government of Nanjing University and the Financial and Tax Institute of Shandong University of Finance. Fourthly, the research emphasis on urban and rural public service field in our country is concentrated in basic public service, equalization, urban and rural overall development, urban and rural gap, rural public products, sports public service and public finance. The research emphasis has been gradually transferred from the public product (2004), urban and rural overall development (2005), urban and rural public service (2006–2007) of the early stage to equalization of basic public service (2008–2010) and urban and rural basic public service (2010). Since "the 11th five-year plan", the domestic research has tended to specific contents such as social insurance, sports public service, infrastructure, etc. The research pays more attention to the evaluation on public service, to discuss on public service in combination of the theme of urbanization. Fifthly, there are two sudden nodes during the whole time period: public product and urban and rural overall development. The little node quantity indicates that the research on this field is not active enough, without significant emerging trend. Of course, it may be due to the short term of the research on this field in our country.

These researches mainly explore the equalization of public services from four aspects. First, it is the research on the specific contents of the basic public services. Secondly, it is the argument on the unbalanced situation of urban and rural public service. Just as what is proposed by Wu [14] that the unbalanced allocation of urban and rural public resources in our country is mainly expressed on infrastructure, basic education, social insurance and public medical health. According to Li [6], the unbalanced allocation of urban and rural public resource in our country is embodied on social insurance resource, social welfare resource, public health resource, basic education resource and infrastructure construction. Thirdly, explore the reasons for unbalanced urban and rural public service. It is regarded by some scholars that the subsidy on industry by agriculture and the subsidy on city by village in early stages of our country is the fundamental reason for unbalanced urban and rural public resource allocation [2]. It is considered by some scholars that the long term unbalanced urban and rural public resource allocation is related to the thoughts of "inevitable primary accumulation", "insufficient national financial resources" and "obstruction on efficiency by justice" in the society [15]; some scholars emphasize economic development level [5], and that the finance is the initiator of the evil [7]. Fourthly, explore the practice of promoting the equalization of urban and rural public service. Some scholars propose on ideology aspect to formulate the development strategy in accordance with the urban and rural integrated development, to increase the investment intensity in rural areas [18], to break through the functional restraint of "economic-oriented government", and to create public service-oriented government [16]; some scholars propose on financial aspect to take the investment by the Party Central Committee as the leading force, and to improve the efficiency of implementation of policy [11]. Some scholars think that it is needed to standardize the government expenditure behavior, and clarify the functions of various levels of governments, to increase the financial investment of the central and local governments [2]. Some scholars advocate to promote the balanced allocation of urban and rural public resources through marketization [1,19], but it is needed to avoid the corruption generated thereby. Some scholars think that it is available to conduct allocation on public resources by non-profit organizations [13]. Some scholars think that the balanced allocation of public resources is actually a problem about institutional arrangement in essence; To change the administrative philosophy of local government, to establish sustainable financial expenditure mechanism of rural public resource, to establish the peasants-participating public resource allocation decision mechanism, and to perfect the supervision and restraint mechanism of balanced allocation of social public resource, are four path choices for promoting the balanced allocation of public resources [6]; some scholars propose that it is necessary to realize the integration and association within the system, between the systems, between government and the society as well as among the diversified subjects of the society [4]. Besides, some scholars propose the method to improve the dual development on urban and rural areas from the aspect of specific field of public resources such as infrastructure, public education and medical health.

To sum up, the existing researches have laid firm foundation for us to continue the exploration on the urban and rural public service field, but there are still deficiencies on these researches. Firstly, compared with the discussion over the country (for example, 31 provinces and cities), there is obviously insufficient discussion on the equalization of urban and rural public services. Secondly, most researches are only conducted superficially on the unbalanced allocation of public service, resulting in superficial and impractical reform path. Thirdly, the existing researches are static, taking no population mobility and demand variability into consideration.

3 Changes on Urban and Rural Population Structure Characteristics in China

In recent ten years, there have been great changes on urban and rural population structure in China, which are embodied on aspects such as space, ages, family, education, income and employment. As for the population, the urban population in our country in 2011 exceeded more than 50% of the total population, forming a "neck and neck" situation on urban and rural population. On space distribution, the trend of migration from rural to urban area still goes on, and weight transition of urban and rural population and the adjustment of population density have become normalcy. On aspect of age groups, the fierce urban and rural population aging trend still goes on, and the situation of economic increase depending on "demographic dividend" has passed. On aspect of employment selection, the urban and rural population rushes to the tertiary industry (service industry), to make the employment transferred from "industry-oriented" to "service-oriented" form. With the resultant force of decreased family population and higher income, it has been the general situation for public service to lean to fields such as medical health and pension.

3.1 Changes on Space Distribution of Urban and Rural Population

Since the establishment of the nation, China has had an increasingly grown population, which increased to 1.36 billion in 2013 from 0.54 billion in 1949. The urban population has been on the rise, which increased to 0.73 billion in 2013 from 0.0577 billion in the early years of the new nation. Compared to the "up and down" situation of urban population, the rural population proportion was on a slow and continuous downtrend. In the early years of the new nation, the rural population in our country was near to 90%, which decreased to 46.27% in 2013.

Extend the analysis vision field to the four major economic regions, i.e., the east region, the middle region, the west region and the northeast region. The changes of urban and rural population show both generality and difference. On one hand, the changing trends of urban and rural population proportion in the east region, the middle region, the west region and the northeast region are almost the same, i.e., the proportion of urban population increases year-by-year, as shown in Table 1. On the other hand, there is significant difference on the proportion of urban population among the four economic regions. At the end of "the 10th five-year plan" (2005), the proportion of the urban population of the east region had been near to 60%, and the proportion of the urban population of the northeast had been near to 55%, while the proportion of the urban population

Table 1. Changes on proportion of urban population in the four major economic regions in China (2005–2013)

Region	2005	2006	2007	2008	2009	2010	2011	2012	2013
China	42.99	44.34	45.89	46.99	48.34	49.95	51.27	52.57	53.73
The east region	59.23	60.15	60.87	61.65	62.48	64.43	65.19	66.11	66.92
The middle region	37.58	38.96	40.27	41.73	43.03	44.44	46.28	47.98	49.26
The west region	35.18	36.15	37.31	38.53	39.61	41.45	42.81	44.26	45.43
The northeast region	54.77	55.15	55.42	56.22	56.39	57.04	57.98	58.75	59.35

Data source: Obtained by arrangement of "China Statistical Yearbook 2014" of the middle region and the west region was between 35%–38%. During 2006–2013, the urbanization of population in east region slowed down, with only 6.77% growth during 8 years; the middle region had the quickest growth speed, with 10.3% growth; the west region had a growth speed of 9.28%; the northeast region had the slowest growth speed, with only 4.2% growth during 8 years. Moreover, the active force for urbanization during the latest ten years in China was in the middle region and the west region, which are also the regions with the largest development potential in the future.

3.2 Changes on Age Structure of Urban and Rural Population

It is agreed by most domestic and foreign experts that "demographic dividend" is the main active force for the rapid development of 30 years since the reform and the opening-up policy. The young and middle-aged labor force plays a huge role in the rapid economic growing period. However, as time goes by, the population proportion of national labor force significantly decreases. During 2011–2014, the proportion of the population of 16–59 years' old decreased year-by-year, from 0.941 billion in 2011 to 0.916 billion in 2014. Correspondingly, the proportion of the population above 60 and 65 years' old increased year-by-year.

Up until the end of 2013, except for Tibet and Xinjiang regions, the 29 regions of the whole country had entered into the aging society to varying degrees. In which the aging degree of Tianjin, Shanghai, Jiangsu and Shandong of the east region, Anhui and Hunan of the middle region as well as Sichuan and Chongqing of the west region had exceeded than 10%. The top three regions of aging degree were Chongqing, Sichuan and Jiangsu.

Viewing from the four major economic regions, the proportion of the labor force population of 15–64 years' old in the east region is higher than that of the middle region and the west region, as shown in Table 2. In consideration that the permanent resident population of the east region occupies 37% of the 31 provinces and cities, which is much higher than that of the west region, the middle region and the northeast region, the development power in the east region is more sufficient and higher.

Seen from the aspect of dependency ratio, the national aging population dependency ratio increased from 8% in 1982 to 13% in 2013; the children dependency ratio decreased from 54.6% in 1982 to 22.2% in 2013. Aging of population

Table 2. Comparison on population age structure of the four major economic regions (2013)

Region	0–14(%)	15–64(%)	Over 65 (%)
The east region	14.87	75.52	9.61
The middle region	18.34	72.09	9.57
The west region	18.2	71.89	9.9
The northeast region	11.3	79.07	9.63

has a considerable influence on family and the society. Compared with the east region, the middle region and the northeast region, the aging population dependency ratio in the middle region is on the high side, and that in the west region and the northeast region is on the low side. The dependency ratio of children in the west region is the most highest, and that in the northeast region and the east region is on the low side. As a whole, the dependency ratio of families in the west region is the highest (38.29%), and that of the northeast region is the lowest (26.57%), and the middle region and the east region are between the two.

3.3 Changes on Employment Characteristics of Urban and Rural Population

During the 30 years since the reform and opening-up policy, the changes on employment structure of national urban and rural population are firstly embodied on employment population distribution of three industries; it appears in a situation that the proportion of the employment population of the primary industry decreases, and that of the secondary industry increases but with frequent fluctuation, and that of the tertiary industry continuously increases. The national total employment population in 2013 was 769.77 million, in which 382.4 million were urban employment population and 387.37 million were rural employment population. The employment population between urban and rural areas appeared in a "fifty-fifty" situation.

There are totally different employment structures in urban and rural areas. The urban employment population includes the people working in state-owned units, collective units, joint stock partnership units and joint ownership units, as well as in foreign-funded enterprises, private enterprises and individual enterprises. There are mainly three types of employment population in rural areas: the employment population in private enterprises, individual employment and faming population. Since 2004, the proportion of population working in private enterprises of rural employment population has exceeded than that of individual enterprises, showing the agriculture industrialization and enterprise-oriented development trend, as shown in Fig. 1.

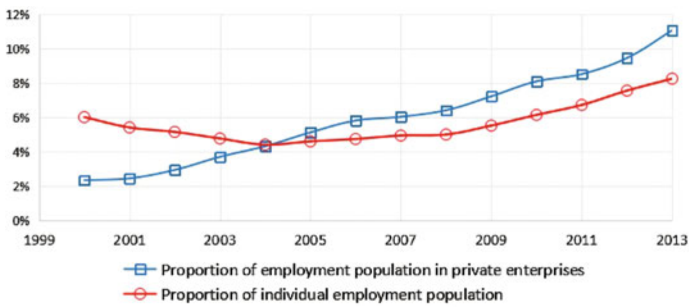

Fig. 1. Changes on proportion of employment population in private and individual enterprises in rural areas of China (2000–2013)

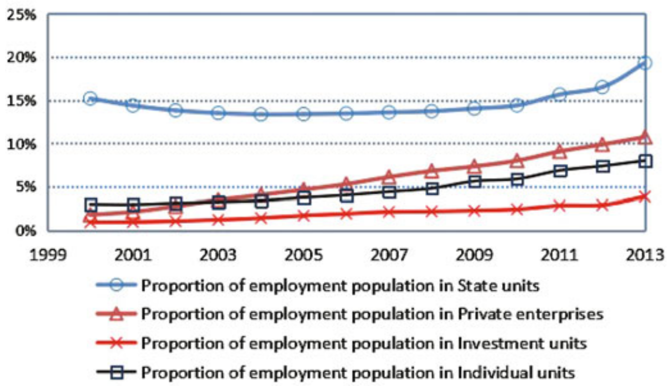

Fig. 2. Changes on proportion of urban employment population in China (2000–2013)

A large part of urban employment population "works in institutions as well as enterprise and public institutions of various levels", and please refer to Fig. 2 for the urban employment population situation. If the urban employment population working in state-owned enterprises, collective enterprises, joint-stock enterprises and associated enterprises is collectively called as "state enterprises", we can see two major changes of the national employment. Firstly, the employment population of "state units" appears in a slow rising trend. In the "state units", the employment population in state-owned units, collective units, joint stock partnership units and joint units decreases, and that in limited liability companies and joint-stock companies increases. These changes are corresponding to the state-owned enterprise reform and the separation of ownership and management, as well as the mixed ownership reform. Secondly, the employment population in private enterprises, investment units (foreign investment as well as investment made by businessmen of Hong Kong, Macau and Taiwan) and individual employment increases. The increase speed of the employment population of private enterprises is the fastest, followed by individual employment, and the investment unit is the slowest.

3.4 Changes on Family Characteristics of Urban and Rural Population

During 1949–2010, there was a small fluctuation in family scale in our country, decreasing from 4.43 persons for each household, which was the maximum value, to 3.10 persons for each household. In 2013, the national per household scale decreased to 2.98 persons for each household. When making comparison among the families in the east region, the middle region, the west region and the northeast region, the middle region has the largest family household scale, achieving 3.19 persons for each household. The northeast region has the smallest family household scale, with only 2.76 persons for each household. The middle region and the west region have the family household scales of 2.98 persons and 3.04 persons respectively.

From the comparison on urban and rural residents income situations among the east region, the middle region, the west region and the northeast region, we can know that the per capital income of the urban residents in the east region is the highest, and that in the west region is the lowest, and that in the middle region and the northeast region is between the two. The urban resident income in the east region is 1.44 times of that in the west region, and the per capita net income of rural residents is 1.76 times of that in the west region. Viewing from the data in the recent ten years, the proportion of income between residents in the east region and the west region gradually decreases, from 1.52 in 2005 to 1.43 in 2013, and the proportion of rural resident income decreases from 1.98 in 2005 to 1.76 in 2013.

According to the data, the top four expenditures for urban residents are "food", "transportation and communication", "culture, education and entertainment" and "clothing"; the top four expenditures for rural residents are "food", "residence", "transportation and communication" and "medical health". There are great difference on public service demands between rural residents and urban residents. "Transportation and communication" is the common part for urban and rural residents, but rural residents need more on the improvement of "residence" and "basic medical service", while urban residents pay more attention on "culture, education and entertainment".

It can be known from the comparison on urban residents expenditure in the east region, the middle region, the northeast region and the west region (as shown in Table 3) that the top four expenditures for urban residents in the four regions are "food", "transportation and communication", "culture, education and entertainment" and "residence". In which the consumption on "food" (37.07%) is the largest in the west region; the consumption on "transportation and communication" (16.36%) and "culture, education and entertainment" (13.35%) are the largest in the east region; the consumption on "residence" is the largest in the northeast region. It can be known according to the expenditure of rural residents among the east region, the middle region, the northeast region and the west region (as shown in Table 4) that the top four expenditures for rural residents in the four regions are "food", "residence", "transportation and communication" and "medical health". In which the consumption on "food" occupies the largest proportion (38.17%) in the west region; the consumption on "residence" (20.74%) occupies the largest proportion in the northeast region; the "transportation and communication" (13.22%) occupies the largest proportion in the east region; the consumption on "medical health" (12.16%) occupies the largest proportion in the middle region. Therefore, the urban and rural residents in the four regions have different emphasis on public service supply, and the quality and quantity of public service supply shall be improved according to the emphasis of resident expenditures.

Table 3. Proportion of per capita consumption expenditure of urban residents in the four major economic regions (2013)

Region	Unit	Food	Clothing	Residence	Household articles	Transportation equipment and communication	Culture, and entertainment	Medical education	Others health
National	%	35.02	10.55	9.68	6.74	15.19	12.73	6.2	3.88
The east region	%	35.33	9.04	9.45	6.61	16.36	13.15	5.78	4.29
The middle region	%	35.68	11.36	10.02	6.97	13.28	12.87	6.38	3.41
The north-east region	%	32.28	12.19	11.25	5.92	13.44	11.62	9.08	4.23
The west region	%	37.07	11.51	9.57	6.67	12.99	11.93	6.69	3.57

Data source: obtained by calculation and arrangement of "China Statistical Yearbook 2014"

Table 4. Per capital consumption expenditure of rural residents in the four major economic regions (2013)

Region	Unit	Food	Clothing	Residence	Household articles	Transportation equipment and communication	Culture, and entertainment	Medical education	Others health
National	%	37.67	6.62	18.62	5.84	12.01	7.33	9.27	2.64
The east region	%	37.35	6.66	16.98	5.66	13.22	8.12	8.86	3.16
The middle region	%	34.45	7.82	17.28	4.03	12.27	9.02	12.16	2.96
The northeast region	%	37.42	6.1	20.74	6.34	10.33	6.94	9.46	2.36
The west region	%	38.17	6.84	18.98	5.85	12.09	6.12	9.46	2.49

Data source: obtained by calculation and arrangement of "China Statistical Yearbook 2014"

3.5 Changes on Space and Characteristics of Floating Population

The floating population of China in 2014 was 0.253 billion, occupying 18.5% of the total population of the whole country. Liu, et al. [8] conducted measurement on the directivity and activeness of regional floating population in our country, and divide the floating population regional type into four types. In which the urban agglomeration regions such as the Pearl River Delta, the Yangtze River Delta and Beijing are the active regions for net inflow. The rural areas in the east region and the middle and west regions with concentrated population are the active regions for net outflow. The periphery or rural areas of the developed urban agglomeration in Zhejiang, Fujian, Guangdong in the east region are the active balanced regions. The vast middle region, the west region, Shandong, Hebei and north Jiangsu in the east region, Jilin and Liaoning in the northeast region are the non-active regions. There is relatively stable distribution proportion of floating population in the east region, the middle region and the west region during 2000–2010, with the increase rate of 115%–120%. The floating population in the east region occupies 2/3 of that of the whole country, and with rapid growth speed. The floating population concentration area in coastal regions gradually diffuses, with a continuous trend [9]. This trend is very significant in the Yangtze River Delta area, and the diffusion in the two floating population concentration areas of the Pearl River Delta and the Beijing-Tianjin-Hebei region is relatively limited. Megalopolises such as provincial capitals of inland regions attract a large amount of floating population; at the same time, there is significant northward movement on the distribution center of floating population (Table 5).

Table 5. Differentiation on zones of floating population in China [10]

Index	Year	The east region	The middle region	The west region
Total floating population (10 thousand persons)	2000	5110.4	1237.8	1552.6
	2010	10987.1	2661.9	3407.1
	The growth rate during the 10 years	115.00%	115.10%	119.40%
Proportion of floating population in the whole country (%)	2000	64.7	15.7	19.7
	2010	64.4	15.6	20
Proportion of floating family resister (%)	2000	11.1	3	4.4
	2010	22.1	5.8	8.8

When making comparison on the population floating regional difference in the east region, the middle region and the west region, we can find that the population floating in the east region is mainly the floating to other provinces, and that in the middle region is mainly the floating within county, and that in the west region is mainly the floating between provinces. As a whole, the floating between provinces occupies an important role; however, the within-province floating has a more fierce development trend, with the scale not less than the cross-province floating. Because of the lower cost and smaller obstruction, the floating within province of population will become the mainstream, and local urbanization will become the main method for the urbanization in our country.

Besides, the domestic population floating mode appears in significant "domestication trend". Most Chinese families adopt the "progressive floating mode", i.e., some family members enter into cities to work and live firstly. There are differences on the characteristics of family floating in different regions. For example, "the complete family type floating occupies the highest proportion in the middle region and the cross-county floating, which occupies a relatively low proportion in economic developed regions and under developed regions. This phenomenon illustrates that the threshold or living cost for family reunion in developed regions is relatively high, and the under developed regions fail to have an attraction for family reunion to floating population because of the lack of high quality resources" [17].

3.6 Countermeasures and Suggestions on Promoting of Equalization of Urban and Rural Public Service

Based on the change features on urban and rural population structure characteristics, the author proposes three suggestions and specific measures for promoting the equalization of urban and rural public services in China.

(1) Increase the Flexibility of Urban and Rural Public Service Supply Modes

Strengthen the statistical investigation, and accurately master the urban and rural population characteristics. It is suggested to constitute the yearly population sample survey working group by the statistical bureau and related departments by relying on existing population census organizations in our country, to develop yearly survey on population quantity, age, structure, distribution, residence and public service willing. Hold the joint conference of the statistic department, the public security department, the family planning department, the civil affair department, the environmental-protection department, the financial department and the population and society department according to the requirements on data collection, to clarify the rights and obligations of various departments on coordination for collection index. Establish urban and rural public service evaluation index system, to conduct analysis on data collected by each year by multiple forms including service outsourcing, cooperation between governments, franchising, subsidy and voluntary services, and the government releases the "Survey Report on Urban and Rural Public Services Situations in China" to the whole country each year. Change the method of allocating financial capital according to registered population, to promote the coordination between the urban permanent residence population and the central fiscal appropriation.

Eliminate the urban-oriented policies, and deepen the household registration system reform. Explore the way to take the ID card as the national use and unchanged for lifelong social guarantee number, and implement the social insurance one-card system for the national social insurance unities. On the premise of giving respect to the autonomous right of peasants to live and stay in cities, encourage them to go to the town. Prohibit taking the giving up of contractual right of land, right to the use of curtilage and the collective benefit distribution right as the conditions for peasants to settle down in cities. Broaden the residence migration policy, and take the legal stable residence or the legal stable employment registered residence as the basic conditions, to allow rural residents to apply for the registration of permanent residence household, and broaden the settling conditions for purchasing, building and inheriting of houses in cities, and simplify the population registration system with the principle of "conducting management on population through house, to achieving between population and household".

Promote the interaction of population, and construct integrated labor force market. It is suggested to drive the equalization of urban and rural public service by the urban and rural human resource integration. Establish the urban-rural unified employment standard, to desalt the localization and census register conditions of employment field, determine the subjective position of the labor force market, and realize the allocation of labor force resources by the market. Establish the labor force market with "online + offline" dual platforms, and improve the construction of information network, to establish the information system with the joint participation of enterprises, job seekers and occupation introduction institutions. Perfect the employee training and promotion system, and perfect the incentive mechanism, and encourage enterprises to maintain the employee training rights, and enlarge the promotion space for peasant workers, to ensure them to acquire the living capital in cities in an effective way.

(2) Promote the Balance and Accessibility of Urban and Rural Service Supply

Through giving directional difference to the rural area, relieve the unbalanced urban and rural structure. Further perfect the infrastructure construction of transportation in rural areas, to realize the smooth roads, and finish the construction of outward roads of poor villages. Improve the management and maintenance level of rural roads, and stable the road situation of rural roads, and extend the service life, and solidify the rural roads construction achievements. Promote the urban-rural integration, and perfect the urban system planning and village and town building plan for all the urban and rural areas. Pay more attention on aging population and school children on rural public service resources.

Promote development on small and middle-sized cities, and find out supporting point for city back seeding countryside. It is suggested to conduct comprehensive consideration on terrain and economic conditions on the basis of building the center cities in the middle region and the west region, to select a batch of type I and type small-sized cities, to cultivate and encourage them to grow larger and stronger, to form different layers of radiation circles, to provide substantial support for the development of rural areas.

Formulate differential equalized strategy according to regional characteristics. Conduct consideration by linking the infrastructure and the accessibility of public services with the space behaviors of residents, to strengthen the accessibility of public space, employment, administrative center and other comprehensive public services. Conduct different environment governance measures between urban and rural areas, and lay the emphasis on environment improvement (such as on aspects of drinking water, toilet, rubbish and waste water processing) in rural areas, and lay the emphasis on air quality and traffic congestion improvement in urban areas. According to the public service levels in the east regions, the middle region, the west region and the northeast region, formulate different propelling schemes. Highlight the characteristics of urban and rural areas, and strengthen the advantages of landscapes in urban and rural areas. Avoid rural areas copying the urban community mode, or substituting rural landscape with urban elements, and replacing greenbelts with firm grounds. It is not advocated to promoting the unified allocation standard between rural and urban areas, to avoid the loss of rural characteristics and folk culture in rural areas.

(3) Strengthen the Effective Supply to Important Groups and Key Areas

Improve the public service supply level and guide the peasant workers to integrate in cities in an orderly way. Perfect the infrastructure construction of the labor force market, and set up and integrate the "urban and rural labor force market information platform" integrated with enterprise employment information, labor force employment hunting information, industry employee information and employment policy. Increase the employment stability of peasant workers, and improve the vocational skill quality of peasant workers by means such as releasing free training tickets and implementing enterprise training fee deduction taxes and duties, to increase opportunities for employment. Increase the participation of the peasant worker group to urban public affairs, and set up peasant worker service platform in communities, to help them adapt to the city life as soon as possible by providing services such as formality agency, living guidance, employment consultation and children entrance information, etc.

Construct service network, so as to improve the medical and pension services for senior citizens in urban and rural areas. Conduct general investigation on the data, residence and family conditions of the senior citizens in national urban and rural areas, to establish documents for the senior citizens. Arrange medical health institutions or nursing institutions for the aged in urban and rural areas, to build the pension community integrated with medical and pension services, to form the urban-rural covering and reasonably functional medical and pension service networks with sharing resources between pension service and medical health service. Improve the ability of door-to-door service for senior citizens by the basic level medical health institutions, and encourage medical institutions to provide green channel for senior citizens to seek for medical service, and encourage nursing institutions for the aged to provide medical service for senior citizens. Guide the enterprises to develop integrated pension communities integrated with residence, health care, pension, recovery and entertainment; guide the community health service institutions to conduct transformation and upgrading, and encourage the comprehensive medical institutions to cooperate with nursing institutions for the aged, to give play to the radiation and leading functions of medical alliance.

Abstract. This paper adopts cashflow sensitivity of cash holding model to investigate the influence of economic cycles and accounting conservatism on corporate financial constraints, and to investigate the different impact of the two mechanisms from the property right perspective. Our results show that the recession of economic cycles aggravates the degree of corporate financial constraints, and this negative influence is more apparent on non-SOEs than SOEs. Moreover, the increase of accounting conservatism can release corporate financial constraints, and the alleviating effect of accounting conservatism is more significant on non-SOEs.

Keywords: Economic cycle · Accounting conservatism · Financial constraints

1 Introduction

Financial constraints can effect the corporate innovation [9] and investment efficiency [10], which seriously restrict the further development of corporates and ultimately affect economic growth. The World Bank report [7] shows that 75% of non-financial listed companies in China choose financial constraints as a major obstacle to business development, the highest percentage in 80 surveyed countries. Chinese corporates are facing the test of financial constraints.

China's economy characteristics has been markedly different from the past 30 years. It mainly expresses in the following aspects: (i) economic growth tailed off to around 7%, or lower; (ii) a large sum of money flows into the real estate and infrastructure construction instead of the real economy; (iii) the real economy such as manufacturing achieve consistently poor performance. The lack of capital in the real economy is detrimental to the long-term sustainable economic growth. And capital flowing into the real estate sector may not be able to promote economic growth and add to economic stability. Instead, it may boost the housing prices and make the real economy more difficult. Against this background, it is of practical significance to study the causes and solutions of the financial constraints of traditional enterprises.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_146

Theories have studied the causes of financial constraints from information asymmetry, agency costs, firm size and political connection [6,19,23]. However, all these studies are carried out from the microperspective. After taking these factors into account, the phenomenon that the degree of financial constraints of Chinese corporates fluctuates with the macroeconomic can't be explained. Trying to find out the reason, this article raises the first question: since the fluctuation of economic cycle is one of the main characteristics of market economy, do the economic cycles affect the corporate financial constraints? If so, what is the influence mechanism?

Accounting conservatism is an important index to measure the quality of accounting information [3,4]. Fair value has been questioned after 2008 financial crisis, while theories begin to rethink the positive effect of accounting conservatism [17,24]. The increases in conservatism improve the firm information environment and lead to subsequent decreases in information asymmetries between firm insiders and outsiders [15]. And accounting conservatism reduces under investment in the presence of information frictions [2]. So this article raises the second question: is it easier for the enterprises with high accounting conservatism to get financing in the capital markets? Can accounting conservatism ease the financial constraints, especially in the economic recession?

Using the financial data of Chinese listed A - share listed manufacturing companies, we test whether and how economic cycle and accounting conservatism affect corporate financial constraints to obtain the empirical evidence. Our first contribution is our explicit focus on the impact of economic cycles on corporate financial constraints. Typically, existing studies tend to focus on studying the cause of financial constraints from the enterprise's perspective. Macroeconomics and enterprise behaviors are disjointed in existing research [11]. There is a strong evidence, however, that the economic cycles can influence corporate financial constraints. As financial constraints may be specific to different property rights, we investigate the different impact from the property right perspective. It can broaden the research horizon on influencing factors of financial constraints from purely concerning about the internal factors of corporates to the external macroeconomic environment.

The second main contribution of this paper is that we pertain to providing an approach to ease financial constraints suffered by Chinese traditional enterprises. We suggest that it's beneficial for corporates to concern about the external business environment, especially the economic cycles. As for the impact of economic cycles-there are two representative views: the first is that the effect of the economic cycles on each firm is exactly the same, so changes in the economic cycles do not lead to additional losses for individual firm [16]; Another view is that the profitability of a firm is linked to the economic cycles, and its investment and business strategies are effected by economic cycles [18]. Our research confirms that the recession of the economic cycle aggravates corporate financial constraints. Enterprises should take advance measures to cope with the lough business environment. Moreover, we study the positive effect of accounting conservatism on decreasing corporate financial constraints and make a useful supplement to the economic consequences of accounting conservatism. It will inspire the traditional enterprises to improve accounting information quality for decreasing financial constraints.

The remainder of the paper is organized as follows. Section 2 explains the relevant theoretical analyses and our hypotheses. Section 3 presents our research sample and model. Section 4 shows our main empirical findings, and Sect. 5 presents our conclusion.

2 Theoretical Analyses and Hypothesis

In the economic recession, reduced external demand leads to production downsizing, which inevitably damage enterprises profitability. Further, there is a reduction in internal funds. So, enterprises must rely on more external financing to meet funding needs. Bernanke and Gertler [6] point out that enterprises suffer higher external financing costs and more serious cash-flow problems during the downturn. This is mainly caused by the tough external business environment. Besides that, the deterioration of corporate operating situation leads to the increase of information asymmetry. At the same time, investors become more cautious with big confidence attack. The stock market is in depression, so enterprises are difficult to raise enough funds by issuing shares. In addition, financial institutions such as banks may reduce the loan amount and raise the loan interest rate to control the default risk, increasing the difficulty of obtaining loans from financial institutions. According to financial accelerator theory, enterprises suffer more serious financial constraints because the external capital suppliers require a higher risk premium to compensate for possible loss risk in a recession. On the contrary, the optimistic expectations help to ease the financial constraints in the macroeconomic boom. It can be seen that there is a significant negative correlation between the degree of financial constraints and the economic cycles. Therefore, this paper gives the first hypothesis:

Hypothesis 1: The economic cycles can influence the degree of corporate financial constraints. During the boom, the degree of financial constraints is relatively low, while in the economic recession, the degree of financial constraints is high.

Based on the soft budget constraint theory, the influence of economic cycle on financial constraints can be different due to property rights. On the one, SOEs take more political tasks than non-SOEs. The government is more likely to give stealth or explicit support to help SOEs out of troubles when SOEs involve in financial risks [21]. On the other, the long-term mutually beneficial contract between the state-owned banks and the SOEs can alleviate the information asymmetry between the two. So SOEs enjoy preferential treatment in bank loans. The Property rights, to a certain extent, can weaken the influence of economic cycle on corporate financial constraints. So, this paper gives the second hypothesis:

Hypothesis 2: Compared with SOEs, non-SOEs suffer more serious financial constraints.

Enterprises with poor financial status may carry out earnings management to meet the financing requirements to get funds. Creditors and shareholders are in a weak situation with less information and can't effectively supervise the use of funds. So enterprises are more prone to moral hazard and adverse selection. Creditors and shareholders will require a higher risk premium for taking a greater default risk. Therefore, under the same conditions, the higher degree of information asymmetry, the more serious financial constraints enterprises suffer. Some studies show that accounting conservatism can help to ease the agency conflict. Beaver and Ryan [5] find that accounting conservatism mitigates agency conflicts between management and creditors by undervaluing net assets and discouraging management from transferring creditor interests to shareholders through asset substitution. Lafond and Roychowdhury [14] argue that management share holding ratio is negatively correlated with accounting conservatism because accounting conservatism eases agency conflicts between management and shareholders by suppressing earnings management and over-investment. As a signal transmission mechanism, accounting conservatism can effectively reduce the agency costs and avoid the moral hazard and adverse selection caused by information asymmetry. It shows that accounting conservatism plays a positive role in easing financial constraints. Based on this, *Hypothesis 3* is proposed.

Hypothesis 3: Under the same conditions, the improvement of accounting conservatism can alleviate the corporate financial constraints.

Due to the special national situation of our country, the SOEs still occupy the dominant position in the market economy. SOEs not only have more resources and policy advantages, but also enjoy the implicit guarantees from government. When the SOEs fall into financial troubles, the government is more willing to provide financial assistance and banks are more willing to provide loans. It reduces investors' concern of accounting conservatism, that is, accounting conservatism has little effect on alleviating the financial constraints of SOEs. On the contrary, accounting information quality of non-SOEs is one of the most important factors considered by the external capital suppliers. The conservative accounting policies can help enterprises obtain financing from banks and investors. In the downturn, non-SOEs suffer more serious financial constraints, so it is extremely important for non-SOEs to obtain financing from external markets. Using accounting conservatism to show their stable profitability and good operating conditions can alleviate the financial constraints. Viewed from the bank point, SOEs also have the credit quotas granted by banks. So the financial constraints suffered by SOEs aren't serious even in the downtown and the financial constraints caused by economic downturn will be more serious in non-SOEs. Based on the above analysis, the hypothesis 4 is proposed.

Hypothesis 4: Under the same conditions, the increase of accounting conservatism weakens the negative influence of economic recession on corporate financial constraints, and the interaction is more significant in non-SOEs.

3 Research Sample and Model Design

3.1 Definition of Variables

(1) Financial constraints

Both cash flow sensitivity of investing model and cash flow sensitivity of cash holding model are widely used in present research about financial constraints. However, due to the completely opposite conclusions in different studies using cash flow sensitivity of investing model, this paper uses cash flow sensitivity of cash holding model to measure financial constraints. And Almeida et al. [1] also prove that the cash flow sensitivity of cash holding model can overcome the defect of cash flow sensitivity of investing model.

(2) Accounting conservatism

Accounting conservatism is typically defined in the empirical accounting literature as the differential verifiability required for recognizing gains as compared to losses [4, 22]. More precisely, conservatism is the practice of reducing earnings in response to "bad news", but not increasing earnings in response to "good news". Basu [4] uses the positive stock returns to express good news and negative stock returns to show bad news, and construct the following model to measure enterprises' accounting conservatism.

$$\mathrm{EPS}_{i,t}/P_{i,t-1} = \alpha_0 + \alpha_1 \mathrm{EPS}_{i,t} + \alpha_2 \mathrm{RET}_{i,t} + \alpha_3 DR_{i,t} \times \mathrm{RET}_{i,t} + \varepsilon_{i,t}, \tag{1}$$

where i indicates the firm, $\mathrm{EPS}_{i,t}$ is earnings, $\mathrm{RET}_{i,t}$ is returns, and $DR_{i,t}$ is a dummy variable that equals 1 if $\mathrm{RET}_{i,t}$ is less than 0, and 0 otherwise. So α_2 is the good news timeliness measure and α_3 is the incremental timeliness for bad news over good news, or conservatism.

Khan and Watts [13] improved the Basumodel. They considered firm-year specific coefficients α_2 (timeliness of good news) and α_3 (conservatism) can be expressed by linear functions of firm-year characteristics that are correlated with the timeliness of good news and conservatism:

$$\text{G-SCORE} = \alpha_2 = \mu_1 + \mu_2 \mathrm{SIZE}_{it} + \mu_3 \mathrm{LEV}_{it} + \mu_4 MB_{it}, \tag{2}$$

$$\text{C-SCORE} = \alpha_3 = \lambda_1 + \lambda_2 \mathrm{SIZE}_{i,t} + \lambda_3 \mathrm{LEV}_{i,t} + \lambda_4 MB_{i,t}, \tag{3}$$

where SIZE_{it} is the natural log of the market value, MB_{it} is the market-to-book ratio, and LEV_{it} is the debt-to-equity ratio. Replacing α_2 and α_3 in Eq. (1) by Eqs. (2) and (3), respectively, yields the following empirical regression model:

$$\begin{aligned} \mathrm{EPS}_{i,t}/P_{i,t1} = {} & \alpha_1 + \alpha_2 DR_{i,t} + (\mu_1 + \mu_2 \mathrm{SIZE}_{i,t} + \mu_3 \mathrm{LEV}_{i,t} + \mu_4 MB_{i,t}) \\ & \times \mathrm{RET}_{i,t} + (\lambda_1 + \lambda_2 \mathrm{SIZE}_{i,t} + \lambda_3 \mathrm{LEV}_{i,t} + \lambda_4 MB_{i,t}) \\ & \times DR_{i,t} \times \mathrm{RET}_{i,t} + \varepsilon_{i,t} \end{aligned} \tag{4}$$

(3) Economic cycle

Domestic scholars use different methods to divide the economic cycle. Jiang and Liu [12] used GDP growth rate to distinguish different economic cycle. Shi and Zhang [20] divided the economic cycle based on the relationship between the real economic growth rate and the potential economic growth rate. In addition, Dong Jin (2006) [8] used a variety of measurement methods such as linear trend method, H-P filter method, B-P filter method and the production function method to divide China's economic cycle. This paper references the research of Jiang and Liu [11], etc., and use the annual GDP growth rate as the surrogate variable of the economic cycle (Clycle_GDP). First, GDP growth rate as a continuous variable can effectively avoid the error of using subjective dummy variables; And the use of continuous variable can also effectively avoid the systemic impact of institutional change, such as the implementation of new accounting standards, the split share structure reform.

(4) Property rights

This paper divides enterprises into SOEs and non-SOEs only, and researches the influence of economic cycle and accounting conservatism on financial constraints from these two respects. The property rights are defined as dummy variables, which are judged according to the ultimate controller of the listed company. If it's a SOE, it equals 0 and 1 otherwise.

(5) Control variables

Referencing the model of the existing research, this paper selects the operating cash flow (Cfo), enterprise size (Size), asset liability ratio (Lev), growth (growth), profitability (Roa), short-term borrowing difference (△Debt) as the control variables. The more sufficient operating cash flow, the more liquidity the company has, indicating that the company is in a good condition. So the expected sign is negative. Company size is defined as the natural logarithm of the total assets at the end of the year. Large scale companies are more resistant to risks. So, the default risk is smaller and the expected sign is positive. The higher the debt-to-asset ratio, the weaker the solvency, so the expected sign is positive. Enterprises will undertake a higher cost of capital if they have a higher growth and more likely to fall into financial distress. But on the other hand, they have better development potential and less defaultrisk. Profitability is the enterprises' operating efficiency. The better the enterprise's profitability, the less likely the default occurs. The sign is expected to be positive.

3.2 Model Design

As for the research model of financial constraints, Almeida's cash flow sensitivity of cash holding model has been recognized by many scholars. The model suggests that if enterprises suffer higher financial constraints, more cash will be held from the enterprise's cash flows to prepare for investment opportunities, and the cash flow sensitivity of the enterprise will be higher. In order to verify the four hypotheses, this paper builds extension models based on Almeida's cash flow sensitivity of cash holding model.

(1) Test the influence of economic cycles on corporate financial constraints

In order to test the influence of the economic cycle on financial constraints suffered by enterprises, this paper adds a cross-term between the operating cash flow and the economic cycle to cash flow sensitivity of cash holding model, and prove whether the economic cycle affect the financial constraints by checking the coefficients of the cross terms. As for the *Hypothesis 2*, the group multiple regression analysis is performed according to the different property rights.

$$\begin{aligned}\triangle\text{Cash} = &\beta 0 + \beta 1\, Cfo + \beta 2\,\text{Cycle\_GDP} + \beta 3\,\text{Cycle\_GDP} \times \text{Cfo} + \beta 4\,\text{Size}\\ &+ \beta 5\text{Lev} + \beta 6\,\text{Roa} + \beta 7\,\text{Growth} + \beta 8\,\triangle\text{Debt} + \varepsilon\end{aligned} \tag{5}$$

(2) Test the influence of accounting conservatism on corporate financial constraints

In order to test the influence of accounting conservatism on the degree of financial constraint, this paper adds the cross-term between accounting conservatism and operating cash flow to cash flow sensitivity of cash holding model, and confirm the role of accounting conservatism by observing the coefficients of the cross terms. As for the *Hypothesis 3*, the group multiple regression analysis is performed by property rights.

$$\begin{aligned}\triangle\text{Cash} = &\beta 0 + \beta 1\,\text{Cfo} + \beta 2\,\text{Conserv} + \beta 3\,\text{Conserv} \times \text{Cfo} + \beta 4\,\text{Size}\\ &+ \beta 5\,\text{Lev} + \beta 6\,\text{Roa} + \beta 7\,\text{Growth} + \beta 8\,\triangle Debt + \varepsilon.\end{aligned} \tag{6}$$

(3) Test the influence of economic cycle and accounting conservatism on corporate financial constraints

In order to test the interaction of economic cycles and accounting conservatism on the degree of financial constraints, this paper adds the cross-terms of economic cycle, operating cash flow and accounting conservatism to cash flow sensitivity of cash holding model. We observe the coefficients of the three cross-terms to verify how the financial cycles and the accounting conservatism interact the corporate financial constraints. And the group multiple regression analysis is performed by property rights also.

$$\begin{aligned}\triangle\text{Cash} = &\beta_0 + \beta_1\,\text{Cfo} + \beta_2\,\text{Conserv} + \beta_3\,\text{Cycle\_GDP} \times \text{Cfo}\\ &+ \beta_3\,\text{Cycle\_GDP} \times \text{Cfo} \times \text{Conserv} + \beta_3\,\text{Conserv} \times \text{Cfo}\\ &+ \beta_4\,\text{Size} + \beta_5\,\text{Lev} + \beta_6\,\text{Roa} + \beta_7\,\text{Growth} + \beta_8\,\triangle\text{Debt} + \varepsilon.\end{aligned} \tag{7}$$

3.3 Sample Selection and Data Sources

The sample consists of all A-share listed Chinese manufacturing enterprises between 2007 and 2015. The sample selection criteria are as follows: (1) Excluding enterprises with missing data; (2) Excluding companies with negative net assets; (3) excluding enterprises with uncertain property rights. Finally, 6933 samples are obtained, including 3975 SOEs and 2958 non-SOEs. In addition, extreme values of 1% and 99% of the relevant variables are Winsorized to eliminate the effects of extreme values. All financial data comes from CSMAR database and we use Stata11.0 to analysis the data (Table 1).

Table 1. Sample distribution

Year	2008	2009	2010	2011	2012	2013	2014	2015	Total

4 Empirical Results

4.1 Descriptive Statistics

Table 2 provides descriptive statistics for the variables, while the whole sample is grouped by property rights. Table 3 reports the descriptive statistics of the variables in SOEs and non-SOEs. It can be seen that the mean value of △Cash is −0.00048, the minimum value is −0.759 and the maximum value is 0.636, which indicates that enterprises have large differences in cash holdings; And the mean value of △Cash of non-SOEs is significantly larger than that of SOEs, indicating that non-SOEs are more cautious than SOEs; The mean of Cfo is 0.0472, the minimum value is −4.27 and the maximum is 0.549, indicating that cash flows of different enterprises is also a gap. The mean of Conserve is 0.0397, the minimum is −0.00223 and the maximum is 0.276, which shows that accounting conservatism are widely used in Chinese enterprises, but there are big differences among enterprises. The mean of Conserving SOEs is 0.0397, and the mean of the non-SOEs is 0.0476, which indicates that non-SOEs have higher accounting conservatism than SOEs. The mean of Lev is 0.432, indicating that debt financing is one of the

important financing channels. The mean of the growth is 0.376, the minimum is −1, and the maximum is 665.5. Assets scale and debt level of SOEs are higher than those of non-SOEs, but the non-SOEs have higher growth and profitability.

4.2 Correlation Analysis

Table 4 reflects the results of the correlation analysis. It can be seen that the relationship between the dependent variable and independent variables is consistent with the hypothesis. Cfo is positively correlated with △Cash, indicating that A-listed manufacturing enterprises generally have financial constraints. Cfo is negatively correlated with Cycle_GDP, which indicates that the economic cycle has obvious inhibitory effect on the external financing ability of enterprises. Conserv is negatively correlated with Cfo, which indicates that the improvement of accounting conservatism can alleviate the financial constraints suffered by enterprises; In the following empirical regression analysis, a more comprehensive summary will be made. In addition, all the correlation coefficients are less than 0.6, indicating that there is no multicollinearity between them.

4.3 Empirical Results and Analysis

(1) Economic cycle and financial constraints

The regression results of the regression model (5) are shown in Table 5. The regression coefficients of Cfoare positive at the significance level of 1%, whether in the regression of all samples or the sample of SOEs and non-SOEs, indicating that financial constraints is a serious problem in both SOEs and non- SOEs. And the coefficient of Cfo in non-SOEs is 0.947, which is significantly larger than 0.200 in SOEs, indicating that the financial constraints suffered by SOEs are more significantly. Then the coefficients of the cycle-GDP $*$ Cfo are analyzed. The coefficients are negative in the three regression at the 0.01significantly level, which shows that the economic cycle has a s negative correlation with the corporate

financial constraints. The first Hypothesis has been confirmed. The coefficient of Cycle-GDP ∗ Cfo of SOEs is −1.910, while the coefficient of Cycle-GDP ∗ Cfo of non-SOEs is −2.254, which shows that the financial constraints of non-SOEs are more affected by the changes in the economic cycle. The Hypothesis 2 has been confirmed.

(2) Accounting Conservatism and Financing Constraints

The regression results of the regression model 6 are shown in Table 6. It should be noted that the coefficients of the cross-variable Conserv×Cfo are significantly negative in the three regression results, indicating that the increase of the accounting conservatism can alleviates the financial constraints suffered by the enterprises. The coefficient in SOEs is −2.913 and the coefficient in non-SOEs is −4.162, which shows that the degree of accounting conservatism of non-SOEs has a greater influence on financial constraints, the hypothesis 3 has been confirmed.

(3) Economic cycles, accounting conservatism and financial constraints

The regression results of model (7) are shown in Table 7. The coefficients of the cycle-GDP × Cfo × Conserv are significantly negative in the three regression results, indicating that the improvement of the accounting conservatism weakens the negative influence of economic cycles. In other words, enterprises with higher accounting conservatism can get the external financing easier during the downturn. And the coefficient of SOEs is −5.870, while the coefficient of non-SOEs is −35.547, which shows that the positive role of accounting conservatism in easing financial constraints during the downturn can be more obvious in non-SOEs. The *Hypothesis 4* has been confirmed.

5 Conclusion

This paper examines the interaction of the economic cycle and accounting conservatism on corporate financial constraints using the data of A-share listed manufacturing companies from 2008 to 2015 from the property right perspective. It is found that the macroeconomic recession aggravates the financing difficulty of enterprises and cause more serious corporate financial constraints. And this negative influence is more significant on non-SOEs. Besides, the improvement of corporate accounting conservatism can help to alleviate the financial constraints suffered by enterprises, and this positive influence is more significant on non-SOEs as well. We test the dynamic response of enterprises in the face of the economic cycle recession by combining the economic cycle with the micro-enterprise behavior. The micro-enterprisescan weaken the negative influence of the economic recession by increasing accounting conservatism, which not only helps to understand micro-transmission mechanism of economics cycle, but also helps enterprises to improve cash using efficiency.

The shortcomings of the study: As the national macro-data is annual announcement, only the annual data of the sample companies can be chosen in order to match with the macro data. It reduces the length of research period and may not accurately reflect the influence of macroeconomic fluctuations monthly on corporate financial constraints. In addition, the accurate measurement model is the basis of empirical research. Although there are many measurement methods abroad, there is no conclusive conclusion. Domestic research in this area is a reference to foreign research. Therefore, the focus of future research is create a more accurate accounting conservatism measurement method based on China's institutional background.

Abstract. Traffic light control is an issue that metropolitan cities are confronted with because of ever-increasing vehicles growth. A proper timing strategy can release the congestion level and minimize vehicle delays better than standard fixed signal timing (FST) strategy. In this paper, a self-adaptive Q-learning based traffic light green time control strategy (QTGCS) is designed to reduce the congestion. Q-Learning acts as the learning mechanism for light at each intersection as an independent agent to release itself by operating traffic light duration dynamically. Q-Learning is based on discrete representation of state and action spaces. In order to make QTGCS not independent of the environment and designer criterion, Fuzzy Q-learning based traffic light green time control strategy (FQTGCS) is proposed by applying the fuzzy logic control to optimize timing strategy based on the number of vehicles receiving from the adjacent intersections. We show through simulation that our algorithm effectively over the real road networks.

Keywords: Light control · Reinforcement learning · Q-learning · Fuzzy logic control

1 Introduction

Traffic congestion has been an urgent problem of metropolitan cities in the world. It is generally recognized that traffic signal improvements offer the biggest payoff for reducing congestion and increasing the effective capacity of existing road networks, and the adaptive traffic signal control systems hold the most promise for improvement. Reinforcement learning approach implicitly models the dynamics of complex systems by learning the control actions and the resulted changes of traffic flow. Meanwhile, it seeks the (sub)optimal signal plan from the learned input-output pairs. RL, usually formalized as a framework of Markov decision process (MDP), assumed that an intersection behaves similar to an intelligent agent learning to plan green times in each cycle using current traffic information.

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_147

Specifically, Q-learning obtains Q-function by learning an action-value function. Thus, Q-learning is well-suited RL algorithm that obtains an optimal action-selection policy for given traffic state in any road networks. If traffic light indicates a suitable signal for vehicles, unnecessary waiting time of road users and the level of congestion state will be reduced compared to standard fixed signal timing (FST) strategy.

There are lots of researches aimed at reducing the congestion by the road users through RL methods. The isolated traffic signal was defined as an agent of RL, agent try to learn relationships between actions and their effect on the environment [1]. Extensive studies tried to implement RL or integrate with other algorithms for light timing, such as neuro-fuzzy [8] and kernel method to approximate Q-function, which is applied to estimate the feature vector [6]. Multi-objective RL proposed for traffic signal control in [7], in this approach, consolidating all rewards in one Q-function to obtain a global objective instead a multi-objective optimization problem. In [5], Q-learning algorithm acts as learning mechanism that react with environment for light intersections to release itself and in [4,9] taking advantage of fuzzy logic, the state and actions is set by a fuzzy algorithm which can be learned from an isolated intersection environment. In consideration of the correlation with adjacent intersections, there are also few researches aimed to coordinate light timing strategy together in small area separately [2], but how to form specific cooperation region not mentioned especially in large-scale road networks.

Fuzzy logic has the advantage of interpreting the linguistic values in terms of logical variables. With the aid of this, the traffic congestion situation can be clearly classified and comprehended [3]. Most of the fuzzy models regularly query the traffic conditions in order to decide whether to extend or terminate a current green phase based on Q value or reward value but not congestion relation on the adjacent sections. In this paper, we formulate the traffic light timing problem as an MDP, design a self-adaptive Q-learning based traffic light green time control strategy(QTGCS). In order to make QTGCS not independent of the environment and designer criterion, Fuzzy Q-learning based traffic light green time control strategy (FQTGCS) is proposed based on the number of vehicles receiving from the adjacent intersections. The indistinguishable boundary can be used evaluate the state approached next step. In the development process, we use SUMO simulator, an open-source software to help the real-world traffic light simulation. We show that FQTGCS yields a policy that has better performance than both the FST and QTGCS.

2 Traffic Lights Timing Strategy

2.1 Traffic Phase Model

The traffic light infrastructure consists of roads and nodes. A road connects two nodes, and can have several lanes in each direction. Phase is the permission which determines the duration of green time for traffic flows in one or some directions at the intersections. It plays an important role in ITS especially in light timing method. In this paper, we have defined two phase models: one for three-arm intersection phase model is shown in Fig. 1.

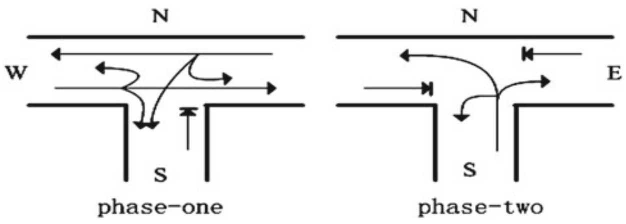

Fig. 1. Three-arm intersection phase model

Another four-arm intersection phase model is shown in Fig. 2. We can see easily from the figure that each model including four-phase consist of left-turning, right-turning, straight-going, and U-turn.

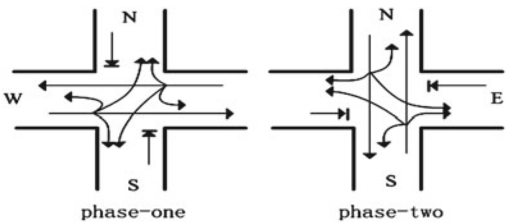

Fig. 2. Four-arm intersection phase model

In Fig. 1, phase-one denotes for the east-west direction, traffic light turns out to be green at a given time and vehicles get the pass permission, and for the south direction, the light is red at an three-arm intersection; phase-two is quite the reverse at that junction, the south direction for green light, and for the east-west direction, the light is red. In Fig. 2, phase-one denotes light turns green in the east-west direction and vehicles get the pass permission, and for the south-north direction, the light is red at a four-arm intersection; phase-two also denotes at that junction on the opposite way. In a FST strategy, the phases are set in a round-robin (RR) manner and the duration of green time for each phase is assigned in advance.

Due to the dynamic and uncertain nature of the traffic environment, we suppose that the phase of release order is changing frequently for light timing. The study will set phase selection strategy according to vehicles density. If the vehicles density in phase-one direction is higher, then choose phase-one; otherwise choose phase-two. In such way, which phase obtained the evacuation right can be easily determined.

$$\text{phase}(t) = \begin{cases} \text{phase-one} & \rho_{\text{phase-one}} > \rho_{\text{phase-two}} \\ \text{phase-two} & \rho_{\text{phase-one}} \leq \rho_{\text{phase-two}}, \end{cases} \tag{1}$$

where, phase(t) is the phase we have choose by phase selection strategy, $\rho_{\text{phase-one}}$ is vehicles density of phase-one direction, $\rho_{\text{phase-two}}$ is the density of phase-two direction.

2.2 MDP Framework

An MDP provide a coherent theoretical framework for which action is chosen in state s at each time step, and finally find a sequential decision by controller. In traffic light timing, we regard each traffic light as an control agent, and describe the process as a four-tuple (S, A, P, R), where S and A are the state space and action space, respectively, and every element $s \in S$ is called a state. Every element $a \in A$is called an action; $P : S \times A \times S$ is the transition probability which is a finite set of probability distributions in which an element $p(s, a, s')$ denotes the probability given the current state-action pair (s, a) to next state s'; and $R : S \times A \times S$ is the reward function, and $r(s, a, s')$ denotes immediate control performance received after transitioning from state s to state s', due to action a, where s,$s' \in S$, and $a \in A$. Hence, the whole traffic environment state is Markov, and the goal is to choose the optimal policy π^* that maximizes the total discounted reward, as:

$$\pi^* = \arg\max_{\pi} V^{\pi}(s). \tag{2}$$

In Eq. (2), $V^{\pi}(s)$ is the value function accumulated under the policy, which defined as follows:

$$V^{\pi}(s) = \sum\nolimits_{s' \in S} P(s, a, s')[R(s, a, s') + \gamma V(s')], \tag{3}$$

where $\gamma \in (0, 1)$ is the discount factor, we use the value function denote the discounted sum of the rewards.

In reinforcement learning, we can easily formulate light timing strategy within the MDP framework described, and the light at a signalized intersection as a learning agent. With this, light agent observe the congestion situation of the environment around, and take an action which based on exploration strategy, act on the environment and obtain a reward to evaluate the action. The light agent learning through the trial-error experience to achieve the optimal policy.

2.3 Q-Learning Algorithm

MDPs required having a good model in its implementation. Therefore, in this research we use Q-learning which from reinforcement learning with a model-free approach, and the traffic light at junctions as a learning agent. The light agent are not necessary to know how the environment works. It works by estimating the values of state-action pair, called Q-value, which represents the maximum discounted sum of future rewards an agent except to receive if it starts in state s, choose action a and then continues to follow an optimal policy.

This paper designed a distributed traffic light control strategy based on Q-learning. In such traffic light timing control model, each traffic light is an agent in Q-learning, agent chooses green time of traffic light as the action of agent, the density of vehicles in traffic lane at the intersection as the state, vehicles' average traveling time as the reward of Q-learning in traffic lane. Learning system interact with the environment constantly to get feedback and adjust map strategy of state to action.

The update of Q-learning formula is as follows:

$$Q(s,a) = (1-a)Q(s,a) + a\left[R(s,a) + \gamma Q^{\max}(s',a')\right], \tag{4}$$

where, α is the learning rate, and is the discount factor to decide convergence rate, $R(s,a)$ in function is the reward incurred by the light agent for taking an action a when the current state s and end up in state s', $Q(s,a)$ is the sum of future rewards to evaluate the performance of action we have took. It is an iterative method that modifies the estimates of Q-value. In the learning process, according to the Q-learning update rule set so that, the estimates converge to the optimal Q-value and the light agent's knowledge tends to be precise.

In this paper, Q-values are updated by the Q-learning update rule using Boltzmann based exploration strategy. The light agent decides its action based on the current learnt Q-value, the next section with Boltzmann exploration strategy that is used by the light agent to update Q-value and subsequently for choosing actions, the formulate is defined as follows:

$$p[a\,|s] = \frac{e^{\frac{Q(s,a)}{-t}}}{\sum_{a \in A} e^{\frac{Q(s,a)}{-t}}}, \tag{5}$$

where A is action space and τ is temperature parameters, $p[a\,|s]$ is probability that select a action in state s. The states represent the traffic density in the lanes connected to the junction described in Sect. 2.4, the action which represents the time for the highest congestion phase get the green light on.
Light timing control algorithm process based on Q-learning is shown below:

Step 1. initialize Q-learning algorithm parameters;
Step 2. analyzing the state of surrounding environment;
Step 3. according to the state, the light agent will select by action selection strategy;
Step 4. action act on the environment, and make environment changed, meanwhile the light agent obtain the reward according to reward function, and update the Q-value by this reward;
Step 5. if not satisfy the stop condition, return to step 2.

2.4 Fuzzy Logic Control Optimization Strategy

Consider the incoming traffic flows react on the congestion level of joint junction, and even if calculate the optimal state-action pair, there must be some disparities between actual optimal solution. For the consideration above, in this section, we propose a method to optimize action solution based on fuzzy logic control strategy. With fuzzy logic strategy, the learning agents coordinate with joint agents by information sharing, namely, the light agent allot green time to the phase that maintained the highest congestion level and obtain the status of approach phase flows by the vehicle information, these data are used to decide whether to extend or shrink the current light through-phase to achieve action solution optimization point. Furthermore, we use the density of vehicles to measure phase congestion level, and defined model discussed above in Fig. 3.

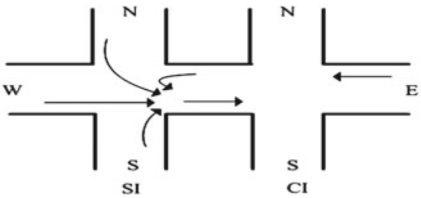

Fig. 3. Phase flow model

In this method, a fuzzy description of the traffic density during each phase at the intersection and its joint intersection, and the reward are implemented respectively, means fuzzify. After that, we develop fuzzy rulebase and initialize the reward values by the if-then relations.

(1) Fuzzy sets

A fuzzy set is a pair (U, A) where for each element $x \in U$, here U is a set, and A, a membership function, is the degree of membership of x in (U, A). The closer $A(x)$ to 1, the higher likelihood of $x \in A$, and the closer $A(x)$ to 0, the lower would be. We use trigonometric membership function in this paper. The domain of traffic density during the phase at the intersection is $[0, 1]$, the density level will be divided into four categories, density level below 0.25, density level between 0.25–0.5, density level 0.5–0.75, and the density level above 0.75, furthermore the fuzzy sub-sets of traffic density is "zero" (Z), "low" (L), "medium" (M), "high" (H), the membership function of each sub-sets is shown in Fig. 4:

The domain of the action reward is the real unit interval $[-2, 2]$, the four fuzzy sub-sets of reward is "zero" (Z), "small (S), "medium" (M), "medium big" (MB), "big" (B), the membership function of subsets is shown in Fig. 5:

Traffic light optimize action selection strategy according to density situation at current intersection (CI) and its joint intersection (JI), to maintain synergy between traffic lights in a small scale, and improve the traffic capacity of the total traffic road network efficiently.

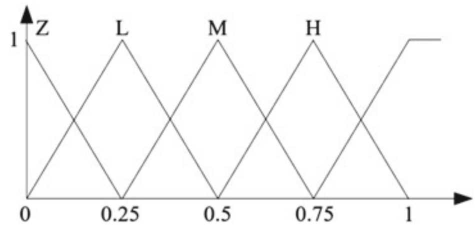

Fig. 4. Membership function for the phase of vehicle density

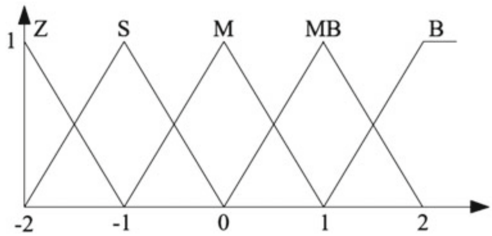

Fig. 5. Membership function for the reward

(2) Fuzzy database

In this section, we develop the fuzzy database as follows:

- If the traffic density of the phase at current intersection is M, at the same time, the approach density of traffic flows at joint intersection is L, then we can define the action reward is M;
- If the traffic density of the phase at current intersection is H, the approach density of traffic flows at joint intersection is Z at the same time, then the action reward is MB.

Thus with linguistic descriptions of traffic density as input, so the phase of vehicle density is determined by the fuzzy rules given in Table 1 described as:

$$\begin{aligned} &\text{If } CI \text{ is } TD_i \text{ and } JI \text{ is } TD_j, \text{ then } T_{\text{green}} \text{ is } r, \\ &(i, j = Z, L, M, H; r = Z, S, M, MB, B) \end{aligned} \tag{6}$$

where CI is the current intersection and its phase density TD_i, TD_j is the density approach from the joint intersection JI, r describes the green time to be extend or shrink. The fuzzy database is defined in Table 1

3 Experiments

In order to verify the validity and correctness of the traffic light control strategy. In this paper, the vehicle induction system (SVIS) is based on the shortest path

Table 1. Fuzzy database

Action reward		Corresponding intersection phase density			
		Z	L	M	H
Current intersection phase vehicle density	Z	Z	S	M	MB
	L	S	S	M	MB
	M	S	M	MB	MB
	H	M	MB	MB	B

algorithm. Simulation and experiment on the road network through the open-source software SUMO simulator, which is wrote by java, the road network is a part of the U.S. State of Vermont. In the formula about traffic light control strategy is based on Q-learning, we set α is 0.7, and γ is 0.9. The road network is shown in Fig. 6 (Table 2):

Table 2. Road network information

Attribute	Quantity
The number of traffic lights (3-way or 4-way intersection)	51
Number of road sections	206
Starting point	8
Terminal point	8
Departure speed (v/h)	1440
Total simulation time	15000

The data of the algorithm is evaluated in this experiment is:

(1) Count the quantity of vehicles in traffic system per 100 s;
(2) Count intersection vehicles average travel time in each phase.

Fig. 6. Road network

In SVIS, in traffic light control strategy based on Q-learning algorithm (QTGCS), light timing based on action information, and in the fixed-time green light control strategy (FTGCS), traffic light phase update based on fixed-time 50 s set by system. The evaluation data of SVIS and QTGCS were compared with the evaluation data obtained by SVIS and FTGCS. The quantity of vehicles in traffic system is shown in Fig. 7, and intersection vehicles average travel time in the lane is shown in Fig. 8 as follows:

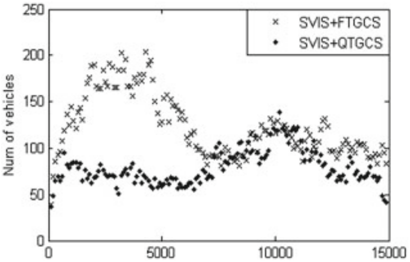

Fig. 7. The quantity of vehicles in traffic system

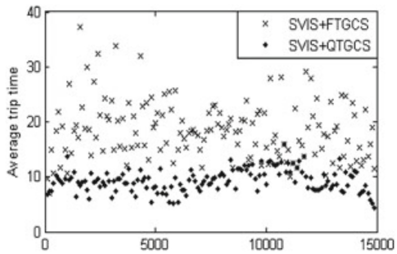

Fig. 8. Intersection vehicles average travel time in the lane

From Figs. 7 and 8, we can observe that the evaluation data obtained in SVIS and QTGCS collaboration is better than SVIS and FTGCS. The experimental results show that the FTGCS can improve the efficiency of traffic system and reduce vehicle travel time, compared with the traditional fixed-time strategy, based on the QTGCS can using real-time information of the road network, deploy green light of traffic light reasonably, and shorten vehicle travel time and delay time.

In SVIS, vehicle path selection based on induction information, and through the fuzzy logic control according to vehicles information to optimize timing scheme (FQTGCS), the light timing based on fuzzy optimize action. The evaluation data of SVIS and FQTGCS were compared with the evaluation data obtained by SVIS and QTGCS. The quantity of vehicles in traffic system is shown in Fig. 9, and vehicle average travel time in the lane is shown in Fig. 10:

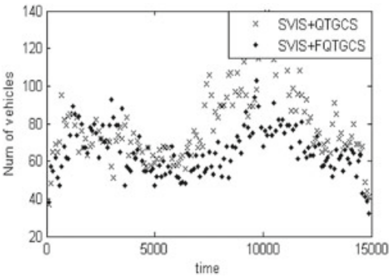

Fig. 9. The quantity of vehicles in traffic system

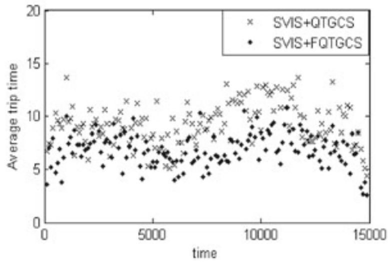

Fig. 10. Vehicle average travel time in the lane

From Figs. 9 and 10, we can observe that the evaluation data obtained the FQTGCS performance better than QTGCS. The experimental results show that the FQTGCS can improve the efficiency of traffic system and reduce vehicle travel time, compared with QTGCS. And the FQTGCS can using real-time information of the road network, deploy green light of traffic light reasonably, and shorten vehicle travel time and delay time.

4 Conclusion

In this paper, we formulated the traffic light timing strategy as a MDP problem, and applied Q-learning algorithm with Boltzmann based exploration strategy and fuzzy logic control strategy. A light learning agent will represent an intersection, where an agent can control the traffic light as much as road connected to the junction. The state will represent the congestion situation around the junction, it is seen from the traffic density of each phase in the intersection. And action represent which phase will get the green time to the light. Our algorithms are adaptive in nature and do not require road network model information, it can control traffic light in real-time by traffic information. Simulation results show that the performance of traffic system has been improved by the proposed traffic light timing strategy. In the current work, we only control traffic light with the information from joint junction without the light around. Thus, in the future, one could develop to coordinate the lights connected in a small area, and we intend to do our assumption in the future.

Abstract. Orderly and efficient operation of the network security innovation, and actively promote the coordination effect of innovation network, is the key to further promote the economic development, is also an important way to achieve an innovative country. Based on the connotation of the collaborative governance, run, and the network structure of governance logic thinking and further analysis of the preliminary exploration to construct the basic framework of innovation network collaborative governance, in order to solve the existing problems such as insufficient innovation network effects play.

Keywords: Collaborative innovation · Innovation network · Inter-subjective relationship · Collaborative governance

1 Introduction

With the development of the economy, the model of single enterprise innovation gradually evolved into cooperative innovation, further promoting the development of innovation network. Collaborative innovation is the key impetus to promote the development of economy, it is complicated innovate organization. Cooperating the innovation network is a process that main bodies take the flowing of knowledge as the carrier from communication, coordination and cooperation to collaborative [15]. Therefore, the external formal of collaborative innovation is the development of innovation network, to realize the collaborative innovation is the ultimate purpose to form the innovation network.

Through the various innovative elements (micro and macro elements) innovation network use different collaborative ways to achieve nonlinear interaction

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_148

and coupling, coming into being effective knowledge flowing and optimized allocation in the self-organizing mechanism, the coupling mechanism, the network drive mechanism and coordination mechanism, to produce the overall effect is greater than the sum of the parts. In innovation network resources knowledge and behavior characteristic of subjects have great difference. There often appears the phenomenon such as fuzzy relations and negative interaction in the operation of the network. Perrow [8] proposed in a tight and complex system, the complex and unpredictable interaction between non-standard parts (namely different standards or specifications or character of the individual) will bring disastrous threat. Some integrate both parts of the performance equation-process and productivity from collaboration [6,7]. Throughout the domestic and international related researches, these mostly focus on collaborative innovation performance, operating carrier (mainly is knowledge), running mechanism and the role of subjects. Although some scholars proposed to attaches great importance to the network of relationships and interactions between subjects, but not for an in-depth studying, and about the process of innovation network operation controlling and synergies playing is not enough. In order to achieve the goals of innovation network, orderly and efficient operation of network organizations is necessary. How complicated and challenging collaboration can be, even though it may be needed now more than ever [2]. So we need to do more. Collaborative governance can effectively guarantee the network relationship, benign interaction and effective synergy [21], more suitable for the process controlling of innovation network operation.

The general governance focuses on network governance in a single point, line or dimension, ignoring the design and planning of overall network governance. However, collaborative governance emphasizes the integration of the network structure, the relationship and interaction [29]. Finally, "synergy" includes multiple subjects participating and cooperating, and integrity, interactive and sustainability; "Governance" is aimed at the network nodes, the relationship of network and the overall network, also includes the control of the governance target and the mechanism. Therefore, collaborative governance can guarantee network efficient operating. In view of this, this research refers to the thought of collaborative governance and try to build collaborative governance framework in innovation network, to better solve the problems in the innovation network operation, providing a reference for the management and development of innovation network.

2 The Connotation of the Collaborative Governance and Implementation

2.1 The Connotation of the Collaborative Governance

Collaborative governance theory comes from the coupling of synergy theory and governance theory. The collaborative governance study has got much more attention and is still in hot with different points, including highlight government administration [13,28], the multi-agent participating, and the multi-level cooperation governance [17,22]. Recently, studying on politics and environment performance by collaborative governance has blossomed, which concluded that different corporation tensions came different effective [1,3,26]. The UN commission on global governance in 1995 stressed that collaborative governance is a continuous process of reconciling different conflicting stakeholders and taking united action [11]. Jin [16] analyzed the collaborative governance of sublimation, and pointed out that in the era of the Web2.0 collaborative governance focus on system innovation, emphasizing the public power in the participation in the reasonable allocation between subjects, to break the shackles of the traditional single center model, realize the development in governance. On the basis of previous studies, this paper argues that "collaborative governance" is the multiple stakeholders in the governance mechanism establish cooperation, and through the network members multilateral interacting and coordinating to solve conflicts, control of conflicts and build cooperation in the advantageous network environment, finally, to guarantee the orderly operation and realize the goal of innovation network.

2.2 Implementation of Collaborative Governance

A 'Collaborative governance' model should include mechanisms for contributing more systematically, consistently and transparently [23]. About mechanism, studies include trusting and sharing mechanism, interactive process controlling and innovation property allocation mechanism [20,27]. Zhang [33] put forward that the collaborative model emphasizes to the idea of collaboration as the dominant factor, advocated by the regulation and government guidance to construct multi-center collaborative governance system; stressed the microeconomic foundation building, and used cognitive guidance mechanism and the balance of interests distribution mechanism to fully implement the bodies' self-management and from two aspects of process and result to ensure synergy mechanism long-term operating. Deng et al. [14] considering with the whole network, discussed collaborative governance mechanisms and analyzed the interaction between these mechanisms. Han et al. [32] concluded that the governance of innovation network not only need to pay attention to the subjects' relationship, but also to the effective guidance and governance of the communication and interaction between subjects, to provide scientific and efficient operation, policy, economic and technical environment for enterprise collaborative innovation network. Based with the previous researches, this paper holds that the implementation of the collaborative governance supported and safeguarded by collaborative governance mechanism, through guiding and controlling the relationship between network nodes, the network interaction, coordination effect and the interaction of the three tries to achieve self-management and overall coordination effect optimization.

3 The Logical Framework of Innovation Network Collaborative Governance Based on Expending JM Model

The relationships, interaction and collaboration is namely the logic of collaborative governance. Johanson and Mattsson [18] put forward to the relationship and interaction model (JM model), it organically linked the coupling relationship between network nodes and their interaction behavior. Sun [24] extended JM model on this base. He thought the relationship and interaction also involves the logic of network governance, and further to expand JM model from the two-dimensional structure to three-dimensional structure which also included interactive results-the collaborative (governance performance). Extended JM model provides a new perspective for innovation network governance. For this, we need to define the connotation of relationships and interactions in innovation network, as well as the possible synergies.

3.1 The Relationships Between Network Node

Granovetter [12] stressed that in the market, there are Strong relationship (Strong Ties), Weak relationship (weak Ties) and Free trade (Arms-length Ties) three forms among subjects, the Strong relationship means the subjects are more passionate and interactive, have high-integrity, frequent-interaction resources exchange. However, weak relationship is on the contrary. The degree of embedding in actual innovation network (strength of relationship between different subjects) and the network density (the ratio between network nodes connection number and maximum connection number) can influence the flow of knowledge in network, thus influence on the effect of collaborative innovation [30]. Michelfelder and Kratzer [19] analyzed that strong relationship with embedded characteristics, deepen relations and strengthen interaction mainly through the necessary commitment and contract. On the one hand, commitment encourage special assets investment to curb opportunism behavior; through mutual understanding, on the other hand, as well as the basis of continuous interaction, to promote trust based on emotional and relationship regulation emergence, to enhance internal convergence. Fliervoet et al. [10] analyzed collaborative governance through social network and proved that the relatively high network density improves the potential for collective action and collaboration. Strong relationship emerging based on weak relationship, weak relationship make network maintain high independence and flexibility, thus easier to expand relations connecting.

Innovation network continuously evolve in such main aspects as knowledge creation, diffusion and use [9]. Essentially, it is a kind of social relation network. Network relying on knowledge demands to establish relationship is weak relationship, which mainly is interests-oriented to make the network operation. With the interaction is increasingly deep, the cooperation presents diversification, the role of subjects shows the dynamic and diverse. Finally, weak relationship evolves to strong relationship to achieve greater knowledge sharing. In terms of knowledge's acquisition and integration, strong relationship promotes tacit knowledge flowing, and weak relationship promotes explicit knowledge flowing. Low cost characteristics of weak ties can absorb new knowledge and resources more, but generally causing the low-stable dominant network, insufficient knowledge flowing. Strong ties guarantee stable network, the cooperation of high willingness and sufficient knowledge flowing, strong relationship. Of course, too much strong ties will restrict the development of the network and the spread of knowledge. For these, we need to have different priorities. For most of China's national high-tech industry base, the high density of innovation network, for example, should be properly promote weak relationship evolve to the strong relations, designing and building complete industry chain and technology chain, to achieve higher conversion rate and win-win among the members. Meanwhile, it should be paid attention to the weak relationship developing to obtain more knowledge, especially the heterogeneous knowledge. In this way, in innovation network weak relationship strengthen the heterogeneous knowledge acquisition, strong relationships improve the efficiency of knowledge sharing.

3.2 The Interaction in Network

Interaction is another important dimension to collaborate in innovation network. It is mainly reflected in knowledge sharing and learning, the rational resources' allocation and its optimization, and so on [4]. Knowledge sharing is one of the process of knowledge flows, knowledge flow efficiency directly affects the synergy of innovation network [25]. In innovation network, for the difference of knowledge quality and quantity among subjects, and the difference of division, the complementary of knowledge, there is the relationship between knowledge supply and demand. Interactions between the main body, causing continuous circulating knowledge in the network between different subjects, to accelerate the process of collaborative innovation. Knowledge flows is one of the most common form in innovation activities, also is important activities to bring value-added. Therefore, this article regards knowledge flows as interaction in innovation network. In addition to the knowledge sharing, the knowledge flows also include knowledge transfer and knowledge creation. At the early stage of the innovation network operation, knowledge sharing is given priority, namely heterogeneity knowledge exchange among the subjects, so as to realize sharing. Knowledge creation stage is important process of creating new knowledge. Knowledge flows create knowledge synergy, and bring greater knowledge advantage for the whole network.

Competition and cooperation are the two basic forms of interaction in social [31]. In network, the cooperative interaction produces synergy effect, encourages members to pursue common interests, and promotes the knowledge spread effectively in network; benign competition interaction creates a new combination of the knowledge and value, through mutual learning and using knowledge, to reduce opportunism; Malignant competition interaction, however, causes contradictions and conflicts. Finally, hinder the relations developing, further hinder the synergistic effect. The two former increase the degree of familiarity and understanding between subject, reduce the communication cost, and avoid information asymmetry, low knowledge matching degree and the bridging degree for unfamiliar subjects, especially in knowledge.

Interaction of collaborative governance logic stresses the main body of governance is not a single subject, but all the members in network. They work together to promote the development of the network. Based on stakeholder theory [5], multiple participation not only promotes interaction, but also control and guide malignant it. In this way, it deepens understanding and trust among subjects and improves the efficiency of knowledge and resources flowing. Such as regional economic competition forces the Yangtze river delta to seek deep interactions with surrounding areas and other economic belt, and according to the geographical relations and the level of economic set up different levels of city circles. At the same time, improving city circle cooperation interaction, and promoting the development of regional economy.

3.3 The Result of Relationship and Interaction-Collaboration

In the process of interaction, new weak relationship emerges, further to evaluate strong relationship. Similarly, the benign interaction generates positive synergy, and further to strengthen the relationship. The strong and the weak relationship between network nodes, the benign interaction and positive synergy is in favor of achieving the goal together. To be sure, because of the differences of resources and capabilities between subjects directly leads to the result of interactive complex and uncertain and the evolution of and relationship, the collaboration created by relationship and interaction is diversity, dynamism and directivity. The collective rationality of repeated game formed the positive collaboration improved by Pareto, which is the balance of the relationship and benign interaction can generate "social facilitation effect", and add knowledge value, optimize innovation network environment and realize the goal of innovation network. On the contrary, due to the unbalance relationship and vicious interaction, there comes negative synergy, and leads to "social-loafing". Those cause the failure of innovation network targets with the subjects' negative behavior, deceptive interaction, vices and low negative effects.

In innovation network, the demand of knowledge causes to produce relationship, relationship promotes interaction, interaction promotes synergy, in

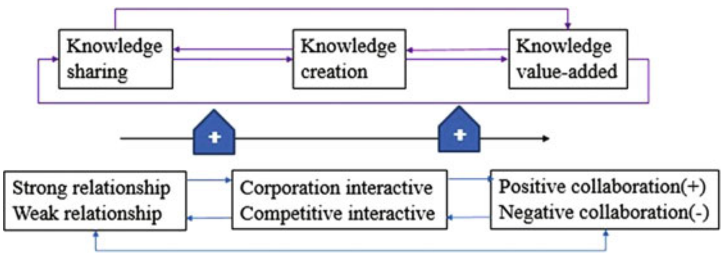

Fig. 1. The collaboration governance logical framework based on expending JM model

turn, synergy impels interaction and make organizational relationships deep. The whole process accelerates knowledge flow, promotes organizational power. Further, Organization network is strengthened. Those promote more subjects to participate in innovation, finally expanding the source of knowledge and the synergy beneficiary, also improving the efficiency of innovation network. New knowledge demands further to build new relationships and lead to a deeper interaction. It is a constant, circulating and spiral-rising process, as shown in Fig. 1, constituting a logic framework of innovation network collaborative governance.

4 Safeguard Mechanism of Collaborative Governance

The another key to success collaborative governance innovation network, is collaborative governance mechanism can forward drive relationship, interaction and coordination, ensure synchronous interaction and the orderly and efficient collaboration. as shown in Fig. 2, is the basic framework of innovation network collaborative governance.

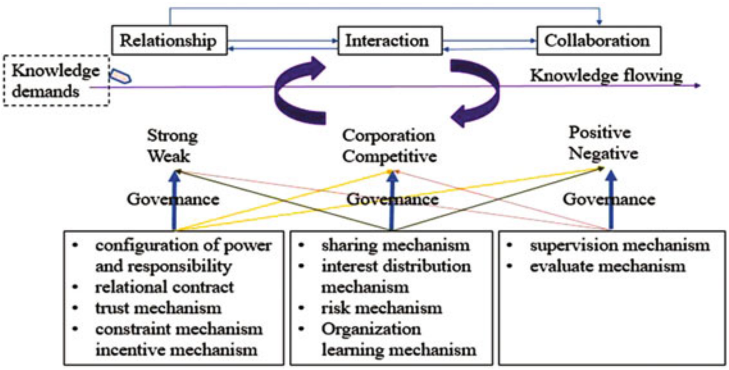

Fig. 2. The basic framework of innovation network collaborative governance

First, the configuration of power and responsibility, relational contract, the trust mechanism, constraint mechanism and incentive mechanism promote weak ties form, further to the strong relationship evolution, meanwhile, to control these two relationships, to make up the malpractice and the insufficiency, to take their advantages, to ensure maximum effect. Accrual configuration make the government, enterprises, universities, research institutes and intermediary service organizations these subjects fully play function advantages, fully coordinate. At the same time, overcome the limitations of self-regulation and government single coordination. Relational contract and trust mechanism prompt relationship formation and strengthen, so as to guarantee the stability of the network, to promote knowledge and resources fully flow and exploit. Among them, the relational contract can product weak relations, to maintain the network openness and the heterogeneity of knowledge, to develop the network value. Trust must be embedded network, could it exist. To product and strengthen the relationship can establish and strengthen trust; On the contrary, the trust is the necessary condition to build strong relationships. On the one hand, Constraint mechanism and incentive mechanism is in favor of reducing the cost of strong relationship, and the contradiction caused by complicated relationship, On the other hand, to encourage the network extension, improve network activity.

Second, establishing sharing mechanism for knowledge and other resources, interest distribution mechanism and risk mechanism to avoid opportunism. Being satisfied subjects with interests' needs, and promoting cooperation and benign interaction, promoting the knowledge's efficient flowing in the network. As well as principal partners in collaborative innovation network, subjects also is competitors, benefit disputes and conflicts among them will affect the overall effect of the collaborative governance. Meanwhile, their some characteristics can affect the formation and development of innovation network collaborative governance. As a result, interest distribution mechanism and risk mechanism reasonable guarantee interest allocation effective and fair. The conclusion of the agricultural model, when knowledge's gap is very big, strong party interaction's will is insufficient, combined with the weak absorption ability is limited, leading to a lower efficiency of interaction. Conversely, when the gap is small, the effective is better. Sharing mechanism which can reduce the knowledge's gap, and can avoid the information asymmetry. In the process of knowledge flows, involving the subjects learn and internalized knowledge. Therefore, organizational learning mechanism needs to further strengthen, to reduce the knowledge differences between subjects, so as to promote knowledge flow.

Third, through establishing supervision mechanism and evaluate mechanism, evaluating subjects' execution and the completion of target. Due to the diversification of innovation network, supervision mechanism is hard to effective operate. For effective supervising the whole process of collaborative governance, firstly, Institutionalized problems such as the organization's powers and the constitution and the profit distribution, and implement the innovation network. Increasing default cost and effectively reducing the coordination costs, to constraints subjects' behavior with institutional in collaborative governance. Second, strengthen moral construction, forming public opinion and supervision mechanism. Supervising subjects' behavior in the process of collaborative governance with moral. Through the evaluate mechanism to clear synergy governance effect, clear and control each problem source in every stage and every node.

Of course, the cooperative governance mechanism is not only for one link in the relationship, interaction and synergy, but on the whole process governance. Constraint mechanism, for example, can also constraint subjects' behavior in the collaborative governance, control interaction. Supervision mechanism and evaluating mechanism is also valid for each link and each movement. And the characteristic of innovation network and collaborative innovation represents the different phase characteristics, cooperative governance mechanism should also be adjusted. In the process of the collaborative governance, collaborative governance logic is the basis of collaborative governance, also is the junction between innovation network and collaborative governance. Collaboration governance mechanism is support and assurance of the collaborative governance. All of them mutually dependent and interacting, forming the prerequisite and guarantee of innovation network collaborative governance, driving the network orderly and efficiently operating, finally to achieve maximum synergy innovation effect.

5 Conclusion

This paper mainly discusses how to solve the problems in the operation of innovation network through cooperative governance, according to the extension of JM model further analysis of the collaborative governance logic, on this basis to analyze the innovation network of cooperative governance, and put forward the safeguard measures of innovation network collaborative governance, so as to support and guarantee for the operation of the collaborative governance, to promote innovation network synergy. Effective cooperative governance mechanism is able to efficiently governance the relationship, interaction and synergy in innovation network. Finally, to solve the relationship which is not clear and soured between the main body in innovation network, network is running off track, collaborative innovation is unsustainable, coordination is inefficient and so on. In the future, further research on collaborative governance mechanism and the strength of the control network relations, and the definition and controlling for the relationship intensity in governance model etc.

Abstract. Chinese housing market is rapidly growing up. However, the study on housing market regulation is inadequate. In this paper, housing price indexes from 2006 to the present are analyzed based on the ARIMA model and intervention analysis, and the change of this index can reflect the effective date and valid date of country's housing price regulation policy. This paper established systematically the quantitative analysis model, studied the timing effects of new regulations, and improved the quality of the house price index by using the monthly data. Based on the model results, we evaluated the performance of the regulation policy of housing price on three criteria including anticipation, conductivity and additivity. This can provide the field evidence for policy makers to design better housing policy.

Keywords: ARIMA model · Intervention analysis · Quantitative analysis · Housing price regulation policy · Performance evaluation

1 Introduction

Since the 30 years of reform and opening up, China's real estate industry gradually changed from the planned economy system to market economic system, and real estate and related industries have been the most important industry in China's regional social economy and played an important role in the national macroeconomic development. However, along with the gradual progress of the marketization process of the housing market, we are facing some unexpected

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_149

negative effects of China's housing market including high housing prices and low housing affordability, housing prices increased too fast, the fever of land speculation. These negative effects demonstrated that the housing market operation mechanism has some limits. The direct consequence is that houses have become unaffordable for the low-income groups being not satisfied and housing structure becoming unbalanced.

To solve the current problems in China's housing market, the government introduced a series of monetary policy and fiscal policy. The policy makers tried to change the performances of banks and real estate developers in the market and cool the overheated housing market by standardizing housing market laws and regulations. Especially after 2008, the rapidly rising housing price has become the focus of public opinion, how to keep housing price away from rapid increases has become a vital problem which the government needs to solve urgently. Under this background, a series of price regulation policy were introduced at the historic moment.

Since 2005, housing price regulation policy which issued by Chinese government can be roughly divided into two categories: First, policy instruments are design to suppress housing prices, such as issuing purchase orders, increasing bank interest rates, raising housing taxes, raising the down-payment ratio of real estate and so on. Second, policy instruments are design to stimulate the housing prices, such as: tax reductions, lower down-payments, lower interest rates, and so on.

Since 2005, little evidence has been found in the efficiency of the existing housing policy. As the housing market policy failure in 2005, China's housing market continued to deteriorate and housing prices in many cities increased sharply in 2006. From 2005 to 2007, the national housing policy focused on increasing bank interest rates and raising tax rates. For example, in May 2006, the State Administration of Taxation issued a notice on strengthening housing business tax levy management. This new tax regulation required that after June 1st, individuals housing purchased less than 5 years shall paid the business taxes at the full rate; In 2007, the People's bank of China increased interest rates by 6 times and the deposit reserve rate by 10 times, it is still failed to control rapid increased property prices.

In 2008, to cope with the financial crisis, the Chinese government decided to stimulate China's housing market rather than suppress it. Therefore, the government launched a series of new policy to stimulate housing prices. These new policies included the temporary exemption of stamp duty on personal sales or purchase housing; the temporary exemption of land value-added tax on personal sales housing; local government can introduce their own policies to encourage housing consumption tax relief and so on. In 2009, the housing price regulation policy was mainly on the inheritance, strengthening and deepening of 2008 real estate regulation policy, while highlighting the focus of strengthening the housing security. Therefore, the early 2009 housing price regulation policy mainly includes several aspects like tax, financial market and housing security. In 2009, while most of the industry was facing a financial crisis, China's real estate industry had achieved a substantial development. However, these stimulation policies since 2008 left a hidden danger to the subsequent regulation. After 2010, the government began to realize that the real estate market may be out of control, so it was very difficult to curb its rising momentum again. In theory, if a series of policies issued by the government can be effective, China's housing prices may change to the expected direction as the policy makers' design. However, policy effects are not obvious in the China's housing market performance.

In this paper, by using the ARIMA model and intervention analysis, we analyze the effectiveness of price regulation in China. So researchers and policy makers can understand the critical issues in China's housing policies including the effectiveness, failure, superposition and neutralization of housing policies. In general, this study can provide policy recommendations for the design of a more effective housing price regulation.

This paper has been organized in the following way. Section 2 begins by laying out the theoretical dimensions of the ARIMA models and previous research in this field, and looks at how ARIMA models can be applied in the China's housing policy research. In Sect. 3, we conduct the empirical model by exploring the ARIMA model and establishing the intervention analysis model to see the results of the housing price regulation. In Sect. 4, we applied the ARIMA model and intervention analysis into China' housing market. Section 5 presents the findings of the research, focusing on the three key themes including the effectiveness of policy, the validity of policy, the neutralization and superposition of policy. In Sect. 6, we present the conclusions about the effectiveness of policies, the validity of housing policies and the superposition between the policies.

2 Literature Review

There are very rich economic research results about national regulation policy effect on housing prices. The existing studies mainly focus on four aspects:

First, it is the analysis of several factors affecting the housing prices to discuss the effect of regulation policies, Such as Wang and Chen [14] in Wuhan City as an example, the author thought that four indicators: sales accounted for below 90 square meters, the new supply area, the money supply (M2), the lending rate, put a significant impact on Wuhan housing prices. This study focuses on the qualitative analysis of the regulatory policy and its effect, but it is lack of accurate interpretation to the effect of regulation policy.

Second, it is the single regulation policy effects on the real estate prices, for example, monetary policy, land policy and tax policy. Nie and Liu [11] thought that China's monetary policy can affect real estate prices, and the money supply was more significant than the interest rate policy regulation function by analyzing the monetary policy from 2005 to 1994. At present, most of the domestic literatures focus on qualitative analysis to study the effect of the policy on the regulation of real estate market, and most research results show that monetary policy has a significant impact on housing prices. This study did not consider the regulation effects of a number of policies under the joint action comprehensively, and be lack of a comprehensive research on overall coordination and interaction.

Third, it is to use a social science or econometric model to analyze, such as Wu [17] based on PSR model to establish housing price regulation policy effectiveness evaluation system, after the solution of pressure, state and response index weight system, through the analysis of the relationship between the three indexes, found that housing price regulation policies in recent years in 2005–2006, and 2011–2012 were relatively effective, proposed when country introduced a more severe structural adjustment policy can make effective control on housing prices.

Fourth, researchers are interesting in evaluating the policy performance. Chen and Fang [3] explored VECM and DSGE model and found that policies on restricting house purchase are mainly directed at speculative demands so that they are suitable for house price control of first-tier cities, while the down payment ratio policy on mortgage is directed at rigid demands and they are fit for non-first-tier cities. Chen W [2] applied a multiple-factor panel data model to show that a high degree of market failure is associated with a high ratio of persistent components in the gap between price and equilibrium. Chen found the housing policies did improve the housing market's efficiency. Feng and Wu [8] studied whether there is an asset bubble in China's residential housing market by using a an equilibrium asset-pricing approach. They did not found the existence of a house price bubble at the national level.

Fifth, non-economic factors such as education showed more impacts on housing prices. Agarwal et al. [1] studied the relation between school allocation rules and housing prices in Singapore by using a quasi-experiment. They found that private housing prices within 1-km zone and in 1-km to 2-km zone from the old school zone decline by 2.9% and 6.0%, respectively, 6 months before the school relocation events. Feng and Lu [7] studied if school quality will affect housing prices in Sanghai, China. They found that a good school may increase housing prices by 17.1%. Wen et al. [15] reported the similar results by using the data from Hangzhou, China. The found that elementary and junior high schools have a significant effect on local housing prices. Furthermore, they reported that the housing price increases by 2.737% or 0.904% when the house is located less than 1 Km from the high school or college.

ARIMA has been an effective approach in the housing market study. Woo and Sung-Suk [16] found ARIMA is a useful in exploring the relation between housing prices and interest rates. Previous studies used logistic model [5,10], GARCH model [4,21], canonical correlation analysis and other methods to analyze the regulation effect of comprehensive policy, mainly through analyzing the change of housing prices, land prices and other major indicators to judge the effectiveness of regulation policy and evaluate the regulation effect of comprehensive policy. Although the research analyzed the overall effect of the real estate regulation policy, there was no analysis of the mutual influence between different time point and type policies.

In recent years, there is a growing research interest from the management science field. In the agent theory, Zhang et al. [19] studied Beijing's housing market by using a multi-agent model. Ge [9] applied another agent model in American housing market. Neural Networks are another popular approach. Lim et al. [13] applied Neural Networks in housing prices predications. Other studies included index theories [6,12,18,20].

In summary, the current study mainly focused on the qualitative study of single and comprehensive regulation policy effect, and there is less literature to use quantitative analysis method to study the regulation policies the superposition and neutralizing effect between regulation policies. Therefore, this article adopts the monthly price indexes between January 2006 and February 2015 to establish housing price regulation policy effectiveness evaluation system based on the ARIMA model and intervention analysis model. Furthermore, this study analyzes the influence of policy factors on the real estate prices empirically. According to the results of the model, we conducted a quantitative performance evaluation on house price regulation policy by years. The quantitative study focuses on three key themes including analyzing the anticipation, conductivity of housing price regulation policy implementation effect in recent years, as well as the mutual influence between different time point housing price regulation policy implementation effect, their hedge and superposition, and reasonable predictions of the effects of policies. These results can provide a scientific basis for the formulation of the new regulation policies.

3 Theoretical Basis

3.1 ARIMA Model

The basic idea of the ARIMA model is to regard the data sequence as a random sequence which is formed by the time lapse of the forecast object, which uses a certain mathematical model to describe the sequence. Once recognized, the model can predict the future value from the past and present value of the time series. The ARlMA model in economic forecasting process not only takes into account the dependence of economic phenomenon in the time series, but also considers the interference of the stochastic volatility, which has a higher accurate rate to forecast the economic operation of short-term trend and is one of the widely used methods. Because the economic data is often autocorrelation and non-stationary time series, and the ARIMA model can effectively deal with autocorrelation and non-stationary data, while the ARIMA model is stable that can effectively combine with the intervention model, the ARIMA model is used to predict the housing price index of our country.

Between January 2006 and February 2015, the monthly housing price index can be seen as a random time series which is formed over time. By analyzing the randomness, stationary and seasonal factors of the housing price index of this time series, using ARIMA mathematical model to describe the correlation or dependence between the values of these single month housing price index. Thus taking advantage of the past and present housing price index to predict the future index, it can achieve the purpose of predicting the influence of housing price regulation policy on the future price.

3.2 Intervention Analysis

Time series are often influenced by special events and situations such as external interventions. Intervention refers to the stand or fall of forecasting model fitting degree, that is the pros or cons of fitting degree between the simulated value generated by the prediction model and the historical actual value.

(1) Intervention variables' form

The basic variables of intervention analysis model are intervening variables. There are two kinds of common interference variables: the first is the sustainable intervening variables, which indicates that there have been affected when T moment happened, then the step function representation can be used; the second is transient interference variables, which expresses that it can been affected just for the moment when it occurs at a certain moment, using unit impulse function. This article not only studied the regulation effect of housing policy at a certain time, but also analyzed the impact of these policies on the future housing prices, so we chose the first kind of intervention variables' form, as Eq. (1):

$$S_t^T = \begin{cases} 0, \text{before intervention events } (t < T) \\ 1, \text{after intervention events } (t < T). \end{cases} \tag{1}$$

(2) Intervention events' form

In the process of policy implementation, the intervention events may have an impact on the regulation effect. The influence of this kind of intervention events may suddenly start, and last for a long time. Set intervention's influence on the dependent variable being fixed, starting from a time T, but the extent of impact is unknown, that is, the size of the dependent variable is unknown. The intervention model of this effect can be written as in Eq. (2):

$$Z_t = \omega S_t^T \tag{2}$$

It is the unknown parameter of the intervention impact strength. While the rough stability series can be into stationary series by differencing, the intervention model can be adjusted in Eq. (3):

$$(1 - B)Z_t = \omega S_t^T, \tag{3}$$

where: B is a backward shift operator. If the intervention event has to lag a number of periods before impact, such as b periods, then the intervention model can be further adjusted in Eq. (4):

$$Z_t = \omega B^b S_t^T \tag{4}$$

where: $S_t^T = 1$,

$$Z_t(1 - \delta B) = \omega, \tag{5}$$

$$Z_t - Z_{t-1}\delta = \omega. \tag{6}$$

By deformation

$$Z_t = \frac{\omega}{1 - \delta B}, \tag{7}$$

where, B is a backward shift operator. According to the forecast results, if the fit of the forecasting model is higher, and the forecast value is also in line with the actual situation, then the prediction model has a certain application value. On the contrary, the prediction model is invalid. So on the basis of the ARIMA model, it is necessary to carry out the intervention analysis. The purpose of our intervention analysis is to assess the specific impact of the other policy intervention or emergency on the economic environment and economic process by using the quantitative analysis.

4 Empirical Study

4.1 Evaluation Index Selection

This paper investigates how the housing market response to the change of the housing price regulation. Thus housing price index is the most direct indicators to reflect the housing price changes. Housing price index is the advantage of "homogeneous", which can exclude the price fluctuations which due to market supply and demand relations and other reasons after the effect of these factors: housing quality, construction structure, geographical location and others. The monthly housing price indexes of 2006 to 2010 can be achieved in the iFinD software directly, while the 2011 to February 2015 index can be calculated by averaging monthly housing price indexes of 70 large and medium-sized cities nationwide. Thus the random time series of housing price index is obtained.

4.2 Evaluation Index Structure

(1) Establishing a single variable ARIMA model

The following figure is a China commodity house actual price index time curve graph (sampling frequency is once a month) from January 2006 to February 2015. It is sharply higher in 2007, 2010 and 2014, and housing price index fell to trough in 2008 (Fig. 1).

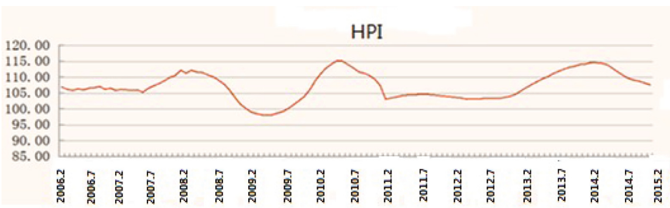

Fig. 1. Real estate price index

Observing the housing price index time curve in Fig. 1, we find that the data is not stable and contain a clear trend. Data is changed into a stationary random sequence by first order difference, as shown in Fig. 2:

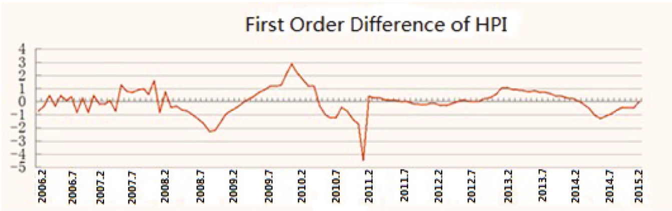

Fig. 2. Sales price index after first - order difference

After the normalization of the original data and repeated recognition of ARIMA model, we determine $p = 1$, $d = 1$, $q = 1$. Carrying out parameter estimation for ARIMA (1, 1, 1) model, we establish the univariate ARIMA model:

$X_t = 0.0190 + 0.8370X_{t-1} + \varepsilon_t 0.2787\varepsilon_{t-1}$, X_t is difference, ε is residuals.

Predicting the residual, the residual series time curve of the model is not a trend term, similar to random white noise, so it pass the model test (Fig. 3).

(2) Establishing intervention analysis model

We use the ARIMA (1, 1, 1) model to take extrapolating forecast for housing price index from January 2006 to February 2015, then use the actual value to minus the predicted value, the difference from which is the impact utility generated by macroeconomic regulation policy, remember to Z_t.

According to the form of selected intervention events, instability can be into a stationary series by differencing, and using housing price index from 2006 January to 2015 February, ARIMA predictive value and economic policy conflict utility, we can estimate the parameter of intervention model (Fig. 4).

By regression in Eq. (8),

$$Z_t = 0.8357Z_{t-1} - 0.0044, \tag{8}$$

where, Z_t is the difference between the actual values and predicted values. Namely in Eq. (9),

$$Z_t = \frac{0.0044}{1 - 0.8357B}. \tag{9}$$

Through the t-test of the regression value of δ, it is found that the estimated parameter δ is significant. So after the intervention analysis, the ARIMA model is in Eq. (10):

$$X_t = 0.0190 + 0.8370X_{t-1} + \varepsilon_t - 0.2787\varepsilon_{t-1} - \frac{0.0044}{1 - 0.8357B}. \tag{10}$$

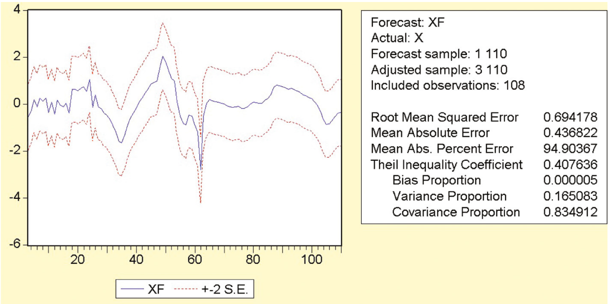

Fig. 3. Model testing

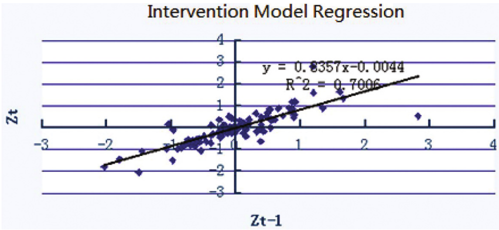

Fig. 4. Residual regression model

5 Results and Analysis

The study shows that the government's housing price regulation policy is not always effective, even if it is a utility policy, it may not take effect in time. We also found that the different policies will affect each other. The following paragraphs will analyze the effectiveness of policy, the validity of policy and the superposition between the policies.

5.1 Effectiveness of Policy

By analyzing the housing price regulation policy since 2006, we can find that there are three main kinds of policies which have a timely effect. First is involved in the adjustment of the relevant taxes. Such as in May 2006, the state promulgated the country of six, and the State Administration of Taxation issued the notice of the relevant issues on strengthening the management of housing business tax collection. This policy promulgation is St2. Taking it into validity test, we can see that the next month policy effectiveness is significant, which indicates that China's commercial housing price index has made the reflection in that month.

Second is to adjust the bank loan interest rate and the first loan ratio. In September 2006, the people's bank of China issued a notice on strengthening the management of the commercial real estate credit, which clearly stipulates that the loans down payment ratio of the second set housing shall not be less than 40%, lending rates may not be lower than 1.1 times of the benchmark interest rate which announced by people's Bank of China over same period and grade, and the proportion of the loans down payment and interest rates will be significantly improved with the increase of volume, the purpose of which is to regulate trade order and rectify the real estate market.

Third is about to investigate and punish the violations of law and discipline and the ownership disputes. However, the policy which can take effect immediately is still relatively less, and most of the policies are lagging, such as the state issued the regulations to strengthen land supply regulation and shorten the period of land development in October 2007, and in the same month, property tax "idling" ten spread to 10 cities. Housing price index began to make the corresponding reflection in December.

5.2 Validity of Policy

Among these housing price regulation policies since 2006, raising lending rates, introducing second-hand housing business tax policies, regulating loans down payment ratio on second homes and other relevant policies played a profound influence on housing price regulation, which has a long period of validity in a period of time after the introduction of the policies. Such as in April 2006.

Interest rates on deposits and loans were raised eight times by the people's bank of China, mortgage interest rates were up-regulated again regulation staged a comeback, the implementation of this policy had an indirect influence on the real estate prices, which continued to 2008; In September 2007, the central bank regulated that as a family unit, the loans down payment on second homes shall not be less than 40%, the interest rate shall not be less than 1.1 times of the benchmark interest rate, cracking down on speculation, which had played a certain influence on price regulation in later three years.

The property market regulation "new country of five" was introduced in the state council executive meeting, which reiterated its adherence to the implementation of the regulation policy which took the purchase limit and credit limit as the core, resolutely crack down on speculative investment, urged all localities to publish the annual housing price regulation targets. "New country of five" also stipulates that tax was levied on personal income of 20% in second-hand housing transaction. This provision would discourage investment demand and affects the volume, which is a positive effect for the real estate regulation, brought inhibitory effect on the residents' improved housing demand. The implementation of these policies had a long-term impact on the housing price regulation in China. And the introduction of the new policy in the recent two or three years, due to the implementation time is not longer, we can't see whether it has a long term.

5.3 Neutralization and Superposition of Policy

In the process of housing price regulation, in the face of different reflection of the market, the later policies released by government will cause a certain influence to the previous policies. This influence is two-sided, either playing a strengthening effect on the previous policies, call superposition effect; or having a conflict to previous policies, call neutralizing effect.

In July 2009, in order to strengthen the supervision of credit funds, banking regulatory bureau released “Interim Measures for the administration of fixed assets loans” and “guidelines for project financing”, to ensure that the fixed assets loan fund is truly used for the needs of the real economy, to prevent diversion of loans, and prevent the bank risk under the trend of rapid loan growth. In the next month of document issuance, the market did not make obvious reflection. We set this policy issuance as St23. In December, the State Council discussed and passed “opinions on the trial of the social insurance fund budget”. The views decided to make the period of the personal housing transfer business tax exemption from 2 years be back to five years. And five ministries and commissions such as the Ministry of finance, Ministry of land and resources, the central bank, the supervision published “notice on the further strengthening the management of land transfer revenue and expenditure”, improving the land developer down-payment. We se this policy as St25.

As you can see, after the promulgation of ST23, St25 began to change significantly, indicating that the market began to be sensitive to the policy enacted in July that year, that is, St25 had a superposition effect on St23.

However, in September 2010, with the introduction of the policy that the national commercial banks suspended issuing residents and families to buy the third and above housing loans (St27), the significance of the impact of the policy enacted in July 2009 (St23) on the market disappeared, which shows that the two policies have a neutralization. As shown in Fig. 5, the asterisk represents a significant effect.

Fig. 5. Policy impact

6 Conclusion

This paper quantitatively analyzes the effectiveness of housing price regulation policy. Empirical analysis results show that mostly policies do not began to take effect in that month, and the policy regulation effect is much poorer in the second half of 2007, the first half of 2008, 2009 and 2012. The effective time of different policy is also different, where the policies have a certain impact on the next two years housing prices in September 2007 and February 2013. Policies launched by government may have overlapping or effect neutralization. These policies are international.

Using ARIMA model and intervention analysis to analyze the effect of the policy intervention, predicting the effect of this policy, the effect of superposition or neutralize is analyzed by linking the policy and previous policy. It will provide reference for the relevant functional departments to formulate effective housing price regulation, so that the policies have been introduced together to achieve the best regulation effect.

Abstract. The paper uses the air pollution data of Mianyang, a city in Sichuan Province, and the death data of its urban and rural residents from 2008 to 2014 to investigate the relationship between air pollution and human mortality. SPSS19.0 is utilized to conduct a descriptive analysis of the correlation between the principal air pollutants (including PM_{10}, NO_2, SO_2) and the mortality (including gender, age, education, respiratory diseases, non-respiratory diseases, and chronic obstructive pulmonary diseases). Hence, the paper shows to what extent air pollution affects the mortality rate of the people in Mianyang, thereby further evaluating the influence of air pollution on the health of the residents. The results indicate that the rising trend of air pollution is consistent with the expansion of industrial production. The paper estimates that the mortality rate is correlated to air pollution during the normal development of society. The government should emphasize air pollution control and take measures to reduce air pollution, so as to improve the quality of life of urban and rural residents and to reduce the mortality caused by air pollution directly or indirectly.

Keywords: Air pollution · Mortality · Descriptive analysis

1 Introduction

Haze related pollution have been proved to be the reason for lung cancers and some other diseases and also have serious impact on and threatening future health consequences across the country [9]. Numerous Chinese and foreign studies have shown that PM_{10} and gaseous pollutants, such as sulfur dioxide (SO_2) and nitrogen dioxide (NO_2), have a significantly negative impact on human

J. Xu et al. (eds.), *Proceedings of the Eleventh International Conference on Management Science and Engineering Management*, Lecture Notes on Multidisciplinary Industrial Engineering, DOI 10.1007/978-3-319-59280-0_150

health. Moreover, a positive correlation between mortality and air pollution has been demonstrated in multiple researches [1,4,8,16]. The 2002 WHO report estimated that the global urban air pollution caused at least 1 million deaths per year and 7.4 million disability-adjusted life years (DALY) [3].

China is one of the countries with severe environmental problems. The concentration of particulate air pollution is far beyond the developed countries in Europe and North America. In the past 30 years, the economy and industry had been developing continuously. The rapid growth of energy consumption has aggravated air pollution, which becomes one of the major risk factors for damaging human health. The irrationality of the energy structure is that coal accounts for nearly 70% of the total energy consumption in China. The PM and gaseous pollutants emitted from coal combustion are the main sources of air pollution. The cities in China face severe air pollution, and the PM10 is much higher than the 20 $\mu g/m^3$ (annual average) and 50 $\mu g/m^3$ (24 h average)–the air quality standards recommended by the WHO.

Mianyang City, which is located in Southwest China, is the second largest city in Sichuan Province in terms of economic output. It has a dry climate and is densely populated. The agriculture, industry, and service (transportation) are well-developed there with a ratio of 15.3: 50.5: 34.2, indicating that the industry represents half of the economic output. Therefore, it is of significance to examine the impacts of air pollution on human health. In order to study the impact of air pollution on the mortality rate of urban and rural residents in Mianyang, the paper conducts a descriptive analysis, investigating the correlation between the principal air pollution data (including PM_{10}, NO_2, SO_2) and the human mortality.

2 Data and Methods

Mianyang City, the main terrain of which is of hills, is located in the northwest of the Sichuan Basin. It has a subtropical humid monsoon climate. Due to the influence of the northerly air flow, Mianyang is dry and cold, with less rainfall during the winter half year; however, controlled by the southerly air flow in the summer half year, it is hot, rainy, and humid. The household population of Mianyang was 5.488 million by the end of 2015.

The data used in this paper include mortality data and air pollution data from 2008 to 2014.

Mortality data: All deaths from 2008 to 2014 are gathered from the Mianyang municipal government. The paper clarifies the diseases into two groups according to WHO International Classification of Diseases (ICD-10): deaths caused by respiratory diseases (J00∼J98) and deaths caused by other diseases (or non-respiratory diseases). It, then, conducts an individual analysis of the chronic obstructive pulmonary disease (COPD). The human mortality data are classified into the following categories: sex-specific mortality, age-specific mortality, education-specific mortality, and mortality caused by respiratory and non-respiratory diseases (the chronic obstructive pulmonary disease is singled out).

Principal air pollution data: The annual average concentration of PM_{10}, NO_2, SO_2 from 2008 to 2014 are provided by the Mianyang Environmental Protection Bureau.

Methods: SPSS19.0 is utilized to conduct a descriptive analysis of the air pollution data of Mianyang and the mortality of its urban and rural residents from 2008 to 2014.

3 Results

3.1 A Descriptive Analysis of Air Pollution and Death Data

The statistical data of air pollution and death in Mianyang from 2008 to 2014 are shown in Tables 1, 2, and 3. The annual average PM_{10} of Mianyang from 2008 to 2014 was 0.059 mg/m^3, and the peak value was 0.082 mg/m^3 in 2008. The annual average SO_2 concentration was 0.015 mg/m^3, and the peak value was 0.029 mg/m^3 in 2009. The annual average NO_2 concentration was 0.019 mg/m^3, and the peak value was 0.039 mg/m^3 in 2009. The average death toll of men and women in Mianyang was 14,140 and 9061, respectively from 2008 to 2014. The average death toll of people with unknown education was 2098, illiterate or semi-illiterate 7404, primary education 10354, secondary education 2963, university and above 298. The average deaths were 2353 for people aging under 44, 6032 for residents from 45 to 64, and 14818 for those ageing over 65. The average deaths caused by respiratory diseases and non-respiratory diseases were 6663 and 16541, respectively. The average deaths caused by chronic obstructive pulmonary diseases were 767.

It can be seen from Table 1 and the corresponding line graph that the Mianyang air pollution generally showed a declining trend from 2008 to 2014. PM_{10}, SO_2 and NO_2 reached their peak from 2008 to 2009. Then, PM_{10} showed a downward trend till 2014. SO_2 and NO_2 declined moderately from 2009 to 2012. After that, SO_2 showed an upward trend from 2012 to 2014, while NO_2 fluctuated repeatedly between 2012 and 2014.

The paper will discuss, from three aspects, why the overall trend of air pollution in Mianyang declined from 2008 to 2014, even though it fluctuated sometimes during this period.

(1) The peak of air pollution between 2008 and 2009 was caused by the 2008 Wenchuan earthquake. The research shows that due to the earthquake, the collapsed buildings, the leakage of toxic gases and radioactive materials lead to the aggravation of air pollution [2]. Because of the great magnitude and severe damage of the 2008 Wenchuan earthquake, Mianyang, located in Longmenshan earthquake zone, was affected by the aftershocks. This earthquake caused heavy casualties and severe property losses, and Mianyang became one of the hardest hit areas. The urban and rural housing, collapsed or damaged, reached 6,284,011and 58,441,355, respectively. In addition, 47% of the industrial enterprises in Mianyang were affected, with 74% of plant damages. Thus, the collapse

and damage of residential buildings and industrial plants caused by the earthquake, to a certain extent, lead to an increase in airborne dust particles and toxic gas content, and exacerbate air pollution, thereby resulting in the Mianyang air pollution peak between 2008 and 2009.

(2) During the restoration and reconstruction process starting from June, 2008, due to the industrial and agricultural losses and the impacts of the earthquake, the local workers tended to find employment outside Mianyang, whereas the enthusiasm of the non-local job seekers, especially skilled workers and high-tech talents, were seriously affected in a certain period of time. Second, because of the severe capital losses caused by the damages to the plants and the equipment, some enterprises need relocation and reconstruction, increasing the costs and slowing down the process of the industrial and agricultural recovery in Mianyang. Moreover, most of the enterprises need a longer recovery period, since the major coal companies stop production due to the disaster; other kinds of electricity supplies are affected; and the main roads and power facilities are severely damaged [7]. During the recovery period, because of the less industrial and agricultural emissions caused by the decreased productivity of the enterprises, and less traffic pollution emissions, the air pollution generally showed a downward trend from 2009 to 2012. After a 3–4 year of recovery, the overall industrial and agricultural industries were recovered in 2012, and the infrastructure was gradually improved, resulting in a rise in air pollution.

(3) The reasons why the air pollution in Mianyang showed a decreasing trend between 2013 and 2014 are twofold. First, according to Sichuan Air Pollution Prevention and Control, compared to 2012, the annual average concentration of PM_{10} should decrease by 10%. Mianyang, as one of the key cities in Sichuan Province, takes strict emission reduction measures to control the coal-fired elevated-source, industrial point source, urban non-point source, and moving source (vehicle pollution), through strict assessment and accountability. Therefore, air pollution emissions are reduced from a number of sources. Second, because of the overall improvement in the environmental awareness of the Mianyang residents, the development of tourism, the promotion of energy conservation, as well as green travel, air pollution emissions are reduced.

Table 1. Air pollution in Mianyang from 2008 to 2014

Year	PM_{10} (mg/m^3)	SO_2 (mg/m^3)	NO_2 (mg/m^3)
2008	0.082	0.015	0.038
2009	0.081	0.029	0.039
2010	0.05	0.021	0.02
2011	0.041	0.016	0.015
2012	0.051	0.001	0.003
2013	0.071	0.009	0.02
2014	0.035	0.012	0.0009

Table 2. The Death Toll in Mianyang from 2008 to 2014

Year/ death toll	Total population of Mianyang	Male death toll	Female death toll	Unknown degree of education death toll	Illiterate/ semi-literate death	Elementary school education death	Middle school education death	University and above education death
2008	5407100	10360	6504	1867	6912	5245	2569	271
2009	5446500	10557	6698	2047	6781	5620	2625	280

3.2 Description of the Relationship Between Air Pollution and Human Mortality in Mianyang from 2008 to 2014

(Note: In order to better reflect the relationship between air pollution and human mortality, the paper uses air pollution values * % to compare with the mortality rate.)

Figure 1 illustrates that the PM_{10} fluctuated between 2008 and 2014. The peak between 2008 and 2009 is partly because the collapsed buildings, the leakage of toxic gases and radioactive materials, due to the Wenchuan earthquake, aggravated air pollution. PM_{10}, SO_2, and NO_2 rose steadily since 2010, during which the male and female mortality showed the same trend. Specially, the male mortality rate increased greatly, indicating that men are more sensitive to the change in air pollution concentration. Under the impacts of the national policies and local laws and regulations, the air pollution concentration has decreased since 2013. However, there is a greater increase in the mortality rate, which contradicts the conclusion. By searching information and literature, the paper finds that Mianyang faced a severe aging problem from 2012 to 2014. More precisely, Mianyang has a large aged population which grows fast. By the end of 2013, the residents aged 60 and above reached 1,07 million, accounting for 19.8% of the total population, and the individuals who die of old age were 22,939 in 2014. Therefore, the 2013–2014 mortality rate is influenced by the aging population [10,14]. Because of the changes in the social demographic structure, the impact of air pollution on human death is reduced.

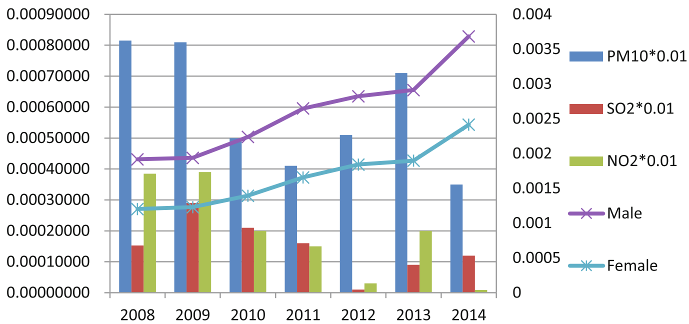

Fig. 1. The relationship between air pollution and gender-specific mortality

Obviously, it can be seen from Fig. 2 that there was a dramatic change in the death rate of residents with primary and secondary education. The reason is because the Mianyang Statistic Bureau changed the classification standard of the education-specific human mortality. That is, people with unknown education, illiterate or semi-illiterate, primary, secondary education, and university and above is changed into junior high and below, technical secondary education, high schools, technical schools, universities and colleges. Hence, between 2013 and 2014, the dramatic changes in human mortality were due to the classification criteria of the Mianyang Statistic Bureau, which was not related to air pollution.

The mortality rate of people with primary school education, illiterate or semi-literate, grew steadily from 2008 to 2013, whereas that of residents with secondary education, university and above showed a stable trend, maintaining the same level. It indicates those in terms of the same air pollution level, the higher the education level, the stronger the awareness of environmental protection. Therefore, these residents tend to take preventive measures more timely and effectively when exposed to air pollution, and they are less affected [5,11]. The impact of air pollution on human death is positively correlated with the educational level of the residents. The more serious the air pollution is, the higher the mortality rate is. However, due to the differences in people's education level, the awareness of air pollution prevention varies considerably. The people with the lower education level may have the lower residents' awareness of air pollution prevention, which results in a higher chance of being affected by the air pollution.

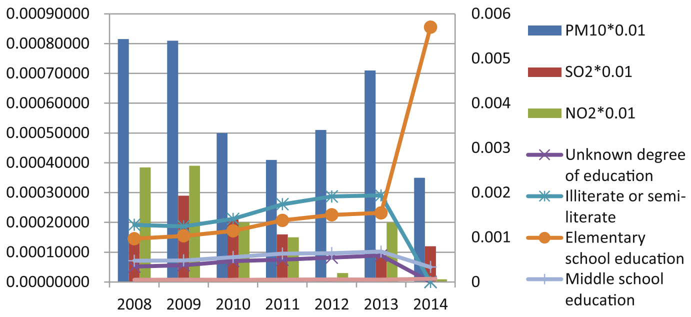

Fig. 2. The relationship between air pollution and education-specific mortality

According to Fig. 3, between 2008 and 2014, the mortality rate of residents aged 0–44 years and 45–64 years showed a stable trend, while that of people aged 65 years and over was consistent with the trend of air pollution between 2008 and 2013, indicating that air pollution impacted individuals aged 65 years and above the most. In terms of residents aged 44 and over, their physical function declines with age, and they are more easily affected by the external environment. Air pollution, to a larger extent, impacts individuals aged 44 and over, the death rate of whom may increase with a rise of the air pollution concentration [13]. However, the mortality rate of people aged 65 years and over in 2013–2014 showed a reverse trend with air pollution, which contradicts the argument that the senior residents are susceptible to air pollution. By searching literature, the paper finds that Mianyang faced a severe aging problem from 2012 to 2014. By the end of 2013, the residents aged 60 and above reached 1,07 million, accounting for 19.8% of the total population. Hence, a high aging population impacts the human mortality.

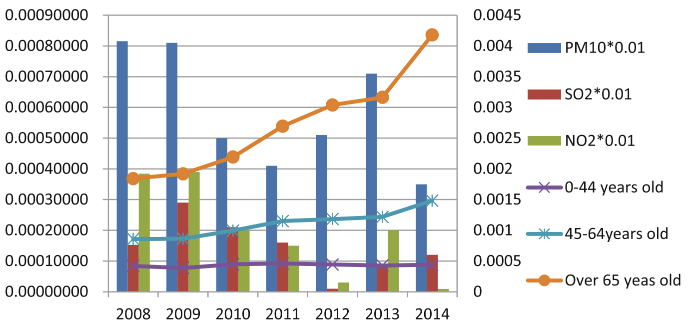

Fig. 3. The relationship between air and age-specific human mortality

It can be seen from Fig. 4 that the mortality rate caused by respiratory diseases showed a steady upward trend from 2008 to 2013, but it grew rapidly from 2013 to 2014. Due to the 2008 Wenchuan earthquake, Mianyang experienced a recovery period of agriculture, industry, and transport infrastructure. As a result, air pollution declined from 2009 to 2011. Nevertheless, the concentration of air pollution increased from 2011 to 2013, which correspondingly saw a rising trend of respiratory diseases-related deaths. It indicates that air pollution has a significant impact on the residents who died of respiratory diseases. During the period of 2013 and 2014, the human mortality rate caused by respiratory diseases showed a reverse trend with air pollution, contradicting the argument that there is, according to existing researches, a positive correlation between respiratory diseases-related deaths and air pollution [6,12,15]. From the Mianyang 2013–2014 government and other reports, the paper finds that this city faced a severe aging problem. Due to the prevalence of respiratory diseases among the senior residents, the 2013–2014 death rate was correlated considerably with the aging population, less with air pollution.

4 Discussion

The paper uses descriptive statistical analysis to investigate the correlation between major air pollutants and residents' mortality in Mianyang City. Given the impacts of natural disasters, national policies, and socio-demographic changes, the paper concludes that the urban and rural residents, who are male, illiterate or semi-literate, or with primary education, the middle-aged or aged, or with respiratory diseases, are more susceptible to the increase in the PM_{10}, NO_2 and concentration.

The accumulation of pollutants and photochemical reactions in various cities leads to complex regional air pollution issues. Mianyang, located in the northwest of Sichuan Basin, has a subtropical humid monsoon climate. The hot, rainy, and wet weather is not conducive to the diffusion of particulate matters, aggravating the air pollution of Mianyang. Furthermore, factors, such a high level exploitation of the rich mineral resources in Mianyang and its emphasis on industry development, contribute to the severe air pollution. Therefore, the Mianyang government should consider the health risk of air pollution, and take effective and feasible measures to tackle this issue, thereby reducing the pollution-related health risks of its urban and rural residents.

Here are four policy suggestions we want Mianyang government can accept and conscientiously implement. First, government needs to improve the local industrial structure by circulation type industrial building, which can reduce air pollution and improve resource utilization efficiency, also can achieve the transformation from primary industry into tertiary industry. Second, attaching great importance to the city public transport priority, vigorously implementing the bus priority development strategy, and increasing the city public traffic investment and construction strength in order to reduce harmful automobile exhaust emissions and protect residents' health. Third, promotion of industrialized and enterprise and market-oriented pollution treatment, encouragement of fund raised from diverse channels and various quarters in society, and intensified collection of charges on urban sewage treatment and garbage disposal, which can effectively reduce every kind of contaminative source. Last but not least, Mianyang government should make the enactment of relevant laws and regulation and raise residents' awareness about the health risks of air pollution to reduce the risk of death for the people, who are male, illiterate or semi-literate, or with primary education, the middle-aged or aged, or with respiratory diseases.

In addition, the study has certain limitations: First of all, due to the high mobility of the Mianyang urban and rural household population, the reported death information may be false or incorrect. Meanwhile, there may be a certain degree of misclassification of death data, which might affect the accuracy of residents' mortality. Secondly, the air pollution concentration measured at the fixed sites represents the exposure level of the urban and rural residents, which may differ, to some extent, from the real exposure level. Moreover, due to damage and impact of the Wenchuan earthquake, there might be a certain deviation of air pollution statistical data gathered at each site, affecting the analysis results.
