ABSTRACT

This manual has been designed for university-based training programs in rehabilitation counseling, psychiatric rehabilitation field sites, and other potential training sites and community programs, that may wish to implement a clinical training program in psychiatric/vocational rehabilitation. The manual is formatted to follow the trainee/student from entry into a field site training program until the completion of that program, typically of six months duration. The manual covers the following topical areas: general field site orientation procedures, documentation of the internship experience itself, record keeping and medical record issues, the processes of assessment and counseling, implementing education/training or employment options with clients, post-employment and follow-along services, and matters pertaining to case closure and student/trainee issues. Each of the topical areas have accompanying instructional materials. There are also complete manuals in psychometric assessment, report writing, treatment planning, and job club implementation. An instructional videotape is included that portrays the implementation of the job club model with persons who have a psychiatric disability (50 minutes) and the realities of financial disincentives to employment (25 minutes). In addition, there is a complete seminar series which includes lectures, reading materials, and case study exercises. (CR)

# CLINICAL INTERNSHIP PROGRAM IN PSYCHIATRIC VOCATIONAL REHABILITATION

## TRAINING MANUAL

### Introduction

This manual has been developed in order for university based training programs in rehabilitation counseling, psychiatric rehabilitation field sites, and other potential training sites and programs in the community who may wish to implement a clinical training program in psychiatric/vocational rehabilitation. The manual is set up to follow the trainee/student from entry into a field site training program until the completion of that program, typically of six months duration. Some programs may wish to extend the training and its curriculum over two academic semesters (30 weeks); others may wish to condense/modify the content to cover only a one semester experience. However, if the material is condensed to 15 weeks, then much of the formal academic components will need to be covered in course work outside of the field site placement. As written, the content of this manual is stand-alone, that is, all of it can be carried out in the field site, quite independent of a formal university training program.

The manual covers the following topical areas: general field site orientation procedures, documentation of the internship experience itself, record keeping and medical record issues, the processes of assessment and counseling, implementing education/training or employment options with clients, post employment and follow-along services, and matters pertaining to case closure and student/trainee issues.

The Manual is tabbed for easy access according to the Table of Contents, and each of the topical areas included in the training manual have accompanying instructional materials. Following the Table of Contents, is a Table of Corresponding Instructional Materials. This Table lists all of the instructional forms, samples, examples, and how-to-kits that the instructor and trainees/students might need to access at a particular field site or which the field site might wish to adopt or modify as part of its operational procedures. There are, also, complete, stand-alone manuals in psychometric assessment, report writing, treatment planning, and job club implementation. The Job club Manual has its own case study and instructional video-tape.

In addition, there is a complete Seminar Series which includes lectures, reading materials, and case study exercises.

The content of the Seminar Series is intended to complement clinical field work with didactic educational materials. Each section of the seminar series includes exemplary or seminal articles related to a particular topic.

### **TRAINING OBJECTIVES**

The training program in psychiatric vocational rehabilitation is designed to provide a highly specialized and intensive training program for individuals pursuing a master's degree in rehabilitation counseling or for individuals with no formal education beyond the bachelor's degree who are currently employed in the rehabilitation field. The contents also lend themselves to a credit course format (three credits for the didactic seminar series; three credits for the field work).

The training objectives involve:

- (1) Supervised training in the practice of interagency collaborative experiences, vocational assessment and counseling, and job development and placement with a focus on clients who have a major psychiatric disability.
- (2) Facilitating multi-cultural learning experiences through didactic information and client contact.
- (3) Providing up-to-date information with regard to the major psychiatric disorders and their treatment.
- (4) Demonstrating how to successfully collaborate between mental health and vocational rehabilitation agencies and programs utilizing a team work model.
- (5) Teaching how to identify and access necessary community resources for individuals with minimal in-place support systems.
- (6) Providing appropriate professional mentoring which includes a code of ethics and concordant standards of practice.
- (7) Developing the skills necessary to facilitate personal empowerment in persons with psychiatric disorders.

### **TRAINER REQUIREMENTS**

In order to successfully implement this training package, certain staff competencies will be necessary, either in place in the field site or available through a program of consultation. This statement is made not to demean the vast experiences of many individuals practicing in psychiatric rehabilitation across the country, but to acknowledge the breadth and depth of the training program itself. For example, many individuals will not be prepared to teach the seminar dealing with psychotropic medications. Thus, a local psychopharmacologist, psychiatric

nurse practitioner, or physician's assistant might be called upon to engage in the training program. A drug and alcohol specialist may assist with dual diagnosis clients and related issues. A licensed psychologist should be available to provide instruction and supervision in the utilization of the various psychometric procedures which require their special credentials and level of expertise. In order to obtain the maximum benefit from this training program, access to a multi-disciplinary setting is highly preferable. Finally, sections of the training manual may be extracted for use by individuals with particular interest areas or background training who may wish to use these sections as part of another ongoing course or as discrete workshop topics.

#### **ACKNOWLEDGEMENT**

Finally, the Project Director and her staff wish to thank the Rehabilitation Services Administration of the U.S. Department of Education and the Staff of RSA Region III in particular for their continued support. It was their faith in the quality of training provided in psychiatric vocational rehabilitation over the years at the University of Pittsburgh which made this training manual a reality.

## TABLE OF CONTENTS

### Clinical Internship in Psychiatric Vocational Rehabilitation

#### I

#### 1. Field Site Orientation

Orientation to the field placement agency  
Programs and Services Offered  
Role and functions of psychiatric rehabilitation  
counselor  
Clinic Policy and Procedures Manual  
Client/Patient Confidentiality Issues  
Psychiatric and Medical Emergencies  
Suicide and Homicide Assessment  
911 Procedures

Office Procedures (mail, xerox, requisitions,  
appropriate telephone etiquette)

Supervisory requirements:  
preparing for supervisory meetings  
taping all client sessions  
readings and instructional video-tapes  
as assigned  
scheduling community site visits  
how to maintain client case records  
professional appearance and demeanor

Group Seminar/Supervision Meetings

#### 2. OSHA Training

Universal Precautions  
Fire and Safety  
In hospital settings TB Test

#### 3. Internship Requirements

RSA Contract Agreement  
Contract with Field Agency  
Malpractice Insurance  
Documentation of Contact Hours/Daily Log  
Individual School Internship Requirements

## Mid-Term and Final Evaluations

### 4. Record Keeping

- Access to and use of Medical Records
- Proper notation (accepted abbreviations, SOAP Format for note taking)
- Release of Information and Consent Forms
- Content of Medical Record
  - Medical examination
  - AIMS Test (Tardive Dyskinesia Assessment)
  - Location of Social History
  - Initial Psychiatric Assessment
  - Child Protective Service Law
  - Criminal History Record
  - Mental Status Examination
- Miscellaneous Medical Record Forms

### 5. Assessment and Counseling

- Conducting the Initial Interview
- Treatment Formulation and Initial Functional Assessment (Money management, transportation, and other independent living skills)
- Written Rehabilitation Plan/ Vocational Goal Setting
- Specific Psychometric Evaluations
  - Psychoeducational Testing (Academic Achievement, Intelligence)
  - Vocational (Aptitude, Values, and Interest) Testing
  - Report Writing
  - Understanding neuropsychological and personality test results
  - Sharing test results and recommendations with clients
- Career Counseling: Choose/Get/Keep Model
  - Education/Training or Employment Decision Paths
  - Non-employment (Quality of Life) Issues

### 6. Education/Training Option

- Exploratory
  - Use of Computerized Career Exploration Systems (Guidance Information System, Discover)
  - Finance Issues (Student Aid, PASS Plan, VR)
  - Career and Educational Resources (OOH, DOT, college catalogues)
- Experiential
  - Volunteer work activities
  - Use of non-credit courses
  - Informational Interviewing and Shadowing
  - Part-time Employment

## **7. Employment Option**

Job Seeking Skills Training (Applications, Resumes, Interviews, Generating Job Leads)

Active Job Search (Following up on job leads, dealing with rejections, placement services)

## **8. Post Employment/Educational Placement Follow Along Services**

Benefits Management

Housing, medical, cash benefits

Use of Community Resources

Day Care, Drug and Alcohol Services

SSA, Psychosocial Rehab Agencies,

Advocacy and Self-Help Organizations

Health Care Services, Public

Welfare Administration

## **9. Case Closure**

Transfer/ discharge issues including formal documentation

Termination Issues (student leaves client)

## **10. Content of Seminar Series**

1. Defining Psychiatric Rehabilitation

1. Defining Mental Disorders

3. DSM-IV Diagnostic System

4. Role of Assessment

Functional Implications

Intelligence Testing

Achievement Testing

Measurement of Personality

Neuropsychological Evaluation

Vocational Testing

5. Major Psychiatric Disorders

Schizophrenia

Mood Disorders

Anxiety Disorders

Personality Disorders

Psychopharmacology

6. Vocational Counseling and Programming

Role of the Psychiatric Rehabilitation Counselor

Vocational Assessment: Formal and Informal

Evaluation and Planning

Career Counseling

7. Job Development and Placement

8. Mental Illness and Substance Abuse

9. Cultural Diversity and Psychiatric Rehabilitation

## **Table of Corresponding Instructional Materials**

### **II**

#### **1. FIELD SITE ORIENTATION**

## PSYCHIATRIC REHABILITATION: THE INTERDEPENDENCE OF TWO WORLDS

LYNDA J. KATZ, PH.D.

### INTRODUCTION: A HISTORICAL PERSPECTIVE

The first non-military vocational rehabilitation legislation, The National Civilian Vocational Rehabilitation Act (P.L. 66-236) also known as the Smith-Fess Act, became law on June 2, 1921. Some twenty years later, in 1943, major revisions were adapted (P.L. 78-113) which not only brought the field of medicine into the vocational rehabilitative process but also made special provisions for the rehabilitation of individuals who were blind and those having mental disabilities. It has been said that the concepts of rehabilitation have derived mainly from work with the physically disabled (Bloom, 1965). No special efforts were made to evaluate whether or not the operationalization of these concepts with the mentally disabled was equally effective, particularly since the vast majority of these individuals were incarcerated in large public institutions, far removed from the concern of community-based agencies or facilities. With the advent of the use of psychotropic medications in the late 1950's, which was heralded as the greatest contribution of psychiatry to the care of the mentally ill since the psychodynamic formulations of Sigmund Freud, the movement to "deinstitutionalize" these large, overcrowded and dehumanizing public hospitals began.

Within twenty years of the Barden-La Folette Act (P.L. 78-113), the Community Mental Health Centers Act of 1963 (P.L. 88-164) became law, ushering in the era of community psychiatry, a new philosophical base for treatment of the mentally ill. The goals of this new approach to treatment included: (1) the provision of service in the individuals' community; (2) the location of facilities near the patients' home; (3) the provision of a comprehensive range of services; (4) the establishment of services which were both immediately available and easily accessible; and (5) the assurance of continuity of care until restoration or rehabilitation was completed (Dorsett, 1964). However, contrary to the early "prevention-oriented" idealism of the early community mental health movement were the realities of the masses of deinstitutionalized chronically ill patients who were moving into the community. While mental health centers were obligated to provide services for all the residents in their respective attachment areas, the provision of "rehabilitative" services was not

one of the five mandated services. Those services which did develop for the patient with chronic mental illness were aftercare and partial hospitalization, both of which were clinical and followed a medical model.

With the 1975 Amendments to the Community Mental Health Centers Act (P.L. 94-63) rehabilitation was deleted as one of the possible services to be offered and transitional services, primarily residential in nature, were added to the new mandated services.

It seemed that the professionals operating the mental health centers not only were not given the resources to develop rehabilitation services, but were more inclined to think in terms of transitional, treatment oriented services for this population (Rubin, 1980, p. 93).

At about the same time, the Vocational Rehabilitation Act of 1973 (P.L. 93-112) placed a priority on services to the severely disabled, the chronic psychiatric population being one of those groups eligible. However, each state was given discretion in how it would serve this new population. By 1978, the Rehabilitation, Comprehensive Services and Developmental Disabilities Amendments (P.L. 95-602) stated clearly that: (1) The Rehabilitation Services Administration (RSA) had a responsibility to meet the vocational needs of the severely mentally disabled; that (2) RSA's responsibility extended to those without a clear potential for independent competitive employment; and finally that (3) States had the option of establishing "Centers for Independent Living" (Rubin, 1980). The mandate for RSA funding for non-vocational rehabilitation services was established.

### The NIMH/RSA Agreement

Such was the dilemma that must have faced administrators in the human service field in the late 1970's: (1) a federal/state rehabilitation program with funds to serve a population of individuals with a chronic/severe psychiatric disability; (2) an earlier discretionary mandate to the individual states who comprise the federal state vocational rehabilitation system, which was then amended in the form of a "nondiscretionary" mandate to provide vocational services to this population; (3) a community mental health program with no mandate and no funds or only categorically pre-determined funds to provide rehabilitation services to this population; and finally, (4) a severely disabled population in need of both services. Then in 1977, the National Institute of Mental Health established guidelines for the development of Community Support Program (CSP) demonstration efforts (Turner and TenHoor, 1978). A CSP was defined as: "A network of caring and responsible people committed to assisting a vulnerable population to meet their needs and develop their potentials without being necessarily isolated or excluded from the community" (p. 329). The target

population for CSPs was adults with a severe or persistent mental or emotional disorder that seriously limited their functional capacities relative to primary aspects of daily living. In order to implement a CSP, the guidelines also specified the existence of a "core service agency," which regardless of the number of direct services provided, must take responsibility for a variety of integrative functions aimed at preventing the severely disabled from becoming isolated in the community.

Community support programs (CSP) and the philosophy underlying their establishment provided a natural meeting point for the philosophies of mental health and rehabilitation (Grantham, 1980). Under the leadership of the CSP staff, a National Institute of Mental Health/Rehabilitation Services Administration Cooperative Agreement was signed in May of 1978. Of equal importance was the fact that this agreement paved the way for the establishment of formalized working relations on state and local levels between the mental health and rehabilitation systems. Three major issues involved in service delivery to persons with chronic psychiatric disabilities were recognized in this cooperative agreement:

- (1) The chronic psychiatric population needs long term availability of support services. This has not been a priority by Community Mental Health Centers over the last decade.
- (2) Funding to support necessary services for the chronic psychiatric population cannot be the responsibility of any one agency alone.
- (3) Rehabilitation services for the chronic psychiatric population must go beyond those who have clear vocational goals (Rubin, 1980, p. 91).

In the 1980's, we began to see on a state-by-state basis the implementation of that NIMH/RSA Agreement of 1978. For example, in September of 1982, the Deputy Secretary for Mental Health for the Commonwealth of Pennsylvania sent out to mental health county administrators, base service unit directors, vocational rehabilitation facility directors, community residential rehabilitation providers, and mental health community program managers a concept paper and resources packet on developing effective vocational services for persons with chronic mental illness (Nelson, 1982). The materials had been previously used as part of the Office of Vocational Rehabilitation/Office of Mental Health (OVR-OMH) Interagency Agreement orientation and training sessions which had occurred that previous June and July. The Office of Mental Health and the Office of Vocational Rehabilitation had agreed to a series of nine premises in order to develop a model for shaping vocational rehabilitation services provided to the mentally ill residents of Pennsylvania. These premises are listed below as they so clearly illustrate the integration of a rehabilitation philosophy into the mental health world, if only, at that point in time, at a conceptual level.

Work is an important part of a normal life.

2. A properly designed work experience is an excellent environment for improving mental health.
3. Vocational rehabilitation services must be integrated into a comprehensive system of treatment and support services which can provide a smooth delivery of services as client needs change.
4. Vocational rehabilitation services should enable individuals to progress at the most efficient pace consistent with their abilities.
5. Clients should be trained in the most realistic setting which is compatible with their needs.
6. Generic resources (community college, vo-tech schools, trade schools, industry) should be used for training whenever possible.
7. Vocational rehabilitation services should be based on the strengths and needs of each individual.
8. A variety of opportunities for substantial, productive work needs to be available (competitive, sheltered and semi-competitive, full and part time).
9. The individual client must be involved in determining the goals and methodology used in his/her rehabilitation program (Nelson, 1982, p. 1).

Similar interagency agreements have been drawn up across the country in states such as Maryland, Idaho, California, Texas, Arizona, Oklahoma, Alabama, Washington, Michigan, and Wisconsin, to name a few. These agreements are in effect as we enter the decade of the 90s.

#### A Mental Health Perspective of Rehabilitation

Psychiatric rehabilitation has as its goal the reduction of social and vocational deficits which are often a sequel to and/or co-exist with a psychiatric illness. Psychiatric disorders are conceptualized as clinically significant behavioral or psychological syndromes or patterns that occur in an individual.

In DSM-III-R each of the mental disorders is conceptualized as a clinically significant behavioral or psychological syndrome or pattern that occurs in a person and that is associated with present distress (a painful symptom) or disability (impairment in one or more important areas of functioning) or with a significantly increased risk of suffering death, pain, disability, or an important loss of freedom (DSM-III-R, 1987, p. xxii).

Chronic psychiatric disorders have been further delimited by the severity of diagnosis and disability and the duration of illness (Minkoff, 1979). Goldman, Gattozzi and Taube (1981) offer the following detailed definition:

The chronically mentally ill population encompasses persons who suffer certain mental or emotional disorders (organic brain syndrome, schizophrenia, recurrent depressive and manic-depressive disorders, and paranoid and other psychoses, plus other disorders

that may become chronic) that erode or prevent the development of their functional capacities in relation to three or more primary aspects of daily living - personal hygiene and self-care, self-direction, interpersonal relationships, social transactions, learning and recreation - and that erode or prevent the development of their economic self-sufficiency (p. 2).

Psychiatric treatment goals involve treating the person in the least restrictive setting, reducing mental disabilities, providing treatment in the community, making a wide range of services available and accessible to all persons who need them, and concentrating on the most severely or chronically disabled. While the focus of one (psychiatry) has been on symptom reduction and/or control, the focus of the other (rehabilitation) has been on community reintegration and attainment of the highest level of personal, social and vocational functioning. And yet, the two systems, psychiatric care and rehabilitation services, ultimately share the same clients/patients, similar processes, and resources for service delivery and congruent outcome goals.

From a mental health perspective, "rehabilitation" has been viewed historically as one phase or distinct unit of service in the continuum of comprehensive services required by persons with mental illness aimed at minimizing the negative consequences of their psychosocial disability. Thus, rehabilitative services, as a distinct and separate entity residing outside the mainstream of mental health services as traditionally defined, were available to these persons through a process of referral which occurred with irregularity, if at all, and in most cases were not inclusive of persons with severe psychiatric disabilities. The absence of rehabilitative services for individuals with chronic mental illness was the result of omission by the mental health system and commission by vocational rehabilitation agencies which saw the population of persons with severe psychiatric disabilities as problematic at the very least, and most certainly, as disruptive of the agencies' long-standing pride in their rehabilitation closure rates.

To illustrate this point with respect to mental health services, Rubin and Lotz (1977) surveyed mental health center administrators in Florida. Each was asked to rank in importance five services (psychotherapy, day treatment, residential, vocational rehabilitation and social club) for the adult chronic patient on a long-term and transitional basis. Vocational rehabilitation was ranked lowest on the list followed by social club. In another survey in 1982, conducted by the Office of Education and Regional Programming (OERP) at Western Psychiatric Institute and Clinic, the Department of Psychiatry at the University of Pittsburgh, mental health administrators from 27 counties in the Western Region of the State of Pennsylvania were asked to identify staff training needs in light of local service delivery needs. Not one of these administrators asked for training in the area of psychiatric rehabilitation for their respective staffs.

However, by the late 1980s these very same agency administrators were asking specifically for training in the area of psychiatric rehabilitation.

Thus, the purpose of this introductory chapter in a text devoted to the area of psychiatric rehabilitation will be: (1) to look at a definition of psychiatric rehabilitation in terms of four distinct frameworks and operational models which have or currently do exist; (2) to generally delineate the characteristics of the population of individuals with a chronic mental illness, their needs and deficits; (3) to review the need for rehabilitation services which exists among this population and in particular among the population of young adults who have a severe psychiatric disability; and (4) to update the definition of psychiatric rehabilitation as it exists interdependently in the worlds of rehabilitation and psychiatry.

### REHABILITATION MODELS AND PSYCHIATRIC DISABILITIES

Traditional rehabilitation services for persons with psychiatric disabilities have historically developed out of three rather distinctive philosophies, each of which is separate from the world of traditional psychiatric care. These three philosophies then have been operationalized and have taken the form of a medical model, a work-focused model, and most recently, a competency-based or community model. Each of these models will now be discussed in light of their efficacy with regard to the population of individuals with severe psychiatric disabilities.

#### The Medical Model

The medical model has traditionally been tied to the area of the physically disabled with rehabilitation encompassing a broad range of medical treatment and restorative services. As part of the medical model rehabilitation approach, a vocational evaluation is prescribed just prior to the patient's discharge. This evaluation is conducted by vocational staff who are usually physically as well as psychologically unrelated to the rest of the multi-disciplinary team. Vocational recommendations are then "lacked on" to the rehabilitation plan despite a rehabilitation philosophy which espouses a "holistic" approach. Psychiatric patients have not fared well with such a practical model because the disability is not restored through external, mechanical or compensatory devices or through treatment procedures which occur in isolation from each other, such as the need for a hand splint, a whirlpool bath, or a speech therapy session in order to secure a successful rehabilitation outcome.

When psychiatric clients enter rehabilitation settings whose programs are based on physical rehabilitation they create havoc because rehabilitation

counselors attempt to apply methods designed for the physically disabled client and the psychiatric clients are usually unresponsive to those methods. Rehabilitation counselors tend to avoid the psychiatric client because of the client's bizarre or unpredictable behavior. To complicate matters, the client's diagnosis tells the rehabilitation counselor nothing about the client's deficits, whereas counselors can usually predict the deficits for clients with medical problems. Often the clients do not see themselves as disabled since their disability is not a visible physical one, and yet they may be helpless and hopeless in terms of gaining employment or learning to manage in the community (Krauss and Slavinsky, 1982, p. 240).

In addition, the time needed to build a relationship with a person with a psychiatric disability with low trust and weak ego boundaries is more extensive. He or she cannot be programmed in pre-established time frames for particular treatment modalities. Moreover, those skills most often intact with the client with a physical disability, such as interviewing skills, making career choices, putting together a resume and formulating relocation options, are most usually impaired or at times non-existent among those persons with a psychiatric disability. Interpersonal competence and the ability to present oneself in a positive light are areas likely to be negatively affected by the illness itself (Krauss and Slavinsky, 1982). Finally, closing a case as successfully rehabilitated, the goal of the vocational rehabilitation agency, seems at times virtually impossible with these individuals whose illness knows no predetermined discrete time intervals.

For those interested in a discussion of how such a model operates, Koltuv and Neff (1968) reviewed their experiences with the Institute for the Crippled and Disabled (ICD) in New York City, a facility that had served persons with physical disabilities for 40 some years. In a pilot project with the New York State Division of Vocational Rehabilitation over a 3-year period, the Institute served 100 individuals with a primary psychiatric disability ("process schizophrenic") (s, p. 254). Services were provided under the auspices of the sheltered workshop where extensive work evaluation occurred followed by training and/or placement recommendations. No data on follow-up of these clients were provided. One of the authors' comments, however, is germane to our discussion of this traditional physical-medicine rehabilitation approach with persons who have the psychiatric disabilities.

In numerous instances, we have found that a client's behavior and work performance, in the workshop, TOWER, and the training classes were at considerable variance with interviewers' impressions of his current functioning and capabilities. Why this happens is unclear. It may be that behavioral specialists...have frames of reference that are inappropriate for making vocational assessments...Perhaps it is because professionals working in the vocational area are hampered by a lack of a general theory of work and

by the incomplete understanding of the articulation between work ability and psychopathology (p. 259).

### The Work Model

Vocationally oriented work-related models of rehabilitation have perhaps the longest history of all, dating back some seventy-odd years. These vocationally oriented programs were also the first to take in persons with psychiatric disabilities. Rehabilitation professionals such as Shiela Akabas of Columbia University's Social Welfare Center (1980) have written that rehabilitation has the most to offer clients when it is clear about its focus of vocational goals. Akabas purports that in accepting a competency-based model of rehabilitation, counselors are adopting an easy path rather than one which is in the best interests of these clients. "It allows the rehabilitation counselor to escape what is difficult - job placement - and to do what she/he may be trained for, namely, counseling" (p. 21). In criticizing the work of Grantham (1980), Akabas questions his search for a value base in rehabilitation, stating that it in fact exists, "...that work is desirable for human well-being and is a right which a society should insure to its population" (p. 21).

Earlier, Newman (1970) had also suggested that traditional methods of restoring socio-vocational functioning were inappropriate. He proposed a program wherein immediate job placement occurred at the start of the rehabilitation process and that after the client was employed, vocational behavior and shaping of appropriate work habits and interpersonal skills would be attempted. Newman viewed traditional training approaches as increasing the anxiety of former mental patients since they did not meet their immediate financial needs and that schools or training sites might actually provide a "shelter" to avoid confronting reality.

One of the most well known work models of rehabilitation for persons with psychiatric disabilities is the Fountain House program in New York City, after which programs such as Thresholds in Chicago and Fellowship House in Miami were modeled. Fountain House, through a Projects with Industry (PWI) grant, secured job placements for its residents with 50 small businesses and light industries in New York City for the purpose of providing on-the-job training. Over 150 individuals are served on a daily basis through this program and when and if the worker cannot fulfill his/her job duties on any given day, the agency staff member who has previously learned the job with the worker fills in the position, thus assuring the employer a continual and regular work force (Skellely, 1980 and Beard, Propst, & Malamud, 1982).

Olshansky (1980), long recognized for his work in the field of vocational rehabilitation and workshop settings, proposed a shift in perspective from psychiatry to rehabilitation if appropriate services were ever to be provided to the population of persons with chronic schizophrenia. He viewed the psychiatrist as

having a very limited role in the ongoing delivery of services to these individuals. Specifically, he would serve as a consultant to the rehabilitation specialist and he would be the administrator of drugs. Chronic schizophrenia would be regarded as a behavior and management problem rather than an untractable disease process. "But for this shift in perspective to be meaningful, 'work' would become the central activity within the rehabilitation process" (p. 128). For Olshansky, work prevents isolation in the chronic patient; it requires socialization and attention to external tasks and signals. It provides an opportunity for earning an income and gaining self-respect and also serves as a means of daily surveillance which identifies regression at an early stage while providing a regular routine for those who are incapable of any kind of autonomy or of organizing their time in an orderly way. Olshansky's answer to the availability of work opportunities is the creation of more sheltered workshops, many of which would be terminal as opposed to transitional in nature. Olshansky (1980) concluded:

One problem associated with the suggested shift is that of persuading the psychiatrists to move back and rehabilitation specialists to move forward. It would probably be easier to persuade psychiatrists... than rehabilitation specialists... Ironically, he (the rehabilitation specialist) is still not committed to the rehabilitation perspective and to the value of work for the chronic schizophrenic. Like so many psychiatrists, he still thinks that given more time, he can counsel the chronic schizophrenic back to health and well-being (p. 129).

The most recent approach to the rehabilitation of persons with severe and disabling mental illness emanating from the work model is that of supported employment. This innovative rehabilitation technology, supported employment, was developed initially in response to the needs of persons with moderate and severe mental retardation. These individuals traditionally were limited to work activity programming, sheltered workshop placement, competitive placement with no job site training or follow-up, or failed to meet eligibility criteria for VR services in the first place (Revell, Wehman, & Arnold, 1984). The development of various supported work models for persons with developmental disabilities was pioneered by Bellamy in Oregon, Wehman in Virginia and Brown in Wisconsin. Supported employment is paid work, in a work environment with nondisabled workers, for persons with severe disabilities who cannot maintain employment without ongoing assistance from a service provider responsible for employment support. Supported employment includes the provision of: 1) intensive initial training of persons with a severe handicap generally done on the work site; 2) continuing intervention to assist the individual in accomplishing specific work tasks to sustain employment; and 3) retraining to

allow persons with severe handicaps to remain employed in the original job or to transfer to another job (Report from the Study Group on Supported Employment, 1985).

While supported employment was first authorized in 1984 under the Developmental Disabilities Assistance and Bill of Rights Act (P.L. 91-517, as amended, Section 102 (E) and (F)), it had not been officially mandated in Rehabilitation legislation until the Rehabilitation Act Amendments of 1986 (P.L. 99-506; Section 7 (18)). State project demonstration grants in the area of supported employment were awarded by the Rehabilitation Services Administration, U.S. Department of Education, beginning in 1985, under the Special Projects and Demonstration discretionary grant category as authorized under Section 311 (a) (1) of the Rehabilitation Act (50 Federal Register 25407, Section 373.14 (a), June 18, 1985). Under the Rehabilitation Act Amendments of 1986, which authorized the supported employment formula grant program under Title VI, Part C of the Act, supported employment is defined and its relationship to most individuals with chronic mental illness addressed in particular.

(18) The term "supported employment" means competitive work in integrated work settings--(A) for individuals with severe handicaps for whom competitive employment has not traditionally occurred or (B) for individuals for whom competitive employment has been interrupted or intermittent as a result of a severe disability, and who because of their handicap, need ongoing support services to perform such work. Such term includes transitional employment for individuals with chronic mental illness. For the purposes of the Act, supported employment as defined in this paragraph may be considered as acceptable outcome for employability (p.6).

The recognition that employment and job retention strategies, and in particular the use of a supported employment model, with persons who have a chronic mental illness are somehow unique and that they require more linkages brought about the convening of a state-of-the-art (SOTA) conference in Washington, DC, in March of 1987. It was the privilege of this author to participate in the SOTA conference. It became clear that major issues (implementation strategies, particular needs of persons with long term mental illness, social welfare disincentives, trained personnel) were in need of further study if policy-level decisions and regulatory standards were to be relevant and meaningful with this particular population of persons "traditionally not in the workforce" (p. 1 Monograph: Supported Employment for Chronically Mentally Ill Individuals, 1987). These issues will most likely be addressed with the reauthorization of the Rehabilitation Act.

#### The Competence Model

The competence or community model of psychiatric rehabilitation follows principles which were first summarized by Lamb (1977), appear to follow early

conceptualizations of rehabilitation which focused on the whole person (Whitcomb, 1960; Wright, 1960), and later were modified by Anthony (1980). Lamb's model stresses the social and emotional competence of the individual and the important role that environment plays in the process. The goal of rehabilitation under this model is the development of the individual to the point where he/she can cope with a residual disability while achieving his/her maximum psychological and vocational potential. Work is seen as something which can be enjoined or from which one can be disengaged. It is essentially replaced in the hierarchy of rehabilitation values by support systems in the environment which speak to the whole of the individual. Lamb's (1977) ten principles are as follows:

1. Rehabilitation should be primarily in the community.
2. The rehabilitation plan needs to be comprehensive, including social and vocational rehabilitation, individual or group psychotherapy, psychoactive drugs if needed, financial assistance and the provision of a supportive living arrangement if required.
3. A high priority should be given to learning "in vivo."
4. The goal is to focus on the healthy personality.
5. The focus should be reality factors rather than intrapsychic phenomena, and on changing behavior rather than changing basic character structure.
6. In working with chronic patients, high but realistic expectations must be maintained so patients can strive to attain their full social and vocational potential.
7. Rehabilitation efforts should be aimed at giving the patient a sense of mastery over his internal drives, his symptoms, and the demands of his environment.
8. An "institutional alliance" develops among psychiatric patients in which they relate more to the institution than to an individual.
9. Relatives are more to be relied upon as primary care agents.
10. Rehabilitation goals must be clearly defined in each phase of rehabilitation (Grantham, 1980, pp. 2-3).

The overall goal of psychiatric rehabilitation for Lamb (1977) is "to expand the remaining well part of the person instead of to remove or cure pathology" (p. 3). It is with this particular statement that the work of Anthony (1979) seems most in agreement. For Anthony, it is the lack of interpersonal social skills and work-related skills which must be repaired regardless of the psychiatric disability involved. He bases this conclusion on the results of his extensive review of the literature which indicates that:

1. Successful adjustment to a work environment does not correlate significantly with adjustment to living or learning environments.
2. Clients often lose their jobs, not due to an inability to perform tasks, but because of skill deficits in emotional and interpersonal functioning.
3. Clients who lose their jobs often don't possess the skills to get another one and either don't try to find one or return to their rehabilitation for help.
4. There is no relationship between hospital based work treatment and competitive employment.
5. Thirty to fifty percent of discharged patients obtain employment and only twenty-five percent retain it (p. 129).

What then follows is Anthony's approach to skill training under the competence model. The "empathy-trained" counselor proceeds to utilize a rehabilitation process based on work adjustment training, career counseling, and career placement, three essential components to the vocational rehabilitation process. Since this model also recognizes that not all psychiatric disabilities will be amenable to rehabilitation through improved skill behavior, the counselor also looks to the environment in order to evaluate whether it can be adapted to accommodate the client's deficits. Anthony, much like Olshansky, would have us alter the knowledge base and technical proficiency of the rehabilitation specialist (but obviously in different areas) if the rehabilitation process is to be successful with the psychiatrically disabled population. He does not particularly concern himself with the timing or location of the process as long as the basic ingredients as he sees them are delivered. Anthony's competency model, then, in many respects is a psychosocial revision of Olshansky's work model. Thus rehabilitation strategies and outcome goals are updated in light of the 1978 amendments to the Rehabilitation Act, which extended vocational rehabilitation's responsibility to those without a clear potential for independent competitive employment.

### The Comprehensive Center Model

The fourth model of psychiatric rehabilitation which will be discussed was alluded to by Grantham (1980) when he reviewed the community support program model and its relationship to rehabilitation and mental health. "It is a program which provides linkages among agencies, focuses on problems in living rather than personality restructuring, is comprehensive and provides for easy access, relies on the helping skills of people rather than professional labels, and makes available opportunities for consumers and other citizens to have input" (p. 13). Thus programs such as Fellowship House in Miami (Rubin, 1980) and Thresholds in Chicago (Dincin and Witheridge, 1982) have been described as

fulfilling the CSP Mandate.

Fellowship House is viewed as the "core service agency" which is prescribed by the NIMH guidelines. The core service agency is committed to helping people with severe psychiatric disabilities improve their lives whether by the direct support services it provides or through a series of integrative functions which link the severely disabled person to the existing community or, when necessary, through the establishment of a therapeutic community milieu if none exists. The ten components of such a core service agency (Turner and TenHoor, 1978) include: identification of the population at risk; assistance in entitlement applications; crisis stabilization in the least restrictive setting with hospitalization available when other options are unavailable; psychosocial rehabilitation services; supportive services of indefinite duration; medical and mental health care; backup support to families, friends and community members; involvement of concerned community members in planning, housing and work opportunities; protection of client rights and case management.

While Dincin and Witheridge (1982) do not label Thresholds as a core service agency they do describe the agency as a comprehensive psychiatric rehabilitation center which provides reality-based treatment for discharged patients at high risk for rehospitalization. In an effort to evaluate the effectiveness of such a comprehensive rehabilitation program, a total of 102 clients were randomly assigned at intake to either a full-time comprehensive program or a part-time supportive treatment program at a different location. Comprehensive treatment was seen to include: individual casework, vocational rehabilitation, social rehabilitation, residential facilities, academic programming and prevention of rehospitalization. The supportive treatment program relied almost exclusively on rehabilitative services and facilities available in the surrounding community. The comprehensive treatment program was staffed with 30 full-time workers and other part-time and volunteer help while the supportive treatment program had two part-time staff and several trainees and volunteers. A psychiatrist was available to the supportive program every two weeks to meet with clients to prescribe and monitor the use of psychotropic medication. In the comprehensive treatment program the consulting psychiatrist also co-lead discussion groups with a nurse around issues of noncompliance and medication. After nine months, 14% of the comprehensive treatment group subjects had been rehospitalized in contrast to 44% in the supportive treatment group. However, it should be noted that all rehospitalized subjects had histories of more frequent admissions than did the subjects who were not rehospitalized. In terms of employment, only 39% of either group were gainfully employed either part-time or full-time at the time of follow-up, and clients assigned to the supportive treatment group actually earned on an average more than did the comprehensive treatment group (Bond, Dincin, Setze, and Witheridge, 1984).

As a final outcome, Dincin and Witheridge (1982) reported a significant cost reduction through use of the comprehensive program, which while 11 times the cost of the supportive treatment, amounted to only two-thirds of the total expenditure of public funds when inpatient hospital days were entered into the cost-benefit analysis.

Based on their studies at Thresholds, the authors (Bond et al., 1984) concluded:

Vocational is one of the most poorly understood aspects of psychosocial rehabilitation. The paradigm used for physical disabilities (evaluation-training-placement) is not appropriate for most of the long-term mentally ill. For one thing, psychiatric clients do not ordinarily require the specific sorts of retraining that those with physical or cognitive disabilities need (Newman, 1970). Moreover, while most disabilities can be said to be "stabilized" (in the sense the condition is unlikely to change in the short term), mental illness is less predictable. Thus, evaluation, as conducted in traditional vocational rehabilitation settings, is also less meaningful. Moreover, work limitations are not easily detected through standardized tests. For such reasons, psychosocial rehabilitation emphasizes the shaping of good work habits and attitudes (which many psychiatric clients lack), and de-emphasizes client assessment and training for particular vocations. However, despite the emphasis on employment at Thresholds, graduates have a far from impressive employment rate. It is time to examine why this is true and to ask whether the Fountain House Model has been "oversold." Unlike rehospitalization statistics, employment rates are rarely reported (Anthony et al., 1978). The methods for reporting employment rates vary drastically among studies. We can offer a number of possible explanations for the Thresholds vocational statistics: that the economy has been in recession, that the value of the vocational program rests not with its rate of employment success, but with its ability to improve social functioning, raise self-esteem, and structure daily activities; or that the modest employment rates which we have reported are nonetheless above the base rates reported for the general psychiatric population. Others, such as Wilder (1976), have concluded that the goal of competitive employment is beyond the grasp of a large proportion of the long-term mentally ill population and that we should therefore redirect our efforts toward designing permanent sheltered or semi-sheltered employment programs tailored to the needs of the psychiatric population. Where we disagree with Wilder (1976) is in his implication that transitional employment approaches are unnecessary, since clients who eventually find competitive programming would succeed in any case. A wide range of vocational programming, including transitional employment, sheltered employment, and skill training (for uneducated and unskilled) would probably be ideal (pp. 19-20).

Both of these programs, however, lie in the domain of the rehabilitation world as opposed to the world of mental health. More specifically, they are not based in a psychiatric treatment service or community mental health center but are rather extensions of the psycho-social rehabilitation model. However, it seems rather clear at this point in time, particularly in view of the national commitment of NIMH and the RSA to provide services to persons with long term and severe mental illness, that the mental health community will become more immediately involved in the rehabilitation process. Grantham (1980) in his review of the impact of community support programs wrote:

Given the co-mingling of service populations, problems addressed, and services rendered, it is conceivable that rehabilitation for the mentally ill could become the responsibility of the mental health system. It would appear to be no real problem for mental health to add a role which functions around vocational counseling, placement and follow through services. The list of services detailed by the CSP...leaves this possibility wide open.....Efficiency may dictate that the best prepared agency assume program control. In the initial agreements on CSP, control was yielded to NIMH (p. 14).

Just as the need for periodic rehospitalization has been recognized as a legitimate need for certain individuals who are chronically psychiatrically disabled (Mosher and Keith, 1979; Bachrach, 1979) so the issue of work as an end goal in the rehabilitation process has been opened to question. "Rehabilitation of persons with mental disabilities in the final analysis will be defined as a competence in problems-of-living issue. It will be geared toward determining whether work contributes to a healthy adjustment and where indicated, assisting in the achievement of appropriate work behaviors" (Grantham, 1980, p. 14).

#### An Integrative Model

The final model, and the one with which the authors are most familiar, functions as part of a large comprehensive psychiatric service and utilizes an altered definition of successful outcome in rehabilitation for persons with chronic mental disabilities. This definition takes into account the issues of periodic rehospitalization while addressing the need for alternatives to competitive employment with this population (Katz-Garris, McCue, Garris and Herring, 1983). The Department of Neuropsychological Assessment and Psychiatric Rehabilitation was established within the Department of Psychiatry at the University of Pittsburgh, School of Medicine, Western Psychiatric Institute and Clinic in 1977. The Department's purpose is to facilitate community reintegration of the patient population so that these individuals might achieve their potential

for independent living, which may or may not include employment and the need for periodic rehospitalization. The philosophy of the program is goal-oriented, purposeful, functional, and educational; and, therefore, assessment and therapeutic services have as their focus the enhancement of functional skills. Programming includes comprehensive assessment services, prevocational evaluation and training, career planning and counseling, and supportive group experience in conjunction with the patient's primary treatment program. All rehabilitation focused activities are initiated and implemented in light of two basic assumptions: (1) that all treatment/rehabilitation services are collaborative endeavors between the primary treating clinician, the rehabilitation counselor, and the patient; and (2) that timing of rehabilitation-related programming is predetermined in order to insure synchronized or simultaneous undertakings. Collaboration is both formal and informal. The rehabilitation counselor takes an active role in maintaining lines of communication between the primary clinician and all other treatment and rehabilitative services, with primary responsibility for linkages with vocational rehabilitation services in the community. The following diagram (Table 1) illustrates the kinds of treatment/rehabilitative services offered throughout the course of the psychiatric treatment program.

In an effort to determine the effectiveness of its rehabilitation-oriented service which functioned as a component of psychiatric services offered by a large, urban, university-based hospital, the Department conducted a follow-up study on 277 patients out of a total of 342 who had received such services, two and one-half years prior to follow-up.

Regarding the effectiveness of services provided by the Department of Psychiatric Rehabilitation in relation to the program's overall goal of community reintegration, three separate outcome measures were assessed. Relative to the first outcome measure, productive activity, 43.3% of the sample were categorized as productively engaged and 56.7% were not active. The second outcome measure, quality of community adjustment, utilized a self-rating scale measuring the patients' level of satisfaction with their adjustment to the community. These data revealed that 65.9% of the sample considered themselves satisfied, while 34.1% were not satisfied. Turning to the final outcome measure, amount of community involvement, 41.1% of the sample were rated as having been involved in the community, while 58.8% were not involved or only minimally involved (Katz-Garris, McCue, Garris and Herring, 1983, p. 333).

In addition, certain critical variables (age, sex, and educational background) were found to be significantly related to the outcome criteria. And perhaps as important for the field of psychiatric rehabilitation, this study demonstrated the utility of nontraditional outcome measures in evaluating the effectiveness of

services. Such outcome measures are more in keeping with the broadened mandates of rehabilitation legislation and policies while directly responding to the NIMH/RSA Cooperative Agreement's goals and guidelines.

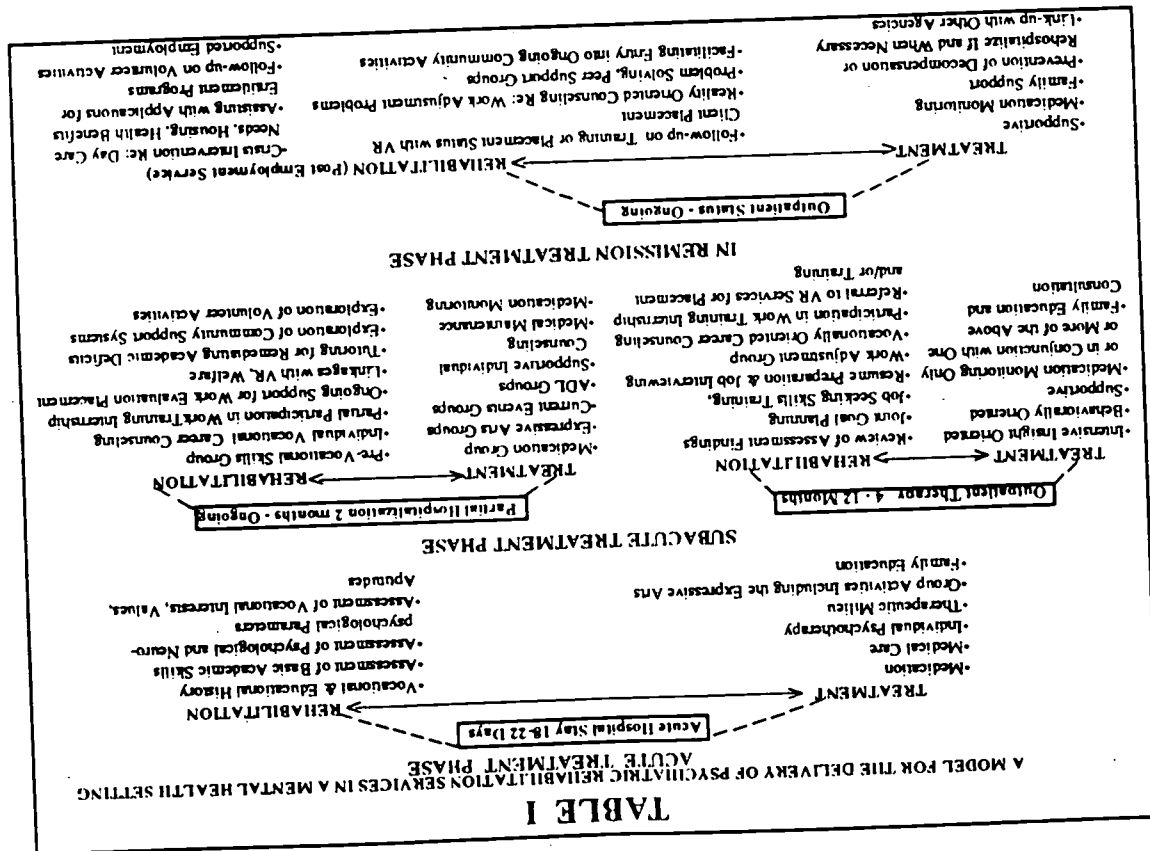

### REHABILITATION NEEDS OF PERSONS WITH PSYCHIATRIC DISABILITIES

Thus far, we have reviewed the historical process which has brought the fields of psychiatry and more broadly mental health and rehabilitation to a common meeting ground in the area of services to persons with chronic mental illness. In addition, we have reviewed in some detail, the often disparate underlying philosophies of rehabilitation--medical, vocational and competency-based--which have also converged in meeting the needs of this population. It is left for us now to review the characteristics of this population, their specific needs and those special issues which emerge for the practitioner regarding the provision of services for persons with psychiatric disabilities in order to meet their special needs.

#### Characteristics of the Population

Roughly speaking, persons with chronic mental illness are comprised of three groups of individuals: deinstitutionalized persons, "revolving door" persons who go in and out of hospitals, and individuals with chronic disability who are not hospitalized (Cutler, 1981). Bachrach (1979) further differentiated the population by location and distinguished between five separate subgroups which represented "fallout from the deinstitutionalization movement" (p. 388). According to Bachrach these individuals once constituted the totality of persons residing in state hospitals but now they are: (1) patients released from the hospital; (2) persons who have never been hospitalized, but at an earlier time would have been; (3) old long-stay residents of the hospital who have not been released; (4) recent admissions of short-term patients; and finally (5) new long-stay patients "...a build-up of long-term residents from among recent admissions who are unlikely to be considered good risks for community care and probably will not be discharged" (p. 388).

Lamb (1979) studied a group of 101 residents of board-and-care home facilities in the state of California which had developed in the community to fill the vacuum created by the deinstitutionalization of California's state hospital system. He sought to examine the characteristics of this population and how these residential facilities might have replaced the state hospital in terms of patient needs. The median age of the population was 39 years, with a range of 22 to 63 years. There were nearly twice as many men as women; 92% of the group had been previously diagnosed as psychotic and had been hospitalized from 0 to 28 years; and 42% of the population had resided in the board-and-care facility

## A Historical Perspective

for 5 years or more. Only a little more than a third of this population had contact with a mental health professional and this was generally the psychiatrist who visited the facility for medication management. Thirty-one percent of the group had been hospitalized during the previous year while 32% of the sample "exhibited severe overt major psychopathology" (p. 130). Sixty percent of the residents had received community vocational rehabilitation services, but only 12 of the 61 persons who had received services were still involved; one in a competitive employment setting, three in a training program and eight in sheltered workshops. One-fourth of the residents who had received vocational rehabilitation services reported that they had been unable to do the work required in the sheltered workshop or were fearful that they could not. With an additional 10% it appeared that the vocational counselor had overestimated their strengths and had placed these individuals in training programs beyond their capabilities. "In most cases, the vocational counselor had not been part of a therapeutic team that included a primary therapist or case manager" (Lamb, 1979, p. 133). Finally, 52% of the residents had no goals to change anything in their lives, and in those 30 years of age and older with a lifetime history of six months of hospitalization or more, the lack of motivation was even greater. In discussing the issue of motivation and goals Lamb (1979) comments:

Perhaps some would benefit from better drug management. And surely this group should be the object of a concentrated effort at outreach from community agencies to provide individual and group psychotherapy and social and vocational rehabilitation. At the same time, it must also be recognized that there are persons in board-and-care homes just as there are persons in society generally for whom we do not have the answers with regard to making their lives happy, anxiety-free, and meaningful (p. 133).

In 1980, a NIMH-sponsored survey was designed to study a random sample of 1,471 chronically mentally disabled adults being served by community support systems (programs) in terms of demographic characteristics, clinical histories, and level of functioning (Tessler, Bernstein, Rosen and Goldman, 1982). The median age of the group was 42 years, with the proportion of men (47%) and women (53%) nearly equal. While one-third of the group were high school graduates, only 25.9% were employed at the time of the survey, and of those only 41.8% were employed in competitive settings. The remainder were working in "sheltered workshops (37.1%), in paid transitional employment programs (11.2%), in unpaid work training programs (8.7%), or as volunteers (1.2%)" (p. 209). Of those surveyed, 92.3% had been hospitalized for psychiatric care at some point in time with a median admission rate of 3.1. In terms of current functioning, the most problematic skill deficits were in managing transportation money, adhering to medication regimens, meal preparation, verbalizing

## Psychiatric Rehabilitation: A Handbook for Practitioners

needs and securing appropriate services. Others suffered from obesity, under-nourishment, medication side-effects and impaired motor control. "Contrary to the popular conceptions, the vast majority of CSP clients did not have behavioral problems that threatened or violated important social norms..." (Tessler, Bernstein, Rosen and Goldman, 1982, p. 209). In concluding their findings these authors wrote:

This article has addressed three interrelated questions: Is the CSP serving a chronically mentally ill population? Are the ten components of a community support system actually in use? And, finally, are the neediest individuals receiving services? In each case, the preliminary answer is a qualified yes (p. 211).

While a non-federally funded CSP, a group of agencies established themselves as a core service committee (agency) under the NIMH guidelines for community support systems in the Oakland section of the City of Pittsburgh in the state of Pennsylvania. This community has a sizable resident population of persons with chronic mental illness due in part to the availability of Western Psychiatric Institute and Clinic, various transitional living facilities, and the availability of affordable housing in the area. The general needs of this group have been documented in a variety of studies and reports which have been conducted throughout the Western Region of Pennsylvania over the past several years, and all have underscored the need for additional and innovative support programs for persons with chronic mental illness who reside in the community. A major element of the comprehensive services needed for this population includes innovative approaches to "linking" services, which is a particularly complex process because of the variety of administrative agencies, both public and private, state and local, which are involved in service delivery in the state.

As part of its CSP function, the committee identified a target population to be addressed by the NIMH guidelines which have been previously discussed in this chapter. This population consisted of 250 former patients who were being served by one or more of the participating agencies. Most of the patients (75%) were female while 42% of them were between the ages of 55 and 69. Seventy-four percent were unemployed and those who did work did so in sheltered workshops or vocational rehabilitation centers. Of those discharged from hospital settings, 40% had more than ten hospitalizations, while only 26% had not been rehospitalized during their community tenure. The committee concluded that these post-hospital patients in general: (1) had very poor self-concepts and showed dependency needs; (2) lacked the motivation or capability to make contact with sources of assistance and support; (3) were unable to meet basic living needs and often lacked the resources to secure housing, adequate food and

clothing; (4) had a difficult time finding and keeping jobs; (5) had difficulty using leisure time in a satisfying or rewarding manner; (6) were unable to establish and maintain social and personal relationships so that the natural folk-support systems were inadequate; and (7) most needed sustained contact with the mental health and medical systems for ongoing treatment and medication (The Development of an OAKLAND Community Support System, 1983).

Thus, it becomes clear that the population nationally surveyed, as well as that specifically defined in California and Pennsylvania, share common characteristics of a chronic condition. Investigators such as Summers (1981) and Krauss and Slavinsky (1982) suggest that chronicity may have more to do with the persistence of social and vocational deficit than the continuance of systems and that the essential feature of chronicity may be functional deficit. While specifically addressing that population having been diagnosed as schizophrenic, Summers writes: "The residual deficit of the schizophrenic lies primarily in the area of social and vocational functioning, rather than psychotic symptoms" (p. 712).

Support for this contention can be found in the review by Gunderson and Mosher (1975) of the cost of schizophrenia in the United States. A conservative estimate of such costs on an annual basis amounted to \$11.6 billion. Of this total amount, only one-fifth can be derived from the direct delivery of services, while the remaining four-fifths is the result of the loss of productivity among this population. With respect to readmission rates, Gunderson and Mosher (1975) note that despite the doubled utilization of outpatient care by schizophrenic patients between 1971 and 1973, "rehospitalization rates do not appear to have been affected" (p. 904). "Thus it may not be the lack of outpatient facilities so much as their failure to provide meaningful treatment for (persons with schizophrenia) that account for their lack of impact on readmission rates (p.904)." In addressing ways in which the cost from loss of productivity among this population might be diminished, Gunderson and Mosher point to: (1) the increased use of alternative housing; (2) greater emphasis on vocational rehabilitation "during all phases of treatment and smoother reentry into working situations from residential care" (p. 905); and (3) increased governmental, both federal and local, efforts to "support and coordinate rehabilitative services specifically designed for mental patients" (p. 905).

### Needs and Deficits

Krauss and Slavinsky (1982), after reviewing the sociologist Strauss's comprehensive model for the analysis of the needs of individuals with chronic mental illness, which includes: prevention and management of medical crises; control of symptoms; regimens of carrying-out treatments; prevention of isola-

tion; adjustment to changes in the course of the disease; normalizing life-style and interactions with others; and funding, conclude that deficiencies emerge that would have "serious implications for the planning and implementing of care for the psychiatric chronically ill" (p. 38).

The severity of the illness, the long-range nature of the disorder, the lack of effective technology to treat the disorder, the extreme stigma, and the extent of the social disability involved all combine to create a unique human experience with a unique set of problems (p. 46).

Cutler (1981) has defined the needs of persons with chronic mental illness in terms of the environmental spheres in which five functional need-areas are carried out. These five functional areas are components of a service delivery system which deals with (1) personal needs; (2) social needs; (3) productive activities; (4) recreational needs and (5) the ability to get services. Essential to each component is the provision of case management. "The goal of case management is to assure that long-term patients are enmeshed in a social support system that can be designed in the least restrictive environment" (p. 349). Unlike the non-psychiatrically disabled chronic population, those with a mental disability often present with a wide variety of bizarre and disturbing symptoms and behaviors which not only impinge on the individual but also cause a negative reaction in those with whom they associate. Coping with the basic necessities of daily living is a major undertaking. When one adds other basic life needs such as work, leisure-time activities, and rewarding social interactions, it is near impossible for the patient who is chronically ill to fulfill such needs without formal assistance.

In short, chronic patients lack what Mary Ann Test...has called "network cement." They simply do not stick themselves to other people. On the contrary, they have a tendency to avoid others except for those who share the same living quarters. It is important that those who are designated to make up a support services network for the chronic patient be highly attuned to this fact (Cutler, 1981, p. 349).

With respect to the area of productive activities in particular, in our society, having a meaning in life is most often determined by what one does with his/her life. In an existential sense, "the what I am" often defines the "who I am." Where I am in the continuum of productivity is not so much an issue as the fact of being within that continuum in the first place. As the reader may recall being productively engaged was one of the outcome variables used in the Katz-Garris, et al. psychiatric rehabilitation outcome study which expanded upon the traditional criteria, recidivism and employment. Investigators such as Turner and

Gartell (1978) in their study of the social factors involved in psychiatric outcome point out that, although there is evidence for an important interdependence between competence [social competence is defined as an acquired capacity for socially effective behavior and "corresponds to the individuals' level of psychosocial development" ...and... "ability to meet expectations set by society" (Phillips, 1966, p. 47)] and type of severity of psychopathology, the two are separable in terms of their relationships to outcome. They would have us conclude, moreover, that "the enhancement of competence as a critical and distinct therapeutic goal...deserves as much attention in the treatment process as do the dynamics underlying symptom expression" (p. 379). Meaningful activity, whether it be paid work, volunteer experiences, training, etc., is an *in vivo* arena for the development of social competence and as such is an essential ingredient of the psychiatric rehabilitation process from the perspective of mental health as well as from the perspective of rehabilitation. It is here again that we see the convergence as well as the interdependence of the two once separate worlds.

Schumacher (1980), in his comprehensive review of significant studies which have dealt with the coordination of services for persons with mental illness, has extracted certain critical variables in the psychosocial adjustment of persons with long-term mental illness. In reviewing the area of productive activities and most specifically work, Schumacher comments that long-term follow-up and repeated hospitalizations may remain an important or continuing feature of these individuals and that rehabilitation can only be planned and carried out with the expectation of giving long-term support, but that "(r)ehabilitation programs alone may not be the long-term answer to the severely mentally ill" (p. 53).

Bachrach (1979) took Schumacher's statement to its logical conclusion when she wrote that reality is absolutely essential in the planning of services for persons with chronic mental illness. She suggested six dimensions to the planning process which include: (1) the need for mental hospitals; (2) the importance of precise planning goals; (3) the unique service needs of the chronically mentally ill; (4) the need for interagency planning; (5) the importance of a functioning and sensitive patient tracking system; and (6) an appreciation of the attitudinal structure within which mental health services are delivered. The need for mental hospitals is "consistent with an understanding of the nature of chronicity that holds that for some patients relapse is inevitable and is best dealt with in hospital settings" (p. 389). But just as important and in keeping with the purpose of this chapter:

The uniqueness of planning for the chronically mentally ill lies in the fact that those supportive human services that are traditionally considered to be a domain of social services or rehabilitation, and not of medicine, play a

somewhat different role. Provision of these supplementary services must be understood as being part of the basic treatment regimen.

In short, the so-called medical model and the human services model must merge for the successful care of the chronically mentally ill (Bachrach, 1979, p. 390).

Bachrach's work has been updated and her hypotheses empirically tested in the recent work by Bond and Boyer (1988). These authors analyzed the outcome of some 21 programs reported in the literature between the years of 1963 and 1986 which utilized a controlled or quasi-controlled design in the measurement of vocational rehabilitation outcomes. The authors concluded:

Do psychiatric vocational programs help clients achieve competitive employment? The answer is complicated by the diverse outcome measures used. If the criterion is the competitive employment rate at the end of the follow-up period, then only two studies yielded significant results. If the criterion is job starts in competitive employment, then four other studies might qualify. Compiling the summary judgments given...only four of twenty-one studies showed an overall advantage to experimental subjects on competitive employment. Moreover these four studies each have methodological limitations. The general conclusion is that none of the approaches...have demonstrated efficacy in helping clients achieve and maintain competitive employment over any sustained period of time.

In contrast, when the criterion was paid employment (including transitional and sheltered employment), eight of ten studies indicate that when clients are given intensive support and are placed in jobs that are not too demanding, they often function at a level beyond usual expectations. Both intensive support and positive expectations that clients can succeed appear to be important elements (pp. 252-253).

### The Young Adult Chronic Patient: A Special Need

Before concluding this final section on the rehabilitation needs of persons with psychiatric disabilities, it is important to recognize the existence of, as well as the special needs of, an increasingly growing population of young adult patients with chronic mental illness. They can be characterized generally by three distinguishing features: (1) that for the most part since the onset of their illnesses, they have lived in an era of deinstitutionalization (Caton, 1981); (2) that they manifest, despite a variety of symptom profiles, severe difficulties in social functioning; and (3) that they tend to use mental health services extensively and inappropriately, "in ways that drain the time and energy of clinicians yet do not conform to viable treatment plans" (Pepper, Kirshner and Ryglewicz, 1981, p. 463).

Bachrach (1982) has done an excellent job of reviewing the literature with respect to the young adult with chronic mental illness in which she highlights patient clinical characteristics such as their mobility, their inability to handle

stress, their use of psychiatric services in a revolving-door fashion, their inability or unwillingness to hook-up with a system of care, their hostility, belligerence toward and demanding manipulative behavior toward therapeutic staff, their use of street drugs, their low tolerance for frustration, and their impulsive behaviors which often result in encounters with the law. Schwartz and Goldfinger (1981) go so far as to say that it is not their needs which distinguish them from other persons with chronic mental illness, but rather problems which result from their style of interaction with existing community-based services. "At present, these 'new chronic patients' are disoriented, disengaged, and difficult for all who come in contact with them" (p. 474).

Pepper, Kirschner and Ryglewicz (1981) have reported on their efforts at the Rockland County (New York) Community Mental Health Center to study this population and the services offered them. Among the variety of programs were a crisis service, a sheltered workshop, a residential program, an acute day treatment program, and a growth advancement (social) program. While preliminary findings of their work were based on clinical judgments of involved staff, it is not surprising that the need for residential programs was seen as one of the most glaring deficits in the service delivery package.

While the Rockland study (Pepper, Kirschner and Ryglewicz, 1981) reported clinical estimates of over one-third of their study population in need of long-term hospitalization, Bachrach (1982) posits that a series of eight program principles shared by successful model programs for persons with chronic mental illness appear to hold for the young adult patient as well. She discusses each of these components in detail for the interested reader, but we shall only list them in this discussion for our present purposes as her presentation needs no further elaboration. The eight principles include: (1) a full range of services including psychiatric, medical, rehabilitative, vocational, social and residential programs; (2) the coordination and integration of resources; (3) individualized treatment including more creative vocational programs; (4) specially trained staff who can bridge the gap between the hospital and community and who can work flexibly and integratively in diverse service settings; (5) flexible programs which take into account follow-up mechanisms and family involvement; (6) hospital services as well as nontraditional and noninstitutional settings; (7) cultural relevance and compatibility; and (8) top priority assignment in the services delivery system not encumbered by limiting external system constraints such as eligibility for care management services which is tied to previous extended or significant periodic hospitalization.

#### CONCLUSION

In conclusion, psychiatric rehabilitation had been frequently viewed as a component in the continuum of comprehensive services required by hospitalized

persons with mental illness to facilitate their re-entry into the community (Menuck, 1978; Schulman, 1980). However, the concept of psychiatric rehabilitation has taken on a broader meaning in the 1980's as a consequence of the era of deinstitutionalization, the consumer movement, the rights of the handicapped legislation and litigation, the economic recession of preceding years, and the continuing growth of technology both within and without the field of human services. Psychiatric rehabilitation is the comprehensive continuum of services, which includes medical, social, psychological, vocational, recreational, residential, and inter-agency and linkage services. Psychiatric rehabilitation can no longer be seen as strictly vocational in nature and thus somehow separate from the treatment process. Psychiatric rehabilitation is the treatment process, in the broadest sense of the word, since its underlying philosophical base is grounded in the concept of the whole person, the holistic approach. Its outcome is restoration and the restitution of dignity (Oberman, 1965). Such overwhelming and broadly defined goals can only be achieved if the process is viewed similarly.

This chapter title has used the word "interdependence" in order that the discrete components of psychiatric rehabilitation might be more clearly understood. While there are those who will continue to emphasize specific programmatic initiatives at the expense of others, equally legitimate, in the implementation of the process, it becomes exceedingly clear that particularly with respect to the needs of persons with chronic psychiatric disabilities, this pre-determined, compartmentalized process is not now functional, if it ever was. The worlds of psychiatric and rehabilitation share an uneven track record, at best, when one considers these persons with chronic mental illness whose numbers have not diminished. In light of the overwhelming costs to our nation, both financially and in terms of human waste, a mutually interactive and reciprocal process in the field of psychiatric rehabilitation among professionals, care givers, agency administrators and legislators is essential.

## Chapter XI

# ROLE OF THE REHABILITATION PRACTITIONER

LYNDA J. KATZ, PH. D.

### INTRODUCTION

In this final chapter we will discuss the role of the rehabilitation practitioner, the ways in which this role may be affected by as well as effective with the population of persons with psychiatric disabilities. In so doing it will be important to ask the questions: What can be expected from the mental health/rehabilitation service delivery system? What can be expected from the patients/clients who are in need of such services? And, what are the expectations (attitudes) of the professionals who work in the service delivery system and interact with the consumers of service? Once we have discussed what might be expected in practice, we will examine the relationship which exists between the practitioner and the individual who is psychiatrically disabled, the various setbacks faced by the rehabilitation practitioner as the goal achievement process is activated and finally how regrouping can occur as a function of the process of care continuity.

### A FRAMEWORK FOR THE PRACTITIONER

#### Expectancies of the System

The literature that does exist in the field seems relatively clear and unequivocal that if rehabilitation efforts are to be successful with the population of persons with psychiatric disabilities, and particularly those with a chronic illness, programs and services within the system must be conceptualized and implemented within the framework of an integrative model. Such a model utilizes multiple resources which have prearranged linkage relationships at the community or inter-agency level as well as at the agency level. In reality however, such inter-agency linkages are more fiction than they are fact. The problem is not a new one, and in fact, proposals to deal with inter-agency cooperative agreements and schema for inter-agency coordination date back into the early 1970's.

One such model (Black, 1976) utilized a decidedly structural approach to the problem. While acknowledging that the areas of life which must be linked in the provision of "support services" for any human being are "housing, socialization, recreation, education, work or other means of economic support, and necessary medical and psychiatric treatment services" (Black, 1976, pp. 37-38), the "linking" function in this model is confined to a discrete entity, a "Day

Center" (p. 36). The Center would have "physical space with minimal staff and volunteer services" and would provide "four essential rehabilitation functions," namely: "1) (t)he availability of treatment continuity; 2) (p)rovision for advice and guidance or an advocacy function; 3) (t)he opportunity for continuity of contact and of observation of ex-patient behavior," and "4) (t)he provision of some direct specialized support services as may be necessary depending upon the actual characteristics of the population to be served" (p.37).

The difficulty with such a structural model is that it posits responsibility for coordination of services on yet another agency in an already existing multiple-resource system. As such it faces two major obstacles to success: (1) credibility in the community of professionals whose expertise, successes and failures are going to be somehow linked by "minimal staff" and volunteers; and (2) the ultimate segregation of a population of persons with psychiatric disabilities who would be inclined to use the facility as a substitute public institution-type day room. Black does acknowledge the difficulty in terms of funding to "get governmental budget interest in a Day Center as a specialized institution" (p.40), but in so doing he obviates the entire concept of an integrated model of service delivery. Instead of integration we have a new agency vying for funding, client, acceptance and its piece of the turf. Finally, as with most well-meaning advocates, who must make a strong case for their own wares in the marketplace, Black relegates issues of housing, education, and employment to positions of lesser prominence within the broad domain of mental health endeavors.

We should be less concerned that mental health authorities provide decent housing for ex-mental patients, but rather with how the mental health providers keep sufficiently in touch with ex-mental patients to provide them with what they require when they are in need of treatment. It is actually the responsibility of the institutions of society to deal with the living arrangements for these and other destitute or unfortunate human beings who require roofs over their heads and food and clothing (p.38).

Such an approach with its focus on a structure which casually places the responsibility for care support services on "other institutions of society" is out of step with a comprehensive approach to treatment and/or rehabilitation. In the words of Lamb (1981): "Community residential care is one of the most important arenas in today's struggle to create quality programs for the chronically mentally ill" (p.1). The importance of residential rehabilitation services has been recognized by the Department of Public Welfare of the Commonwealth of Pennsylvania. This recognition has led to the formulation of regulations regarding their operation (8600 Mental Health-Community Residential Rehabilitation Services, Pennsylvania Bulletin, Vol. 12, No. 19, Sat., May 8, 1982, pp. 1487-1499).

Community Residential Rehabilitation Services (CRRS) are specifically designed and operated to assist persons with chronic psychiatric disability

to live as independently as possible through the provision of training and assistance in the skills of community living and by serving as an integrating focus for the person's rehabilitation...CRRS can exist only in a system of services for their clientele and cannot function without ties to other service providers. Rehabilitation of severely psychiatrically disabled individuals requires many and diverse services...CRRS have an obligation to work cooperatively with other service agencies and with local coordinating and planning groups toward the development and operation of a comprehensive service system which can meet the needs of chronically mentally ill persons in a continuous, timely and coordinated manner (Section 8601.2, p. 1487).

Thus, these regulations, while directed toward the functioning of residential facilities, make it clear that linkages within and between diverse services are essential to the rehabilitation of persons with chronic mental illness and that there is an obligation imposed by law to work cooperatively in the development and operation of a comprehensive service system.

Schumacher (1980) recognizing, at least implicitly the pitfalls created by the kind of model proposed by Black, suggested that the coordination of services at the agency level may be less feasible than the coordination of services at the client level. In so doing Schumacher recommended the assignment of client advocates and follow-along personnel during or at the time of the client's hospitalization who remain with the client throughout long-term adjustment. In his proposal a specific group or consortium of agencies would "develop and implement the "position of mental health advocate who has contact and referral skills" (60). The agency is replaced by a person who will now integrate and coordinate the services needed by individual patients/clients. In addition, Schumacher suggested:

Overlapping programs should involve the local-city-wide or county-wide consortia of agencies that could be directed by a joint team with central administrative responsibilities. This would include the total health care of the chronically mentally ill patient (p. 60).

His suggestion is perhaps as self-defeating as that of Black. Schumacher would have his joint team "direct" the total health care of clients through a central administrative structure. However whether it be a jointly appointed advocate or a joint administrative team, the function and therefore the process is the issue far more so than the mechanism, the agency, the person, the team, the contractual agreement or the regulatory standards. The function or process is that of case management. Often, however, when this function is relegated to a specific agency or individual apart from the existing cadre of services, it becomes even less the concern of the multiple professional rehabilitation providers than it already is in some cases.

One model adopted by a large Canadian psychiatric hospital (Waylenski, Plummer & Litman, 1981), while directing its efforts to the aftercare of specific problem patients, is demonstrative of a process, functional approach without specific superimposed structural (facility, staff administration) components. Staff commitment to community placement as well as an understanding, both affectively and cognitively, of the crisis of discharge for many patients were seen as essential attitudinal components. In addition, five features of the program were seen to have contributed to its effectiveness: 1) an aftercare assessment which others have conceptualized as a service plan; 2) community-institutional team planning meetings, weekly and monthly with varying levels of staff and community participation; 3) a transitional staff member who would be available to patients as a constant, benign and enabling body to move throughout the institution and community, including home visits; 4) an approach to patient care which is immediate and frequent particularly in the immediate period following discharge; and, 5) the establishment of personal relationships with the staff of as many community-based aftercare services as possible. "We have developed a small but highly effective transitional program to facilitate aftercare for such patients and a minimum of formal procedures and without additional personnel. Moreover, the program has shown very low re-admission rates" (p. 496).

Among the summary of recommendations by the Switzer Fellows on the topic of Schumacher's paper (Switzer Fellows, 1980), the following quotation highlights the issue of an integrated model of service delivery from the perspective of case management.

There needs to be greater emphasis on the role of case-management, including advocacy, to facilitate client access to services. This should begin during or at the time of a client's hospitalization or entry into the system, and remain with the client throughout an essentially open-ended rehabilitation process. Case-management is viewed here as an important and necessary function which can best be provided by professionals of varying disciplines. It may best be provided by the individual with the strongest relationship with the client. Case-management is a process of 'tracking people' and not paper! (p. 67)

### Expectancies that Relate to the Patient Population

Krauss and Slavinsky (1982), in a very cogent fashion, present a rationale for viewing chronic illness, much like our system of care and rehabilitation, from an integrated approach. Specifically, it is postulated that no one current theoretical perspective on chronic psychiatric illness whether it be medical-technical, epidemiological, sociological, intrapsychic or the mental illness myth model can account for the phenomenon of chronic mental illness or psychiatric disability. They point out that chronic psychiatric illness is not a diagnosis or a specific diagnostic category, it is not unique to a particular age group and it is not a social class related phenomenon. Rather, Krauss and Slavinsky (1982) characterize a chronic disorder as differentiated from an acute or transient situational disorder, as: "severe, permanent, stigmatized and contagious" (p.20).

The severity of a chronic illness is often difficult for the practitioner to comprehend much less mitigate. Recognition of the "enormity of the burden of the illness to patient and others is a prominent feature of chronic illness" (Krauss & Slavinsky, p. 20). The practitioner gets merely a glimpse of the degree of impairment during a therapeutic session, for example, when the patient moves in and out of the real world and constantly seeks reassurances in relation to past events, fears or delusional material.

One such individual, while discussing experiences in a partial hospitalization discussion group which focused on the patients' perceptions of themselves and their concerns about the perceptions of others, abruptly asked her therapist if she would ever have a baby. She then began a dialogue with herself on whether ex-prisoners were worse than ex-mental hospital patients, finally concluding that Patty Hearst surely had friends and someone had married her. During one particularly stressful period during which her medication dosage appeared to be exacerbating her painful symptomatology, the patient desperately fearing reinstitutionalization took to bed rest. A caring family then served as "in-home" hospitalization. Mother acted as competently as any skilled nurse until the acute exacerbation subsided. In this particular case, because of the family's long-term commitment to the care of this young woman, rehospitalization did not occur, medication was readjusted based on years of experience in observing and monitoring their daughter's behavior, and the patient who had recently been terminated from a work adjustment program because of absenteeism, was able to reenter a partial hospitalization day program.

Throughout the experience family and patient sought reassurances from the therapist that the painful, anxiety-ridden, panic-like state would subside and the patient would be able to continue with her rehabilitation process. Instead of regarding the acute episode as a failure of treatment, the therapist reinforced the strength and motivation of the patient to regain her hold on reality and return from her delusion-ridden preoccupations and hallucinatory thought processes. Her pain was real and her impairment severe to the degree that engagement in social relationships or work experiences was impossible. Flexibility in a service delivery system which would facilitate the patient's re-entry into a less stressful day program was of paramount importance. Without an appreciation of the severity of chronic psychiatric disorders such use of the system would not have occurred.

Permanence of psychiatric disability is a factor which must be faced by the rehabilitation practitioner in much the same manner that a chronic physical disability is accepted. And yet, while a sense of hopelessness often pervades the rehabilitation process with persons who have severe psychiatric disabilities, this is not the case when an individual patient or client has a diagnosis of diabetes or blindness. If rehabilitation is to be successful in the case of the chronic physical

illness, acceptance of its permanence is seen as a positive step in the life adjustment process in spite of periods of exacerbation, medication adjustment or other complicating medical factors or sequelae. In writing about the chronically mentally ill Krauss and Slavinsky (1982) point out that the illness may be episodic, "marked by periods of remission and exacerbation" (p.22) They continue:

This episodic phenomenon, with its waxing and waning of symptoms, has become more serious and noticeable in the wake of deinstitutionalization. These episodes were simply less noticeable and less important in total care institutions where the vast majority of the chronically ill previously spent their lives (p. 22).

The stigma of psychiatric illness has been well documented in the past and continues to exist. According to Goffman (1963) the term stigma refers to an attribute of a person that is deeply discrediting, and by definition the person with a stigma is perceived as not quite human. "On this assumption we exercise varieties of discrimination....we construct a stigma-theory, and ideology to explain his inferiority and account for the danger he represents, sometimes rationalizing an animosity based on other differences..." (Goffman, p. 5).

In a study by Wicas and Carbuccio (1971), counselor attitudes toward the culturally deprived black, the ex-mental patient, and the ex-convict were examined. A total of 112 rehabilitation counselors and school counselors were asked to respond to a forced choice questionnaire regarding their client preferences in various situations. The culturally deprived black was most accepted by the counselor and by society, as the counselor perceived it. The ex-mental patient was seen as "least acceptable for positions dealing with trust and responsibility, least in control of his fate, and least able to be helped by community programs (Schumacher, 1980, p. 51).

In another study, Hartlage and Roland (1970) investigated employer attitudes toward the former mental patient, the persons with mental retardation, and those individuals with major amputations with respect to work-related behaviors. While those with amputations were considered a average or better than average employment risks, the former mental patient and the person with mental retardation were regarded as below average and poor employment risks. There was, moreover, the greatest concern expressed among the employers for persons with psychiatric disabilities and their tolerance for work pressure.

The rehabilitation practitioner, then, cannot be overly condemning of the employer or society-at-large in their response to persons with mental disabilities and the negative attribution process which follows. The counselor must come to grips with his own prejudice and fears, whether real or imagined, if he/she is to effectively deal with the stigmatized patient. In the case of the patient discussed previously, a former therapist had told the patient that she should never have

children and to put that idea out of her mind. For the patient, that directive became a preoccupation as she attempted to deal with her sense of self-worth. Were ex-mental hospital patient's "better" than ex-prisoners? Were mentally ill people as bad as mentally retarded persons? Would any man ever want to marry her knowing of her psychiatric history? Could the people she encountered on the bus tell that she had been in a state hospital? The family also struggled with her stigma as they contemplated moving to another state so that she "might have a fresh start."

The stigma attached to the psychiatric disorder then leads to a sense that the illness is contagious. It may be "detrimental to others" or "put others at risk" (Krauss and Slavinsky, 1982, p. 28). Inheritability and predisposition for particular psychiatric disorders are real issues. The vulnerability of children to a parent's episodic illness, the stress on other family members particularly if financial resources are limited, and the daily strains of coping with bizarre or inappropriate behaviors, periodic deterioration of living skills, neighbors and relatives' questions etc., cannot be overlooked.

In summary, the characteristics of a chronic psychiatric illness, severity, permanence, stigmatization and contagion are what the rehabilitation professional can expect to encounter in working with this population. They must be dealt with in a realistic manner. Otherwise, the practitioner can be overwhelmed by his or her reactions to this group of individuals. Olschansky (1980) in writing about persons with chronic schizophrenia points out that many are not likeable, they are "unkempt, uncooperative and unpredictable" (p.127). They are perceived of as educational and vocational failures, chronic losers and at times frightening. There is at times a tendency to not forgive them their misfortunes and to resent their dependency. How far can the practitioner stretch the theoretical concepts of empathy, unconditional regard, positiveness and genuineness?

Test and Stein (1975) point out that while their treatment emphasis is on ways to increase appropriate, adaptive behaviors in a patient's repertoire, there are times when a more direct way of dealing with inappropriate and antisocial behavior is necessary in order to attain treatment goals. "Social learning theory is abundant with examples of the fact that behavior is responsive to its consequences. Toward these ends we have found that holding patients responsible for their behavior is an effective means of minimizing inappropriate and antisocial behavior" (p. 78).

We adamantly disagree with the argument that direct feedback will be untherapeutic because it will cause a patient to 'fall apart'. Our experience indicates that although it certainly may be stressful, one of the key ways any individual learns to behave appropriately is by being given accurate information about the effects of his behavior. Murphy et al. (1972) made this point well by stating, 'It is unclear to me how a patient will ever learn to please others and obtain pleasure in return if...disapproval is always

copied' (pp. 14,79).

Finally, as we conclude this section on expectancies, it is important to recognize that as research continues in the area of the severe psychiatric disabilities, some investigators and practitioners are becoming increasingly convinced that the population is not a homogeneous one in terms of expectation levels. Hogarty (1971) writes of low tolerance for stress and high tolerance for stress subgroups. Others (Easton, 1974; Lamb and Goertzel, 1972; Wilder, Kessler, and Caulfield 1968; and Richmond, 1969-70) have looked at high and low expectation halfway houses, while still others have investigated high and low expectation vocational programs (Koltuv and Neff, 1968; Loeb & Scholes, 1966; Bond & Dincin, 1986).

In the Lamb and Goertzel (1972) study, long-term mental patients were randomly assigned to one of two community settings. In the high expectation settings which included a halfway house, a day care center and a vocational workshop, the patients' level of vocational and social functioning were found to increase, with the high expectation group less likely to be labeled as deviate, less often stigmatized, and less segregated. However, there were a group of patients for whom high expectation settings were not appropriate, but who were able to continue to function in low expectation environments.

#### INTEGRATING A KNOWLEDGE BASE INTO PRACTICE

##### The Relationship Between the Practitioner and the Client

While current treatment practices with individuals who have chronic psychiatric disabilities have focused on medication and a variety of social support and group experiences, there is reason to believe that a need exists for a supportive psychotherapeutic counseling relationship as well. Just as the patient with a chronic mental illness moves at times episodically into the acute phase of his/her illness, this same movement occurs in and out of established programs and group settings. Without a supportive and ongoing one-on-one relationship, the patients' attempts at rehabilitation become fragmented, disconnected and highly stressful at each point when program and service options need to be renegotiated. This supportive other can be a mental health clinician, a rehabilitation counselor, an activities or expressive arts therapist, or a residential advisor. But in any case, that practitioner must be properly prepared to deal with the uneven course of the rehabilitation process where the individual with a chronic psychiatric illness is concerned. The practitioner must provide the experience for a trusting relationship, a means to understand the stressors which precipitate problems, an ongoing listener for expressed feelings and concerns whether pathological or healthy, an energizer for corrective actions and alternative behavioral strategies, and an accepting, caring respondent when things go wrong. "The patient-therapist relationship...transcends professional discipline and theoretical bias. The very act of investing energy in the establishment and maintenance of an individual

relationship with someone who has a chronic psychiatric illness lends a kind of validation to (the) person and their life's experience" (Krauss & Slavinsky, p. 203). For an excellent discussion of the supportive therapies and their practice the reader is referred to Krauss and Slavinsky's (1982) *The Chronically III Psychiatric Patient and the Community*, Chapter Seven, *The Supportive Therapies*. A recent investigation, which will now be discussed in some detail, highlights for us the importance of the therapeutic relationship to the rehabilitation of the severely psychiatrically disabled.

In an effort to evaluate the effectiveness of strategies to return persons with chronic mental illness to the work force, a pilot project was implemented and tested by Ciardiello (1981). Program effectiveness was evaluated in terms of vocational rehabilitation outcome/employment status, clinical outcome, career maturity outcome, program participation and implications for work. Thirty-two continuing care clients from the Community Mental Health Center of Rutgers Medical School were selected for the study on the basis of meeting specific criteria which defined chronic mental illness. The pilot program provided services to each patient on a full-time, daily basis for a period of seven months. Following a battery of pretests, 16 subjects were randomly assigned to a control group which received existing rehabilitation services only. Sixteen were also assigned to the experimental group which received the pilot vocational rehabilitation program in addition to existing services.

Results of this study, while necessitating somewhat cautious interpretation because of certain methodological shortcomings including the absence of blind raters, nonetheless merit review in light of the preceding discussion on the relationship between the client with a chronic psychiatric disability and his or her therapist or counselor. Ciardiello (1981) reported a significant correlation between the number of individual counseling sessions attended by program participants and employment status which was defined as paid employment. The more individual counseling sessions attended, the more likely was the program participant to be employed. In addition, the amount of time spent on individual counseling was highly correlated with the amount of time participants spent in group counseling sessions. Ciardiello concluded, "The results discussed above suggest that the individualized attention characteristic of the client-counselor relationship was an effective component of this pilot program and a key variable in the vocational success of the chronically mentally ill" (p. 33). And although not statistically significant, the total amount of time worked by the experimental group exceeded that for the control group.

In terms of results reported on the various rating scales employed, the experimental group subjects were rated significantly higher than the control group on five of twelve ego functions including reality testing, judgment, regulation and control of drives, thought processes, and adaptive regression in the service of the ego. Results from the SCL-90, a measure of psychiatric

symptom level, found the experimental group reporting fewer psychiatric symptoms than those individuals in the control group. The hypothesis that the stress associated with working and/or involvement in a work program increases psychiatric symptomatology was not found to be the case" (p.38).

Overall, results of the study suggested that: 1) The more times clients had spent working prior to becoming or involved in the study, the less likely they were to become involved in counseling; however, the amount of time they spent in counseling was positively related to the amount of time they worked during the program. 2) There was an association between levels of career maturity and the clients' willingness to attend counseling sessions, both group and individual. 3) Counseling appeared to increase the participants' motivation to work. And finally, 4) Certain aspects of ego-functioning were affected by counseling while others were not. Ciardiello concluded:

Given the short duration of the program and the bleak, general employment picture which existed at the time of the study, the results.....suggest that there are useful techniques available to assist psychiatrically disabled clients to enter the workforce. The results of this study suggest that counseling is a crucial element in such an effort....(p.42).

The relationship between the practitioner and the client with a psychiatric disability is, then, the glue, so to speak, which enables the rehabilitation process to stick together or in its absence, become unglued. Krauss and Slavinsky (1982) have suggested certain necessary ingredients in the therapeutic relationship with this population which deviate from the approach of more traditional psychotherapy relationships. "Expressions of opinions, genuine agreement or disagreement with the patient, and well-chosen acts of self-disclosure will all help to make the person of the therapist a viable part of therapy" (p. 203). Appropriate expression of emotion on the part of the therapist to the events and issues which comprise the therapeutic dialogue is seen as a mechanism whereby the individual patient or client can learn about the reciprocity of relationships. They conclude:

There is a particular bittersweet quality to developing a psychotherapy relationship with someone who has a chronic psychiatric illness. One can neither ignore the real deficits caused by the illness nor fail to be attracted by the tenacity, and perhaps, the vulnerability of the person who is afflicted. There is much that is unattractive about a chronic psychiatric illness, but the establishment of an individual relationship moves beyond the illness to the person and is often the medium for new-found hope on the part of the therapist and the patient (p. 204).

## THE NECESSITY FOR GOALS

### The Goal Setting Process

Psychiatric rehabilitation by its very nature is a goal directed process and as such implies a change in the individual client/patient's current level of functioning which is somehow negatively perceived or experienced. Whether that goal

be symptom reduction, alleviation of stress, an increase in socially appropriate behaviors, maximization of independent living skills, or vocational competence, all goals are contingent upon the validity of the assessment of the particular individual's strengths, deficits, psychopathological symptoms, support systems, natural environment, motivation and ability to change. Goal attainment is ultimately connected with an understanding of the individual with a psychiatric disability regardless of the setting in which the rehabilitation process occurs. As mentioned previously, high and low expectation studies conducted with ex-mental hospital patients, who have subsequently been moved into a variety of residential treatment and vocational programs, have given us some insights about the appropriateness of goals and the congruity of these goals between the individual patient/client and the rehabilitation practitioner (Easton, 1974; Lamb & Goertzel 1972; Loeb, Kaufman, Silk-Gilbran, & Gioe, 1974; Menapace, 1977; Richmond, 1969-70; Wilder, Kessel, & Caulfield, 1968).

In reviewing the literature on halfway houses for psychiatric patients in the community Wilder, Kessel and Caulfield (1968) identified two contrasting rehabilitation approaches to transitional residences. One they labeled "nurturing," which emphasized the "illness" aspects of the residents and the other the "high-expectations" approach, which appeared to be directed at the "health" of the individual (p. 103). Their retrospective study of 42 residents of a high-expectation halfway house in New York revealed that older, better motivated more employable residents, who generally had neither severe adjustment problems with their families nor severe clinical symptomatology, did best in the high-expectation setting. Younger patients, on the other hand, closer to the adolescent onset of their illness, required a separate more structured nurturing environment. In addition, there were those individuals who, having benefited from the residential program, were to successfully return to their families as opposed to living independently. In differentiating the success from the failure group in this study, the authors found the failure group (rehospitalized suicides, inappropriate use of the residence as a manipulative device with significant others) to be younger, with more severe symptomatology, poorer family adjustment, and less motivation to enter the residential program in the first place. The most striking difference between the two groups was in their ability to gain rapid employment (within one month of residence).

The authors cautioned, however, that the use of vocational status as both a predictive variable, the ability to gain rapid employment, and as a criterion for defining success, the ability to gain and maintain employment, is objectionable. Rapid employment can be easily manipulated by a facility that merely requires its potential residents to have been gainfully employed for several weeks while on hospital passes. Forty percent of the residents were rehospIALIZED within a year after entering the residence. This outcome seemed to have been influenced

by the young age, single status, and inability of the group to live either with their family or to make it on their own and made "our sample more vulnerable to rehospitalization than the general population of discharged psychiatric patients" (p. 107). Finally, the study's investigators concluded that the pre-established time limited goal of six months of transitional residence was not appropriate for this population. This finding resulted in the introduction of a nine-month time limit residential goal: "three months to get settled, three months to enjoy it, and three months to prepare for leaving--a true rebirth" (p. 108).

In the Lamb and Goertzel study (1972) which utilized a random assignment of ex-state hospital patients to high or low expectation programs in the community, patients who were assigned to the high-expectation setting were not less likely to be rehospitalized than those in the traditional low-pressure setting. However, the contribution of the high-expectation setting was that of increasing the patient's level of vocational and social functioning. Two years after referral, "one half of the patients in the demonstration group were involved in structured activities more than 90% of the time, either in a vocational capacity or in fulfilling the role of a housewife, while only one in five in the comparison group were so occupied" (p. 134). Those in the demonstration group were also significantly more involved with other people. In terms of long-term and short-term goals progression from a facility where social skills were learned prior to engagement in a vocational program was not particularly effective for many of the long-term patients. In discussing this issue, Lamb and Goertzel reported that many of the residents experienced difficulty in the day treatment center where social and verbal skills were emphasized and appeared to have greater success if they went directly to a structured vocational program where social skills were learned in the vocational setting in the halfway house. "In some cases the expected improvement in social skills did not occur but the client derived great satisfaction from his vocational progress. Most of his gratification in the community and heightened self-esteem may stem from the world of work" (p. 134).

The authors concluded their discussion of the efficacy of such high-expectation programs for persons with chronic psychiatric disabilities with the observation that as "mental health professionals are unable to predict with any degree of consistency which long-term patients will, in fact, benefit from exposure to a high-expectation program.....we feel this kind of program should be offered to all long-term patients entering the community" (p. 135).

A follow-up study was conducted on two groups of clients who had completed a rehabilitation program at Horizon House in Philadelphia, Pennsylvania, those who had retained employment and those who had lost their jobs (Loeb, Kaufman, Silk-Gilbran & Gioe, 1974). The groups did not differ in demographic characteristics: 1) length of last employment; 2) estimated total lifetime employment; 3) length of number of previous psychiatric hospitalizations; 4) duration of program involvement, or type of employment. However, the job retention group differed significantly from the unemployed group in that: 1)

more of them had learned of jobs on their own; 2) their perceptions of job duty or expectations were consistent with employment realities; 3) their satisfaction with their work was greater; and 4) their willingness to inform supervisors and peers of their psychiatric histories was more prevalent.

The results of this study suggest rehabilitation goals which: 1) address the encouragement of more independent job-getting and/or the interpretation of already assured jobs as "still dependent upon the client's initial interview with the 'potential employer'" (p. 170); 2) a rethinking of and more realistic approach towards counseling clients with regard to the sharing of information about their psychiatric involvement; and, finally 3) the need for additional counseling services following program completion to "provide continued support and to assist in the identification and remediation of job-related problems" (p. 171). This last recommendation was predicated on the fact that most of those individuals in the study who left their jobs were "unhappy for a long period before doing so and then typically left with little or no notice" (p. 171). Such results add to our understanding of the goal planning process which must constantly take into account an ongoing process of assessment of current functioning, goal reformulation, and client participation in the goal setting process.

### The Nature of Goals

The goal-oriented rehabilitation process with the client who is psychiatrically disabled is not one smooth, consistent or even progression. Thus, the concept of long-term goals takes an added dimension with this population, which then colors the desired end or outcome. That dimension is time itself. Specifically, the practitioner must take into account not only the "timing" of the steps in the rehabilitation and/or treatment planning process, but also the time required to achieve mutuality of goal acceptance, the time taken up by set-backs in the client's goal attainment, and the time needed for continued, supportive follow-up and follow-along. The dimension of time has a topographical character, with its high points (achievements), plateaus (stabilization and maintenance periods) and low points (regressions, crises, unforeseen complications). Realistic goal planning must of necessity deal with shorter terms, discrete, tangible time-segmented objectives. Otherwise, long-term goals will for all time appear unattainable by both the practitioner and the patient/client.

Having addressed the temporal aspects of the goal-oriented rehabilitation process, it is important to point out, or in some cases reiterate what the reader may have already gleaned from the discussion, certain issues which affect or influence the quality and substance of the goals themselves. Intermittent hospitalization and the need for brief and/or longer-term treatment of the symptomatic characteristics of the illness are realities in the long-term adjustment period of the individual. There are those individuals for whom the attainment of independent living or semi-independent living with the opportunity for a pre-arranged and

structured social support system is an appropriate rehabilitation goal. On the other hand, social skill acquisition, in and of itself, may never be attainable. There may be those individuals who would seem to fair better in protected work-oriented settings where the goal of rehabilitation is the maintenance of their work skills and productivity, which perhaps in a singular fashion would reinforce the individual's self-worth and sense of personal identity. When work is the goal and it is quite obviously not a rehabilitation absolute, preparation for work should be graded and job placement accomplished with the expectation of interruptions and breaks in the employment process. Moreover, "overly vigorous rehabilitation efforts can have negative results with clients who may need 'low-expectation' settings" (Schumacher, 1980, p. 58).

Finally, while what we have said thus far about goals implies a concept of reasonableness or rationality and collaboration in the goal formulation process, goals must also possess a quality of measurability. Goals, in and of themselves, while exceedingly high-sounding, significant and worthy of achievement, tell us nothing about how they are to be attained or as Roger Mager (1972) so aptly remarked "how we will know one when we see one" (p. 11). The patient/client and the practitioner need to have identified patient performances which when summed up result in mutual agreement on goal attainment. Goals, then, which are based on thoroughly assessed problem areas, are contingent upon patient-specific performance measures and practitioner-specific or agency-specific operating procedures or methods. Lastly, they are conceptualized and implemented within a specified time frame, the complexities of which we have previously discussed.

The establishment of goals is at the very essence of the practice of psychiatric rehabilitation. Their implementation and attainment is a vital/function for anyone in the role of a rehabilitation practitioner. Goals for living are inherent in the human condition and as such are essential to the quality of life of persons with psychiatric disabilities.

### SETBACKS IN THE REHABILITATION PROCESS

#### Managing Episodic Illness: Crisis Intervention

"Clinical experience has shown us that most long-term psychiatric illnesses, when viewed in their totality, are episodic in nature. This happens even with continued treatment and compliance with treatment regimes" (Krauss & Slavinsky, 1982, p. 101). These authors adeptly describe the predicament which then faces the rehabilitation practitioner who "must learn to live with uncertainty" (p. 102).

What is meant by uncertainty in this context? Very simply, it means tolerating a lack of understanding about the etiology of chronic illness, about the long-term course of treated chronic illness, about ultimate prognosis, or even about the mechanisms of action of most treatment

techniques. It means...to try something new...creating something new...to assess the effectiveness of a treatment plan, to admit that it is a failure, to reassess, and then start all over again...to admit to oneself that there is a great deal that one does not yet know...admitting to the patient that one doesn't know everything...dismissing the thought of transferring the untractable patient as one's immediate reaction to getting nowhere...It means working very, very hard (pp. 102-130).

With the chronically psychiatrically disabled the intermittent nature of their illness may be viewed in terms of crisis theory. Krauss and Slavinsky (1982) postulate that any change in the life situation of these individuals, whether it involves symptom exacerbation, changes in roles, treatment personnel or issues or environmental fluctuation, etc., which requires additional coping or readjustment on the part of the patient may be considered a crisis. Relief for the immediate stress or prevention of further deterioration are of paramount concern. And, as we have pointed out at an earlier time, the intermittent, episodic nature of a permanent and severe psychiatric disability is not diagnosis specific. That is, it is not only in the case of chronic schizophrenia that the illness is marked by episodes of crises and resultant regression. Several cases will now be discussed which illustrate this point.

One case involved a 20-year-old female with a diagnosis of anorexia and bulimia. This young woman spent the greater part of her childhood in a residential rehabilitation program because of a learning disability and severe acting out behavior which manifested itself in tantrums and physical attacks on other family members, particularly her mother. At the time of her referral to the psychiatric rehabilitation service, she was hospitalized on account of her anorexic condition. Rehabilitation efforts over a two-year period following this hospitalization were directed at vocational planning and family therapy. Over that period of time she was rehospitalized once for acute symptom relief (significant weight loss) and unsuccessfully attempted three separate vocational programs.

Prior to the patient's most recent crisis, this young woman's counselor had shifted focus from vocational planning to more psychotherapeutic issues, involving her emancipation from the role of child and her need to assume a measure of responsibility for her personal behavior. During this time the patient began to disclose previously secreted information regarding her continued physical aggression towards mother and her sexual promiscuity, which had been employed in an effort to establish some sense of self-worth by the patient. Within a period of six-weeks following her last hospitalization she had gained 35 pounds and while still binge-eating she was no longer bulimic. The patient blamed mother for the weight gain, and while both her counselor and family therapist were away for a week's period, tried to have herself again admitted to the hospital. Admission was denied and subsequently the patient cut her wrists, just enough to get herself admitted to a local community hospital. Once there she requested

a transfer so that she could again be placed on a diet in the specific treatment unit she had previously been a part of and where she could be with her friends. In consultation with the counselor, the local hospital agreed not to transfer the patient to her former setting.

Another case involved a 47-year-old married male with a history of alcohol abuse, depression, a seizure disorder secondary to childhood measles and encephalitis and a progressively deteriorating organic brain disease. This individual had been known to the mental health and vocational rehabilitation system over a number of years and had previously been trained as an orderly. He was followed on a regular basis by a psychiatrist for both his medication needs and supportive therapy and was referred several times over a five-year-period for vocationally oriented rehabilitation services. He had been previously arrested for attempted manslaughter and was known to brag about his physical strength ("my hands are lethal weapons") in order to intimidate others whenever he was placed in a new situation that was anxiety producing. In addition, he had problems with excessive profanity in his verbal language, which while partially organically based, would deteriorate further when increased anxiety further limited his voluntary efforts at control.

At the time of his most recent referral to the psychiatric rehabilitation service, the patient had expressed an interest in performing some meaningful activity even if he could no longer return to work. Over the period of three months, the counselor worked out a voluntary position at a local vocational workshop which was of particular interest to the patient and began to prepare him for his initial interview there, with special emphasis on appropriate personal disclosures and statements of bravado. In the meantime, his wife was also seen to help develop job seeking skills, as the patient's disability income was no longer adequate to support the family and his eventual employment became less and less likely.

One week following a very successful "practice" session with his therapist, the patient arrived at his interview for the volunteer position and began by immediately telling the interviewer how he had held a knife to his brother's head when they were children and of the many times he nearly bludgeoned people to death during a fight. Needless to say, the interviewer became terrified and terminated the process. The patient had then regressed under the stress of a new condition to previous maladaptive behaviors and was not able to carry through the successful practice session in the counselor's office to the new setting.

The final case which we will discuss is illustrative of another existential dynamic in the life of a former patient, namely the flight into health. A 40-year-old divorced, Russian-Jewish immigrant with a previously diagnosed schizoaffective disorder was seen by a counselor in the psychiatric rehabilitation program for a period of one year. She entered vocational counseling with aspirations to become a computer programmer. She had been a drafting instruc-

tor in the Soviet Union previously and had on her own, after relocating to this country, completed a computer training program. While she did poorly in the training program, she continued to seclude herself in her room to study computer manuals and proceeded to lose a series of three different jobs as a computer technician in a matter of weeks. Being a proud woman, in addition to secluding herself in her room to study, she also avoided leaving the house or interacting with anyone on a social basis because of her embarrassment at being on welfare.

As counseling continued, however, the patient reformulated her vocational goals and made a decision to enter the barbering profession, having found a mentor who was willing to employ her once she completed barber's school. Arrangements were then made with the local Office of Vocational Rehabilitation to fund her course of study. Over the next several months the patient began to improve her appearance, she no longer hid in her house, and found a part-time job as a manicurist. Feeling much more at ease, self-assured and less depressed, she took herself off of medication to which her primary clinician, unbeknownst to the counselor, acquiesced. Within a few weeks the patient became overtly psychotic, was rehospitalized, and while on the inpatient unit tried to strangle herself.

In all three cases, the rehabilitation counselor would begin again to help restabilize the client, reestablish mutually agreed upon goals, and continue to work with the patient once the crisis state had come under control. At no time did the counselor abandon the patient and in two of the cases reestablished the working relationship during the inpatient stay.

Krauss and Slavinsky (1982) summarize the goals of crisis intervention with the patient with chronic mental illness as follows: 1) symptomatic relief; 2) hope; 3) maintenance in the least restrictive settings; 4) support for family and significant others; 5) stabilizing the course of the illness; 6) growth; and, 7) preventative education. These three cases serve to illustrate the operationalization of these goals. Helping a patient to live with uncertainty while simultaneously helping him/her to gain maximum control over his/her life and illness is one of the most important aspects of the role of the rehabilitation practitioner. "If it is difficult to be the clinician involved in the management of an episodic illness, the difficulty now where approaches that of being the individual who must experience such an illness" (Krauss and Slavinsky, 1982, p. 130). These authors conclude:

Although there may be continued problems and discomfort, it is not the end of the world. Learning to swing with change is a large part of being an adult in our world...Not all anxiety, sadness, or negative feelings are 'bad' for a person. Everyone experiences them. It is always possible to grow... (p. 131).

### Secondary Gains and Psychiatric Illness

In addition to the complexities of working with individuals who have a chronic, episodic illness, two other issues emerge in the process of psychiatric rehabilitation which influence the role of the rehabilitation practitioner, and which can be viewed as setbacks. The issue of disability income maintenance and

the secondary gains to be derived from clinging to the role of a sick person have been addressed by Lamb and Rogawski (1978). The second issue, staff burn-out, has also been discussed by Lamb (1979).

While beneficial consequences for persons with psychiatric disabilities may be derived from a source of income when they are unable to work or support themselves by other means, in some instances the availability of Supplemental Security Income grants have had negative effects in the maximization of the individuals' potential for meaningful and/or productive activity. On the one hand, as Lamb and Rogawski (1978) point out, the change in the name of the funding mechanism from Aid to the Disabled to Social Security Income has had an important effect on delabeling and destigmatizing the funding in the eyes of persons with psychiatric disabilities. In addition, medicaid and food stamps which have been added to the basic federal grant are exempt from taxation. When these benefits are pooled with the resources of another recipient, the standard of living achieved may be greater than the individual could obtain from certain low-paying sheltered employment situations or low-level competitive jobs.

With a move in the recent past by certain states to tighten up grant allocations, numerous psychiatrically disabled clients were among the "abled-bodied poor" who would only be eligible for a three-month period of funding within any calendar year. Having received notices of their grant terminations, many patients appeared at psychiatric rehabilitation services requesting vocational evaluations, training and/or job placement. Within a matter of several weeks to a month, advocates for the disabled had either stopped the process of eligibility determination in some cases or had succeeded in exempting certain disabilities from the review process. The same fear which had motivated these patients to seek vocational services now served to return them to their previous levels of apathy and self-styled security from the pressures of daily existence. Since the current status of the law still contains disincentives for recipients to secure employment, as significant earned income is deducted from their grant, it is up to the rehabilitation practitioner to insure that comprehensive services are available to these clients and that their progress or lack thereof be monitored. It is the recommendation of Lamb and Rogawski that:

If clients react adversely, manifest a recrudescence of symptoms, or seem refractory to active help, the professional should at any time in the process be able to reset their goals and accept the clients' limitations and possibly their need for a passive dependent lifestyle that will make minimal demands on them. With this perspective, professionals will leave the door open to treatment and rehabilitation opportunities in the future. In the meantime, they will offer the patient those services that he can or will accept, including the option to call at times of crisis or great stress (p. 1223).

### Staff Burnout

Wilder and Plutchik (1981) have identified seven key symptoms of staff burnout in the human service field from which they have proceeded to set up a model for burnout prevention based on a needs assessment, a stressors assessment, and a coping assessment strategy. These key symptoms are: 1) decreased job satisfaction, manifested by decreased ideation and enthusiasm and disillusionment; 2) increased negative attitudes, hardening and avoidance in relationships with patients; 3) staff/co-worker relationships characterized by increased irritability; 4) increased discontent and decreased identification with the organization; 5) increased irritability with family members; 6) increased personal maladaptive functioning, including increased negative self-concepts, exhaustion, apathy, denial, hypermania, physical symptoms, drinking, etc.; and finally 7) a decreased standard of job performance, both qualitatively and quantitatively resulting in a feeling of being trapped or a desire to leave the work setting.

While staff burnout may occur in any work setting, the mental health/rehabilitation world of work is particularly vulnerable to this process. And although the patient population varies from setting to setting and no one population group has a corner on the market, those who work with patients with long term and severe mental illness appear to be particularly susceptible to this existential phenomenon. Lamb (1979) has postulated that as the rehabilitation field has become increasingly committed to serving this population, an influx of inexperienced staff with enthusiasm and good intentions have entered the service delivery system who are unprepared to deal with these new consumers of service, and who in a "year or two...lose their enthusiasm...no longer like their contact with long-term patients,...get bored, frustrated, and resentful"....and "worst of all, become ineffective" (p. 396). For Lamb, the major reason for such burnouts has been the failure of mental health/rehabilitation professionals to recognize that the population of the psychiatrically disabled is not a homogeneous one. These patients differ greatly in their motivation and ability to cope with stress, the types of stress and pressures to which they can respond effectively, and the overall life adjustment they can make with respect to vocational rehabilitation goals or primarily those of a psychosocial nature.

Certain concepts about the practice of psychiatric rehabilitation must, therefore, be understood and addressed if the process of staff burnout is to be prevented or at the very least ameliorated. First, "(M)ental health professionals must accept the slow pace at which most long-term patients progress" (Lamb, 1979, p. 396). Patients/clients will "fail" and they will drop out, some for periods of time and others permanently. But this situation is not so different from the reality of life for all individuals whether they be psychiatrically disabled or not. Perfection is simplistic as it may sound, is not a requirement for human existence, and has its unattainable nature ever dettered, in any permanent sense,

the purposeful goal-directed behavior of the human species. Those of us in the field of psychiatric rehabilitation need always to temper our idealism with a certain amount of pragmatic realism which does not in any way serve to make us negativistic or fatalistic, neither for ourselves or for the individuals we serve. Secondly, as Lamb (1979) reminds us, while the theory of normalization is a value for modern day practitioner, for many persons it will only be realized in a limited way.

Some long-term patients may need to live in a sheltered environment that is by its very nature segregated. They may be able to participate only in community activities that are low-key and geared to them and their fellow patients. Their manner and appearance, even with optimal doses of psychoactive drugs and optimal amounts of psychosocial treatment, may set them apart (p. 397).

Such an understanding, however, does not give the practitioner license to collude with the patient in disregarding his ego strengths or to cease in the practitioners' efforts to detect such strengths and the "hidden motivation for growth that often manifests itself in distorted or indirect ways" (Lamb, p. 397). There is an obligation rather to establish realistic expectations of the patient/client and to derive job satisfaction at times from "simply improving the quality of a patient's life rather than increasing his level of functioning"; (Lamb, p. 397). At the risk of offending the high minded reader, a homely analogy has more than once come to the mind of this author. Not all of the summer garden's flowers bloom at the same precise moment; it is the unfolding over time that is most rewarding to the tender and to the observer. And, more often than not, the last rose of the season is the most exquisite single blossom unless prematurely smitten by the chill of winter. While our patients are many times difficult to perceive as beautiful and worthy creations of nature, neither are we the practitioners and professionals in the field so totally disposed.

Thus comes our final comment, which has also been eloquently addressed by Lamb (1979). Those who work in the field of psychiatric rehabilitation "must also become aware of their own motivations for working in the helping professions" (Lamb, p. 397).

To what extent do I get vicarious gratification from my patients' accomplishments or acting out? How much does my sense of being productive depend upon my bringing about significant change in my patients? To what extent am I in this field to get help for myself and to resolve my own problems? How much do I need to have contact with verbal, attractive patients and to be admired and loved by them? (Lamb, p. 397)

Lamb concludes: "A clear awareness of our own motivation and needs can be a crucial factor in preventing later disillusionment or burnout..." (p. 398).

### REGROUPING: THE NECESSITY FOR CARE CONTINUITY

When in the course of the process of psychiatric rehabilitation the practitioner and the client must "begin again" to reestablish goals after a crisis, symptom exacerbation or other major setback, the backbone upon which the success of the regrouping process will be built is the concept of care continuity. Bachrach (1981) has delineated a set of seven dimensions which she sees as necessary to the concept of continuity of care as it applies to persons with chronic psychiatric disabilities. It is this author's contention that if such a conceptualization of caregiving is present in the practice of psychiatric rehabilitation, the regrouping process can occur without bringing about additional stressors and setbacks for the patient/client and the helping person. We will now summarize Bachrach's seven dimensions:

1. Continuity of care has a longitudinal nature, and as such, anticipates and incorporates for the patient his or her needs for intermittent, short-term and longer-term elements of service which are not disconnected because of the nature of the patients' episodic illness.
2. Continuity of care is planned on an individual basis not as a function of the service delivery system into which groups of patients are then fit.
3. Continuity of care is comprehensive in nature and therefore is not the single domain of any single helping profession or support agency.
4. Continuity of care is a flexible process which accommodates the nonlinear progression of the psychiatrically disabled individual.
5. Continuity of care is characterized by the concept of a relationship and whether it be personal or institutional, that relationship means that the patient "is able to rely, over time, on having associations with a person or persons who are interested in him and who respond to him on a personal level" (Bachrach, p. 1451).
6. Continuity of care must incorporate the notion of accessibility in all of its meanings: physical environment, financial, psychological; when accessibility is hampered by the very nature of the person's disability, continuity of care will be predicated on the existence of an enabler who assists the person to gain access to the system.
7. Continuity of care implies and is contingent upon the existence of linkages in the system so that communication between the client and the service providers and among the service providers themselves does occur.

### WORKING THE SYSTEM

Finally, we would like to add an eighth dimension to Bachrach's concept of care continuity. In many ways and perhaps even more so with the population of

persons with psychiatric disabilities, the practitioner must learn to "work the system." A familiarity with the regulations, laws, entitlement programs, appeals process, etc., that affect the world of these consumers is essential for the rehabilitation practitioner. Even if the individual practitioner does not have a level of expertise in the area of legal rights, and/or requirements, knowing what questions to ask and where to turn for the answers are essential functions of the practitioner's role particularly in terms of regrouping. Outside of those individuals who work for one of the state offices of vocational rehabilitation, few practitioners, for example, are aware of Section 501 of The Rehabilitation Act of 1973 (PL 93-112) or Section 402 of The Veterans Readjustment Assistance Act (Cite), both of which provide for an affirmative action program affecting the mentally restored person or veteran. Section 501 deals particularly with Federal Government agencies and their hiring practices and allows for "two special hiring programs for 'mentally restored' individuals" (Russell & Pardes, 1981, p. 5). The role of the rehabilitation practitioner may vary in terms of the quality and quantity of activity levels throughout the rehabilitation process, but at no time is it more necessary to have a surge of energy and renewed commitment to the client than at times of regrouping. And needless to say, this renewed vigor must be accompanied by a sound and useful knowledge base of the systems, within and between which the goal of continuity of care for persons with psychiatric disabilities is either thwarted or accomplished.

### CONCLUSION

In summary, the focus of this final chapter has been on the role of the rehabilitation practitioner in terms of: 1) expectations of the system of service delivery and of the client; 2) the ongoing therapeutic relationship between the rehabilitation practitioner and his/her client; 3) the establishment of realistic and congruent goals with the consumer of services; 4) the setbacks in the rehabilitation process which are inherent in the treatment of a severe, chronic and episodic illness; 5) setbacks that result from the secondary gains which can be derived from the role of being a sick person and from those factors which lead to burnout on the part of the practitioner; and finally, 6) the necessity for a system of care continuity to insure the process of regrouping by the practitioner and the client with a psychiatric disability.

While the various authors who have presented materials in this text, based on their common and unique experiences in the field of psychiatric rehabilitation, do not propose to have all the answers, nor for that matter to have raised all of the possible questions and concerns of those in the field, they have attempted to deal with major areas of concern in a practical and forthright manner. So, too, this final chapter has been this author's perceptions and insights into the role of

the rehabilitation practitioner. This role and its many and diverse functions mirror the complexities and subtleties, unknowns, working hypotheses, and research investigations about the disability itself which results from a psychiatric illness. We in the field must always be open to new knowledge, new ways of doing things, reexamining our current practices, and refining on a continuous basis our skills and abilities. We have no choice in this matter as the very fluid and individual nature of the disability with which we are concerned and the population of individuals which it affects demand such. Psychiatric rehabilitation, when all is said, is a challenge worthy of the commitment, energy, and skill of all who would work in this field.

THE CONCEPT OF MENTAL ILLNESS AND ITS DIAGNOSIS

## THE CONCEPT OF MENTAL ILLNESS AND ITS DIAGNOSIS

Lynda J. Katz, Ph.D.

Historically, the concept of mental illness has been derived from clinical work with individuals who have deviated to some degree from what society in general has regarded as normal or nonpathological behavior, both on an intrapersonal and interpersonal level. The meaning of mental illness, therefore, has been distilled from the theoretical notion of "abnormality," and operationalized across societies and eras in terms of its manifestations in major functions of living. The identification of persons with mental illness has been of concern over the years because of the enormous implications it has for public policy and decision making activities, particularly those concerned with resource allocation and the expenditure of public dollars. It has been estimated that, at a minimum, some two million persons in the United States can be considered to be chronically mentally ill (Goldman et al, 1981). Many have spent the majority of their lives in mental institutions, others have experienced repeated short term hospital stays while remaining in the community (Rutman, 1987). Psychiatric illness ranks fifth among major disease categories contributing to limitations in activity (Kottke et al, 1982), and of those nearly 1.5 million severely and moderately disabled persons with chronic mental illness who reside in the community, some 550,000 receive Supplemental Security Income (Anderson, 1982). Moreover, the number of individuals with psychiatric disabilities amount to nearly 40% of the state vocational rehabilitation agencies' caseloads, nationally, and at the same time, those with chronic and severe mental illness are the least successfully rehabilitated of all disability groups. It has been ascertained also that less than 15% of persons with severe psychiatric disabilities are successfully employed. Thus, decisions

regarding the establishment of priorities (research vs. prevention vs. rehabilitation) and how initiatives under these various priorities will be financed will be directly influenced by the criteria selected to define mental illness and who will be identified as falling under those particular disease category criteria.

In order to understand how the concept of mental illness has been operationalized, it is useful to identify those specific criteria which have been utilized in the process. Scott (1958) summarized those criteria in his review of the field (see Table I below.) Thus, under the first criterion, exposure to psychiatric treatment, anyone who has sought mental health services might arbitrarily be included among those who would be identified under the category, mental illness. If the presence of a psychiatric diagnosis and objective psychological symptoms are the criteria utilized then the number of persons identified lessens and appears to rely heavily upon the medical profession to define the presence or absence of a disease process or illness. In like manner some define mental illness solely in terms of maladaptive social behaviors.

Table 1

**Criteria of Mental Illness**

---

Exposure to psychiatric treatment  
Psychiatric diagnosis  
Objective psychological symptoms  
Social maladjustment  
Failure of positive striving  
Subjective unhappiness

---

Adapted from: Scott, W.A. (1958).

Still others view it as an intrapsychic phenomenon, i.e., anyone who is unhappy

and experiences some kind of psychological difficulty inside him or herself might meet the defining and necessary criterion to be classified as mentally ill. The implication here is that each criterion provides a partial explanation and definition of the term mental illness.

Underlying these criteria of mental illness are four concepts of abnormality which derive from the fields of biological medicine, sociology, psychology, and statistics. Since the definition of mental illness comes from clinicians in an attempt to define current practice, what happens if mental illness is defined under one of these criteria separately? If the clinician's concept of abnormality is based on a biological model, then mental illness is seen as a symptom of an underlying physical abnormality. In this case mental illness would be diagnosed by physicians who work with persons who have physical illnesses and disorders. Implicit is the idea that illness is universal to mankind.

If abnormality is viewed from a sociocultural perspective, i.e., if the clinician believes that the only reason persons are mentally ill is because of poverty, then mental illness is not seen as resulting from an underlying biological dysfunction. Instead it is felt that if people were not so poor, if problems of early nutrition were addressed, or if persons were provided improved access to health care, then there would not be mental illness. The sociocultural concept of mental illness focuses on interpersonal and social behavior. In addition, deciding if particular symptoms are an expression of disease or illness implies a social value judgment. The definition of mental illness results from a judgment regarding the interaction of an individual with his or her environment. Therefore, those designated as having mental illness will vary from society to society and from era to era. Adjustment, then, is

viewed as adherence to social norms. This concept of abnormality makes it difficult to distinguish between mental illness and social deviance or between insanity and criminality. People can commit a crime or break the law, that is, their thinking can deviate from social norms, and yet not have mental illness. Also, as Szasz (1969) has pointed out in his distinction between physical illness and the social role of the patient, within the sociocultural concept of mental illness a person can live and function normally or have nothing wrong and constantly seek help.

On the other hand, the theoretical bias might be that people, for whatever reason, become confused and distressed because they cannot come to grips with who they are and how they relate to the world. In this case, the clinician will stress that intervention takes place at the psychological intrapersonal level. And finally, if a person is interested in epidemiological research, policy administration, or the allocation of funds, he or she may have still another way of defining mental illness, i.e., a statistical or numbers model.

It is important to consider these underlying theoretical biases because they affect and often dictate approaches to treatment. If mental illness is viewed as resulting from social and environmental forces, then concerns will be directed toward changing policy issues, funding, and constraints on personal freedom rather than with the use of medication. The perspective taken by Thomas Szasz (Detre & Jarecki, 1971) illustrates an extreme example of this viewpoint. Although a psychiatrist himself, he takes a dim view of the profession. He believes that there is no biological basis for mental illness and that we label people because we do not know any other way of dealing with them. Others take an even more extreme view. Laing, an English psychiatrist, views the illness of schizophrenia as a form of creativity. He

believes that, in fact, people are not ill at all, but that society has impeded the expression of their own uniqueness (Torrey, 1983).

The first two criteria in Table 1, exposure to psychiatric treatment and psychiatric diagnosis, would be of concern to those involved in epidemiological research or allocating resources. For instance, when studying the use of a particular drug, it is important to ensure that those for whom one drug has been prescribed all have the same diagnosis, based upon symptoms. Similarly, a study concerned with how many social workers, VR counselors, or doctors are needed in the country necessitates an overall sense of how many persons require service from such health professionals. Taken by itself, the first criterion, counseling by a psychiatrist or psychologist, is so broad an interpretation of mental illness that most of us would have problems with it.

Mental illness as defined by current psychiatric practice is a multivariant concept. As such there is no clear distinction between mental and physical illness. If such a distinction were to be made, mental illness might be defined as a value judgment regarding the need for corrective interventions, based upon both the qualitative and quantitative properties of the social and/or psychological characteristics of an individual in the absence of precipitating biophysical abnormalities. However, such a distinction is not justified if, indeed, there are mental illnesses which have a basis in physical abnormality. What we are saying, therefore, is that you can measure the degree of physical fitness, the degree of social adjustment, the degree of subjective distress, and also the degree of severity of distress and seriousness of an illness. So in order to decide whether behavior has some psychiatric significance we evaluate it in terms of three basic bodies of information: sociocultural (environmental), biological, and psychological. These three areas become the

data base.

Environmental determinants of abnormal behavior can be considered at maturity or during development. At maturity, physical or psychological stress caused by life events, frustrations, conflicts, or pressures are thought by the proponents of this view to be causes of mental illness. Some suggest that moon phases, geomagnetic forces, or seasons of the year play a role in abnormality. Sociocultural considerations like urbanization, population density, social attitudes, social class, unemployment, and poverty are often cited as environmental determinants of abnormal behavior. During development, child rearing practices, mistiming of events, under- or over-exposure to necessary events, occurrence of unusual events, prenatal or postnatal events, emotional trauma during childhood, and social isolation at critical periods might all be considered determinants of abnormal behavior.

Psychologists and psychiatrists who adopt the biological concept of abnormality consider mental illness to be like any other illness. They characteristically assume that the primary cause of abnormal behavior is a defect or deficiency in the biological constitution of the individual.

Psychological theories, such as Freud's theory of psychoanalysis, the socially oriented theories of Adler, Fromm, and Sullivan, or Ellis' cognitively oriented theory all consider the primary cause of abnormal behavior to reside within the mind of the individual.

The mental illness of autism provides us with a good example of these three different theoretical biases and the data base from which they are derived. Autism was first described in 1943 by a psychiatrist, Kanner. Psychiatry in America at that time was bound by psychoanalytic thought. The psychiatric community concluded that autism was the result of a poor parent-

child relationship. For whatever reason, a cold, rejecting mother was not able to make her child feel comfortable, loved, and warm. As a result, the child withdrew. (Keep in mind that under a medical model the cause of a disease is important because it can tell us something about how to treat the disease.) If autism is the result of an interpersonal distancing between mother and child (she did not love the child, so the child became cold and withdrawn), then the way to treat the autism is to put the mother in therapy. This helps the mother learn to be warm and loving. The child is also placed in play therapy so that he or she might learn how to become close to or fond of objects. Then, hopefully, the child will become more connected to people; and after 7 years of therapy for both mother and child, the disease is cured. Although this cure did not occur, the treatment continued to be viable for a long time; not out of maliciousness, but because that was all that was known about autism at the time.

The late 1950s and early 1960s brought the development of learning theory and the increased use of behavior therapy. In fact, psychologists so disillusioned with the current expensive but ineffective treatment methods began to suspect something was wrong with the psychoanalytic model. They theorized that autism was a learned response to the environment. Maybe indeed there was some coldness here, but the child learned it. They did not blame the mother anymore. Instead, psychologists suggested that for whatever reason -- maybe by virtue of biological makeup, maybe by virtue of circumstances at the time -- the child had not learned to be responsive. Therefore, the treatment approach was to teach responsiveness. Lovass and his colleagues (1965) began to do behavioral training: that is, teaching skills such as eye contact, how to verbalize, or to be comfortable with hugging. So

here again, the treatment was based on the theoretical basis of the person doing the treatment. That behavior therapy was believed to work for a variety of disorders was based upon an underlying learning theory clinical orientation. Autism was seen as a learned response and the treatment involved relearning more appropriate behaviors.

It turns out that there was some success with this method. Lovass was able to demonstrate that behaviors could be taught but these behaviors were environmentally specific. That is, a child could be taught to attend to a task in the classroom; but if he or she were taken on a field trip, the skills did not generalize. Autism was neither cured nor was the cause discovered. The concern during this era, however, was with changing the behavior not with establishing cause.

This behavioral approach to treatment dominated the treatment of autism until the late 1960s and early 1970s. At that time another theoretical shift occurred in psychiatry and psychology. Professionals again became interested in the biological origins of behavior. Autism was classified as a developmental disability and researchers began to investigate the illness from a genetic perspective. They asked whether there might be some brain chemical, either absent or defective, that caused the illness. Autism, then began to be studied in this way. Because the patients could not generalize learned behaviors it was important to try to understand the nature of, and, if possible, establish the cause of the illness. Research took on a distinct biological perspective. At present there is much work being done with the use of various medications with autistic children because there is evidence to support the involvement of a metabolic or chemical imbalance in the disease process. The origin of some cases of autism have been traced to the Fragile X Syndrome.

At least one out of ten persons who are autistic have a disarranged chromosome, although that same chromosome is known to be responsible for the inheritance of other disorders as well.

What does this mean in terms of treatment? What does conceptualizing autism as a biological disorder have to do with the treatment of persons who have the illness? A great deal of effort is now going into prevention by isolation of the gene or chromosome that is responsible. Researchers are trying to find the source and alter it. At the very least, a prenatal diagnosis gives people an opportunity to decide whether or not they want to take the risk. There are many ramifications of the recent discoveries. They suggest that genetic engineering or a drug developed to affect an identified chemical imbalance might point to a different approach to the treatment of autism. At the same time, however, we have children with autism who still need to be taught, and so behavioral methods have not been discarded but rather incorporated into a multi-factorial view of the disease and its treatment.

#### DEFINITION OF MENTAL ILLNESS

Mental illness cannot be adequately defined from any one theoretical basis. In fact, mental illness is a complex of the biological basis of behavior, the environment in which the person exists, and the innerworkings of each person. Table 2 presents the definition of mental illness used for this discussion. First, in order for an individual to be diagnosed with a mental disorder there must be evidence of social dysfunction on the job, within the family, or in society. Secondly, there must be symptoms of psychological and biological discomfort; that is, distress, discomfort, and pain are involved. And third, it is inferred that disturbances in the mechanisms that regulate mood

and cognition are the basis for the symptoms. This definition encompasses the lowest common denominator of agreement. It includes all those persons whose symptoms are so pronounced that almost any observer would agree they are dysfunctional but excludes those socially competent individuals with a character neurosis whose "illness" some clinicians would dispute.

**Table 2**

**Definition of Mental Illness**

- 
1. Evidence of social dysfunctioning
  2. Symptoms of psychological and biological discomfort
  3. Disturbances in the mechanisms that regulate mood and cognition
- 

Adapted from: Modern Psychiatric Treatment by Thomas P. Detre and Henry G. Jarecki, 1971.

Social dysfunction is probably the least controversial of these three criteria. Even if you do not accept the fact that most mental illness is the result of a biological dysfunction, most people will accept the fact that, if an individual is unable to function in society, he or she has a problem. Social functioning is the result of the complex interplay between an individual's biologic equipment, early life experiences and training, and a given situation at a particular point in time. Parents recognize early on that their infant children are not peas in a pod. Some are placid and quiet while others are irritable or cry for the first 6 months of life. Parts of the personality are present the day a child is brought home from the hospital. We all come into this world with certain traits. We either have good eyesight or we have poor eyesight. We have an easy disposition or we are sensitive and irritable. Next, all of us are exposed to environments that reinforce certain behaviors but not

others. We learn to be aggressive and speak our minds or we learn to keep our mouth shut because it is safer. At some point in life we have to deal with crises and we each do this in particular ways. If we examine social dysfunctioning in depth, we find adaptational deficiencies. All of us come into this world with some things we do better than others. Generally in life, we prefer to put ourselves in situations in which we capitalize on what we do well and avoid those things that we don't do so well.

An individual's adaptational deficiencies determine which events are most likely to disturb him or her and influence the symptoms if he or she falls ill. If a client encounters a situation that requires him or her to react in a way he or she cannot, then the client is likely to become anxious and confused. The more urgent and prolonged the demand and the more poorly developed the biological capacities or social skills necessary for adequate response, the more severe the discomfort is likely to become. Moreover, once illness develops those social skills that were the most poorly established before becoming ill are usually the first to become impaired (Detre & Jarecki, 1971).

The following example illustrates this phenomenon. Alice is a young lady who grew up in an average American family, attended public school, and was an average student. There were never any problems; however, she was not a particularly outgoing person in her growing up years. She had several friends, not many, but was close with her family. Alice and the family did things together most of the time. She was active in the church and in a church social group, did not date often, and would be described in her school yearbook as "Miss Average - She will succeed."

After a few years of business school, Alice took a clerical job in a large company. The job entailed filing, typing, and self-directed work. There was

not much contact with the public. She did not have to do a lot of emergency phone answering or handling crises. The work came in every day and she did it. At the end of the day the work was all done; that day's tasks complete. There was no disorder, things were filed, and the desk was cleared of work on a daily basis. Alice worked faithfully with no problems. She still lived at home, went out to dinner with the family, or occasionally would go out with a friend. Generally, she was a quiet person. Her work performance ratings were always excellent in terms of quality and productivity. She got along with everybody, never causing problems.

One day the chief executive officer's administrative secretary resigns. Since he is a good company person, he decides, "Before I go outside to look for another employee, I think I want to look at our work force, and maybe I can reward someone who has done an outstanding job. Maybe I will promote him or her to be my administrative assistant." He consults with personnel. They look at records, and, lo and behold, there is Alice. Everybody says, "This is a fine employee. The quality and quantity of work and ability to get along with her peers is excellent." She is offered the position. This is a promotion, a real honor, and she accepts.

Most of the time of the administrative assistant of a CEO is spent putting out fires, taking phone calls, placating irate people, scheduling meetings, and handling conflicts. Even if he/she is in the middle of typing a report, the work is put aside, the crisis handled, and the individual goes back to the interrupted task. So our Alice, then, in this new job, has had to give up her routine and orderly way of proceeding. Work starts to pile up as she tries to deal with phone calls, emergencies, conferences, travel arrangements, and unhappy clients.

Alice, like all of us, came into life with some assets and some deficits. Up to this point she has managed to capitalize on her assets. Her first job played on her strengths. She had organizational skills, perseverance, minded her own business, and did very well. Now, however, she is in a position that demands a change in her behavior. She must be extremely flexible, be willing to postpone things, stay after work, come in early, and get things done even though there is too little time. Alice's desk is never organized anymore. She is asked to exist in chaos and yet to be flexible. She must also do things that she has never really practiced much -- talk, be sociable, and smile constantly even if she does not feel like it.

In addition, Alice now has to make arrangements for just about everything. If the boss wants her to pick him up at the airport, she must drop everything and go. Throughout all of this, Alice is becoming anxious and somewhat confused. These feelings build as the situation continues. Some of the symptoms of stress are beginning to emerge. Alice stays later at work. By the time she gets home her stomach is so upset that she does not want to eat. The only thing she wants to do is go to her room. This behavior continues for the first week.

By the second week on the job she is not eating at all. She arrives at work at 5:00 in the morning, not leaving until 7:00 or 8:00 at night. She has no energy left; so even if she wanted to spiff herself up or look nice, she can't. It is all she can do to drag herself in every morning. Her family urges her to go out more. Alice responds, "I don't feel like going out, just leave me alone. You go. I just need to rest."

The third week goes by. She has lost about fifteen pounds and actually has no appetite. Her sleep is becoming disrupted. She is agitated, often

pacing in her room at night. Formerly orderly and compulsive, it takes more energy to keep things in their place; a concern that is becoming more and more important to her. She neglects her appearance. In the morning she does not want to leave home and begins to call up and say, "I can't come into work. I'm ill this morning." She misses a day or two of work. When she gets back, things are piled up even higher because she has missed two days. She gets sick on the job, goes home, and decides, "I can't come in for the rest of the week." Finally, then, she does not want to leave her room. So she does not.

This is an example of the process of social dysfunctioning. To measure its severity one must decide whether or not existing limitations have become more pronounced, whether previous personality problems have become more evident, and whether the symptoms are more numerous or more bizarre. Alice did not really talk to people that much, but now she will not talk to anybody. She is staying in her room. Previous personality problems have escalated. She has lost fifteen pounds. She is not sleeping. She is pacing. She does not want to leave her room. She is doing nothing with the family, and is in danger of being fired from her job due to absenteeism. When someone is in that much distress and we judge the situation to be severe, the next question we ask is, "Must this person have treatment? Must we intervene?"

Treatment is mandated when an individual's illness weakens his or her impulse control, manifests itself in catastrophic social dysfunctioning, is marked by major disturbances in biologic functions, or when one or more of these factors are persistent in time or are progressive in severity. When a person's psychological discomfort endangers his or her life or that of others, or paralyzes his social functioning, treatment is mandatory. Otherwise, it is

not.

Exercise 1: What Would You Say About Alice?

Keeping these things in mind, refer to Table 2. Social dysfunctioning is one of the parameters of mental illness that can be observed. Nobody has to infer it. We do not always have to intervene, however, when persons are under stress. Knowing what you do about Alice, would you be comfortable saying that she meets the definition of mental illness presented?

Here are two scenarios. Scenario one: A month has gone by. Now Alice will not leave her room. The family is so distraught that they call the minister with whom Alice has been close all these years. They say, "Please talk to her. We do not know what else to do. Please talk to her."

The minister, who has training as a pastoral counselor, comes and engages her in conversation; Alice cries and tells him what is going on. They work through it. He reminds her, "Well, there are other ways to get promoted. I know you want everybody to be proud of you, but you were doing a wonderful job until you changed positions."

She dries her eyes and agrees, "You're right. I'm going to go back, and I'm going to ask to go back to my old job. Or I'll just get a job someplace else. Maybe I'd like to continue to talk to you."

Scenario two: The minister comes and goes through this same process, but with no impact whatsoever. Alice does not talk. She just cries, wrings her hands, paces the room off and on but does not talk.

Now, given those two sorts of outcomes, would one of those make you more comfortable in saying that she meets the criteria for the definition of

mental illness presented? The point is that sometimes it is difficult within given circumstances to distinguish the difference between a transitory adjustment reaction to a stressor and mental illness. The variables that are probably most important in this determination are those of severity and duration. First, how severe are the symptoms; second, how long do they persist? Is there deterioration of biological functions that are life-threatening or at the very least, harmful to physical health with no relief or remission in sight? If so, we can be fairly sure that we are dealing with mental illness.

Now you can make some speculations and test your hypothesis. The minister tried talking to her. It did not do any good. Alice did not improve. Next, it may be that her family takes her to a psychiatrist who takes a history and prescribes medication. When a client is in need of sustained biological interventions, you have further evidence that the episode is not transitory, reactionary, and will not respond solely to psychological interventions.

Persons who are seen as suffering from a severe mental illness are not those with adjustment disorders or those having an adverse reaction to stress. The persons we work with in the vocational rehabilitation system are those who, for some reason, have very real and sustained functional limitations which result in their inability to adequately evaluate their own strengths and assets; they have never developed coping mechanisms; and their pattern of social dysfunctioning has continued for many years.

## THE USE OF DIAGNOSIS

Ultimate proof that psychopathology exists must lie in the successful treatment of abnormal behavior. In medical specialties generally, successful

treatment is considered to be dependent upon the recognition of the cause of the disease or illness under study. Before looking for a cause of a particular dysfunction or disorder, that dysfunction or disorder must be isolated, however crudely, and it must be recognized and differentiated from other symptoms. This effort has led to the classification of mental illnesses or the identification of different types of diseases and disorders and their relationships to each other. Classification involves a logical way of putting together the symptoms to help us decide exactly with what syndrome or group of symptoms we are dealing. We do this so that we know what to do about the symptoms and so that we can predict the course of the illness, response to treatment, and which intervention strategies might be most effective. Diagnoses or classifications are not negative data but rather they provide a basis for better educated understanding of individuals who present with specific symptoms. For instance, if we take someone into a rehabilitation setting who has a cyclical illness, we have to build that fact into the rehabilitation plan. Recurring illness does not have to be seen as failure.

A way to classify diseases and symptoms is necessary to insure that all professionals are talking about the same thing. If I say this person has schizophrenia, you all would know and agree, as much as possible, that this was true. Why is that important? It is important because if the client were on inappropriate medication or none at all, it would have dire consequences to his or her functioning. If the client does not understand his or her illness, this also could have serious implications. The diagnosis tells something about the coping mechanisms of the client and what kind of support systems have to be built into the rehabilitation process. If the counselor knows that there is the potential for impaired judgment to exist in persons with schizophrenia, or

that these persons might have problems confiding in others or using support groups, then they can apply this knowledge in terms of rehabilitation planning.

What is classification then? It is the process of reducing complex phenomena by arranging them into categories according to some pre-established criteria. The classification of mental illness can be seen as a filing system for the easy handling of data, as a means of facilitating communication among professions, and as a means of labeling entities to establish categories and to unify certain relationships among different categories. In psychiatry, such

## THE DSM-IV DIAGNOSTIC SYSTEM

Lynda J. Katz, Ph.D.

Diagnostic and Statistical Manual, Fourth Edition, (DSM-IV), is one of the two major classification systems used today. The other is the ICD-9-CM, the International Classification of Diseases, 9th Revision, Clinical Modification. While the DSM-IV is not a Bible, so to speak, it is a useful tool; and its revisions since 1979 (DSM-III) speak to the dynamic nature of the diagnostic process. It is helpful in enabling us to conceptualize mental disorders in order to proceed with appropriate treatment interventions.

The DSM-IV like its predecessors, DSM-III and DSM-III-R, is based on a five-axial model of diagnosis, a model which attempts to bring together all of the theoretical concepts discussed previously regarding our understanding of mental disorders. Since there is no etiological position adopted with the Manual, persons who are either dynamically, biologically, or behaviorally trained can still agree on the diagnostic formulations contained therein.

The definition of a mental disorder contained in the DSM-IV remains the same as that presented earlier. Specifically, each of the mental disorders is conceptualized as:

- (1) a clinically significant behavioral or psychological syndrome
- (2) that occurs in an individual

- (3) which is associated with present distress or disability or with significantly increased risk of death, pain, disability or an important loss of freedom
- (4) not merely an expectable and culturally sanctioned response
- (5) a manifestation of a behavioral, psychological or biological dysfunction, whatever its original cause
- (6) not merely a conflict with society (1994, p. xxi-xxii).

Hence, the five axes of the DSM-IV present a compromise statement that infers dysfunction in one or more areas. A mental disorder is associated with distress or disability. Why the "or"? Because, a person could have a bipolar disorder, manic episode, and hardly be distressed. Most people who are in a state of mania are really quite happy to be there. It is fun for a time to be euphoric and on top of the world. We can hardly call that distress; but in fact, it is a disability in the sense that running out and charging \$10,000, making inappropriate statements on the job, or being overly aggressive could get the person in trouble. The criterion "not only a conflict with society" addresses those cultures that label persons as crazy or deviant if they do not go along with or accept the prevailing social ideology (previous Soviet Union, as an example). There was an awareness that persons who differed from the mainstream might be labeled as mentally ill. Finally, a mental disorder occurs in individuals, not in groups, as in group hysteria or in a particular religious cult. If we are going to use the label mental disorder, the DSM-IV requires that it must occur in individuals.

The definition of mental illness is on the one hand very inclusive and, on the other hand, very exclusive. If you look at

those criteria listed previously, you can understand why homosexuality or an alternative lesbian life style, once considered to be mental disorders, can no longer be classified as such. They do not meet the criteria. Homosexuality does not have to be associated with distress, and it certainly does not have to cause a disability. So in DSM-IV as in DSM-III and DSM-III-R, homosexuality does not meet criteria for inclusion into the diagnostic manual as it did in DSM-II.

On the other hand, learning disabilities were not previously considered to be mental disorders. Now, why were they added? The diagnosis of a specific learning disability in no way conflicts with the criteria used to define a mental disorder. Persons who work with children and childhood illnesses were very much concerned that learning disabilities be included in the Diagnostic Manual. Giving this disability a medical diagnosis recognizes it as a legitimate disability. In terms of the rehabilitation system, that legitimacy has significant consequences for service delivery. Before LD was recognized by DSM-III, it was not considered a medical disability by the Rehabilitation Services Administration. In 1980, after it was incorporated into DSM-III, it was then considered by RSA as a legitimate medical diagnosis in terms of eligibility for VR services.

The DSM-IV is based on a multi-axial model that is concerned with five major categories of assessment:

Axis I      Clinical Disorders  
              Other Conditions that may be a focus of clinical

	attention
Axis II	Personality Disorders — Mental Retardation
Axis III	General Medical Conditions
Axis IV	Psychosocial and Environmental Problems
Axis V	Global Assessment of Functioning

In the words of the DSM-IV: "The use of the multiaxial system facilitates comprehensive and systematic evaluation with attention to the various mental disorders and general medical conditions, psychosocial and environmental problems, and level of functioning that might be overlooked if the focus were on assessing a single presenting problem" (p.25). It is recognized that having a psychiatric disability or disorder does not preclude a physical illness. The staff in general hospital emergency rooms have often told persons with a psychiatric history "There's nothing wrong with you. It's in your head. Go home". In reality, some persons with chronic mental disorders show a high incidence of physical disorders.

Axis I and II. Axis I and II comprise the entire classification of known mental disorders. All mental disorders except personality disorders and mental retardation are listed on Axis I. These are noted on Axis II so that their presence might not be "overlooked when attention is directed to the usually more florid Axis I disorders" (p. 26).

Multiple diagnoses are allowed. In other words, a person could have several diagnoses under one axis, with the principle diagnosis generally listed first. Provisional diagnoses can be made; the clinician is permitted to say, "I'm not sure. I think this might be the case." Usually, admitting to unsureness is the

safest route. In addition, there are provisions for specifying the severity and course of the various disorders and whether they are recurring.

**Axis III.** This axis includes any current general medical condition relevant to the understanding or management of the individual. These medical conditions do not have to be related to the psychiatric disorder (but some may be), but they are relevant to the treatment of the person. When a mental disorder is judged to be "a direct physiological consequence of the medical condition, a Mental Disorder Due to a General Medical Condition should be diagnosed on Axis I and the general medical condition should be recorded on both Axis I and Axis III" (p.27).

If a patient/client has schizophrenia and diabetes, it is extremely important to know that in terms of their treatment. We know, for example, that drug metabolism is highly effected by general body metabolism and that noncompliance with medications is often a problem among individuals affected by the negative effects of a schizophrenic disorder.

**Axis IV.** Psychosocial stressors are addressed here. Psychosocial stressors may affect the diagnosis, treatment and prognosis of mental disorders. "A psychosocial or environmental problem may be a negative life event, an environmental difficulty or deficiency, a familial or other interpersonal stress, an inadequacy of social support or personal resources, or other problem relating to the context in which a person's difficulties have developed" (p. 29, DSM-IV). When, on the other hand, the

psychosocial or environmental problem is the primary focus of clinical attention, it is also recorded on Axis I with a code derived from the section of the DSM-IV manual dealing with "Other Conditions That May Be a Focus of Clinical Attention"(P. 675).

Determining how to proceed with treatment interventions for Axis IV problems may well involve determining the chronic vs acute nature of the problem as well. For example, an unemployed male client might talk about his other problems. He might say, "Yesterday, I was living in a supervised apartment. I got in a fight with my roommate and I was told that I have to be out of my apartment by Friday". He continues, "Before I became ill, you know, before I had to be hospitalized, I was married and I have kids. My visitation rights were taken away because I was abusive, but I'd like to be able to get to see my kids again. It's important to me. My wife keeps fighting me on this in court". If a clinician were trying to determine what to attend to first, he/she could weigh the chronic vs acute nature of the stressors and then proceed with an action plan. In this case, the first concern would be with housing.

Axis V. The clinician assesses the client's psychological, social, personal, and occupational functioning on Axis V in terms of overall level of functioning. The Global Assessment of Functioning Scale (GAF) is used for this purpose. This instrument can be used to rate the individual's current level of functioning at the time treatment is initiated and then later at discharge. It can also be used as a measure of premorbid

functioning as one prognostic indicator. A copy of the GAF Scale is attached.

## Global Assessment of Functioning (GAF) Scale

Consider psychological, social, and occupational functioning on a hypothetical continuum of mental health–illness. Do not include impairment in functioning due to physical (or environmental) limitations.

**Code** (Note: Use intermediate codes when appropriate, e.g., 45, 68, 72.)

- 100 Superior functioning in a wide range of activities, life's problems never seem to get out of hand, is sought out by others because of his or her many positive qualities. No symptoms.
- 91 Absent or minimal symptoms (e.g., mild anxiety before an exam), good functioning in all areas, interested and involved in a wide range of activities, socially effective, generally satisfied with life, no more than everyday problems or concerns (e.g., an occasional argument with family members).
- 80 If symptoms are present, they are transient and expectable reactions to psychosocial stressors (e.g., difficulty concentrating after family argument); no more than slight impairment in social, occupational, or school functioning (e.g., temporarily falling behind in schoolwork).
- 71 Some mild symptoms (e.g., depressed mood and mild insomnia) OR some difficulty in social, occupational, or school functioning (e.g., occasional truancy, or theft within the household), but generally functioning pretty well, has some meaningful interpersonal relationships.
- 60 Moderate symptoms (e.g., flat affect and circumstantial speech, occasional panic attacks) OR moderate difficulty in social, occupational, or school functioning (e.g., few friends, conflicts with peers or co-workers).
- 51 Serious symptoms (e.g., suicidal ideation, severe obsessional rituals, frequent shoplifting) OR any serious impairment in social, occupational, or school functioning (e.g., no friends, unable to keep a job).
- 41 Some impairment in reality testing or communication (e.g., speech is at times illogical, obscure, or irrelevant) OR major impairment in several areas, such as work or school, family relations, judgment, thinking, or mood (e.g., depressed man avoids friends, neglects family, and is unable to work; child frequently beats up younger children, is defiant at home, and is failing at school).
- 31 Behavior is considerably influenced by delusions or hallucinations OR serious impairment in communication or judgment (e.g., sometimes incoherent, acts grossly inappropriately, suicidal preoccupation) OR inability to function in almost all areas (e.g., stays in bed all day; no job, home, or friends).
- 21 Some danger of hurting self or others (e.g., suicide attempts without clear expectation of death; frequently violent, manic excitement) OR occasionally fails to maintain minimal personal hygiene (e.g., smears feces) OR gross impairment in communication (e.g., largely incoherent or mute).
- 11 Persistent danger of severely hurting self or others (e.g., recurrent violence) OR persistent inability to maintain minimal personal hygiene OR serious suicidal act with clear expectation of death.
- 0 Inadequate information

The rating of overall psychological functioning on a scale of 0–100 was operationalized by Luborsky in the Health-Sickness Rating Scale (Luborsky L: "Clinicians' Judgments of Mental Health," *Archives of General Psychiatry* 7:407–417, 1962). Spitzer and colleagues developed a revision of the Health-Sickness Rating Scale called the Global Assessment Scale (GAS) (Endicott J, Spitzer RL, Fleiss JL, Cohen J: "The Global Assessment Scale: A Procedure for Measuring Overall Severity of Psychiatric Disturbance," *Archives of General Psychiatry* 33:766–771, 1976). A modified version of the GAS was included in DSM-III-R as the Global Assessment of Functioning (GAF) Scale.

## Examples of How to Record Results of a DSM-IV Multiaxial Evaluation

*Example 1:*

Axis I	296.23	Major Depressive Disorder, Single Episode, Severe Without Psychotic Features
	305.00	Alcohol Abuse
Axis II	301.6	Dependent Personality Disorder Frequent use of denial
Axis III		None
Axis IV		Threat of job loss
Axis V	GAF = 35 (current)	

*Example 2:*

Axis I	300.4	Dysthymic Disorder
	315.00	Reading Disorder
Axis II	V71.09	No diagnosis
Axis III	382.9	Otitis media, recurrent
Axis IV		Victim of child neglect
Axis V	GAF = 53 (current)	

*Example 3:*

Axis I	293.83	Mood Disorder Due to Hypothyroidism, With Depressive Features
Axis II	V71.09	No diagnosis, histrionic personality features
Axis III	244.9	Hypothyroidism
	365.23	Chronic angle-closure glaucoma
Axis IV		None
Axis V	GAF = 45 (on admission) GAF = 65 (at discharge)	

*Example 4:*

Axis I	V61.1	Partner Relational Problem

# Decision Trees for Differential Diagnosis

The purpose of these decision trees is to aid the clinician in understanding the organization and hierarchical structure of the DSM-IV Classification. Each decision tree starts with a set of clinical features. When one of these features is a prominent part of the presenting clinical picture, the clinician can follow the series of questions to rule in or rule out various disorders. Note that the questions are only approximations of the diagnostic criteria and are not meant to replace them.

The Psychotic Disorders decision tree is the only one that contains disorders that are mutually exclusive (i.e., only one disorder from that section can be diagnosed in a given individual for a particular episode). For the other decision trees, it is important to refer to the individual criteria sets to determine when more than one diagnosis may apply.

**ASSESSMENT**

## FUNCTIONAL ASSESSMENT

Gregory T. Slomka, Ph.D.

Traditional forms of assessment have generally been directed at native ability or capacity, ie., measures of inherent ability. This reflects a psychometric tradition in testing which was established in the 1950s. Measures of general ability such as intelligence and aptitude tests have been increasingly questioned in regard to their ability to predict outcomes with specific clinical populations. Over the years questions have been raised regarding the significance of scores on psychometric tests and their capacity to predict the ability of persons having disabilities to survive in the community.

It was perhaps within the traditions of services for persons diagnosed with mental retardation that this question was most poignantly raised. Traditional assessment with this population relied heavily upon evaluation of formal intelligence with little consideration of other factors. With mandates for least restrictive treatment alternatives and the development of community based treatment services came an awareness of glaring discrepancies in the ability of traditional assessment technologies to aid in treatment and service planning. An anti-psychometric movement, in conjunction with the burgeoning development of "behaviorism," arose within some quarters of the field of the developmental disabilities. Central in this regard was the criticism that traditional testing led only to the generation of generic labels, ie., "Moderate Mental Retardation." Assessment solely for diagnostic or classification purposes was viewed as counterproductive, since it showed little benefit in advancing the predictive potential of individual habilitation efforts.

Within this zeitgeist, we saw the emergence and subsequent development

of a radically different assessment technology, that of functional assessment. In only a few years over 125 functional assessment instruments were developed. These instruments purported to increase treatment planning efficacy by refocusing the assessment upon a pragmatic evaluation of individual strengths and weaknesses that a client might show in his or her adaption to specific environmental contexts. At this point, we tended to see dichotomous camps of those who held rigidly to "traditional assessment" and those who ignored this source of data only to focus on outcome measures of adaptive skill competency. In their landmark overview text Mental Deficiency (Clarke and Clarke (1976)), offered an alternative approach toward evaluation.

S.1

Table 1 summarizes their definition of "assessment" which unified aspects from both camps. Central to this model is the recognition of the need to combine

Table 1

#### **An Integration of Traditional and Functional Assessment Approaches**

---

Assessment ...

- 1) Describes an individual at a particular point in time in terms of intellectual, social, emotional, educational, and allied variables with reference to a normative or contrast population.
- 2) Predicts performance of an individual at a future point in time.
- 3) Provides a profile of assets and deficits in order to determine the starting point for further intervention.
- 4) Provides an objective means to monitor progress over time.

---

From: Clarke & Clarke, 1976.

assessment technologies so as to develop an appreciation of client need "in toto."

The field of psychiatric rehabilitation has also seen an evolution of a functionally based system of assessment. The literature has reflected that in

terms of outcome traditional psychodiagnostic assessment methodologies did not correlate with eventual vocational outcome, community adjustment, or with the elucidation of skills requisite for overall community adjustment. A high degree of individual variability can frequently be seen among individuals sharing the same diagnosis. Ratings of personal, social, and work adjustment have, however, correlated highly with eventual client outcome. These ratings also have helped to describe how individual differences affect outcome.

A goal of psychiatric rehabilitation is to assure that an individual with a psychiatric disability can perform those skills necessary to live, work, and learn in his or her community with the least amount of support. Persons with psychiatric disabilities must be able to perform certain functional skills in order to maintain themselves independently in the community or to become re-integrated into the community at large. This is accomplished through two mediums: 1) teaching clients the skills necessary to function as independently as possible, and 2) developing community and environmental resources necessary to support or strengthen functioning if clients fall short of independence. Functional assessment methodologies provide not only a basis for individual prescriptive treatment planning, but also offer a means of addressing various systems-related concerns, such as evaluating intervention effectiveness, monitoring outcomes, and planning for anticipated needs.

The remainder of the discussion will focus upon a further elaboration of functional assessment issues as they pertain to individuals with chronic mental illness. The need to rely not upon any single modality for assessment, but to incorporate functional assessment methodologies into a larger framework of comprehensive evaluation will be emphasized throughout this discussion.

## THE DEFINITION AND USES OF FUNCTIONAL ASSESSMENT

Simply defined, functional assessment is the measurement of what a person can and cannot do. That is, the elucidation of behavioral strengths and weaknesses as they relate to particular goals. It is undertaken to aid in determining the impact of physical and mental impairments on behavior.

S.2

Functional assessment offers a broad range of potentially useful information in the treatment of persons with chronic mental illness. A comprehensive functional assessment allows for

S.3

- a) the specification of both abilities and limitations in terms of self-care and instrumental skill functions;
- b) the identification of the presence or absence of social and interpersonal skill deficits and strengths;
- c) the identification of remediation, training, or compensation techniques; and
- d) the identification of educational, vocational, and community support needs.

Strategies utilized in the process of functional assessment vary considerably both in terms of methodology and content. These strategies include both formal and informal techniques. In terms of informal techniques, the presenting background history and psychological test results provide a rich source of antidotal information which is pertinent to the formation of impressions about functional skill integrity. In particular, psycho-educational, medical, and psychological test reports that provide expanded discussion of pertinent observations about performance, as well as scores, can be quite helpful. Third party reports of functional abilities are an additional resource which may be acquired from family members, professional colleagues, or others

S.4

knowledgeable about the client's skills. These types of information can often serve as a springboard for the development of more formalized assessment techniques. Caution is raised, however, regarding the use of information acquired in this fashion because such information lacks objectivity.

## THE METHODOLOGIES OF FUNCTIONAL ASSESSMENT

Within the context of "formal" functional assessment, rating scales or questionnaires are often considered in the forefront, as these are the most prevalent and readily available techniques. They represent, however, but one methodology available for use in functional assessment. Table 2 presents four distinct models which can be applied to the functional assessment process.

S.5

Table 2

### Methods of Functional Assessment

---

Behavioral Interviewing

Direct Observation

Self-Observation

Checklists, Questionnaires, and Rating Scales

---

**Behavioral Interviewing Techniques.** In this methodology, the patient is asked to provide a direct or personal description of assets, deficits, and possible excesses in terms of critical behaviors. Some interviewers utilize a structured interview schedule; that is, all clients assessed would be screened across the same set of questions. Other practitioners are far less structured and utilize behavioral interviewing techniques within the context of a more open-ended, problem-centered interview. There are even recommended

assessment methodologies, such as those associated with the Vineland Social Maturity Scale, in which a formal questionnaire (rating scale) provides the basis for an interview. The interviewer does not simply ask a respondent to rate behavior item by item, but rather seeks descriptions of client ability across varied settings, and then utilizes this information to later rate and quantify items on the behavioral questionnaire.

Many clinicians favor the behavioral interviewing methodology for a number of obvious reasons. It "personalizes" the assessment experience and increases the personal role of the client in treatment planning. Critical behavioral issues can be immediately explored in terms of a hierarchy "What"... "When"... "Where"... and "How" so as to obtain knowledge of contingencies and reinforcers that may maintain or preclude specific behaviors. Behavioral interviewing also lends itself to refocusing the client upon phenomenological issues, i.e., what he or she may be doing, thinking, and feeling in specific situations. This process facilitates opportunities for the client to gain insight into those factors which may be contributing to his or her current condition. Finally, in such a process the patient is in an excellent position to aid in hierarchically organizing the "strengths" and "needs" lists. The prioritization of intervention goals becomes a personalized experience for the client. For the clinician, factors which might interfere with such a process become immediately recognized and can become the object of further counseling intervention.

**Direct Observation Techniques.** One of the most potent means available for functional assessment is the direct observation methodology. Here the client is directly observed "in vivo" or in simulated experiences and his or her

behavior is critically evaluated. A good example of this can be seen in the work of the occupational therapist. In order to assess lunch making skills, the client can be taken to an equipped kitchen facility and directly observed across a number of variables which include planning, organization, technique, and outcome. Although direct observation represents both the most valid and reliable means of behavioral assessment, it is also the most costly in terms of manhours.

Typically, we would be more likely to rely on time-sample event recording when using this methodology. Within a particular setting, at specified time intervals, specifically objectified behaviors can be observed in terms of presence, absence, frequency, duration, or intensity. In this fashion, multiple staff members could assume some responsibility for observation and recording of relevant data, thus making the process less labor intensive. Handbooks of behavior therapy are usually replet with examples of how direct observation and recording techniques can be implemented to evaluate behavior. It is often staff ingenuity that leads to novel approaches toward this type of assessment.

**Self-Observation Techniques.** A related, but frequently ignored methodology, borrows many of the time- or event-sampling techniques of observational strategies, but uses the client to monitor the identified behavior. At specified time intervals, for example, the client stops, makes a behavioral "check," and enters data. These techniques are particularly valuable for cumulatively monitoring behavior over protracted time periods. Personal attention to appearance and hygiene represent a category of behavior well suited to this technique. In addition, log books, diaries, and event counters (frequency tallies) might be utilized. Central in this methodology is the

opportunity for the client actively to self-monitor behavior. In many persons with chronic mental illness, the deficit in the ability to self-monitor represents a primary impediment toward gaining greater social and community acceptance. The greater assimilation on the part of the client of critical self-appraisal of performance rather than reliance on third party evaluations offers an important barometer of autonomy and potential for success in independent living.

**Checklists, Questionnaires, Rating Scales.** Functional assessment inventories offer a number of distinct advantages in terms of feasibility, breadth of coverage, and economy of application. A number of instruments have been developed and applied across diverse treatment settings. They vary considerably in terms of length and breadth of coverage. In this paradigm, various behaviors are evaluated for presence-absence, quality, frequency, etc. They exist in a number of forms. Ratings may be provided by third parties familiar with the client, such as staff or family. Equivalent forms exist where the client rates his or her own behavior as well. There are instruments which focus exclusively around limited aspects of adaptive functioning, such as vocational skill competencies or self-care skills, while others provide more global ratings across a number of disparate behavioral categories. The attached Appendix provides reference to a diverse sampling of functional rating scales applicable across a number of patient groups. Despite the apparent diversity and availability of standardized rating scales, there remain a number of practical limitations associated with their use. Practitioners frequently report lack of sufficient specificity of the material sampled in comparison to the environmental contexts in which their clients function. An instrument

S.6

S.7

S.8

might under- or over-sample particular categories of behavior. Those which provide quantitative scores based on normative standardization frequently suffer from restrictive parameters associated with the reference population. A classic example of this is seen in the application of the prototypical functional inventory which is used with persons who are mentally retarded, the Adaptive Behavior Scale. The normative base for this instrument was clients who were institutionally served as opposed to clients who were served in community based programs. Although one of the most frequently cited assessment instruments in use with this population, it remains restricted in its normative application to only institutionally served clients.

Despite these limitations, the rating scale methodology serves a very valuable function in initial case management and service planning by providing a checklist for identification of the presence/absence of critical skills. In terms of aiding in monitoring treatment or service intervention, rating scales and checklists can serve as a base for pre- and post-intervention measures of performance and thus serve as outcome measures. The ideal instrument would offer not only an indication of the "presence or absence" of critical skills, but also the provision of scales which permit objective rating of the frequency of occurrence of targeted skills and the severity of behavioral deficits or maladaptive behaviors. As the development of inventories becomes more refined, we should see improvements particularly in this latter direction.

There remains yet another alternative for the practitioner of functional assessment, that of the development of unique, environmentally or programatically specific instrumentation. A sampling of standardized inventories can be taken in association with an inventory of critical behaviors important in a specific environmental context. Agency or program specific rating scales can

then be developed. Such measures can be utilized to develop targets for programmatic intervention. It is also quite reasonable to attempt local normatization of such instruments, or to attempt development of criterion validation. An example of this might be that 80% of clients who scored above a specific rating scale score were also successful in transferring to a higher level of programming, it may become reasonable to develop as a treatment plan goal for other clients the attainment of a similar score as an indication of readiness for advancement. Here we see evidence of an instrument not only identifying targets for intervention, but also serving as a criterion measure in a treatment plan.

#### **GENERAL PRINCIPLES OF FUNCTIONAL ASSESSMENT**

Regardless of the methodology utilized for obtaining information regarding client assets and liabilities there are certain general principles which can be applied in conducting the assessment and extending this information into generalizations appropriate for treatment or service planning. Cohen and Anthony (1984) provide a number of practical recommendations in this regard. We have taken a number of these principles, which are shown in Table 3, and expanded upon them. Adherence to these principles helps to assure that functional assessment will be both meaningful and practical.

S.9

**Table 3**

**The Principles of Functional Assessment**

---

Functional assessment needs to relate to an overall rehabilitation goal that is environmentally specific.

The language of functional assessment must be behaviorally defined.

Functional assessment is always individualized.

Functional assessment must be comprehensive.

Functional assessment requires active client involvement.

Functional assessment should focus on strengths as well as deficits.

Functional assessment requires that the client and the evaluator understand both present and anticipated needs.

---

From: Cohen & Anthony, 1984.

**Functional assessment must relate to an overall rehabilitation goal that is environmentally specific.** The objective of assessment is to gain an understanding of the client's assets and liabilities as they relate to skill demands that are likely to be confronted within particular environments. The needs of the client may vary significantly across the settings in which he or she functions, i.e., the residential, the vocational work place, the educational, or recreational. Assessment must, therefore, be "context specific". The evaluator cannot presume that a strength or deficit observed in one environment will necessarily translate across varied boundaries. A central problem we confront in dealing with persons with long term mental illness is the possibility that skills may not generalize across contexts. It is therefore important for the evaluator to consider actively the number of domains in which a particular behavior might have to be assessed. This principle further

S.10

S.11

reinforces the concept of "ecological validity" discussed earlier.

Environmental specificity is also significant because it is this feature which distinguishes functional assessment from more traditional forms of psychometric assessment. Traditional psychological assessment provides a general description of cognitive performance and personality. This description is gathered within the context of a unique social and environmental circumstance--the consulting room. Inferences are drawn and generalized to the broader environment based upon objective results and impressions. Traditional psychological assessment does not, however, provide an opportunity to assess either behavior as a function of the environment in which it occurs or to extend generalizations by specifying how behavior may differentiate across environments. Functional assessment, however, offers a means to assess behavior with "situational specificity." It thereby offers an excellent medium by which to expand upon the results of more traditional assessment methodologies. Utilization of both types of assessment is, therefore, highly recommended.

The language of functional assessment must be behaviorally defined. A "skill" represents a set of behaviors that are both observable and measurable, and therefore, "teachable." If we as evaluators are going to translate successfully observations of client performance into statements which program staff can act upon, we must convey this information in objective terms. If we are going to attempt to monitor client change, our observations must be in terms which are measurable. The "Rule of the five W's" is an aid in conceptualizing behavior in this fashion. Behaviors must be defined by WHO is performing it, WHAT behavior is the focus of the intervention, as well as by the circumstances associated with the behaviors -- the (WHERE, WHEN, and with

S.12

S.13

S.14

S.15

WHOM). These statements are advanced "positively" and in a language of "doing." Expectations for both the client and support personnel are clearly delineated in terms of issues of "personal responsibility."

**Functional assessment is always individualized.** Each client carries with him or her a unique and distinct phenomenology which sets him or her apart from every other individual. Too often the utilization of a stereotyped approach to behavioral assessment and treatment planning results in the re-application of "pat" formulations of problems and interventions. Too rigid an adherence to a mechanistic formulation of skill deficits that does not take into account "personal" variables can result in glaring failure. Clients are not "black boxes" that respond to stimulus-response hierarchies.

S.16

Let us take an example of a not infrequent behavioral problem or symptom, enuresis. The sudden emergence of this problem in a client recently transferred to your program could signal any one of a number of possible underlying etiologies that would influence eventual treatment. So often in "behaviorally oriented" functional assessment there is a tendency to view outcome behavior to the exclusion of potential cause. In this case, the behavior manifested could have its basis in a functional etiology, i.e. anxiety related to transfer. From a psychodynamic perspective enuresis could represent regression to more primitive behavior in the face of weak ego defenses that have been challenged. From a behavioral perspective this same symptom could represent a manifestation of "learned helplessness" that was previously displayed when the client was confronted with uncertainty. A complex alternative set of hypothesis could be derived if we consider medical causes. Could uresis be a function of the sudden onset of diabetes, which is

often accompanied by increased urinary frequency? What about the possible neurological causes, such as normal pressure hydrocephalus? Finally, we must also consider yet another factor ever present when serving neuropsychiatric populations. The side effects of medication must be evaluated. This example sets the stage for the next principle of functional assessment.

**Functional assessment must be comprehensive.** It could be argued that this principle relates not only to the breadth and scope of the assessment methodology, per se, but also to the overall status of the client. That is his or her physical, emotional, social, and cognitive status. The above example highlights the fact that functional assessment does not occur in a vacuum. The active consideration of other assessment data accrued through multidisciplinary means is essential before embarking on treatment.

S.17  
S.18  
S.19  
S.20  
S.21

This principle has other important implications. Assessment needs to occur across multiple environments. A comprehensive functional assessment also provides for the development of a data base. This data base allows for the construction of short term and intermediate range goals which are built sequentially into more global, long term goals. Such sequential planning is frequently facilitated by organizing the items in a functional assessment inventory into developmental sequences that reflect the normal order of the attainment of more complex behaviors.

Developing a comprehensive functional assessment means it is necessary to go beyond the assessment of pragmatic physical skills, i.e. meal preparation, grooming, handling public transportation. Behaviors must be cast in light of the emotional and intellectual status of the client because problems in these spheres can significantly negatively influence skill acquisition.

**Functional assessment requires active client involvement.** The extent to which the client is actively involved in the processes of both assessment and treatment planning enhances the probability that he or she will understand "what" will be required and "why". At first glance this may seem obvious. There is, however, a significant issue which relates to persons with long term mental illness and the problem of motivation. Indeed, special effort may have to be given to engaging the client in the assessment and planning process. Active incorporation of the client into treatment planning can aid in "empowerment". The better attuned the client becomes to what is required of him or her and, more importantly, to why it is required, the chances for successful rehabilitation increase.

S.22

**Functional assessment should focus on strengths as well as deficits.** Our ultimate objective is to delineate what the client can as well as cannot do. Often, assessment personnel can slip into a tendency to overfocus on the identification of skill deficits. Functional deficits frequently noted in persons with chronic mental illness include the following:

S.23

S.24

- impairment of abstract attitude
- concrete thinking
- inability to make generalizations
- misinterpretation of spoken, written language
- failure to attend
- lack of motivation
- failure to persist in tasks

- lack of eagerness at work
- inability to get along with others
- lack of initiative
- psychomotor abnormalities
- disturbance of memory and learning
- slow to process information
- difficulty in categorizing and organizing input

An important aspect of rehabilitation intervention, however, is the identification of areas of residual strength. Frequently it is upon these areas that the therapeutic intervention can be built in order to "remediate" or "compensate for" deficits. It is also important to note that persons with long term mental illness often readily develop a negative self-focus. Anticipation of failure can be a significant stumbling block. The identification of residual strengths can become an important source of therapeutic benefit for certain clients. The development of an improved self-image through this process then influences more positive motivation toward program goals.

**Functional assessment requires that the client and the evaluator understand both present and anticipated needs. Rehabilitation effort is understood as a "process" that is ongoing. So, too, must evaluation be understood. The practitioner must assume the perspective, "Where is my client currently; where does he or she need to be in the immediate and long term future?"** As indicated previously, it is critical that efforts be directed toward a superordinate goal. Assessment and intervention provide the bridges to span the gaps between the client's current status and intended outcomes. The process runs smoothly to the degree that both the client and practitioner

S.25

agree upon realistic goals and methods. Comprehensive functional assessment provides a valid basis for the decision making regarding intermediate goals which build logically toward more extended goals.

By considering the principles outlined above we can further refine our definition of functional assessment. According to Lawton (1971) functional assessment refers to "any systematic attempts to measure objectively the level at which a person is functioning in any of a variety of areas such as physical health, quality of self-maintenance, quality of role activity, intellectual status, social activity, attitude toward the world and toward self, and emotional status (p. ). Conceived in this fashion, functional assessment as a methodology offers an approach to the central question confronted by service providers: How may I help my clients/patients who have chronic impairment to achieve maximum quality of life and independence in daily activities?"

At its simplest, functional assessment represents a means to describe abilities. Our goal as service and treatment providers is to develop a performance oriented data base or profile of our clients. From this profile problems and needs are mutually identified, interventions are planned, and long term goals are developed. Periodic re-evaluation across these performance measures provides the means to quantitatively ascertain progress toward the attainment of long term goals. In effect, functional assessment data provides a foundation of data relevant for many types of both case management as well as treatment related services.

If one adopts the recommendations described above for conducting any type of functional assessment, that is, behaviorally defining skills and needs in terms that are observable and measurable and following the "rule of the

five W's", one has the groundwork available for the ready translation of raw data into prescriptive treatment plans.

We emphasize that functional assessment remains only one spoke in a more intricate wheel. Each client presents unique physical and biological endowments, cognitive strengths and weaknesses, affective characteristics, and interpersonal skills. The failure to assess instrumental community based adult daily living (ADL) skills or vocational skills against the backdrop of the aforementioned variables can lead to complications. We have attempted to convey the need to develop service planning only after comprehensive evaluations are complete. The most successful rehabilitation strategies are those which are built upon the client's existing skills, talents, and resources.

### **SPECIAL FUNCTIONAL IMPAIRMENTS IN POPULATIONS WITH CHRONIC MENTAL ILLNESS**

The development of knowledge about how psychopathology is uniquely manifested across various syndromes is one function of the DSM-III-R classification system. We must, however, look beyond mere description and further examine how various symptom constellations impact daily functioning. The symptoms themselves can represent significant impediments to adaptive functioning. We will begin with a consideration of the psychoses and consider potential repercussions of such symptoms on performance. Delusions, hallucinations, and fantasies interfere with performance by blocking or diverting attention from reality demands. Autistic preoccupation significantly interferes with the ability to attend to or respond to interpersonal cues from the world at large. These symptoms are the most obvious, florid, and immediately disabling. They are, however, the symptoms which respond most

S.33

S.34

immediately to neuroleptic medications.

There are a number of more residual secondary symptoms which can be manifested even in the face of controlled Schneiderian First Rank Symptoms. Social isolation can reflect itself in anxiety or in severe interpersonal discomfort in social situations. Diminished attention to grooming and hygiene or the improper modulation of behavior in public may negatively influence social acceptance. Oddities in speech and mannerisms might further exacerbate this. Suspiciousness associated with paranoid ideation can radically affect factors such as response to constructive criticism. Subtle thought disorganization and impaired judgement and reasoning can negatively influence complex problem solving. The person who deals with the environment successfully possesses the ability to interpret social cues and react within the boundaries of normal social convention. It can be readily seen, therefore, that psychotic symptoms alone or in combination can seriously interfere with adaptive functioning.

We can also associate functional limitations with the symptoms accompanying the affective disorders. Depression, for example, conveys impressions of dysphoric mood and diminished performance ability. Clients vary significantly in the degree to which neurovegetative (sleep, appetite, and arousal state) symptoms are manifested. Fatigue and decreased energy can radically affect performance level on the job or in educational arenas. These symptoms may dissipate or they may remain chronically refractory in some patients, thus having long term repercussions. We are now also increasingly recognizing the "cognitive" as well as the affective repercussions of depressive disorders. Severe impairment in occupational efficiency, memory and concentration, and practical problem solving can occur and can be more

functionally debilitating in the workplace than the mood disturbance.

We have only briefly highlighted the "functional" ramifications of symptoms in order to emphasize the need to assess their impact upon a client's "everyday functioning." It is indeed relevant to take the individual symptomology associated with any DSM-III-R major psychiatric disorder and attempt to conceive its impact upon the client in the domains as seen in Table 4. The breakdown of symptom related problems into such subsets is one means of further understanding their specific impact and then individualizing potential intervention or compensatory strategies.

Table 4

S.35

**Sub-sets of Symptom-Related Problems**

---

Sensory-perceptual disturbance

Cognitive disturbance

Language related disturbances

Praxic (motor) disturbance

Disrupted executive functions

---

There is further advantage to maintaining a symptom-related focus while conducting functional assessment. Once symptoms and problems are clearly defined with this population, it is important to identify the factors which maintain them. Here we are emphasizing the need to understand the etiological underpinnings of problematic behavior from a biopsychosocial perspective. Treatment efforts should follow as a function of the identification of casual determinants. Psychological factors related to genetic, metabolic, and physical abnormalities may require primarily pharmacological

models of intervention. To the degree that psychosocial factors may influence the course of a disorder (onset, exacerbation, relapse and chronicity,) behavioral and social interventions will be more appropriate. In this case the clinician would focus more specifically on the antecedent and consequent events that maintain problematic behavior. Frequently, it is a combination of both treatment strategies that is required.

### **BEHAVIORAL ASSESSMENT STRATEGIES**

We will focus next on how environmental factors can be more specifically examined to assess their influence on behavior. The practitioner engages in intensive analysis of the factors that support and maintain problematic behavior. Many resources are available which describe the principles of applied behavioral analysis. This discussion will touch briefly on only four important components of the process: the understanding of the **SETTING** in which the behavior takes place, the **FREQUENCY** or **DURATION**, and the **ANTECEDENT** as well as the **CONSEQUENT** influences.

S.36

**Setting.** The first functional assessment principle discussed by Cohen and Anthony (1984) focused on the need for environmental specificity. The first critical question to be answered is, "In what situations does problematic behavior occur?". In the home? ... At work? ... In public places? ... In isolation? One attempts to establish how generalized or situationally specific the problematic behavior may be. This indicates how complex and focused the resources associated with intervention must be. For example, will the strategies utilized in the Job Club be the same as those applied in the residential program?

**Frequency.** It is next important to ascertain the frequency or intensity of the problematic behaviors. Not only must we be interested in how frequently problematic behavior occurs, but also in the relative severity. A low frequency severe behavior problem such as self-abuse occurring once or twice a week would be considered more critical for intervention than a high frequency obsessive-compulsive behavior problem that is quite innocuous, such as hand wringing.

**Antecedent influences.** One next focuses on antecedent conditions. What led up to the behavior in question? Antecedent events are rich and complex in their presentations and cover a number of spheres beyond the "behavioral" one that is most commonly conceived. A few examples are seen in Table 5.

S.37

**Table 5**

**Antecedent Events that may lead to Problematic Behavior**

---

<u>EVENT CATEGORY</u>	<u>EXAMPLE</u>
Cognitive	Impulsive cognitive set, failure to appreciate full ramifications of action
Affective	Feeling dysphoric on a particular day
Interpersonal	Low self-esteem with overreaction to ridicule
Situational	Repeat of same circumstances encountered last week
Imaginary	Fantasy of worst case scenario - "I'm sure I'll fail."
Biological	Lack of sleep the night before, and forgot morning medications

---

Any one or a combination of these factors could trigger problematic behavior. The practitioner's job is to delineate isolated (infrequent) antecedent events from those which are encountered more frequently and tend, therefore, to sustain the problematic behavior.

**Consequence.** The consequence of a behavior affects its frequency, duration and intensity. Consequences serve to strengthen, weaken, or extinguish a problematic behavior. The "art" in applied behavioral intervention centers on the ability to grasp the nuances of the reinforcement hierarchies that shape behavior. Simply defined, reinforcers are environmental consequences which increase the probability a preceding behavior will occur or be learned in the future. In populations of persons with chronic psychiatric disability, an important function in rehabilitation is one of propogating a set of new, socially appropriate reinforcers to help sustain desired behaviors.

## BEHAVIORAL EXCESSES, DEFICITS, AND ASSETS

S.38

One can well imagine at this point that a comprehensive assessment of a person with a long term chronical mental illness could result in the identification of multiple problematic behaviors. The practitioner is faced with numerable issues which have the potential to positively or negatively impact behavior in a particular program. One means of dealing with this potential "information overload" is to reframe behaviors in the context of excesses, deficits, and assets. In this fashion, the most problematic negative behaviors are identified (the deficits and excesses), while at the same time the focus of the client is also directed toward his or her assets. These assets represent

"building blocks." By "keying" on assets, adaptive behavior can be strengthened and problematic behavior displaced.

Behavioral excesses represent maladaptive behaviors that occur at rates or intensities so high that they interfere with normal adaptive functioning. Handwashing, a routine activity, becomes pathognomic in the patient with obsessive-compulsive disorder when it occurs 50 times a day. Behavioral deficits represent necessary behaviors that occur with insufficient frequency, inadequate intensity, or in an inappropriate form. The "negative symptoms" of clients having schizophrenia are representational of this class of deficits. Behavioral assets include the social competencies, coping efforts, skills, interests, and abilities of the client, as well as his or her available social supports.

Moving beyond the simple identification of "strengths and needs" one needs to translate outcome goals to specific behavioral categories that will become the object of treatment intervention. This is readily seen in the following example. A middle aged male with a chronic history of refractory schizophrenic symptomology is discharged from a state hospital to your care. He presents with very good social-conversational skills. His delusions, however, remain quite chronic. He becomes self-absorbed with their content, particularly when he is alone or idle. He spends greater than 70% of every idle hour engaged in "self-talk." Lower rates of reported delusional references are reported when he is engaged in social activities. When information is reported and structured in this fashion, it becomes readily apparent what strategies you might immediately consider regarding intervention.

We will address one further point in this regard-- the need to train ourselves to refocus our assessments on identification of assets. It becomes

increasingly easy to slip into a cognitive set in which we focus primarily on analysis of client deficits. We are repeatedly reminded to focus on assets from a number of quarters. You have noted that even in DSM-III-R diagnostic formulations there is an emphasis on assets or a documentation of "the highest level of adaptive functioning". In conducting functional assessments one should attempt to develop an "Inventory of Assets." We emphasize the need to go beyond the simple listing of strengths as might be ascertained from an adaptive behavior rating scale. The inventory should include an analysis of the supplemental information that can be derived from interview, collection of records, and review of history, all of which make this information more situationally relevant. The following questions can be used to organize this information:

1. What are the areas in which the client has consistently functioned best now and in the immediate past?
2. What does my client view as his or her most significant asset?
3. What is the extent of his or her available resources in terms of interpersonal and social supports?
4. What agencies and helping professionals are available to be mobilized in his or her behalf? With whom are there established favorable relationships?
5. What personal motivations and incentive to change have been identified?
6. What are the positive aspects of my therapeutic alliance with this client?

When we move beyond the simple listing of "assets" to considering their implications in terms of "systems related issues" that are pertinent to the

client's support, we have laid a foundation for the transfer of this information into viable recommendations for service or treatment.

### THE NESTED SKILLS APPROACH TO ASSESSMENT AND TRAINING

We will offer one final strategy to be incorporated in the methodologies of functional assessment recommended as appropriate for use with this population. Critical in the rehabilitation of the individual with long term chronic disability is the question of whether or not the client can be trained and carry out routines of behavior. Our lives do not consist of carrying out discrete, isolated behaviors. Rather, our behavior reflects intricate routines and sub-routines organized in a complex interdependent fashion. Groups of actions are organized to meet the environmental demands with which we are confronted.

S.39

Up to now we have only spoken of functional assessment and intervention strategies occurring in a unitary or discrete fashion. Are they present or absent? How frequently do they occur? A more critical question centers on the ability of the client to carry out complex multi-step operations and integrated actions. How effective is he or she in adapting behavior in the face of conflicting or changing environmental demands. How complex a routine is he or she capable of carrying out?

Let's consider an example taken from the assessment of self-care skills associated with early morning routines. Typically we would assess component skills associated with the discrete activities involved, i.e., toileting, washing, shaving, toothbrushing, grooming, dressing. When we think of our own behavior, we quickly realize how we rely upon "routines" in conducting such activities. It is frequently the case that we could assess our client and find

him or her fully competent when asked to perform appropriately each isolated activity. Missing in this limited analysis, however, is the evaluation of the degree to which the client can self-initiate and self-monitor these activities. Specifically, is he or she self-motivated to perform this sequence of activities daily? Are there breakdowns in the sequence such that day to day they are completed in "hit or miss" fashion? Are some behaviors initiated appropriately, but haphazardly carried out? Clients facing the consequences of long term chronic mental illness typically have not lost the basic skills in conducting such activities, but have developed deficiencies in the "executive functions" which relate to planning, organizing, or maintaining such activities. Although this is perhaps an overly simplistic example, one can extend the analogy to some of the complex behavioral expectancies we impose on our clients. We must be mindful of breaking our assessment and training strategies into formats that permit a determination of how well the client can proceed through multi-step and sequential operations. Critical in this regard is the question, "Can the client consistently maintain these sequences?". We will frequently find that we do not have to engage in skill acquisition training, as much as we have to refocus on developing strategies that will aid the client in the more effective use of the self-monitoring, judgement, and reasoning skills needed to maintain daily routines.

## RESOURCE MANAGEMENT

Once the functional assessment has been conducted and goals identified, resources must be inventoried and organized before proceeding with the rehabilitation plan. The client and counselor must actively consider the required resources which will have to be brought to bear in program

implementation. This relates to multiple factors such as time, money, agencies, facilities, or transportation. There will need to be a delineation of who will assume the responsibility to carry out individual aspects of the plan. A comprehensive assessment of the client's capacity to carry out complex behaviors as highlighted above should aid greatly in determining the degree to which support will have to be extended in various areas. This support, in turn, will facilitate the client's maximum participation in the rehabilitation process.

## SUMMARY

An overview of principles associated with functional assessment has been provided. An attempt was made to highlight a variety of methodologies available toward this end. Within this context, special considerations were advanced which related to the assessment needs of clients having chronic psychiatric disability. We return to the comments made at the beginning of this presentation. Functional assessment was conceived as an important tool to supplant limitations associated with more traditional testing for treatment planning. We would hope that the practitioner utilizing the functional assessment technologies described above not only incorporates them wisely, but also extends the general philosophy of assessment which has been advanced. In a truly comprehensive approach toward assessment, adoption of a functional approach toward testing provides a definition of the client's: 1) information processing style, 2) cognitive strengths and deficits, 3) problem solving skills, 4) coping resources, 5) personality style, as well as 6) strengths and weaknesses in environmentally specific skills that pertain to his or her residence, work, and social milieus.

S.40

Functional assessment represents not a mechanistic approach to problem identification via the pat administration of behavior rating scales, but rather it represents a philosophy which can be adapted toward more traditional forms of medical, psychological, and social casework assessment strategies as well. Indeed, this philosophy can be adapted to any evaluation which attempts to contribute to the understanding of how the quality of life and independence of a client with chronic mental illness can be furthered.

We will now conduct an exercise which helps illustrate a number of the points we made in this presentation.

## PSYCHOSOCIAL SUMMARY

Client Name \_\_\_\_\_

Evaluator \_\_\_\_\_

## CRITICAL SKILLS CHECKLIST

Client name \_\_\_\_\_ Evaluator \_\_\_\_\_

ID Number \_\_\_\_\_ Agency \_\_\_\_\_

Date \_\_\_\_\_

**INSTRUCTIONS:** Circle the appropriate category indicating how well each of the following critical skills are performed according to the definition key below:

Very Poor (1) - skill performance is very poor or absent

Poor (2) - skill performance is poor or inconsistent at best

Adequate (3) - skill performance is adequate (meets current needs)

Good (4) - skill performance is good (effective, consistent/efficient)

Superior (5) - skill performance is highly satisfactory (particular strength)

No (N) - cannot be determined; skill performance in need of further evaluation

The Environmentally Specific Comments section is used to specify environmental and behavioral parameters in summarizing skill performance, i.e., quantity: frequency, duration, consistency, reliability; quality: thoroughness, accuracy, desirability, expediency, efficacy; and level of independence: level/frequency of supervision, prompting. Comments here should further elucidate client strengths which may be capitalized upon, as well as deficit areas which may be targeted for intervention.

Specify the environment for which this assessment was completed: \_\_\_\_\_

**A. LANGUAGE/COMMUNICATION**

- engages in every day conversation 1 2 3 4 5 N
- understands verbal commands, directions 1 2 3 4 5 N
- responds to nonverbal contextual cues 1 2 3 4 5 N
- expresses needs & feelings 1 2 3 4 5 N

Environmentally Specific Comments:

---

---

---

**B. MEMORY AND LEARNING**

- recalls basic environmental information (names, address, telephone and Social Security number, simple directions) 1 2 3 4 5 N
- remembers appointment times and schedule of activities 1 2 3 4 5 N
- recalls long-term information (work or educational history) 1 2 3 4 5 N
- comprehends written materials 1 2 3 4 5 N
- learns from hands-on experience 1 2 3 4 5 N
- learns from verbal instructions 1 2 3 4 5 N

Environmentally Specific Comments:

---

---

---

**C. ATTENTION/CONCENTRATION**

- sustains attention to aurally presented information 1 2 3 4 5 N
- sustains attention to task at hand 1 2 3 4 5 N

Environmentally Specific Comments:

---

---

---

**D. PROBLEM SOLVING AND CONCEPTUALIZATION**

- makes reasonable decisions 1 2 3 4 5 N
- formulates a plan 1 2 3 4 5 N
- carries out a plan 1 2 3 4 5 N
- generalizes a concept across settings 1 2 3 4 5 N
- responds to constructive criticism 1 2 3 4 5 N

Environmentally Specific Comments:

---

---

---

**E. DAILY LIVING**

- attends to personal hygiene (shower, shampoo, deodorant) 1 2 3 4 5 N
- uses a telephone 1 2 3 4 5 N
- engages in leisure time activities 1 2 3 4 5 N
- reads a newspaper 1 2 3 4 5 N
- budgets money 1 2 3 4 5 N
- plans a nutritionally balanced meal 1 2 3 4 5 N
- prepares meals adequately 1 2 3 4 5 N
- shops for personal items 1 2 3 4 5 N
- uses public transportation 1 2 3 4 5 N
- accesses necessary resources (Social Security, Medical care, etc.) 1 2 3 4 5 N

Environmentally Specific Comments:

---

---

---

**F. SELF APPRAISAL AND JUDGMENT**

- evaluates severity of external stressors 1 2 3 4 5 N
- copes with mild stress 1 2 3 4 5 N
- seeks support if unduly stressed 1 2 3 4 5 N
- verbalizes relevant and appropriate personal goals 1 2 3 4 5 N

Environmentally Specific Comments:

---

---

---

**G. STAMINA AND TOLERANCE**

- tolerates a 6-8 hour workday 1 2 3 4 5 N
- lifts objects 35-50 lbs 1 2 3 4 5 N
- traverses 100 yards without fatigue 1 2 3 4 5 N

Environmentally Specific Comments:

---

---

---

**KEY:**

- 1 = Very Poor
- 2 = Poor
- 3 = Adequate
- 4 = Good
- 5 = Superior
- N = In need of further evaluation

## FUNCTIONAL ASSESSMENT

Gregory T. Slomka, Ph.D.

### Slide 1.

#### ASSESSMENT (Clarke & Clarke, 1976)

- 1) Describes an individual at a particular point in time in terms of intellectual, social, emotional, educational, and allied variables with reference to a normative or contrast population.
- 2) Predicts performance of an individual at a future point in time.
- 3) Provides a profile of assets and deficits in order to determine the starting point for further intervention.
- 4) Provides an objective means to monitor progress over time.

### Slide 2.

#### FUNCTIONAL ASSESSMENT

A MEASURE OF WHAT A PERSON CAN OR CANNOT DO  
(STRENGTHS/WEAKNESSES) IN PARTICULAR SITUATIONS AND IN  
LIGHT OF PARTICULAR GOALS AND OBJECTIVES

Slide 3.

RATIONALE FOR FUNCTIONAL ASSESSMENT OF CMI INDIVIDUALS

- 1) PROVIDES INFORMATION ON SPECIFIC ABILITIES AND FUNCTIONAL LIMITATIONS.
- 2) IDENTIFIES THE PRESENCE OF SOCIAL/INTERPERSONAL DEFICITS.
- 3) IDENTIFIES LEARNING STYLES AND EFFECTIVE COMMUNICATION TECHNIQUES.
- 4) IDENTIFIES REMEDIATION AND COMPENSATION CONSIDERATIONS.
- 5) PROVIDES INFORMATION REQUIRED FOR PLANNING AND ACCOMMODATION TO CHANGE.
- 6) IDENTIFIES EDUCATIONAL AND TRAINING NEEDS.
- 7) IDENTIFIES JOB PLACEMENT NEEDS.
- 8) IDENTIFIES COMMUNITY SUPPORT NEEDS.

Slide 4.

SOURCES OF FUNCTIONAL ASSESSMENT DATA

- DIAGNOSTIC INFORMATION
- TEST RESULTS
- QUESTIONNAIRES AND SURVEYS
- DIRECT OBSERVATIONAL TECHNIQUES
- CLIENT SELF MONITORING
- CLIENT INTERVIEW
- SIGNIFICANT OTHERS
- HISTORICAL INFORMATION
- PRACTITIONER COLLABORATION

Slide 5.

METHODS OF FUNCTIONAL ASSESSMENT:

- BEHAVIORAL INTERVIEWING
- DIRECT OBSERVATION
- SELF-OBSERVATION
- CHECKLISTS, QUESTIONNAIRES, AND RATING SCALES

Slide 6.

FUNCTIONAL ASSESSMENT INSTRUMENTS

FUNCTIONAL ASSESSMENT INVENTORY (FAI)

PERSONAL CAPACITIES QUESTIONNAIRE (PCQ)

PATIENT'S ASSESSMENT OF OWN FUNCTIONING INVENTORY (PAOFI)

REHABILITATION INDICATORS (RIs)

Slide 7.

SCALES IN THE FUNCTIONAL ASSESSMENT INVENTORY  
(FAI) GROUPED ACCORDING TO APPARENT CONTENT

<b>Motor</b>	<b>Psychological and intellectual</b>
Upper extremity functioning	Learning ability
Hand functioning	Judgment
Coordination	Memory
Ambulation or mobility	Literacy
Motor speed	Language functioning
Capacity for exertion	Perceptual organization
Endurance	Persistence
Speech	Work habits
	Consistency of behavior with rehabilitation goals
<b>Social and biographical</b>	Accurate perception of disability
Effective interaction with people	
Personal attractiveness	
Skills	<b>Sensory</b>
Work history	Vision
Absence from work due to treatment or medical problems	Hearing
Stability of condition	
Social support system	<b>Environmental</b>
	Access to job opportunities
	Economic disincentives
	Acceptability to employers

Slide 8.

SAMPLE RATING SCALES OF THE FAI

**Functional Limitations Scale No. 10: Endurance**

- 0 -- No significant impairment
- 1 -- Can work full day with rest periods arranged
- 2 -- Can work only about half-time
- 3 -- Unable to work for more than 1 or 2 hours a day

**Functional Limitations Scale No. 13: Judgment**

- 0 -- No significant impairment
- 1 -- Sometimes makes unsound decisions: doesn't take time to  
consider alternative or consequences of behavior
- 2 -- Frequently makes rash or unwise decisions; often displays  
inappropriate behavior or choices
- 3 -- Could be dangerous to self or others as a result of foolish  
or impulsive behavior

**Functional Limitations Scale No. 27: Work History**

- 0 -- No significant impairment
- 1 -- Has little or no work experience due to youth or other reasons acceptable to most employers
- 2 -- Work history includes such negative aspects as frequent tardiness or frequent job changes with periods of unemployment
- 3 -- May have periods of unemployment as great as 5 years; references when available are poor

**Strength Items**

- Has an unusually attractive physical appearance
- Is extremely bright, or has an exceptional verbal fluency
- Is extremely motivated to succeed vocationally

Slide 9.

**FUNCTIONAL ASSESSMENT PRINCIPLES  
(COHEN & ANTHONY, 1984)**

**FUNCTIONAL ASSESSMENT NEEDS TO RELATE TO AN OVERALL REHABILITATION GOAL THAT IS ENVIRONMENTALLY SPECIFIC.**

**THE LANGUAGE OF FUNCTIONAL ASSESSMENT MUST BE BEHAVIORALLY DEFINED.**

**FUNCTIONAL ASSESSMENT IS ALWAYS INDIVIDUALIZED.**

**FUNCTIONAL ASSESSMENT MUST BE COMPREHENSIVE.**

**FUNCTIONAL ASSESSMENT REQUIRES ACTIVE CLIENT INVOLVEMENT.**

**FUNCTIONAL ASSESSMENT SHOULD FOCUS ON STRENGTHS AS WELL AS DEFICITS.**

**FUNCTIONAL ASSESSMENT REQUIRES THAT THE CLIENT AND THE EVALUATOR UNDERSTAND BOTH PRESENT AND ANTICIPATED NEEDS.**

Slide 10.

**FUNCTIONAL ASSESSMENT MUST RELATE TO AN OVERALL REHABILITATION GOAL THAT IS ENVIRONMENTALLY SPECIFIC.**

Slide 11.

AREAS IN WHICH ADAPTIVE FUNCTIONING MIGHT BE ASSESSED

SELF-CARE

HOUSEKEEPING

LEISURE

PERSONAL BUSINESS AND FINANCE

CONSUMER ACTIVITIES

SCHOOL

WORK

SPECIAL EVENTS

Slide 12.

FUNCTIONAL ASSESSMENT REQUIRES THAT SKILLS AND  
DEFICITS BE BEHAVIORALLY DEFINED.

Slide 13.

WORKER ROLE KNOWLEDGE AND SKILLS

- APPROPRIATE VOCATIONAL GOAL
- ADEQUATE KNOWLEDGE OF VOCATIONAL OPTIONS
- APPLICATION SKILLS
- INTERVIEW SKILLS
- CLIENT/CO-WORKER INTERACTIONAL SKILLS
- CLIENT/SUPERVISOR INTERACTIONAL SKILLS
- ADEQUATE KNOWLEDGE OF WORKER ROLE REQUIREMENTS

Slide 14.

FUNCTIONAL COMMUNITY SKILLS

- TRANSPORTATION SKILLS
- FUNCTIONAL ACADEMIC SKILLS
- SELF-CARE SKILLS (HYGIENE, NUTRITION)
- USE OF MONEY
- MANAGEMENT OF PERSONAL AFFAIRS
- MEDICAL CARE

Slide 15.

SOCIAL AND COMMUNICATION SKILLS

- FACE TO FACE COMMUNICATION
- SOCIAL INVOLVEMENT
- LEISURE AND RECREATION
- TELEPHONE SKILLS
- ABILITY TO MEET PEOPLE
- ABILITY TO "GET ALONG" WITH OTHERS

Slide 16.

EFFECTIVE FUNCTIONAL ASSESSMENT IS ALWAYS INDIVIDUALIZED.

Slide 17.

FUNCTIONAL ASSESSMENT MUST BE COMPREHENSIVE.

Slide 18.

VOCATIONAL FUNCTIONING AND POTENTIAL

THE DEGREE TO WHICH A CLIENT DEMONSTRATES CAPACITY TO APPRAISE REALISTICALLY HIS/HER OWN VOCATIONAL POTENTIAL AND TO EXHIBIT PHYSICAL AND EMOTIONAL ENDURANCE NECESSARY TO ACHIEVE VOCATIONAL OBJECTIVES

Slide 19.

ECONOMIC INDEPENDENCE

THE DEGREE TO WHICH THE CLIENT CAN FUNCTION  
INDEPENDENTLY IN SOCIETY WITHOUT RELIANCE ON PUBLIC  
SUPPORT FOR INCOME AND SOCIAL SERVICE

Slide 20.

PHYSICAL FUNCTIONING

THE DEGREE TO WHICH THE CLIENT DEMONSTRATES THE  
CAPACITY FOR REDUCTION OF SYMPTOMS, IMPROVED PHYSICAL  
TOLERANCE, DEVELOPMENT OF PRACTICAL COMPENSATORY  
MECHANISMS, AND INCREASED ENDURANCE

Slide 21.

PSYCHOSOCIAL FUNCTIONING

THE DEGREE TO WHICH A CLIENT DEMONSTRATES SOCIAL AND  
PSYCHOLOGICAL ADAPTABILITY WHICH SERVE TO ENHANCE  
FEELINGS OF SECURITY, ADEQUACY, FUNCTIONAL CAPABILITY,  
EMOTIONAL STABILITY, AND SOCIAL INTERACTION

Slide 22.

FUNCTIONAL ASSESSMENT REQUIRES ACTIVE CLIENT INVOLVEMENT.

Slide 23.

FUNCTIONAL ASSESSMENT SHOULD INCLUDE A MEANS FOR  
MEASUREMENT OF BEHAVIORAL SKILLS STRENGTHS AS WELL AS  
DEFICITS.

Slide 24.

FUNCTIONAL DEFICITS FREQUENTLY NOTED IN THE CMI

- IMPAIRMENT OF ABSTRACT ATTITUDE
- CONCRETE THINKING
- INABILITY TO MAKE GENERALIZATIONS
- MISINTERPRETATION OF SPOKEN, WRITTEN LANGUAGE
- FAILURE TO ATTEND
- LACK OF MOTIVATION
- FAILURE TO PERSIST IN TASKS
- LACK OF EAGERNESS AT WORK
- INABILITY TO GET ALONG WITH OTHERS
- LACK OF INITIATIVE
- PSYCHOMOTOR ABNORMALITIES
- DISTURBANCE OF MEMORY AND LEARNING
- SLOW TO PROCESS INFORMATION
- DIFFICULTY IN CATEGORIZING AND ORGANIZING INPUT

Slide 25.

FUNCTIONAL ASSESSMENT REQUIRES AN UNDERSTANDING OF BOTH PRESENT AND NEEDED LEVEL OF FUNCTIONING OF THE CLIENT.

Slide 26.

FUNCTIONAL ASSESSMENT IS A MEANS TO DESCRIBE ABILITIES.

Slide 27.

THE GOAL OF FUNCTIONAL ASSESSMENT

TO DEVELOP A PERFORMANCE-ORIENTED DATABASE OR PROFILE

Slide 28.

FROM THIS PROFILE:  
PROBLEMS OR NEEDS ARE IDENTIFIED  
INTERVENTIONS ARE PLANNED  
LONG RANGE GOALS ARE DEVELOPED

Slide 29.

FUNCTIONAL ASSESSMENT PROVIDES CORE INFORMATION FOR  
"CASE MANAGEMENT".

Slide 30.

FUNCTIONAL ASSESSMENTS REQUIRE SKILLS BE BEHAVIORALLY DEFINED.

Slide 31.

A SKILL IS A SET OF BEHAVIORS THAT IS:

OBSERVABLE  
TEACHABLE  
MEASUREABLE

Slide 32.

RULE OF THE FIVE "Ws"

WHO IS PERFORMING

WHAT BEHAVIORS ARE THE FOCUS

AND THE CIRCUMSTANCES (WHERE, WHEN, WITH WHOM)

Slide 33.

**FACTORS OF PERSONS HAVING CMI WHICH INFLUENCE VOCATIONAL OUTCOME**

1. ADJUSTMENT TO DISABILITY
2. COGNITIVE/INTELLECTUAL ABILITIES
3. DECISION MAKING ABILITIES
4. DEPENDENCY ON OTHERS FOR FINANCIAL SUPPORT
5. DISINCENTIVES (E.G., SEVERELY LIMITING MEDICAL CONDITIONS)
6. PREMORBID EDUCATIONAL LEVEL
7. EMOTIONAL STATUS
8. INDEPENDENCE IN LIVING, MOBILITY, AND JOB PERFORMANCE

Slide 34.

9. MARITAL STATUS AND NUMBER OF DEPENDENTS
10. MOTIVATION AND EGO STRENGTH
11. PERCENT OF TIME ABLE TO WORK
12. PHYSICAL STATUS
13. PRODUCTIVITY (INCLUDING CREATIVE AND COMMUNITY ACTIVITIES)
14. SOCIAL FUNCTIONING
15. DEGREE OF TRAINING REQUIRED FOR JOB COMPETENCE FOLLOWING ILLNESS/INJURY

Slide 35.

**SUB-SETS OF SYMPTOM-RELATED PROBLEMS:**

1. SENSORY-PERCEPTUAL DISTURBANCE
2. COGNITIVE DISTURBANCE
3. LANGUAGE RELATED DISTURBANCES
4. PRAXIC (MOTOR) DISTURBANCE
5. DISRUPTED EXECUTIVE FUNCTIONS

Slide 36.

IMPORTANT COMPONENTS OF THE PROCESS OF  
APPLIED BEHAVIORAL ANALYSIS:

SETTING  
FREQUENCY/DURATION  
ANTECEDENT INFLUENCES  
CONSEQUENCES

Slide 37.

ANTECEDENT EVENTS THAT MAY LEAD TO PROBLEMATIC BEHAVIOR

<u>EVENT CATEGORY</u>	<u>EXAMPLE</u>
Cognitive	Impulsive cognitive set, failure to appreciate full ramifications of action
Affective	Feeling dysphoric on a particular day
Interpersonal	Low self-esteem with overreaction to ridicule
Situational	Repeat of same circumstances encountered last week
Imaginary	Fantasy of worst case scenario - "I'm sure I'll fail."
Biological	Lack of sleep the night before, and forgot morning medications

Slide 38.

EXCESSES  
DEFICITS  
ASSETS

Slide 39.

NESTED SKILLS APPROACH

Slide 40.

A FUNCTIONAL APPROACH TOWARD PSYCHOLOGICAL TESTING PROVIDES A

DEFINITION OF:

1. INFORMATION PROCESSING STYLE
2. COGNITIVE STRENGTHS AND DEFICITS
3. PROBLEM SOLVING SKILLS
4. COPING RESOURCES
5. PERSONALITY STYLE

## Chapter II

# ASSESSMENT IN PSYCHIATRIC REHABILITATION

GREGORY T. SLOMKA, PH.D.

### INTRODUCTION

Advances in biological psychiatry have appreciably improved the ability of patients with chronic psychiatric conditions to achieve more efficacious levels of symptom control. Despite improved symptom management the functional outcomes of these chronic conditions for many individuals present significant restrictions upon their capacity to meet the demands of fully independent and autonomous functioning. Conditions like schizophrenia, with early and incipient symptom formation beginning in adolescence, and evolving over the crucial periods in which independence and autonomous functioning skills are developed and practiced, can be particularly devastating.

In addition, individuals with severe and chronic psychiatric conditions display varying degrees of impairment in personal, social and occupational adjustment (Brewin, et al, 1988). Further, physical disorders that have potential to limit adaptive competency frequently go undetected in populations with chronic psychiatric disabilities (Lecman, 1975; Koranyi, 1979; and Hall, 1980). Evidence of deficits in cognitive, perceptual, and motor performance have also been documented (Erikson & Binder, 1986; George & Neufeld, 1985). Thus, clients with chronic mental illness manifest not only major psychiatric symptoms but also varying degrees of impairment across a wide range of behaviors necessary for autonomous functioning.

The material presented in this chapter is based on the premise that a comprehensive assessment must be a prerequisite for treatment planning. A comprehensive assessment methodology identifies not only the client's strengths and deficits across a wide range of behaviors necessary for adaptive functioning in the community, but also helps to determine the most efficacious remediation strategies appropriate for each client. The supportive and maintenance rehabilitation practices (Bennett, 1988) required by individuals with severe and chronic psychiatric conditions necessitate a higher level of sophistication in an assessment practice and a capacity for ongoing evaluation than has previously been available.

### DEFINITION OF PSYCHIATRIC REHABILITATION ASSESSMENT

Assessment in psychiatric rehabilitation can be broadly defined as a comprehensive, multidisciplinary process which provides relevant, objective

Slomka, G.T. (1992). Assessment in psychiatric rehabilitation. In Katz, L.J. (Ed.) Psychiatric Rehabilitation: A Handbook for Practitioners. St. Louis: MI. pp. 33-82.

BEST COPY AVAILABLE

information about the client. This methodology takes into account both retrospective and prospective information. It represents an ongoing process that continues over the course of intervention or treatment. Comprehensive assessment provides an overview of not only the client's current functional skills, but an examination of past performance history. It provides the information from which individualized rehabilitation goals will be developed, prioritized and evaluated. In addition to fulfilling a prescriptive function as the basis for treatment planning, results may also be utilized to help predict future client functioning and needs, as well as aid in defining resource allocations. McCue (unpublished manuscript) has provided definitional criteria for factors constituting psychiatric rehabilitation assessment standards. An expanded discussion of each criterion is presented below.

**Assessment must be comprehensive.** Data are gathered from as many sources as is necessary to gain as detailed a description of the client as possible. These sources include physical, behavioral, affective, social and vocational spheres.

**Assessment is multidisciplinary.** In order to effect a comprehensive evaluation, it is necessary to appropriate data from multiple sources. This includes obtaining retrospective and current reports on state of functioning. Typically, reports of medical, psychiatric and, when necessary, allied health professions are accrued. Psychoeducational test records can also be extremely valuable. Formal behavioral and functional assessments can contribute significantly toward specifying the needs of a client. There remains a plethora of other specialized evaluations which might be acquired depending upon other complications with which a client may present, e.g., ophthalmological, speech or audiological evaluations.

**Why the emphasis on so wide a spectrum of assessment in clients with chronic mental illness? A review of health status helps illustrate this point.** It is not uncommon to confront a number of primary and secondary health related problems in populations manifesting chronic psychopathology (Koranyi, 1979; Leeman, 1975; and Hall, 1980). Not only many nascent medical problems go undiagnosed in this population, but individuals with severe chronic disabilities also often display limited insight into the significance of their symptoms and consequently underreport them in clinical contacts. Certain of these conditions and their treatments have the potential to influence both mental status and general adaptive skill competencies. Aside from the identification of undiagnosed acute or chronic conditions, it is important to have knowledge of the client's general physical integrity. Physical limitations could influence factors such as stamina and length of time the client can be expected to participate in programming. Subtle conditions such as cardiac abnormalities or diabetes could substantially influence susceptibility to fatigue. Sensory impairment such as

diminished visual acuity or reduced auditory efficiency can go unnoticed in patients with severe impairments.

**Assessment should offer a longitudinal perspective of the client.** The fact that we are dealing with a population manifesting chronic psychiatric disorders indicates that we may confront changes in baseline psychiatric status, e.g., acute or subacute exacerbations of symptomatology. Knowledge of the past course of the illness can be helpful in predicting and preventing recidivism, or at least in reducing its potential severity. There are also situations in which the client's present state of functioning represents a significant decline from a previous level of performance. The presence of pseudodementia in a client with severe, chronic, refractory depression is exemplary.

**Knowledge of premorbid functioning has other predictive utility.** Evidence of a stable premorbid history can be prognostically favorable and can implicate areas of strength which might be tapped in treatment. The patient with a "first break" symptom display followed by a period of stable recovery is regarded as significantly less vulnerable to decompensation than a patient with multiple recurrent bouts of severe psychiatric illness. Knowledge of patient treatment successes also is invaluable. Thus, there is a wealth of data available regarding the client if a panhistorical approach is adopted regarding information gathering.

**Assessment is ongoing.** In the context of service provision, the process of assessment in psychiatric rehabilitation is not a discrete or unitary function. Although the major investiture of effort is focused on the initial pre-treatment evaluation, the process of assessment is not limited to this phase of treatment planning or service provision. The progress of the client in treatment requires ongoing assessment to evaluate success in the attainment of goals and to modify intervention efforts to meet evolving needs. Unfortunately, these changes do not always reflect progress. Clients with chronic psychiatric conditions must be consistently evaluated for markers of potential deterioration because by the nature of their chronic condition, they are susceptible to decompensation. The attainment of success in one aspect of a program does not exclude the client from vulnerability to deterioration in another. Success in the vocational arena without subsequent improvement in social adaptation might lead to a stress-related decompensation which was triggered by the transfer of a work site or a promotion. Any major transition a client experiences has the potential to necessitate significant re-evaluation of needs.

**Assessment must be undertaken in a systematic fashion.** In reviewing the licensure or certification of psychiatric treatment programs, one is impressed with the degree to which reviewers focus on assurance of the development of adequate treatment plans. They place great emphasis on systematic treatment planning. It can be argued that a systematic approach towards assessment is as necessary as systematized treatment planning. The more structured and cohesive

this process, the greater the probability that the formulation of intervention plans will meet the true individual needs of the client.

Systems vary in the formal structure they impose on assessment. In some instances, all clients pass through standardized "battery" of procedures. In others, the process is highly individualized according to client need. We lack systematized studies of outcomes of fixed versus flexible assessment strategies. Intuitively, beginning with brief multimodal assessments and focusing on more and more refined data collected based on identified need, holds obvious merit. In the planning of assessments, it is beneficial to control not only what should be assessed, but also how, when and by whom. If a client is served by multiple resources, it is necessary to centralize, guide and direct the procurement of assessment information to maintain efficient data accrual and to prevent duplications and gaps. A major aspect of good rehabilitation management is the coordination of such efforts.

#### THE CHANGING FRAME OF REFERENCE IN REHABILITATION ASSESSMENT

Traditional assessment methodologies of one to two decades ago were primarily concerned with the identification of traits, attitudes, behavior characteristics and the medical-diagnostic documentation of factors to support diagnostic and etiologic inferences. Contemporary rehabilitation needs force our evaluation efforts to be directed away from classificatory decision-making to strategies which focus more directly upon the description of environmental functioning and adaptation. We have experienced a paradigm shift from rehabilitation efforts steeped in a pathologically oriented view to a more optimistic problem-centered view that examines the dynamic characteristics of the individual and his/her environment. When the outcomes of assessment are examined in this context, it is easy to determine the relative efficacy of such information for treatment planning.

We can dichotomize orientations toward assessment on a continuum which at one extreme is focused on products or scores. At the other extreme is an emphasis on the processes or strategies a client utilizes to solve tasks. The "nomothetic tradition" views testing as a means to use scores based on normative criteria for classification or discrimination purposes. An example of an inference derived from this orientation would be, "The client's two-point code on the MMPI is consistent with a diagnosis of Depression." Such a statement provides a limited yield for individuals interested in the day to day support of such a client. A modification of the nomothetic tradition, criterion referenced testing, offers some greater yield in the context of the prediction of outcome. Consider this predictive statement for example: "85% of clients who scored at or above this criterion score were successful in transitional employment." Outcome measures of this type have greater relevance for program planning.

The "idiographic tradition" represents an interest in the qualitative aspects of the behavior observed in testing. When used in combination with the known history, it provides a means to describe what is unique about that client as he or she engages in test activities. An example of such an inference would be, "While completing puzzle constructions the client brought to bear strengths in the verbal domain to help himself compensate for his visuo-motor defect." This information provided constructive information regarding a potential means to adapt training strategies based upon an inference derived about the client information processing style.

The examples cited above allow us to focus on two principal outcomes derived from testing: scores and observations. In the discussion which follows, we will attempt to reframe the utilization of traditional psychological assessment methodologies in a context which permits the furtherance of the description of relevant client attributes.

#### Technical Aspects of Assessment

Assessment is a comprehensive process of deriving meaning from test scores so as to achieve as broad and as detailed a description or understanding of the client as is necessary for the rehabilitation programming in question. Three basic challenges must be met in the description of any assessment methodology. The first set of demands refers to psychometric properties. Procedures must meet criteria for validity and reliability. The tools utilized to assess behavior should have demonstrable validity for measuring intended behaviors or traits. Reliability is also crucial. Data must be collected consistently across staffing patterns and varying test circumstances. Second, there are institutional constraints which place limits on the manpower, time, resources and settings in which assessments can be conducted. The third factor, utility, may, however, be the most crucial. The "utility" of any assessment methodology refers to how useful the derived data may be for decision making. We can extend this criterion to the concept of ecological validity, i.e., the ability of a test to go beyond ranking or categorizing behavior, so as to further our understanding of how specific patterns of strengths and weaknesses will contribute to an understanding of the client's daily functioning.

It is also important to emphasize that test results and observations alone are an insufficient basis for placement, treatment or diagnostic decisions. There is a whole universe of information available to complement this process: psychosocial history, medical and developmental history, functional evaluation of current life circumstances, available environmental supports, the nature of intercurrent stressors, etc.

It appears at first glance that the assimilation of a tremendous amount of information is required to conduct a comprehensive assessment. This is, indeed, true. There remains, however, the realities of time, resources and energy which

limit the scope of the assessment process. The challenge in the development of assessment and data collection systems is the balance of accurate and reliable information from individual and situational resources. In this regard, we must seriously entertain how additional assessment strategies might be modified to meet current needs. Rehabilitation, perhaps, oversimplistically conceived, represents a learning process; an effort to assist clients toward a meaningful reintegration with their community. Our success in this regard is very much determined by our capacity to make valid, appropriate and reliable assessments of the variables which will influence this process.

Contemporary treatment intervention and service demands further require that our methods be aimed more toward evaluating client's abilities and deficiencies in the environments in which they will function. Stated in yet another way, we are interested in defining the dynamic characteristics of the individual that will lead to success or failure in specific environments. Tests which lack generalizability outside the context of the consulting room have little meaning or relevance.

Regardless of the assessment methodologies utilized, be they traditional objective psychological tests or behaviorally anchored functional assessment procedures, the previously stated criterion of an ecologically valid description of client functioning must be fulfilled. In addition, the methodological criteria of reliability, validity and utility must also be met.

With this overview of basic assessment principles complete, we will turn to a discussion of traditional methods of psychological evaluation and attempt to explicate how greater functionally relevant information can be derived from these methods. In this process the following domains will be examined for their relative contribution to differential client description and rehabilitation planning: general ability level, information processing strengths/weaknesses, problem solving skills and coping resources.

#### TRADITIONAL METHODS OF PSYCHOLOGICAL TESTING APPLIED TO PSYCHIATRIC REHABILITATION

##### Intelligence Testing

Intelligence testing represents one of the earliest forms of psychological testing. It has traditionally focused on an end-product or outcome score, the intelligence quotient. This score has been utilized both as a means of classification and as a predictor of potential. One can, indeed, make some arbitrary inferences regarding potential outcome using a single molar score such as the IQ. For example, in considering two individuals with WAIS-R IQ's of 118 and 82 it is readily apparent which would have greater success in a professional occupation versus an unskilled labor position. We live, unfortunately, with biases which cause us to assume a specific cognitive set when we hear IQ score. This

illustration emphasizes that a unitary conceptualization of intelligence based upon an IQ score alone could be very misleading. Intellectual processes are multidimensional in nature. We will, therefore focus this discussion on how intelligence testing can be utilized to describe differential ability and serve as a first order level of analysis regarding the identification of any specific deficiencies in information processing that could influence learning and adjustment.

#### THE WECHSLER INTELLIGENCE SCALES

The Wechsler Scales represent the most widely utilized tests of general intelligence. They exist in three forms: adult, child, and preschool versions (Wechsler, D., 1967; Wechsler, D., 1974; and Wechsler, D. 1981). They evolved from the Wechsler Bellevue Scale (Wechsler, D., 1944), the first instrument to utilize a deviation IQ score. This represented a departure from the model offered by the Stanford-Binet Intelligence Scale (Terman, L. and Merrill, M., 1960), in which the individual's performance was compared relative to his own age. The Wechsler model ranks standing relative to an age-matched normative population, a statistically more robust technique for describing intelligence over the course of development. The Wechsler Scales were also a radical departure from the Stanford Binet in that they permitted an opportunity for analyzing differential abilities via analysis of both subtest performance and the differences between overall Verbal and Performance IQ scores. In comparison to the Stanford-Binet, which offers only an IQ or Mental Age score, this expansion in coverage provides an important base for the pragmatic description of the client in terms of cognitive strengths and deficits.

Discussion of the Wechsler Scales will be limited to the adult version. The WAIS-R is an individually administered intelligence test consisting of eleven subtests: 6 Verbal and 5 Performance subtests (See Table 1). Full administration can take up to 90 minutes. The Verbal Subtests consist of tasks which tap verbal conceptual ability, practical judgment and reasoning, numerical reasoning, immediate auditory attention span, acquired knowledge and general verbal proficiency. The Performance subtests involve more visuosperceptual and visuomotor skills in task completion. Spatial and nonverbal reasoning skills are tapped in these tasks. In addition, demands are imposed for speed dependent performance on a number of these tests. Subtests are scored as Scaled Scores with a mean of 10 and standard deviation of 3. The WAIS-R also offers the more familiar deviation IQ score with a mean of 100 and a standard deviation of 15. Scores in the range of 90-109 are considered indicative of average intellectual ability.

##### Verbal Subtests

Information. This subtest consists of 29 factual questions arranged in order of increasing difficulty. They are reminiscent of "Trivial Pursuit" questions. The test measures an individual's mental alertness and foundation of factual knowl-

edge concerning the world--knowledge that adults presumably acquire if given adequate educational opportunity. It requires intact long term memory and the ability to access remote factual material. Success on this subtest is associated with past education, social and cultural experience and literacy. Poor performance, therefore, could be due to poverty of educational opportunity, cultural experience or to low intelligence. For the most part, this subtest requires recall of facts; however, a few items do require analytic reasoning ability. It provides an index of knowledge available to the client for practical problem solving. If we consider intellectual ability reflecting the capacity to adapt knowledge in novel problem solving situations, performance on this subtest has the potential to influence adaption significantly. Defects in judgment and poverty in associational content may be seen in patients with psychiatric disabilities. This is exhibited not only in client's active symptoms, but also in individuals manifesting a more chronic debilitating course. Thus, noting any discrepancy between past levels of learning and ability to recall factual knowledge can be prognostically valuable.

**Comprehension.** This subtest consists of 16 questions of increasing difficulty, 13 of which test common sense judgement and practical reasoning, with the remaining three assessing the ability to interpret proverbs. The questions basically pose a conventional social situation and require a response. This subtest represents one measure of abstract verbal-conceptual ability. Like the Information subtest, Comprehension reflects the social and cultural background of the person tested. Long term memory is required, as is the ability to express ideas verbally.

Since the Comprehension subtest requires the use of inferences and judgments although limited in its breadth, this test does provide some insight into practical social problem solving. It also requires the client to provide more lengthy expository responses. It lends itself well therefore to the qualitative analysis of response content. Bizarre responses can give clues to psychopathology which might not have been observed clinically. Persons with schizophrenia

for example may do poorly on this subtest because they often lack the intact judgment necessary to perform well. Their responses may be arbitrary, highly egocentric or concrete. High scores on Comprehension in persons with chronic and severe mental disorders usually suggest good reality contact and can be viewed as an index of stability.

**Similarities.** The Similarities subtest is made up of 14 items which require the individual to explain the commonality between two objects or concepts. The format is similar to other verbal analogy tasks in aptitude batteries. It is a test of logical thinking and verbal concept formation. Individuals must be able to generalize between two objects within a specific class. Responses usually fall into one of three categories: concrete, functional or abstract. Subjects respond to questions such as, "In what way are a screwdriver and hammer alike?" A "functional" response would identify a common use of the objects such as, "You fix things with both." A less sophisticated "concrete" response would be, "They both have handles." An "abstract" response to the same question would be "Tools." The more abstract the response, the better the score and the imputed general level of reasoning ability. The ability to work with abstract ideas and to see relationships is considered an important higher level cognitive skill for daily problem solving. Thus, this test offers an excellent measure of higher level intellectual abilities. Also, the test is useful because of its lesser dependence upon memory, educational experience, and cultural background.

In persons with significant psychiatric disorders, the complex cognitive skills required in this subtest are particularly sensitive to deterioration. A loss of "abstract attitude" has been commonly attributed to patients with chronic schizophrenia or brain damage. Persons with psychoses or affective disorders may do especially poorly on this subtest. Persons having depression may lack the energy to invest in the active problem solving demands associated with this test. Long term schizophrenic illness is reflected generally by quite concrete responses. More acute thought disorder would be reflected in unusual associational content or clang associations.

**Vocabulary.** The Vocabulary subtest is made up of words, hierarchically arranged in order of difficulty, which the individual is required to define. It is a measure of the ability to recall and express previously acquired word meanings. This measure of functional lexicon of knowledge is again strongly related to both educational and cultural experiences. This subtest is widely accepted as the best single estimate of general, as well as verbal intelligence. However, because of the likelihood of educational, as well as social and cultural biases, caution should be exercised in the exclusive use of Vocabulary as the sole predictor of baseline intelligence.

The Vocabulary subtest is considered a "hold" test. It tends to be relatively resistant to change in the face of age, cerebral dysfunction, or psychosis. It is,

therefore considered as one means to estimate premorbid intellectual abilities. The Vocabulary subtest in limited circumstances can also aid in differentiating between persons with functional psychiatric disorders and those with organic disease. Persons with schizophrenia may have a tendency to let down their guard when faced with the relatively innocuous vocabulary tasks and thus expose evidence of a thought disorder as reflected by their poor judgment, idiosyncratic associations, or highly egocentric or confabulatory responses. They may miss very simple words, but be fully accurate with rather complex word meanings. The client with organic involvement tends to show more consistently concrete responses without unusual embellishments.

**Arithmetic.** The Arithmetic subtest consists of 14 mathematical statement problems presented orally and solved without benefit of pencil and paper. Responses are timed and bonus points are accrued for efficacious performance. The test primarily taps arithmetic reasoning ability. It does not exceed a seventh grade level of computational ability. Requisite skills for adequate performance include basic arithmetic proficiency, verbal comprehension, attention and immediate memory, logical reasoning and concentration. On more complex items, individuals are required to manipulate information so as to conduct complex multi-step operations. This latter ability is highly sensitive to psychopathological states such as anxiety or depression which can result in impaired concentration. Clients with attention deficit disorder would also be expected to perform very poorly on this subtest. It can serve as a gauge of active intercurrent thought disorder in that digressive reasoning, thought blocking and other cognitive difficulties would seriously impede performance. At a more pragmatic level, it provides insight regarding general efficiency in the types of day to day problem solving all individuals encounter.

**Digit Span.** The Digit Span subtest is divided into two components: Digits Forward and Digits Backward. Each component consists of random number series presented orally. The number of digits in each series increases with each item, from three to nine on Digits Forward and from two to eight on Digits Backward. In Digits Backward, the subject is required to reverse the order of digits mentally and repeat them backwards in this new format.

The Digit Span subtest requires immediate auditory attention, concentration, and memory. The reverse sequencing in Digits Backward requires greater cognitive flexibility because clients must not only hold information, but mentally manipulate it. Digit Span has been demonstrated to be very sensitive to both brain damage and anxiety. Persons with major depressive disorders tend to do poorly, as do persons with schizophrenia who have deteriorated. Individuals diagnosed with schizophrenia who are either cognitively intact or free of anxiety, however, perform relatively well on Digit Span. It is emphasized that Digit Span is not a formal test of memory, per se. It is a test of apperceptive span, i.e.,

attention. We find that even patients with Alzheimer's Disease who have severe memory impairment, can perform reasonably well on Digits Forward. At a more pragmatic level, this subtest gives some indication of how much information the client is immediately capable of acting on or incorporating. Weakness on this measure would show cause to examine carefully how much information is being presented to the client at any one time.

#### Performance Subtests

The Performance subtests of the WAIS-R are distinguished by their reliance on visual-perceptual, visual-motor and spatial reasoning skills for their completion. A substantial demand is made upon psychomotor integrity by the inclusion of speed dependent assembly tasks. A number of these tasks do focus primarily upon non-verbal as opposed to verbal reasoning skills in task completion. The Verbal-Performance dichotomy has led to a popular misconception of Verbal subtests as being exclusively language based, left hemisphere mediated cognitive operations, and the Performance subtests representing exclusively right hemisphere, visuospatial abilities. It will become readily apparent that verbal reasoning skills cannot be dissociated from a number of the Performance subtests.

**Picture Completion.** The Picture Completion subtest consists of 20 pictures in which the individual must identify a missing element under time constraints (20 seconds for each item). The test requires visual acuity, visual perception and scanning ability, and the capacity to differentiate essential from nonessential detail. The person must visually organize a gestalt or a conceptualization of the picture, attend and concentrate, and observe for incongruities or incongruities within the picture. Recall of information from long term memory and the ability to screen-out irrelevant information are the requisite skills for performance on this test. The content of the pictures, however, imparts a potential cultural bias which may have to be considered.

In populations with psychiatric disabilities, exemplary errors include bizarre responses from persons with schizophrenia and the frequent insistence from those exhibiting paranoid symptoms that there are, in fact no missing parts. Compromised performance is also reported in persons with schizophrenia who have deteriorated. Again, a dichotomy can be seen in error analysis between concrete-functional thinking versus abstract-conceptual ability. Weak attentional capacity, that is, inconsistent screening of the environment for relevant cues can also be inferred.

**Picture Arrangement.** Individuals are asked to arrange 10 sets of randomly presented cartoon pictures so that they tell a logical, coherent story. Story sequences are presented in sets of from three to six pictures which vary in the degree of difficulty and the complexity of the social situation involved. Bonus credits are awarded based upon speed of response. This subtest measures several

major cognitive skills including visual acuity and perception, social awareness, planning skills, the ability to form and test hypotheses, and logico-sequential reasoning. It is considered a measure both of general ability, as well as social intelligence. Reliance upon interpretation of social consequences renders the subtest culturally biased for some populations because the test demands awareness of social conventionality. It is thought of as the nonverbal counterpart to the Comprehension subtest. Clients can, however, frequently be heard to verbalize to themselves while performing this subtest. As such, clients may frequently reveal compensation for what may be weak nonverbal or visual information processing ability. A helpful adjunct in test administration is a "testing of limits" procedure in which the client is asked, after completing the task, to explain the logic associated with his or her arrangement. This procedure helps elucidate defects in social judgments and reasoning.

**Block Design.** The Block Design subtest is perhaps the most recognized of the Performance subtests. It requires the individual to assemble nine different designs from cubes based upon a two dimensional model or template of a block arrangement. The blocks have two red sides, two white sides, and two sides that are half red and half white, split diagonally. Of the nine designs, the first four require designs derived from a 2 X 2 configuration, with the remainder requiring a more complex 3 X 3 arrangement. The test is considered the most stringent spatial reasoning task within the WAIS-R. It requires complex spatial analysis and synthesis at the perceptual level, as well as concerted visuo-motor integrational effort. Attention and concentration, reasoning, and motor integration skills are necessary to perform this part-to-whole constructional task efficiently.

This subtest has been demonstrated to be very sensitive to brain damage. Performance of persons with schizophrenia on the Block Design subtest tends to be relatively intact. In this regard, this subtest can offer a limited differential between functional schizophrenia and possible structural brain dysfunction.

**Object Assembly.** The Object Assembly subtest, another constructional task, is made up of four puzzles which the subject is required to assemble. Performance is scored for both time and accuracy. Object Assembly requires the ability to perceive and construct an object, not by using a model as in the Block Design test (a copying task), but by making sense of, i.e., visually grasping complex elements and integrating them into a meaningful whole. Like the Block Design subtest, it is a measure of visuo-spatial integrational ability.

One must form visual concepts and quickly translate them into a motor response. This often requires cognitive flexibility and persistence in organizing and reorganizing under time constraints. Both persons with schizophrenia and brain damage may do poorly on this task. Because of the psychomotor speed demands required, persons with depression also tend to do poorly on Object Assembly. The effects of neuroleptic medication on psychomotor skills may also

have a detrimental effect on performance. Significant discrepancies in performance favoring Block Design over Object Assembly have the functional implication of suggesting the client's enhanced potential to work from a "model" or "template" vs. independently. Task persistence and the capacity to engage in hypothesis testing efforts without giving up in frustration are relevant attributes to observe for on both Block Design and Object Assembly.

**Digit Symbol.** Digit Symbol is a coding or matching task performed under time constraints. The individual is asked to draw symbols in empty blocks below numbers (from 1 to 9) by using a code. It is the only paper-and-pencil task on the WAIS-R. Its associational task demands serve as an excellent measure of cognitive flexibility and efficiency, as the client must constantly shift cognitive sets. In addition to cognitive flexibility, problems with this subtest may also reflect motor problems. The complexity and speed determinants of this subtest make it highly susceptible to anxiety effects. It is also highly sensitive to brain dysfunction. Very good scores on this subtest contraindicate any effects associated with active severe psychopathology on cognitive efficiency.

#### Analyses of WAIS-R Performance

It can be readily seen that adopting a "process" oriented approach to the analysis of WAIS-R subtest performance can contribute significantly to a further understanding of information processing strengths and deficits unique to a client. In addition, there are three levels of quantitative analysis derived from the WAIS-R. First, is the derivation of the Full Scale IQ score, a general index of current functioning. In populations with chronic mental illness it is essential to understand whether current functioning represents any deterioration from a higher level of premorbid functioning. Evidence of deterioration immediately flags a need to ascertain what factors may contribute. We may be dealing with transient acute effects which tend to be reversible. There remains a possibility, however, of dementia in association with a long term chronic psychiatric disorder, especially in the schizophrenic spectrum disorders.

A second level of analysis involves any variability among the IQ scores. Is there any significant difference between the Verbal and Performance IQ? A discrepancy of 15 points or greater between the Verbal and Performance scores can implicate at a first-order analysis a relative strength or deficit between language and non-language based cognitive processes. For example, a low Verbal IQ in comparison to an above average Performance IQ suggests the potential to confront reduced abstract verbal-concentration ability, limited development of language-based academic skills, and potentially weak verbal memory. The opposite configuration, weaker Performance IQ, implicates the possibility of less adequate visuomotor integrational skills that could have a negative impact upon writing ability or constructional skills, non-verbal reason-

ing, math skills, or the capacity to deal with novelty or ambiguity. Visually mediated learning or instrumental skill learning may be weaker than verbally mediated learning strategies.

Finally, we can consider pattern analysis. A scaled score (on a scale of 1-20) is assigned each subtest based on relative performance. A scaled score of 10 (s.d.±3) is considered average. When subtest results are used, it is easy to plot the average of the combined Verbal and Performance subtest scores. Analysis is then undertaken of the clients' performance on each subtest relative to a standard based upon the Verbal and the Performance scaled score averages. Relative to the client's "own level of performance," scores 2-3 points over and above his/her average represent an area of special strengths; scores 2-3 points below average represent areas of distinct weakness.

A number of strategies have been developed to further the process of differential pattern analysis by moving beyond individual score variation to consider how specific clusters of subtests may vary. Very consistently, factor analytic studies have demonstrated three reliable clusters of subtest performance on the WAIS-R and WISC-R. Table 2 summarizes these results.

Table 2. Factor Structure of the WAIS-R	
Factor	Subtests
Verbal Concept Formation	Information
	Comprehension
	Vocabulary
	Similarities
Freedom from Distractibility	Arithmetic
	Digit Span
Perceptual Organization	Block Design
	Object Assembly
	Picture Completion

The Information, Comprehension, Vocabulary, and Similarities subtests represent a Verbal Concept Formation cluster. Low scores across all four of the subtests are commonly associated with cultural disadvantage, developmental language disorders, learning disabilities, and academic underachievement. Considering the difficulty a patient with a psychiatric disability might have with formal thought organization, remembering that all four of these subtests make critical demands on expressive skills, one could look to these four scales as a means to assess quality of the formal organization of thought and communicative

ability. There is also a Freedom from Distractibility factor which consists of the Arithmetic and Digit Span subtests. Attentional impairment and anxiety could selectively mitigate performance on these tests. In fact, this factor serves as a quite reliable indicator in attention deficit disorders in both children and adults. Finally there is the Perceptual-Integrative factor based on the visuo-perceptual, integrative, and motor assembly components of the Block Design, Object Assembly, and Picture Completion subtests.

A similar method of cluster analysis is the one proposed by Bannatyne (1974). This methodology has associated with it some demonstrated efficacy in the description of learning disability subtypes. The literature is replete with other combinations of WAIS-R subtest factors (Sattler, 1988). One must be careful with their application as many are based on clinical intuition rather than empirical validation.

It should be apparent to the reader that there is a wealth of data available from the WAIS-R that offers the opportunity to develop a number of heuristic assumptions about general ability and preferential styles of information processing that could have a potential impact upon general adaptation, problem solving skills, and new learning. It is emphasized that the WAIS-R was validated as a general intelligence measure. The clinico-heuristic assumptions discussed above remain limited in their applicability. At this level of analysis they do not serve as sufficient grounds to base formalized treatment recommendations. They can, however, serve in: 1) documenting current functioning level, 2) providing a baseline measure against which past performance can be contrasted so as to determine positive or negative change in levels of performance, 3) adding yet another reference standard against which performance on academic skill measures or neuropsychological tests can be contrasted and 4) providing first-order level analysis hypotheses to guide and direct the direction of further testing.

While there are a number of other general and special ability measures which serve the function of documenting cognitive efficiency like the Stanford Binet IV, Peabody Picture Vocabulary Test, Raven's Standard Progressive Matrices Test, and Test of Nonverbal Intelligence, these latter measures lack the tradition the WAIS-R has enjoyed in ecological and outcome research studies across a variety of disability subtypes. Further, they lack the multidimensional descriptive utility of this instrument. It is not uncommon to see a number of the above measures incorporated as part of a larger neuropsychological test battery to further test hypothesis generated at the level of WAIS-R profile analysis.

#### ACHIEVEMENT TESTING

With consideration having been given to the assessment of the client's core cognitive facilities as measured by intelligence tests, we now turn to the examination of the functional implications of performance on achievement tests.

The diverse instruments which are available for this purpose take two basic forms: 1) comprehensive batteries which assess word recognition, spelling, arithmetic and reading comprehension; and 2) specialized batteries which focus in depth upon one area of academic skill function. The latter tests are typically applied only when a specific deficit in performance has been identified. These latter tests have greater relevancy for remedial and prescriptive educational intervention.

At this level of the assessment, the most common question confronting the client with chronic mental illness is, "What are the current or residual academic skill competencies displayed by the client relative to his or her measured level of intellectual functioning and psychiatric condition?" The documentation of intact and well developed academic skills is prognostically favorable. This indicates the client is essentially retaining previously learned material and is not encountering difficulties in day-to-day problem solving. For the client who was formerly employed, the prospects are unlikely that any supplemental basic educational supports will be required prior to occupational re-entry. Well developed fundamental literacy skills open up a broader range of training and educational options through the use of texts or other lexically driven self-instructional paradigms. The identification of any generalized or specific academic deficits can, however, be particularly problematic for rehabilitation planning. The approach toward intervention will focus on either remediation or compensation depending upon the careful specification of the nature of any identified academic skill deficits.

Consider how the approach to referral for academic skill training in two post-institutional clients with chronic mental illness might vary. The first referral involves a patient institutionalized intermittently for 20 years with no employment during this time, weak skills associated with independence and self-reliance, and poor money management skills. Premorbidly, normal intelligence and no school problems are noteworthy. The other patient presents with a similar scenario, but with a history of early, severe academic dysfunction and functional illiteracy. Both are en route to a residential treatment program. This question arises, "How would each client's individual functional academic deficits be remediated or compensated?" Who should be expected to gain in money management skills as a function of re-education versus who will have to be counseled to accept significant external supervision of personal funds? One client appears to need only intervention to compensate for lack of practice. The other will require more extensive special instructional intervention. To address such questions, it is necessary to transcend the simple reporting of grade equivalent scores on academic achievement measures. Rather, it is important to consider the potential ramifications of the client's current ability level and the

demands incurred for academic skill proficiency across the settings in which he/she will function. The academic assessment database, thus, contributes one important source of information regarding how sophisticated a client may be in community survival skills.

When there is a variance between expected and actual levels of performance on achievement tests, the reason must be clearly ascertained before proceeding with interventions. This variance could result from a specific learning disability, underlying cerebral dysfunction, limited sociocultural and educational opportunities or underachievement. Scores on achievement tests are reported as grade equivalents, standard scores and percentiles. Knowledge of past performance, i.e., how far client went in school, his or her premorbid IQ, and his or her occupational experiences, offer opportunities to estimate premorbid levels of performance. The younger the client the more rehabilitation staff can rely upon grade equivalent scores. If the client had a 10th grade education, do his or her skills still cluster around that level? A psychometrically more valid means is to compare achievement test standard scores to an IQ score. Hence a client with an IQ of 104 and with a reading skill standard score of 84 is clearly impaired. Like Verbal-Performance IQ differences, disparities of 15 or more points between achievement test standard scores and IQ scores are considered clinically significant.

Achievement testing also provides information related to a client's general cognitive efficiency and the capacity to apply his or her knowledge in practical problem solving--an important consideration in community service planning. How well the client transcends simple calculation or reading recognition skills and attacks complex numerical reasoning or comprehension problems relates directly to the capacity to deal with practical problem solving in everyday living. Components of the functional assessment of community living skills should certainly be based on degree of primary academic skill competency manifest in the client. A firm foundation of knowledge about academic strengths and weaknesses also helps the counselor to distinguish between a lack of motivation or effort, and genuine learning problems. Knowledge of academic strengths and weaknesses can contribute not only to educational and vocational planning, but also to the prediction of the potential of therapeutic techniques. For example, strengths in reading and writing would support the use of bibliotherapy techniques, diaries or the self-recording of events associated with cognitive-behavior therapy techniques.

#### PERSONALITY ASSESSMENT

Accurate knowledge of core personality characteristics and the nature of a client's psychopathology is essential in both treatment and rehabilitation planning. Traditionally, personality assessment has been applied to aid in differential

diagnosis. This discussion will focus instead upon how knowledge gained from personality assessment methodologies aids in the understanding of the client's adaption and coping skills. These factors are more germane to rehabilitation management and planning issues. Assessment conducted solely for purposes of diagnosis and classification as has been discussed contributes minimally to rehabilitation planning. It is not, however, necessary to abandon traditional methods of personality assessment because of this valid criticism. What is required is the reformulation of its products in constructs which are more meaningful for rehabilitation planning and management. Knowledge of the client's attributes in the following areas can be particularly beneficial in rehabilitation management: self-perception of individual attributes and deficits; tolerance for stress; preferred coping strategies; social and interpersonal skill functions; social comprehension and social judgment; and reality testing.

This process is accomplished through direct observation, obtaining third party ratings of behavior on questionnaires, or through self-report techniques. The first two techniques represent methodologies borrowed from applied behavioral analysis and will be discussed at length in the section which deals with Functional Assessment. Discussion will be limited in this context to the contribution of objective personality inventories in defining the above criteria.

Before actual personality assessment measures are described, it is necessary to consider two factors which distinguish personality assessment as a distinct methodology. The first factor involves the techniques used in the actual testing situation. When conducting personality assessments, we are evaluating samples of behavior objectively and in a standardized fashion, i.e., drawing inferences from normative criteria and then generalizing from this information. There are two types of personality assessment techniques: objective and projective methods. Objective tests consist of techniques which do not vary. Clients, regardless of circumstance, are rated across the same categories of behavior, beliefs, or attitudes. This applies to self-rating, as well as inventories which rely on third party ratings of behavior. Objective tests always culminate in scores which are compared against some criterion. This distinguishes them from projective techniques in which the patient is confronted with unstructured material and the responses are open-ended and thus, somewhat less amenable to objective scoring procedures.

The second factor to be emphasized in discussing personality assessment is that inherent in this process is the need for good clinical judgment. At one level of analysis we have objective results or scores. It is necessary, however, to combine these results with knowledge of the patient's past history, the clinician's theoretical orientation, and an analysis of the nuances personality factors and their relationships to pathological conditions. Personality assessment represents a fluid or dynamic process. Therefore, in a sense, all personality assessment is

subjective. We tend to see a greater reliance on objective methods because they tend to better define the parameters of our decision making. With knowledge of a test's validity the clinician can be reasonably certain of the probability associated with conclusions drawn from that instrument. It is important to recall that the inferences derived from personality testing remain heuristic hypotheses that require further validation through our experience with the client. This information, combined with the clinical history can serve an important function in structuring rehabilitation planning decisions. The discussion of the application of two such objective personality assessment methodologies follows.

Minnesota Multiphasic Personality Inventory (MMPI). The MMPI, an objective personality instrument, was conceived in the 1940's as a means to assess degree and type of maladjustment. It is steeped in the conceptualization of psychopathology at that time which manifested a great interest in the identification of enduring personality traits (Dahlstrom, Welsh and Dahlstrom, 1972). The instrument consists of 566 true-false items. A reading comprehension level of sixth to eighth grade equivalence is required. There also exist alternate short forms of this instrument.

The administration of the MMPI culminates in a profile configuration plotted for 10 clinical scales and 3 validity scales. Scores are reported as T-scores with a mean of 50 standard deviation of 10. A score two standard deviations above the norm ( $T > 70$ ) is considered clinically significant. Interpretation is first based on consideration of the overall profile validity. A central question to be addressed before interpreting any objectivity inventory is, "What was the patient's response set while taking it?" On MMPI, three validity scales, L, F, and K are available to define the client's approach in responding. These scales help identify whether the patient is biasing his or her responses through excessive denial or exaggeration of symptomatology. If extreme deviation is noted, the examiner must adjust his or her interpretation accordingly. If the validity scores are within normal limits, interpretation can proceed.

The most elemental interpretive strategy used with the MMPI are the two-point codes. The patient's two highest critically elevated scores are referenced in an interpretative manual or "cookbook", and a description, relative to a normative comparison group, can be made of the special attributes and characteristics which patients with a similar profile share. Limiting the interpretation of the MMPI at this level of analysis offers little in the way of descriptive information that might be useful to an interdisciplinary team.

A more sophisticated interpretation of the MMPI is associated with exhaustive consideration of the validity scale profile topology; the overall clinical scale profile shape (did it represent an abnormal, neurotic, psychotic, character pathology, or an acute vs. chronic configuration?); the two point interpretive guide; a summarization of the implications of the scores for each scale; low score

patterns and their significance; and finally, a consideration of the implications of the numerous research scales and their contributions to the understanding the client. The result is an enhanced description of not only predominant traits and symptoms that aid in differential diagnosis, but data which contribute to the formulation of hypotheses regarding preferred coping styles, potential for success in adaptation, activity level, psycho-sexual concerns, and the quality of both intrapsychic life and interpersonal skills. The combination of this information, plus the known clinical history, facilitates the development of programmatic inferences regarding the level of necessary support and supervision, need for special accommodation, stress tolerance, etc.

**Millon Clinical Multi-Axial Inventory (MCMI).** We will briefly consider one other objective personality inventory, the MCMI (Millon, 1982). It, like the MMPI, represents a broad focused, multifactorial approach towards personality description. The MCMI is similar in many respects to the MMPI, but in its development Millon attempted to devise a shorter (178 item) and potentially more valid instrument, especially as pertains to contemporary notions of psychopathology. This effort culminated in an inventory in which 21 personality dimensions are profiled in a fashion somewhat akin to the MMPI. A primary focus of this instrument is, however, on the Axis II symptomatology indicative of personality disorders. The MMPI is viewed as primarily focused on Axis I, primary mental disorder symptomatology.

The emphasis of the MCMI is not exclusively on Axis II disorders. It also provides a description of varied symptom patterns which are not necessarily enduring or characterological, but rather reactive. These latter scales suggest what types of symptomatology might be manifest when the patient's coping resources are seriously taxed. For example, is the patient likely to manifest primarily anxiety symptoms, revert to substance abuse, or regress into psychoticism when significantly stressed? Another way in which this instrument is helpful is in enlarging the clinical description of the patient. Taking Major Depression as an example, cardinal DSM III-R symptoms include: dysphoria, low energy, neurovegetative symptoms, etc. There are, however, unique attributes which differentiate individuals who share this diagnosis. The identification of the degree to which a patient with this diagnosis might also manifest a tendency toward somatic preoccupation, overdependence, passive-aggressiveness, psychoticism, or substance abuse would obviously influence case management decisions. The MCMI, with its focus on both enduring personality traits plus "reactive" symptomatology, helps to enlarge the focus of critical behaviors around which the client may be monitored.

The objective personality inventories discussed above are representative of the class of multifactorial or multi-symptom techniques. A wide array of single symptom inventories are also available. These inventories provide more

expansive coverage of a single condition like depression, anxiety or psychoticism. As these instruments contribute primarily to clinical and psychiatric versus rehabilitation management, we are restricting our discussion of them.

**Projective Tests.** We will only briefly touch on these tests as like the single symptom inventories, their merit appears to be associated more with the conduct of intensive psychotherapy rather than with the pragmatics of service coordination and case management. As previously discussed, these techniques rely upon ambiguous stimuli as opposed to the question and answer type formats of the MCMI or MMPI. In the application of these techniques, it is hoped the patient will reveal his or her inner conflicts, motives, drives, coping strategies, ego defenses, and reality testing abilities. The theoretical underpinnings of these techniques are based upon how the dynamics of early development shape the structure of the self, and, in turn, how they influence the way the patient organizes and perceives his/her world. These techniques provide a window into the phenomenology of the individual patient and a view of the genesis and development of psychopathological processes.

Examples of projective techniques include drawings: human figures or settings; or incomplete sentences: "Most times I wish I could \_\_\_\_\_," or "Teachers made me feel \_\_\_\_\_." The Rorschach Techniques (Exner, 1974) and the Thematic Apperception Test (TAT) (Bellack, 1986) represent the hallmarks of this methodology. An analysis of the perceptual functions associated with the inkblot material of the Rorschach remain a valuable technique for differential diagnosis of schizophrenic disturbance even though the conventional psychodynamic interpretations of the content have become questioned in a number of quarters. The TAT on the other hand, presents a more realistic visual stimuli to which the subject responds by making-up a story. These interpersonal scenes provide not only a window into the psychodynamics of the individual, but also can be pragmatically interpreted when used with patients with chronic mental illness as an index of residual social skills. Their ability to interpret complex social scenes and respond in conventional fashion can be quite prognostic. The identification of potential sources of conflict (e.g., parents and authority figures) can be valuable for treatment planning.

**Functional Implications of Personality Assessment.** Summarized below are a sampling of the more functionally oriented inferences that can be derived when applying personality assessment methodologies with patients who exhibit chronic and severe major psychiatric disorders:

- Definition of the severity of the disorder
- Definition of chronicity and possible course
- Identification of the prominent primary as well as secondary symptomatology

Identification of potential sources of conflict

The provision of new hypotheses to be considered in furthering the understanding and treatment of the patient

It is not intended that the tests results alone are sufficient to develop predictive outcome statements. Personality assessment is a four stage process that involves: 1) a review of the relevant history, 2) a direct clinical interview, 3) an analysis of actual test data, and 4) when possible, the extension or modification of conclusions based on information derived either from third party sources familiar with the client or from direct observations. Family members and service providers can provide invaluable information regarding a client's actual adaptation and coping skills. As will be discussed in the Functional Assessment section, there have been a number of strategies developed to objectively evaluate social and interpersonal adjustment. Accrual of such data certainly extends the veracity of the inferences developed through the use of the more traditional measures described above.

### NEUROPSYCHOLOGICAL EVALUATION

#### Introduction

Neuropsychological testing has been traditionally associated with the elucidation of the nature and significance of brain damage. Increasingly, the neuropsychological examination is no longer being utilized exclusively for the purposes of differential diagnosis, but to help guide and direct the development of rehabilitation strategies. In this discussion we will not specifically focus on the mechanism of brain damage *per se*, but on the cognitive and information processing strategies that are ultimately subserved by cerebral mechanisms and how these functions can be impaired in severe and chronic psychiatric conditions. Cognition in this context will be defined as "broadly pertaining to the encoding, transformation, storage, and use of information for the purposes of regulating behavior" (George & Neufeld, 1988 p. 264). Our operational principle, thus, stresses learning or skill acquisition and problem solving abilities underlying all rehabilitation strategies. The understanding of how cognitive and information processing skills may be compromised in clients manifesting severe psychiatric disabilities becomes an important determinant in the assessment of their potential to benefit from specific types of rehabilitation interventions. This section expands upon the data base derived from evaluations of both intelligence and academic achievement, as well as personality characteristics to include sensory, motor and diverse higher cognitive functions such as attention, memory, and complex problem solving abilities. In this fashion, it is possible to more specifically delineate the individual strengths and weaknesses of the client in learning and problem solving.

#### Rationale

According to Boll (1977) neuropsychological assessment is a form of human ability testing that is unique for its attempt to further the understanding of brain-behavior relationships in both normal and impaired individuals. The neuropsychological assessments of a population of individuals who manifest severe psychiatric conditions has a long history. This includes the study of the schizophrenic spectrum disorders, as well as depression and mania (Miller, 1975; Goldstein, 1978; Heaton, Baade & Johnson, 1978; Heaton & Crowley, 1981; and Flor-Henry, 1983). More recently, Townes, et. al. (1985) undertook an investigation of nearly 500 patients referred for psychiatric treatment and who subsequently received neuropsychological testing. Twenty-five neuropsychological variables were considered in a Q-type factor analysis of patient performance. Their results revealed five distinct subtypes of neuropsychological performance within this population. The subtypes included: no impairment, profound impairment, an intermediate group in which basic intellectual faculties were preserved but deficits in complex problem solving skills were delineated, and two additional groups in which some modality specific information processing deficits were exhibited, i.e., one group with weak visuospatial skills and the other with weak language faculties. Interestingly the neuropsychological subtypes were found to be independent of primary psychiatric diagnosis. This study has been cited frequently as the basis for a competency-based model of classification that allows for the matching of treatment intervention strategies to the unique cognitive ability structure of the client.

Thus, in chronic psychiatric conditions, in addition to deficits in thought process organization, communication skills, and behavior problems, a variety of underlying cognitive processing problems can also be exhibited. It has been the contention of a number of authors (Erikson & Binder, 1986; Yorzawitz, 1986; and Liberman et al., 1986) that the cognitive and problem solving deficits inherent in these populations have ostensibly been ignored. A number of rehabilitation failures could be related to an inappropriate match between rehabilitation program expectations and the inherent cognitive ability structure of the client.

#### Neuropsychological Evaluation: Aims and Purposes

The neuropsychological evaluation is in many respects similar to standardized intelligence and achievement testing. Objective, standardized tests are administered and the results are scored relative to normative criteria. The hallmark of the neuropsychological tests is their validation as mechanisms to distinguish normal from impaired cerebral functioning. Hence, they have the capacity to allow for the development of inferences regarding the presence or absence of brain damage, the delineation of its location and severity, and more importantly, in the context of this discussion, the capacity to describe adaptive consequences for the individual undergoing evaluation.

A comprehensive neuropsychological test battery is typically composed of tests which tap basic sensory-perceptual faculties, psychomotor proficiency, higher level visuospatial integrative skills, constructional abilities, receptive and expressive language, attention, memory, and complex problem solving skills. Test batteries can be broadly conceptualized in three typologies: fixed batteries, flexible batteries, and the individualized or "patient-centered approach". Comprehensive approaches like the Halstead-Reitan Neuropsychological Battery (HRNB) (Reitan & Wolfson, 1985) or the Luria-Nebraska Neuropsychological Battery (LNNB) (Golden, Hammek, & Purisch, 1980) are representative of the fixed battery tradition. Coverage is provided across a number of performance domains relevant for clinical decision making. The LNNB consists of 268 discrete test items which can generally be administered in less than 2 1/2 hours. Its structure and composition make it readily applicable for use even with persons moderately impaired by psychiatric illness. The HRNB, on the other hand, can take up to 6 to 8 hours to administer. It typically also includes the WAIS-R, achievement testing, and the MMPI. Many clinicians augment it with other tests they find particularly useful. It contains several major component tests, some of which demand 20-40 minutes to complete. Moderately impaired psychiatric populations who cannot tolerate extended attention and effort tend to do quite poorly. It is, however, recognized as an extremely valid means for diagnosing structurally based cerebral dysfunction.

The breadth of coverage afforded by these instruments exacts a toll in time, effort, and energy demands on the part of the client. A number of these procedures also do not lend themselves readily to test-retest paradigms essential for short term monitoring of client performance. In some instances, while a test may have high differential validity, its utility for rehabilitation planning with this population may not be obvious. More often, the neuropsychologist will tailor a battery of tests to meet presenting needs. This includes consideration of such extrinsic factors as the nature of the referral question, immediacy of need, past level of premorbid functioning, and intrinsic factors such as client stamina, tractability, frustration tolerance, sensory-perceptual integrity, etc. Proponents of this latter approach represent the flexible or individualized approach. Here, it is not uncommon to utilize a brief core or screening battery and expand testing differentially based on those findings. Yozawitz (1986) and Erickson & Binder (1986) provide exemplary core neuropsychological screening batteries adapted specifically for the assessment of clients with chronic and severe psychiatric disorders.

#### Functional Domains of Neuropsychological Performance and their Adaptive Implications

As indicated above, there are a number of performance domains assessed in a neuropsychological battery. Rather than recapitulating a list of tests relevant

to the assessment of any of these dimensions, the current discussion will focus instead upon how inferences drawn from observed performances in these areas lead to an understanding of learning, problem-solving, and general adaptation. Discussion will be structured along the lines of a hierarchical model of information processing. For example, Johnson & Mykelbust (1967) described the components of problem solving as a function of sensation, perception, memory, symbolization and conceptualization. A simpler heuristic model appropriate for understanding the implications of neuropsychological performance on everyday functioning would include input, consolidating, incorporating, and output. This model proposes a hierarchical organization of these skills as they refer to: input, the stage where information is first acted upon, i.e., primary information processing functions; processing or consolidation, the intermediate neuropsychological functions where active mediation of information occurs, i.e., information is assembled and made meaningful; an integration stage which requires input from working memory; and finally, executive functions which are brought to bear to guide and direct output or the products of cognitive activity. A discussion of each of the primary domains of neuropsychological assessment included within a comprehensive battery is provided along with examples of how these functions might be compromised by functional psychiatric conditions, and thus influence rehabilitation outcome.

**Sensory-Perceptual Functions.** In order for behavior to occur, sensory systems must activate. At this level of analysis, the rule-out of any limitations in visual, auditory, or tactile-sensory processing is necessary. Deficits in basic sensory input have the potential to drastically limit active information processing and thus, ultimately limit learning or adaptation. Assessment typically begins with a coarse screening of visual and auditory faculties. Subtle problems with visual acuity while reading or failure to comprehend verbal instructions are not uncommon correlates of dysfunction at this level. It is not uncommon for staff to have experience with clients who have lost and not replaced eye glasses, fail to follow through on purchase of hearing aides, or to observe clients who are so unaware of such limitations that they do not seek consultations for the amelioration of these problems in the first place. Problems of this type typically represent peripheral rather than central nervous system related disturbances of perception.

Evidence of neglect, imperception, or suppressions would, however, suggest the potential for more cortically-based impairment. That is, information either is incompletely processed or not processed at all. These problems are typically lateralized, occurring only on one side of the body. Their most frequent cause is stroke. The frequency of such problems is typically very low, unless neurological problems are also part of the clinical picture. In populations with severe chronic psychiatric disabilities we tend to see a more subtle manifestation

of a similar, but distinctly different phenomenon, that of attentional impairment. In this instance, sensory-perceptual facilities themselves are not impaired, but it is the client's selective capacity to orient and attend that is dysfunctional. Information processing is an active-directive process. That is, we must be aroused, focused and attentive in order to perceive. Particularly in severe or acute stages of illness, these faculties can be severely impaired by primary psychiatric symptoms. In clients diagnosed with schizophrenia, for example, the selective filtering mechanisms appear to be dysfunctional. The patient may be attending to internal autistic stimulation at the expense of losing information from the world at large. In more acute manifestations of this illness, active hallucinations impair on-going information processing. In severe anxiety disorders the patient's cognitive focus is often so limited by his obsessional ideation that the individual misinterprets events or misses the events entirely. Cognitive psychology has amply demonstrated how persons having depression interpret almost any situation as negative, denying the obvious positive aspects of events which occur in their lives.

Another important related factor to be determined is how much information the client is capable of processing at a given moment. The number of discrete bits of information in an auditory or visual modality that the patient can act upon could significantly affect his or her ability to benefit from complex instructional paradigms or to understand complex directions. Knowledge of such selective information processing problems would cause the rehabilitation specialist to minimize the complexity of instructions or directions. In other words, before embarking on psychoeducational or vocational planning it is advisable to know something of the client's ability to assimilate information.

Before closing our discussion of sensory-perceptual abilities, mention should be made of tactile-kinesthetic functions. Here we refer to how well the client interprets information presented on the skin. Tasks to measure tactile functions include finger localization, point and pressure sensitivity, graphesthesia (interpretation of symbols or shapes drawn on the skin), and stereognosis (identification of palpated three dimensional objects). You may ask what relevance such tasks hold? First the early development of writing and reading is a multi-sensory experience. A deficit in tactile or haptic (muscle or joint) feedback can seriously retard development of writing skills and, hence, contribute to an overall retardation of reading abilities. More germane to adult populations, however, would be deficits seen in quality control or assembly line work that are secondary to diminished tactile accuracy. Imagine a machinist or auto mechanic displaying such dysfunction. More personally, picture what it would be like to function with diminished perception of sharp-dull, hot-cold or rough-smooth, in terms of the work you do around your own home.

Psychomotor Skills. In this domain abilities measured include speed,

dexterity, coordination, and strength. This includes not only upper-body and hand performance, but overall psychomotor integrity. A number of these procedures have been utilized in vocational evaluations. The Purdue Pegboard Test represents just such a commonly utilized methodology. In this test, the client is timed across 30 second intervals to measure how many pegs he or she can fit into holes using the right, left, or both hands simultaneously. Speed, dexterity, and coordination are assessed. Over the course of these and other exams, performance on the right side of the body relative to the left is contrasted. A right hand dominant individual should perform motor tasks with greater proficiency as compared to the left. Asymmetries and discrepancies from this expected performance pattern become the object of further investigation. Early developmental or acquired cerebral dysfunction could contribute to such performance asymmetries.

When compared against norms, performance across tests of psychomotor integrity can be particularly helpful in vocational decision making. For example, the Purdue Pegboard Test provides an indicator of the average performance of industrial assembly line workers. This gives some indication of the patient's performance relative to the standards in the field. When assessing psychomotor skills, we are also interested in the ability to carry out complex motor programs. Here, planning, regulation, and modification of performance in the face of changing feedback becomes more involved.

From an applied rehabilitation perspective there are a number of potential findings which are of significance. For example, motor slowing is not necessarily evidence of structurally based central nervous system dysfunction. The effects of neuroleptic medications on the extrapyramidal system can limit performance. Psychomotor slowing is a prevalent symptom associated with depression. Motor impersistence or fine control and regulation problems are frequently manifest in patients exhibiting hypomanic symptoms. Tremor from anxiety can significantly mitigate skilled movements. We can see evidence of diminished strength in persons who have been chronically institutionalized and who have not been sufficiently stimulated or have failed to maintain muscle tone. These individuals typically require work hardening programs before they can engage in demanding programming. Multisystemic medical disorders could also exert an influence on performance. Finally, we sometimes confront patients who can perform discrete skills adequately, but cannot integrate these skills into a series of complex behavioral sequences. A deficit in executive functions secondary to defect state schizophrenia might result in such difficulties with complex motor programming.

**Spatial Integrative and Constructural Skills.** As we move up the scale in level of complexity from primary sensory-perceptual and psychomotor functions, we encounter tasks which require the integration of visual, spatial and

motor skills. Spatial disorientation refers to any defect in the ability to relate to position, direction, or movement of an object in space. This relates pragmatically to real world functions such as right-left orientation, body schema organization, directional sense, distance estimation, and topographical orientation. At a first level of analysis these tasks are assessed via mechanisms which require mental manipulation or revisualization skills.

These processes become much more complex when we add a motor or constructional component to the problem solving task. Here, reference back to the discussion of the Block Design and Object Assembly subtests of the WAIS-R is in order. Observation of a client's performance on such tasks offers important insights regarding visuo-spatial conceptualization skills, problem solving style (orderliness and planning), and speed. Qualitatively we note the sophistication, thinking processes, temperament, impulse control, and self-attitude manifested by the client. These subtests provide an excellent opportunity to observe work habits under challenging conditions. A further function of assessment in this domain is to rule-out any secondary developmental information processing difficulties, distinct from the CMI condition, that could limit adaption, e.g., a non-verbal learning disability.

**Language Functions.** Aphasia examination represents a mainstay of the neuropsychological evaluation. Proficiency in both expressive and receptive language skills is assessed under conditions of varying complexity. The components of this examination include spontaneous speech, repetition, comprehension, naming, reading, and writing. Combinations of deficits in these areas form the basis for the differential diagnosis of aphasic syndromes. The base rates for specific aphasic syndromes in this population is low. Evaluation in this area is, nonetheless, extremely useful.

Language serves as the basis both for thought (internal communication), as well as for speech, our primary means of communication with the world at large. Both schizophrenia and depression are noteworthy for exerting both subtle and profound influences on communicative effectiveness. Neuropsychological testing offers a unique and unobtrusive medium to examine for such effects. In terms of the pragmatic utilization of language, we look first towards the communicative efficiency of expressive language. Is speech articulated clearly, well formed, and fluent? Does it conform to the general rules applied to language use, i.e., grammar and syntax? How sophisticated is it in terms of organization, complexity and coherence. A fundamental question in terms of functional ramifications is: How well do expressive language functions translate into the patient's ability to articulate his or her personal and social needs and enable him or her to communicate with the world at large?

We look in similar fashion at receptive language faculties. Can the client understand progressively more complex verbal material? (From phonemes, to

words, to phrases, to sentences and interrogatives which contain complex relative, attributive and comparative structures). These lines of inquiry focus on how well the client can take directions, how complex these directions can be, and what special learning paradigms will need to be incorporated into training to compensate for any identified weaknesses in receptive language faculties.

**Memory and Attention.** These faculties refer to the ability to acquire new information, organize it, encode it into long term memory store, and retrieve it. Information must first be actively processed if it is to be learned. We are not passive receptors of sensory information. We select that to which we wish to attend. We filter and augment sensory information based on our personal and experiential histories. Before we can even consider memory efficiency, the first order of analysis is the rule-out of any dysfunction in attention or decreased motivation as factors limiting performance. Here, we assess for the presence or absence of any modality specific sensory dysfunction, general or specific attention deficit disorder, effects of functional psychopathology, or motivational symptoms. Depression, schizophrenia, dysthymic disorders, and anxiety and phobic disorders can all affect selective filtering mechanisms. We can conceive of this on a continuum of subtle through severe effects. A subtle effect might be reflected in depressive thought where negative introjects contaminate the interpretation of information. The patient is convinced of his or her low self-worth and selectively refuses any evidence to the contrary in his or her thinking. Hence, performance suffers. Moderate impairment may be seen in the obnoxious client who is missing relevant information about his life circumstances secondary to his or her "myopic" preoccupation with trivial concerns. Such a client might answer current events questions incorrectly due to lack of awareness. The obvious worst case scenario would be the client who exhibits impaired reality contact associated with schizophrenia. It is not uncommon to confront serious errors on temporal orientation questions in the acutely symptomatic patient.

With attentional faculties given due consideration, memory processes can next be considered. Memory is generally assessed across three stages: immediate (attention), short term (new learning), and long term (remote). Memory is assessed in a modality specific fashion; that is, the rule-out of any differential strengths or weaknesses in verbal, visual, spatial, and tactile-sensory memory. This helps define areas of learning which might be either emphasized or limited in training. We are also interested in encoding strategies, i.e., those activities the client uses to organize, categorize, and semantically or visually structure material that is to be learned. We attempt to ascertain what, if any, strategies might be applied to augment memory organization. These faculties all relate to new learning or short term memory strategies. Remote memory refers to the ability to recall or retrieve previously learned material from memory stores.

Therefore, it is important to assess recall of relevant material that might be based on educational experiences, as well as the client's personal history. Thus, we can see that dysfunction which occurs in memory can occur at a number of levels.

One does not expect to confront classical amnesic states (organic memory disorders) when evaluating the rehabilitation of clients with chronic mental disorders. The exception to this might be a history of head trauma or long term alcoholism as comorbidity factors. Rather, the emphasis is generally placed upon how impaired attentional capacity secondary to functional psychopathology can impede memory and new learning.

**Complex Problem Solving Skills.** Under the rubric of this heading are included proficiencies in the application of intelligence and academic skill competency in problem solving. Since this material has already been discussed, this section describes a more limited set of higher cognitive operations which are critical for autonomous functioning. Here, the focus will be on complex, simultaneous, and sequential cognitive operations and the executive functions.

As a patient interacts with the social world, he or she is confronted with tasks which demand cognitive flexibility, speed and efficiency, the ability to identify concepts and to apply novel reasoning, the ability to perform in the face of changing circumstances, and the ability to recall incidental material from the past to aid in contemporary problem solving. A wide variety of neuropsychological tests involve challenges for the integration of a variety of information processing and problem solving skills. Examples include the Category Tests (Halstead, 1947), Wisconsin Card Sorting Test (Berg, 1948), Raven's Standard Progressive Matrices Test (Raven, 1960), Trail Making Tests (Reitan & Wolfson, 1985), etc.

An individual is also expected to exhibit broad-based, self-regulating capacities necessary for sustained goal-directed behavior. These capacities include: planning, self-monitoring, the use of internal language mediation, motor control, and cognitively-mediated, goal-directed behavior. As can be seen these processes overlap with several of the neurocognitive capacities previously described. These executive functions are included as a separate category because together these procedures characterize the client's ability to employ active cognitive strategies in an on-going and adaptive manner. Tests, at this level of analysis, contribute to knowledge of the client's "metacognitive" processing abilities.

Deficits in these executive functions can frequently be encountered in chronic psychiatric conditions, especially schizophrenia (Pogue-Geile & Zubin, 1988). If one contrasts deficits commonly encountered in defect-state schizophrenia and the behavioral dysregulation of clients with frontal lobe damage sustained in head injury, a number of commonalities are apparent: deficits in long term planning; diminished skills for self-evaluation; weak selective attention; problems with the ability to inhibit impulsive behavior; problems with complex

integration and understanding of the physical, social and psychological worlds and deficits in the planning and regulation of motor behavior

Patients who have sustained severe traumatic brain injury pose a number of substantial rehabilitation challenges within the community after their acute care needs are met. While clients can be trained in discrete skills, their ability to carry out these skills effectively and autonomously within the community has remained typically impaired. Deficits in forming goals, planning, and the monitoring of behavior may be confronted. These deficits in self-regulation and self-direction are similar to those that are manifest by clients having long term mental illness, especially those having long years of debilitating schizophrenic illness. It is interesting to note that a great deal of theoretical conjecture has focused on whether or not schizophrenia can indeed be explicable as a form of frontal system pathology. The purpose of this discussion is not conjectural, but pragmatic. What can we derive from this comparison? The premise advanced in this discussion is that neuropsychological testing offers insights into cognitive factors which may underlie or may be associated with least some of the functional deficits seen in clients with chronic mental illness. Whether or not these cognitive deficits are secondary to underlying cerebral dysfunction or are a component of the neuropsychiatric disorder, their effects upon adaptation are significant and they need to be considered in rehabilitation planning.

#### SUMMARY

This section has offered both a description and a redefinition of traditional assessment techniques. Effort was made to focus upon the cognitive and information processing deficits which may underlie forms of chronic mental disorder and which may contribute to limitations in instrumental task performance. In addition, a rationale for "process oriented vs. psychometric approach" toward assessment was discussed. Functional assessment methodologies will be considered next.

#### FUNCTIONAL ASSESSMENT

##### Introduction

Traditional forms of psychometric assessment have generally been directed at native ability or capacity, i.e., measures of inherent ability. This reflects a tradition in testing which was established in the 1950's. Measures of general ability such as intelligence and aptitude tests have been increasingly questioned in regard to their ability to predict outcomes with specific clinical populations. Over the years questions have been consistently raised regarding the significance of scores on any psychometric test to predict the ability of persons having disabilities to adapt in the community.

It was perhaps within the tradition of services for persons diagnosed with

mental retardation that this question was most poignantly raised. Traditional assessment with this population relied heavily upon the evaluation of formal intelligence with little consideration of other factors. With mandates for least restrictive treatment alternatives and the development of community-based treatment services came an awareness of glaring discrepancies in the ability of traditional assessment technologies to aid in treatment and service planning. An anti-psychometric movement in conjunction with the burgeoning development of "behaviorism" arose within some quarters of the field of the developmental disabilities. Central in this regard was the criticism that traditional testing led only to the generation of generic labels, i.e., "Moderate Mental Retardation." Assessment solely for diagnostic or classification purposes was viewed as counterproductive, since it demonstrated little benefit for advancing the predictive potential of individual rehabilitation efforts.

Within this zeitgeist, the emergence and subsequent development of a radically different assessment technology, functional assessment, occurred. In only a few years over 125 functional instruments were developed. These instruments purport to increase treatment planning efficacy by refocusing the assessment process upon the pragmatic evaluation of individual strengths and weaknesses that a client might show in his or her adaptation to specific environmental contexts. Dichotomous camps of those who held rigidly to "traditional assessment" and those who ignored this source of data only to focus on outcome measures of adaptive skill competency developed.

In their landmark text *Mental Deficiency*, Clarke and Clarke (1976), offered reappraisal. Summarized below is their integrative definition of "assessment":

Assessment....

1. Describes an individual at a particular point in their development of intellectual, social, emotional, educational and allied variables with reference to a normative or contrast population.
2. Predicts performance of an individual at a future point in time.
3. Provides a profile of assets and deficits in order to determine the starting point for further intervention.
4. Provides an objective means to monitor progress over time (p. 371)

Both systems or philosophies of assessment were recognized as having relevance to the total description of the client.

The field of psychiatric rehabilitation has also seen the evolution of functionally based systems of assessment guiding and directing intervention. The literature has reflected that in terms of outcome, traditional applications of psychodiagnostic assessment methodologies did not correlate with eventual vocational or community adjustment outcomes, or contribute to the elucidation

of skills requisite for overall community adjustment. Testing conducted purely for classification purposes shed no light on the individual variability so frequently seen among individuals sharing the same diagnosis. Ratings of personal, social, and work adjustment have, however, helped to describe how individual differences affect outcome.

A goal of psychiatric rehabilitation is to assure that an individual with a psychiatric disability can perform those skills necessary to live, work and learn in his or her community with the least amount of support (Anthony et al., 1990). Persons with psychiatric disabilities must be able to perform certain functional skills in order to maintain themselves independently in the community or to become re-integrated into the community at large. This is accomplished through two basic forms of interventions: 1) teaching clients the skills necessary to function as independently as possible, and 2) developing community and environmental resources necessary to support or strengthen the functioning of clients who fall short of independence. Functional assessment methodologies provide not only a basis for individual prescriptive treatment planning, but also offer a means of addressing various systems-related concerns, such as evaluating intervention effectiveness, monitoring outcomes, and planning for anticipated needs. The remainder of this discussion will focus upon functional assessment issues as they pertain to individuals with chronic mental illness. The need to rely upon not one single modality for assessment, but to incorporate functional assessment methodologies into a larger framework of comprehensive interdisciplinary evaluation, will be emphasized throughout this discussion.

#### THE DEFINITION AND USES OF FUNCTIONAL ASSESSMENT

Simply defined, functional assessment is the measurement of what a person can and cannot do. That is, the elucidation of behavioral strengths and weaknesses as they relate to particular goals. It is undertaken to aid in determining the impact of physical and mental impairments on behavior. Functional assessment offers a broad range of potentially useful information in the treatment of persons with chronic mental illness. A comprehensive functional assessment allows for the:

- a) specification of both abilities and limitations in terms of self care and instrumental skill functions;
- b) identification of the presence or absence of social and interpersonal skill deficits and strengths;
- c) identification of remediation, training, or compensation techniques; and
- d) identification of educational, vocational and community support needs.

Strategies utilized in the process of functional assessment vary considerably both in terms of methodology and content. These strategies include both formal

and informal techniques. In terms of informal techniques, the presenting background history and psychological test history provide a rich source of anecdotal information which is pertinent to the formation of impressions about functional skill integrity. In particular, psychoeducational, medical, and psychological test reports that provide expanded discussion of pertinent observations about performance, as well as scores, can be quite helpful. Third party reports of functional abilities and needed resources may be acquired from family members, professional colleagues, or others knowledgeable about the client's skills. These types of information can often serve as a springboard for the development of more formalized assessment techniques. Caution is raised, however, regarding the unsystematic use of information acquired in this fashion because such information lacks objectivity.

### THE METHODOLOGIES OF FUNCTIONAL ASSESSMENT

Within the context of "formal" functional assessment methodologies, rating scales or questionnaires are often considered in the forefront, as these are

Table 3. Methods of Functional Assessment

Behavioral Interviewing
Direct Observation
Self-Observation
Checklists, Questionnaires, and Rating Scales

the most prevalent and readily available techniques. They represent, however, but one methodology available for use in functional assessment. Four distinct models can be applied to the functional assessment process (Liberman, 1982).

**Behavioral Interviewing Techniques.** In this methodology, clients are asked to provide direct or personal descriptions of their assets, deficits, and possible excesses in terms of critical incidents or behaviors. Some interviewers utilize a structured interview schedule; that is, all clients assessed would be screened across the same set of questions. Other practitioners are far less structured and utilize behavioral interviewing techniques within the context of a more open-ended, problem-centered interview. A prototypic structured interview, the Vineland Adaptive Behavior Scale (Sparrow, Balla, & Cicchetti, 1984), utilizes a formal questionnaire (rating scale) as the basis for the interview. The interviewer does not simply ask a respondent to rate behavior item by item, but rather seeks descriptions of client ability across varied settings, and then utilizes this information to later rate and quantify items on the behavioral questionnaire.

Many clinicians favor the behavioral interviewing methodology for a number of obvious reasons. It "personalizes" the assessment experience and increases the personal role of the client in treatment planning. Critical behavioral

issues can be immediately explored in terms of a hierarchy: "What" ... "When" ... "Where" ... and "How" so as to obtain knowledge of contingencies and reinforcers that may maintain or preclude specific behaviors. Behavioral interviewing also lends itself to refocusing the client upon phenomenological issues, i.e., what he or she may be doing, thinking, or feeling in specific situations. This process facilitates opportunities for the client to gain insight into those factors which may be contributing to his or her condition. Finally, in such a process the patient is in an excellent position to aid in hierarchically organizing "strengths" and "needs" lists. The prioritization of intervention goals becomes a personalized experience for the client. For the clinician, factors which interfere with the development of insights become immediately recognized and can become the object of further counseling interventions.

**Direct Observation Techniques.** One of the most potent means available for functional assessment is direct observation. Here, the client is directly observed "in vivo" or in simulated experiences and his or her behavior is critically evaluated. An example of this can be seen in the work of the occupational therapists. In order to assess lunch making skills, for example, the client can be taken to an equipped kitchen facility and directly observed across a number of variables which include planning, organization, technique and outcome. Although direct observation represents both the most valid and reliable means of behavioral assessment, it is also the most costly in terms of manpower and resource utilization.

Typically, time-sample event recording offers a more efficient means to achieve the same purpose. Within a particular setting, at specified time intervals, objectified behaviors can be observed across parameters such as presence-absence, frequency, duration or intensity. In this fashion, multiple staff members could assume some responsibility for observation and recording of relevant data, thus making the process less labor intensive. Handbooks of behavior therapy (for example, Rimm & Masters 1977), are usually replete with examples of how direct observation and recording techniques can be implemented to evaluate behavior. It is often staff ingenuity that contributes more to novel applications of this type of assessment than technical manuals.

**Self-Observation Techniques.** A related, but frequently ignored methodology borrows many of the time or event-sampling techniques of observational strategies, but uses the client to monitor the identified behavior. For example, at specified time intervals, the client takes a behavioral "self-examination", and enters data. These techniques are particularly valuable for cumulatively monitoring behavior over protracted time periods. Improvement of personal attention to appearance and hygiene represent categories of behavior well suited to this technique. In addition, log books, diaries and event counters (frequency tallies)

might be utilized. Central in this methodology is the opportunity for the client to gain experience in actively self-monitoring behavior. In many persons with chronic mental illness, a deficit in the ability to self monitor behavior represents a primary impediment toward gaining greater social and community acceptance. The greater assimilation on the part of the client of critical self-appraisal skills rather than reliance on third party evaluations offers an important barometer of autonomy and potential for success in independent living.

Checklists, Questionnaires, Rating Scales. Functional assessment inventories offer a number of distinct advantages in terms of feasibility, breadth of coverage, and economy of application. A number of instruments have been developed and applied across diverse treatment settings. They vary considerably in both length and breadth of coverage. In this paradigm, various behaviors are evaluated for presence-absence, quantity, frequency, etc. Inventories exist in a number of forms. Ratings may be provided by third parties familiar with the client, such as staff or family. Equivalent forms exist where the client rates his or her own behavior as well. There are instruments which focus exclusively around limited aspects of adaptive functioning, such as vocational skill competencies or self-care skills, while others provide more global ratings across a number of disparate behavioral categories. Acker, 1990; Wallace, 1986; Green & Gracely, 1987; and Weisman, 1975, provide reference to a diverse sampling of functional rating scales applicable across a number of patient groups.

Despite the apparent diversity and availability of standardized rating scales, there remain a number of practical limitations associated with their use. Practitioners frequently report lack of sufficient specificity of the material sampled in comparison to the environmental contexts in which their clients function. An instrument might under- or over-sample particular categories of behavior. Those which provide quantitative scores based on normative standardization frequently suffer from restrictive parameters associated with the reference population in question. An example of this is seen in the application of a prototypical functional inventory which is used for persons who are mentally retarded, the Adaptive Behavior Scale (Nihira, Foster, Shellhaas, & Leland, 1974). The normative base for this instrument were clients who were institutionally served rather than those who had exclusively been served in community-based programs. Although one of the most frequently cited assessment instruments in use with this population, it remains restricted in its normative application because of its standardization on institutionally served clients.

Despite these limitations, the rating scale methodology serves a very valuable function in initial case management and service planning by providing a checklist for identification of presence or absence of critical skills. In terms of aiding in the monitoring of treatment or service interventions, rating scales and checklists can serve as a basis for pre-and post-intervention measures of

performance and thus serve as valuable criteria for outcome measurement. An ideal instrument would offer not only an indication of the "presence or absence" of critical skills, but also the provision of scales which permit objective rating of the frequency of occurrence of targeted skills and the severity of behavioral deficits or maladaptive behaviors. As the development of inventories becomes more refined, we should see improvements particularly in this latter direction.

There remains yet another alternative for the practitioner of functional assessment, that of the development of unique, environmentally or programmatically specific instruments. A sampling of standardized inventories can be accomplished along with an inventory of behaviors considered critical within a specific environmental context. Agency or program specific rating scales can be developed as hybrids of other assessment tools. Such measures offer the potential to better serve individual programmatic interventions and needs. It is also quite reasonable to attempt local normalization of such instruments, or to attempt development of criterion validation. An example of this might be the determination that 80% of clients who scored above a specific rating scale score were also successful in transferring to a higher level of programming. In such a scenario, an outcome measure on a rating scale becomes one of the critical factors evaluated in the process of determining readiness for programmatic advancement. Thus, instrumentation serves the purpose of not only identifying targets for intervention, but also as a criterion measure in evaluating outcomes and service planning.

#### GENERAL PRINCIPLES OF FUNCTIONAL ASSESSMENT

Regardless of the methodology utilized for obtaining information regarding client assets and liabilities, there are certain general principles which can be applied in conducting the assessment and extending this information into generalizations appropriate for treatment or service planning. Cohen and Anthony (1984) provide a number of practical recommendations in this regard. A number of principles have been adapted and expanded upon for this discussion. Adherence to these principles helps to assure that functional assessment will be both meaningful and practical.

Functional assessment must relate to an overall rehabilitation goal that is environmentally specific. The objective of assessment is to gain an understanding of the client's assets and liabilities as they relate to skill demands that are likely to be confronted within particular environments. The needs of the client may vary significantly across the settings in which he or she functions, i.e., the residential, the vocational program or work place, or educational and recreational programs. Assessment must, therefore, be "context specific." The evaluator cannot presume that a strength or deficit observed in one environment will necessarily transfer across program boundaries. A central problem confronted in dealing with persons with long term mental illness is the possibility

that newly learned skills may not generalize across contexts. It is therefore important for the evaluator to consider actively the number of domains in which a particular behavior might have to be assessed. The principle further reinforces the concept of "ecological validity" discussed earlier.

Environmental specificity is also significant because it is this feature which distinguishes functional assessment from more traditional forms of psychometric assessment. Traditional psychological assessment provides general descriptions of cognitive performance and personality attributes. These descriptions are gathered within the context of a rather unique social and environmental circumstance--the consulting room. Inferences are drawn and generalized to the broader environment based upon objective results and impressions gathered in this context. Traditional psychological assessment does not, however, provide an opportunity to assess behavior as a function of the environment in which it occurs or to extend generalizations by specifying how behavior may differ across environments. Functional assessment, on the other hand, offers a means to assess behavior with "situational specificity." It thereby offers an excellent medium by which to extend the results or inferences derived from more traditional assessment methodologies. Utilization of both types of assessment, is, therefore, highly recommended.

The language of functional assessment must be behaviorally defined. A "skill" represents a set of behaviors that are both observable and measurable, and therefore, "teachable." If we as evaluators are going to translate successfully observations of client performance into statements which program staff can act upon, we must convey this information in objective terms. If we are going to attempt to monitor client change, our observations must be in terms which are measurable. The "Rule of the W's" is an aid in conceptualizing behavior in this fashion. Behaviors must be defined by WHO is performing it, WHAT behavior is the focus of the intervention as well as by the circumstances associated with the behavior--the (WHERE, WHEN, and with WHOM). These statements are advanced "positively" and in a language of "doing." Expectations for both the client and support personnel are clearly delineated in terms of "personal responsibility."

Functional assessment is always individualized. Clients carry with them a unique and distinct phenomenon which sets them apart from every other individual. Too often the utilization of a stereotyped approach to behavioral assessment and treatment planning results in the re-application of fixed formulations of problems and interventions. Too rigid an adherence to a mechanistic formulation of skill deficits that does not take into account "personal" variables can result in treatment failure.

An example of this problem can be illustrated by considering the implications of the development of enuresis in a client. The sudden emergence of this

problem in a client recently transferred to a new setting could signal any one of a number of possible underlying etiologies that would influence eventual treatment. So often in an exclusively "behaviorally oriented" functional assessment methodology there is a tendency to view outcome behavior to the exclusion of potential cause. In this case, the manifest behavior could have its basis in a functional etiology i.e., anxiety related to the transfer. From a psychodynamic perspective, enuresis could represent regression to more primitive behavior in the face of weak ego defenses that have been challenged. From a behavioral perspective this same symptom could represent a manifestation of "learned helplessness" that was previously displayed when the client was confronted with uncertainty. A complex alternative set of hypotheses could be derived if we consider medical causes. Could the enuresis be a function of the sudden onset of diabetes, which is often accompanied by increased urinary frequency? Neurological complicity is also possible, i.e., normal pressure hydrocephalus. Finally, we must also consider other factors ever present when serving neuropsychiatric populations, the side effects of medication. This example sets the stage for the next principle of functional assessment.

Functional assessment must be comprehensive. It could be argued that this principle relates not only to the breadth and scope of the assessment methodology, per se, but also the overall status of the client; that is, his or her physical, emotional, social and cognitive status. The above example highlights the fact that functional assessment does not occur in a vacuum. The active consideration of other assessment data accrued through multidisciplinary means is essential before embarking upon treatment.

This principle has other important implications. Any efforts at functional assessment result in the development of a descriptive data base. This data base allows for the construction of short term and intermediate range goals which are built sequentially into more general long term goals, which in turn lead to a final primary objective. Such sequential planning is frequently facilitated by organizing the items in a functional assessment inventory into developmental sequences that reflect the order of attainment of more complex behaviors.

Developing a comprehensive functional assessment methodology also means it is necessary to go beyond the assessment of pragmatic physical skills, i.e., meal preparation, grooming, or handling public transportation. Behaviors must be cast in light of the emotional and intellectual status of the client because problems in this sphere can significantly negatively influence skill acquisition. Any identified information processing deficits must be considered when developing both training methodologies, as well as well as strategies that will be utilized to sustain "maintenance" behaviors.

Functional assessment requires active client involvement. The extent to which the client is actively involved in the processes of both assessment and

treatment planning enhance the probability that he or she will understand "what" will be required and "why." At first glance this may seem obvious. There is, however, a significant issue which relates to persons with long term mental illness and the problem motivation. Indeed, special effort may have to be given to engaging the client in the assessment and planning process. Active incorporation of the client into treatment planning can aid in "empowerment." As clients become attuned to what is required of them and, more importantly, why it is required, the chances for successful rehabilitation increase.

**Functional assessment should focus on strengths as well as deficits.** The ultimate objective is to delineate what the client can as well as cannot do. Often, assessment personnel can slip into a tendency to overfocus on the identification of skill deficits. Functional deficits frequently noted in persons with chronic mental illness include the following (McCue, Unpublished manuscript):

- impairment of abstract attitude and concrete thinking
- inability to make generalizations
- misinterpretations of spoken, written language
- failure to attend
- lack of motivation
- failure to persist in tasks
- inability to get along with others
- lack of initiative
- psychomotor abnormalities
- disturbance of memory and learning
- slow to process information
- difficulties in categorizing and organizing input

An important aspect of rehabilitation interventions, however, is the identification of areas of residual strength. Frequently it is upon these areas that the therapeutic interventions are structured in order to "remediate" or "compensate" for such deficits. It is also important to note that persons with long term mental illness often readily develop a negative self-focus. Anticipation of failure can be a significant stumbling block. The identification of residual strengths can become an important source of therapeutic benefit for certain clients. The development of an improved self-image through this process then influences more positive motivation toward program goals.

**Functional assessment requires that the client and the evaluator understand both present and anticipated needs.** Rehabilitation effort is understood as a "process" that is ongoing. Evaluation must be conceptualized in the same context. The practitioner must assume the perspective: "Where is my client currently?" Where does he or she need to be in the immediate and long term future?" As indicated previously, it is critical that efforts be directed toward a

superordinate goal. Assessment and subsequent intervention strategies provide the bridges to span the gaps between the client's current status and intended outcomes. The process runs smoothly to the degree that both the client and practitioner agree upon realistic goals and methods. Comprehensive functional assessment provides a valid basis for decision making regarding intermediate goals which build logically toward more extended goals.

Conceived in this fashion, functional assessment as a methodology offers an approach to the central question confronted by service providers: "How may I help my clients who have chronic impairments to achieve maximum quality of life and independence in daily activities?"

At its simplest, functional assessment represents a means to describe abilities. Our goal as service and treatment providers is to develop a performance oriented data base or profile of our clients. From this profile, problems and needs are mutually identified, interventions are planned, and long term goals are developed. Periodic re-evaluation across these performance measures provides the means to quantitatively ascertain progress toward the attainment of long term goals. In effect, functional assessment data provide a relevant foundation for many types of case management and treatment related services. If one adopts recommendations described above for conducting any type of functional assessment, that is, behaviorally defining skills and needs in terms that are observable and measurable and following the "rule of the five W's", one has the groundwork available for the ready translation of raw data into prescriptive treatment plans.

It is emphasized that functional assessment remains only one spoke in a more intricate wheel. Each client presents with unique physical and biological endowments, cognitive strengths and weaknesses, affective characteristics, and interpersonal skills. The failure to assess instrumental community-based adult daily (ADL) skills or vocational skills against the backdrop of the aforementioned variables can lead to complications. Attempts at treatment intervention or service implementation should occur only after a comprehensive evaluation is complete. Further, the most successful rehabilitation strategies are presumed to be those which are built upon the client's existing skills, talents and resources.

#### SPECIAL FUNCTIONAL IMPAIRMENT IN POPULATIONS WITH CHRONIC MENTAL ILLNESS

The development of knowledge about how psychopathology is uniquely manifest across various syndromes is one function of the DSM-III-R classification system. We must, however, look beyond mere description and further examine how various symptom constellations might have an impact upon daily functioning. Symptoms themselves can represent significant impediments to adaptive functioning. The psychoses will be evaluated for their potential impact upon performance. Delusions, hallucinations, and fantasies interfere with perfor-

mance by blocking or diverting attention from reality demands. Autistic preoccupation significantly interferes with the ability to attend to or respond to interpersonal cues from the world at large. These symptoms are the most obvious, florid, and immediately disabling. They are, however, the symptoms which respond most immediately to neuroleptic medication.

There are a number of more residual, secondary symptoms which may be manifest even in the face of well controlled Schneiderian first-rank symptoms. Social isolation can reflect itself in anxiety or in severe interpersonal discomfort in social situations. Diminished attention to grooming and hygiene or the improper modulation of behavior in public may negatively influence social acceptance. Oddities in speech and mannerisms might further exacerbate this rejection. Suspiciousness associated with paranoid ideation can radically affect factors such as response to constructive criticism. Subtle thought disorganization and impaired judgment and reasoning can negatively influence complex problem solving. The person who mediates the environment successfully possesses the ability to interpret social cues and react within the boundaries of normal social convention. It can easily be seen, therefore, that psychotic symptoms alone or in combination can seriously interfere with adaptive functioning, especially social adaptation.

We can also associate functional limitations with the symptoms accompanying the affective disorders. Depression, for example, conveys impressions of dysphoric mood and diminished performance ability. Clients vary significantly in the degree to which neurovegetative (sleep, appetite and arousal state) symptoms are manifest. Fatigue and decreased energy can radically affect performance level on the job or in educational arenas. These symptoms may dissipate or they may remain chronically refractory in some patients, thus, imposing long term repercussions. Both "cognitive," as well as the affective repercussions of depressive disorders are now recognized. Severe impairment in occupational efficiency, memory and concentration, and practical problem solving can occur and be more functionally debilitating in the workplace than the mood disturbance.

We have only briefly highlighted some of the "functional" ramifications of symptoms in order to emphasize the need to assess their impact upon a client's "everyday functioning." It is relevant to take the individual symptomatology associated with any DSM-III-R major psychiatric disorder and attempt to conceive of its impact upon motor, cognitive, language, social or executive functions. The breakdown of symptom related problems into subsets is one means of further understanding their specific impact and then individualizing potential intervention or compensatory strategies. There is a further advantage of maintaining a symptom related focus while conducting functional assessments. Once

symptoms and problems are clearly defined with this population, it is important to identify the factors which maintain them. Here the emphasis is upon etiological underpinnings of problematic behavior from a biopsychosocial perspective. Treatment efforts should follow as a function of identification of causal determinants. Psychological factors related to genetic, metabolic, and physical abnormalities require primarily pharmacological models of intervention. To the degree that psychosocial factors may influence the course of a disorder (onset, exacerbation, relapse and chronicity), behavioral and social interventions will be appropriate. In this case the practitioner would focus specifically on the antecedent and consequent events that maintain problematic behavior. Frequently, it is a combination of both treatment strategies that is required.

#### Behavioral Assessment Strategies

Environmental factors must be specifically examined to assess their potential influence on behavior. The practitioner engages in intensive analysis of the factors that support and maintain problematic behavior. Many resources are available which describe the principles of applied behavioral analysis. This discussion touches briefly on only four important components of the process: an understanding of the Setting in which the behavior takes place, its Frequency or Duration, and the Antecedent as well as the Consequent influences on a particular behavior or set of behaviors.

**Setting.** The first of the Cohen and Anthony (1984) functional assessment principles discussed focused on the need for environmental specificity. A critical question to be answered is, "In what situations does problematic behavior occur?". In the home?...At work?...In public places?...In isolation? One attempts to establish how generalized or situationally specific the problematic behavior may be. This indicates how complex and focused the resources associated with intervention must be. For example, with a client served in two treatment settings, will the strategies utilized in a partial hospitalization program be the same as those applied in a residential treatment program?

**Frequency.** It is important to ascertain the frequency or intensity of problematic behaviors. Not only are we interested in how frequently problematic behavior occurs, but also in its relative severity. A low frequency, severe behavior problem such as self-abuse occurring once or twice a week would be considered more critical for intervention than a high frequency obsessive-compulsive behavior problem that is quite innocuous, such as hand wringing.

**Antecedent influences.** One next focuses on antecedent conditions. What led up to the behavior in question? Antecedent events are rich and complex in their presentations and cover a number of spheres beyond the "behavioral". These include biological determinants such as amount of sleep or affective and situational factors. Any one or a combination of these factors could trigger

problematic behavior. The practitioner's role is to delineate isolated (infrequent) antecedent events for those which are encountered more frequently and tend, therefore, to sustain problematic behaviors.

Consequences. The consequences of a behavior affects frequency, duration, and intensity. Consequences tend to strengthen, weaken or extinguish problematic behavior. The "art" of applied behavioral intervention centers on the ability to grasp the nuances of the reinforcement hierarchies and motivational needs that shape behavior. Simply defined, reinforcers are environmental consequences which increase the probability that a preceding behavior will occur or be learned in the future. In populations of persons with chronic psychiatric disabilities, an important function is one of propagating a set of new, socially appropriate reinforcers to help sustain desired behaviors.

#### Behavioral Excesses, Deficits and Assets

The nature of the psychiatric problems clients with severe, chronic disabilities face has the potential to result in the identification of a wide variety of "deficits". The practitioner is also faced with numerous variables which have the potential to positively or negatively impact behavior within a particular program. One means of dealing with this potential "information overload" is to reframe behavior in the context of excesses, deficits, and assets. In this fashion, the most problematic negative behaviors are identified (the deficits and excesses), while at the same time the focus of client is also directed toward his or her assets. The assets represent islands of intact skills or abilities... "building blocks." By "keying" on assets, adaptive behavior can be strengthened and problematic behavior displaced or reduced in frequency.

Behavioral excesses represent maladaptive behaviors that occur at rates or intensities so high that they interfere with normal adaptive functioning. Handwashing, a routine activity, becomes pathognomic in the patient with obsessive-compulsive disorder when it occurs 50 times a day. Behavioral deficits represent necessary behaviors that occur with insufficient frequency, inadequate intensity, or in an inappropriate form. The "negative symptoms" of clients diagnosed with one form of chronic schizophrenia are representative of this class of deficits. Behavioral assets include social competencies, coping efforts, skills interests and abilities of the client, as well as his or her available social supports.

Moving beyond the mere identification of "strengths and needs" requires the capacity to translate outcome goals into specific behavioral categories that will become the object of treatment interventions. This is readily conveyed in the following example. A middle-aged male with a chronic history of refractory schizophrenic symptomatology is discharged from a hospital to your care. He presents with very good social-conversational skills. His delusions, however,

remain quite chronic. He becomes self-absorbed with content, particularly when he is alone or idle. He spends greater than 70% of every idle hour engaged in "self-talk". However, reduced rates of documented delusional references are reported when he is otherwise engaged in social activities. When information is reported and structured in this fashion, it becomes readily apparent what strategies might immediately be considered regarding intervention.

We will address one further point in this regard--the need to persistently refocus our ongoing assessments on the identification of client assets. A pitfall for the professional working with seriously compromised clients is a tendency to slip into a cognitive set in which the focus is primarily upon the analysis of client deficits. Therefore, in conducting functional assessments it is valuable to develop an "inventory of assets." There is a need to go beyond the simple listing of strengths as might be ascertained from an analysis of adaptive behavior rating scale results. This inventory should include an analysis of supplemental information that can be derived from interviews, accrual of client records and retrospective review of history, all of which help make this information more situationally relevant. The following questions can be used to organize this information:

1. What are the areas in which the client has consistently functioned best now and in the immediate past?
2. What does the client view as his or her most significant asset?
3. What is the extent of his or her available resources in terms of interpersonal and social supports?
4. What agencies and helping professionals are available to be mobilized in his or her behalf? With whom are there established favorable relationships?
5. What personal motivations and incentive to change have been identified?
6. What are the positive aspects of my therapeutic alliance with this client?

When staff move beyond the simple listing of "assets" to considering their implications in terms of "systems related issues" that are pertinent to the client's support, a foundation is laid for the transfer of this information into viable recommendations for service provision or treatment planning.

#### The Nested Skills Approach to Assessment and Training

One final strategy to be incorporated in the methodologies of functional assessment will be discussed. Critical in the rehabilitation of the individual with long term chronic disability is the question of whether or not the client can be trained to carry out routines of behavior. Daily living experiences are not limited to the carrying-out of discrete, isolated behaviors. Rather, our daily behavior reflects intricate routines and sub-routines organized in a complex interdependent fashion. Groups of actions are organized to meet the environmental

demands with which we are confronted. Up to now we have only spoken of functional assessment and intervention strategies occurring in a dichotomous fashion: "Are they present or absent?" ... "How frequently do they occur?" A more critical question centers on the ability of the client to carry-out complex multi-step operations and integrated actions. How effective is he or she in adapting behavior in the face of conflicting or changing environmental demands? How complex a routine is he or she capable of carrying out? In order to address these issues, data from the neuropsychological evaluation of executive functions take on special importance.

An example taken from the assessment of self-care skills associated with early morning routines will be considered. Typically, we would assess component skills associated with the discrete activities involved i.e., toileting, washing, shaving, toothbrushing, grooming, dressing. When we consider human behavior, we quickly realize how we rely upon "routines" in conducting such activities. It is frequently the case that when clients are screened across these behaviors, it is determined they are fully competent when performing each isolated activity. Missing in this limited analysis, however, is the evaluation of the degree to which the client can self-initiate and self-monitor sequences of these activities. Specifically, is the client self-motivated to perform these sequences of activities daily? Are there breakdowns in the sequences such that day-to-day they are completed in "hit or miss" fashion? Are some behaviors initiated appropriately but haphazardly carried out? Clients facing the consequences of long term, chronic mental illness typically have not lost the basic skills in conducting such activities, but may have instead developed deficiencies in the "executive functions" which relate to planning, organizing, or maintaining such activities. Although this is perhaps an overly simplistic example, one can extend the analogy to some of the complex behavioral expectancies staff impose upon clients. We must be mindful of breaking our assessment and training strategies into formats that permit a determination of how well the client can proceed through multi-step and sequential operations. Critical in this regard is the question, "Can the client consistently maintain these sequences? In a number of instances it may be found that we do not have to engage the client in skill acquisition training. Rather, what may be required is a refocus on the development of strategies that will aid clients in more effectively utilizing the self-monitoring, judgement, and reasoning skills needed to maintain and adapt their daily behavioral routines.

#### Resource Management

Once the functional assessment has been conducted and goals identified, resources must be inventoried and organized before proceeding with the rehabilitation plan. The client and counselor must actively consider the required resources which will have to be brought to bear in program implementation. This relates to multiple factors such as time, money, agencies, facilities, or transpor-

tation. There will need to be a delineation of who will assume the responsibility to carry-out individual aspects of the plan. A comprehensive assessment of the client's capacity to carry-out complex behaviors as highlighted above should aid greatly in determining the degree to which support will have to be extended in various areas. This support, in turn, will facilitate the client's maximum participation in the rehabilitation process.

#### SUMMARY

An overview of principles associated with both traditional psychometric and functional assessment has been provided. An attempt was made to highlight a variety of methodologies available toward this end. Within this context, special considerations were discussed which relate to the assessment of social, cognitive, and adaptational limitations of clients with severe and chronic psychiatric disabilities. Functional assessment was addressed as both a philosophy or orientation and as a technique. Thus, even traditional psychometric assessment methodologies if interpreted in the context of everyday problem solving skills can take on greater relevancy in client description. In a truly comprehensive approach toward assessment, adoption of a functional approach toward testing provides a definition of the client's 1) information processing style, 2) cognitive strengths and deficits, 3) problem solving skills, 4) coping resources, 5) personality style, and 6) strengths and weaknesses in environmentally specific skills that pertain to his or her residential, employment, and social living circumstances.

Functional assessment represents more than the mechanistic application of structured behavioral assessment strategies for the purposes of problem formulation. Rather, it represents a philosophy which can be adapted toward any of the more traditional forms of medical, psychological, and social casework assessment strategies as well. Indeed, this philosophy can be adapted to any evaluation which attempts to contribute to the understanding of how the quality of life and independence of a client with chronic mental illness can be furthered.

Special emphasis in this discussion has also focused on applications of neuropsychological evaluation techniques. Yozawitz (1986) and Erickson & Binder (1986) have taken the notion of competency based neuropsychological profiles and have applied them in the context of rehabilitation programming. Liberman, et al, (1986) summarize approaches to both social skill and social problem solving training focused on the unique information processing capacities (attentional and cognitive) of clients that could influence performance.

Thus, it would appear that we have available technologies which have the potential to further enhance rehabilitation outcome through the enhanced development of client ability structure. The future requires the development of paradigms that will assess the efficacy of such enhanced descriptions of client ability.

## CHAPTER 7

# ACHIEVEMENT TESTING

Lynda J. Katz  
Gregory T. Slomka

### INTRODUCTION

During the mid-1970s the use of standardized tests among a variety of elementary, secondary, and post-secondary educational programs came under severe criticism. It had been reported that the use of standardized achievement tests in particular involved over 80% of American school children, with some of these children taking 26 achievement tests during a school career (National School Boards Association, 1977). It has been postulated that this national concern with standardized tests has resulted from competition among the "baby boom" generation children of the late 1940s and early 1950s for "scarce slots in the choicest schools and businesses," so that their stakes of doing well or poorly on tests went up. Second, those same baby boomers were looking back on their experiences with years of taking standardized tests and were very sensitive to the perceived abuses of such testing (Strenio, 1981, p. xviii). The main criticisms of these tests have centered around the quality of the tests themselves, the use to which they are put, the behavior of the test industry (some 40 to 50 test publishers responsible for 90% of the tests used in the country today), and the consequences for society of the misuse of these tests. In addition, major court cases and federal legislation for exceptional children have addressed specifically the use of tests and testing as part of the overall assessment process (*Larry P. v. Riles* and P.L. 94-142), again in response to these same criticisms.

In November, 1975, at a conference on testing sponsored by the National Association of Elementary School Principals and the North Dakota Study Group

on Evaluation, 25 national organizations including the U.S. Office of Education drafted the following statement:

We believe that the public, and especially educators, parents, and children, need fair and effective assessment processes that can be used for diagnosing and prescribing for the needs of individual children.

We also believe that the use of fair, effective assessment practices is one way of being held accountable for providing quality education for all students.

We have grave reservations, however, about any continued use of so-called IQ tests.

In regard to standardized achievement tests, we have agreed on the following recommendations:

1. The profession needs to place a high priority on developing and putting into wide use new processes of assessment that are more fair and effective than those currently in use and that more adequately consider the diverse talents, abilities, and cultural backgrounds of children.
2. Parents and educators need to be much more actively involved in the planning and processes of assessment.
3. Any assessment results reported to the public must include explanatory material that details the limitations inherent in the assessment instruments used.
4. Educational achievement must be reported in terms broader than single-score national norms, which can be misleading.
5. Information about assessment processes should be shared among the relevant professions, policy makers, and the public so that appropriate improvements and reforms can be discussed by all parties.
6. Every standardized test administered to a child should be returned to the school for analysis by the teachers, parents, and child.

---	---

7. Further, the standardized tests used in any given community should be made publicly available to that community to give citizens an opportunity to understand and review the tests in use.
8. The professions, the public, and the media need to give far greater consideration to the impact of standardized testing on children and young people, particularly on those below the age of ten.
9. A comprehensive study should be conducted on the actual administration and use of standardized tests and the use of test scores in the schools today. (National School Boards Association, 1977, p. 18)

Thus, it is relevant and timely more than a decade later to

- review the historical development, classification, and psychometric properties of traditional achievement tests;
- update their status and use in terms of contemporary educational and clinical research and practice;
- consider the relationship of achievement testing to ecological and sociocultural variables and their use with special population groups; and
- take a futuristic look at the impact of modern computer technology on test construction and utilization.

Such a discussion may determine whether these recommendations regarding the use of achievement tests long since made, have been or will need to continue to be addressed.

### Historical Development of Achievement Tests

The standardized objective achievement test based upon a normative sample was first developed by Rice in 1895. His spelling test of 50 words (with alternate forms) was administered to 16,000 students in grades 4 through 8 across the country. Rice went on to develop tests in arithmetic and language, but his major contribution was his objective and scientific approach to the assessment of student knowledge (DuBois, 1970). Numerous other single-subject-matter achievement tests were developed in the first decade of the twentieth century, but it was not until the early 1920s that the publication of test batteries emerged: in 1923, the Stanford Achievement Test at the elementary level; and in 1925, the Iowa High School Content Examination (Mehrens & Lehmann, 1975). Since the 1940s, there has been a movement toward testing in broad areas as well, such as the humanities and natural sciences rather than in specialized, single-subject-

matter tests. Moreover, attention has been directed toward the evaluation of work-study skills, comprehension, and understanding, rather than factual recall per se. In the 1970s, standardized tests were developed that were keyed to particular test books, the use of "criterion-referenced" tests (CRTs) emerged (their dissimilarity from norm-referenced tests will be addressed in the next section), and the development of "tailored-to-user specifications" tests (Mehrens & Lehmann, 1975, p. 165) was initiated.

Now in the 1990s, the literature on achievement testing is concerned with latent-trait theory, item-response curves, and an assessment of learning achievement that is brief into the instructional process. The intrinsic nature of achievement tests themselves is changing. Computer-adaptive testing is not the computerization of standardized norm-referenced paper-and-pencil tests but a radically different approach. The approach is based on a concept of a continuum of learning and where a particular child fits on that continuum so that his or her experience with testing is one of success rather than failure. To appreciate fully this dramatic shift in the conceptualization of the assessment of achievement it is first necessary to understand (a) the nature of tests which fall under the domain of achievement; (b) the psychometric underpinnings of achievement tests; (c) the basis for criterion-referenced as opposed to norm-referenced measurement; and (d) particular issues which arise when achievement tests are used for particular purposes.

### Classification of Achievement Tests

Achievement tests have generally been categorized as single-subject tests, survey batteries, or diagnostic tests and further dichotomized as group or individually administered tests. Reference to the *Ninth Mental Measurement Yearbook* (1985) reveals the prevalence of multitudinous published objective tests, and elsewhere it has been reported that some 2,585 standardized tests are in use (Buros, 1974). Table 7.1 is a listing of the most commonly used achievement tests. They have been categorized as (a) group administered, (b) individually administered, and (c) modality specific tests of achievements, which can be either group or individually administered.

Typically one administers achievement tests in order to obtain an indication of general academic skill competencies or a greater understanding of an individual's performance in a particular area of academic performance. In this regard achievement tests are specifically designed to measure "degree of learning"

Table 7.1. Commonly Used Achievement Tests (Continued)

Modality Specific Achievement Tests (Continued)	
Keymath Diagnostic Arithmetic Test	Connolly, A. J., Nachtmam, W., & Pritchett, E. M. (1971). <i>The Keymath Diagnostic Arithmetic Test</i> . Circle Pines, MN: American Guidance Service.
Sequential Assessment of Mathematics Inventories	Reisman, F. K. (1985). <i>Sequential Assessment of Mathematics Inventories</i> . San Antonio, TX: Psychological Corporation.
Stanford Diagnostic Mathematics Test	Beatty, L. S., Madden, R., Gardner, E. G., Karlson, B. (1976). <i>Stanford Diagnostic Mathematics Test</i> . Cleveland, OH: Psychological Corporation.

in specific content areas. There are several distinct applications of achievement tests which vary as a function of the setting in which they are applied. Tests such as the Metropolitan Achievement Tests, Stanford Achievement Tests, California Achievement Tests, and Iowa Tests of Basic Skills represent instruments which typically consist of test category content in six or more skill areas. The benefit of the battery approach is that it permits comparison of individual performances across diverse subjects. Because all the content areas are standardized on the same population, differences in level of performance among skill areas can reflect areas of particular strength or deficit. Many of these instruments provide a profile as well as a composite score that allows ready comparison of levels of performance between tests. The representative content of these batteries typically includes core assessment of language, reading, and mathematics abilities. The extensiveness of the coverage of allied curricula, that is, science, humanities, and social studies, varies significantly. Sax (1974) provides a description of the major differentiating characteristics of 10 of the most commonly used achievement test batteries.

In contrast to the "survey" type tests or screening batteries described above are the more content focused diagnostic achievement tests. Although any of the survey instruments is available to identify areas of academic strength or weakness (Radencich, 1985), they are not in themselves sufficient for diagnostic or remediation planning purposes. Their use in screening large groups helps to identify those individuals in need of more specific individualized diagnostic evaluation. Through the use of a diagnostic battery an area of identified deficit is examined in a more extensive fashion to determine what factors contribute to the academic dysfunction. Typically, these tests include a broad enough sampling of material so that areas of need are specified in order to develop remedial instructional objectives. For example, the Woodcock

Reading Mastery Test (Woodcock, 1973) provides five subtests which examine component processes associated with overall reading ability. These include Letter Recognition, Word Attack, Word Recognition, Word Comprehension, and Passage Comprehension. More in-depth examination at this level permits hypothesis generation regarding the nature of the specific academic deficit to be further tested. Similar tests are available to assess other aspects of academic performance: mathematics, spelling, writing, language skills, etc. Refined assessment at this level is necessary for differential diagnosis and remedial intervention. Screening batteries simply do not permit sufficient evaluation of an area for this kind of decision making to take place.

Although most achievement tests have the potential to be used as screening instruments to identify individuals in need of remedial instruction, fewer instruments are actually used for diagnostic purposes. In a national survey, Goh, Teslow, and Fuller (1981) reported that the Wide Range Achievement Test and the Peabody Individual Achievement served as the general achievement batteries most commonly utilized by school psychologists. In the area of specific achievement tests, the Key Math Diagnostic Achievement Test, Illinois Test of Psycholinguistic Abilities, and Woodcock Reading Mastery Tests ranked as the instruments used most frequently for the assessment of specific academic content areas.

### Criterion-Referenced versus Norm-Referenced Achievement Tests

One other highly significant dichotomy must be addressed when discussing the classification of achievement tests and certain of their psychometric properties, namely, the distinction between criterion-referenced tests (CRTs) and norm-referenced tests (NRTs). While it is not possible to differentiate one from the other in terms of visual inspection (a criteri-

on-referenced test can also be used as a norm-referenced test: for example, Basic Achievement Skills Individual Screener), there are intrinsic differences between the two approaches to achievement testing. Traub and Rowley (1980) described the decade of the 1970s as a time when "the notion of criterion-referenced measurement captured and held the attention of the measurement profession unlike any other idea" (p. 517). Mehrens and Lehmann (1975) asserted that the issues of accountability, performance contracting, formative evaluation, computer-assisted instruction, individually prescribed instruction, and mastery learning created a need for a new kind of test, the criterion-referenced test.

The concept of criterion-referenced achievement measurement was first detailed in the 1963 paper by Robert Glaser entitled "Instructional Technology and the Measurement of Learning Outcomes: Some Questions." In that landmark publication Glaser wrote:

Underlying the concept of achievement is the notion of a continuum of knowledge acquisition ranging from no proficiency at all to perfect performance. An individual's achievement level falls at some point on this continuum as indicated by behaviors he displays during testing. The degree to which his achievement resembles desired performance at any specified level is assessed by criterion-referenced measures of achievement or proficiency. . . . Criterion levels can be established at any point in instruction. . . .

Criterion-referenced measures indicate the content of the behavioral repertory. . . . Measures which assess student achievement in terms of a criterion standard . . . provide information as to the degree of competence attained by a particular student which is independent of reference to the performance of others. (p. 519).

Glaser further stated that achievement measures are appropriately used to provide information regarding a student's capability in relation to the capabilities of his or her fellow students as well. Where an individual's relative standing along the continuum of attainment is the primary concern, the appropriate achievement measure is one that is norm referenced. Whereas both CRTs and NRTs are used to make decisions about individuals, NRTs are usually employed where a degree of selectivity is required by a situation, as opposed to situations in which concern is only with whether an individual possesses a particular competence and there are no constraints regarding how many individuals possess that skill. Thus, at the core of the difference between the two kinds of tests is the issue of variability. "Since the meaningfulness of a norm-referenced score is basically dependent on the relative

position of the score in comparison with other scores, the more variability in the scores the better" (Popham, 1971). This obviously is not a requirement of the criterion-referenced measure.

Because of basic differences in the theories underlying test construction, there have been several hundred publications on CRTs dealing with such issues as test reliability, determination of test length (Millman, 1973), score variability (Hambleton & Cignor, 1978; Hambleton, 1980), and test validity (Linn, 1982). The psychometric properties of CRTs have undergone close scrutiny and one of the most critical dimensions reviewed has been the issue of validity. In the words of Linn (1980):

Possibly the greatest short-coming of criterion-referenced measurement is the relative lack of attention that is given to questions of validity of the measures. The clear definitions of content domains and well-specified procedures for item generation of some of the better criterion-referenced measures places the content validity of the tests on much firmer ground than has been typical of other types of achievement tests. Content validity provides an excellent foundation for a criterion-referenced test; but . . . more is needed to support the validity of inferences and uses of criterion-referenced tests. Unfortunately, the accumulation and reporting of evidence to support the uses and interpretations of criterion-referenced tests is the exception rather than the rule.

In their review of 12 commercially prepared criterion-referenced tests, Hambleton and Eignor (1978) did not find a single one that had a test manual that included satisfactory evidence of validity (Hambleton, 1980). Validity has too often been assumed by both developers and users of criterion-referenced tests. This is no more acceptable for a criterion-referenced test than it is for any other test. It is time that questions of validity of the uses and interpretations of criterion-referenced tests be given the attention they deserve. (p. 559)

Despite these criticisms from the point of view of traditional test construction theory, criterion-referenced measurement has been found to have major utility with respect to the development of computer-assisted, computer-managed, and self-paced instructional systems. In all of these instructional systems, testing is closely allied with the instructional process, being introduced before, during, and after the completion of particular learning units as a monitoring, diagnostic, and prescriptive mechanism (Anastasi, 1982). Moreover, it has had practical application with respect to concerns with minimum competency testing (Hunter & Burke, 1987; Lazarus, 1981) and mastery testing (Harnisch, 1985; Kingsbury & Weiss, 1979).

## Curriculum-Based Measurement

In addition to criterion-referenced and norm-referenced tests of achievement, one additional "hybrid"—which appears to be surfacing, particularly in the area of special education—*curriculum-based measurement* (CBM), merits a brief note in this review. From the Institute for Research on Learning Disabilities at the University of Minnesota, Deno (1985) and his colleagues have proposed a method of measurement which lies somewhere between the use of commercialized tests and informal teacher observations. Their initial research with the procedure in the areas of reading, spelling, and written expression, and concerns with reliability, validity, and limitations are reviewed by Deno. Among the limitations are its utility only with the domain of reading at present, its lack of stability estimates as indicative of reliability, and its lack of generality that enables aggregation across curricula.

However, one aspect of CBM that appears to mark a distinct embarkation from traditional achievement testing is the concept of frequent measurement. In addition to the work of Mirkin, Deno, Tindal, and Kuehnle (1982) on the measurement of spelling achievement with learning disabled students, Le Mahieu (1984) has reported on the extensive use of a program of frequent assessment known as the Monitoring Achievement in Pittsburgh (MAP) which began in 1980 and involves 81 schools with a total enrollment of 40,000 students. Students are tested every six weeks with curriculum-based measures developed by committees of teachers. Serious risks in this kind of achievement testing involve the potential for teachers to narrow the curriculum and to teach to the assessment instrument as well as for students themselves to develop and refine test-wise behaviors as opposed to attaining specific academic skills.

## USE OF ACHIEVEMENT TESTS

### Achievement Tests in Education

Within the context of educational programs there is a continual process of evaluation which also includes teacher-made tests and letter-grade performance standards. The continuous monitoring of student performance within a particular academic content area provides means not only to assess student progress but also to link instructional strategies and learning objectives with identified student learning needs and/or skill deficits. The periodic administration of achievement tests has traditionally been viewed as an educationally sound procedure by professionals in the field.

despite criticisms with respect to the misuse or inappropriate use of these tests.

From a positive perspective, Anastasi (1988) provides a summary of their usefulness in educational settings. First, their inherent objectivity and uniformity provide an important tool in assessing the significance of grades. While individual classroom performance measures can be susceptible to fluctuation due to a number of variables, their correlation with achievement test scores provides a useful comparative validity criterion for grades. They are especially useful in the identification of students whose limited progress in a content area will require remedial intervention. Within this context, individualization of specific needs can be identified so that individual and group curricula can be modified. In this regard, the use of achievement tests prior to the initiation of training can become particularly efficacious. When these measures are utilized at the end of an instructional period they have the potential to serve as a means for assessing the quality of instructional programming and aiding in programmatic evaluation.

In general, then, achievement tests are used to make decisions, decisions which may involve instructional, guidance, or administrative issues. For example, what is the efficacy of a particular method of instruction? What are the specific outcomes of learning? Is there a need for remediation? Are grading practices accurate? Is the curriculum responsive to the acquisition of basic and/or specific academic skills? Is counseling appropriate for any given student? Is appropriate placement a concern? Thus, the breadth of the assessment will be predicated upon the rationale for the use of particular achievement measures. Table 7.2 illustrates the types of questions or problems which may be addressed and the expected benefit(s) to be derived from the testing process.

### Achievement versus Aptitude

One further point which any review of achievement tests must certainly address with respect to their classification and use is the notion of aptitude versus achievement. This contrast dates back to the preoccupation of educational psychologists in the 1920s and 1930s with the role of heredity versus environment in the learning arena. This early simplistic notion that innate capacity or potential could be measured by aptitude tests independent of an individual's learning history or "reactional biography" (Anastasi, 1984, p. 363) has been disavowed. Replacing the traditional concepts of aptitude and achievement in psychometrics is the concept of "developed abilities," the level of development attained by an individual in one or more

Table 7.2. Achievement Tests: Purpose and Outcome

PURPOSE OF TESTING	OUTCOME CRITERION
Screening:	Identification of students potentially eligible for remedial programming
Classification/Placement:	Specific academic deficiencies have been ascertained. Question now arises regarding whether student meets eligibility criteria.
Prescriptive Intervention:	A specific developmental arithmetic disorder is manifested in a child identified with visuo-perceptual processing problems. What curriculum adjustments appear warranted?
Program Evaluation:	Administrators seek to evaluate benefits of an accelerated reading program for gifted students

abilities (Anastasi, 1982, p. 395). In line with this conceptualization of the measurement of abilities, Anastasi provides a continuum of testing in terms of the "specificity of experiential background" that particular tests presuppose. The continuum ranges from course-oriented achievement tests to broadly oriented achievement tests to verbal-type intelligence to "culture-fair" tests. This continuum more accurately reflects the overlapping of aptitude and achievement tests. This analysis has been demonstrated empirically over and over in terms of the high correlations between achievement and intelligence tests. "In some instances, in fact, the correlation between achievement and intelligence tests is as high as the reliability coefficients of each test" (Anastasi, 1982, p. 395).

Finally, Anastasi notes that the continued labeling of some tests as aptitude or achievement measures has led to misuses of test results—in particular, the identification of certain children as underachievers when their respective achievement test scores are lower than their scholastic aptitude or intelligence test scores. In the words of Anastasi:

Actually, such intraindividual differences in test scores reflect the universal fact that no two tests . . . correlate perfectly with each other. . . . Among the reasons for the prediction errors in individual cases are the unreliability of the measuring instruments, differences in content coverage, the varied effects of attitudinal and motivational factors on the two measures, and the impact of such intervening experiences as remedial instruction or a long illness. (p. 396)

### Scoring Systems Associated with Tests of Academic Achievement

Before further discussion of the application of achievement test data, it is necessary to consider how the results of these tests are conveyed. Raw scores

derived from achievement tests are typically converted to age or grade equivalent scores, standard scores, or percentile scores. Hoover (1984) makes a useful distinction between two scoring dichotomies. *Developmental scores* compare individual performance to that of a series of reference groups that differ systematically and developmentally in average achievement, with developmental scores being expressed as age or grade equivalent scores. *Status scores* compare test performance with a single normative reference group and are expressed as standard scores and percentiles. It is important to distinguish between the two types of measurement as each has unique strengths and limitations.

#### *Developmental Scores*

*Age Equivalent Scores.* Educational Age (EA) represents a scoring criterion which has come under significant criticism and is used very infrequently in reporting educational test data. The scaling of items on some achievement tests is presented in a developmental sequence such that a particular score represents mean level of performance for a specific age reference group. An individual who attains a specific score on the test is reported to function at a particular age level. This system of score reporting is useful for descriptive purposes, especially for "measuring growth." As in grade equivalent scores which will be discussed next, serious flaws are encountered when one attempts to utilize such scores for comparative purposes, however.

*Grade Equivalent Scores.* A grade equivalent score (GE) reflects the presumed level of performance of an average student at a particular grade level. For example, if the mean score of a group of sixth graders on an

achievement test is reported as  $\bar{m} = 6.2$ . children who attain the same score are imputed to function at a level of performance commensurate with sixth graders in general. Although it is quite important to have available a continuous scale describing developmental level as a means to demonstrate progress in attainment and growth, the GE represents one of the most frequently misinterpreted sources of educational data. First, it should be noted that GE scores are reported in a format that reflects both grade level and month. The typical school year is approximately 10 months. Hence, scores of 6.2 and 6.9 contrast levels of performance commensurate with the beginning and end of the school year. There are, however, limitations on direct interpretation of GE scores. The scaling of achievement test data is rarely a continuous process. Scores for many grade equivalents are frequently extrapolated or interpolated and consequently do not reflect actual derived scores. They are in fact estimations based on a hypothetical grade equivalent curve. The use of such a scale also presumes that the teaching of such skills is a continuous process reflected across grades. This is not, however, reflected in the reality of the educational experience. Gains made by students are more realistically seen as a combination of spurts and plateaus, and not as a continuous process as is mathematically interpolated in scale construction.

The most significant limitation in the use of GE scores appears to arise because they are ordinal measures. The difference between a one-year gain in proficiency at a lower grade level in comparison to that same gain at a higher grade level may be significant. Further, because most of the basic core academic competencies are taught within the first through eighth grades, one cannot presume that grade equivalent scores associated with the terminal stages of the educational career are equivalent. Finally, it must be noted that relatively small differences in performance can result in exaggerated differences in grade-level equivalency owing to the nature of scale construction.

The most frequently cited problem with using GE scores is the potential for misinterpretation of significant differences in level of performance. For example, a fourth grader obtains a score of 6.7 in reading. One cannot directly compare this youngster to other sixth graders. It is an erroneous assumption to state that this child's reading ability is commensurate with that of a sixth grader. His reference group remains fourth graders. He clearly demonstrates well-above-average performance in comparison to this reference group. One cannot, however, compare him to sixth graders who by the nature of their development and experience with reading, are different from our fourth

grader. Because of the inherent potential for parents to set inappropriate standards of performance for their children based on such scores, the use of scores has been abandoned in many quarters.

#### *Status Scores*

A wide variety of standard score methodologies are available for reporting test results. These represent scores scaled along a continuum which permits one to ascertain where a particular score may fall in comparison to other scores in a distribution. There are two distinct advantages to the utilization of this scoring system. Standard scores permit the opportunity to compare individual performance to a normative standard, and they make possible the comparison of individual performance across two or more different tests. The latter represents an important criterion for the application of achievement tests within the context of a larger test battery.

*Percentiles.* Percentile rank represents a point in a distribution at or below which the scores of a given percentage of subjects fall. If a student scored at the 95th percentile, this would mean his or her score was better than 95% of the other students who took the same test. When clearly conveyed in the context of a psychological report, this scoring methodology represents one of the most readily understandable forms of test description. The potential for inappropriate comparisons of level of performance as reflected in the GE score example is significantly reduced.

*Standard Scores.* Standard scores represent raw scores which have been scaled relevant to a constant mean and standard deviation. As a function of the magnitude of the standard deviation, one can through linear transformation readily ascertain how far from the mean performance lies. Most tests standardize scores within defined age groups. Therefore, regardless of the age of the subjects under evaluation, a specific standard score will have the same meaning. For example, if two students, ages 8 and 10, obtain the same standard score on a reading test, relative to the normal curve, one can readily distinguish that in comparison to their age mates, they are functioning at equal distance from the mean. Standard score conversions also include *z* scores, *t* scores, and occasionally stanine scores which can be interpreted in like manner. In general, standard scores are considered the more accurate and precise means of reporting test results. Finally, it is not uncommon for test developers to provide multiple methods for performance description. For example, the Wide Range Achievement

Test-Revised provides grade equivalent scores, age-based standard scores, and percentiles.

### Achievement Test Scores and the Diagnosis of Learning Disabilities

The relevance of understanding the scoring systems utilized in the interpretation of achievement test results can be dramatically illustrated when one considers the educational diagnosis of a specific learning disability. Learning disabilities have become the dominant handicap of school-age children in the country with some 42% of all students ages 3 to 21 in special education programs diagnosed as learning disabled (Databank, 1985).

A basic assumption underlying learning disabilities is the failure of the student to acquire primary academic skills at levels expected for age, grade placement, and level of intellectual functioning. The identification of individuals with learning disabilities has traditionally been based on the notion of a "significant discrepancy" between ability level and demonstrated academic skill attainment. Regardless of which of the many formulas is used to diagnose a learning disability, all require data from standardized achievement tests. Thus, the use of achievement testing has become an integral component in the differential diagnosis of learning disabilities. In this regard, the concept of "significant discrepancy" has been an important one for it forms the basis for distinguishing specific learning disability diagnoses from conditions such as underachievement or mental retardation.

Under Public Law 94-142, the Education for All Handicapped Children Act of 1975, it was specified that a team could render a determination of specific learning disability if a child does not achieve at his or her ability level when provided with appropriate educational instruction and if a severe discrepancy exists between intellectual ability and achievement in one or more of seven areas of achievement including oral expression, listening comprehension, written expression, basic reading skills, reading comprehension, mathematics calculation, or reasoning. Specifically excluded along with mental retardation were other factors which could impinge on limited academic proficiency, such as peripheral sensory or motor handicaps, emotional disturbance, or socioeconomic or cultural disadvantage. The actual specification of the means of ascertaining discrepant performance is left vague in this definition. Algozzine, Ysseldyke, and Shinn (1982) emphasize that the field of learning disabilities has always suffered a definitional dilemma. Federal guidelines have not appreciably cor-

rected this situation. No clear consensus across school districts exists nationally for arriving at workable definitions of learning disability diagnoses.

In spite of the lack of consensus regarding definition, the notion of severe discrepancy has been defined most frequently by the use of an ability-achievement discrepancy. Inherent in this conceptualization of learning disability is the potential for at least average intellectual functioning with academic performance well below expectations. A number of strategies have been applied in an attempt to operationalize criteria representative of a severe discrepancy.

*Deviation from grade level.* A commonly encountered criterion to define a potential learning disability might be "grade level performance in academic achievement two grade levels below expectation for age." This criterion has been criticized as inadequate for a number of reasons. First, as previously discussed, grade-level equivalents represent the weakest psychometric criterion upon which to base comparisons of academic performance. Second, utilization of such a constant criterion fails to take into consideration the significance of discrepant performance at various points in the continuum of educational programming. For example, performance two grade levels below expectation in a third grader can be far more significant than the same magnitude of score deficit in an eighth grader. Further, in the assessment of adult populations, the efficacy of grade equivalent scores lose predictive validity. It is extremely difficult to ascertain whether eighth-grade academic skills in a 40-year-old are indicative of any significant disparity in level of performance.

Finally, problems have been identified with potential identification of learning disabled students. Use of grade-level discrepancy criteria tends to overidentify children whose intellectual functioning is low average and to underidentify those students who may be above average. A student with an IQ of 82 might in fact be functioning at a grade level which is not discrepant for his or her overall level of intellectual functioning. On the other hand, a fourth grader who is reading just below grade level, but who has an IQ in the superior range, who should clearly be reading at well above grade level expectations, would be excluded.

*Standard Score Discrepancy Models.* The process of comparing standard scores derived from academic and intelligence tests holds apparent benefits over grade discrepancy scores on purely psychometric grounds. Typically, a criterion level is arbitrarily selected, a 1 or 2 standard deviation point discrepancy between

general ability and achievement test score. This methodology can, however, also impose bias into the discrimination process. Many such models do not take into consideration the regression of IQ on achievement. One cannot assume direct correspondence between IQ and standard score equivalents. It can be demonstrated that academic achievement test scores fall somewhat short of IQ for individuals manifesting above-average performance, and in lower-functioning individuals, academic achievement scores are actually higher. The use of a simple discrepancy score formula implicitly assumes a perfect correlation between general ability and achievement tests which in fact does not exist. It would also require that each test be based on the same standard score distribution.

*Regression Equations.* The most sophisticated methodologies available for determining significant score discrepancies are based upon complex computations or tables designed from formulas based upon regression equations. A number of strategies have been developed, each with unique distinguishing properties. A number of reviews are available (Forness, Sinclair, & Guthrie, 1983; Reynolds, 1984; Wilson & Reynolds, 1984) which describe the characteristics of these methodologies. There remains, however, no one mathematical model which is commonly accepted or in fact utilized.

Reynolds (1984) reports on the findings of the Work Group on Measurement Issues in the Assessment of Learning Disabilities, a study section formed in 1983. This group was delegated the responsibility of addressing questions directed toward identification of "best practice" solutions to the learning disabilities definitional dilemma. In their findings, models of discrepancy analysis based upon grade-equivalent scores were rejected outright. Factors related to their imprecision and their ready misinterpretation were noted. Most critical, however, was the inherent lack of the mathematical properties necessary for conducting comparative analyses that are associated with this scoring system. The group concluded that age-based standard score discrepancy models represent potentially the best methodology available. However, while developmental standard scores are to be preferred over grade level of status standard scores, their value has been challenged also because they require greater growth for below-average children than for average or above-average children (Clarizio & Phillips, 1986).

One cannot, however, focus exclusively on the concept of discrepancy as the sole basis for the diagnosis of a learning disability. To quote Reynolds (1984), "The establishment of a severe discrepancy is

a necessary but insufficient condition for the diagnosis of a learning disability" (p. 468). A host of factors other than specific learning disability can contribute to significant academic underachievement. Among these are limited sociocultural opportunity, dysmaturational, sensory-perceptual dysfunction, or functional psychiatric impairment. It is Reynolds' bias, however, that only when a severe discrepancy can be demonstrated is a child considered eligible for diagnosis of LD.

### Some Thoughts on the Validity Issue

There are, among educators and researchers, those who question the focus on the *reliability* of the discrepancy between IQ and achievement rather than on its *validity* (Shepard, 1983). In a study by Shepard and Smith (1983), which evaluated the identification practices of psychologists and teachers within the state of Colorado involving 1,000 student files and 2,000 specialists, 50% of those professionals surveyed were unaware that an IQ of 90 falls at the 25th percentile. For children with IQs of 90, the expectation was that achievement would be at grade level (the 50th percentile) because the IQ was "in the normal range" (Shepard, 1983). The authors continued that these specialists were also unaware that after the first or second grade it is not uncommon for large numbers of children to have grade-equivalent scores below their grade placement. Other technical problems identified in the study also complicate the identification of LD: (1) Most of the tests used in the diagnosis of LD are technically inadequate with the exception of the WISC-R and one or two achievement batteries; (2) Many clinicians were unaware of the difference between technically adequate and inadequate tests; (3) Specialists often selected technically inadequate measures even when more valid instruments were available, their choices tending to follow traditional preferences associated with each professional group; (4) Many clinicians continued to apply inaccurate conventional wisdom regarding the symptoms of LD disorder (relying on interpretations of subtest scatter as underestimating normal patterns of difference, etc.).

Reynolds (1984) and the Task Force advanced a number of recommendations which attempted to bridge this validity-reliability gap with respect to the diagnosis of LD:

1. Instruments applied should meet criteria defined in PL 94-142.
2. Well-standardized national norms should form the

- basis for statistical comparison of individual level of performance.
3. Normative comparisons should be based upon co-normed samples. The ideal scenario is one in which the two tests compared are normed on the same sample. Where this is not possible, the two normative groups should be clearly comparable.
  4. Only individually administered tests of achievement and intellectual ability should be utilized.
  5. Age-based standard scores based upon a common scale represent the most statistically robust means for score comparison.
  6. Measures employed should conform to acceptable criteria for validity and reliability.
  7. Special technical considerations should be addressed when using performance based measures of achievement (e.g., writing skill).
  8. Bias studies should have been conducted and reported.

In summary, while the psychometrics involved in scoring and interpreting the results of achievement tests can be fraught with complexity and controversy, as illustrated in the case of the diagnosis of learning disabilities, the consequences of the resolution of the issues involved are even further reaching. Consider the effects of labeling, the contraction of teacher competence to deal with a variety of learning styles in the classroom, the allocation of resources available to those students with the most severe disability, and the costs of providing for special education resources themselves (Shepard, 1983). All of these can be viewed as negatives. It is not difficult nor unrealistic to extrapolate these same issues to include diverse groups of students in educational programs today. Thus, we are left with ethical responsibilities to insure the appropriate utilization of achievement tests based on the most current thinking and research available which is macrocosmic rather than microcosmic in nature.

Messick (1980) has argued this point in his "Test Validity and the Ethics of Assessment." He had written earlier, with specific reference to the measurement of personality, that tests should be evaluated not only in terms of their measurement properties but also in terms of their potential social consequences (Messick, 1965). Messick emphasized the importance of construct validity, arguing "that even for purposes of applied decision making reliance upon criterion validity or content coverage is not enough" (Messick, 1975, p. 956), and that "the meaning of the measure must also be comprehended in order to appraise potential social consequences sensibly" (Messick,

1980, p. 1013). He defined test validity as an overall evaluative judgment of the adequacy and appropriateness of inferences drawn from test scores, opining that values questions arise with any approach to psychological testing whether it be norm referenced or criterion referenced, a construct-based ability test or a content-sample achievement test. This evaluative judgment of test validity is based on (a) convergent and discriminate research evidence as to the test scores interpretability in terms of the particular construct under review, (b) an appraisal of the value implications of that interpretation, (c) justification of the relevance of the construct and its utility of the particular application proposed, and (d) dealing with the potential social consequences of the proposed use as well as the actual consequences upon implementation of the testing procedure.

Intervening in the model between test use and the evaluation of consequences is a decision matrix to emphasize the point that tests are rarely used in isolation but rather in combination with other information in broader decision systems. The decision process is profoundly influenced by social values and deserves, in its own right, massive research attention beyond the good beginning provided by utility models. (Messick, 1980, p. 1025)

Messick concluded his remarks by paraphrasing Guion: "The formulation of hypotheses is or should be applied science, the validation of hypotheses is applied methodology, but the act of making . . . [a] decision is . . . still an art" (p. 1025).

### The Use of Achievement Tests in Clinical Practice

Achievement testing conducted with clinical populations is generally regarded as an extension of intelligence and aptitude testing. It provides one further means to ascertain "general ability level." Results are typically utilized for drawing inferences regarding the capacity of the individual under evaluation to apply knowledge or native intelligence in practical problem-solving situations. One equates intelligence and exposure to educational opportunity with the ability to conform with the demands of achievement testing at commensurate levels of success. Typically, one is not engaging in achievement testing with this population in anticipation of identification of potential performance discrepancies, but to gauge overall adaptive competency. The identification of any significant discrepancies would of course result in further clinical

investigation. Cognitive as well as noncognitive variables would then be explored.

*Achievement Test Results Applied in Neuropsychological Evaluation.* Achievement tests play a definitive role in the administration of standard neuropsychological test batteries. For example, a number of extended versions of the Halstead-Reitan Neuropsychological Test Battery include an administration of the Wide Range Achievement Test or other age-appropriate screening battery within the test protocol. Data derived from such tests offer clinical utility beyond discrepancy analysis. They can be used as a method to infer an estimated level of premorbid intellectual functioning (Lezak, 1983). As basic academic skill competencies are generally not susceptible to significant deterioration in mild to moderate generalized cerebral dysfunction, standard scores derived from general achievement test measures offer one means to interpolate a coarse estimation of premorbid functioning when other means of documentation are not available.

Achievement test results can be incorporated in the pattern analysis of other neuropsychological test variables to aid in the specification of the effects of focal lesion processes. For example, problems exclusively with the spatial components of arithmetic processes in an individual manifesting no evidence of linguistic defects would help suggest a post-Rolandic lesion of the right cerebral hemisphere, when other markers of right hemisphere dysfunction are present. It is not uncommon to consider achievement test performance within the context of a formal aphasia examination as a means to extend the assessment to the integrity of lexical skill functions and writing ability.

Beyond their application in the documentation of the effects associated with focal lesion processes, such test results hold even greater potential utility in aiding in the development of hypotheses regarding functional limitations associated with cerebral dysfunction. As primary academic skill competencies are intimately related to aspects of autonomous functioning in a number of instrumental activities associated with daily living, the degree of preservation of such primary skills as reading and arithmetic abilities can be important prognostic indicators associated with long term recovery and adaptation.

*Achievement Test Results Applied to Rehabilitation Assessment Methodologies.* In the areas of both psychiatric and vocational rehabilitation, the specification of the degree to which core academic competencies are developed holds a number of prognostic

implications. With low-level functioning individuals the specification of primary literacy skills is an important determinant of the level of complexity of programming in which they might participate. The degree to which a learning curriculum might emphasize effective reading comprehension might be potentially exclusionary, for example.

An important component of the rehabilitation assessment is determination of the degree to which any remedial intervention might be required prior to implementing programming. Inadequate educational opportunity or underachievement related to psychosocial factors must be distinguished from developmental academic disorders and conditions which cause a loss of previously attained ability. Intervention strategies to remediate or supplant deficient academic skills are determined by the thorough analysis of their cause. Prognostically, it is important to identify those individuals functioning at their plateau versus those who have the potential to develop these skills further.

In summary, with the use of achievement testing in clinical settings the focus is typically divested towards two lines of inquiry: (a) obtaining knowledge of the degree to which basic academic skill competencies developed in a particular individual, and (b) examining individual performance within a particular area of academic performance. The basic referral question in large measure determines what armamentarium of techniques will be brought to bear in the assessment. It will also influence how test scores will be compared and interpreted.

## COGNITION, METACOGNITION, AND ACHIEVEMENT TESTING

The application of cognitive theory research to educational psychology can be traced back as early as 1960 with the publication of David Ausubel's paper "The Use of Advance Organizers in the Learning and Retention of Meaningful Verbal Material," the later work of Rothkopf (1965) on mathemagenic behaviors, Ausubel's (1968) test, *Educational Psychology: A Cognitive View*, Anderson's (1972) work on how to construct achievement tests to assess comprehension, and the work of Martin and Säljö (1976a, 1976b) who argued that a description of what is learned is more important than a summary of how much is learned (Clarke, 1982). Glaser (1981) reviewed current research in cognitive and developmental psychology addressing its potential influence on the development of new psychometric methodology. He cited Bartholomae's (1980) work on error analysis with college

students in remedial writing programs and Siegler's (1976) work on rule assessment in the acquisition of scientific concepts as illustrative of the "necessary interrelationships between the analytical assessment of performance and effective instruction" (Glaser, 1981, p. 929). Interest in the assessment of mastery or competence can be traced also to developments in cognitive psychology, artificial intelligence, and language understanding. Herein the works of Chase and Simon (1973) on the chess master and the work of Larkin, McDermott, Simon, and Simon (1980) on problem solving in the area of elementary physics were cited by Glaser.

Finally, research in the realm of metacognition—the knowledge, regulation, and management of one's own cognitive processes and products (Flavell, 1976)—has led to a concern with the measurement of these self-regulatory skills in terms of predicting successful problem solving which then leads to learning. Metacognitive abilities develop with maturity, and current research in learning instruction has demonstrated that these skills may be less well developed in those individuals who have learning disabilities.

Thus, it becomes quite clear that an understanding of the learning process and its assessment can yield more fruitful data than those traditionally obtained by achievement tests. This is particularly important in light of the social-educational demands outlined by Glaser (1981) which will shape and mold the future of educational assessment:

- the shift from a selective educational system to one designed to help individuals succeed in educational programs (zero-reject system)
- the requirement for improved levels of literacy and problem-solving ability in a variety of knowledge and skill domains (minimum competency and mastery certification)
- the need to understand individual differences in the process of measurement so that abilities can be improved to facilitate further learning (cognitive, sociocultural, gender specific)

The application of cognitive and metacognitive principles with respect to the measurement of learning have been detailed in the areas of reading (Curtis, 1980; Curtis & Glaser, 1983), spelling (Henderson & Beers, 1980; Nolen & McCartin, 1984), and foreign language (Fischer, 1981; Stevenson, 1983; Terry, 1986). Curtis and Glaser (1983) describe the current level of understanding and the theoretical framework utilized to study the process of learning to read, a process which involves a complex of interrelated

skills (word decoding, accessing semantic word information, sentence processing, and discourse analysis), proficiency in one affecting success in the others. The results of traditional reading achievement tests have made it impractical to diagnose reading problems in terms of remediation or instructional strategies thus far. However, current theory on efficiency in word identification, the qualitative features of semantic knowledge, and research on schemata can be utilized as a form of construct validity and thus allow measurement of achievement that reflects both the development of competence and the process of instruction. "With developing knowledge of reading it should be possible to establish standards of performance . . . [and] . . . combined enterprise representing test design based on knowledge of human learning and performance, psychometric requirements, and studies of test use should improve our ability to link testing and instruction" (Curtis & Glaser, 1983, p. 144).

### Diagnostic Applications of Achievement Test Results

As an illustration of the application of cognitive and metacognitive strategies in the process of achievement testing, the remainder of this discussion focuses on an expanded level of analysis that can be undertaken in the clinical setting for purposes of both diagnosis and remediation interventions.

*Reading.* Assessment of the skills brought to bear by a reader in decoding words generally represents the first level of analysis in diagnostic assessment. One is interested in determining how sophisticated word attack skills may be relative to age and intellectual ability. Two types of decoding activities are typically utilized in reading: (a) a "phonetic" approach in which words are systematically analyzed based on the blend of their phonological properties, and (b) a visually based process in which whole words or word parts are immediately recognized, that is, "sight recognition" vocabulary. Typically in normal readers whole word recognition skills increasingly supplant the need to decode individual words phonologically. As the lexicon of sight recognition vocabulary increases with reading experience, semantic and contextual cues become incorporated in the reading process. It is usually only on confrontation with unfamiliar words that a reader has to resort to phonological decoding (Curtis, 1980).

A major portion of diagnostic reading assessment focuses on the sophistication and accuracy of decod-

ing skills. This assessment is accomplished through the presentation of reading material presented as isolated phonemes, nonsense words, familiar and unfamiliar words, as well as words presented "in context," that is, in the form of sentences or complex paragraphs. At a first level of analysis the rule-out of basic visuo-perceptual dysfunction is necessary. The reader must be able to appreciate fully the visuo-symbolic configuration of letters and words. Here one is concerned with the rule-out of visual-sequential and modality specific attentional deficits which could prevent the accurate assimilation of the written material. Perceptual errors such as reversals (reading "b" for "d" or "p" for "q") would also be excluded.

With the rule-out of primary perceptual dysfunction, analysis of grapheme-phoneme correspondence is undertaken. Basic decoding ability is ascertained for vowels, consonants, and consonant blends of letter combinations. Increasing the level of complexity of syllabic blends permits analysis of any sequential information-processing deficits that may be present. One is interested in the capacity not only to analyze and decode written material sequentially, but aural material as well.

There are tasks which tap auditorization or syllabication, that is, the ability to decode the component phonetic properties of a word. On the Auditory Analysis Test, for example, one is asked to say "Germany" without the "ma" sound, thus transforming the remaining syllables to "journey." Some individuals, who on a task like the Word Attack subtest of the Woodcock Reading Mastery Tests are reasonably successful in reading isolated phonemes, have great difficulty blending these same sounds into their appropriate phonological expression when confronting them in complex words. For example, when asked to read "phonological," the student struggles to isolate "pho" . . . "no" . . . "loge" . . . "ee" . . . "cal" only to pronounce the word then as "phonograph," a word more embedded in auditory memory. Frequently the effort required to analyze words laboriously in this fashion is exacted at great expense in terms of comprehension and memory for material read.

Assessment techniques which require rapid identification of words serve as a means to assess sight recognition vocabulary. Speed of recognition is not a factor controlled for in many types of reading tests. "Automatic recognition" represents the most sophisticated and efficient means of reading. Reading performed at this level taxes working memory minimally and frees the reader to focus on the semantic organization of the material for greater understanding and for committing textual information to memory. There

are, however, individuals who have not attained adequate levels of sight recognition skills. They maintain a more labored phonologically based reading style. These individuals may present a variety of deficits which impede their ability to process complex visuo-symbolic material. This might involve visual inattention, visuo-perceptual processing problems, spatial or gestalt recognition deficits, or weak visual memory. An analysis of the approach taken during "word attack" can be helpful in isolating the contributing deficit or deficits.

Within this context, the overall complexity of the word presented can be important. Errors encountered with relatively simple reading material can suggest problems in processing the basic visual morphology of written material. In terms of the simultaneous processing of visual input, there may be a finite limit on how complex a word can be for it to be realized. In attempts to compensate, some children "guess" at the whole word by processing only the prefix or first few syllables. Poor visual gestalt functions or whole word recognition skills are usually typified by gross lexical "word substitution" errors. Here words which share a similar visual gestalt to the word at hand are substituted, often resulting in flagrant misreading. In this regard it is necessary to rule out impulsivity as a contributing factor. The absence of other evidence of attention deficit disorder symptoms in ancillary testing or observation is particularly helpful.

Finally, comparisons of the relative efficiency of oral and silent reading under timed conditions can be potentially useful. A sample of oral reading of both word recognition material and passage material can be extremely beneficial. Dramatic improvement in passage versus isolated word reading immediately suggests the potential for the reader to compensate via the use of semantic cues. There are students whose oral reading efficiency can be significantly compromised by anxiety or inhibition. Far greater efficiency can be expressed by them in silent reading.

*Spelling.* Standardized spelling tests permit an opportunity to ascertain whether skills are developed at levels commensurate with age and grade level expectations. Individualized assessment of spelling ability requires obtaining a broad sample of actual oral or written spelling skills. Multiple-choice format tasks characteristic of some achievement tests are inadequate for they permit the use of opportunistic compensatory strategies that could potentially mask true spelling deficits. In assessing spelling abilities it is useful to combine both the use of graded word lists as well as a sample of spelling in context, for example a

Table 7.4. Deficits in Higher Cortical Functioning Associated with Mathematics Difficulties

Visuo-perceptual dysfunction	"Static" or "kinetic" reversals in number recognition or writing (example: reading 6 for 9) leading to calculation errors.
Spatial processing problems	Deficits in the ability to appreciate spatial properties could lead to difficulty in learning concepts such as borrowing or carrying. Failure might be seen in the linear ordering of the operations associated with long division or multiplication. Concepts associated with geometry and higher-level mathematics may be conceptually too demanding.
Sequential information processing deficits	Tasks involving complex multistep operations are failed.
Attention deficit disorder	Failure to appreciate the full ramification of a problem with impulsive errors noteworthy, i.e., missed steps or procedures in routine problem solving well within the respective area of ability.
Memory dysfunction	Failure to acquire skills reliant upon rote memorization such as "times-tables" or deficiencies in efficient discursive reasoning problems because of weak immediate memory. Persistent requests for repetition of material.
Language dysfunction	Failure to appreciate the nuances of complex "statement problems" because of the complexity of their logico-grammatical structure or failure to develop working vocabulary of mathematical terminology.

psychopathology can significantly influence general efficiency. Individuals who manifest attention deficit disorder diagnoses may be especially error prone. Their impulsivity results in inadequate assimilation of all aspects of the problem or faulty planning in that all sufficient steps for task completion are not carried out. In this regard, developmental models of pragmatic and conceptual skills associated with mathematical skills acquisition as proposed by Reisman (1982) are helpful.

At different age levels, differing cognitive styles may be brought to bear in problem resolution. More than one means to go about solving a particular problem can be chosen. The level of sophistication of the processes brought to bear in task resolution can in itself be diagnostic. Even though a correct answer is ultimately obtained, the strategies utilized in reasoning may be developmentally deficient, hence affecting overall efficiency in performance. Greater "automation" and use of "formal operations" with maturity are anticipated. Lack of expression of efficient problem-solving strategies can be diagnostically important.

Standardized achievement tests are helpful, therefore, in identifying both the failure to develop appropriate numerical reasoning or problem-solving strategies as well as in identifying their type. Multiple pathways can lead to the expression of developmental arithmetic problems, however. It is important for the assessment of mathematical ability to be tied to the

larger domain of higher cognitive functioning. This would involve more rigorous assessment than a comparison with IQ scores. The identification of any associated cognitive dysfunction could affect very significantly the design of remedial or adaptive instruction. A number of discrete developmentally based higher cognitive processing problems have been identified in Table 7.4 and their functional implications discussed.

As can be seen from this brief sampling of deficits associated with higher cognitive functioning, a number of discrete deficits can follow from developmentally based or acquired cerebral dysfunction. Functional psychopathology and anxiety effects can selectively compromise performance and should be ruled out as well.

## ACHIEVEMENT TESTING WITH SPECIAL POPULATIONS

### Exceptional Children

Under the educational opportunity safeguards included within Section 504 of the Rehabilitation Act and P.L. 94-142 are specific components dealing with the process of evaluation. What is mandated by law is that all students who potentially have an educational disability receive a comprehensive evaluation that

fairly assesses their abilities and does not discriminate against them because of cultural or racial factors or a disabling condition. Moreover, in all areas of exceptionality, federal and state legislation require the development of individualized education plans (IEPs) for handicapped students. Educational assessment data from standardized tests provides one necessary source of information used in the development of strategies for diagnostic prescriptive teaching. Here diagnostic achievement testing plays a particularly important role not only in identifying areas in need of remediation but also in placement and classification decisions. With the importance attached to assessment in the identification, diagnosis, placement, and instruction of children with disabling conditions, it is no surprise that the use of achievement tests, particularly the use of norm-referenced measures, has come under increasing criticism (Fuchs, Fuchs, Benowitz, & Barringer, 1987; Fuchs, Fuchs, Power, & Darley, 1985; LaGrow & Prochnow-LaGrow, 1982; Ysseldyke et al., 1980; Ysseldyke & Shinn, 1981).

Fuchs et al. (1987) conducted an extensive study of the 27 most well-known and commonly used tests in special education in order to determine the degree of participation of children with handicaps in the creation of test norms, and item selection, and in the establishment of their reliability and validity. Fourteen of these tests were measures of achievement classified as either screening (battery) or diagnostic (content specific). The user manual and/or technical supplement of each test was then analyzed in terms of (a) norms, (b) item development, (c) internal and test-retest reliability, and (d) concurrent and predictive validity. In only two of the achievement measures were children with handicaps included in the norming process and on only one measure were they included in item development. Otherwise, no other information was available. Such findings led the authors to state: "[I]f, in fact, test constructors have not validated their instruments for use with handicapped people, they should issue cautionary statements in manuals and elsewhere regarding confidence in interpretation based on these tests" (p. 269. Note: The quotation in Fuchs is taken from Standard 14.2, p. 79, the Standards for Educational and Psychological Testing, 1985).

Numerous studies have analyzed the performance on standardized tests of academic achievement of students with learning disabilities (Caskey, 1986; Estes, Hallock, & Bray, 1985; McGue, Shinn, & Ysseldyke, 1982; Shinn, Algozzine, Marston, & Ysseldyke, 1982; Webster, 1985), behavioral disturbances (Altrows, Maunula, & LaLonde, 1986; Eaves,

& Simpson, 1984), and hearing impairments (Allen, White, & Karchmer, 1983; Karchmer, Milone, & Wolk, 1979; Trybus & Karchmer, 1977), as well as students who are gifted (Karnes, Edwards, & McCallum, 1986). The findings from these studies and others demonstrate empirically (a) the variability in test results across achievement measures; (b) particular item biases where low SES is a factor; (c) the influence of the examiner on the testing process; (d) the differential effect of diagnosis; and (e) the roles of time pressure, anxiety, and sex (Doolittle, 1986; Plass & Hill, 1986). It is critical that the professionals who utilize these tests be aware of the significant validity issues involved when assessing persons with disabilities or other areas of exceptionality.

### Minority Children

Cautionary comments have been made also by those persons concerned with the standardized testing of minority students. Critics of the testing movement assert that tests which purport to measure achievement, among other things, are biased against certain ethnic/racial groups. Those in favor of testing regard test misuse as the real problem. Underlying the debate is the belief by the critics that the model used to assess performance and competence in society is monocultural. "A main criticism is that the model ignores the relevance of culturally different experiences that foster other equally important competencies essential to the survival of the group or individual" (Williams, 1983, p. 192). Similarly, Green and Griffore (1980) report that in one study 46% of the errors made on Gray's Oral Reading Test by minority children were due to dialect differences. Others have suggested that lack of "test-wiseness" (Millman, Bishop, & Ebel, 1965) may serve to lower the scores of minority students on tests of aptitude and achievement. Johnson (1979), commenting about the variables that may invalidate test scores for African-Americans and other minorities, wrote:

Many factors operate to attenuate or lower test scores, and these factors tend to have their greatest effects on Blacks and other minority applicants. These include factors which affect the actual performance of individuals on the test, such as socioeconomic status, differences in educational opportunity, motivation, narrowness of content of the tests, atmosphere of the testing situation, and the perceived relevance of the test to success. They also include factors that affect the test score more directly such as the composition of the group used for item tryouts and item selection and analysis which precede the actual standardization, composition of the standard-

ization or normative group, and the techniques and procedures employed in item construction. Also, the validity or appropriateness of tests often differ for Black and white applicants, in relation to the same future performance of criterion. (p. 3)

In addition, it has been substantiated that minority and white children are exposed to different curricula through the practice of ability tracking (Coleman, 1966; Findley, 1974; Green & Griffore, 1980; McPartland, 1969). Reviewers of the hundreds of ability grouping studies conducted since the 1920s have concluded that while superior students may benefit from this method of curricular offering, students with lower class ranking may not. The primary areas of concern are exposure to undemanding curricula and the social stigma attached to students in low-ability groups.

In a study by Abadzi (1985), the effects on both academic achievement and self-esteem of students placed in ability grouping classrooms were investigated with a population of 767 students from grades 4 to 8 in a large Texas school district. Contrary to earlier studies, her findings were that high-ability students did not maintain in the long run the performance gains made in the first year of grouping. Only the lower-level high-ability students in grouped classes were to benefit from the educational and social opportunity provided the highest-ability students. Students near the cutoff score in all groups were the ones most influenced by grouping in terms of both achievement and self-concept. Support for these findings was provided in spite of a general downward trend in performance at the end of elementary school that was characteristic of the school district's test scores and those of other districts as well. The author hypothesized that the steady drop in scores with the high-ability students may have been the result of reduced achievement motivation brought on by a "sense of invincibility, which the high status of the program combined with nonexistent exit criteria helped reinforce" (Abadzi, 1985, p. 39).

The concept of achievement motivation raised in Abadzi's conclusions has been systematically studied since the publication of David McClelland's *The Achievement Motive* (1953). This concept has been defined as a learned motive, unconscious in nature, resulting from reward or punishment for specific behavior. While studies utilizing this definition of achievement motivation have been conducted across racial groups, they have been criticized because of their ethnocentric design, methodology, and instrumentation. Castenell (1984) suggests that future research incorporate the definition espoused by Katz

(1969) and Maehr (1974) which posits that (a) achievement motivation is conscious, (b) the need to achieve is universal to all groups, but (c) "because different groups have different life experiences it is likely that situations or a set of tasks will evoke different group responses" (p. 442).

This section on special populations concludes with guidelines set forth by Williams (1983) that are highly reminiscent of the recommendations put forth in 1975 and cited at the beginning of this chapter. They would appear to encompass concerns regarding the use of achievement tests regardless of students' race, color, national origin, or handicap.

- Test constructors should foster an awareness of the limitations of the tests and the meaning attributed to test scores.
- Test constructors should educate their consumers in selecting tests in terms of particular goals and objectives of educational evaluation.
- Test constructors should bear responsibility for including minorities in all aspects of test development and not limit this to the standardization sample.
- Test consumers must assume some responsibility for developing skills in administering tests and interpreting results in light of the culturally diverse experiences that pupils bring into the testing situation.
- The educational community should minimize or eliminate intelligence testing or substitute appropriately modified assessment techniques and interpretive procedures that consider cultural differences.
- The educational community should focus on achievement rather than intelligence or aptitude testing to eliminate pernicious connotations and unfair placement practices that limit future educational attainment and opportunity. (p. 205)

## THE FUTURE OF ACHIEVEMENT TESTS

### Computer Adaptive Testing

The final section of this chapter is a discussion of the growth and impact of computerized adaptive testing on the measurement of achievement and what this product of modern technology means to the field of measurement. This is a fitting topic to conclude the previous narrative because computer adaptive testing is the direct result of advances in the fields of psychometrics, mathematics, cognitive learning theory, educational measurement, human engineering, and sci-

ence technology. It relies as heavily on Glaser's criterion-referenced measurement as it does on Ausubel's cognitive approach to learning, Deno's curriculum-based measurement, Messick's concern with test validity, and Anastasi's continuum of testing.

Overall, educational research and development is most currently preoccupied with enhancing the instructional value of tests, or as Haney (1985) describes it, "making testing more educational" (p. 4). He states that one need not be a dyed-in-the-wool social Darwinist to recognize that the use of standardized testing is increasing because it serves some important social functions. However, certain deficits that currently exist tend to negate the value of these tests: (a) Most testing programs violate the one nearly universal desideratum in all learning theories—in order to learn, an individual needs to receive rapid and specific feedback; (b) Most standardized tests have a very uncertain relationship to the specific teaching and learning that occurs in particular schools and classrooms; (c) The frequent concern to keep standardized testing programs secure limits their educational utility. It is these deficits, both narrowly and broadly defined, that the process of adaptive testing can be seen to rectify.

Adaptive testing is based on the premise that a measurement continuum should parallel a learning/teaching continuum, and if this learning continuum could be adequately measured by an underlying scale extending through its entire range, a student could enter and exit the measurement continuum at points appropriate to his or her current development regardless of age or grade levels (Forbes, 1986). This test development system is based on a measurement model popularly named the Rasch Model after its originator. This model is also referred to as a one-parameter model in contrast to three-parameter models of latent traits which are based not only on item difficulty (single parameter) but also on item discrimination (slope of the difficulty) and on the level of chance performance (guessing).

All item-response theory models must have an item data bank from which test items are drawn in the process of test construction. These items are computer stored and are then retrieved following a logical format. Utilizing a computer, the test can be presented to the student on a video screen with the computer keyboard serving as the response mechanism. Under such a procedure, the computer presents one preconstructed test selected from a group of such tests. The test is tailored so that the computer "jumps" the person to the appropriate item-difficulty range and then gives a preselected sequence of items based on

the correctness or incorrectness of the previous response. Generally, fewer items are required to measure performance at a predetermined level of measurement error than is the case with traditional testing procedures. Computerized adaptive tests have been shown also to take less than half the testing time required by traditional achievement tests and to provide more precise ability estimates across the entire ability range. Because the ability estimates and the item parameters are calibrated on a common scale, these estimates are theoretically independent of the particular sample of persons taking the test and the particular sample of items selected by each examiner.

Seminal work done by Weiss (1980) focused on applying computerized adaptive testing to the measurement of achievement, using a methodology to extend beyond the aptitude measurement to which this type of testing had been limited previously. In addition to extending the use of item-characteristic curve theory (ICC) methods from ability testing to the problems of achievement testing, the project was also concerned with developing solutions to unique problems raised in achievement testing, that is, assessment in multiple content areas, mastery testing, the issue of stability of measurement over time, and the effects of immediate feedback as to the correctness or incorrectness of test responses. The findings of this three-year research project supported the use of ICC theory and methods and computerized adaptive testing for the measurement of achievement. However, many new questions were raised in addition to those originally addressed by the research that were in need of further study.

Finally, one of the first studies to compare and equate achievement scores from three alternative methods of testing—paper-administration, computer-administration and computerized adaptive testing—was conducted by Olson (1986) with all students in grades 3 to 6 within three California school districts. A total of 575 students were involved in the study. Results of the study indicated that (a) analysis of variance showed no significant differences among the three measures in terms of the comparability of measurement precision; (b) computerized adaptive testing (CAT) required only one fourth of the testing time required by the paper-administrated test; (c) the computerized adaptive test provided a more precise ability estimate with smaller variance than either of the other two measures; and (d) the ability estimates calculated from a 20-item CAT tended to show more precision than tests of 55 to 62 items used with the other two measures.

This section on adaptive testing concludes with the

futuristic predictions raised by Hsu and Sadock (1985) in their review. *Computer-assisted Test Construction: The State of the Art*. The authors foresaw the following as commonplace in testing of the future:

1. The development of item construction theories that take advantage of artificial intelligence and the phrase recognizability of the computer.
2. The development of item banks in the area of criterion-referenced achievement tests and in conjunction with textbook publication.
3. Item calibration and test design available on microcomputer.
4. The regular use of computers in test administration.
5. The application of IRT in test design by non-measurement specialists.
6. The use of computerized adaptive and diagnostic testing in the classroom.

Writing about achievement tests in the 1984 edition of the *Handbook of Psychological Assessment*, Fox and Zerkin concluded: "[While] standardized tests are not perfect and can be misused and misunderstood . . . they are currently the best instruments educators have available for assessing the quality of curriculum and for individualizing and improving instructional programs for each child" (p. 130). These conclusions no longer hold.

It is no longer possible to call these standardized measures of achievement the "best" instruments available. It is hoped that the present discourse has led the reader to question practices of the present because of knowledge of the present and to look to the future with eager anticipation. Tests can be a flexible passport into that future or a rigid barrier bound to the past. It is our job as professional educators, in the broadest sense, to insure the former. When describing the failure of the testing profession to inform the public about the meaning of "objective" standardized tests, Srenio (1981) states: "At a minimum, testers have an obligation to avoid placing their particular jargon in any context that makes it even harder for the layman to interpret than it already is" (p. 65). The authors of this chapter hope that they have not been guilty of this same failing.

"Then you should say what you mean," the March Hare went on.

"I do." Alice hastily replied; "at least—at least I mean what I say—that's the same thing, you know."

"Not the same thing a bit!" said the Hatter; "why, you might just as well say that 'I see what I eat' is the same thing as 'I eat what I see!'"

—Lewis Carroll

## Minnesota Multiphasic Personality Inventory\*

The Minnesota Multiphasic Personality Inventory (MMPI) is a standardized questionnaire which elicits a wide range of self-descriptions that are scored to give a quantitative measurement of an individual's level of emotional adjustment and attitude to test taking. Since its development by Hathaway and McKinley in 1940, not only has it become the most widely used clinical personality inventory, but it has over 6000 published research references (Alker, 1978). Thus, in addition to its clinical usefulness, it has also stimulated a vast amount of literature and has frequently been used as a measurement device in research studies.

The test format consists of 566 affirmative statements which can be answered "true" or "false." The different categories of responses can be either hand or machine scored and summarized on a profile sheet. An individual's score as represented on the graph can then be compared with the scores derived from the normative sample on which the test was originally standardized.

Presently, the MMPI has a total of 13 scales of which 3 relate to validity and 10 to clinical or personality indices (see Table 7-1). These scales are known both by their scale numbers and by scale abbreviations. In addition, there are a large number of experimental scales which have been created for research purposes, and new scales are constantly being reported in the literature. Examples of such scales include ego strength (ES), dependency (Dy), dominance (Do), prejudice (Pr), and social status (St).

The majority of MMPI questions are relatively obvious with respect to content and deal largely with psychiatric, psychological, neurological, or physical symptoms. However, some of the questions are psychologically obscure in that it is not intuitively obvious what underlying psychological process they are assessing. For example, the item "I sometimes tease animals" is empirically answered "false" more frequently by depressed subjects than normals. Thus, it was included under scale 2 (depression) even though it does not, on the surface,

appear to directly assess an individual's degree of depression. For the most part, however, the statements are more direct and self-evident, such as "I wish I could be as happy as others seem to be" (true) or "I cry easily" (true), both of which also reflect an examinee's level of depression. The overall item content is extremely varied and relates to such areas as general health, occupational interests, preoccupations, morale, phobias, and educational problems (see Table 7-2).

Once a test profile has been tabulated, the scores are frequently arranged or coded in such a way as to summarize and highlight the significant peaks and valleys. However, it is extremely important to take into consideration all the scale scores of the profile. In many instances, the same scaled score on one test profile can mean something different on another profile when the elevations or lowerings of other scales are also considered. For example, an elevated scale 3 (hysteria) may indicate an individual who denies conflict, demands support from others, expresses optimism, and is somewhat interpersonally naive. However, if this elevation is also accompanied by a high 4 (psychopathic deviate), there is likely to be a strong undercurrent of repressed anger. This anger is usually expressed indirectly, and any negative effects on others are likely to be strongly denied. Thus, it is important that the clinician not utilize purely quantitative or mechanical formulas for interpreting the profile but rather examine the scores

Table 7-2. Content Classification of the MMPI with Illustrative Items.

Category	Representative Items	No. of Items
Attitudes		19
Religious	I believe in a life hereafter.	16
Sexual	I am worried about sex matters.	72
Social	I am a good mixer.	15
Test taking	It is always a good thing to be frank.	12
Education	I liked school.	81
General health	I have diarrhea once a month or more.	
Masculinity-femininity	If I were an artist I would like to draw flowers.	55
Mood	I usually feel that life is worthwhile.	56
Morale	I am certainly lacking in self-confidence.	33
Occupation	I think I would like the work of a librarian.	18
Phobias	I am afraid to be alone in the dark.	29
Preoccupations	Evil spirits possess me at times.	46
Miscellaneous	I dream frequently.	98

within the overall context of the other scale evaluations and valleys. Not only should a particular scale be examined within the context of the overall test configuration, but additional sources such as behavioral observations, other psychometric devices, and relevant history can be extremely helpful in increasing the accuracy, richness, and sensitivity of personality descriptions.

A further important general interpretive consideration is that the scales represent measures of personality traits rather than simply diagnostic categories. Although the scales were originally designed to differentiate normal from abnormal behavior, it is generally regarded as far more useful to consider the scales as indicating clusters of personality variables. For example, scale 2 (depression) may suggest such characteristics as mental apathy, self-depreciation, and a tendency to worry over even relatively small matters. This approach has characterized the extensive research performed on the meanings of the two highest scales (two-point code types) which are summarized in the later portions of this chapter. Rather than merely labeling a person, this descriptive approach creates a richer, more in-depth, and wider assessment of the individual being tested.

## HISTORY AND DEVELOPMENT

The original development of the MMPI was begun in 1939 at the University of Minnesota by Starke R. Hathaway and J. Charnley McKinley. They wanted an

instrument which could serve as an aid in assessing adult patients during routine psychiatric case workups and which could accurately determine the severity of their disturbances. Furthermore, they were interested in developing an objective estimate of the change produced by psychotherapy or other variables in a patient's life.

The basic approach during construction of the MMPI was empirical criterion keying. This refers to the development, selection, and scoring of items within the scales based on some external criterion of reference. Thus, if a clinical population was given a series of questions to answer, the individuals developing the test would select questions for inclusion or exclusion based on whether or not this clinical population answered differently from a comparison group. Even though a theoretical approach might be used initially for the development of test questions, the final inclusion of the questions would not be based on this theoretical criterion. Instead, test questions would be selected based on whether or not they were answered in a different direction from a contrasted group. For example, a test constructor may believe that an item such as "sometimes I find it almost impossible to get up in the morning" is a theoretically good statement to use in assessing depression. However, if a sample population of depressed patients did not respond to that question differently from a normative group, then the item would not be included. Thus, if a person with hysterical traits answers "true" to the statement "I have stomach pains," it is not so important whether he actually does or does not have stomach pains, rather it is more important from a test construction point of view that he says he does. In other words, the final criterion for inclusion of items within an inventory is based on whether or not these items are responded to in a significantly different manner by a specified population sample.

Using this method, Hathaway and McKinley began with an original item pool of over 1000 statements derived from a variety of different sources. These sources included previously developed scales of personal and social attitudes, clinical reports, case histories, psychiatric interviewing manuals, and personal clinical experience. The original 1000 statements were reduced and changed until there were 504 statements which were considered to be clear, readable, not duplicated, and balanced between positive and negative wording. The statements themselves were extremely varied and were purposely designed to tap as wide a number of areas as possible in an individual's life (see Table 7-2). The next step was to select different groups of normal and psychiatric patients to whom the 504 questions could be administered. The normals were primarily friends and relatives of patients at the University of Minnesota hospitals who were willing to complete the inventory. They consisted of 226 males and 315 females who were screened with several background questions including age, education, marital status, occupation, residence, and current medical status. If they were under the care of a physician at the time of the screening interview,

they were excluded from the study. This group was further augmented by the inclusion of other normal subjects such as recent high school graduates, Work Progress Administration workers, and medical patients at the University of Minnesota hospitals. This composite sample of 724 individuals was closely representative in terms of age, sex, and marital status of a typical group of individuals from the Minnesota population as reflected in the 1930 census. The clinical group was comprised of patients representing the major psychiatric categories who were being treated at the University of Minnesota hospitals. These patients were divided into clear subgroups of 50 in each category of diagnosis. If there was any question regarding a patient's diagnosis or if a person had a multiple diagnosis, then he was excluded from the study. The resulting subgroups were hypochondriasis, depression, hysteria, psychopathic deviate, paranoia, psychasthenia, schizophrenia, and hypomania.

Once the normals and psychiatric patients had been administered the 504-item scale, Hathaway and McKinley could then compare their responses. If a specific item was able to correctly differentiate between these two groups, then it was included in the resulting clinical scale. For example, the item "Much of the time my head seems to hurt all over" was answered "true" by 12% of the sample of hypochondriacs and only 4% of the normals. It was thus included in the clinical scale for hypochondriasis. The comparisons, then, were between each clinical group and the group of normals rather than among the different clinical groups themselves. By use of this selection procedure, tentative clinical scales were developed.

This was still not the final step in the scale constructions. Just because the items were endorsed differently by the group of 724 Minnesota normals than by the patients from various clinical populations did not necessarily indicate that the items could then actually be used for clinical screening purposes. The next step was to attempt to cross-validate the scales. This was accomplished by selecting a new group of normals and comparing their responses with a different group of clinical patients. The items which still provided significant differences between these groups were selected for the final version of the scales. It was reasoned, then, that these items and the scales comprised of these items would thereby be valid for differential diagnosis in actual clinical settings.

Whereas this procedure describes how the original clinical scales were developed, two additional scales were also developed using slightly different approaches. The scale of masculinity-femininity (Mf) was originally intended to be able to differentiate male homosexuals from males with a more exclusively heterosexual orientation. However, there were found to be few items which could effectively perform this function. The scale was then expanded to distinguish items which were characteristically endorsed in a certain direction by the majority of males from those which were characteristically endorsed in a certain direction by females. This was accomplished in part by the inclusion of items from the

Terman and Miles I Scale (1936). The second additional scale was social introversion (Si) which was developed by Drake in 1946. It was initially developed using empirical criterion keying in an attempt to differentiate female college students who participated extensively in social and extracurricular activities from those who rarely participated. It was later generalized to reflect the relative degree of introversion for both males and females.

It soon became apparent to the test constructors that persons could alter the impression they made on the test by various test taking attitudes. Hathaway and McKinley thus began to develop several scales that could detect the types and magnitude of the different test taking attitudes which were most likely to invalidate the other clinical scales. The four scales that were developed were the cannot say (?), the lie (L), the infrequency (F), and the correction (K) scales. The cannot say scale (?) is simply the total number of unanswered questions. If a high number of these are present, it would obviously serve to reduce the validity of the overall profile. The lie scale represents a naïve and unsophisticated effort on the part of the examinee to create an overly favorable impression. The items selected for this scale were those which indicated a reluctance to admit to even minor personal shortcomings. The F scale is comprised of those items that were endorsed by less than 10% of normals. A high number of scorable items on the F scale, then, reflects that the examinee is endorsing a high number of unusually deviant responses.

Perhaps the most sophisticated of the validity scales is K which reflects an examinee's degree of psychological defensiveness. The items for this scale were selected by comparing the responses of known psychiatric patients who still produced normal MMPI's (clinically defensive) with "true" normals who also produced normal MMPI's. Those items which differentiated between these two groups were used for the K scale. Somewhat later, the relative number of items endorsed on the K scale was used as a "correction" factor. The reasoning behind this is that if some of the scales were lowered because of a defensive test taking attitude, then a measure of the degree of defensiveness could be added back into the scale to compensate for this. The result would be a more accurate appraisal of the person's clinical behavior. The scales which are not given a K correction are those whose raw score still produced an accurate description of the person's actual behavior.

The MMPI was originally copyrighted and published by the University of Minnesota Press in 1943. It was later published and distributed by the Psychological Corporation (1943) along with newly developed standard manuals, forms and scoring materials. Recently (1983), it has again been published and distributed by the University of Minnesota Press and is distributed by Interpretive Scoring Systems. Over the past 40 years it has been translated into numerous languages, and it is available in many nations throughout the world.

#### RELIABILITY AND VALIDITY

Reliability studies performed on the MMPI have not been overly encouraging. For example, test-retest reliabilities for psychiatric patients, in which retesting

was performed less than a year after the initial measure, range from a low of .50 to highs in the range of .90, with median scores in the .80s. Proponents of the MMPI have pointed out that fluctuations in test scores are to be expected. This is especially true for psychiatric populations since the effects of treatment or stabilization in a temporary crisis situation are likely to be reflected in a patient's test performance. Bergin (1971) has demonstrated that scale 2 (depression) is particularly likely to be lowered after successful treatment. Thus, test-retest reliability may actually be an inappropriate method of evaluating this scale for certain types of populations. This defense of the test's reliability is somewhat undermined by the observation that test-retest reliability is actually more stable for psychiatric populations than for normals. Whereas the median range for psychiatric patients is around .80, median reliabilities for normals are around .70. Split half reliabilities are likewise low, having an extremely wide range from .05 to .96, with median correlations in the .70s. Reliability, then, has not proved to be one of the MMPI's strong points.

Further difficulties relate to the construction of the scales themselves. One significant problem is that intercorrelations between many of the scales are quite high probably because of the extensive degree of item overlap. Sometimes the same item will be simultaneously used for the scoring of several different scales, and most of the scales have a relatively high proportion of items common to other scales. For example, scales 7 (psychasthenia) and 8 (schizophrenia) have fairly high item overlap which is reflected in correlations ranging between .64 and .87 depending on the population sampled (Dahlstrom and Welsh, 1960). Scale 8, which has the highest number of items (78), has only 16 items that are unique to it (Dahlstrom, Welsh, and Dahlstrom, 1972). Because of the high intercorrelations between scales, several factor analytic studies have been conducted which have consistently found that two major variables could account for most of the variance (Block, 1965; Dahlstrom and Welsh, 1960; Dahlstrom et al., 1972, 1975; Welsh, 1956). All of this strongly suggests that there is a high degree of redundancy regarding what the scales measure.

The fact that the different scales correlate so highly can, in part, be understood by considering that the original selection of the items for inclusion in each scale was based on a comparison of normals with different clinical groups. The items, then, were selected based on their differentiation of normals from various psychiatric populations, rather than their differentiation of one psychiatric population from another. Even though the psychiatric groups varied from the normals on several traits, this manner of scale construction did not serve to develop accurate measurements of these different traits. Rather, the scales are filled with many heterogeneous items and measure multidimensional, often poorly defined attributes. This approach has also resulted in many items being shared with other scales. In contrast, an approach in which specific psychiatric groups had been compared with one another would more likely have resulted in scales with less item overlap that could also measure more unidimensional traits.

A final difficulty relating to scale construction is the imbalance in the number of "true" as opposed to "false" items. In the L scale, all the items are scorable if answered in the "false" direction; on the K scale, 29 of 30 items are scored if answered "false"; and scales 7, 8, and 9 have a ratio of approximately 3 to 1 of "true" as compared to "false" items. The danger of this imbalance is that persons having response styles of either acquiescing ("yea saying") or disagreeing ("nay saying") will answer according to their response style rather than to the content of the items. A theoretically sound approach to item construction would have an even balance between the number of "true" and "false" answers. Some authors (Edwards, 1957, 1964; Messick and Jackson, 1961) have even suggested that test results do not reflect psychological traits as much as generalized test taking attitudes. Thus, a controversy has arisen over "content variance," in which an examinee is responding to the content of the items in such a way as to reflect psychological traits, as opposed to "response style variance," in which responses reflect more the examinee's tendency in a certain biased direction. In a review of the literature, Koss (1979) concluded that although response sets can and do exist, the examinee's tendency to respond accurately to the item content is far stronger.

These difficulties with reliability and scale construction would suggest that the MMPI's validity is questionable. Rodgers (1972) has even referred to the MMPI as a "psychometric nightmare." However, even though the strict psychometric properties are not satisfactory, this has been somewhat compensated by extensive validity studies. More specifically, the meanings of two- and three-point profile code types have been extensively researched, as have the contributions which the MMPI can make towards assessing and predicting specific problem areas. Dahlstrom et al. (1975), in Volume 2 of their revised MMPI handbook, cite 6000 studies investigating profile patterns. This number is continually increasing (see, for example, Bennet and Schubert, 1981; Conley, 1981), and past studies provide extensive evidence of the MMPI's construct validity. For example, violence in women has been associated with elevations in scales 4 (masculinity-femininity) and 5 (psychopathic deviate), and these individuals can be described as defensive, lacking contact with their impulsiveness, nonconforming, and being at variance with the stereotyped definition of femininity (Huesmann, Lefkowitz, and Eron, 1978; McCreary, 1976). A further example is that the development of alcoholism has been found to occur more frequently in persons having elevations on scales F, 4, and 9, which suggests that they are gregarious, impulsive, and less socially conforming (Hoffman, Loper, and Kammeier, 1974). Individual clinicians can consult research on code types to obtain specific personality descriptions and learn of potential problems to which a client may be susceptible. It is primarily because of these extensive validity studies that the MMPI continues to be used.

## ASSETS AND LIMITATIONS

In the discussion of reliability and validity, several limitations associated with the MMPI were highlighted. These included marginally adequate reliability and problems related to the construction of the scales, such as item overlap, high intercorrelations between scales, multidimensional poorly defined scales, and imbalances between the relative proportion of "true" as opposed to "false" items. Added to these difficulties are criticisms that the test is too long and that many of the items are considered to be offensive, especially those related to sex and religion.

A significant caution related to the construction of the MMPI is that it is generally inadequate for the assessment of normal populations. The items were selected on the basis of their ability to differentiate — in a bimodal population — normals from psychiatric patients. Thus, extreme scores can be interpreted with a fairly high degree of confidence, but moderate elevations must be interpreted with appropriate caution. An elevation in the range of 1 standard deviation above the mean is more likely to represent an insignificant fluctuation of a normal population than would be the case if a normally distributed group had been used for the scale construction. This is in contrast to a test like the California Personality Inventory (CPI) which used a more evenly distributed sample (as opposed to a bimodal one) and, as a result, can make meaningful interpretations based on moderate elevations. Evaluation of normals is further complicated by the observation that many normal persons achieve high scores. Thus, neither the items themselves nor the scales were designed for the assessment of normals.

Another difficulty with the MMPI is that its organization can be misleading since the scales labels use traditional diagnostic categories. A person might read a scale such as "schizophrenia" and infer that a person with a peak on that scale therefore fits that particular diagnosis. Although it was originally hoped that the MMPI could be used to make differential psychiatric diagnoses, it was soon found that it could not adequately perform this function. Thus, even though schizophrenics may score high on scale 8, so do other psychotic groups. Also, moderate elevations can occur for normal persons. With the publication of the most recent *Diagnostic and Statistical Manual of Mental Disorders* [DSM III; American Psychiatric Association (1980)], the traditional labels upon which the scale names were based became somewhat outdated. This causes further confusion related to diagnosis since the scales reflect older categories. For example, scales 1, 2, and 3 are called the "neurotic triad," and scale 4 is labeled psychopathic deviate; yet clinicians are often faced with translating scale elevations into DSM III terminology.

In order to compensate for the difficulties related to scale labels, clinicians should become aware of the current meanings of the scales based on research rather than the meanings implied by the often misleading scale titles. This can

be helped in part by the use of scale numbers rather than titles. For example, scale 8 suggests such attributes as apathy, feelings of alienation, philosophical interests, poor family relations, and unusual thought processes rather than "schizophrenia." It is the clinician's responsibility to determine which of these attributes are most characteristic of the person being evaluated. Clinicians should also be aware of the relations between scales as represented by the extensive research performed on two- and three-point code types. Usually the patterns or profiles of the scales are more useful and valid than merely considering individual scale elevations. It is this body of research which is far more significant than the work done on the original normative sample. In fact, the size (724) and representativeness (Minneapolis adults) of the normative sample have frequently been questioned. Anastasi (1982) (p. 506) suggests that it is more appropriate to view this sample as a "non-normative fixed reference group" which can be used to compare and define the different scale scores. The subsequent research performed on empirical code profiles is far more useful than the original normative scale comparisons. It is the extensiveness of research in this area which represents what is probably the strongest asset of the MMPI.

A further significant asset is the MMPI's immense popularity and familiarity within the field. Extensive research has been performed in a variety of areas, and new developments have included abbreviated forms, new scales, the use of critical items, and computerized interpretation systems. The MMPI has been translated into all the major world languages and is available in numerous countries. Normative and validity studies have been conducted on several different cultural groups (Butcher and Pancheri, 1976), which makes possible the comparison of data collected from varying cultures. In contexts where no norms have been developed, at least the test format lends itself to developing more appropriate norms which can then be used in these contexts.

Although the MMPI has been used in the assessment of persons from different cultural contexts, such assessments should be made with extreme caution. There are likely to be even larger cultural differences for a personality test such as the MMPI than for ability tests. Cultural differences would be especially pronounced if a clinician used the original Minnesota norms rather than ones developed for the particular group he was evaluating (Butcher and Pancheri, 1976). When interpreting the profiles of culturally divergent groups, clinicians should have a knowledge of the beliefs and values of that culture and should consult appropriate norms when available. There are a wide variety of possibilities as to why persons from different cultural groups score in a certain direction. Although scores may be due to the accurate measurement of different personality traits, they may also be the result of cultural tendencies to acquiesce by giving socially desirable responses, differing beliefs relating to modesty, role conflicts, or varying interpretations of the meaning of items. Profiles may also reflect the results of racial discrimination in that scales associated with anger, impulsiveness, and frustration may be elevated.

Related to the cultural issues is the importance of taking into consideration a variety of demographic variables. It has been demonstrated that age, sex, race, place of residence, intelligence, education, and socioeconomic status are all related to the MMPI scales. Often the same relative elevation of profiles can have quite different meanings when corrections are made for demographic variables. Some of the more important and well researched of these will be discussed here and should be taken into account when interpreting test profiles.

**Age.** Typically, elevations occur on scales 1 (hypochondriasis) and 3 (hysteria) for older normal populations (Leon, Gillum, Gillum, and Gouze, 1980). On the other hand, scales 4 (psychopathic deviate), 7 (psychasthenia), and 8 (schizophrenia) are commonly elevated for younger populations (Marks, Seeman, and Haller, 1974). As the population which is sampled becomes older, the deviations of the latter group of scales tend to decrease. A further finding has been that scale 9 (mania) is more commonly elevated in younger persons but decreases with age until it becomes the most frequent low point in older populations (Gynther and Shimkuras, 1966). As a general rule, the left side of the profile (scales 1, 2, and 3) increases with age, which parallels the trend in older persons towards greater concern with health (scales 1 and 3) and depression (scale 2). Conversely, the right side of the profile decreases with age, which parallels decreased assertiveness (scale 4), increased introversion (scales 2 and 0), and a decrease in energy level (scale 9). However, in specific cases there may also be a complex interaction with gender, health, socioeconomic status, and ethnicity. In addition to considering scale elevations related to aging, it may be helpful to evaluate individual item content. Swenson, Pearson, and Osborne (1973) provide a list of 30 items which are likely to be affected by aging such as No. 9: "I am about as able to work as I ever was" (false) and No. 261: "If I were an artist I would like to draw flowers" (true). An analysis of these items indicates that older persons generally express a decrease in hostility (No. 39, 80, 109, 282, and 438), have more "feminine" interests (No. 132 and 261), and are more dutiful, placid, and cautious (Gynther, 1979a).

A significant feature found within adolescent populations is a general elevation in many of the MMPI scales. This has led to the development of a separate set of adolescents norms (Marks et al., 1974) which should be used when interpreting an adolescent profile.

**Race and Culture.** In general, test results obtained from black psychiatric patients need to be interpreted with a good deal of caution. This would involve correlating as many additional sources of information as possible, including other test findings, psychosocial history, and interview data. A consistent finding within black populations is a tendency to score higher on both scales 8 (schizophrenia) and 1 (hypochondriasis). What is significant is that elevations on

scale 1 may not actually reflect somatic concerns (Miller et al., 1968), and the "psychotic" profiles (scales 8 and F) of blacks could result in inaccurate interpretive descriptions of their behavior (Gynther, 1979b; Smith and Graham, 1981). Other scale elevations occurring frequently in blacks are on L, F, and 9 (mania; Gynther, 1972, 1978a; Miller et al., 1968). In a review of the literature, Gynther (1972, 1978) stressed that the most consistent finding was that normal blacks scored higher on scales F, 8 (schizophrenia), and 9 (mania). This was true regardless of age, gender, or urban versus rural environment. The MMPI scores themselves reflect higher levels of nonconformity, alienation, and impulsivity. However, these trends may be due merely to different values and perceptions rather than higher levels of maladjustment. At this point, the issue of MMPI bias against blacks has not been resolved, and further studies relating to actual behavioral predictions are needed (Pritchard and Rosenblatt, 1980).

If one assumes that blacks' scores on the MMPI are biased, there are two approaches towards diminishing the difficulties associated with scale differences between blacks' and whites' scores. One is to decrease the importance of scales F, 8, and 9 when interpreting a black person's profile. A second strategy is the use of the R scale which is comprised of 27 items to which blacks and whites respond differently (White, 1975). By means of this scale, adjustments can be made on scales F, 4, and 8 which theoretically compensate for the effects of differing cultural background.

Although black versus white scale differences are more frequently encountered in the literature, similar research has been conducted, and norms developed, for a number of other groups. This includes work on populations from Israel (Merbaum and Hefetz, 1976), Pakistan (Mirza, 1977), South Africa (Lison and Van der Spuy, 1977), Chile (Rissetti, Butcher, Agostini, Elgueta, Gaete, Margulies, Morlans, and Ruiz, 1979), Mexico (Nunez, 1968, 1980), and Japan (Tsushima and Onorato, 1982), as well as on Mexican-Americans (Padilla and Ruiz, 1975; Quiroga and Bessner; Reilly and Knight, 1970). Whenever clinicians work with different cultural groups, they should consult the specific norms that have been developed for use with these groups, as well as become familiar with any research that may have been carried out with the MMPI on these groups. Useful sources are Butcher and Pancheri's (1976) handbook for cross-national MMPI research and a review of current cross-cultural research by Butcher and Clark (1979).

**Intellectual Level.** Individuals with higher intelligence and education frequently score higher on "feminine" interests (scale 5). Furthermore, scales L and F decrease as intellectual level increases (Gynther and Shimkuras, 1966). As a result, either low scores on scale 5 (masculinity-femininity) or higher elevations on the L or F scale take on increased significance with more educated populations. Thus, a man with a university education who has an average or moderate elevation (T = 50-65) on scale 5 (masculinity-femininity) may actually be more

representative of men who place a strong emphasis on traditional expressions of masculinity. Likewise highly educated persons scoring moderate elevations on L or F may be more characteristic of other persons who score somewhat higher.

The advantages and cautions for using the MMPI clearly indicate that a considerable degree of psychological sophistication is necessary. Both its assets and its limitations must be understood and taken into account. The limitations are numerous and include marginally adequate reliability, problems related to scale construction, excessive length, offensive items, limited usefulness for normal populations, misleading labels for the scales, inadequacy of the original normative sample, and the necessity of considering demographic variables. However, these limitations are balanced by a number of significant assets especially the extensive research relating to the meanings of the different scales and the relations between scales. Further assets are the MMPI's familiarity in the field, the development of new norms, and extensive research relating to specific problem areas. Of central importance is the fact that the MMPI has repeatedly proved itself to be of practical value to clinicians, especially because the variables that the scales attempt to measure are meaningful and even essential areas of clinical information. Butcher (1979) has poignantly summarized the current status of the MMPI by calling it "an outmoded but as yet unsurpassed psychopathology inventory" (p. 34).

### NEW DEVELOPMENTS

In addition to the standard approaches to the MMPI, a number of significant developments have served to enhance the usefulness and information which can be derived from this test. Most of these developments are also attempts to compensate for the test's deficiencies which have already been discussed. They include abbreviated forms, new scales, critical items, and computerized interpretations.

Criticism regarding the extreme length of the MMPI has led to the development of several abbreviated forms. The one which has achieved the most popularity, but also the most severe criticism (Newmark, 1981), has been Kincannon's (1968) Mini-Mult. The form consists of 71 items and was developed by omitting items which had the greatest degree of scale overlap. Scales Mf and Si were also excluded. The overall scale configurations correspond fairly closely with the standard long form of the MMPI, with correlations ranging from .60 to .89. Two major criticisms of the Mini-Mult are that scales L, F, and Ma have low correlations with corresponding long-form scales and that it underestimates extreme scores. In order to correct the first of these criticisms, Dean (1972) revised the Mini-Mult scales L, F, and Ma until they correlated at a level of .80 with their corresponding long-form scales. The resulting 86-item MMPI abbreviation has been referred to as the Midi-Mult. Another short form was developed by Spera and Robertson (1974) who attempted to correct the second criticism by

including Grayson's (1951) critical items which are significant items relating to pathology. These items can be analyzed according to their individual content but also serve to make the clinical scales more sensitive to extreme dimensions of pathology. The resulting 104-item form has been called the Maxi-Mult. Whereas, both the Mini- and Midi-Mults have been found to be insensitive to extreme levels of pathology, the Maxi-Mult is good for assessing these populations (Fauschingbauer and Newmark, 1978). However, it is inadequate for mildly pathological outpatients and normal college samples, and these inadequacies have been found to be particularly pronounced in the assessment of females (Newmark, Owen, Newmark, and Fauschingbauer, 1975; Newmark and Thibodeau, 1979).

Two additional short forms have been found to be more versatile than these variations of Kincannon's Mini-Mult. The FAM (Fauschingbauer, 1974) was developed using similar methods to the Mini-Mult. However, the inclusion of significantly more items (166) and the somewhat different organization of these items have resulted in correlations of .85 or greater with the standard long form. Another short form is the MMPI-168 (Overall and Gomez-Mont, 1974) which uses only the first 168 items of the standard MMPI. The rationale for this is that most of the reliable variance in the standard MMPI can be accounted for in these initial 168 items (Overall and Gomez-Mont, 1974). Both these short forms have been found to be extremely useful with psychiatric inpatients and normal college populations, but they are somewhat deficient in the assessment of mildly pathological outpatients (Newmark and Thibodeau, 1979). Thus, the selection of which abbreviated short form to use should depend primarily on its relative appropriateness for specific populations. Whenever possible, clinicians should validate a short form they are using within their population of interest (Greene, 1983).

Since the initial publication of the MMPI, over 300 new scales have been developed. Their purpose has been to assist in evaluating the different content responses a client makes. Some of these scales have been developed for normals and are unrelated to pathology, such as dominance (Do) and social status (St). Others relate more directly to pathological dimensions, and often use the original data from Hathaway and McKinley's standardization sample. It is beyond the scope of this chapter to discuss all of the major new scales, but several of the most frequently used ones will be outlined.

One of the most popular developments has been the reorganization by Harris and Lingo (1955, 1968) of the standard scales into more homogeneous content categories. These subscales were constructed by intuitively grouping together items which seemed to reflect a single trait or attitude. The Harris and Lingo subscales represent a specific breakdown of the already existing scales 2, 3, 4, 6, 8, and 9, and are presented here:\*

\*From *Subscales for the Minnesota Multiphasic Personality Inventory: An Aid to Profile Interpretation* by Robert E. Harris and James C. Lingo (1968). Reprinted by permission of James C. Lingo, Department of Psychology, University of Michigan.

Scale 2 (Depression)

- D1 Subjective Depression
- D2 Psychomotor Retardation
- D3 Physical Malfunctioning
- D4 Mental Dullness
- D5 Brooding

Scale 3 (Hysteria)

- Hy1 Denial of Social Anxiety
- Hy2 Need for Affection
- Hy3 Lassitude-Malaise
- Hy4 Somatic Complaints
- Hy5 Inhibition of Aggression

Scale 4 (Psychopathic Deviate)

- Pd1 Familial Discord
- Pd2 Authority Conflict
- Pd3 Social Imperturbability
- Pd4A Social Alienation
- Pd4B Self Alienation
- Pd4 Alienation (a summation of 4A and 4B)

Scale 6 (Paranoia)

- Pa1 Persecutory Ideas
- Pa2 Poignancy
- Pa3 Moral Virtue

Scale 8 (Schizophrenia)

- Sc1A Social Alienation
- Sc1B Emotional Alienation
- Sc1 Object Loss (a summation of Sc1A and Sc1B)
- Sc2A Lack of Ego Mastery, Cognitive
- Sc2B Lack of Ego Mastery, Conative
- Sc2C Lack of Ego Mastery, Defective Inhibition, and Control
- Sc2 Lack of Ego Mastery (a summation of Sc2A, Sc2B, and Sc2C)
- Sc3 Sensorimotor Dissociation

Scale 9 (Hypomania)

- Ma1 Amorality
- Ma2 Psychomotor Acceleration
- Ma3 Imperturbability
- Ma4 Ego Inflation

Serkownele (1975) has used a similar approach to develop subscales for scales 5 and 0. They can be used as an extension of the Harris and Lingoes scales:

- Scale 5 (Masculinity-Femininity)
- Mf1 Narcissism-Sensitivity
  - Mf2 Stereotypic Feminine Interests
  - Mf3 Denial of Stereotypic Masculine Interests
  - Mf4 Heterosexual Discomfort-Passivity
  - Mf5 Introspective-Critical
  - Mf6 Socially Retiring
- Scale 0 (Social Introversion)
- Si1 Inferiority-Personal Discomfort
  - Si2 Discomfort with Others
  - Si3 Staid-Personal Rigidity
  - Si4 Hypersensitivity
  - Si5 Distrust
  - Si6 Physical Somatic Concerns

Scoring directions for the earlier Harris and Lingo's subscales can be found in Dahlstrom et al. (1975), and scoring directions for both sets of subscales can be found in Graham (1977). Although the Harris and Lingo's subscales show high intercorrelations with the parent scales (Harris and Lingo's, 1968), the internal consistency of these scales is somewhat low (.04-.85; Gocka, 1965). Several initial validity studies are available (Boerger, 1975; Calvin, 1975; Gordon and Swart, 1973) which demonstrate their potential clinical usefulness. Validity and reliability studies are not yet available for Serkownek's (1975) subscales. The practical importance of both subscales is that they provide a useful supplement for interpreting the original scales. For example, a clinician can assess whether a person scoring high on scale 4 (psychopathic deviate) achieved that elevation primarily because of family discord (Pd 1) or authority problems (Pd 2) and social imperturbability (Pd 3). Based on this knowledge, more accurate evaluations can be made of such areas as acting out potential or response to psychotherapy.

In contrast to the attempt of Harris and Lingo's to develop subscales for already existing MMPI scales, Wiggins (1966) developed scales based on an overall analysis of the contents of the MMPI items. He began with item clusters which were based on such areas as authority conflicts and social maladjustment. These clusters were revised and refined using factor analysis and evaluations of internal consistency. The results are the following 13 scales:

- SOC Social Maladjustment
- DEP Depression
- FEM Feminine Interests
- MOR Poor Morale
- REL Religious Fundamentalism
- AUT Authority Conflict

PSY	Psychoticism
ORG	Organic Symptoms
FAM	Family Problems
HOS	Manifest Hostility
PHO	Phobias
HY	Hypomania
HEA	Poor Health

The Wiggins scales have acceptable levels of reliability, and validity studies have so far been promising (Boerger, 1975; Lachar and Alexander, 1978; Payne and Wiggins, 1972; Peteroy et al., 1982). Norms and directions for scoring are available in Graham (1977), as well as in Fowler and Coyle (1969) and Wiggins (1971). Like the Harris and Lingoes subscales, the Wiggins categories can provide additional useful information in the interpretation of the standard MMPI scales.

Two other frequently used scales are the MacAndrews (1965) scale (AMac) for alcoholism and Barron's (1953) ego strength scale (Es). Both scales were constructed using empirical methods in which items were selected based on response frequencies of a criterion group as compared to the frequencies of a suitable comparison group. The MacAndrews (1965) scale (also AMac, MAC, Mac scale) consists of 49 items which significantly differentiate between outpatient alcoholics and nonalcoholic psychiatric outpatients. Persons scoring high on this scale are characterized as uninhibited, sociable and they use repression and religion as means of attempting to control rebellious, delinquent impulses (Finney, Smith, Skeeters, and Auvenshine, 1971). The scale has been found to effectively differentiate alcoholic from other psychiatric patients (Clopton, 1978b; Clopton, Weiner, and Davis, 1980; Svanum, Levitt, and McAdoo, 1982) and to identify persons who are at a high risk of later developing alcohol-related problems (Williams, McCourt, and Schneider, 1971). However, the scale has difficulty differentiating alcohol abusers from other substance abusers (Burke and Marcus, 1977), and appropriate caution should be taken in assessing males as opposed to females since female alcoholics have consistently higher scores than males with similar difficulties (Butcher and Owen, 1978). Barron's (1953) ego strength (Es) scale consists of 68 items and was designed to assess the degree to which patients benefited from psychotherapy. However, validity studies have produced somewhat mixed results. Graham (1978) summarizes these studies by suggesting that Es is successful in predicting the response of neurotic patients to insight-oriented therapy, but is not useful for other types of patients or other kinds of treatments. In a correlational study with other tests, Harmon (1980) found that Es relates to the degree to which a person has an underlying belief in self-adequacy, along with tolerant, balanced attitudes.

An alternative method of constructing new scales is the interpretation of single items. Several attempts have been made to isolate those items which are

considered critical to the presence of psychopathology. Answering in a significant direction on these items could represent serious pathology regardless of how the person responded on the remainder of the inventory. These items have been referred to as "pathognomonic items," "stop items," or more frequently, "critical items." It has been assumed that the direction in which a person responds represents a sample of the person's behavior and acts as a short scale which indicates his general level of functioning. Two of the most frequently used lists of critical items are Grayson's (1951) list of 38 items and Caldwell's (1969) more comprehensive list of 69 items (see Appendix I). Both of these were intuitively derived and are useful in differentiating patients undergoing crises from those who are not in crises (Koss, Butcher, and Hoffman, 1976). Furthermore, the Caldwell items were helpful in differentiating which category of crisis a particular patient was in (acute anxiety, depressed-suicidal, mental confusion, etc.). In contrast, the Grayson items could indicate that the person was in crisis, but they were limited primarily to being able to specify the presence of psychotic complaints (mental confusion, persecutory ideas). Attempts to establish an efficient cutoff score for differentiating normals from psychiatric patients have met with only minimal success due to the extensive response overlap between the two groups (Koss et al., 1976). It is most advantageous, then, to look at the individual content of the items in relation to what specific types of information they reveal rather than to look at the overall number of items answered.

A recent list of critical items was developed by Lachar and Wrobel (1979) for use with computerized MMPI reports. It attempts to provide a wide range in content, to possess face validity, and to result in valid samples of behavior. The list, which comprises 98 items, was developed through both empirical and intuitive procedures.

A final important development in approaches to the MMPI is the use of computerized interpretation systems. The number of such services has grown considerably since 1965 when the first system was developed by the Mayo Clinic. Major providers are the Roche Psychiatric Service Institute (RPSI), Clinical Psychological Services, Inc. (using the Caldwell Report), the Institute for Clinical Analysis (ICA), and Behaviordyne Psychodiagnostic Laboratory Service. A description and evaluation of these services is included in Buros's *Eighth Mental Measurements Yearbook* (Nos. 617-624, 1978). Each of the computerized systems has a somewhat different approach. Some provide screening, descriptive summaries, and cautions relating to treatment, whereas others are highly interpretive or may provide optional interpretive printouts for the clients themselves. The rationale behind computerized systems is that they can accumulate and integrate large amounts of information derived from the vast literature on the MMPI which even experienced clinicians cannot be expected to recall. However, serious questions have been raised regarding an increase in the

possibility of misuse by untrained personnel. Computerized services are limited to standard interpretations and are not capable of integrating the unique variables that are usually encountered in dealing with clinical cases. This is a significant factor which untrained personnel may be more likely to either overlook or inadequately evaluate. In response to these issues, the American Psychological Association (APA) developed a set of guidelines to ensure the proper use of computerized interpretations (1966). It should be stressed that although computerized systems can offer information from a wide variety of accumulated data, their interpretations are still not end products. Like all test data, they need to be placed in the context of the client's overall background and current situation, and integrated within the framework of additional test data.

### INTERPRETATION PROCEDURE

Seven steps in interpreting an MMPI have been recommended by Webb, McNamara, and Rodgers (1981). They should be followed with a knowledge and awareness of the implications of demographic variables such as age, culture, intellectual level, education, social class, and occupation. A summary of the relation between MMPI profiles and some of the main demographic variables including age, culture, and intellectual level has already been provided. While looking at the overall configuration of the test (step 5), clinicians can elaborate on the meanings of the different scales and the relations between scales by consulting the interpretive hypotheses associated with them. (These can be found in the sections on "Validity Scales," "Clinical Scales," and "Two-point Codes.") The discussion of the various scales and codes represents an attempt to integrate and summarize the work of a number of different clinical and research sources, the most important of whom have been Dahlstrom et al. (1972); Gilberstadt and Duker (1965); Grahahm (1977); Lachar (1974); Marks et al. (1974); and Webb et al. (1981). The seven steps in interpretation follow:

1. The examiner should initially note the length of time required to complete the test. For a mildly disturbed person with an average I.Q. and 14 years or more of education, the time for completion should be between 60 and 75 minutes. If two or more hours are required, the following interpretive possibilities must be considered: (a) major psychological disturbance, particularly a severe depression or functional psychosis; (b) below-average I.Q. or poor reading ability resulting from an inadequate educational background; or (c) cerebral impairment. If, on the other hand, an examinee finishes in less than an hour, one should suspect an invalid profile, an impulsive personality, or both. For individuals with reading difficulties, particularly certain aphasic conditions, a tape-recorded method of administration might be considered.
2. Note any erasures or pencil points on the answer sheet. The presence of a few of these signs may indicate that the person took the test seriously and

reduces the likelihood of random marking; a great number of erasures may reflect obsessive-compulsive tendencies.

3. Complete the scoring and plot the profile. Specific directions for tabulating the raw scores and converting them into profiles are provided in Appendix J. Compile additional information including I.Q. scores, relevant history, demographic variables, and observations from steps 1 and 2.

4. Arrange the test scores in the following manner:

- a) Arrange the ten clinical scales in order of descending elevation and place the three validity scales last.
- b) Using the following Welsh code symbols, indicate the relative elevation of each scale:

<i>Range</i>	<i>Elevation Symbol</i>
Over 99 T	**
90-99 T	*
80-89 T	"
70-79 T	'
60-69 T	-
50-59 T	/
40-49 T	:
30-39 T	#
Under 30 T	No symbol

In other words, all T scores above 99 have two asterisks (\*\*) after them, all T scores between 90 and 99 have one asterisk after them. The following is an example of how to Welsh code a set of T scores:

*Before Welsh coding (step 4a):*

No.	1	2	3	4	5	6	7	8	9	0			
Scale	Hs	D	Hy	Pd	Mf	Pa	Pt	Sc	Ma	Si	L	F	K
T score	75	60	66	65	43	80	85	92	83	50	56	63	44

*After Welsh coding:*

8\*796''1'432-0/5:L/F-K:

This coding not only allows for a shorthand method of recording the results but also is used in many MMPI handbooks to look up profile interpretations. For example, the test profile given can be summarized as an 87, and a personality description could be looked up under that abbreviation in books such as Dahlstrom, Welsh, and Dahlstrom (1972, 1975) or in the section on two-point codes in this chapter. Mild elevations in a person's profile (T = 60-65) represent tendencies or trends in the individual's personality, although interpretations should be

treated cautiously. Elevations above 70 are more strongly characteristic of the individual and are increasingly likely to represent core features of one's personality dynamics.

An equally acceptable alternative is to simply note the highest and lowest clinical scales as well as relative scores on the validity scales. Code types can be determined by looking at the two or three highest elevations. If the scores need to be summarized, they can be arranged in descending order of elevation with the validity scales presented in their original order (L, F, K) at the end. A clinician might also wish to place them in the order in which they occur on the profile sheet (L, F, K; 1, 2, 3, etc.). However, any summary of scores should always include and be described in terms of T scores.

5. Examine the overall pattern or configuration of the test and note the relative peaks and valleys. Typical configurations, for example, might include the "conversion V" typical of hysterical disorders or elevated scales 4 and 9 which reflect a high likelihood of acting out behavior. The overall configuration can then be used to amplify or modify the interpretations derived from step 4. Note especially any scales greater than 70 or less than 40 as being particularly important for the overall interpretation. The meaning of two-point code configurations can be determined by consulting the section in this chapter which discusses them. In approaching diagnosis, the discussions of both the scales and the code types attempt to use DSM III categories when possible, but sometimes traditional DSM II categories such as neurosis are also used. The tester may also wish to consult one of the MMPI handbooks listed in the recommended readings for a more complete understanding and interpretation of the profile which has been obtained.

6. Score the critical items (see Appendix I) and make note of which ones indicate important trends. It is often helpful to go over these items with the client and obtain elaborations, or to establish whether or not the person understood what the item was asking.

7. Examine the answer sheet and note which questions were omitted. A discussion with the client of why he chose not to respond might shed additional light on how he is functioning psychologically and what areas are creating conflict for him.

## THE VALIDITY SCALES

### The ? Scale

The ? scale is usually not considered to be a scale as such since it does not directly measure any specific personality trait. It is simply a total of the number of items which have been left unanswered throughout the entire test questionnaire. If there are less than 30 items that have been left unanswered ( $T = 50$ ), the test

results are considered to be valid only if the other validity scales are within normal limits. Moderate elevations, in which from 30 to 60 questions have been omitted ( $T = 50-70$ ) may indicate either a reading difficulty or obsessional indecision. Additional possibilities to explain this degree of indecisiveness are the presence of extreme intellectualization, unusual interpretations of the items, or legalistic overcautiousness perhaps due to a paranoid condition. As the number of unanswered items increases above 60, the likelihood of a valid profile becomes increasingly more remote. Any questionnaire having 100 or more unanswered questions represents an invalid profile, and clinical conclusions based on the profile cannot be accurately made.

### The L Scale

The L scale includes 15 items selected on the basis of face validity which indicate whether or not an individual is presenting, either consciously or unconsciously, a naively perfectionistic view of himself. The items all represent attitudes and values which, although rated highly in our culture, are rarely found in all but the most conscientious of individuals. For example, responding "false" to the statement "I do not like everyone I know" suggests an unrealistically positive self-perception. The scale was designed to identify a deliberately evasive response, although it also indicates individuals who are relatively defensive, naive, or unsophisticated. L is determined by counting the total number of "false" responses in items number 15, 45, 75, 105, 135, 165, 195, 225, 255, 285, 30, 60, 90, 120, and 150.

**T = 56-63.** Moderate elevations suggest a strong need to appear in a favorable light and may indicate psychological rigidity or conscious deception. These traits may be associated with limited intelligence or educational background unless they can be explained on the basis of occupation (e.g., clergy). The individual who scores in this range is likely to present himself as overly conforming and conventional, and will usually give socially approved answers concerning self-control and moral values.

**T = 64-69.** Individuals scoring in this range have a naive, unrealistic view of the world and utilize denial, repression, and perhaps conscious deception. They exaggerate their moral qualities and positive scruples but do so in a rigid, self-centered, and uncompromising manner. Underneath they tend to be insecure, self-critical, and frustrated, and they expend a lot of effort glossing over any flaws they see in themselves. They have little insight into their own behavior and usually make poor candidates for psychotherapy.

**T = 70 or More.** These scores are extremely rare and represent an intensification of the trends already mentioned. Such people are usually highly introspective

and ruminative, and have difficulty establishing interpersonal relationships. This may occur in paranoid individuals (check scale 6) or during conscious deception by sociopaths.

### The F Scale

The F scale consists of 64 items on which 90% of the normal population agrees. In other words, each item would be endorsed by only one out of ten normals. Representative statements are "I can easily make other people afraid of me, and sometimes do for the fun of it" (true) and "I have nightmares every few nights" (true). Thus, an elevation on the F scale represents a significant variation from the norm suggestive of nonconventional thinking in which the individual is likely to exaggerate or at least be unusually open concerning his psychological difficulties. Furthermore, the scale does not measure any one specific trait but rather a diversity of unusual responses. Increasing elevations on F are usually accompanied by heightened elevations on most of the other clinical scales.

High scores suggest the following possibilities: (1) endorsing deviant items in an attempt to intentionally look pathological, (2) a lack of cooperation, (3) random responding, (4) incorrect understanding of the items, and (5) a cry for help. Occasionally, individuals who are intensely anxious may get extremely high F scores and yet still have a generally valid overall profile. If K is correspondingly low, this pattern is sometimes referred to as "a cry for help" because of the overt and explicit admission of distress combined with the assumption on the part of the examiner that the individual is attempting to call attention to his need for treatment.

**T = 55 or Less.** Usually such individuals are free from stress and can be described as honest, dependable, calm, and conventional. They also tend to have narrow interests, engage in conventional thinking, and sometimes attempt to deny or minimize problems. They may even be attempting to "fake good," particularly if K is elevated.

**T = 55-65.** An F scale score within this range suggests independent and mildly nonconformist thinking, as well as some negativity and pessimism. If scores are in the upper part of this range, it may also reflect some degree of restlessness, instability, moodiness, and dissatisfaction.

**T = 65-80.** This elevation indicates markedly unconventional, unusual thinking and is typical of rebellious, antisocial, schizoid, or "bohemian" personalities. Within adult populations, a T score from 70 to 80 can reflect ego disorientation and feelings similar to psychotic or severely neurotic patients. Other possibilities which should be considered are that the individual is "faking bad," clerical errors

in scoring, malingering, or a borderline state. Adolescents who are relatively normal but are struggling with identity problems and exhibiting nonconformist behavior may score within this range. This emphasizes the importance of using a different set of norms for adolescents, particularly for this scale.

**T = 80 or More.** The overall profile should be approached with caution, is probably invalid, and may reflect clerical errors in scoring, lack of cooperation, distortion due to confused and delusional thinking, or an overt attempt to falsely claim mental symptoms.

### The K Scale

The K scale was devised to measure guardedness or defensiveness in test taking attitudes as well as a tendency to describe oneself in an overly positive manner. Individuals who score high on K are relatively without insight into their interpersonal relationships, and have a great desire to obtain the approval and confidence of others. Representative items are responding "false" to "I frequently find myself worrying about something" and "I find it hard to make talk when I meet new people." Persons scoring high may have significant underlying conflicts but are unwilling to discuss these difficulties and spend a considerable amount of effort in defensively concealing their true thoughts and feelings. This scale is in many ways similar to the L scale but differs primarily in that it is more subtle and effective. Whereas only naive, moralistic, and unsophisticated individuals would score high on L, more intelligent and psychologically sophisticated persons might have high K scores and yet be unlikely to have any significant elevation on L.

**T = 45 or Less.** This indicates a lack of normal defensiveness which is often associated with a poor self-concept, acute pathology, malingering, or "a cry for help." Usually the person's defenses are not functioning adequately, and he has a poor degree of emotional and behavioral controls. It is important to note, however, that persons of lower social class frequently obtain low K scores without necessarily reflecting these other characteristics. Likewise, adolescents often score low on the K scale, which indicates openness and a certain degree of self-criticism centered around a search for identity and a close examination of their personal values.

**T = 50-60.** Moderate elevations suggest adequately functioning defense mechanisms, self-acceptance, and good ego strength. There is usually a balance between self-disclosure and appropriate self-protection. Although such individuals are willing to admit to socially acceptable limitations, they may tend to minimize other conflicts.

**T = 61-72.** With increasing elevations, there occur corresponding increases in individuals' defensiveness and stronger tendencies to overlook faults in themselves, their families, and their life situation. There are also corresponding lack of insight and general resistance to psychological evaluation. Not only are these people intolerant of personal flaws and insecurities, but they also are unaccepting of unconventional or nonconformist behavior in others. Although extremely concerned that they present a positive image to others, nonetheless they are not accurately aware of many of the impressions that others have of them. They view the psychological problems of others as weaknesses and are reluctant to be placed in a patient role.

Moderate elevation on K is a positive sign for successful psychotherapy, but individuals with scores above  $T = 65$  have difficulty benefiting from therapeutic intervention. Generally speaking, the prognosis tends to be poor with either extremely high or extremely low scores. A moderate elevation on an adolescent's profile is a contraindication of acting out.

**T = 72 or More.** Higher elevations show continued intensification and rigidification of the characteristics discussed under  $T = 61-72$ .

#### The F - K Index

The ratio between F and K can be used as an indication of "faking good" or "faking bad" and is computed by subtracting the raw score of K from that of F.

**When  $F - K = +11$  or More.** This is a "fake bad" pattern and suggests a conscious attempt to look bad, for example, in malingering. It could also be a "cry for help" as a response to an acute life crisis, or it may reflect an overdramatization by a narcissistic, histrionic, self-indulging, and unstable person ("psychochondriac") who is attempting to manipulate pity and attention from others. A further possibility may be that the individual is acutely psychotic and has a distorted perception of his self as compared to the way in which others perceive him.

**$F - K = -11$  or Less.** This strongly suggests that the person is defensively minimizing any conflicts he might have in an attempt to look good. Interpretations of the clinical scales (1-0) should be evaluated keeping this in mind.

**$F - K = -20$  or Less.** This represents doubtful validity of test results because of an exaggerated need to cover up any areas of conflict. This may be the result of overt conscious deception, extreme rigidity, or a clear negativism and refusal to cooperate.

## THE CLINICAL SCALES

### Scale 1: Hypochondriasis (Hs)

Scale 1 attempts to assess the degree to which an individual has an undue concern with physical health. Elevations typically reflect exaggerated expressions of vague and nonspecific disorders in which subjects are covertly seeking to control and manipulate others. They will often be pessimistic, whiny, sour, and passive-aggressive, frequently making others around them miserable. Furthermore, they are egocentric, immature, and lacking in insight concerning the emotional component of their bodily complaints. Thus, not only do they focus their psychological and emotional complaints into physical channels, they also lack insight into this process. Since their degree of psychological sophistication is minimal, they have a difficult time with self-reflection, and psychotherapy with these individuals tends to be slow and difficult. Typically, they have demonstrated a high degree of skill in frustrating physicians as they demand care and attention, yet criticize and reject the help which is offered to them. The long, involved, and almost ritualistic listing of their complaints has sometimes been referred to as an "organ recital."

Scale 1 is often somewhat elevated along with scales 2, 3, and 7; this may reflect depressive conditions, anxiety states, and somatoform or dissociative disorders. A "conversion V" occurs when there are elevations on scales 1 and 3 with a significantly lower (10 points or more) scale 2. In these individuals, psychological conflicts are masked by a histrionic personality in which there is usually the presence of "somatized" complaints (see 13/31 code type). Although there tends to be a low to moderate increase in scale 1 during the presence of actual physical disease, the higher elevations are restricted to hypochondriacal traits.

**Moderately Low Scale 1 (T = 40–50).** These persons can be described as showing good judgment and being generally alert, capable, and responsible. Interpersonally, they may appear to others as conscientious, perhaps to the point of being moralistic. However, most interpretations of a low score on scale 1 should be made cautiously, since this primarily indicates merely a lack of physical complaints.

**High Scorers (T = 65 or More).** These persons are pessimistic, narcissistically egocentric, and stubborn; they manipulate others with their complaints and generally make others around them miserable as a result. Typically they have been to a large number of physicians and have rejected and criticized the "help" which has been offered to them. The symptoms are usually not reactions to immediate stress, but rather are long-standing problems. The anxiety level of such people is also usually low (check scale 7), but if it is somewhat elevated or

can be increased. this improves the prognosis in psychotherapy. As scores increase above 70. there is an intensification of all these trends.

### Scale 2: Depression (D)

Scale 2 includes 60 items which measure the extent to which an individual expresses worry, discouragement, and low self-esteem. The questions are centered around the five major features of depression which include brooding, physical slowness, subjective feelings of depression, mental apathy, and physical malfunctioning. An elevation on scale 2 is the most frequent peak seen with psychiatric patients when admitted to hospitals, and scale 2 provides the best single index of a person's current level of satisfaction, comfort, and security. High scorers on scale 2 tend to be seen by others as aloof and withdrawn as well as silent, retiring, and self-critical.

Although an elevation on scale 2 generally indicates the level of pessimism/optimism, the meaning of that trend varies according to the relative elevations of other scales. In establishing a differential diagnosis within the different types of "neurotic" disorders, it is particularly important to look at possible elevations on 1, 2, 3, and 7. For this reason, scales 1, 2, and 3 are often referred to as the "neurotic triad," and elevations in one of them will frequently be accompanied by elevations in the other two. It is also common to have an accompanying elevation on scale 7, which reflects that the self-devaluation and intropunitiveness of the depression also include tension and nervousness. However, moderate elevations on scales 2 and 7 are desirable for a favorable prognosis in psychotherapy since they reflect an introspective orientation as well as some awareness of personal problems. Of equal importance is that scales 2 and 7 measure the degree of psychological discomfort, pain, and anxiety the person is undergoing which can also be important motivators for change. Thus, they are often referred to as the "distress scales" (see code type 27/72). Another important configuration is an elevation on scales 2 and 8 which indicates that the depression also includes a sense of isolation, alienation, disaffiliation, and unusual thoughts (see code type 28/82).

The possibility of suicide increases when scale 2 is elevated, particularly if that elevation is accompanied by elevations in 4, 7, 8, and/or 9. However, there is no completely valid and useful "suicidal profile" as such. Certainly elevations on scales 2, 4, 7, 8, and 9 are reflective of conditions which excite or release suicidal behavior, but rigid interpretive and predictive formulas should be avoided. If there is *any* suspicion of suicidal potential raised by either test scores or any other means, additional assessment should be made as comprehensively as possible. Furthermore, specific indications of suicidal tendencies may be observed in the person's responses to the critical items that refer to guilt and suicide (see Appendix I).

**Low 2 (T = 28–44).** Individuals scoring low on scale 2 are likely to be active, alert, cheerful, and outgoing. They are seen by others as enthusiastic, self-seeking, and perhaps given to self-display. In certain cases, a low 2 may represent a denial of depressive feelings, particularly in a cyclothymic, labile person.

**Moderate Elevations (T = 60–69).** If 2 is the only elevated scale, this is usually indicative of a reactive depression resulting from a current life crisis. If the elevation typifies a more permanent component of their personality, such people tend to be pessimistic, have a narrow range of interests, and be particularly adept at convincing themselves of their own helplessness and hopelessness. Furthermore, they may feel unable to work, have poor morale, and be dejected and discouraged. Others are likely to see them as aloof, timid, and inhibited.

**High Elevations (T = 70–85).** Often psychiatric patients with a clinically significant level of depression score in this range. Individuals with high scores tend to worry over relatively insignificant problems, and will typically feel helpless and hopeless with regard to interpersonal problem solving. Social withdrawal, indecision, worry, and pessimism are often characteristic features. At extremely high elevations (T = 80 or more), there will typically be a loss of appetite, sleep disturbances, extreme apathy, and self-deprecation with some delusional thinking. If 2 is the only high point on the profile, this probably represents a depressive response to a situational crisis. Scale 2 usually shows a significant decrease following successful therapy.

### **Scale 3: Hysteria (Hy)**

Scale 3 is comprised of 60 items centered around assessing (1) the presence of specific physical complaints and (2) defensive denial of emotional or interpersonal difficulties. What is significant in persons with conversion disorders is that these themes occur simultaneously. In other words, such people establish a certain degree of adjustment by maintaining an exaggerated degree of optimism and channeling any personal conflicts into the body where these conflicts are indirectly expressed through physical complaints. Furthermore, they constantly demand affection and support from others, but they do so in indirect and manipulative ways. Frequently, they will have traits consistent with a histrionic personality in that they are socially uninhibited and highly visible, yet their contact with others is superficial, self-centered, and extremely naive. They often act out sexually and aggressively, with a convenient lack of insight into either their underlying motives or the impact of their behavior on others.

If there is an elevation in scale 3, the individual is unlikely to be psychotic despite accompanying elevations on scales 6 or 8. Although it is certainly possible that such a profile may in some cases still reflect a psychotic condition,

this interpretation should be approached with caution. The "neurotic triad" and the "conversion V" have been mentioned in discussing scales 1 and 2 (see code types 12/21, 13/31, and 23/32). A further frequent and noteworthy profile occurs when scale 3 is accompanied by an elevation on K, particularly if scales F and 8 are lowered. Such individuals are likely to be affiliative, inhibited, and overconventional, and have an exaggerated need to be liked, and approved of, by others (see code 38/83).

**Low 3 (T = 24-44).** Low scorers on scale 3 are usually conventional, constricted, and controlled. They are sometimes described as socially nonparticipating, conforming, and having narrow interests.

**Moderate Elevations (T = 60-69).** Individuals scoring moderate elevations are likely to be well-functioning persons with some histrionic personality traits. They are often described as naive, self-centered, and having strong needs to see themselves in a favorable light. Typically, they lack insight into their interpersonal relations, and tend to be indirect and manipulative in their attempts to have their social needs satisfied by others. If scale 1 is significantly higher than 3, there will most likely be a tendency to redirect their emotional conflicts into physical complaints during times of stress.

**High Elevations (T = 70-80).** Higher elevations on scale 3 reflect persons who are conforming, immature, naive, childishly self-centered, and impulsive. They are demanding of affection and support, and yet seek these in covert and manipulative ways. Interpersonal communications are often used to obtain an emotional effect on others rather than to accurately convey information, and their relationships are superficial and immature. There is a lack of insight into the motivations for their behavior, which is maintained by perceiving events globally rather than attending to the specific and often relevant details of a situation. Their main defenses are denial and repression which often result in a displacement or conversion of psychological conflicts into the physical realm. Since one of their central needs is to be liked, they often respond to therapy in an enthusiastic and overly optimistic manner. However, when their defenses are challenged, they will become intolerant and attempt to manipulate the therapist into a nonconfrontive and overly supportive role. This frequently culminates in the expression of impossible demands which are made on the therapist. Their resistance to treatment tends to be whiny, and is interspersed with complaints of mistreatment by the therapist and the implication that they are being misunderstood. At times, high 3 scorers can be verbally aggressive with their core conflicts revolving around issues of dependence versus independence.

**Scale 4: Psychopathic Deviate (Pd)**

The 50 items in scale 4 are designed to measure general social maladjustment. More specifically, the questions deal with the individual's degree of alienation from his family, the extension of difficulties to school and to authority figures in general, social imperviousness, and alienation both from self and from society. This scale also measures the degree of impulse control, and elevations on this scale are nearly always associated with acting out behaviors. Furthermore, people with elevations on scale 4 have difficulty learning from the consequences of their behavior and spend a good deal of time trying to beat the system. A significant rationale for the development of this scale is that quite frequently, high scale 4 personality types make an excellent initial impression. As a result, they may go undetected by acquaintances and even friends until they are confronted with a situation which demands a sense of responsibility, consideration, and the expression of loyalties. This scale, then, can potentially assess such persons even though, at the time of testing, they may not be engaged in, or may not for some time have been involved with, impulsive acting out behavior.

If there is a corresponding elevation on scale 9, there will almost always be a history of consistent impulsive behavior. Not only do such individuals have a certain degree of anger and impulsiveness, they also have the energy to act on these impulses. Often their behavior occurs in such a way as to damage their families' reputation, and criminal antisocial acts are not uncommon. If elevations are, for example, between 55 and 65, and these are the relative high points, such trends would still be present, but they may be channeled in less extreme and more socially accepted manners, possibly resulting in adequate or even excellent levels of adjustment (see code type 49/94). Further significant and frequently encountered profiles are elevations on scales 4 and 8 (see 48/84 code type) suggestive of psychotic expressions of antisocial behavior, or elevations on scales 4 and 3 (see 34/43 code type) in which antisocial behavior is expressed through numerous covert and disguised means. Another common corresponding elevation is on scale 2, which suggests anxiety and guilt related to an antisocial person being caught and perhaps facing the consequences of his behavior (see code 24/42).

**Low Elevations (T = 20-44).** Low scores on scale 4 reflect persons who are conventional, overidentified with social status, cheerful, and good tempered. They are likely to be balanced, modest, and persistent in working towards their goals, although sometimes they have difficulties asserting themselves in heterosexual relationships.

**Moderate Elevations (T = 60-69).** Moderate elevations are common among adolescents (14-20 years old), and reflect attempts to formulate their separate

identity and independence outside the home. Thus, the admission of alienation which the elevation suggests may be the result of an adolescent's search for identity, rather than a permanent and enduring character trait. Therefore, moderately high scores for adolescents should be handled with caution, and separate adolescent norms should always be used. However, extreme scores or other correspondingly high elevations may still reflect significant pathology. Moderate elevations are also found in counterculture groups which reflect their own as well as their peers' disregard of the values and beliefs of the mainstream culture. Graduate students also show high points on this scale, especially those in the humanities and social sciences. More positive characteristics to be found with moderate elevations include frankness, deliberateness, assertion, sociability, and individualism.

**High Elevations (T = 70-85).** High 4s are characterized by an angry disidentification with their family, society, or both. They have an apparent difficulty in planning ahead as well as a disregard for the consequences of their behavior. Thus, they have an inability to profit from experience, including psychotherapy. Generally, therapy is less effective for high 4 adolescents than it is for high 4 adults. Individuals scoring in this range have a consistent tendency to get into trouble, and can be described as angry, rebellious, impulsive, alienated, and strongly disliking rules and regulations. Usually, their social relationships are shallow, and they rarely develop strong loyalties. It is common to find that in the past, they have been involved in legal problems and heavy drinking, and have had poor work and marital adjustments. Sometimes they leave an initially good impression which is often described as "charming," but longer acquaintance reveals their unreliability, moodiness, and generalized resentment. Their true characteristics are often difficult to identify until a period of stress results in an outbreak of irresponsible, untrustworthy, and antisocial behavior. Usually such individuals are relatively free from conflicts and do not show anxiety until actually in the midst of serious difficulties. Although they seem to demonstrate an apparent lack of concern about potential danger at some future time, they are sensitive to, and even feel remorse when faced with, the actual consequences of their behavior.

#### **Scale 5: Masculinity-Femininity (Mf)**

Scale 5 includes 60 items having to do with general interests, vocational choices, and an activity-passivity dimension. Although it was originally designed to measure the relative degree of psychological masculinity or femininity in a male college population, it has turned out to be a far from pure measure. For example, it is definitely correlated with both education and intelligence. More specifically, there are five basic dimensions on which the items seem to be

centered. These are personal and emotional stability, sexual identification, altruism, feminine occupational identification, and denial of masculine occupations. When the items are scored for females, the scale is merely inverted. Thus, elevations for either males or females can generally be seen as indicating a nonidentification with traditional masculine or traditional feminine roles.

Since scale 5 is usually not considered a clinical scale and is subject to wide fluctuations related to factors such as education, it is often not interpreted in the same manner as the more "clinically" oriented scales. It is rather used to color or flavor the meanings of other high or low points. A useful approach is to determine single peaks or code types without considering scale 5. Once interpretations have been made without this scale, then the possible implications of 5 can be included. For example, elevations on scales 3, 4, and 5 can be interpreted first by referring to scales 3 and 4 and to the 34/43 code. Later, the meaning of scale 5 can be taken into consideration within the context of scales 3 and 4, but the implications of a person's level of education, occupation, and socioeconomic status also have to be taken into account.

The issue, of course, arises as to whether or not scale elevations are a valid indicator of homosexuality. Although the scale was originally designed with the hope of diagnosing such tendencies, it has become more associated with the previously mentioned characteristics of aesthetic interests, vocational choices, and activity versus passivity. Elevations, especially extremely high ones, may in some cases reflect a homosexual orientation, but this is never sufficient in and of itself to make such a diagnosis. Furthermore, homosexuals who wish to conceal their preference can do so with relative ease since the item contents are relatively transparent with respect to the dimensions they are attempting to measure.

Within normal male populations, elevations reflect imagination, sensitivity, a wide range of cultural interests, and a tendency to be able to apply oneself to work. Furthermore, moderately high scorers are frequently seen as inner directed, clever, curious, and having good judgment and common sense. Males who score low usually typify traditional masculine interests and are seen as adventurous, easygoing, and sometimes coarse.

Females who score high are usually found in traditionally male roles and occupations, particularly the areas of mechanics and science. They are frequently perceived as being adventurous, dominating, aggressive, competitive, and confident. Low female scorers are often described as placing a high value on traditional female interests, and are usually sensitive and modest. However, extreme caution should be used in interpreting low female scores, especially for women of higher intellectual and educational levels.

A frequent pattern with males consists of elevated scales 4 and 5. Such a profile represents a nonconventional individual who is flamboyant in expressing his unconventional beliefs and often is identified with the counterculture. He may, for example, take pleasure in openly defying and challenging conventional

modes of appearance and behavior. In contrast, a low 5 accompanied by a high 4 is characteristic of an exaggerated, perhaps even compulsive, display of masculinity. In females, a high 5 and 4 reflects a tendency to rebel against the traditional female role, and as the elevation of scale 4 increases, the specific expression of this rebelliousness becomes correspondingly more deviant. On the other hand, females with a high 5 and a low 4 are also angry and hostile but are unable to express these feelings directly, which thus creates a good deal of inner turmoil and conflict. In males, there is sometimes a pattern of an elevated 5, with accompanying elevations in scales 2, 7, and occasionally 4. Usually such persons have developed a life-style in which they present themselves as weak, inferior, guilty, and submissive. They are typically self-effacing, and shun any outward appearance of strength and pride. The stereotype of the withdrawn "egghead" or the self-critical school clown is representative of this profile. Whereas this pattern is found with an elevated 5 in males, females who demonstrate this style will show a valley on 5.

**Males. Low 5 ( $T = 26-40$ ).** Males scoring low on scale 5 can be expected to place a high degree of emphasis on traditional expressions of masculinity. They characteristically prefer action to contemplation, and their range of interests tends to be somewhat narrow. Usually they will lack originality and have little insight into their motivations primarily because of a basic lack of interest in self-exploration. They are frequently seen by others as self-indulgent, independent, and narcissistic. In keeping with these traditional expressions of the male role, they place a high degree of emphasis on physical strength and athletic prowess. Their masculine strivings often take on an almost compulsive quality in that these strivings can be overdone and inflexible. However, the overt behaviors may represent attempts to reassure themselves of their strength, power, and control which actually may serve to conceal serious questions regarding their masculinity.

**Moderate 5 ( $T = 41-59$ ).** Scores centering around the mean will reflect an average degree of identification with the masculine role and usually represent traditional values with regard to vocational and avocational interests.

**Moderate Elevations ( $T = 60-75$ ).** Moderate elevations reflect aesthetic interests and an individual who is sensitive, imaginative, and expresses a variance from the culturally prescribed male role. College or seminary students usually score within this range, particularly if they have literary or artistic interests. They typically are introspective, are psychologically sophisticated, and have a wide range of interests. Their values tend to be idealistic; they are inner directed; and they have the ability to communicate their ideas clearly and effectively. In some men who score particularly high on scale 5, there is a rejection of masculinity combined with a relatively passive, effeminate, and noncompetitive personality.

*High Elevations (T = More than 75).* Although this may reflect an extremely high degree of artistic interest, there is usually conflict over sexual identity and sometimes homosexual trends may be present. Individuals within this range are basically passive, and there is frequently a history of marital problems due to a difficulty in assertively fulfilling their partners' needs. In some situations, extremely high 5s develop a reaction formation against passivity in which they may display an exaggerated expression of masculinity similar to a low-scoring 5.

**Females. Low 5 (T = 20-45).** This is one of the poorest scale indicators, and research relating to its meaning is generally lacking. Extreme caution should be used when making interpretations, especially for women of higher intellectual and educational levels. Some women scoring within this range are described as passive, submissive, yielding persons and may even have become living caricatures of the female stereotype. They may attempt to assume, or at least appear to assume, an extreme number of burdens which they may later use to create guilt and loyalty in others. In these cases, it is not unusual to find low 5 scores correlated with corresponding elevations in the "neurotic triad" (scales 1, 2, and 3).

*Moderate 5 (T = 45-55).* It is fairly frequent for women to have this as a relative low point in their overall test profiles. This is reflective of average, middle-class expressions of the culturally endorsed feminine role, which also corresponds to an average avocational interest pattern.

*Moderate Elevations (T = 56-65).* Women scoring within this range are frequently seen as active, assertive, and competitive in interpersonal relations.

*High Elevations (T = More than 65).* Women in this range are frequently described as confident, spontaneous, and uninhibited; they usually are found in traditionally masculine occupations and activities. Furthermore, they may be rebelling against the traditional female role and feel uncomfortable in many heterosexual situations. As the scale elevation increases, there is likewise an increase in aggressiveness and a certain "tough-minded" approach to the world. It is relatively rare to find this as a high point in females.

#### Scale 6: Paranoia (Pa)

Scale 6 includes 40 items which attempt to assess an individual's degree of suspiciousness, interpersonal sensitivity, and self-righteousness. The basic clinical picture of the paranoid personality includes delusional beliefs, ideas of reference, feelings of persecution, pervasive suspiciousness, grandiose self-beliefs, and interpersonal rigidity. In attempting to measure these variables, the scale 6

items range from questions regarding overt psychotic content to milder questions on the perceived ulterior motives of others. More specifically, the item content can be grouped around three basic categories having to do with (1) ideas of external influence, (2) poignancy, and (3) moral virtue.

With normal individuals, moderate elevations on scale 6 suggest that the person is emotional and softhearted, with an excess of personal sensitivity. However, the characteristics of low scorers are not consistent, and there are some differences between males and females. Males are frequently seen as cheerful, balanced, decisive, lacking in a strong sense of conscience, self-centered, and having a narrow range of interests. Females are usually described as balanced, mature, and reasonable. Within more disturbed populations, elevations frequently indicate the presence of delusions of self-reference, an extreme rigidity of attitude, disordered thought processes, and a grandiose self-concept.

Many of the items found in scale 6 are obviously socially undesirable, and therefore some paranoids may decide to answer them in an "unparanoid" direction. For example, the statement "Someone has control over my mind" is fairly transparent as to what it is attempting to assess and thus may not be admitted to. For this reason, the scale is considered one of the weakest, at least with regard to its original intent of detecting paranoid thinking. In fact, many extremely paranoid persons show no elevation at all. Thus, a low score does not necessarily exclude the possibility of a paranoid personality, even if the validity scales are normal. In fact, a low 6 may even be an indicator of paranoid thinking since paranoids typically attempt to hide their suspiciousness out of fear of others' reactions. This is especially true for bright and psychologically sophisticated persons. They could, for example, even mask their paranoid functioning within the context of a more socially approved group such as the Minute-men. However, if the scale is definitely elevated, this tends to be a good indicator of paranoid processes.

If there are pronounced elevations on scales 6 and 8 regardless of implications derived from elevations on other scales, this is highly suggestive of paranoid schizophrenia (see 68/86 code type). Occasionally, an elevated 6 and 3 profile occurs which indicates a repression of hostile and aggressive feelings. Overtly, these people might deny suspiciousness and competitiveness, and even see the world in naively accepting, positive, and almost Polyannaish terms. They can quickly develop comfortable, superficial relationships with relative ease. However, as the relationship's depth and closeness increase, the underlying hostility, egocentricity, and even ruthlessness become more apparent (see 36/63 code type).

**Low 6 (T = 27-44).** Persons with low scores are difficult to place in a clear-cut category, and there are differences between males and females. Whereas both are perceived as being balanced, males are also cheerful, decisive, lacking in a

strong sense of conscience, and self-centered, with a narrow range of interests. Females are more frequently described as mature and reasonable. However, there is likely to be a high degree of variability in the characteristics of low scorers so interpretations should be made with appropriate caution. It is important to differentiate the low scores of normal persons from those of paranoid persons who are attempting to hide their suspiciousness. In these cases, paranoids can have the same features as high 6 scorers in that they are touchy, moody, overly cautious, and extremely sensitive in personal relationships. Furthermore, they are often stubborn, evasive, and wary, and they feel that dire consequences will result from revealing themselves to others. However, they tend to be somewhat better put together than high scorers, and typically find more socially acceptable ways to focus and express their paranoid traits.

**Moderate Elevations (T = 60–75).** As the elevation within this range increases, there is also a corresponding increase of undue interpersonal sensitivity. Even moderate criticisms from others can set off a depressive reaction in which the individual will brood over, enlarge, and ruminate on such statements. These people frequently report feelings of being limited and pressed by the social and vocational aspects of their lives. As scale 6 elevations increase, there is a correspondingly higher likelihood of outright suspiciousness, distrust, and resentment which may become focused on either real or imaginary wrongs. Their most frequent defense mechanism is the projection of blame and hostility onto others, and what hostility such individuals do express is done in a covert and indirect manner. Often, for example, they might develop a self-punishing, intropunitive role outwardly, yet arrange social situations in which others will become the victims of their indirectly expressed hostility. They can then fall back on a “what did I do?” position, thus neutralizing criticism directed at them.

**High Elevations (T = More than 75).** With elevations in this range, it may be important to consider the content and implications of the individual scale items to differentiate between an overt psychotic delusional system and a more coherent paranoid personality disorder. This distinction can also be aided by referring to the relative elevation of scale 8. It is often helpful to have the person describe why he responded to certain items in a particular way. If the overall profile is valid, an elevation above T = 75 is more likely to suggest a disabling level of pathology. It will certainly indicate a paranoid person who is brooding and suspicious, ruminates on grudges, and feels he has not gotten a fair deal out of life. Frequently, such people have delusions of reference, feelings of persecution, and the likelihood of fixed obsessions, compulsions, and phobias. In treatment, there is a high likelihood that they will be rigid and overly argumentative. They may use either the actual termination of treatment or the implied possibility of termination to protect their system as well as to manipulate and control the therapist.

**Scale 7: Psychasthenia (Pt)**

Scale 7 consists of 48 items which measure the extent of symptoms related to anxiety, irrational fears, self-devaluation, and excessive doubt. In general, it is the MMPI's best single indicator of anxiety and ruminative self-doubt. However, the items are usually fairly obvious about the information they are requesting, and a defensive orientation can easily reduce the elevation. For this reason, there is a full 1 K addition which is used as a corrective measure to counter the effects of such a defensive position.

Individuals who score high on scale 7 will typically be obsessively worried, tense, indecisive, and unable to concentrate. They will almost always show extreme obsessional thoughts and utilize the defense mechanisms of intellectualization, rationalization, isolation, and undoing in an attempt to reduce anxiety and tension. However, high scorers on psychasthenia are not the same as individuals who utilize a compulsive defense system. In fact, many rigidly compulsive persons score low precisely because their system effectively wards off such feelings as insecurity, anxiety, and self-doubt. Within a medical context, high scale 7 scorers characteristically overreact and show an extreme amount of concern about relatively minor medical problems. They are usually seen as rigid, anxious, fearful, and agitated, and they typically have cardiac complaints or problems relating to their gastrointestinal or genitourinary systems. Within more normal populations, moderate elevations suggest persons who are dissatisfied, verbal, individualistic, and high strung. They will also tend to have perfectionistic orientations combined with excessively high standards of morality.

As with scale 2, some elevation on scale 7 reflects a favorable prognosis for psychotherapy because there is a sufficient degree of internal discomfort to increase the motivation for self-evaluation and change. These two scales are extremely important clinically since they provide an index of the degree of psychological pain the person is experiencing, and they are often referred to as the "distress scales" (see code type 27/72). However, if the scale elevation is extremely high, this may preclude talking therapy and indicate the need for medication until the individual is sufficiently relaxed to resume more effective communication. Another important consideration is the relative elevation of 7 and 8. If scale 7 is higher, it suggests that the person is continuing to struggle with, and feel anxious about, a psychotic process. However, a scale 7 which is significantly lower than scale 8 can indicate that the person has given up and allowed the psychosis to become more fixed (see code type 78/87).

**Low 7 (T = 20-44).** In general, an individual who scores within this range has a relaxed, alert attitude, is self-confident, and rarely worries over relatively insignificant difficulties. Even if self-referred, it is rare to see low scale 7 scorers in clinical populations. Low male scorers are frequently described as balanced,

efficient, independent, relaxed, self-confident, and secure. Women who score low on scale 7 are similarly described as balanced, relaxed, and confident, but also as cheerful, alert, and placid.

**Moderate Elevations (T = 60–74).** Moderately high scorers tend to be conscientious, orderly, and self-critical, and to worry over minor problems. Typically, they are perfectionistic and have excessively high moral standards. As the scale elevation within this range increases (T = more than 65), there is also the likelihood of strong anxiety, tension, and worry. Rationalization and intellectualization become increasingly more prominent but are likely to be generally inefficient in controlling anxiety.

**High Elevations (T = More than 75).** With higher elevations, the same general patterns just discussed become even more pronounced. Furthermore, these people are often described as rigid, meticulous, religious, worrisome, and apprehensive. Elevations nearing 80 or more are likely to reflect levels of anxiety sufficiently high to disrupt the individuals' ability to perform daily routine tasks. Furthermore, they may have disabling feelings of guilt, as well as fixed obsessions, compulsions, or phobias, and may be extremely fearful and agitated. The defense mechanisms which are being utilized are unlikely to effectively bring about relief, and the constant rehashing of problems does not create effective solutions because of excessive uncertainty and indecisiveness.

#### **Scale 8: Schizophrenia (Sc)**

Scale 8 is the longest one on the MMPI and consists of 78 items which were originally intended to differentiate normals from schizophrenics. However, this differentiation has not been entirely successful primarily because the pattern of schizophrenia is highly varied, and includes complex and sometimes contradictory behavioral features. Thus, great care should be taken when attempting to make a diagnosis of schizophrenia, and other sources of data should be taken into account. Furthermore, the scale should not be interpreted too narrowly since a limited conception of its significance may lead merely to a label rather than to a more full and in-depth understanding of the individual's personality.

Scale 8 items are extremely varied and attempt to assess such factors as unusual thought processes, apathy, feelings of social alienation, poor family relations, and peculiarities of perception. Still other questions are directed towards reduced efficiency, difficulties in concentration, impulse control, a general inability to cope, and general fears and worries. There are basically three wide categories into which the items can be divided: (1) social and emotional alienation, (2) lack of ego mastery, and (3) bizarre sensory experiences.

If the individual has a pronounced elevation on scale 8, he is likely to feel alienated, misunderstood, and apart from social situations. There will be a

feeling that somehow he is lacking something significant in his ability to adapt and adjust, and it is unlikely that he will have developed adequate social skills. Furthermore, he may have fundamental questions regarding his personal worth and identity. Many high scorers are painfully withdrawn, have few if any social relationships, and are highly involved in their inner fantasy life. They have a difficult time communicating as well as in maintaining coherent and focused thought processes. Even with moderate elevations, there is likely to be some difficulty thinking and communicating. Even when high scorers are making apparent sense, a person will have the feeling that he is missing the more significant aspects of what they are trying to say. Typically, they avoid making unequivocal statements and will usually not stay on any one idea for an extended length of time.

Clinically, schizophrenic patients usually score between 80 and 90. Thus, with scores below 80, a diagnosis of schizophrenia should be made cautiously. Sometimes, elevations up to 90 are found for extremely anxious patients, adolescent adjustment reactions, prepsychotics, and borderline personalities.

Elevations on scales 4 and 8 frequently occur in individuals who developed an early distrust towards the world. They usually see interpersonal relationships as dangerous and often respond with angry rebelliousness (see 48/84 code type). A rather infrequent but significant pattern which needs to be understood contains elevations on scales 8 and 9 (see 89/98 code type). Individuals with this pattern usually have an extremely difficult time dealing with others, not only because they feel alienated but also because they continually deflect any coherent attempt to focus on a situation. This pattern is extremely difficult to work with therapeutically because these people have a difficult time focusing their attention, and not only have a distorted view of the world but also have the energy to act on these distorted perceptions. Other frequently occurring profiles are the prognostic considerations related to scales 7 and 8 (see scale 7 and the 78/87 code type) and the schizoid configuration of elevated F, 2, 4, 8, and low 0 (see scale 2).

**Low 8 (T = 21-44).** Low scorers on scale 8 are often compliant, overly accepting of authority, concrete, and practically oriented. In addition, they are usually controlled, restrained, friendly, and adaptable.

**Moderate Elevations (T = 60-74).** Since scale 8 has 78 highly varied items, the personality descriptions resulting from moderate elevations likewise tend to be highly varied. Thus it is important to look at the overall scale configurations and to include other relevant data. At the lower end of this range, it is not uncommon to find benign or "neurotic" profiles. Often these individuals tend to have abstract interests, are not interested in practical matters, and are not highly involved with people. They frequently have philosophical interests and approach tasks from an innovative perspective, and others may see them as aloof and

uninvolved. These latter characteristics are especially likely if there is an additional elevation on scale 0. Adolescents who are seen for evaluation frequently score in this range.

Within the upper ranges of moderate elevations, it is sometimes difficult to distinguish between a sense of general alienation or blatant psychotic content. In assessing the presence of psychotic processes, it is helpful to note whether scales F and 6 are elevated and to look at individual scale items, particularly the critical items (see Appendix I).

**High Elevations (T = 75–90).** If scale 8 scores are near 75, the individual typically appears unusual, unconventional, and eccentric, but can often maintain an adequate social and vocational adjustment. This is particularly true if the other clinical scales are relatively low. With higher elevations, however, these individuals become progressively more socially withdrawn and have a difficult time relating to others effectively. They often withdraw and tend to be highly invested in autistic, wish-fulfilling fantasies. In even the most basic interpersonal situations, they have a difficult time knowing what is expected of them. As the elevation reaches above 80, and if the overall profile appears valid, there is an increasing likelihood of a significant thought disorder complete with confusion and strange thoughts, beliefs, and actions.

#### **Scale 9: Hypomania (Ma)**

Scale 9 includes 46 fairly heterogeneous items which assess the relative degree of an individual's energy level, expansiveness, egotism, and irritability. The scale was originally developed using a group of psychiatric patients who had diagnoses of hypomania and mild acute mania. Their clinical syndrome involved cyclical periods of euphoria, increased irritability, and unproductive activity, much of which could be seen as distractive maneuvers designed to stave off an impending depression. The test items themselves can be broken down into general categories having to do with psychomotor retardation, amorality, imperturbability, and ego inflation.

Among normal males, high scorers are characteristically warm, enthusiastic, outgoing, and uninhibited. Furthermore, they can often be easily offended, are hyperactive and tense, and have an unusual capacity for sustained effort. Other characteristics are that they are frequently generous, affectionate, adventurous, expressive, and individualistic; they enjoy alcohol; and they are interested in national and political matters. Female normals who score relatively high tend to be frank, courageous, idealistic, and often seen by others as talkative, enthusiastic, and versatile.

A general consideration, however, is that the scale can reflect the level of energy at the time of testing and is therefore somewhat subject to fluctuations

depending on the individual's mood. Of particular importance is the fact that manic patients, at the time of their initial hospitalization, are often too flighty and incoherent to take the test. When they finally calm down, there can be a strong deflation which may result in a low score on scale 9. Thus, a low score on 9 does not necessarily exclude the possibility of a manic diagnosis. However, as the scale score increases there is increasing likelihood of distractibility, narcissism, poor control, and superficiality. There may also be difficulties in interpersonal relations, aggressive impulses, and amoral behavior.

Low scorers often lack a normal degree of optimism, are listless and apathetic, have low self-esteem, and lack initiative and drive. If their scores are extremely low, this usually reflects a significant depression, even if scale 2 is not significantly elevated.

Two important profile patterns are the relation of scale 9 to scale 2 and its relation to K. Although scales 2 and 9 are usually negatively correlated, in some cases they may both be high (see code type 29/92). This may reflect several possible conditions but, in particular, suggests an agitated state in which the person is acutely aware of pressure from hostile impulses. A combined 2 and 9 elevation may also occur with certain types of organic brain lesions or in individuals with an introspective preoccupation and heightened narcissistic absorption, for example, disturbed adolescents who are experiencing "identity" problems. If scale 9 is moderately elevated and scales 2 and 7 are low, the individual may have an almost compulsive need to seek security through interpersonal power and narcissistic competitiveness. If an elevated K scale is found with an elevated 9, the individual additionally tends to be managerial, autocratic, and power hungry, but also has a high degree of compulsive energy directed towards organizing others. If, on the other hand, K is low, the individual is usually not overly defensive, but may be extremely competitive, narcissistic, and threatened by situations in which he must be submissive or dependent. His self-esteem is based on eliciting weakness and submission from others, but what he actually receives is usually a grudging deference and respect. In females, this profile is often accompanied by an exhibitionistic self-display of physical attractiveness. In therapy, there typically occur a wide range of self-display, power struggles, and a poor likelihood of success due to control issues, flightiness, and an unwillingness to look at one's inner pain and weakness.

**Low 9 (T = 21-44).** Low 9 scorers usually have an extremely low level of energy and are listless, apathetic, pessimistic regarding the future, and lacking in self-confidence. They may, for example, find it difficult to get out of bed in the morning as well as to maintain enough energy to function effectively throughout the day. If 9 is extremely low, this may reflect a serious depression, even though scale 2 might be within normal limits. However, a significant demographic variable is that it is more frequent to find low scores in older individuals than in

younger ones. Thus, if a low score is found in a younger person, it carries greater significance since it is relatively unusual.

**Moderate Elevations (T = 60-74).** Moderately high scores on 9 are typical from individuals who are pleasant, energetic, enthusiastic, and sociable and who have a wide range of interests. They are usually optimistic, independent, and self-confident, particularly if there are correspondingly low scores on scales 2 and 0. Within higher elevations (65-75), it becomes somewhat difficult to distinguish a normal, energetic, active and ambitious person with a productive life, from a hypomanic who is ineffective, nonfocused, and hyperactive. Thus, the clinical interview and historical data may become particularly useful at this point.

**High Elevations (T = More than 75).** With higher elevations, there is an increasing probability that individuals are maladaptively hyperactive and agitated, have low impulse control, and become irritable even over relatively small obstacles and delays. They are likely to quickly develop relationships, but since they are restless and unable to remain focused for any length of time, these relationships are usually lacking in any real depth. Their enthusiasm tends to be intense but short-lived, and the expression of their energy is scattered and generally unproductive. In elevations exceeding 80, there is an increasing likelihood of characteristically manic behaviors including a flight of ideas, inflated feelings of self-importance, and hyperactive expressions such as pacing and nervous twitches.

#### **Scale 0: Social Introversion (Si)**

Scale 0 is comprised of 70 items which were selected from the responses of college students on an introversion-extroversion continuum. The scale is a fairly stable measure of the extent to which an individual participates in social events and his degree of comfort in interpersonal relations. The social introvert, as suggested by an elevation on scale 0, often has limited social skills, withdraws from many interpersonal situations, and feels uncomfortable in social interactions.

Normal males who score high on scale 0 are typically modest, inhibited, lacking in self-confidence, conforming, sensitive, submissive, and generally deficient in poise and social presence. Normal high-scoring females are modest, shy, self-effacing, sensitive, and prone to worry. Low male scorers, on the other hand, are typically sociable, expressive, exhibitionistic, socially competitive, and verbally fluent. Furthermore, they are somewhat dominant, persuasive, manipulative, and opportunistic. Females are similarly sociable, enthusiastic, talkative, assertive, and adventurous. Although low scores may suggest interpersonal warmth and a relatively high degree of comfort in social relationships, extremely low scores may reflect a person with a wide range of well-developed social techniques who has many social contacts. However, his interactions can often be characterized as flighty and superficial.

In general, scale 0 serves to color many of the other scales in terms of how comfortable and involved the individual is with interpersonal relationships. Typically a low score on 0 reduces the degree of pathology that may be suggested by other scale elevations and indicates that the person has most likely developed socially acceptable outlets for difficulties he may be experiencing. Higher scores, on the other hand, reflect a relatively low level of social adeptness and competence. This is of particular importance if scale 0 elevations are accompanied by a high 2 or 8, in which case the individual is unlikely to have developed an adequate social support system and will typically have a low level of social skills accompanied by strong feelings of social alienation.

**Low 0 (T = 25-44).** Low scorers are often warm, sociable, outgoing, gregarious, and involved with groups. However, extremely low scores may suggest that these people have very well-developed social techniques but perhaps have few close and meaningful relationships. Behind their somewhat well-developed external image, they may have underlying feelings of insecurity, a high need for social approval, extreme sensitivity, and unresolved conflicts regarding fears of dependency.

**Moderate Elevations (T = 60-69).** Moderate scorers tend to be reserved, aloof, shy, timid, retiring, and often experienced by others as difficult to know.

**High Elevations (T = 70-85).** Individuals who score high on scale 9 are usually acutely aware of the discomfort they feel in most social situations. They are perceived by others as shy, introverted, and anxious while around people. Typically, they have feelings of inferiority, lack self-confidence, are moody, and do not have a social support group to help them through difficulties.

## TWO-POINT CODES

In this section, we will consider the meaning of the two highest scales. This approach can often assess the relationship between test patterns and indicate how these patterns relate to various classes of nontest behavior. The selection of which two-point codes to include has been based on their frequency of occurrence, the thoroughness of the research performed on them, and their relative clinical importance. Thus, some two-point codes will not be discussed.

An important consideration is that this approach is most appropriate for disturbed populations in which T score elevations are at least 70 and preferably higher. The descriptions are clearly oriented around the pathological dimensions of an individual. The two-point code descriptions, then, do not have the same divisions into low, moderate, and high elevations as the individual scores but are directed primarily towards discussions of high elevations. When considering

two-point codes which are in the moderate range ( $T = 65-70$ ), interpretations should be made with caution and the more extreme descriptions should be considerably modified or even excluded.

Usually, the relative elevation of one of the scales in relation to the other does not make much difference as long as the elevations are still somewhat similar in magnitude. A general approach is that if one scale is 10 points or more higher than the other, then the higher one gives more color to, or provides more emphasis for, the interpretation. Specific elaborations are made for scales in which a significant difference between their relative elevations is especially important. If the scales have an equal magnitude, then they should be given equal emphasis.

In some cases, three or more scales might be equally elevated, thereby making it difficult to clearly establish which scales represent the two-point code. In these cases, clinicians should look at the descriptions provided for other possible combinations. For example, if a particular profile had scales 2, 7, and 8 elevated, then the clinician should look up the 27/72 code as well as codes 78/87 and 28/82. The descriptions of all three of these codes can then be integrated into a more meaningful and accurate interpretation. When there are third or fourth scales that are frequently elevated along with the two-point code, they too will be discussed.

In developing meaningful interpretations it is important to continually consider the underlying significance of the elevated scales. This means taking into account such factors as the manner in which the scales interact, the particular category of psychopathology they suggest, and the recurring patterns or themes indicated. Whenever possible, DSM III classifications have been used, but the term "neurosis" is used occasionally because of its ability to summarize a wide variety of disorders and/or ability to refer to a cluster of related scales ("neurotic triad"). In describing a specific individual, there will always be some characteristics described in the code types which are highly accurate for that person and others which are not particularly relevant or accurate. Clinicians, then, will need to continually reflect on their data so as to develop descriptions that are both accurate and relevant.

## 12/21

Difficulties experienced by patients with the 12/21 code type revolve around physical symptoms and complaints which can be either organic or functional. Common complaints relate to pain, irritability, anxiety, physical tension, fatigue, and overconcern with physical functions. In addition to these symptoms is the presence of a significant level of depression. Their characteristic style of handling psychological conflict is through repression and attending to real, exaggerated, or imagined physical difficulties. Regardless of whether or not these physical

difficulties are organically based, these individuals will exaggerate their symptoms and use them to manipulate others. In other words, they elaborate their complaints beyond what can be physically confirmed, often doing so by misinterpreting normal bodily functions. Typically they have learned to live with their complaints and use them to achieve their own needs. They lack insight, are not psychologically sophisticated, and resent any implications that their difficulties may be even partially psychological. This code pattern is more frequently encountered in males and older persons.

The three varieties of patients which this code is likely to suggest are the generalized hypochondriac, the chronic pain patient, and persons having recent and severe accidents. General hypochondriacs are likely to have significant depressive features and to be self-critical, indirect, and manipulative. If their difficulties are solely functional, they are more likely to be shy and withdrawn, whereas persons with a significant organic component are likely to be loud complainers. Furthermore, complaints are usually focused around the trunk of the body and involve the viscera, in contrast to the 13/31 code in which complaints refer more frequently to the central nervous system and peripheral limbs. When the 12/21 code is produced by chronic pain patients with an organic basis, they are likely to have given in to their pain and learned to live with it. Their experience and/or expression of this pain is likely to be exaggerated, they use it to manipulate others, and they may have a past history of drug or alcohol abuse which represents attempts at "self-medication." The most common profile associated with heavy drinkers consists of elevations in scales 1, 2, 3, and 4. Such persons will experience considerable physical discomfort, digestive difficulties, tension, depression, and hostility, and will usually have poor work and relationship histories. The third category of patient associated with 12/21 codes involves persons who are responding to recent, severe accidents. Their elevations on scales 1 and 2 reflect an acute reactive depression which occurs as a result of their response to the limiting effects of their condition.

The most frequent diagnosis with this code is hypochondriasis, and the somatic overconcern can be further supported if there is a corresponding elevation on scale 3. With a 127 profile, the likelihood of anxiety neurosis is increased. Such people will be fearful, anxious, nonassertive, dependent, and weak, and through the use of their helplessness, they will manipulate others into taking care of them. If scales 1 and 2 are elevated along with 8 and/or F, the person might be diagnosed as having a schizophrenic disorder with somatic delusions. With only moderate elevations in scale 8, the individual may still be hypochondriacal but with the presence of some mild somatic delusions, interpersonal alienation, and mild mental confusion. Less frequent patterns are 124, 126, and 126 4 which may reflect a personality disorder, especially a passive-aggressive personality experiencing depression.

## 13/31

The 13/31 code type is associated with the classic "conversion V" which occurs when scale 2 is significantly lower (10 points or more) than scales 1 or 3. As 2 becomes lower in relation to 1 and 3, the likelihood of a conversion disorder increases. This pattern is further suggested in males with correspondingly high scales 4 and 5, and in females with a correspondingly high 4 but lowered 5. There is typically very little anxiety experienced by persons with these profiles since they are converting psychological conflict into physical complaints. However, this can be checked by looking at the corresponding elevations of scales 2 and 7. If these are also high, it indicates that persons are experiencing anxiety and depression perhaps because their conversions are currently unable to effectively avoid their conflicts.

Persons with "conversion V's" will typically engage in extensive complaining about physical difficulties. Complaints may involve problems related to eating such as nausea, anorexia, or bulimia, and there may be the presence of vague "neurological" difficulties such as dizziness, numbness, weakness, and fatigue. However, there is often a sense of indifference and a marked lack of concern regarding these symptoms. These individuals have a strong need to appear rational and socially acceptable, yet nonetheless control others through histrionic and symptom-related means. They defensively attempt to appear as hypernormal, which is particularly pronounced if the K scale is also elevated. Usually they are extremely threatened by any hint that they are unconventional and tend to organize themselves around ideals of service to others. Regardless of the actual original cause of the complaints, there is a strong need to exaggerate them. Even if their complaints were originally caused by an organic impairment, there will be a strong functional basis to their problems. Interpersonal relationships will be superficial, with extensive repression of hostility, and oftentimes there will be an exhibitionistic flavor to their interactions. If scale 3 is higher than scale 1, this allows for the expression of a certain degree of optimism and, interestingly enough, any conversion will most likely be to the trunk of the body. Thus, patients might complain of such difficulties as gastrointestinal disorders, or diseases of the lungs or heart. Furthermore, this suggests the strong use of denial and repression. These people are passive, sociable, and dependent; they manipulate others through complaints about their "medical" problems. Conversely, if scale 3 is lower than scale 1, the person tends to be significantly more negative, and any conversion is likely to be to the body extremities such as the hands or legs. If scores are very high on scale 8, a corresponding peak on scale 1 is associated with somatic delusions.

When the "conversion V" is within the normal range (less than 70), persons will be optimistic but somewhat immature and tangential. Under stress, there will usually be an increase in their symptom-related complaints. They can be described as responsible, helpful, normal, and sympathetic.

The most frequent diagnoses with 13 codes are hypochondriasis, conversion disorder, and histrionic personality. Anxiety may be present if either scale 7 or 8 is elevated, but it is usually absent. The 13/31 profile is also found in pain patients with an organic injury whose symptoms typically worsen under stress.

#### 14/41

The 14/41 code is encountered somewhat rarely, but it is important since persons with these elevations will be severely hypochondriacal. Their interpersonal interactions will be extremely manipulative but rarely antisocial. They will be able to maintain control over their impulses but will do so in a way which is bitter, self-pitying, and resentful of any rules and limits that are imposed on them. Furthermore, they will be egocentric, will demand attention, and will express continuous concern with their physical complaints. There will be some similarities to other high-scoring 4s in that they may have a history of alcohol abuse, drug addiction, and poor work and personal relationships. Usually, they will be resistant to therapy, although they may have a satisfactory response to short-term, symptom-oriented treatment. However, long-term therapy will be difficult and characterized by sporadic participation.

The two most frequently encountered diagnoses will be hypochondriasis and a personality disorder, especially antisocial personality. Differentiation between these two can be helped by noting the relative strength of either scale 1 or 4, as well as other related scales. Profiles involving "neurotic" features (anxiety, somatoform, dissociative, and dysthymic disorders) are characterized by a relatively higher scale 1 with 2 and/or 3 also elevated, whereas personality disorders are more strongly suggested when scale 4 is the primary high point.

#### 18/81

Peaks on scales 1 and 8 are found with persons who present a variety of vague and unusual complaints. They may also experience confusion, disorientation, and difficulty concentrating. Focusing on their physical symptoms represents a means of organizing their thoughts, although the beliefs related to these symptoms may represent delusions. Their ability to deal effectively with stress and anxiety is extremely limited. They will experience interpersonal relationships with a considerable degree of distance and alienation. Others will perceive them as eccentric or even bizarre. They will distrust others and may disrupt their relationships because of difficulty in controlling their hostility. There may even be paranoid ideation which will probably, but not necessarily, be reflected in an elevated scale 6. For the most part, their level of insight will be poor, which will make them difficult candidates for psychotherapy.

Common scales which are elevated along with 1 and 8 are 2, 3, and/or 7. These serve to color or give additional meaning to 18/81. Thus, an elevated scale 2 will emphasize self-critical, pessimistic dimensions; 7, the presence of fears and anxiety; and 3, the likelihood of conversions and/or somatic delusions.

The 18/81 code is frequently diagnosed as schizophrenia, especially if the F scale is also high. With a normal F, hypochondriasis is an important possibility, but if scale 7 is elevated an anxiety disorder is also strongly suggested.

### 19/91

The 19/91 code is rarely encountered but is important in that it may suggest organic difficulties relating to endocrine dysfunction or to the central nervous system. There will be extensive complaining and overconcern with difficulties, but these patients may paradoxically attempt to deny and conceal their complaints at the same time. In other words, they may be significantly invested in avoiding confrontations relating to their complaints, yet will make a display of these techniques of avoidance. They will typically be extroverted, talkative, and outgoing, but also tense and restless. The expectations they have of themselves will be extremely high, yet their goals will be poorly defined and often unobtainable. If there is not an organic basis to their complaints, then their behavior may be an attempt to stave off an impending depression. Often this depression will be related to strong but unacceptable dependency needs.

Both hypochondriasis and manic states are frequent diagnoses and may occur simultaneously. These may be in response to, and exacerbated by, an underlying organic condition, an impending depression, or both. Corresponding elevations on scales 4 and 6 make the possibility of a passive-aggressive personality an important diagnostic consideration.

### 23/32

Persons with elevations on scales 2 and 3 are lacking in energy. weak, apathetic, listless, depressed, and anxious. They feel inadequate and have difficulty accomplishing their daily activities. Much of their energy is invested in excessively controlling their feelings and behavior. Although situational stress may act to increase their depression, usually this depression is long-standing, and they have learned to live with their unhappiness and general lack of satisfaction. Their level of insight is poor, they will rarely volunteer for psychotherapy, and they usually do not show significant improvement during psychotherapy. This is primarily because their main dynamic is denial and situations such as therapy represent a threat to their style of avoidance. By keeping their relationships superficial, they achieve a certain level of security. Interpersonally, they appear immature, childish, and socially inadequate.

There are some important male-female differences in the expression of this code type. Males are more ambitious, industrious, serious, and competitive, but also immature and dependent. They strive for increased responsibilities, yet also fear them. They want to appear normal and receive recognition for their accomplishments, yet they often feel ignored and their level of work adjustment is often inadequate. In contrast, females are more apathetic and weak, and experience significant levels of depression. They have usually resigned themselves to long-term unhappiness and a lack of satisfaction. Although there is often significant marital strife, they rarely seek divorce. They also rarely seek treatment and seem resigned to living with their unhappiness.

Dysthymic disorder is the most frequent diagnosis given to this code. Corresponding elevations on scales 4, 6, and 0 may provide additional information relating to the personality of these persons. With a high scale 4, there is more likely to be an angry, brooding component to their depression, with underlying antisocial thoughts, yet their external behavior is usually overcontrolled. An elevated scale 6 suggests that their depression relates to extreme interpersonal sensitivity and distrust, whereas a high 0 indicates that they are socially withdrawn and introspective. An additional diagnosis which should be considered is a major depression with psychotic features, especially if scales F and/or 8 are also elevated.

#### 24/42

The most significant aspect of the 24/42 code is that these persons have an underlying antisocial trend to their personality with difficulty maintaining control over their impulses. However, once they act on their impulses, they experience guilt and anxiety regarding the consequences of their actions. This anxiety usually occurs too late to serve as an effective deterrent, and these individuals are unable to plan ahead effectively. The depression they experience then is probably situational, and the distress they do feel may reflect a fear of external consequences rather than an actual internalized moral code. Once the situation has subsided, there is usually further acting out. For this reason, the 24/42 code is sometimes referred to as reflecting an antisocial personality who has been caught. Although such people may promise to change and their guilt is generally authentic, their acting out is usually resistant to change. Effective therapy must include clear limits, a change in their environment, warm supports, and continual contact.

The history of persons with high scales 2 and 4 is often characterized by heavy drinking and/or drug abuse which serves as a form of self-medication for their depression. Their interpersonal relationships are poor, which is reflected in numerous family difficulties and sporadic employment. Their prospects for long-term employment are rarely favorable. These problems have often resulted

in numerous legal complications. Such persons respond to their failures with self-criticism and self-doubt. The initial impression that they give may be friendly or even charming, and in a hospital setting they may attempt to manipulate the staff.

The hostility which is present with the 24/42 code may be expressed either directly or indirectly. A more direct expression is suggested if scale 6 is high, since these individuals may feel justified in externalizing their anger due to real or imagined wrongs which have been committed against them. In contrast, a low 6 may reflect a suppression or unconscious denial of hostility. If there are high energy levels suggested by a high scale 9, the persons may be extremely dangerous and volatile, and they may have committed violent behaviors.

The 24/42 code is associated with personality disorders, especially passive-aggressive or antisocial personalities. This is further strengthened if scale 6 is also high. However, this code may also reflect an adjustment disorder with a depressed mood. An important distinction to make is whether the depression is reactive or chronic. If chronic, then difficulties related to anxiety, conversions, and depression (neurotic features) will be more likely to be predominant, especially if scales 1 and 3 are also high. A reactive depression is more likely to represent an antisocial personality who has been apprehended for his impulsive acting out. If scale 4 is extremely elevated (above 90), there may be a psychotic or prepsychotic process, especially if F and 8 are also high.

## 26/62

The most significant feature of the 26/62 code is extreme sensitivity to real or imagined criticism. These individuals will sometimes read between the lines of what others say in such a way as to create rejection, yet their conclusions will be based on insufficient data. Even minor criticism is brooded over and elaborated upon. Usually, they have long histories of difficulties with interpersonal relationships. Others describe them as resentful, aggressive, and hostile. In order to protect themselves from the impending rejection of others, they will often reject others first which results in other people avoiding them. When they are avoided, they then have evidence that they are being rejected which gives them a justification for feeling and expressing anger. They can then blame others for their difficulties. This cycle is thus self-fulfilling and self-perpetuating, yet such people have difficulty understanding the part they play in creating the interpersonal responses which are directed towards them.

If scales 7, 8, and possibly 9 are also high, there is a greater likelihood of a psychotic or prepsychotic condition, especially paranoid schizophrenia. A more controlled, well-defined paranoid system with a generally adequate level of adjustment may be suggested when scales 2, 6, and F are only moderately elevated. Further possible diagnoses with the 26/62 code are a dysthymic disorder and, if scale 4 is also elevated, a passive-aggressive personality.

## 27/72

The 27/72 code is extremely common in psychiatric populations and reflects persons who are depressed, agitated, restless, and nervous. This may be accompanied by slowed speech and movements, as well as by insomnia and feelings of social and sexual inadequacy. Scales 2 and 7 reflect the relative degree of subjective turmoil the person is experiencing and therefore are often referred to as the "distress scales." Even though 27/72 persons usually express a great deal of pessimism regarding treatment and the future in general, their psychological distress is ordinarily reactive, and with time, they can be expected to improve. With most patients, the disorder took between one month and one year to develop, and if they report for treatment, it will be their first need for such intervention. The majority are married and their courtships were fairly brief, many marrying within one month of their initial dating. They can be characterized as being perfectionistic, meticulous, and having a high need for recognition. Their thinking is often obsessive, and they experience a wide variety of phobias and fears. Interpersonally they have difficulty asserting themselves, and will be self-blaming and self-punishing. They will rarely be argumentative or provocative. Their consciences are strong and inflexible, and they will often be extremely religious in a rigidly fundamental manner. Physical complaints may include weakness, fatigue, chest pain, constipation, and dizziness.

Moderate elevations on scales 2 and 7 can indicate a good prognosis for therapy, since this suggests that the person is introspective and is experiencing a sufficient amount of distress to be motivated towards change. However, if these scales are extremely high, then the person may be too agitated to be able to focus and concentrate. In such cases, medication may be necessary to relax him sufficiently enough to be able to function in a psychotherapeutic context. The presence of suicidal thoughts is a definite possibility, especially if scales 6 and 8 are also elevated, and the suicidal potential of these patients must be carefully evaluated.

The diagnoses of psychotic and "neurotic" conditions occur with equal frequency with the 27/72 code. The most likely diagnosis in the psychotic direction is either a psychotic depression or a mixed bipolar disorder, and the most important differentiating data come from the client's history. "Neurotic" patients can be either anxious or obsessive-compulsive. However, with only moderate elevations, they may be normals who are fatigued and exhausted, with a high degree of rigidity and excessive worry. This code occurs more frequently with males 27 years or older from higher educational backgrounds.

## 28/82

Persons with the 28/82 code complain of depression, anxiety, insomnia, fatigue, and weakness, as well as mental confusion, memory impairments, and difficulties

in concentrating. They may also feel withdrawn, alienated, agitated, tense, and jumpy. Their motivation to achieve is characteristically low as is their overall level of efficiency. Often they will have fears relating to an inability to control their impulses including suicide. There may also be the presence of delusions and hallucinations, especially if scale 8 is greater than 85. This list of complaints presents a highly diverse description of attributes, only some of which may be present in any specific case. The presence or absence of these complaints must be determined by means other than mere scale elevations. These may include investigating critical items, the use of additional scales such as those developed by Harris and Lingoes, clinical interview data, and personal history. Of particular importance is the determination of the degree to which suicide is a possibility.

Most persons with the 28/82 code are diagnosed as either psychotically depressed or schizophrenic, especially if scale 8 is higher than scale 2. However, a certain percentage can be "neurotic," especially when scales 2 and 8 are only moderately elevated.

### 29/92

Although anxiety and depression are present with the 29/92 code, there is also a high level of energy which predominates. This energy may be associated with a loss of control, or it may also serve to defend against experiencing underlying depressive feelings. By speeding up their level of activity, these individuals can distract themselves from unpleasant depressive experiences. At times this will be successful, but they may also use alcohol in order either to relax or to decrease their depression. With moderate elevations, this code will at least reflect tension and restlessness.

If both scales are in the higher elevations, it suggests a mixed bipolar depression. However, both scales can change according to the particular phase the patient is in. This code can also reflect certain types of brain-injured patients or a cyclothymic disorder.

### 34/43

Persons having peaks on scales 3 and 4 are immature and self-centered with a high level of anger which they have difficulty expressing. Thus, it will often be expressed in an indirect, passive-aggressive style. Outwardly, such individuals are continually trying to conform and please other people, but they still experience a considerable degree of anger and need to find ways of controlling or discharging it. They might at times participate in vicariously acting out their aggression through developing a relationship with an individual who directly and spontaneously expresses his hostility. Such a relationship might be characterized by the 34/43 individuals' covertly encouraging and fueling the other person's angry

expressions, yet on a more superficial social level, disapproving of them. Typically, these individuals will have poor insight regarding their own behavior. If scale 6 is also high, their lack of insight will be even more pronounced since their hostility will be projected onto others. Usually, past interpersonal relationships have been difficult. There may be a history of acting out, marital discord, and alcohol abuse. Conflicts relating to dependence versus independence are significant since both of these needs are intense. Females are more likely than males to have vague physical complaints. Furthermore, their relationships will be superficial, and will be characterized by naive expectations and a perfectionistic view of the world which is maintained by glossing over and denying conflicts.

The 34/43 code most clearly fits the pattern of a passive-aggressive personality. If both scales are extremely elevated (T greater than 85), then there may be fugue states in which aggressive and/or sexual impulses will be acted out.

### 36/63

A 36/63 code type indicates that persons are extremely sensitive to criticism, and repress their hostile and aggressive feelings. They are fearful, tense, and anxious, and may complain of physical difficulties such as headaches or stomach problems. Overtly, these people might deny suspiciousness and competitiveness, even seeing the world in naively accepting, positive, and perfectionistic terms. They can quickly and easily develop comfortable, superficial relationships. However, as the relationship's depth and closeness increase, their underlying hostility, egocentricity, and even ruthlessness become more apparent. If scale 6 is higher than scale 3 (by more than 5 points), these individuals will attempt to develop some sense of security in their lives by seeking power and prestige. Their ability to acquire personal insight is limited since they are psychologically unsophisticated and resent suggestions that their difficulties may be even partially psychological. They will usually blame their personal problems on others, which creates one of their major difficulties in relationships. In therapy, they will typically terminate abruptly and unexpectedly, and they can be ruthless, defensive, and uncooperative. If scale 3 is higher than scale 6 (by more than 5 points), their tendency to blame will be reduced, and such people will be more likely to deny any conflicts or problems. This will be consistent with a tendency to idealize both themselves and their world. They will be more likely to develop somatic complaints rather than paranoid ideation, and the chance of a psychotic process is significantly reduced.

### 38/83

The somewhat rare 38/83 code involves symptoms of anxiety, depression, and complaints such as headaches, gastrointestinal disturbances, and numbness. If

scale 8 is significantly higher than scale 3, these individuals may also have thought disturbances including mental confusion, disorientation, difficulties with memory, and at times, delusional thinking. Although they have unusual experiences related to their thought processes and feel socially alienated, they also have strong needs to appear normal and strong needs for affection. However, they feel that if others knew how unusual their experiences were, they would be rejected. Thus, they are extremely afraid of dependent relationships. In order to protect themselves, they use extensive denial which makes their capacity for insight poor.

An important variation from the 38/83 code is when scale 3 is accompanied by an elevation on K, with low F and 8. Persons with this profile are likely to be affiliative, inhibited, and overconventional, and to have an exaggerated need to be liked and approved of by others. Frequently, they maintain an unrealistic, yet unassailable, optimism. They emphasize harmony, perhaps even at the cost of sacrificing their own needs, attitudes, and beliefs. Furthermore, high 3s with low F scores are extremely uncomfortable with anger and will avoid it at all costs. Typically they will also avoid independent decision making and many other situations in which they must exert their power. Since they have an exaggerated sense of optimism and are usually unaware of their personal conflicts, these individuals rarely appear in mental health clinics. It is almost as if any feelings of anger, tension, or defeat are intolerable. Such feelings seem to represent both a personal failure and, perhaps more importantly, a failure in their attempts at controlling their world by developing an overconventional, exaggeratedly optimistic, and inhibited stance.

A frequent diagnosis is schizophrenia, especially if 8 and F are highly elevated. When scale 3 is relatively higher than scale 8, and 8 and/or F is less than 70, somatoform or dissociative disorders (hysterical neurosis) are important considerations.

#### 45/54

High scores on scales 4 and 5 reflect persons who are self-centered, inner directed, and not only nonconformist but likely to openly express this nonconformity in a challenging, confrontive manner. They may also have significant problems with sexual identity and experience sexual dysfunction. A further area of conflict revolves around ambivalence relating to strong but unrecognized dependency needs. Overt homosexuals who make obvious displays of their orientation may have this code, especially if scales 4 and 5 are the only peaks in an otherwise normal profile. However, the 45/54 code should in no way be considered diagnostic of homosexuality but simply, at times, consistent with such an orientation. To obtain further information associated with this or any profile in which scale 5 is a high point, it is extremely helpful to interpret the third highest scale and give it the degree of importance usually associated with the second

highest point. Thus, a 456 profile might be interpreted as if it were a 46 code type.

There are some important differences between males and females having this code. Males will be openly nonconformist, but if they are from higher educational levels, they will be more likely to direct their dissatisfaction into social causes and express organized dissent towards the mainstream culture. In these cases, especially if scale 9 is moderately elevated, their pattern of elevation is sometimes referred to as the "peace corps profile." They are dissatisfied with their culture, sensitive, and aware, but they also have the energy to attempt to create change. They are often psychologically sophisticated, and can communicate clearly and openly. In contrast, elevated scales 4 and 9 accompanied by a low scale 5 suggest a high probability of sexual acting out and the probable development of a "Don Juan" type personality. These men are self-centered and have difficulty delaying their gratification, and behind their overt displays of affection is an underlying current of hostility.

Females with the 45/54 code will be openly rebelling against the traditional feminine role. Often motivating this rebellion is an intense fear related to developing dependent relationships. A further alternative interpretation is that these women are merely involved in a subculture or occupation which emphasizes traditionally male-oriented activities.

#### 46/64

Persons with the 46/64 code type are hostile, brooding, distrustful, irritable, self-centered, and usually unable to form close relationships. They have significant levels of social maladjustment often related to continually blaming others for their personal faults. This style of blaming prevents them from developing insight into their own feelings and behavior, since they are constantly focusing on others' behavior rather than their own. They lack self-criticism, and are highly defensive and argumentative especially if L and K are also high. Although they lack self-criticism, they are highly sensitive to real or imagined criticism from others, often inferring hostility or rejection when this was not actually intended. In order to avoid rejection and maintain a certain level of security, they become extremely adept at manipulating others. Often they will have a history of drug addiction or alcohol abuse.

Frequent corresponding high points are on scales 2, 3, and/or 8. Males with high 8s are often psychotic, especially paranoid schizophrenic or prepsychotic, but with 2 and/or 3 also elevated, the chances of a borderline condition are significantly increased. These men are likely to be angry and have significant conflicts relating to their own denied, but strong, needs for dependency. They are likely to rebel against authority figures and may use suicidal threats as a means of manipulating others. Females with a 46/64 code type may be psychotic

or prepsychotic, but they are more often passive-aggressive personalities. If scale 3 is also elevated, they will have intense needs for affection and will be egocentric and demanding.

**47/74**

Persons with high scores on scales 4 and 7 experience guilt over their behavior, and are brooding and resentful. Although they are frequently insensitive to the feelings of others, they are intensely concerned with their own responses and feelings. They justify this insensitivity because they feel rejected or restricted by others. Their behavioral and interpersonal difficulties follow a predictable cycle in which they will alternately express anger and then feel guilty over their behavior. While they feel angry they may have little control over their behavior, which results in impulsive acting out. This is then followed by a phase of excessive overcontrol accompanied by guilt, brooding, and self-pity. Frustrated by these feelings, they may then attempt to selfishly meet their needs through such means as alcohol abuse, promiscuity, or aggressive acting out. Thus the cycle continues and is usually fairly resistant to change. These persons respond to limit setting with anxiety and resentment, often either testing the limits or completely ignoring them. This frequently leads to legal problems and to difficulties in their work and home relationships. Although they do feel genuine and even excessive guilt and remorse for their behavior, their self-control is still inadequate and their acting out continues. This is a chronic pattern, and therapeutic attempts to decrease the anxiety of these individuals may actually result in an increase in their acting out because the control created by their guilt and remorse is diminished. Diagnostically, the 47/74 type is most likely to be either an antisocial personality or experiencing an anxiety disorder.

**48/84**

Persons with the 48/84 code are strange, eccentric, and emotionally distant, and have severe problems with adjustment. Their behavior is unpredictable and erratic, and may involve strange sexual responses. Usually there will be antisocial behavior resulting in legal complications, and these individuals are nonconforming, lack empathy, and are impulsive. Sometimes they will be members of strange religious cults or unusual political organizations. In their early family histories, they learned that relationships were dangerous because of constant confrontation with intense family conflicts. They were rejected and, as a result, felt alienated and hostile, sometimes attempting to compensate with counterrejection and other forms of retaliation. Their academic and later work performance has usually been erratic and characterized by underachievement. In interpersonal relationships, their judgment is generally poor and their style of communication

is likely to be inadequate. Often others feel as if they are missing important elements or significant connotations of what the 48/84 is saying, but they can't figure out exactly what or why.

If F is elevated with a low scale 2, these individuals are typically aggressive, cold, and punitive, and have a knack for inspiring guilt and anxiety in others. Often they take on roles in which such behavior is socially sanctioned, for example, a rigid law enforcement officer, an overzealous clergyman, or a school disciplinarian. Their behavior may range all the way from being merely stern, punitive, and disapproving to encompassing actual clinical sadism. Underneath these overt behaviors, they usually have a deep sense of alienation, vulnerability, and loneliness, which may give rise to feelings of anxiety and discomfort.

Criminal behavior occurs frequently in males with a 48/84 code type, especially with an elevated scale 9. The crimes are likely to be bizarre, and often extremely violent, involving homicide and/or sexual assault. These behaviors are usually impulsive, poorly planned, without apparent reason, and generally self-defeating, eventually resulting in self-punishment. Females are less likely to act criminally, but their relationships will usually be primarily sexual and they will rarely become emotionally close. Often they will form relationships with men who are significantly inferior to themselves and who could be described as losers.

The most likely diagnosis is a schizoid or paranoid personality. However, a psychotic reaction — often paranoid schizophrenia — is also common, especially with elevations on scale 6.

#### 49/94

Persons with 49/94 codes not only feel alienated and have antisocial tendencies, but also have the energy to act on them. They can be described as self-indulgent, sensation seeking, impulsive, oriented towards pleasure, irritable, extroverted, violent, manipulative, and energetic. They have poorly developed consciences, with a marked lack of concern for rules and conventions. Since they are free from anxiety, talkative, and charming, they can often make a good initial impression. However, their relationships are usually shallow because any sort of deeper contact with them brings out the more problematic sides of their personality. An investigation of their past history typically reveals extensive legal, family, and work-related difficulties. The 49/94 code, when found in persons over age 30, suggests that this pattern is highly resistant to change. In adolescent males, it is associated with delinquency.

There are numerous difficulties encountered in therapy with these persons. They are unable to focus for any length of time and are constantly embarking on often irrelevant tangents. Furthermore, they have difficulty delaying their gratification and usually do not learn from experience. They will often be

irritable, and if confronted by a therapist, their fairly extensive hostility will be expressed. Thus, therapy is likely to be slow, frustrating, and often unproductive.

With a correspondingly low 0, this code is likely to reflect a person with highly developed social techniques who will use these skills to manipulate others. Thus, he may be involved in elaborate, antisocial "con" games. If scale 3 is correspondingly high, it decreases the chance of acting out. In these cases, the expression of hostility is likely to be similar to that of the 34/43 code in that it will be indirect and often passive-aggressive. When scale 6 is elevated along with scales 4 and 9, extreme caution should be taken since these individuals will be very dangerous and have poor judgment. Their acting out will often be violent and bizarre, and will appear justified to themselves because of strong feelings of resentment towards others.

The most likely diagnosis is an antisocial personality, although caution should be made especially when categorizing adolescents since these scales are more commonly elevated for both normal and abnormal adolescents. If scale 8 is also high, it may reflect either a manic state or schizophrenia.

### 68/86

The key feature of people with the 68/86 code type is that they are suspicious and distrustful, often perceiving the intentions of others as suspect and questionable. They will be extremely distant from others with few or no friends. They can be described as inhibited, shy, resentful, anxious, and unable to accept or appropriately respond to the demands that are made of them. This is because they are highly involved in their fantasy world, uncooperative, and apathetic, and because they have poor judgment and experience difficulty concentrating. Their sense of reality is poor, and they often experience guilt, inferiority, and mental confusion although sometimes their affect will be flat. The content of their thoughts can be expected to be unusual if not bizarre, frequently containing delusions of grandeur and/or self-reference. Surprisingly, their past work history is often adequate, but an intensification of their symptoms brought on by stress will usually disrupt their ability to work. Persons with this code are more often single and younger than 26 years of age. If they are married, their spouses are frequently also emotionally disturbed.

The most frequent diagnosis is paranoid schizophrenia, especially if scale 4 is also elevated. These persons will experience depression, inappropriate affect, phobias, and paranoid delusions. If scale 7 is 10 points or more lower than scales 6 and 8, this pattern is referred to as the "paranoid valley" and emphasizes the presence of paranoid ideation. If F is highly elevated while scales 6 and 8 are above 80, this does not necessarily indicate an invalid profile. A paranoid state is also a frequent diagnosis with the 68/86 code; less frequently, organic brain disorders or severe anxiety disorders may be diagnosed.

**78/87**

The 78/87 code often occurs among psychiatric patients and reflects a level of agitation sufficiently intense to disrupt their daily activities. Usually this profile represents a reaction to a specific crisis. They may have been previously functioning at a fairly adequate level until some event or series of events triggered off a collapse in their defenses. Their style of relating to others is passive, and they have difficulty developing and sustaining mature heterosexual relationships. They are lacking in self-confidence, often experience insomnia, and may have hallucinations and delusions. Common feelings include guilt, inferiority, confusion, worry, and fear, and they may have difficulties related to sexual performance. There may be significant suicidal risk, which can be further evaluated by looking at the relative elevation of scale 2, checking relevant critical items, taking a careful history, and asking relevant questions related to their thought processes.

The extent of elevations on scales 7 and 8, and the relative heights between them, have important implications both diagnostically and prognostically. If scale 7 is higher than scale 8, the person's psychological condition is more susceptible to improvement and tends to be more benign. This has a tendency to be true regardless of the elevation of 8, so long as 7 maintains its relatively higher position. The higher scale 7 suggests that the person is still actively fighting his problem and has some of his defenses still working. Thus, engrained bizarre thought patterns and withdrawn behavior have not yet become established. A relatively higher scale 8, on the other hand, reflects more fixed patterns and is therefore more difficult to treat. This is particularly true if scale 8 is over 75. If scales 7 and 8 are both greater than 75 (with scale 8 relatively higher), this suggests an established schizophrenic pattern, especially if the "neurotic triad" is low. Even if schizophrenia can be ruled out, the condition tends to be extremely resistant to change, as for example, with a severe, alienated personality disorder. If scale 2 is also elevated, this raises the possibility of either a dysthymic or obsessive-compulsive disorder.

**89/98**

The 89/98 code suggests persons who are highly energetic, perhaps to the point of hyperactivity. They will be emotionally labile, tense, and disorganized, with the possibility of delusions of grandeur sometimes with a religious flavor, especially if scale 6 is also elevated. Their goals and expectations will be unrealistic; they often make extensive plans which are far beyond their means to accomplish. Thus, their aspirations will be significantly higher than their actual achievements. Usually, they will have significant complaints related to insomnia. Their interpersonal relationships are childish and immature, and they will usually be fearful, distrustful, irritable, and distractible. This likewise makes psychotherapeutic

approaches to them extremely difficult. Furthermore, their level of insight is poor, they resist psychological interpretations of their behavior, and they cannot focus on any one area for any length of time.

The most frequent diagnosis is schizophrenia, possibly a schizoaffective disorder with manic states. If there are extensive delusions and hallucinations, antipsychotic medication may be indicated. Sometimes the relative elevation of F can be used as an index of the relative severity of the disorder.

## CHAPTER 10

# COMPREHENSIVE NEUROPSYCHOLOGICAL ASSESSMENT BATTERIES

Gerald Goldstein

This chapter is the first of three covering the area of neuropsychological assessment. It will provide a general introduction to neuropsychological assessment and deal specifically with the extensive standard test batteries used with adults. Neuropsychological assessment is a relatively new term that has essentially replaced the older terms *testing for brain damage* or *testing for organicity*. Lezak (1983) indicates that these procedures are used for three purposes: diagnosis, provision of information important for patient care, and research. A significant component of the patient care function is rehabilitation planning and monitoring (Golden, 1978; Goldstein & Ruthven, 1983; Meier, Benton, & Diller, 1987). The focus of neuropsychological assessment has traditionally been on the brain-damaged patient, but there have been major extensions of the field to psychiatric disorders (Goldstein, 1986; Gruzelier & Flor-Henry, 1979; Yozawitz, 1986), functioning of normal individuals (Kimura & Durnford, 1974), and normal aging (Goldstein & Shelly, 1975; Reed & Reitan, 1963).

Perhaps the best definition of a neuropsychological test has been offered by Ralph Reitan, who describes it as a test that is sensitive to the condition of the brain. If performance on a test changes with a change in brain function, then the test is a neuropsychological test. However, it should be noted that comprehensive neuropsychological test batteries should contain not only neuropsychological tests. They should also contain some tests that are generally insensitive to brain dysfunction, primarily because such tests are often useful for providing a baseline against which extent of

impairment associated with acquired brain damage can be measured. Most neuropsychological assessment methods are formal tests, but some work has been done with rating scales and self-report measures. Neuropsychological assessment is rarely conducted through a structured interview outside a test situation.

A comprehensive neuropsychological test battery is a procedure that assesses all the major functional areas generally affected by structural brain damage. We use the term ideally because none of the standard, commonly available procedures entirely achieves full comprehensiveness. Some observers have described the comprehensive procedures as screening batteries because feasibility and time constraints generally require a sacrifice of detailed investigations of specific areas in order to achieve comprehensiveness. In Harsher's chapter (12), we will learn more about what a clinical neuropsychologist does when asked to explore a particular area in detail rather than do a comprehensive evaluation. While the term *screening* may be justifiable in certain respects, the extensive standard batteries in common use should not be grouped with the brief, paper-and-pencil screening tests used in many clinical and industrial settings. That is, they do not simply screen for presence or absence of brain damage, but also evaluate a number of functional areas that may be affected by brain damage. Because brain damage radically affects cognitive processes, most neuropsychological tests assess various areas of cognition, but perception and motor skills are also frequently evaluated. Thus, neuropsychological tests are generally thought of as assessment instruments

a variety of cognitive, perceptual, and motor skills. That is not to say that brain damage does not affect other aspects of the personality, but traditionally the standard neuropsychological tests do not typically assess these other areas. Perhaps the most important reason for this preference is that cognitive tests have proven to be the most diagnostic ones. While personality changes may occur with a wide variety of psychiatric, general medical, and neurological conditions, cognitive changes appear to occur most dramatically in individuals with structural brain damage.

Numerous attempts have been made to classify the functional areas typically affected by brain damage, but the scheme proposed in what follows is a reasonably representative one. Perhaps the most ubiquitous change is general intellectual impairment. Following brain damage, the patient is not as bright as he or she was before. Problems are solved less effectively, goal-directed behavior becomes less well organized, and there is impairment of a number of specific skills such as solving arithmetic problems or interpreting proverbs. Numerous attempts have been made to epitomize this generalized loss, perhaps the most successful one being Goldstein and Scheerer's (1941) concept of impairment of the abstract attitude. The abstract attitude is essentially a phenomenological concept having to do with the way in which the individual perceives the world. Some consequences of its impairment involve failure to form concepts or to generalize from individual events, failure to plan ahead ideationally, and inability to transcend the immediate stimulus situation. While the loss is a general one involving many aspects of the individual's life, it is best observed in a testing setting where the patient is presented with a novel situation in which some problem must be solved. Typically these tests involve abstraction or concept formation, and the patient is asked to sort or categorize in some way. The Goldstein-Scheerer (1941) tests, perhaps the first neuropsychological battery, consist largely of sorting tests, but also provide the patient with other types of novel problem-solving tasks.

Probably the next most common manifestation of structural brain damage is impairment of memory. Sometimes memory impairment is associated with general intellectual impairment, sometimes it exists independently, and sometimes it is seen as an early sign of a progressive illness that eventually impairs a number of abilities other than memory. In most but not all cases, recent memory is more impaired than remote memory. That is, the patient may recall his or her early life in great detail, but may be unable to recall what happened during the previous day. Often, so-called

primary memory is also relatively well preserved. That is, the patient may be able to repeat immediately what was just presented to him, such as a few words or a series of digits, but will not retain new information over a more extended period of time, particularly after intervening events have occurred. In recent years, our capacity to examine memory has benefited from a great deal of research involving the various amnesic syndromes (e.g., Butters & Cermak, 1980; Squire, Slater, & Chace, 1975; Warrington & Weiskrantz, 1982), and we have become quite aware that not all brain-damaged patients experience the same kind of memory disorder (Butters, 1983). A detailed assessment is generally required to identify specifically the various types of memory disorder, and the comprehensive batteries we will be discussing here generally can detect only the presence of a memory disorder and provide an index of its severity.

Loss of speed in performing skilled activities is an extremely common symptom of brain damage. Generally, this loss is described in terms of impaired psychomotor speed or perceptual-motor coordination. While its basis is sometimes reduction of pure motor speed, in many instances pure speed is preserved in the presence of substantial impairment on tasks involving speed of some mental operation or coordination of skilled movement with perceptual input. Thus, the patient may do well on a simple motor task, such as finger tapping, but poorly on a task in which movement must be coordinated with visual input, such as a cancellation or substitution task. Tasks of this latter type are commonly performed slowly and laboriously by many kinds of brain-damaged patients. Aside from slowness, there may be other disturbances of purposive movement that go under the general heading of apraxia. Apraxia may be manifested as simple clumsiness or awkwardness, an inability to carry out goal directed movement sequences as would be involved in such functional activities as dressing, or as an inability to use movement ideationally as in producing gestures or performing pretended movements. While apraxia in one of its pure forms is a relatively rare condition, impairment of psychomotor speed is quite common and seen in a variety of conditions.

A set of abilities that bridge movement and perception may be evaluated by tasks in which the patient must produce some form of construction or copy a figure from a model. Among the first tests used to test brain-damaged patients was the Bender-Gestalt (Bender, 1938), a procedure in which the patient must copy a series of figures devised by Wertheimer (1923) to study perception of visual gestalten. It was found that many patients had difficulty copying these fig-

ures, although they apparently perceived them normally. These difficulties manifested themselves in reasonably characteristic ways, including various forms of distortion, rotation of the figure, simplification, or primitivation and perseveration. The copying task has continued to be used by neuropsychologists, either in the form of the Bender-Gestalt or a variety of other procedures. Variations of the copying task procedure have involved having the patient draw the figure from memory (Benton, 1963; Rey, 1941), from a verbal command, for example, "Draw a Circle" (Luria, 1973), or copy a figure that is embedded in an interfering background pattern (Canter, 1970). Related to the copying task is the constructional task, in which the patient must produce a three-dimensional construction from a model. The most popular test for this purpose is the Kohs Blocks or Block Design subtest of the Wechsler Scales (Wechsler, 1955). While in the timed versions of these procedures the patient may simply fail the task by virtue of running out of time, at least some brain-damaged patients make errors on these procedures comparable to what is seen on the copying tasks. With regard to block design type tasks, the errors might involve breaking the contour of the model or incorrectly reproducing the internal structure of the pattern (Kaplan, 1979). Thus, a constructional deficit may not be primarily associated with reduction in psychomotor speed, but rather with the inability to build configurations in three-dimensional space. Often, this ability is referred to as visual-spatial skill.

Visual-spatial skills also form a bridge with visual perception. When one attempts to analyze the basis for a patient's difficulty with a constructional task, the task demands may be broken down into movement, visual, and integrative components. Often, the patient has no remarkable impairment of purposive, skilled movement and can recognize the figure. If it is nameable (the patient can tell you what it is) or if it is not, it can be correctly identified on a recognition task. However, the figure cannot be accurately copied.

While the difficulty may be with the integration between the visual percept and the movement, it has also been found that patients with constructional difficulties, and indeed patients with brain damage in general, frequently have difficulties with complex visual perception. For example, they do poorly at embedded figures tasks (Teuber, Battersby, & Bender, 1951) or at tasks in which a figure is made difficult to recognize through displaying it in some unusual manner, such as overlapping it with other figures (Golden, 1981b) or presenting it in some incomplete or ambiguous form (Mooney, 1957).

Some brain-damaged patients also have difficulty when the visual task is made increasingly complex through adding elements in the visual field. Thus, the patient may identify a single element, but not two. When two stimuli are presented simultaneously, the characteristic error is that the patient reports seeing only one. The phenomenon is known as extinction (Bender, 1952) or neglect (Heilman, 1979).

Many brain-damaged patients also have deficits in the areas of auditory and tactile perception. Sometimes, the auditory impairment is such that the patient can hear, but sounds cannot be recognized or interpreted. The general condition is known as agnosia and can actually occur in the visual, auditory, or tactile modalities. Agnosia has been defined as "perception without meaning," implying the intactness of the primary sense modality but loss of the ability to comprehend the incoming information. Auditory agnosia is a relatively rare condition, but there are many disturbances of auditory perception that are commonly seen among brain-damaged patients. Auditory neglect can exist and is comparable to visual neglect; sounds to either ear may be perceived normally, but when a sound is presented to each ear simultaneously only one of them may be perceived. There are a number of auditory verbal problems that we will examine in the discussion of language. Auditory attentional deficits are common and may be identified by presenting complex auditory stimuli, such as rhythmic patterns, which the patient must recognize and reproduce immediately after presentation. A variety of normal and abnormal phenomena may be demonstrated using a procedure called dichotic listening (Kimura, 1961). It involves presenting two different auditory stimuli simultaneously to each ear. The subject wears earphones, and the stimuli are presented using stereophonic tape. Higher-level tactile deficits generally involve a disability with regard to identifying symbols or objects by touch. Tactile neglect may be demonstrated by touching the patient over a series of trials with single and double stimuli, and tactile recognition deficits may be assessed by asking the patient to name objects placed in his or her hand or to identify numbers or letters written on the surface of the skin. It is particularly difficult to separate primary sensory functions from higher cognitive processes in the tactile modality, and many neuropsychologists perform rather detailed sensory examinations of the hands, involving such matters as light touch thresholds, two-point discrimination, point localization, and the ability to distinguish between sharp and dull tactile stimuli (Semmes, Weinstein, Ghent, & Teuber, 1960).

The neuropsychological assessment of speech and language has in some respects become a separate discipline involving neuropsychologists, neurologists, and speech and language pathologists. There is an extensive interdisciplinary literature in the area (Albert, Goodglass, Helm, Rubens, & Alexander, 1981), and several journals that deal almost exclusively with the relationships between impaired or normal brain function and language (e.g., *Brain and Language*). Aphasia is the general term used to denote impairment of language abilities as a result of structural brain damage, but not all brain-damaged patients with communicative difficulties have aphasia. While aphasia is a general term covering numerous subcategories, it is now rather specifically defined as an impairment of communicative ability associated with focal damage to the hemisphere of the brain that is dominant for language—the left hemisphere in most people. Aphasia is generally produced as a result of disorders that have a sudden onset, notably stroke and head trauma, but it may sometimes be seen in cases of other localized diseases such as brain tumors and focal infections. Stroke is probably the most common cause of aphasia.

Historically, there have been numerous attempts to categorize the subtypes of aphasia (Goodglass, 1983), but in functional terms, the aphasias involve a rather dramatic impairment of the capacity to speak, to understand the speech of others, to find the names for common objects, to read (alexia), write (agraphia), calculate (acalculia), or to use or comprehend gestures. However, a clinically useful assessment of these functional disorders must go into their specific characteristics. For example, when we say the patient has lost the ability to speak, we may mean that he or she has become mute or can produce only a few utterances in a halting, labored way. On the other hand, we may mean that the patient can produce words fluently, but the words and sentences being uttered make no sense. When it is said that the patient does not understand language, that may mean that spoken but not written language is understood, or it may mean that all modalities of comprehension are impaired. Thus, there are several aphasic syndromes, and it is the specific syndrome that generally must be identified in order to provide some correlation with the underlying localization of the brain damage and to make rational treatment plans. We may note that the standard comprehensive neuropsychological test batteries do not include extensive aphasia examinations. There are several such examinations available, such as Boston Diagnostic Aphasia Examination (Good-

glass & Kaplan, 1983) and the Western Aphasia Battery (Kertesz, 1979). Even though they may be used in conjunction with a neuropsychological assessment battery, they are rather lengthy procedures in themselves and require special expertise to administer and interpret.

For various reasons, it is often useful to assess attention as part of the neuropsychological examination. Sometimes, an attention deficit is a cardinal symptom of the disorder, but even if it is not, the patient's level of attention may influence performance on tests of essentially all the functional areas we have been discussing. A discussion of attention may be aided by invoking a distinction between *wide aperture* and *narrow aperture* attention (Kinsbourne, 1980). Wide aperture attention has to do with the individual's capacity to attend to an array of stimuli at the same time. Attention may be so narrowly focused that the total picture is not appreciated. Tests for neglect may in fact be assessing wide aperture attention. Narrow aperture attention has to do with the capacity to sustain attention to small details. Thus, it can be assessed by vigilance tasks or tests like the Picture Completion subtest of the Wechsler scales. Brain-damaged patients may manifest attentional deficits of either type. They may fail to attend to a portion of their perceptual environment, or they may be unable to maintain sufficient concentration to complete successfully tasks requiring sustained occupation with details. Individuals with attentional deficits are often described as distractible or impulsive, and in fact, many brain-damaged patients may be accurately characterized by those terms. Thus, the assessment of presence and degree of attention deficit is often a highly clinically relevant activity. Recently, Mirsky (in press) has proposed a useful division, based upon a factor analytic study of attentional tasks, dividing them into tests that evaluate encoding, sustaining concentration, focusing, and shifting attention from one aspect of a task to another.

In summary, neuropsychological assessment typically involves the functional areas of general intellectual capacity, memory, speed and accuracy of psychomotor activity, visual-spatial skills, visual, auditory, and tactile perception, language, and attention. Thus, a comprehensive neuropsychological assessment may be defined as a procedure that surveys at least all of these areas. In practical terms, a survey is all that is feasible if the intent of the assessment is to evaluate all areas. It is obviously generally not feasible to do an in-depth assessment of each of these areas in every patient, nor is it usually necessary to do so.

## PROBLEMS IN CONSTRUCTION AND STANDARDIZATION OF TEST BATTERIES

It will be assumed here that neuropsychological tests share the same standardization requirements as all other psychological tests. That is, there is the need for appropriate quantification, norms, and related test construction considerations, as well as the need to deal with issues related to validity and reliability. However, there are some special considerations regarding neuropsychological tests, and we will turn our attention to them here.

### Practical Concerns in Test Construction

Neuropsychological test batteries must of necessity be administered to brain-damaged patients, many of whom may have severe physical disability, cognitive impairment, or a combination of the two. Therefore, the stimulus and response characteristics of the tests themselves, as well as the stimulus characteristics of the test instructions, become exceedingly important considerations. Neuropsychological test materials should, in general, be constructed with salient stimuli that the patient can readily see or hear and understand. The material to be read should not require high levels of literacy, nor should the grammatical structures be unduly complex. With regard to test instructions, the potential for multimodal instruction giving should ideally be available. If the patient cannot see or read, it should be possible to give the instructions verbally, without jeopardizing the clinician's opportunity to use established test norms. The opportunity should be available to repeat and paraphrase instructions until it is clear that the patient understands them. It is of crucial importance in neuropsychological assessment that the examiner achieve maximum assurance that a test was failed because the patient could not perform the task being assessed, not because the test instructions were not understood. This consideration is of particular importance for the aphasic patient, who may have a profound impairment of language comprehension. With regard to response parameters, efforts should be made to assure that the test response modality is within the patient's repertoire.

In neuropsychological assessment, it is often not the failure to perform some specific task that is diagnostic, but the failure to perform some component of a series of tasks in the presence of intact function in

other areas. As an example, failure to read a passage is not specifically diagnostic, because the inability to read may be associated with a variety of cognitive, perceptual, and learning difficulties. However, failure to be able to transfer a grapheme or a written symbol to a phoneme or sound in the presence of other manifestations of literacy could be quite diagnostic. Individuals with this type of deficit may be able to "sight-read" or recognize words as perceptual patterns, but when asked to read multisyllabic, unfamiliar words, they are unable to break the word down into phonemes and sound it out. In perhaps its most elegant form, neuropsychological assessment can produce what is called a double dissociation (Teuber, 1959): a task consistently failed by patients with a particular type of brain disorder accompanied by an equally difficult corresponding task that is consistently passed, and the reverse in the case of patients with some other form of brain disorder. Ideally, then, neuropsychological assessment aims at detailed as possible specification of what functional deficits exist in a manner that allows for mapping of these deficits onto known systems in the brain. There are several methods of achieving this goal, and not all neuropsychologists agree with regard to the most productive route. In general, some prefer to examine patients in what may be described as a linear manner, with a series of interlocking component abilities, while others prefer using more complex tasks in the form of standard, extensive batteries and interpretation through examination of performance configurations. The linear approach is best exemplified in the work of A. R. Luria (1973) and various collaborators, while the configural approach is seen in the work of Ward Halstead (1947), Ralph Reitan (Reitan & Davison, 1974), and their many collaborators. In either case, however, the aim of the assessment is largely that of determining the pattern of the patient's preserved and impaired functions and inferring from this pattern what the nature might be of the disturbed brain function. The difficulty with using complex tasks to achieve that end is that such tasks are really only of neuropsychological interest if they can be analyzed by one of the two methods described here.

### Issues Related to Validity and Reliability

311

Neuropsychological assessment has the advantage of being in an area where the potential for development of highly sophisticated validation criteria has been very much realized in recent years and will surely

achieve even fuller realization in the near future. We begin our discussion with this consideration, and are first occupied with the matters of concurrent and predictive validity. A major review of validation studies was accomplished by Klove (1974) and updated by Boll (1981). Reitan and Wolfson (1985) have written an entire volume on the Halstead-Reitan battery, which contains a brief review of pertinent research findings in addition to extensive descriptions of the tests themselves and case materials. These reviews essentially covered only the Wechsler scales and Halstead-Reitan Battery, but there are several reviews of the work with the Luria-Nebraska Neuropsychological Battery as well (e.g., Golden, 1981b). We will not deal with the content of those reviews at this point, but rather focus on the methodological problems involved in establishing concurrent or predictive validity of neuropsychological tests. With regard to concurrent validity, the criterion used in most cases is the objective identification of some central nervous system lesion arrived at independently of the neuropsychological test results. Therefore, validation is generally provided by neurologists or neurosurgeons. Identification of lesions of the brain is particularly problematic because, unlike many organs of the body, the brain cannot usually be visualized directly in the living individual. The major exceptions occur when the patient undergoes brain surgery or receives the rarely used procedure of brain biopsy. In the absence of these procedures, validation is dependent upon autopsy data or the various brain imaging techniques. Autopsy data are not always entirely usable for validation purposes, in that numerous changes may have taken place in the patient's brain between time of testing and time of examination of the brain. Of the various imaging techniques, the CT scan is currently the most fruitful one. Cooperation among neuroradiologists, neurologists, and neuropsychologists has already led to the accomplishment of several important studies correlating quantitative CT scan data with neuropsychological test results (e.g., Hill & Mikhael, 1979). Beyond the CT scan, however, we can see the beginnings of even more sensitive indicators, including measures of cerebral metabolism such as the PET scan (Positron Emission Tomography), the Xenon enhanced CT scan, and the advanced imaging techniques that may develop from the new method of nuclear magnetic resonance (NMR). Recently, more generally available and even more sensitive measures of cerebral metabolism have appeared, including generations of the PET scan allowing for greatly im-

proved resolution SPECT (Single Photon Emission Computerized Tomography) which allows for studying brain metabolism in settings in which a cyclotron is not available, and the evolving method of magnetic resonance imaging spectroscopy. These exciting new developments in brain imaging and observation of brain function will surely provide increasingly definitive criteria for neuropsychological hypotheses and assessment methods.

Within neuropsychological assessment, there appears to have been a progression regarding the relationship between level of inference and criterion. Early studies in the field as well as the development of new assessment batteries generally addressed themselves to the matter of simple presence or absence of structural brain damage. Thus, the first question raised had to do with the accuracy with which an assessment procedure could discriminate between brain-damaged and non-brain-damaged patients, as independently classified by the criterion procedure. In the early studies, the criterion utilized was generally clinical diagnosis, perhaps supported in some cases by neurosurgical data or some laboratory procedure such as a skull X-ray or an EEG. It soon became apparent, however, that many neuropsychological tests were performed at abnormal levels, not only by brain-damaged patients, but by patients with several of the functional psychiatric disorders. Because many neuropsychologists worked in neuropsychiatric rather than general medical settings, this matter became particularly problematic. Great efforts were then made to find tests that could discriminate between brain-damaged and psychiatric patients or, as sometimes put, between "functional" and "organic" conditions. There have been several reviews of this research (Goldstein, 1978; Heaton, Baade, & Johnson, 1978; Heaton & Crowley, 1981; Malec, 1978), all of which were critical of the early work in this field in light of current knowledge about several of the functional psychiatric disorders. The chronic schizophrenic patient was particularly problematic, because such patients often performed on neuropsychological tests in a manner indistinguishable from the performance of patients with generalized structural brain damage. By now, this whole issue has been largely reformulated in terms of looking at the neuropsychological aspects of many of the functional psychiatric disorders (e.g., Gruzelier & Flor-Henry, 1979; Henn & Nasrallah, 1982), largely under the influence of the newer biological approaches to psychopathology.

Neuropsychologists working in neurological and neurosurgical settings were becoming increasingly interested in validating their procedures against more

refined criteria, notably in the direction of localization of brain function. The question was no longer only whether a lesion was present or absent, but if present, whether the tests could predict its location. Major basic research regarding this matter was conducted by H.-L. Teuber and various collaborators over a span of many years (Teuber, 1959). This group had access to a large number of veterans who had sustained open head injuries during World War II and the Korean conflict. Because the extent and site of their injuries were exceptionally well documented by neurosurgical and radiological data, and the lesions were reasonably well localized, these individuals were used productively in a long series of studies in which attempts were made to relate both site of lesion and concomitant neurological defects to performance on an extensive series of neuropsychological procedures ranging from measures of basic sensory functions (Semmes, Weinstein, Ghent, & Teuber, 1960) to complex cognitive skills (Teuber & Weinstein, 1954). Similar work with brain-wounded individuals was accomplished by Freda Newcombe and collaborators at Oxford (Newcombe, 1969). These groups tended to concentrate on the major lobes of the brain (frontal, temporal, parietal, and occipital), and would, for example, do contrasts between the performances of patients with frontal and occipital lesions on some particular test or test series (e.g., Teuber, 1964). In another setting, but at about the same time the Teuber group was beginning its work, Ward Halstead (1947) and collaborators conducted a large-scale neuropsychologically oriented study of frontal lobe function. Ralph M. Reitan, who was Halstead's student, adopted several of his procedures, supplemented them, and developed a battery of tests that were extensively utilized in localization studies. Reitan's (1955) early work in the localization area was concerned with differences between the two cerebral hemispheres more than with regional localization. The now well-known Wechsler-Bellevue studies of brain lesion lateralization (see review in Reitan, 1966) represented some of the beginnings of this work. The extensive work of Roger Sperry and various collaborators (Sperry, Gazzaniga, & Bogen, 1969) with patients who had undergone cerebral commissurotomy also contributed greatly to validation of neuropsychological tests with regard to the matter of differences between the two hemispheres, particularly the functional asymmetries or cognitive differences. Since the discoveries regarding the major roles of subcortical structures in the mediation of various behaviors (Albert, 1978), neuropsychologists have also been study-

ing the relationships between test performance and lesions in such structures and structure complexes as the limbic system (Scoville & Milner, 1957) and the basal ganglia (Butters, 1983).

The search for validity criteria has become increasingly precise with recent advances in the neurosciences as well as increasing opportunities to collect test data from various patient groups. One major conceptualization largely attributable to Reitan and his co-workers is that localization does not always operate independently with regard to determination of behavioral change, but interacts with type of lesion or the specific process that produced the brain damage. The first report regarding this matter related to differences in performance between patients with recently acquired lateralized brain damage and those who had sustained lateralized brain damage at some time in the remote past (Fitzhugh, Fitzhugh, & Reitan, 1961, 1962). Patients with acute lesions were found to perform differently on tests from patients with chronic lesions. It soon became apparent, through an extremely large number of studies (cf. Filskov & Boll, 1981) that there are many forms of type-locus interactions, and that level and pattern of performance on neuropsychological tests may vary greatly with the particular nature of the brain disorder. This development paralleled such advances in the neurosciences as the discovery of neurotransmitters and the relationship between neurochemical abnormalities and a number of the neurological disorders that historically had been of unknown etiology. We therefore have the beginnings of the development of certain neurochemical validating criteria (Davis, 1983). There has also been increasing evidence for a genetic basis for several mental and neurological disorders. The gene for Huntington's disease is close to being discovered, and there is growing evidence of a significant genetic factor contributing to the acquisition of certain forms of alcoholism (Steinhauer, Hill, & Zubin, 1987). In general, the concurrent validity studies have been quite satisfactory, and many neuropsychological test procedures have been shown to be accurate indicators of many parameters of brain dysfunction.

A persistent problem in the past has been the possible tendency of neuropsychological tests to be more sensitive than the criterion measures. In fact, a study by Filskov and Goldstein (1974) demonstrated that neuropsychological tests may predict diagnosis more accurately than many of the individual neurodiagnostic procedures commonly used in assessment of neurological and neurosurgical patients (e.g., skull X-ray). It would appear that with the advent of the CT

scan and the even more advanced brain imaging procedures, this problem will be diminishing. A related problem involves the establishment of the most accurate and reliable external criterion. We have always taken the position (Goldstein & Shelly, 1982; Russell, Neuringer, & Goldstein, 1970) that no one method can be superior in all cases, and that the best criterion is generally the final medical opinion based on a comprehensive but pertinent evaluation, excluding, of course, behavioral data. In some cases, for example, the CT scan may be relatively noncontributory, but there may be definitive laboratory findings based on examination of blood or cerebral spinal fluid. In some cases (e.g., Huntington's disease) the family history may be the most crucial part of the evaluation. It is not being maintained here that the best criterion is a doctor's opinion, but rather that no single method can stand out as superior in all cases when one is dealing with a variety of disorders. The diagnosis is often best established through the integration by an informed individual of data coming from a number of sources. A final problem to be mentioned here is that objective criteria do not yet exist for a number of neurological disorders, but even this problem appears to be undergoing a rapid stage of solution. Most notable in this regard is the *in vivo* differential diagnosis of the degenerative diseases of old age, such as Alzheimer's disease. There is also no objective laboratory marker for multiple sclerosis, and diagnosis of that disorder continues to be made on a clinical basis. Only advances in the neurosciences will lead to ultimate solutions to problems of this type.

In clinical neuropsychology, predictive validity has mainly to do with course of illness. Will the patient get better, stay the same, or deteriorate? Generally, the best way to answer questions of this type is through longitudinal studies, but very few such studies have actually been done. Even in the area of normal aging, in which many longitudinal studies have been accomplished, there really have been no extensive neuropsychologically oriented longitudinal studies. There is, however, some literature on recovery from stroke, much of which is attributable to the work of Meier and collaborators (Meier, 1974). Levin, Benton, and Grossman (1982) provide a discussion of recovery from closed head injury. Of course, it is generally not possible to do a full neuropsychological assessment immediately following closed head injury, and so prognostic instruments used at that time must be relatively simple ones. In this regard, a procedure known as the Glasgow Coma Scale (Teasdale & Jennett, 1974) has well-established predictive validity. Perhaps one of the most extensive efforts directed

toward establishment of the predictive validity of neuropsychological tests was accomplished by Paul Satz and various collaborators, involving the prediction of reading achievement in grade school based on neuropsychological assessments accomplished during kindergarten (Fletcher & Satz, 1980; Satz, Taylor, Friel, & Fletcher, 1978). At the other end of the age spectrum, there are currently several ongoing longitudinal studies contrasting normal elderly individuals with dementia patients (Danziger, 1983; Wilson & Kaszniak, 1983). However, we do not yet know from these studies and other ongoing longitudinal investigations what the best prognostic instruments are for predicting the course of dementia or for determining whether or not an elderly individual suspected of having dementia will deteriorate or not.

An important aspect of predictive validity has to do with prediction of treatment and rehabilitation outcome. Ben-Yishay, Gerstman, Diller, and Haas (1970) were able to show that a battery of neuropsychological tests could successfully predict length of time in rehabilitation and functional outcome in patients with hemiplegia. There have been several studies (reviewed by Parsons & Farr, 1981) concerned with predicting outcome of alcoholism treatment on the basis of neuropsychological test performance. The results of these studies are mixed, but in general it would appear that test performance during the early stages of treatment may bear some relationship to outcome as evaluated by followup. Before leaving this area, I should mention that there are several not fully documented but apparently reasonable clinical principles related to prediction of treatment outcome. In general, patients with relatively well-circumscribed deficits and perhaps underlying structural lesions, tend to do better in treatment than do patients with more global deficits. Some data suggest that early intervention for aphasic adults, perhaps within two months post-onset, is more effective than treatment initiated later (Wertz, 1983). Ben-Yishay, Diller, Gerstman, and Gordon (1970) have suggested that an individual's level of competence on a task to be trained is related to his or her ability to profit from cues utilized in the training procedure.

In general, studies of predictive validity in neuropsychological assessment have not been as extensive as studies involving concurrent validity. However, the data available suggest that neuropsychological tests can predict degree of recovery or deterioration to some extent and have some capacity to predict treatment outcome. Because many neurological disorders change over time, getting better or worse, and the treatment of neurological disorders is becoming an

increasingly active field (Reisberg, Ferris, & Gershon, 1980), it is often important to have some foreknowledge of what will happen to the patient in the future in a specific rather than general way and to determine whether the patient is a good candidate for some form of treatment. Efforts have also been made to predict functional abilities involved in personal self-care and independent living on the basis of neuropsychological test performance, particularly in the case of elderly individuals (McCue, Rogers, Goldstein, & Shelly, 1987). The extent to which neuropsychological assessment can provide this prognostic information will surely be associated with the degree of its acceptance in clinical settings.

Studies of the construct validity of neuropsychological tests represent a great amount of the corpus of basic clinical neuropsychological research. Neuropsychology abounds with constructs: short-term memory, attention, visual-spatial skills, psychomotor speed, motor engrams, and cell-assemblies. Tests are commonly characterized by the construct they purport to measure; Test A is one of long-term memory; Test B is one of attention; Test C is one of abstraction ability; Test D is a measure of biological intelligence, etc. Sometimes we fail to recognize constructs as such because they are so well established, but concepts like memory, intelligence, and attention are in fact theoretical entities used to describe certain classes of observable behaviors. Within neuropsychology, the process of construct validation generally begins with an attempt to find a measure that evaluates some concept. Let us begin with a simple example, say the desire to develop a test for memory. Memory, as a neuropsychological construct, would involve a brain-behavior relationship. That is, neuropsychologists are concerned with how the brain mediates memory and with how impaired brain function affects memory. There are memory tests available, notably the newly revised Wechsler Memory Scale (WMS-R) (Wechsler, 1987), but without experimental studies, that scale would have only face validity. That is, it appears to be a test of memory on the basis of the nature of the test items. However, if we ask the related question, "Does the patient who does well on the scale have a normal memory?" we would have to know more about the test in regard to how well it assesses memory as a construct. Reasonable alternative hypotheses might be that the scale measures intelligence, educational level, or attention, or that these influences confound the test such that impairment of memory *per se* cannot be unequivocally identified.

The problem may be approached in numerous

subtests of the Wechsler Memory Scale are placed into a factor analysis along with educational level and tests of intelligence and attention. It may be found that the memory scale subtests load on their own factor or on factors that receive high loadings from the intelligence and attention tests or from educational level. Another approach may involve giving the test to patients with amnesia and to nonamnestic brain-damaged patients. A more sophisticated study may involve administering the Wechsler Memory Scale to these subjects along with other tests. Studies such as these may reveal some of the following hypothetical findings. The Wechsler Memory Scale is highly correlated with IQ, and so it is not possible to tell whether the scale measures the construct memory specifically or intellectual ability. Some patients cannot repeat stories read to them because they are aphasic and cannot produce words, not because of poor memories. Therefore, interpretation of the measure as an indicator of memory ability cannot be made unequivocally in certain populations. Certain amnesic patients do exceedingly poorly on certain components of the Wechsler Memory Scale, but well on other components. Such a finding would suggest that memory, as a neuropsychological construct, requires further refinement, because there appears to be a dissociation in patients known to have profound loss of memory between certain memory skills that are intact and others that are severely impaired. Still another approach, suggested by Cronbach (1960), is correlation with practical criteria. Individuals given the Wechsler Memory Scale could be asked to perform a number of tasks, all of which involve practical memory in some way, and the obtained data could be analyzed in terms of what parts of the scale predict success or failure at the various tasks.

Another important way of establishing the construct validity of neuropsychological test batteries involves determining capacity to classify cases into meaningful subtypes. In recent years, several groups of investigators have utilized classification statistics, notably R-type factor analysis and cluster analysis, in order to determine whether combinations of test scores from particular batteries classify cases in accordance with established diagnostic categories or into types that are meaningful from the standpoint of neuropsychological considerations. A great deal of effort has gone into establishing meaningful, empirically derived subtypes of learning disability (Rourke, 1985), and there has also been work done in the neuropsychologically based empirical classification of neuropsychiatric patients (Goldstein & Shelly, 1987; Goldstein, Shelly

It is particularly important to note that, at least in recent years, the construct validation of neuropsychological tests has involved a multidisciplinary effort with colleagues in cognitive psychology, the experimental psychology of memory and learning (utilizing both human studies and animal models), linguistics, and sensory and perceptual processes. For example, aphasia testing has been profoundly influenced by basic research in psycholinguistics (Blumstein, 1981), while memory testing has been correspondingly influenced by recent developments in information theory and the experimental psychology of memory and learning (Butters & Cermak, 1980; Squire & Butters, 1984). These experimental foundations have aided significantly in the interpretation of clinical tests, and indeed, many new clinical tests are actually derived from laboratory procedures.

While neuropsychological tests should ideally have reliability levels commensurate with other areas of psychometrics, there are some relatively unique problems. These problems are particularly acute when the test-retest method is used to determine the reliability coefficients. The basic problem is that this method really assumes the stability of the subject over testing occasions. When reliability coefficients are established through the retesting of adults over a relatively brief time period, that assumption is a reasonable one, but it is not as reasonable in samples of brain-damaged patients who may be rapidly deteriorating or recovering. Indeed, it is generally thought to be an asset when a test reflects the appropriate changes. Another difficulty with the test-retest method is that many neuropsychological tests are not really repeatable because of substantial practice effects. The split-half method is seldom applicable because most neuropsychological tests do not consist of lengthy lists of items, readily allowing for odd-even or other split-half comparisons. In the light of these difficulties, the admittedly small number of reliability studies done with the standard neuropsychological tests batteries have yielded perhaps surprisingly good results. Boll (1981) has reviewed reliability studies done with the Halstead-Reitan Battery; the test manual for the Luria-Nebraska Battery (Golden, Hammeke, & Purisch, 1980) reports reliability data for that instrument. The details of these matters are discussed later in our reviews of these two procedures. In any event, it seems safe to say that most neuropsychological test developers have not been greatly preoccupied with the reliabilities of their procedures, but those who have studied the matter appear to have provided sufficient data to permit the conclusion that the standard, commonly used procedures are

at least not so unreliable as to impair the validities of those procedures.

## AN INTRODUCTION TO THE COMPREHENSIVE BATTERIES

The number of generally available comprehensive standard neuropsychological test batteries for adults is not entirely clear. *The Handbook of Clinical Neuropsychology* (Filskov & Boll, 1981) contains chapters on only two batteries: the Halstead-Reitan and Luria-Nebraska. Lezak (1983) lists the Halstead-Reitan, the Smith Neuropsychological Battery, and two versions of batteries derived from Luria's work—one by Christensen (1975a, 1975b, 1975c), and Golden, Hammeke, and Purisch's Luria-Nebraska (originally South Dakota) Battery (1980). Jones and Butters (1983) reviewed the Halstead-Reitan, Luria-Nebraska, and Michigan batteries. Benton, Hamsher, Varney, and Spreen (1983) have produced a manual containing descriptions and instructions for tests these neuropsychologists have been associated with over the years, but there was clearly no intention to present this collection of tests as a standard battery. In this chapter, we will consider only the Halstead-Reitan and Luria-Nebraska procedures. The Michigan Battery (Smith, 1975) will not be reviewed, primarily because it consists largely of a series of standardized tests, all of which have their own validity and reliability literature. This literature is thoroughly reviewed by Lezak (1983).

### The Halstead-Reitan Battery

#### History

The history of this procedure and its founders has been reviewed by Reed (1983). He traces the beginnings of the battery to the special laboratory established by Halstead in 1935 for the study of neurosurgical patients. The first major report on the findings of this laboratory appeared in a book called *Brain and Intelligence: A Quantitative Study of the Frontal Lobes* (Halstead, 1947), the title of which suggests that the original intent of Halstead's tests was to describe frontal lobe function. In this book, Halstead proposed his theory of "biological intelligence" and presented what was probably the first factor analysis done with neuropsychological test data. It is perhaps more significant that the book provides descriptions of many of the tests now contained in the Halstead-Reitan battery. As Reed (1983) suggests, the theory of

biological intelligence was never widely accepted among neuropsychologists, and the factor analysis had its mathematical problems. But several of the tests that went into that analysis survived, and many of them are commonly used at present. In historical perspective, Halstead's major contributions to neuropsychological assessment, in addition to his very useful tests, include the concept of the neuropsychological laboratory in which objective tests are administered in standard fashions and quantitatively scored, and the concept of the impairment index, a global rating of severity of impairment and probability of the presence of structural brain damage.

Ralph M. Reitan was a student of Halstead at Chicago and was strongly influenced by his theories and methods. Reitan adopted the methods in the form of the various test procedures and with them established a laboratory at the University of Indiana. He supplemented these tests with a number of additional procedures in order to obtain greater comprehensiveness, and he initiated a clinical research program that is ongoing. The program began with a cross-validation of the battery and went on into numerous areas, including validation of new tests added to the battery (e.g., the Trail Making test), lateralization and localization of function, aging, and neuropsychological aspects of a wide variety of disorders such as alcoholism, hypertension, disorders of children, and mental retardation. Theoretical matters were also considered. Some of the major contributions included the concept of type-locus interaction (Reitan, 1966), the analysis of quantitative as opposed to qualitative deficits associated with brain dysfunction (Reitan, 1958, 1959), the concept of the brain-age quotient (Reitan, 1973), and the scheme for levels and types of inference in interpretation of neuropsychological test data (Reitan & Davison, 1974). In addition to the published research, Reitan and his collaborators developed a highly sophisticated method of blind clinical interpretation of the Halstead-Reitan Battery that continues to be taught at workshops conducted by Dr. Reitan and associates. The Halstead-Reitan Battery, as the procedure came to be known over the years, also has a history. It has been described as a "fixed battery," but that is not actually the case. Lezak (1976) says in reference to this development, "This set of tests has grown by accretion and revision and continues to be revised" (p. 440). Halstead's original battery, on which the factor analyses were based, included the Carl Hollow Square test, the Dynamic Visual Field Test, the Henmon-Nelson tests of mental ability, a flicker fusion procedure, and the Time Sense

although the Time Sense and Flicker Fusion tests were originally included in the battery used by Reitan. The tests that survived include the Category test, the Tactual Performance test, the Speech Perception test, and Finger Tapping. Halstead also used the Seashore Rhythm test, which is included in the current version of the battery, but was not included in the sub-battery used by Halstead in his factor analyses. There have been numerous additions, including the various Wechsler Intelligence Scales, the Trail Making test, a sub-battery of perceptual tests, the Reitan Aphasia Screening test, the Klove Grooved Pegboard, and other tests that are used in some laboratories but not in others. Alternative methods have also been developed for computing the impairment index (Russell, Neuringer, & Goldstein, 1970).

Bringing this brief history into the present, the Halstead-Reitan Battery continues to be widely used as a clinical and research procedure. Numerous investigators utilize it in their research, and there have been several successful cross-validations done in settings other than Reitan's laboratory (Goldstein & Shelly, 1972; Vega & Parsons, 1967). In addition to the continuation of factor analytic work with the battery, several investigators have applied other forms of multivariate analysis to it in various research applications. Several investigations have been conducted relative to objectifying and even computerizing interpretation of the battery, the most well-known efforts probably being the Selz-Reitan rules for classification of brain function in older children (Selz & Reitan, 1979) and the Russell, Neuringer, and Goldstein "Neuropsychological Keys" (Russell et al., 1970). The issue of reliability of the battery has recently been addressed, with reasonably successful results. Clinical interpretation of the battery continues to be taught at workshops and in numerous programs engaged in training of professional psychologists. The most detailed description of the battery available will be found in Reitan and Wolfson (1985).

#### *Structure and Content*

Although there are several versions of the Halstead-Reitan Battery, the differences tend to be minor, and there appears to be a core set of procedures that essentially all versions of the battery contain. The battery must be administered in a laboratory containing a number of items of equipment and generally cannot be completely administered at bedside. Various estimates of length of administration are given, but it is probably best to plan on about 6 to 8 hours of patient time. Each test of the battery is independent and may be administered separately from the other

tests. However, it is generally assumed that a certain number of the tests must be administered in order to compute an impairment index.

Scoring for the Halstead-Reitan varies with the particular test, such that individual scores may be expressed in time to completion, errors, number correct, or some form of derived score. For research purposes, these scores are generally converted to standard scores so that they may be profiled. Matthews (1981) routinely uses a T-score profile in clinical practice, while Russell et al. (1970) rate all the tests contributing to the impairment index on a six-point scale, the data being displayed as a profile of the ratings. In their system the impairment index may be computed by calculating the proportion of tests performed in the brain-damaged range according to published cutoff scores (Reitan, 1955) or by calculating the average of the ratings. This latter procedure provides a value called the Average Impairment Rating. Russell et al. (1970) have also provided quantitative scoring systems for the Reitan Aphasia Screening test and for the drawing of a Greek cross that is part of that test. However, some clinicians do not quantify those procedures, except in the form of counting the number of aphasic symptoms elicited. We will return to other aspects of the battery's structure after the following description of the component tests.

#### A. Halstead's Biological Intelligence Tests

1. *The Halstead Category Test*: This test is a concept identification procedure in which the subject must discover the concept or principle that governs various series of geometric forms, verbal, and numerical material. The apparatus for the test includes a display screen with four horizontally arranged numbered switches placed beneath it. The stimuli are on slides, and the examiner uses a control console to administer the procedure. The subject is asked to press the switch that the picture reminds him or her of, and is provided with additional instructions to the effect that the point of the test is to see how well he or she can learn the concept, idea, or principle that connect the pictures. If the correct switch is pressed, the subject will hear a pleasant chime, while wrong answers are associated with a rasping buzzer. The conventionally used score is the total number of errors for the seven groups of stimuli that form the test. Booklet (Adams & Trenton, 1981; DeFillippis, McCampbell, & Rogers, 1979) and abbreviated forms (Calsyn et al., 1980; Russell & Levy, 1987; Merrill, 1987) of this test have been developed.

2. *The Halstead Tactual Performance Test*: This procedure utilizes a version of the Seguin-Goddard Formboard, but it is done blindfolded. The subject's task is to place all of the 10 blocks into the board, using only the sense of touch. The task is repeated three times, once with the preferred hand, once with the nonpreferred hand and once with both hands, following which the board is removed. After removing the blindfold, the subject is asked to draw a picture of the board, filling in all of the blocks he or she remembers in their proper locations on the board. Scores from this test include time to complete the task for each of the three trials, total time, number of blocks correctly drawn, and number of blocks correctly drawn in their proper locations on the board.
3. *The Speech Perception Test*: The subject is asked to listen to a series of 60 sounds, each of which consist of a double e digraph with varying prefixes and suffixes (e.g., geend). The test is given in a four-alternative multiple-choice format, the task being to underline on an answer sheet the sound heard. The score is number of errors.
4. *The Seashore Rhythm Test*: This test consists of 30 pairs of rhythmic patterns. The task is to judge whether the two members of each pair are the same as or different from each other and to record the response by writing an S or a D on an answer sheet. The score is either number correct or number of errors.
5. *Finger Tapping*: The subject is asked to tap his or her extended index finger on a typewriter key attached to a mechanical counter. Several series of 10-second trials are run with both the right and the left hand. The scores are average number of taps, generally over five trials, for the right and left hand.

#### B. Tests Added to the Battery by Reitan

1. *The Wechsler Intelligence Scales*: Some clinicians continue to use the Wechsler-Bellevue, some the WAIS, and some the WAIS-R. In any event, the test is given according to manual instructions and is not modified in any way.
2. *The Trail Making Test*: In Part A of this procedure the subject must connect in order a series of circled numbers randomly scattered over a sheet of 8½ × 11 paper. In part B, there are circled numbers and letters, and the subject's task involves alternating between numbers and letters in serial order (e.g., 1 to A to 2 to B, etc.). The score is time to completion expressed in seconds for each part.

3. *The Reitan Aphasia Screening Test*: This test serves two purposes in that it contains both copying and language-related tasks. As an aphasia screening procedure, it provides a brief survey of the major language functions: naming, repetition, spelling, reading, writing, calculation, narrative speech, and right-left orientation. The copying tasks involve having the subject copy a square, Greek cross, triangle, and key. The first three items must each be drawn in one continuous line. The language section may be scored by listing the number of aphasic symptoms or by using the Russell et al. quantitative system. The drawings are not formally scored or are rated through a matching to model system also provided by Russell et al. (1970).
4. *Perceptual Disorders*: These procedures actually constitute a sub-battery and include tests of the subject's ability to recognize shapes and identify numbers written on the fingertips, as well as tests of finger discrimination and visual, auditory, and tactile neglect. Number of errors is the score for all of these procedures.

#### C. Tests Added to the Battery by Others

1. *The Klove Grooved Pegboard Test*: The subject must place pegs shaped like keys into a board containing recesses that are oriented in randomly varying directions. The test is administered twice, once with the right and once with the left hand. Scores are time to completion in seconds for each hand and errors for each hand, defined as number of pegs dropped during performance of the task.
2. *The Klove Roughness Discrimination Test*: The subject must order four blocks, covered with varying grades of sandpaper and presented behind a blind, with regard to degree of roughness. Time and error scores are recorded for each hand.
3. *Visual Field Examination*: Russell et al. (1970) include a formal visual field examination utilizing a perimeter as part of their assessment procedure. It should be noted that many clinicians, including Reitan and his collaborators, frequently administer a number of additional tests mainly for purposes of assessing personality and level of academic achievement. The MMPI is the major personality assessment method used, and achievement may be assessed with such procedures as the Wide Range Achievement Test-R (Jastak & Wilkinson, 1984) or the Peabody Individual Achievement Test (Dunn & Markwardt, 1970). Some clinicians have

Memory Scale (WMS or WMS-R) to the battery, either in its original form (Wechsler, 1945, 1987) or the Russell modification (Russell, 1975a). Some form of lateral dominance examination is also generally administered, including tests for handedness, footedness, and eyedness.

#### Quantitative Structural Considerations

Factor analysis is probably the clearest way of providing a quantitative description of the structure of a test battery. Many such analyses have been accomplished with the Halstead and Halstead-Reitan Battery, going back to Halstead's (1947) original work. Unfortunately, it is exceedingly difficult to compare one factor analytic study with another, largely because the battery has not remained stable over the years. For example, Halstead's original factor analysis involved the Flicker Fusion and Dynamic Visual Field tests, procedures that are rarely if ever used in current versions of the battery. Similarly, more recent factor analytic studies (Newby, Hallenbeck, & Embretson, 1983; Swiercinsky, 1979) utilized the Wechsler Memory Scale and other procedures that Halstead did not use, nor do many users of the battery. We will therefore take the solution of using some of our own factor analytic work (Goldstein & Shelly, 1971, 1972) as illustrative of the results one might achieve using a reasonably stripped down, core battery involving only Halstead's original tests that remain in common use, the WAIS, and the other procedures added to the battery by Reitan. The first of the two analyses utilized a sample of 50 alcoholic inpatients, while the second utilized a sample of 619 neuropsychiatric inpatients with miscellaneous diagnoses. The rotated factor matrices, presented in Table 10.1, are similar in some respects and dissimilar in others.

In both cases, the WAIS verbal subtests in combination with the aphasia screening test form a grouping (Factor 1) that clearly taps language abilities. There is a second factor largely contributed to by the WAIS performance tests, the Category test, and the speed component of the Tactual Performance test. The Finger Tapping test shows a different pattern in the two studies. In the analysis involving only the alcoholic patients, it loads on a factor along with several other tests, including WAIS Digit Symbol and the Seashore Rhythm test. In the case of the larger, more miscellaneous sample, Finger Tapping essentially achieves simple structure, forming its own factor. Thus, what the two factor analyses have in common are a verbal and a complex problem-solving factor. In the case of the alcoholic sample, there are three other

Table 10.1. Two Factor Analyses of the Halstead-Reitan Battery

TEST	ROTATED FACTOR LOADINGS FOR ALCOHOLIC GROUP					ROTATED FACTOR LOADINGS FOR GENERAL PSYCHIATRIC GROUP

Note. Some of the scores have been reflected so that higher scores always indicate above average performance.

perceptual and motor skills, one that receives salient loadings only from the memory and location components of the Tactual Performance Test, and one that receives loadings from the two WAIS numerical tests, Arithmetic and Digit Span. There was a total of only four factors extracted for the large miscellaneous sample: the language and problem-solving factors noted above, a factor that received substantial loadings only from the tactual functions perceptual tests, and a factor that received high loadings only from the Finger Tapping test. While the factor analyses probably differ from each other because of differences in the roles and the specifics of the variables included

(which were not precisely the same), the two analyses taken together provide a reasonably good impression of the abilities tapped by the Halstead-Reitan. They can readily be described as verbal skills, complex problem-solving abilities, and various perceptual and motor skills. In some cases, a purely numerical ability factor may emerge as well as a factor representing the nonverbal memory abilities involved in the memory and location components of the Tactual Performance test. In general, when standard factor extraction termination procedures are used, in our case Kaiser's (1960) rule, the battery seems to be satisfactorily structured into four or five factors. It is interesting to

note that the original Halstead (1947) analysis, even with its different tests and different factoring methods, also generated four factors.

### *Theoretical Foundations*

There are really two theoretical bases for the Halstead-Reitan Battery, one contained in *Brain and Intelligence* and related writings of Halstead, the other in numerous papers and chapters written by Reitan and various collaborators (e.g., Reitan, 1966; Reitan & Wolfson, 1985). They are quite different from each other in many ways, and the difference may be partly accounted for by the fact that Halstead was not primarily a practicing clinician and was not particularly interested in developing his tests as psychometric instruments to be used in clinical assessment of patients. Indeed, he never published the tests. He was more interested in utilizing the tests to answer basic scientific questions in the area of brain-behavior relationships in general and frontal lobe function in particular. Reitan's program, on the other hand, can be conceptualized as an effort to demonstrate the usefulness and accuracy of Halstead's tests and related procedures in clinical assessment of brain-damaged patients. It is probably fair to say that Halstead's theory of biological intelligence and its factor analytically based four components (the central integrative field, abstraction, power, and the directional factor), as well as his empirical findings concerning human frontal lobe function, have not become major forces in modern clinical neuropsychology. However, they have had, in my view, a more subtle influence on the field.

Halstead was really the first to establish a human neuropsychology laboratory in which patients were administered objective tests, some of which were semiautomated, utilizing standard procedures and sets of instructions. His Chicago laboratory may have been the initial stimulus for the now common practice of trained technician administration of neuropsychological tests. Halstead was also the first to utilize sophisticated, multivariate statistics in the analysis of neuropsychological test data. Even though Reitan did not pursue that course to any great extent, other researchers with the Halstead-Reitan Battery have done so (e.g., Goldstein & Shelly, 1971, 1972). Thus, though the specifics of Halstead's theoretical work have not become well known and widely applied, the concept of a standard neuropsychological battery administered under laboratory conditions and consisting of objective, quantifiable procedures has made a major impact on the field of clinical neuropsychology. The other, perhaps more philosophical, contribution of Halstead

was what might be described as his Darwinian approach to neuropsychology. He viewed his discriminating tests as measures of adaptive abilities, as skills that assured man's survival on the planet. Many neuropsychologists are now greatly concerned with the relevance of their test procedures to adaptation—the capacity to carry on functional activities of daily living and to live independently (Heaton & Pendleton, 1981). This general philosophy is somewhat different from the more traditional models emanating from behavioral neurology, in which there is a much greater emphasis on the more medical-pathological implications of behavioral test findings.

Reitan, while always sympathetic with Halstead's thinking, never developed a theoretical system in the form of a brain model or a general theory of the biological intelligence type. One could say that Reitan's great concern has always been with the empirical validity of test procedures. Such validity can be established only through the collection of large amounts of data obtained from patients with reasonably complete documentation of their medical/neurological conditions. Both presence and absence of brain damage had to be well documented, and if present, findings related to site and type of lesion had to be established. He has described his work informally as one large experiment, necessitating maximal consistency in the procedures used, and to some extent, the methods of analyzing the data. Reitan and his various collaborators represent the group that was primarily responsible for introduction of the standard battery approach to clinical neuropsychology. It is clear from reviewing the Reitan group's work that there is substantial emphasis on performing controlled studies with samples sufficiently large to allow for application of conventional statistical procedures. One also gets the impression of an ongoing program in which initial findings are qualified and refined through subsequent studies.

It would probably be fair to say that the major thrust of Reitan's research and writings has not been espousal of some particular theory of brain function, but rather an extended examination of the inferences that can be made from behavioral indices relative to the condition of the brain. There is a great emphasis on methods of drawing such inferences in the case of the individual patient. Thus, this group's work has always involved empirical research and clinical interpretation, with one feeding into the other. In this regard, there has been a formulation of inferential methods used in neuropsychology (Reitan & Wolfson, 1985) that provides a framework for clinical interpretation. Four methods are outlined: level of performance.

BEST COPY AVAILABLE

pattern of performance, specific behavioral deficits (pathognomonic signs), and right-left comparisons. In other words, one examines for whether the patient's general level of adaptive function compares with that of normal individuals, whether there is some characteristic performance profile that suggests impairment even though the average score may be within normal limits, whether there are unequivocal individual signs of deficits, and whether there is a marked discrepancy in functioning between the two sides of the body.

In general, then, Reitan's theoretical framework is basically empirical, objective, and data oriented. An extensive research program, by now of about 35 years' duration, has provided the information needed to make increasingly sophisticated inferences from neuropsychological tests. It thereby constitutes to a significant extent the basis for clinical interpretation. The part of the system that remains subjective is the interpretation itself, but in that regard, Reitan (1964) has made the following remark: "Additional statistical methods may be appropriate for this problem but, in any case, progress is urgently needed to replace the subjective decision-making processes in individual interpretation that presently are necessary" (p. 46).

#### *Standardization Research*

The Halstead-Reitan Battery, as a whole, meets rigorous validity requirements. Following Halstead's (1947) initial validation the battery was cross-validated by Reitan (1955) and in several other laboratories (Russell et al., 1970; Vega & Parsons, 1967). As indicated above, reviews of validity studies with the Halstead-Reitan Battery have been written by Klove (1974) and Boll (1981). Validity, in this sense, means that all component tests of the battery that contribute to the impairment index discriminate at levels satisfactory for producing usable cutoff scores for distinguishing between brain-damaged and non-brain-damaged patients. The major exceptions, the Time Sense and Flicker Fusion tests, have been dropped from the battery by most of its users. In general, the validation criteria for these studies consisted of neurosurgical and other definitive neurological data. It may be mentioned, however, that most of these studies were accomplished before the advent of the CT scan, and it would probably now be possible to do more sophisticated validity studies, perhaps through correlating extent of impairment with quantitative measures of brain damage (e.g., CT scan density measures). In addition to what was done with Halstead's tests, validity studies were accomplished with tests added to the battery, such as the Wechsler scales, the Trail

Making test and the Reitan Aphasia Screening tests, with generally satisfactory results (Reitan, 1966).

By virtue of the level of inferences made by clinicians from Halstead-Reitan Battery data, validity studies must obviously go beyond the question of presence or absence of brain damage. The first issue raised related to discriminative validity between patients with left-hemisphere and right-hemisphere brain damage. Such measures as Finger Tapping, the Tactual Performance test, the perceptual disorders sub-battery, and the Reitan Aphasia Screening test all were reported as having adequate discriminative validity in this regard. There have been very few studies, however, that go further and provide validity data related to more specific criteria such as localization and type of lesion. It would appear from one impressive study (Reitan, 1964) that valid inferences concerning prediction at this level must be made clinically, and one cannot call upon the standard univariate statistical procedures to make the necessary discriminations. This study provided the major impetus for Russell et al.'s (1970) neuropsychological key approach, which was in essence an attempt to objectify higher-order inferences.

There is one general area in which the discriminative validity of the Halstead-Reitan Battery is not particularly robust. The battery does not have great capacity to discriminate between brain-damaged patients and patients with functional psychiatric disorders, notably chronic schizophrenia. There is an extensive literature concerning this matter, but it should be said that some of the research contained in this literature has significant methodological flaws, leaving the findings ambiguous. It may also be pointed out that the constructors of the Halstead-Reitan did not have the intention of developing a procedure to discriminate between brain-damaged and schizophrenic patients, and the assumption that it should be able to do so is somewhat gratuitous. Furthermore, Heaton and Crowley (1981) find that with the exception of the diagnosis of chronic schizophrenia, the Halstead-Reitan Battery does a reasonably good job of differential diagnosis. They provided the following conclusion:

The bulk of the evidence . . . suggests that for most psychiatric patient groups there is little or no relationship between the degree of emotional disturbance and level of performance on neuropsychological tests. However, significant correlations of this type are sometimes found with schizophrenic groups. (p. 492)

This matter remains controversial and has become exceedingly complex, particularly since the discovery

of cerebral atrophy in a substantial portion of the schizophrenic population and the development of hypotheses concerning left-hemisphere dysfunction in schizophrenics (Flor-Henry & Yeudall, 1979). The point to be made here is that the user of the Halstead-Reitan Battery should exercise caution in interpretation when asked to employ the battery in resolving questions related to differential diagnosis between brain damage and schizophrenia. Some writers have advised the addition of some measure of psychiatric disability, such as the MMPI, when doing such assessments (Russell, 1975b, 1977).

Even though there have been several studies of the predictive validity of neuropsychological tests with children (Fletcher & Satz, 1980; Rourke, 1983) and other studies with adults that did not utilize the full Halstead-Reitan Battery (Meier, 1974), I know of no major formal assessment of the predictive validity of the Halstead-Reitan Battery accomplished with adults. Within neuropsychology, predictive validity has two aspects: predicting everyday academic, vocational, and social functioning and predicting course of illness. With regard to the former matter, Heaton and Pendleton (1981) document the lack of predictive validity studies using extensive batteries of the Halstead-Reitan type. However, they do report one study (Newman, Heaton, & Lehman, 1978) in which the Halstead-Reitan successfully predicted employment status on six-month followup. With regard to prediction of course of illness, there appears to be a good deal of clinical expertise in this regard, but no major formal studies in which the battery's capacity to predict whether the patient will get better, worse, or stay the same are evaluated. This matter is of particular significance in such conditions as head injury and stroke, because outcome tends to be quite variable in these conditions. The changes that occur during those stages are often the most significant ones related to prognosis (e.g., length of time unconscious).

In general, there has not been a great deal of emphasis on studies involving the reliability of the Halstead-Reitan Battery, probably because of the nature of the tests themselves, particularly with regard to the practice-effect problem, and because of the changing nature of those patients for whom the battery was developed. Those reliability studies that were done produced satisfactory results, particularly with regard to the reliability of the impairment index (Boll, 1981). The Category test can have its reliability assessed through the split-half method. In a study accomplished by Shaw (1966), a .98 reliability coefficient was obtained.

Norms for the Halstead-Reitan are available in

numerous places (Russell et al., 1970; Vega & Parsons, 1967), but because the battery was never published as a single procedure, there is no published manual to which one can refer for definitive information. Schear (1984) has published a table of age norms for neuropsychiatric patients, but there are no published age- or education-corrected norms for the general population. However, several laboratories have collected local norms. A great deal is known about the influence of age and education on the various tests in the Halstead-Reitan Battery, but this information was never consolidated into tables of norms or through the formulation of equations for calculating appropriate corrections. Similarly, sex differences generally reported appear only on Finger Tapping, with women tapping slightly more slowly than men. It is somewhat unusual for a procedure in as widespread use as the Halstead-Reitan not to have a commercially published manual. However, detailed descriptions of the procedures as well as instructions for administration and scoring are available in several sources including Reitan and Wolfson (1985), Jarvis and Barth (1984), and Swiercinsky (1978).

In summary, the validity of the Halstead-Reitan seems well established by literally hundreds of studies, including several major cross-validations. These studies have implications for the concurrent, predictive, and construct validity of the battery. Reliability has not received nearly as much attention, but it seems apparent that the battery is sufficiently reliable not to compromise its validity. There are few age- or education-related norms, but the relevance of such norms to neuropsychological assessment, particularly with regard to age, is a controversial and unsettled matter. There is no commercially available manual for the battery, and so the usual kinds of information generally contained in a manual are not available in a single place to the test user. However, the relevant information is available in a number of separate sources.

### *Evaluation*

The Halstead-Reitan Battery is without doubt the most widely used standard neuropsychological battery, at least in North America and perhaps throughout the world. Aside from its widespread clinical application, it is used in many multidisciplinary research programs as the procedure of choice for neuropsychological assessment. It therefore has taken on something of a definitive status and is viewed by many experts in the field as the state-of-the-art instrument for comprehensive neuropsychological assessment. Nevertheless, several criticisms of it have emerged

over the years, and some of them are reviewed here. Each major criticism is itemized and discussed.

1. *The Halstead-Reitan Battery is too long and redundant.* The implication of this criticism is that pertinent, clinically relevant neuropsychological assessment can be accomplished in substantially less time than the 6 to 8 hours generally required to administer the full Halstead-Reitan battery. Other batteries are, in fact, substantially briefer than the Halstead-Reitan. Aside from simply giving fewer or briefer tests, another means suggested of shortening neuropsychological assessment is through a targeted, individualized approach rather than through routine administration of a complete battery. The difficulty with this latter alternative is that such an approach can generally be conducted only by an experienced clinician, and one sacrifices the clinician time and expense that can be saved through administration by trained technicians. The response to the criticism concerning length is generally that shortening of the battery correspondingly reduces its comprehensiveness, and one sacrifices examination of areas that may be of crucial significance in individual cases. Indeed, the battery approach was, in part, a reaction to the naiveté inherent in the use of single tests for "brain damage." The extent to which the clinician reverts to a single-test approach may reflect the extent to which there is a return to the simplistic thinking of the past. In general, the argument is that to cover adequately what must be covered in a standard, comprehensive assessment, the length of the procedure is a necessity. From the point of view of patient comfort and fatigue, the battery can be administered in several sessions over a period of days if necessary.

2. *The tests in the Halstead-Reitan Battery are insufficiently specific, both in regard to the functions they assess and the underlying cerebral correlates of those functions.* Most of the tests in the battery are quite complex, and it is often difficult to isolate the source of impairment within the context of a single test. Even as apparently simple a procedure as the Speech Perception test requires not only the ability to discriminate sounds, but to read, make the appropriate written response, and attend to the task. Therefore, failure on the test cannot unequivocally point to a specific difficulty with auditory discrimination. Difficulties of this type are even more pronounced in such highly complex procedures as the Category and Tactual Performance tests. This criticism eventuates in the conclusion that it is difficult to say anything meaningful about the patient's brain or about treatment because one cannot isolate the specific deficit. In (1973) terminology one cannot isolate the

functional system that is involved, no less the link in that system that is impaired. Failure to do so makes it difficult if not impossible to identify the structures in the brain that are involved in the patient's impairment as well as to formulate a rehabilitation program, because one does not really know in sufficiently specific terms what the patient can and cannot do.

This criticism ideally requires a very detailed response, because it implies an approach to neuropsychological assessment substantially different from the one adopted by developers of the Halstead-Reitan. Perhaps the response can be summarized in a few points. The Halstead-Reitan Battery is founded on empirical rather than on content validity. Inferences are drawn on the basis of pertinent research findings and clinical observations rather than on the basis of what the tests appear to be measuring. The fact that one cannot partial out the various factors involved in successful or impaired performance on the Category test, for example, does not detract from the significant empirical findings related to this test based on studies of various clinical populations. In any event, Reitan, Hom, and Wolfson (1988) have shown that complex abilities, notably abstraction, are dependent upon the functioning of both cerebral hemispheres, and not on a localized unilateral system. The use of highly specific items in order to identify a specific system or system link is a procedure that is closely tied to the syndrome approach of behavioral neurology. Developers of the Halstead-Reitan typically do not employ a syndrome approach for several reasons. First, it depends almost exclusively on the pathognomonic signs method of inference to the neglect of other inferential methods, and second, the grouping together of specific deficits into a syndrome is felt to be more often in the brain of the examiner than of the patient. The lack of empirical validity of the so-called Gerstmann Syndrome is an example of this deficiency in this particular approach (Benton, 1961). Another major point is that the Halstead-Reitan Battery is a series of tests in which interpretation is based not on isolated consideration of each test taken one at a time, but on relationships among performances on all of the tests. Therefore, specific deficits can be isolated, in some cases at least, through intertest comparisons rather than through isolated examination of a single test. Returning to our example, the hypothesis that there is impairment on the Speech Perception test because of the patient's failure to read the items accurately can be evaluated through looking at the results of the aphasia screening or reading-achievement test given. Finally, complex tests are likely to have more ecological validity than simple tests of isolated abilities. Thus, the Category

test or Tactual Performance test results can tell the clinician more about real-world functioning than can the simpler tests. Simple tests were developed in the context of neurological diagnosis, while the tests in the Halstead-Reitan Battery seem more oriented to assessing adaptive functioning in the environment.

3. *The Halstead-Reitan Battery is not sufficiently comprehensive, particularly in that it completely neglects the area of memory.* The absence of formal memory testing in this battery has been noted by many observers and appears to be a valid criticism. On the face of it, it would appear that the battery would be incapable of identifying and providing meaningful assessments of patients with pure amnesic syndromes (e.g., patients with Korsakoff's syndrome). The absence of formal memory testing as part of the Halstead-Reitan is something of a puzzlement; although memory is involved in many of the tests, it is difficult to isolate the memory component as a source of impairment. Such isolation is readily achieved through such standard, commonly available procedures as list or paired associate learning.

We know of no formal response to this criticism, but the point of view could be taken that pure amnesic syndromes are relatively rare, and the Halstead-Reitan Battery would probably not be the assessment method of choice for many of the rarely occurring specific syndromes. I would view this response as weak in view of the reported significance of memory defect in a number of disorders (Butters, 1983). Apparently, Halstead did not work with patients of those types, particularly patients with Alzheimer's and Huntington's disease, and so may have failed to note the significance of memory function in those disorders. However, this criticism is probably the one most easily resolved, because all that is required is addition of some formal memory testing to the battery. Many clinicians have already added all or parts of the Wechsler Memory Scale or similar procedures.

4. *The Halstead-Reitan Battery cannot discriminate between brain-damaged and schizophrenic patients.* This matter has already been discussed, and most of the evidence (Heaton & Crowley, 1981) indicates that the performance of chronic schizophrenics on the Halstead-Reitan may be indistinguishable from that of the patient with generalized, structural brain damage. There are essentially two classes of response to this criticism. First, there is a disclaimer that the Halstead-Reitan was ever designed for this kind of differential diagnosis, and so it is not surprising that it fails when it is inappropriately used for that purpose. Second, and perhaps much more significant, is the finding that many schizophrenics have brain

atrophy, as assessed by CT scan, and tests of the Halstead-Reitan type can now be viewed as accurately identifying the behavioral correlates of that condition (Weinberger & Wyatt, 1982). Furthermore, there are now several studies indicating that schizophrenia is a neuropsychologically heterogeneous condition, and that there is a lack of relationship between neuropsychological test results and psychiatric diagnosis in the case of several psychiatric disorders (Goldstein & Shelly, 1987; Townes et al., 1985.)

5. *Findings reported from Reitan's laboratory cannot be replicated in other settings.* Here we have particular reference to the criticisms raised by Smith of Reitan's early Wechsler-Bellevue laterality studies. In a series of papers, Smith (1965, 1966a, 1966b) presented empirical and theoretical arguments against the reported finding that patients with left-hemisphere lesions had lower verbal than performance IQs on the Wechsler-Bellevue, while the reverse was true for patients with right-hemisphere brain damage. Smith was unable to replicate these findings in patients with lateralized brain damage for whom he had Wechsler-Bellevue data; he also presented theoretical arguments against the diagnostic and conceptual significance of this finding. Klove (1974) analyzed the Smith versus Reitan findings in terms of possible age and neurological differences between the studies. Reviewing the research done to the time of writing, he also concluded that most of the research, with Smith as the only pronounced exception, essentially confirmed Reitan's original findings.

In summary, many criticisms have been raised of the Halstead-Reitan as a comprehensive, standard neuropsychological assessment system. While pertinent and reasonable responses have been made to most or all of these critiques, members of the profession have nevertheless sensed in recent years the desire to develop alternative procedures. Despite the pertinent replies to criticisms, there appear to be many clinicians who still feel that the Halstead-Reitan Battery is too long, does neglect memory, and in many cases is insufficiently specific. Some holders of these views adopted an individualized approach, or modified the Halstead-Reitan, while others sought alternative standard batteries.

## The Luria-Nebraska Neuropsychological Battery

### History

This procedure, previously known as the Luria South Dakota Neuropsychological Battery or as the Standard Version of Luria's Neuropsychologica

Tests. was first reported on in 1978 (Golden, Hammekke, & Purisch, 1978; Purisch, Golden, & Hammekke, 1978) in the form of two initial validity studies. One could provide a lengthy history of this procedure, going back to Luria's original writings, or a brief one recording only events that occurred since the time of preparation of the two publications cited above. We will take the latter alternative, for reasons that will become apparent. Prior to the past quarter of a century, Luria was a shadowy figure to most English-speaking neuropsychologists. It was known that he was an excellent clinician who had developed his own methods for evaluating patients as well as his own theory, but the specific contents were unknown until translations of some of his major works appeared in the 1960s (e.g., Luria, 1966). However, when these works were read by English-speaking professionals, it became apparent that Luria did not have a standard battery of the Halstead-Reitan type and did not even appear to use standardized tests. Thus, while his formulations and case presentations were stimulating and innovative, nobody knew quite what to do with these materials in terms of practical clinical application. One alternative, of course, was to go to the Soviet Union and study with Luria. In fact, Anne-Lise Christensen did just that and reported what she had learned in a book called *Luria's Neuropsychological Investigation* (Christensen, 1975a). The book was accompanied by a manual and a kit containing test materials used by Luria and his co-workers (Christensen, 1975b, 1975c). Even though some of Luria's procedures previously appeared in English in the *Higher Cortical Functions* (1966) and *Traumatic Aphasia* (1970), they were never presented in a manner that encouraged direct administration of the test items to patients. With Christensen's publications, the English-speaking public had in hand a manual and related materials that could be used to administer some of Luria's tests. These materials did not contain information relevant to standardization of these items. There was no scoring system, norms, data regarding reliability and validity, or review of research accomplished with the procedure as a standard battery. This work was taken on by a group of investigators under the leadership of Charles J. Golden and was initially reported on in the two 1978 papers cited above. Thus, in historical sequence, Luria adopted or developed these items over the course of many years, Christensen published them in English but without standardization data, and finally Golden and collaborators provided quantification and standardization. Since that time, Golden's group as well as other investigators have produced a massive amount of studies with

what is now known as the Luria-Nebraska Neuropsychological Battery. The battery was published in 1980 by Western Psychological Services (Golden, Hammekke, & Purisch, 1980) and is now extensively used in clinical and research publications. An alternate form of the battery is now available (Golden, Purisch, & Hammekke, 1985), as is a children's version (Golden, 1981a).

### Structure and Content

The Luria-Nebraska is an evolving procedure, and the details presented here will no doubt change over the years. However, the basic structure of the battery will probably remain essentially the same. The current version contains 269 items, each of which may be scored on a 2- or 3-point scale. A score of 0 indicates normal performance. Some items may receive a score of 1, indicating borderline performance. A score of 2 indicates clearly abnormal performance. The items are organized into the categories provided in the Christensen kit (Christensen, 1975c), but while Christensen organized the items primarily to suggest how they were used by Luria, in the Luria-Nebraska version the organization is presented as a set of quantitative scales. The raw score for each scale is the sum of the 0, 1, and 2 item scores. Thus, the higher the score, the poorer the performance. Because the scales contain varying numbers of items, raw scale scores are converted to T scores with a mean of 50 and a standard deviation of 10. These T scores are displayed as a profile on a form prepared for that purpose. The scores for the individual items may be based on speed, accuracy, or quality of response. In some cases, two scores may be assigned to the same task, one for speed and the other for accuracy. These two scores are counted as individual items. For example, one of the items is a block counting task, with separate scores assigned for number of errors and time to completion of the task. In the case of time scores, blocks of seconds are associated with the 0, 1, and 2 scores. When quality of response is scored, the manual provides both rules for scoring, and, in the case of copying tasks, illustrations of figures representing 0, 1, and 2 scores.

The 269 items are divided into 11 content scales, each of which is individually administrable. In Table 10.2 we present the name of each content scale, a brief description of each scale, and a sample item. In the alternate form of the battery, the names of the content scales have been replaced by abbreviations. Thus, the scales listed in Table 10.2 are referred to as the C1 through C11 scales.

Table 10.2. The Luria-Nebraska Major Scales

SCALE	DESCRIPTION AND SAMPLE ITEM
Motor	<p>Contains items assessing a wide variety of motor skills ranging from simple movements to more complex tasks including pretended movements and movements associated with complex verbal instructions.</p> <p>Sample Item: If I knock hard, you knock gently; if I knock gently, then knock hard.</p>
Rhythm	<p>Contains measures of primarily nonverbal auditory perception such as pitch discrimination and appreciation of rhythmic patterns.</p> <p>Sample Item: Now you are going to hear two tones on a tape from this tape recorder. I want you to tell me whether the tones you hear are the same or different.</p>
Tactile	<p>This scale is basically a sensory examination and contains measures of light touch localization, two point discrimination, and tactile recognition.</p> <p>Sample Item: I am going to touch you with the eraser end of the pencil. Tell me where I am touching you (touching fingers, palm and forearm of each upper extremity).</p>
Vision	<p>Contains items assessing basic visual perceptual skills as well as more complex visual-spatial tasks.</p> <p>Sample Item: I am now going to show you several pictures. Tell me what they are. (Subject is presented with cards containing photographs of common objects.)</p>
Receptive Speech	<p>Contains items ranging from perception of single sounds to comprehension of complex grammatical structures.</p> <p>Sample Item: Someone has just told you that "Arnie hit Tom." Who was the victim?</p>
Expressive Speech	<p>Contains items assessing ability to repeat sounds, words, and word groups, to name objects, and to produce narrative speech.</p> <p>Sample Item: Please make up a speech for me about the conflict between generations.</p>
Writing	<p>Contains items assessing ability to analyze words into letters and to write under varying conditions.</p> <p>Sample Item: Please write: physiology; probabilistic</p>
Reading	<p>Contains items assessing ability to make letter to sound transformations and to read simple material.</p> <p>Sample Item: I am going to show you several cards. Read the word on each card.</p>
Arithmetic	<p>Contains items assessing knowledge of numbers, number concept, and ability to perform simple calculations.</p> <p>Sample Item: Please solve these problems. You may also write them down if you like: (1) <math>3 + 4</math>; (2) <math>6 + 7</math></p>
Memory	<p>A brief, formal memory examination including list learning, immediate memory, short-term memory with interference, and paired-associate learning.</p> <p>Sample Item: Now I am going to read you a short story. I want you to listen carefully because when I am finished I want you to repeat to me all that you can remember about the story.</p>
Intellectual Processes	<p>A brief intellectual assessment containing sequencing, problem solving, and abstraction items.</p> <p>Sample Item: What is meant by these expressions: (1) "iron hand"? (2) "green thumb"?</p>

In addition to these 11 content scales, there are three derived scales that appear on the standard profile form: the Pathognomonic, Left Hemisphere, and Right Hemisphere scales. The Pathognomonic scale contains items from throughout the battery found to be particularly sensitive to presence or absence of brain damage. The Left and Right Hemisphere scales are derived from the Motor and Tactile scale items that involve comparisons between the left and right side of the body. They therefore reflect sensory-motor asymmetries between the two sides of the body.

Several other scales have been developed by Golden and various collaborators, all of which are based on different ways of scoring the same 269 items. These special scales include new (empirically derived) right- and left-hemisphere scales (McKay & Golden, 1979a), a series of localization scales (McKay & Golden, 1979b), a series of factor scales (McKay & Golden, 1981), and double discrimination scales (Golden, 1979). The new right- and left-hemisphere scales contain items from throughout the battery and are based upon actual comparisons among patients with right, left hemisphere, and diffuse brain damage. The localization scales are also empirically derived (McKay & Golden, 1979b), being based on studies of patients with localized brain lesions. There are frontal, sensory-motor, temporal, and parieto-occipital scales for each hemisphere. The factor scales are based on extensive factor analytic studies of the battery involving factor analyses of each of the major content scales (e.g., Golden & Berg, 1983). The factor scales and associated codes are listed below (see Table 10.3). The code consists of an abbreviation for the major content scale followed by the number of the scale (e.g., M3 is the third factor scale derived from the Motor scale).

The new right- and left-hemisphere, localization, and factor scales may all be expressed in T scores with a mean of 50. The double discrimination scales are still in an experimental phase, but have been shown to be effective in diagnosis of multiple sclerosis (Golden, 1979). This method involves development of two scales: one contains items on which patients with a particular diagnosis do worse than the general neurological population; the other contains items on which patients do better. Classification to the specific group is made when scores are in the appropriate range on both scales. There are also two scales that provide global indices of dysfunction and are meant as equivalents to the Halstead Impairment Index. They are called the Profile Elevation and Impairment scales.

Luria-Nebraska procedure involves an age and education correction. It is accomplished through com-

Table 10.3. The Luria-Nebraska Factor Scales

CODE	FACTOR SCALES
M1	Kinesthetic-Based Movement
M2	Drawing Speed
M3	Fine Motor Speed
M4	Spatial-Based Movement
M5	Oral Motor Skills
Rh1	Rhythm and Pitch Perception
T1	Simple Tactile Sensation
T2	Stereognosis
V1	Visual Acuity and Naming
V2	Visual-Spatial Organization
Rc1	Phonemic Discrimination
Rc2	Relational Concepts
Rc3	Concept Recognition
Rc4	Verbal-Spatial Relationships
Rc5	Word Comprehension
Rc6	Logical Grammatical Relationships
E1	Simple Phonetic Reading
E2	Word Repetition
E3	Reading Polysyllabic Words
Rg1	Reading Complex Material
Rg2	Reading Simple Material
W1	Spelling
W2	Motor Writing Skill
A1	Arithmetic Calculations
A2	Number Reading
Me1	Verbal Memory
Me2	Visual and Complex Memory
I1	General Verbal Intelligence
I2	Complex Verbal Arithmetic
I3	Simple Verbal Arithmetic

putation of a cutoff score for abnormal performance based on an equation that takes into consideration both age and education. The computed score is called the critical level and is equal to  $.214 (\text{Age}) + 1.47 (\text{Education}) + 68.8 (\text{Constant})$ . Typically, a horizontal line is drawn across the profile at the computed critical level point. The test user has the option of considering scores above the critical level, which may be higher or lower than 60, as abnormal.

As indicated above, extensive factor analytic studies have been accomplished, and the factor structure of each of the major scales has been identified. These analyses were based on item intercorrelations, rather than on correlations among the scales. It is important to note that most items on any particular scale correlate more highly with other items on that scale than they do with items on other scales (Golden, 1981b). This finding lends credence to the view that the scales

are at least somewhat homogeneous, and thus that the organization of the 269 items into those scales can be justified.

### *Theoretical Foundations*

As in the case of the Halstead-Reitan Battery, one could present two theoretical bases for the Luria-Nebraska, one revolving around the name of Luria and the other around the Nebraska group—Golden and his collaborators. This view is elaborated on in Goldstein (1986). It is to be noted in this regard that Luria himself had nothing to do with the development of the Luria-Nebraska Battery, nor did any of his co-workers. The use of his name in the title of the battery is, in fact, somewhat controversial, and seems to have been essentially honorific in intent, recognizing his development of the items and the underlying theory for their application. Indeed, Luria died some time before publication of the battery but was involved in the preparation of the Christensen materials, which he endorsed. Furthermore, the method of testing employed by the Luria-Nebraska was not Luria's method, and the research done to establish the validity, reliability, and clinical relevance of the Luria-Nebraska was not the kind of research done by Luria and his collaborators. Therefore, our discussion of the theory underlying the Luria-Nebraska Battery will be based on the assumption that the only connecting link between Luria and that procedure is the set of Christensen items. Thus, it becomes clear that the basic theory underlying the development of the Luria-Nebraska is based on a philosophy of science that stresses empirical validity, quantification, and application of established psychometric procedures. Indeed, as pointed out elsewhere (Goldstein, 1982, 1986), it is essentially the same epistemology that characterizes the work of the Reitan group.

The general course charted for establishment of quantitative, standard neuropsychological assessment batteries involves several steps: (a) determining whether the battery discriminates between brain-damaged patients in general and normal controls; (b) determining whether it discriminates between patients with structural brain damage and conditions that may be confused with structural brain damage, notably various functional psychiatric disorders; (c) determination of whether the procedure has the capacity to lateralize and regionally localize brain damage; (d) determination of whether there are performance patterns specific to particular neurological disorders, such as alcoholic dementia or multiple sclerosis. In proceeding along this course, it is highly desirable to accomplish appropriate cross-validations and to deter-

mine reliability. This course was taken by Golden and his collaborators, in some cases with remarkable success. Because the relevant research was accomplished during recent years, it had the advantages of being able to benefit from the new brain imaging technology, notably the CT scan, and the application of high-speed computer technologies, allowing for extensive use of powerful multivariate statistical methods. With regard to methods of clinical inference, the same methods suggested by Reitan—level of performance, pattern of performance, pathognomonic signs, and right-left comparisons—are the methods generally used with the Luria-Nebraska.

Adhering to our assumption that the Luria-Nebraska bears little resemblance to Luria's methods and theories, there seems little point in examining the theoretical basis for the substance of the Luria-Nebraska Battery. For example, it seems that there would be little point in examining the theory of language that underlies the Receptive Speech and Expressive Speech scales or the theory of memory that provides the basis for the Memory scale. An attempt to produce such an analysis was made by Spiers (1981), who examined the content of the Luria-Nebraska scales and evaluated it with reference not so much to Luria's theories but to current concepts in clinical neuropsychology in general. However, despite the thoroughness of the Spiers review, it seems to miss the essential point that the Luria-Nebraska is a procedure based primarily on studies of empirical validity. One can fault it on the quality of its empirical validity studies but not on the basis that it utilizes such an approach. It therefore appears that the Luria-Nebraska Battery does not constitute a means of using Luria's theories and methods in English-speaking countries, but rather is a standardized psychometric instrument with established validity for certain purposes and reliability. The choice of using items selected by Christensen (1975) to illustrate Luria's testing methods was, in retrospect, probably less crucial than the research methods chosen to investigate the capabilities of this item set. Indeed, it is somewhat misleading to characterize these items as "Luria's tests," because many of them are standard items used by neuropsychologists and neurologists throughout the world. Surely, one can describe asking a patient to interpret proverbs or determine two-point thresholds as being exclusive "Luria's tests." They are, in fact, venerable, widely used procedures.

### *Standardization Research*

Fortunately, there are published manuals for the Luria-Nebraska (Golden, Hammeke, & Purisc

1980; Golden, Purisch, & Hammeke, 1985) that describe the battery in detail and provide pertinent information relative to validity, reliability, and norms. There are also several review articles (e.g., Golden, 1981b; Purisch & Sbordone, 1986) that comprehensively describe the research done with the battery. A brief review of this material shows that satisfactory discriminative validity has been reported in studies directed toward differentiating miscellaneous brain-damaged patients from normal controls and from chronic schizophrenics. Cross-validations were generally successful, but Shelly and Goldstein (1983) could not fully replicate the studies involved with discrimination between brain-damaged and schizophrenic patients. Discriminative validity studies involving lateralization and localization achieved satisfactory results, but the localization studies were based on small samples. Quantitative indices from the Luria-Nebraska were found to correlate significantly with CT scan quantitative indices in alcoholic (Golden, Graber, Blose, Berg, Coffman, & Block, 1981) and schizophrenic (Golden, Moses et al., 1980) samples. There have been several studies of specific neurological disorders, including multiple sclerosis (Golden, 1979), alcoholism (Chmielewski & Golden, 1980), Huntington's disease (Moses, Golden, Berger, & Wisniewski, 1981), and learning-disabled adults (McCue, Shelly, Goldstein, & Katz-Garris, 1984), all with satisfactory results in terms of discrimination.

The test manual reports reliability data. Test-retest reliabilities for the 13 major scales range from .78 to .96. The problem of inter-judge reliability is generally not a major one for neuropsychological assessment because most of the tests used are quite objective and have quantitative scoring systems. However, there could be a problem with the Luria-Nebraska, because the assignment of 0, 1, and 2 scores sometimes requires a judgment by the examiner. During the preliminary screening stage in the development of the battery, items in the original pool that did not attain satisfactory inter-judge reliability were dropped. A 95% interrater agreement level was reported by the test constructors for the 282 items used in an early version of the battery developed after the dropping of those items. The manual contains means and standard deviations for each item based on samples of control, neurologically impaired, and schizophrenic subjects. An alternate form of the battery is available. To the best of our knowledge, there have been no predictive validity studies. It is unclear whether there have been studies addressed to the issue of construct validity. Stambrook (1983) suggested that studies involved item-scale consistency, factor analysis, and cor-

relation with other instruments are construct validity studies, but it does not appear to us that they are directed toward validation of Luria's constructs. The attempt to apply Luria's constructs has not in fact involved the empirical testing of specific hypotheses derived from Luria's theory. Thus, we appear to have diagnostic or discriminative validity established by a large number of studies. There also seems to be content validity, because the items correlate most highly with the scale to which they are assigned, but the degree of construct validity remains unclear. For example, there have been no studies of Luria's important construct of the functional system or of his hypotheses concerning the role of frontal lobe function in the programming, regulation, and verification of activity (Luria, 1973).

#### *Evaluation*

It is well known that the Luria-Nebraska Battery, at this writing, remains a controversial procedure, and several highly critical reviews of it have appeared in the literature. Adams (1980) criticized it primarily on methodological grounds, Spiers (1981) on the basis that it was greatly lacking in its capacity to provide a comprehensive neuropsychological assessment, Crosson and Warren (1982) because of its deficiencies with regard to assessment of aphasia and aphasic patients, and Stambrook (1983) on the basis of a number of methodological and theoretical considerations. Replies were written to several of these reviews (e.g., Golden, 1980), and a rather heated literature controversy eventuated. This literature was supplemented by several case studies (e.g., Delis & Kaplan, 1982), in which it was shown that the inferences that would be drawn from the Luria-Nebraska were incorrect with reference to documentation obtained for those cases.

These criticisms can be divided into general and specific ones. Basically, there are two general criticisms: (a) the Luria-Nebraska Battery does not reflect Luria's thinking in any sense, and his name should not be used in describing it; and (b) there are several relatively flagrant methodological difficulties involved in the standardization of the procedure. The major specific criticisms primarily involve the language-related and memory scales. With regard to aphasia, there are essentially two points. First, there is no system provided, nor do the items provide sufficient data to classify the aphasias in terms of some contemporary system (e.g., Goodglass & Kaplan, 1983). Second, the battery is so language-oriented that patients with aphasia may fail many of the non-language tasks because of failure to comprehend the test instructions or to make the appropriate verbal

responses indicative of a correct answer. For example, on the Tactile scale, the patient must name objects placed in the hands. Patients with anomia or anomic aphasia will be unable to do that even though their tactile recognition skills may be perfectly normal. With regard to memory, the Memory scale is criticized because of its failure to provide a state-of-the-art comprehensive memory assessment (Russell, 1981). Golden has responded to this criticism through adding additional items involving delayed recall to the alternate form of the battery.

In providing an evaluation of the Luria-Nebraska, one can only voice an opinion, as others have, since its existence has stimulated a polarization into "those for it" and "those against it." I would concur with Stambrook's (1983) view, which essentially is that it is premature to make an evaluation, and that major research programs must be accomplished before an informed opinion can be reached. This research involves more definitive validation with a greatly expanded data base, an evaluation of the actual constructs on which the procedure is based, and assessment of its clinical usefulness relative to other established procedures such as the Halstead-Reitan or individual approaches. The following remark by Stambrook (1983) appears to reflect a highly reasoned approach to this issue: "The clinical utility of the LNNB does not depend upon either the publisher's and test developer's claims, or on conceptual and methodological critiques, but upon carefully planned and well-executed research" (p. 266). In this regard, one might note the discrepancy between the nearly half-century of work with Halstead's test and the barely ten years at this writing of work with Luria-Nebraska. Various opinions have also been raised with regard to whether it is proper to utilize the Luria-Nebraska in clinical situations. My view of the matter would be that it may be so used as long as inferences made from it do not go beyond what can be based on the available research literature. In particular, the test consumer should not be led to believe that administration and interpretation of the Luria-Nebraska Battery provide an assessment of the type that would have been conducted by Luria and his co-workers, or that one is providing an application of Luria's method. The procedure is specifically not Luria's method at all, and the view that it provides valid measures of Luria's constructs and theories has not been verified. Even going beyond that point, attempts to verify some of Luria's hypotheses (e.g., Drewe, 1975; Goldberg & Tucker, 1979) have not always been completely successful. Therefore, clinical interpretations, even when they are based on

Luria's actual method of investigation, may be inaccurate because of inaccuracies in the underlying theory.

## SUMMARY AND CONCLUSIONS

In the first part of this chapter, general problems in the area of standardization of comprehensive neuropsychological test batteries were discussed, while the second part contained brief reviews of the two most widely used procedures, the Halstead-Reitan and the Luria-Nebraska. It was generally concluded that these batteries have their advantages and disadvantages. The Halstead-Reitan is well established and detailed but also lengthy and cumbersome, and neglects certain areas, notably memory. The Luria-Nebraska is also fairly comprehensive and briefer than the Halstead-Reitan but is currently quite controversial and is thought to have major deficiencies in standardization and rationale, at least by some observers. I have taken the view that all of these standard batteries are screening instruments, but not in the sense of screening for presence or absence of brain damage. Rather, they may be productively used to screen a number of functional areas, such as a memory, language, or visual-spatial skills, that may be affected by brain damage. With the development of the new imaging techniques in particular, it is important that the neuropsychologist not simply tell the referring agent what he or she already knows. The unique contribution of standard neuropsychological assessment is the ability to describe functioning in many crucial areas on a quantitative basis. The extent to which one procedure can perform this type of task more accurately and efficiently than other procedure will no doubt greatly influence the relative acceptability of these batteries by the professional community.

## Chapter VI

# VOCATIONAL ASSESSMENT: FORMAL AND INFORMAL EVALUATION AND PRELIMINARY PLANNING

MICHELLE GECKLE, M.ED.  
LYNDA J. KATZ, PH.D.  
LAURA MARSHAK, PH.D.

### INTRODUCTION

As part of the societal and cultural values to which we have all been exposed, work, as a value, has had far reaching consequences for all of us in that society. Freud posited that the meaning of life is to love and to work. Erikson wrote that it is primarily the inability to settle on an occupational identity which disturbs young people. For those of us in the field of rehabilitation, a primary objective of the rehabilitation process is the optimal vocational adjustment of disabled clients.

A necessary step in the achievement of this objective is a thorough, accurate and complete vocational assessment of a particular client's actual and potential level of functioning as this often serves as the foundation for further rehabilitation planning and programming. This assessment needs to include an evaluation of the individual's current level of vocational skills, abilities, strengths and deficits as well as a measure of his or her vocational interests, aptitudes, abilities, basic academic skill levels, work values and working condition preferences. Less tangible, but of equal importance, is the assessment of the client's realism regarding a vocational choice. Factors such as his or her own self-appraisal, knowledge of occupational and educational options, career maturity, and overall attitude toward work, education or training need to be considered. In the words of Lytel (1978):

The counselor working with an emotionally disabled client is confronted with psychological limitations that may affect the client's work behavior in a variety of ways that are difficult to anticipate. With individuals who have a significant mental health treatment record, counselors may be reluctant to enter in rehabilitation plans because of a lack of convincing indicators of employability. As a result of this lack of information, a premature, unfounded decision may be made that a mental health referral is unemployable. To be effective in assessing the emotionally disabled client's employability, the

counselor should not rely on a single indicator, but must use several types of information. In listing the optimal characteristics of employability in mental health cases, Simmons (1965) included high compatibility among occupational choice, desired rewards on the job, personal values, and occupational qualifications. Combining information regarding the client's tested aptitudes with the counselor's appraisal of relevant client self-perceptions can offer a helpful synthesis in determining the employability characteristics of the emotionally disabled referral (p. 134).

Vocational assessment, then, serves a multitude of functions. It is the purpose of this chapter to examine these functions in detail. In addition, these authors will review the environmental factors which have an impact upon the assessment process, procedural and interpersonal; the administration and interpretation of vocational assessment batteries; vocational exploration and planning; the differences inherent in testing special population groups; and finally case material which is illustrative of success and failure and which has its roots in the vocational assessment process.

### A Rationale for the Justification of Vocational Assessment.

The purpose of assessment, the first or diagnostic phase in the psychiatric rehabilitation process, has been summarized by Hursh (1984):

- To screen individuals for decision-making purposes.
- To determine eligibility for services. According to most agency and service systems, such as the state-federal rehabilitation system, eligibility must be determined prior to identification of needed services.
- To identify training needs, including the identification of:
  - a) functional strengths and deficits;
  - b) characteristics of environmental settings which will support or act as barriers to independent functioning;
  - c) services needed to increase individual strengths and environmental supports and reduce or eliminate individual deficits or environmental barriers;
  - d) optimal functional outcome as a result of rehabilitation service delivery.
- To monitor individual progress through and throughout service delivery.
- To evaluate process and outcome variables relative to rehabilitation success (pp. 4-5).

"The objectives of assessment...reflect the range and complexity of decision making incidents that occur throughout the rehabilitation process." In order to respond to such questions, the rehabilitation practitioner must have available

assessment strategies which "attend to different information needs at specific times" (p. 5).<sup>6</sup>

Nevertheless, the rehabilitation practitioner who works with the individual with a psychiatric disability must rely on various means of externally imposed data gathering procedures from which to draw hypotheses, in a logical albeit predictive manner, and thereby formulate a plan of action. In other words, despite the lack of empirical research findings to support the validity of one particular kind or method of data gathering or assessment procedure to effectuate this goal, the practitioner must not only be sufficiently knowledgeable to draw upon what is best - most useful, most relevant, most workable, most efficient - from currently existing assessment procedures, but also to understand and interpret such data so that it yields operational guidelines, concrete recommendations and specific modes of adaptability.

Vocational evaluation is a diagnostic procedure in the overall assessment process whether it takes the form of interviewing techniques, psychometric techniques, work sample or situational assessment techniques or job site techniques. And, while recognizing that the track record of vocational evaluation with the psychiatrically disabled may be without statistically significant results (Cohen & Anthony, 1984; Hursh, 1984; Neff, 1970), it is, nonetheless, the state of the art as it presently exists.

One factor most often overlooked by numerous critics in the area of psychiatric vocational rehabilitation is that of the practitioner's working and usable knowledge regarding the process of vocational evaluation and what information such evaluations yield. Moreover, one cannot operationalize test results compiled from vocational evaluation procedures unless there is a basic understanding of what those results mean, how to communicate them and how to integrate them. Traditionally, the vocational rehabilitation counselor secures vendors to provide him or her with a vocational assessment of a particular client. Once the evaluation is completed the vocational counselor receives a report which he or she then ideally utilizes to make vocational training or job placement plans with the client. The report contains neat phrases concerning manual dexterity, visual-spatial relationships, vocational interests, work readiness habits and various other work related skills. With the non-psychiatrically disabled client the process then proceeds smoothly towards a successful rehabilitation outcome. With the psychiatrically disabled client this is most often not the case.

Psychiatric illness does not strike a single limb or vertebrae or nerve ending. Psychiatric illness is a pervasive phenomenon particularly with those individuals who suffer with a chronic mental illness. If we accept the definition formulated by Deire and Zarecki (1971),

A person is considered to have a psychiatric illness... "when we see evidence of social dysfunctioning coupled with symptoms of psychological and

biologic discomfort, and believe that the dysfunctioning and discomfort are caused by disturbances in the mechanisms that regulate mood and cognition" (p. 23).

then diagnostic or evaluative procedures must be examined and understood by all involved. Social dysfunctioning, behavioral symptomatology, and disturbances in the mechanisms of the body which regulate thinking and emotional stability or lability are far more complex handicaps to deal with in the vocational evaluation process than is any single physical or mental disability. Data compiled on an individual must first be understood in light of the person's disabling condition before it can be interpreted and thereafter utilized in a rational rehabilitation planning process.

Similarly, the mental health worker confronted with test results emanating from a vocational evaluation must understand the content of such an evaluation if he or she is to facilitate and support the client through the transition into the world of work. Sound treatment is based on a thorough and accurate assessment. If the assessment contains evaluative data which the clinician does not understand, and just as importantly cannot utilize, then the entire process is a futile exercise among professionals who operate within their particular domain of expertise and presume that once they have "done their thing" the job is done and their responsibility ends.

It is important at this point to illustrate this state of affairs as it currently has real impact on the vocational rehabilitation of persons with chronic mental illness. The mental health clinician receives a report from the local vocational evaluation and workshop facility which addresses the results of a client's performance on work samples in various simulated work settings. The report includes statements of the individual's manual dexterity in parts assembly, his or her productivity rate on an assembly line task, some observations regarding responsiveness to following directions and his or her high degree of distractibility and attention seeking behavior. The report concludes with a statement addressing the need for the client to continue in the work evaluation setting. After another period of extended work evaluation and personal work adjustment training the vocational evaluator sends his or her final report which states that the client is not suitable for vocational training or competitive employment at this time, and that the sheltered workshop job-slots are completely filled. The case is turned over to the state vocational rehabilitation counselor for disposition with a courtesy correspondence to the mental health clinician. It is possible that: (1) if the mental health clinician knew something about the vocational evaluation process in the initial stages, the client would not have been referred for the evaluation at that point; (2) if the mental health clinician understood the results from psychometric testing conducted previously, attempts could have been made to individualize the vocational work evaluation in the first place, or (3) if

the mental health clinician had a working knowledge of the process of vocational evaluation, plans could have been formalized to place the client in such a program at less frequent intervals and thereby use the alternate daytime for partial hospital programming and/or ongoing therapeutic intervention specifically geared toward adjustment in the work setting.

On the other hand, the vocational evaluator receives the psychiatric evaluation from the local mental health facility which delineates diagnosis, medication levels, past psychiatric history and/or hospitalization, frequency of treatment sessions and ongoing intra- or interpersonal problem areas with a statement that the client would like to return to work. At times in complete disregard of the nature of psychiatric, psychological and social problems, the client is placed in a ready-made work site setting where a standardized package of work sample tasks is utilized. The client is "plugged in" and the evaluation proceeds. Previous psychometric testing is reviewed. However, since the vocational evaluator has more faith in his or her chosen work samples than in aptitude or interest testing, which appear to him or her to be too abstract and not of real utility in the work place in light of job market demands and ease of placement, the evaluation follows the prescribed regimen, sometimes in direct contrast to the earlier testing results. The client with right-hemisphere deficits who lacks visuo-spatial skills is placed on an assembly line task which requires the manipulation and re-assembly of small motor parts. Very shortly thereafter he or she is described as highly distractible and attention-seeking.

Thus, the assessment phase, most critical to all future rehabilitation efforts, has been a dismal failure. Each professional has functioned within his or her own operational framework, has no understanding of what the other's data collection methodology could possibly mean, and therefore will not find it relevant much less usable.

The pervasiveness of this problem has been documented in a recent survey conducted by the Center for Rehabilitation Research and Training in Mental Health at Boston University (Hursh, 1984) regarding vocational evaluation services for psychiatrically disabled persons. A survey questionnaire was developed and distributed on a national level to vocational evaluators, administrators and service providers:

- (1) to identify tests and procedures currently being used with psychiatrically disabled persons;
- (2) to identify characteristics (predictors) which evaluators believe relate to future vocational performances;
- (3) to identify how satisfied practitioners are with current evaluations "technology" in working with psychiatrically disabled individuals;

- (4) to identify areas of need in vocational evaluation practice with psychiatrically disabled persons (p. 1).

The study concluded with the following statement:

...Although psychometric tests continue to be widely used, they do not provide information about work adjustment or interpersonal skills or relate to future vocational outcome...while work samples have been primary tools of vocational evaluations, they are not viewed as a significant tool with psychiatrically disabled persons...Situational assessment is widely used...and viewed as related to vocational outcome...Unfortunately the scope of situational practice is limited and situational activity is not clearly defined...Job site evaluation is seen as a viable and effective tool but is not widely used...

Clearly, practitioners see that for psychiatrically disabled individuals, traditional tests used in traditional ways do not provide information useful for rehabilitation programming efforts...Training for members of the overall evaluation team to understand how to integrate vocational information and to better understand vocational functioning within the rehabilitation process was encouraged (p. 25).

Descriptions of the various methods utilized in the vocational evaluation process are readily available in the literature (Hursh, 1984; Hursh & Anthony, 1983; Pruitt, 1977; Wansborough, 1980). It is not our intent to provide textbook descriptions of situational evaluations or the commercially packaged work sample evaluation systems available as other writers have done this quite eloquently. Rather, the focus of this chapter will be on the experience of a particular hospital and community mental health center-based psychiatric rehabilitation service, the process of formal and informal assessment procedures, and the inherent problems and difficulties which are unique to the vocational evaluation of individuals who have major psychiatric illnesses.

#### THE PROCESS OF REFERRAL

The point at which the process of vocational assessment is initiated typically occurs well in advance of the initial intake interview between client and counselor. Upon receiving no more information than the client's name, whether via receipt of a formal referral form or an informal telephone call from the referring party, the counselor may begin the process of gathering information about the client which will constitute an integral part of the vocational assessment.

#### Use of the Medical Record

First, and of particular relevance to work in an acute care and community-based psychiatric setting, the clinician/counselor involved in vocational assessment, which is one aspect of a multidimensional, comprehensive treatment

approach, should make use of data which is already collected and available. A secondary gain, which has derived from the attention given the client's medical record of late as a result of increasing demands for documentation and accountability by utilization review committees and various third party agencies, is the extensive information about the client which is available and relevant to vocational assessment. This information may, at a later date, expedite implementation of the rehabilitation plan. While some clinicians prefer to conduct the initial interview prior to reviewing information already on record, we would not recommend this approach for several reasons. First, one runs the risk of boring some clients or making them feel as though they are getting the runaround, i.e., that the clinician was not interested enough to have taken the time to prepare properly. This may only increase the frustration and pessimism that may already be present, damage the clinician's credibility with the client, and altogether, waste time which may be used more productively for the clinician and the client. Secondly, at the point in hospitalization that the client arrives for rehabilitation services, he or she usually will present an educational or an employment history in summary form, thus the clinician may receive only sketchy information from the client which will have very little utility in the long run. Of course, clinicians must be sensitive to the fact that information compiled in a client's medical record is subject to incompleteness, lack of contextual specificity, bias, and error, and exercise caution and judgment in the use of this data.

It is important, however, to remember that many clients are very sensitive with respect to what they regard as confidentially shared information about themselves. With highly guarded and/or suspicious clients, care should be exercised in approaching the topic of the client's past medical record or consultation with his/her physician or referring party. The clinician must point out to the client the need to clarify the request for service so that he/she has a general idea of why the client has been referred, and what the client is interested in. While the client may become angry or accusatory, feeling a trust has been betrayed, the counselor should not permit the client to put him or her on the defensive. It is a mistake to allow room for debate or argument on the clinician's "right" to relevant information. The clinician/counselor may reply that there are pieces of information about the client that are clearly relevant to vocational assessment and planning in order to provide the highest quality services possible. Should the client continue to take issue with this, it may be useful to deal with the reasons behind the client's obvious reluctance to share information, being careful not to put the individual on the defensive by saying, i.e., "What are you so afraid of?" Rather, the clinician should explore the reasons behind the anger and defensiveness and what implications this may have for future interactions. Also, it is important for the client to know with whom the clinician intends to share the contents of sessions, the clinician's role in the overall treatment process,

and the clinician's responsibility to serve as a liaison with other professionals who may be involved in the client's treatment.

#### Communication with the Referring Party

Secondly, the referral process is an important linkage between rehabilitation services, acute care inpatient units, and their respective outpatient services. In keeping with the basic assumption that all rehabilitation endeavors are collaborative efforts and to insure continuity of care, referral apparatus and procedures should be well-established, efficient, and designed to enable quick and easy referral. We have found this to be of particular importance in an acute care facility and in any facility which also provides training and education to a variety of health care professionals and students with limited knowledge of rehabilitation services and their availability. Dispensing a supply of referral forms, providing a written, concise description of services; providing the names, locations, and phone numbers of clinicians who are available for consultation and questions; and building in a means for confirmation that the referral has been received and that the initial appointment has been scheduled are extremely important logistical procedures.

It is important to remember that the information gathered from the consultation/referral form cannot substitute for direct communication between the counselor and the referring party. A good time to speak directly with the referring party is after the counselor has had the opportunity to review all available information about the client and following the initial interview with the client. At this time it is best to: 1) clarify the request for services; 2) determine the priority that vocational rehabilitation services have in the client's overall treatment; 3) inquire into the client's current psychiatric status; and finally, 4) determine the approximate length of inpatient stay and disposition plans.

The timing of rehabilitation assessment/services must be synchronized with the treatment team plans. For example, the psychiatrist or primary clinician may have recommended to the client that he/she take six months at a minimum to recuperate from his/her hospitalization prior to actively pursuing vocational endeavors. (This is not an unusual occurrence with persons with schizophrenia and persons with severe depression.) Or, the referring inpatient clinician may make a very specific request, asking only for an assessment with concrete recommendations and short-term goals in order to insure that the client's follow-up clinician will be aware of the client's need for continued vocational rehabilitation services. Others may request documentation of intellectual capacity, aptitudes, and reading comprehension level in order to secure vocational rehabilitation funding which will enable the client to continue his/her college education or vocational training program without need for any additional services from the rehabilitation practitioner.

This time can also be used to inquire about any special precautions or remarks which may have been noted on the referral form, i.e., the client has a history of extreme hostility toward female therapists; is manipulative, demanding, or has a sense of entitlement; has a pattern of overloading or decompensates easily under stress. In some instances it may be necessary to communicate to the referring party that the referral seems premature and what may be done to better prepare the client for active involvement in vocational rehabilitation.

### THE INITIAL INTERVIEW

#### Establishing Rapport

Goals for the initial interview include the following:

- 1) Establishment of rapport--"hooking the client in"
- 2) Initial formulation of the presenting problem(s) -- what is his/her problem and why does he/she have it
- 3) Initial formulation of the client's perception of his/her problems and how he/she prioritizes them
- 4) Clarification of the client's expectations of services and goals and, usually, clarification of services and intervention strategies available
- 5) History taking and information gathering
- 6) Initial determination of services and resources needed
- 7) Preparation for future assessment and assignment of tasks

These goals may need to be modified or narrowed and may vary depending on the nature of the consultation request. Moreover, the counselor should bear in mind that it may be impossible to achieve all of these goals in a single session. Factors such as: though blocking; tangentiality; extreme guardedness; suspiciousness; various neurovegetative symptoms of depression; attention deficits; memory and concentration difficulties; fatigue; preoccupation with other family or psychiatric concerns that may be paramount to the client at the moment; impending discharge; re-emergence of symptoms; or dissatisfaction with disposition plans may interfere with and necessitate modification in the process and pace of the initial interview.

The importance of the initial meeting between the client and counselor should never be underestimated or taken for granted. "Getting off on the right foot", particularly with outclients who are not going to be escorted to the office for future sessions, is an indispensable goal. Rapport is not merely a few introductory comments, a polite breaking the ice before getting down to the "nitty gritty" of history-taking and information gathering. Special care needs to

be taken with clients who have a chronic illness or a long history of involvement with various human service agencies and professionals, but who have experienced minimal positive changes in the quality of their daily lives. Because these clients may frequently be only marginally successful in their attempts to achieve vocational success or maintain employment, they may be highly demoralized, pessimistic, and hopeless, having run the gamut from partial hospitalization programs to several trips through all of the local vocational rehabilitation training facilities. In some cases, the rehabilitation counselor may be the fourth or fifth specialized service professional that the client has seen already in one day!

Conversely, the client may be the fourth or fifth chronically ill and very needy client that the counselor has seen that day. The counselor/clinician needs to guard against writing such clients off because of a stereotypical image of them as unable to make decisions for themselves, helpless, confused, passive, unmotivated or uncooperative. The individual, on the contrary, may be highly suspicious and guarded and may be questioning the counselor's motives. Others may be highly defensive, needing and wanting assistance, while at the same time trying to bolster an already shaken self-image in order to maintain a sense of control over their own lives. Some clients may be in a state where symptoms are remitting but have not as yet cleared. They may be somewhat disoriented or confused from the side-effects of various medications (drowsiness, blurred vision, motor retardation/acceleration, or high distractibility) that have just been initiated or have not yet reached a therapeutic level. Other chronically ill clients may suffer on a nearly continuous basis from various symptoms, such as distracting auditory hallucinations, chronic fatigue and low energy, anxiety, etc.

At the very least, at the time of the initial interview, the client is likely to be quite anxious and may feel very reluctant to share revealing personal information. There may be attempts to present the self in a favorable light through evasiveness around past history because of the client's sense of embarrassment or shame or as an effort to convince the counselor that he/she is worthwhile and therefore deserving of services. On the other hand, some clients may view the counselor as an obstacle between them and some desired vocational goal, someone they must convince or whose support is necessary in order to obtain vocational rehabilitation funding or a medical release from work in order to secure public welfare or Social Security benefits. Anxiety may also be due in part to the client's expectations of being "tested" immediately in some as yet unknown manner, coupled with the not uncommon expectation that his/her performance on these tests will have significant, far-reaching, and irreversible effects on the future. Some clients may then become angry or disappointed upon initially learning that they are not going to be tested immediately, particularly if they are counting heavily on tests to provide "solutions" or answers to their

problems. Early on then, the counselor/clinician may need to assure the client that "testing" is likely to follow in future sessions.

During this initial interview, the counselor/clinician must communicate to the client a genuine concern for the client's well-being, respect for his/her integrity, and a desire to help him/her further desired goals. The counselor must demonstrate a willingness to listen and encourage clients to relate in their own manner. Care should be taken to follow-up on whatever issues the client chooses to share rather than attempting to rigidly adhere to the counselor's agenda. This may not be an easy task in light of the fact that many clients present with the general expectation of being examined, dissected, talked at and acted upon. In some instances clients seem to prefer this type of treatment, trusting that the "expert" knows best, unable or unwilling to accept responsibility for their own treatment decisions, or simply not knowing quite how to assume an active role in their own rehabilitation. Moreover, it is unlikely that such clients will be able to greatly modify such a stance in any hurry just because the counselor is informing them that their input and active participation are not only desirable but necessary. This is not to say, however, that the counselor need not be responsible for providing structure and direction for the interview. In fact, with clients who are highly agitated, whose speech rate is accelerated, tangential, or circumstantial, or with clients who volunteer little or no information, responding to direct questions with monosyllables or brief, unelaborated replies, the counselor may have to make greater efforts to control the pace and content of the interview.

#### Initial Formulation of the Presenting Problem

Generally, individuals who have been referred for vocational rehabilitation services have, at the very least, some uncertainty regarding their vocational future, and optimally, present with a desire to clarify questions about future plans and to learn more about their interests, abilities, and potential. The problems presented by individuals referred for vocational rehabilitation services may be divided into two broad categories: 1) a lack of career direction or goals because of insufficient information about themselves, their interests, abilities, and potential; and, 2) a lack of information about occupational possibilities and the availability of educational or training options to support a vocational goal.

These problems may arise from a wide variety of sources. The individual may have had little or no experience in the process of developing a realistic and feasible vocational goal because of little exposure to the world of work. For example, individuals who have suffered or are facing a severe financial reversal or loss of income and are faced with having to re-enter the job market after an extended absence, adolescents entering the job market for the first time, or individuals who previously functioned well in a vocational area but as a result of their psychiatric illness are not able to resume their former occupations will

request guidance or direction in exploring satisfactory or alternative occupations, and, in some cases, meaningful and productive but avocational activities and options. Individuals with chronic or recurrent episodes of psychiatric illness may also have impaired vocational development because of an inability to maintain employment of longer than brief periods of time. Often individuals with personality disorders display character traits which contribute to ongoing difficulties at work, such as conflictual relationships and chronic dissatisfaction and frustration with their employment situation. At other times the clinician encounters individuals with certain personality disorders who change jobs and training programs rapidly, in a seemingly endless search for the "perfect" job.

Another area which is impaired by psychiatric illness and in which most clients evidence mild to severe deficits is that of job-seeking skills. Areas of common deficits include: the ability to seek and follow-up on sources of job leads, to present one's self in a positive light, and to answer "problem" questions on job interviews. To seek and obtain employment in today's highly competitive and complex job market is a challenging and taxing experience even for individuals without a psychiatric history or illness. For the individual with a psychiatric disability, this can be a terrifying and seemingly impossible task.

#### Initial Formulation of the Client's Perceptions of Problems

Often the client presents with multiple problems... "my only source of income, public assistance, will be cut off in three months... I need a job... but what I'd really like to do is go to auto mechanic's school because I enjoy working on cars and I'd be able to get a better paying job as well." It is essential in this initial interviewing phase to clarify the client's perception of his/her problems, and how he/she prioritizes them. Perhaps it will be necessary to delay the formal vocational assessment, in order to determine the feasibility of the longer range goal (auto mechanic's school), until the more immediate concerns of improving job seeking and interviewing skills have been addressed (loss of income in three months). At other times, the client may not perceive some things as problems, ... "I'm unemployed because the boss is a jerk... no one will give me a job", although, "the doctor said this would be good for me." The client's perception of his/her needs or problems must be clarified, as well as factors contributing to these perceptions.

#### Client's Goals and Expectations of Services

In attempting to clarify the client's request for services, the clinician cannot assume that the client has an adequate and clear understanding of why he/she has been referred or what services are available. More often than not, clients have only a general or rather vague idea... "I think I'm here for testing or some kind of job counseling." Other clients may have unrealistic expectations of services. Many clients arrive with the expectation that the counselor has a job waiting for

them or will immediately refer them to a job. Some clients will expect the counselor to administer some tests, ask a lot of questions, and through some mysterious formula come up with "the right job" for them.

These common misconceptions will often necessitate a brief explanation of services, the counselor's role in overall treatment, and potential benefits for the client. How the counselor may be able to help with vocational or employment concerns must be presented in a meaningful and understandable manner. "Your doctor told me that you had to drop out of school after you became ill, but that you've been thinking about returning to college or perhaps getting into a secretarial training program, and that you were interested in exploring the possibilities... Generally, people come here who are interested in learning more about themselves, the kinds of jobs they might be best suited for... or who have questions about work or school... getting a job or going to school."

In instances where a vocational assessment has been specifically requested, and it will be the first phase in the individual's rehabilitation plan, the counselor must communicate the goal(s) and purposes of the assessment and how the individual may benefit from it. For example, "through this assessment you will gain some information about yourself -- your interests, abilities, aptitudes -- and information about the world of work, career choices, and training and educational programs, in order to help you answer questions you may have about your occupational future, and to make good decisions for yourself. We will try to help you find a good fit between your interests and abilities and the nature and requirements of different jobs."

#### Taking the Vocational History

At the time of the initial interview it is difficult to determine what information will be relevant or useful; thus, the counselor should explore in breadth, knowing that the most relevant information can be pursued in greater depth at a later time. This strategy provides the opportunity to assess the client's self-presentation and his/her perception of his/her difficulties and current situation. The clinician/counselor should note the client's reactions to questions about past educational and work experience. Hypersensitivity to criticism, suspiciousness of the counselor's motives for questions, and evasiveness about particular topics (such as reasons for job terminations or changes in jobs) may be evident and partially related to situational factors. For clients there is often a sense of being on trial, having to prove themselves worthy or a "good investment" in order to receive services, a sense of being judged on their track record. This may be very discouraging and frustrating for a client who has had no work history to speak of or a series of failures in attempts to complete training or hold a job.

The individual is being asked to reveal or share what he/she is likely to perceive as very personal and highly sensitive information about him self/herself. In this society, with the value and importance attached to work, one is often

equated with what one does vocationally. The ability to work and achieve financial independence are considered to be hallmarks of maturity and adulthood. Clients may be all too keenly aware of deficits in these areas and often have very painful memories associated with school and work and the failure to achieve a highly desired goal. Other clients may leave out or downplay the negative aspects of their history in an attempt to present themselves in a very favorable light, to prove worthy of highly desired services. To attempt to assess motivation for comprehensive rehabilitation services on the basis of the initial interview and available background information is not possible and should not be attempted at this time. To do so would only mean ruling out a majority of referrals or potential clients, and is, moreover, contradictory to fundamental principles of rehabilitation.

Because clients are often poor historians and symptoms frequently interfere with the interviewing process -- thought-blocking, tangential/circumstantial speech, anxiety, distractibility, drowsiness secondary to medication -- the counselor should not be in a hurry to force the interview to completion. The initial interview may not be completed in one setting. Some clients sometimes ask to end the session early, or with some clients, such as those still in the active phase of a manic episode, the counselor may have to exercise more control over the content, structure and time limits of the discussion. It is important to remember that educational and employment-related history taking and information gathering consist of much more than recording basic facts -- names, dates, places. With the psychiatrically disabled client, the realm of relevant information is much more broad than with the physically disabled client. Attention must be given to the less tangible but equally important aspects of previous educational or vocational experiences, such as involvement, career maturity, worker attitudes and behaviors.

Work personality, as defined by Gellman (1967), is "...the characteristic pattern of work activity displayed by a person in a work situation. The work personality incorporates work attitudes, behavioral work patterns, value systems, incentives and abilities. It is the behavioral configuration regarded as necessary to function effectively in a work setting." (p. 283) Adjustment to a work environment includes not only task mastery, competencies and skills, but social functioning and characteristics of the environment. For instance, persons with mental illness often experience difficulty in detecting and staging within the covert, unwritten behavioral and attitudinal "norms" which operate in all work settings. Obtaining information which enables the evaluation of specific and general employability factors should yield a profile of characteristics relevant to career planning for use in the later stages of vocational counseling and career planning. Finally, as always with persons with psychiatric disabilities, history taking must include a description of assets, demonstrated skills and abilities and strengths which can be utilized and built upon, not just the client's failures, deficits or liabilities.

### Employment Data

The history taking process should include, but may not be limited to, the following

- what were job duties and responsibilities;
- how were jobs obtained--independently, through a friend or relative, etc.;
- were formal interviews required in order to obtain jobs;
- where were jobs located;
- what factors influenced decisions to accept jobs and to leave jobs;
- how long did jobs last;
- what aspects of jobs were initially attractive to the client; which were problematic; which were gratifying;
- what kinds of situations were faced on jobs--routine procedures or continual changes in duties and responsibilities;
- what situations were easier or more difficult for the client to handle;
- what were sources of satisfaction and dissatisfaction on jobs;
- what aspects of jobs did the client find stressful;
- was the stress occasional or on a nearly continuous basis;
- what were the means of coping with stress and dealing with difficult situations;
- what were the client's initial expectations of jobs and did these coincide with the actual jobs themselves;
- what degree of social contact or interaction was required on jobs;
- were complex, higher level social skills required, i.e., persuasiveness, negotiating, compromising, supervising, coordinating, planning;
- which did the client prefer, dislike, or find difficult.

A broad yet comprehensive exploration of the client's employment history provides information which the client and counselor can draw upon in order to address concerns over pending career or vocational decisions. For example, one client who functioned very well as a janitor on a solitary night shift, contemplated changing to a similar job on a daylight shift because it would provide a better income. However, he was concerned about whether this would be advantageous because it would require substantial changes in non-technical aspects of work performance and he was uncertain as to how this might affect his job performance. Specifically, the daylight job required increased contact with co-

### Vocational Assessment

workers, closer proximity to supervisors, more frequent public contact, and stricter adherence to a dress code. By examining his history of meeting similar demands in past employment endeavors, the client was able to make a more informed decision about whether or not to transfer to the daylight job.

While clarifying the client's employment history, it is important to explore both the objective and subjective reasons given for the termination of specific employment endeavors. Clients are often reluctant to explore details surrounding negative employment terminations. Nevertheless, this aspect of clarifying the employment history is not to be avoided and should be approached with sensitivity. This type of exploration is crucial because the events most clearly related to termination are usually not the result of an isolated or abrupt incident. The identification of the factors which contributed to job loss or losses can be identified and either remediated and/or taken into account in vocational decision making. Quite often, an individual's job losses have been related to difficulties in meeting the social demands of work; these difficulties are often described by the client as simply a matter of experiencing one or more "personality conflicts" with co-workers, supervisors and/or employers. Frequently, clients lack an understanding of what a "good working relationship" with respect to their co-workers means, and experience difficulties in maintaining such or in maintaining boundaries. This lack of knowledge regarding how to maintain effective working relationships can manifest itself in a variety of ways. For example, a client was continuously cited by his boss for socializing or talking too much on the job and at improper times. A second client, in an attempt to maintain a total separation between his work and personal life, created extra distance between himself and his co-workers by telling them that his hands were classified as "lethal weapons." Others relate fairly well with co-workers but experience problems with authority figures such as supervisors and resent being told what to do.

### Self-Appraisal and the Meaning of Work

It is also important to explore the client's perception of his/her own work performance, a self-appraisal of his/her abilities, skills, and general worker characteristics, and the sources, both internal and external (corroborating information, indicators of performance such as raises, promotions, length of employment, etc.), of his/her self-evaluation. One client described herself as "I can do it all." She had had a job as a secretary/bookkeeper and all-around office worker for a small family-owned plumbing business. She had aspired to a position as business manager and felt the only obstacle in her way was the lack of a formal degree. She revealed that she had been unable to complete the first college-level business course she had attempted 3 years earlier. Her MMPI profile was similar to individuals who were described as having a decompensating obsessive-compulsive disorder and she was hospitalized with complaints of depression. It

was important then to ascertain the client's perception of her failure to hold her job and of the difficulty she experienced in achieving a desired goal. A client's acceptance of any limitations imposed by a psychiatric illness, particularly tolerance for stress, while not easily defined, is usually a very significant factor in any given client's self-appraisal.

The need to assess the meaning and value of work to the client, presently and in the past, is also essential. What needs does the client expect that work will fulfill--financial independence, material comfort, security, "something to occupy my time, keep me busy", meeting new people or fulfilling social needs, recognition, feeling productive, or as something to do to avoid negative consequences? The client's perception of locus of control, his/her own ability to effect a vocational future, exert influence, or make changes vs. a belief in fate, chance, a religious deity, or other uncontrollable influences gives a sense of the client's optimism regarding his/her vocational future and whether he/she perceives that efforts will "pay off"; that is, result in any real, concrete, and positive changes in the quality of his/her life.

The counselor should also inquire into any previous exposure or involvement with vocational counseling that the client may have had, and whether these were positive and helpful experiences or nonproductive and demoralizing experiences, and why. Many clients with chronic illnesses have received vocational rehabilitation services on more than one occasion in the past, and may have undergone previous vocational assessment, work evaluations and/or personal work adjustment training. While care must be taken not to accept the results of previous assessments at face value as the client may have been entering an active phase of illness or experiencing an acute life stressor at the time of the evaluation, it is a good idea to investigate the extent and kinds of services previously provided not only to prevent duplication of services but also to complement the usefulness of such prior services and to reduce the likelihood of splitting.

#### Social and Environmental Factors

The counselor needs also to determine what sources of income are available to the client and any financial obligations he or she may have. Often for clients there are possible disincentives to work. After a 10 year psychiatric history, during which the client has received SSDI benefits, it is likely that he/she may be unwilling to jeopardize his/her status by earning more than \$200.00 per month. Most clients (and many professionals) do not have a clear understanding of SSI and SSDI and have in common the misconception that one cannot earn any money at all and continue to receive benefits. Such financial concerns seem to have greater significance for clients than often is recognized by rehabilitation professionals. It may not be in a client's best interest to pursue gainful employ-

ment, and yet this seems difficult for some counselors to accept as these clients will not be considered a "successful closure" by state vocational rehabilitation agencies. When clients are on SSDI, Veteran's Disability, or private insurance disability payments they tend to perceive the risks as even greater. It seems that clients have little or no belief in the "nine month trial work period" which is supposed to serve as an incentive; some may not even be aware of it. Their skeptical stance is somewhat justified in light of the near superhuman efforts required to obtain benefits in the first place, including making the client appear as "sick" or disabled as possible on the part of their primary clinician.

Loss of other related benefits (subsidized rent and housing programs, eligibility for energy/utility assistance, reduced transportation costs, medical assistance) is also an important consideration to clients, particularly if they have had multiple hospitalizations and fear recurrence of illness. The middle-aged or elderly who fear worsening physical health problems have a difficult time understanding that they cannot be denied needed medical care on the basis of an inability to pay for services.

Whether or not the client has a supportive family or other family-like support systems is a relevant concern during the initial data gathering period. Some families may be intolerant of the client, feeling themselves drained both financially and emotionally and may be exerting great pressure on the client to recover from his/her illness and resume a breadwinner role. Some who live at home may experience an atmosphere which is not conducive to rehabilitation efforts. It may be noisy, crowded, or highly conflictual. Is there a place and time to study, are there daycare arrangements for children, is educational achievement or having a legitimate means of support included in the family's values? Other clients may be relatively isolated and lacking in family supports. In these instances their involvement with other social and human service agencies is important to assess. While for still others, religious involvement or social group involvement, such as a leisure learning dance class, are extremely important activities. One client would not consider attending group therapy meetings because they were offered at the same time as his bowling league--a source of achievement, recognition, and satisfaction for the client.

Assessing the client's daily routine and use of leisure time can yield information for future vocational planning. One can learn much just from the client's sleep schedule for example. It is not uncommon for clients to sleep during the greater part of the daytime and remain awake the greater part of the night as a means of tiring stress or avoiding the stress of having to deal with other people. One client continued to express the desire for a job, yet was unable to modify his current sleeping schedule of 5:00 a.m. to 5:00 p.m., which effectively ruled out even applying for employment.

### Educational Background

A client's previous educational experiences will have, in many cases, a real influence on future training or educational programs that may be planned as part of the rehabilitation process. Whether or not the client was in regular or special education classes, the client's reaction to failed grades, particularly difficult classes or easier classes, should be explored. One client, for example, was held back in the second grade which put him in the same class as his younger, more successful brother. He considered this to be a very significant event and decided not to compete with this brother in anything from then on. At the age of 23, he continued to use this event as a reason for not completing any of several, successive training programs.

Further discussion should center on the client's high school curriculum, whether it had an academic, vocational skill, or a general business preparatory focus. How did the client feel about being a student? What were his/her relationships with teachers and authorities; how adequate were his/her study habits, were there any marked changes in grades or school attendance (why and in response to what)? Did a particular teacher or anyone else serve as a positive role model or mentor with special influence on the client? How involved was he/she in sports or other extracurricular activities? What was the quality of his/her social and peer relationships? If the client dropped out of school, what were the precipitating factors, and the family's attitude toward this? Were there any attempts at further education or training since leaving high school? How were they financed? The issue of previous arrangements in order to finance schooling is particularly important with regard to defaulted student loans, as it may mean that the client is ineligible for further financial aid for new training or education in the future, or that he/she may be eligible for rehabilitation deferment on current student loans.

What is the client's attitude toward additional training or education at this time or in the near future? The counselor needs to begin to assess the client's ability to tolerate the structure and demands of school, and if schooling can occur only on a part-time basis, which lengthens training time, can the client sustain motivation for this longer period and would the family be tolerant of this?

### Medical, Psychiatric and Psychological Background Information

While most of this information should be available in the client's medical record, what are of primary importance to the counselor are any functional limitations which may impair the client's ability to perform certain kinds of activities, and whether treatment or intervention can remedy some or all of the functional impairments. The counselor needs to be aware of whether the condition is progressive or can be controlled with ongoing treatment, the client's acceptance or non-acceptance of these limitations, and whether refusal to accept

limitations serves a defensive/protective function for the client.

As with the medical history, the client's psychiatric history is usually well-documented in the medical record. Here the counselor should be aware of the chronicity of the illness, and whether there is likely to be a need for rehospitalization in the future. What were the precipitating factors and what are current stressors, and what is the client's attitude toward and acceptance of the need for treatment, including medication? How the client's illness or symptoms have interfered with independent living or vocational goals, have disrupted relationships or the ability to get and keep employment, or have affected the ability to complete educational or training programs in the past need to be assessed.

Moreover, other psychological testing is frequently available in the medical record and as part of the holistic treatment approach, psychometric, objective tests can yield information relevant to preliminary planning and future career planning. Neuropsychological tests may suggest strategies to be employed or methods to be used in teaching or learning for the client with implications for the training environment. (See Chapter II for a more in-depth discussion of the use of psychological and neuropsychological assessment procedures in rehabilitation planning.)

### PREPARATION FOR FORMAL TESTING

Once the gathering and evaluation of historical and current situational data is well on its way, it may be necessary to introduce the idea of formal testing as part of the vocational rehabilitation process. Again, the element of timing is critical. Optimally this should occur when the client presents with the desire to learn more about him/herself with regard to formulating career plans or goals. The client must be sufficiently engaged and willing to invest him/herself in formal psychometric testing. Since symptomatology may interfere with the testing process, it is wise to avoid testing while the client is in the acute phase of his/her illness. It may be necessary to inquire into such factors as to whether the client has been in the hospital long enough to adjust to the hospital routine and is sufficiently integrated into the therapeutic milieu, has gotten sufficient relief from painful or disturbing symptoms, and whether, in his/her opinion, high priority concerns have been addressed or assurances have been given that these will be worked on, thereby permitting the client to invest him/herself in vocational testing.

Frequently, it becomes necessary to deal with the fact that many clients are unfamiliar with test-taking situations, may not understand the purposes for testing, or may not be able to see any potential benefits to themselves from the testing process. Adults who have been long out of school and who are not test-wise are often overly concerned with accuracy at the expense of speed which can then result in poor total performance scores.

For others, since paper and pencil tests are seen as similar to classroom tests, they are often associated with a history of failure and negative experiences. Other

clients may have had limited experience with tests. Pre-testing orientation exercises may be useful for some clients to help decrease anxiety and increase confidence in their ability to take tests.

The client should understand why the test is being given, the kinds of information it will yield, and how this information will be useful in vocational planning. Letting the client know that the results will be reviewed and interpreted with him/her is also helpful. Clients often view tests as "for the doctors" and expect that they themselves will never see the results. Establishing the relevancy of vocational test results to later educational and training options and potential career direction also helps to decrease anxiety, increase understanding and, consequently, motivation for investment in testing.

In reviewing the relevancy of vocational testing, the counselor should emphasize that results from the overall testing process are more inclusive than any single component of testing, and that while each test plays a useful and contributory part in the overall process, testing of various kinds is still only one aspect of career decision-making. This type of information can help remove the threat of forfeiting a desired outcome--a job or eligibility for further services--for the client who fears poor scores will result in such exclusion. In general it is important to let the client know how the assessment will proceed, what kinds of tests will be administered, and approximately how long the procedure will take. While such small details may seem unimportant to counselors, they are often highly important to clients who may wish to know when to prepare themselves for testing.

Finally, it is usually necessary at times to ascertain a client's reading comprehension level to aid in test battery selection. Age and years of education completed are not always valid indicators in and of themselves. The Wide Range Achievement Test-Revised (WRAT-R) (Jastak & Wilkinson, 1984) is a reliable and easy to administer measure for screening purposes. However, since only reading recognition is measured on the WRAT-R, a measure of reading comprehension is indicated. This is important because most vocational tests are written on a sixth grade reading comprehension level. In some cases, the counselor may need to use a non-reading battery or may opt to read test items aloud.

Counselors are responsible for being familiar with the APA standards for test users as well as standards for tests, manuals, and reports in the book Standards for Educational and Psychological Tests (1974) and should know the tests intimately. It is also the counselor's responsibility to establish conditions which will enable each examinee to do his/her best, above and beyond the standard testing conditions, i.e., noise level, light, ventilation, room temperature, seating arrangements for group administration. Where it is permissible to do so, the counselor may need to modify standard administration procedures when

working with psychiatric clients who may be highly distractible, may exhibit psychomotor agitation or retardation, may experience thought blocking or word finding difficulty, may tire quickly, or who may have difficulty in comprehending, and particularly, remembering test instructions. It may be necessary to (1) repeat instructions; (2) provide further clarification; (3) shorten the testing session or provide frequent breaks; (4) provide verbal redirection to tasks; (5) control the pace of test administration (slowing it down for impulsive responders); or (6) decrease the client's level of anxiety by appropriate modulation of voice tone and rate. The counselor's presentation and behavior during test administration can significantly influence the quality, reliability, and validity of test results. While, after reviewing test instructions with the client, counselors may be tempted to permit clients to take certain kinds of vocational instruments (occupational interest inventories like the California Occupational Preference System (Knapp & Knapp, 1974, 1982) or the Edwards Personal Preference Schedule, (Edwards, 1953, 1959) out of the counselor's office and on to the inpatient unit or home with them, it has been our experience that caution should be exercised with this practice as often the counselor will have to deal with misunderstood instructions or the lack of internal consistency with the same instrument completed in multiple sittings.

### Behavioral Observations

It is essential that counselors be proficient and efficient with testing procedures so that attention may be given to the very important observations of the client's behavior and responses during testing. The client's reactions during testing may be considered a sample of that individual's behavior or response set toward evaluative and/or demanding activities and stress. Also, the client's overall performance must be considered in light of such conditions. Counselors may find it helpful to employ a separate checklist of behavioral observations with enough space to jot down significant observations. Factors which should be noted include the following:

- Affect: broad, within normal limits, flat, constricted, labile, angry, blunted;
- Mood: euthymic, dysphoric, euphoric;
- Attention/Concentration: distractible, marginally engaged, need for redirection to task, sustained;
- Level of Anxiety: mild and appropriate, moderate, severe, hypervigilant, scanning;
- Blocking: interrupted train of speech before thought/idea is completed;
- Psychomotor Agitation/Retardation: excessive motor activity associated with inner tension, restlessness, visible slowing down of

- physical reactions/movements;
- Speech: circumstantial, indirect and delayed in reaching the point, pressured/accelerated, loosening of associations, perseverative, self-deprecatory or excusing one's poor performance;
- Cooperation: defensive, guarded, hostile, suspicious, passive, submitting, eager, willing, challenged, invested, interested, fearful, timid;
- Response Style: impulsive; jumping ahead in directions to ex- ample problems; greater concern with speed than accuracy; con- cern just to complete a test;
- Tolerance for Frustration: gives up easily in face of difficulty, persists till the end of time allotted, uses remaining time to check back over work, randomly responds to items, refuses to even attempt certain tasks, responds to encouragement;
- Response to Obvious Failures: concern with "doing it right", requests for feedback, obsessiveness, erasures, corrections, attempts to explain his/her performance, discounts the importance of the test, attempts to discredit its worth or validity;
- Rapport: easily established, never quite achieved, adequate for testing.

### Pre-Testing Orientation Instruments

The Test Orientation Procedures (TOP) (Bennett & Doppelt, 1967) may be used as a preface to any kind of vocational assessment or testing in an effort to decrease anxiety and increase "test wiseness" by offering practice in taking tests. It can be administered individually or in a group setting with taped instructions and explanations. Designed to be used in a thirty minute session, the TOP consists of easy, test-like exercises in a 20 page practice booklet (a second one is also available for take-home practice) with five tests for speed and accuracy, spelling, vocabulary, arithmetic, and general information.

The USES Pretesting Orientation Exercises (U.S. Department of Labor, 1947-1983) is a mini-test battery of the first 8 parts of the General Aptitude Test Battery (GATB) (U.S. Department of Labor, 1947). While a one and one-half hour administration time is needed, the exercises are flexible enough so that they can be shortened for individuals who need only a refresher orientation to the tests.

### THE TEST BATTERY

Formal assessment and the objective information yielded by psychometric techniques can serve as a "reality tester" for clients allowing individuals to test their assumptions, self-perceptions and appraisals against standardized test results and objective information.

Formal assessment is an integral, and frequently an indispensable component in the process of assisting clients in making sound vocational choices and in developing realistic vocational goals. Among the psychiatrically disabled, it is not uncommon for a client to view his/her own strengths and abilities in a somewhat distorted manner. An individual may hold either a self-deprecating or aggrandized view of his/her own abilities. This is true of adolescent clients in particular, as illustrated in a study by Briscoe, Meulder, and Michael (1981) which examined the degree of the relationship between objective scores on each of the nine standardized ability measures included in the General Aptitude Test Battery and the self-estimates by a sample of 258 high school students of their level of ability in each of the same aptitude areas. The study's authors concluded:

"With the possible exception of skills involving motor coordination, finger dexterity, and manual dexterity, adolescents irrespective of age level appear unable to provide valid self-estimates of their abilities, at least with respect to criteria provided by standardized test measures reflecting the same abilities." (p. 1293)

Test selection should always be done on an individual basis and should be based on a prior determination of what kind of information is desired and why. Vocational assessment should yield a profile of characteristics that are relevant to career decision-making which will help to generate a vocational direction, goal or plan.

The typical formal vocational assessment battery for which the rehabilitation counselor has primary responsibility will usually include measures of academic achievement, interest, aptitude, work values, personal preferences and needs. The following section will provide a brief description of a typical battery with the kind of information it yields, the limitations thereof, reading level required, and a brief note on administration and scoring. (Note: as achievement testing has been addressed at length in another Chapter, it will not be included in the present discussion.)

### INTEREST TESTING

Interest tests are usually the first tests to be administered to clients as they are generally non-threatening, stimulate the client's interest and motivation, facilitate communication, and usually have very clear meaning to the client (high face validity) as their purpose is readily apparent. Interest tests are a useful tool in the process of vocational exploration for a number of reasons. First, they can be used to delineate occupational areas of high interest which will be fruitful for further exploration or to broaden the scope of occupations under consideration. Often a client may have few if any expressed areas of interest; others may feel incapable or hopeless about the future, lacking even fantasies or daydreams. With clients who have been unable to perform successfully on several different

kinds of jobs, there is often a feeling that there is nothing out there for them that may be of interest. Increasing the number of vocational options is especially important for youth with no work experience or exposure and for adults, who through disablement, are no longer able to pursue their former occupation and are feeling at a loss as to where to turn. Conversely, interest tests may be useful in narrowing down the range of occupations under consideration, focusing more specifically on areas of elevated interest, and may be useful with individuals who claim to be interested in "everything," with perhaps little knowledge of actually what specific occupations may entail. Finally, interest tests are useful as a counseling tool, providing a good basis for discussion of the specific likes and dislikes the individual has about a particular occupational choice.

#### SPECIFIC INTEREST MEASURES

The AAMD Becker Reading-Free Vocational Interest Inventory, Revised (R-FVII) (Becker, 1981) is a non-reading vocational preference test for use with mentally retarded and learning disabled persons from the age of 13 to adulthood. The R-FVII furnishes information on a wide range of occupations and job tasks at the unskilled, semi-skilled, and skilled levels, presenting illustrations of individuals engaged in clearly illustrated job tasks. Using forced-choice format for selection (155 triads), examinees are instructed to select the one task they would like to do most. The Inventory yields scores in 11 interest areas for both males and females--Automotive, Building Trades, Clerical, Animal Care, Food Service, Client Care, Housekeeping, Personal Service, Laundry Service, and Maucials Handling. It is a self-administering instrument with no time limits taking approximately 20 minutes to complete. The consumable booklets are hand-scored and individual profiles yield raw scores, conversion (T-scores), percentile ranks and stanines for interpretive purposes. Norms are available for public school grades 7 through 12, both EMR and LD males and females; adult mentally retarded individuals, based on samples from sheltered workshops and vocational training centers. It is a useful tool when there is a need for a non-reading measure of occupational interest with LD clients and clients who cannot be administered the California Occupational Preference System (COPS) (Knapp and Knapp, 1974, 1982) or the Strong-Campbell Interest Inventory (SCII) (Strong, Campbell & Hansen, 1933, 1985) because their reading level is below a 6th grade level.

The Vocational Interest Profile Report (VIP), Rainwater, (1983), based on the Interest Checklist (U.S. Department of Labor, 1979), was designed to help identify areas of occupational interest. The test authors claim that it is especially useful with individuals with no definite work interests and with those who are not aware of the variety of jobs and occupational fields that exist. The VIP consists of 210 items which relate to work activities, selected to reflect a sampling of jobs found in twelve major work categories, divided into 66 subcategories, which are described in the Guide for Occupational Exploration (G.O.E.) (U.S. Department

of Labor, 1979). The VIP and its resultant report are designed for use with USES Guide for Occupational Exploration (G.O.E.), which contains all occupations found in the 4th Edition (Revised) of the Dictionary of Occupational Titles (D.O.T.) (U.S. Department of Labor, 1991), except for military occupations. There are two methods of administration, a paper and pencil format with answers entered into a computer, or administration by computer with the counselor present to explain operating instructions. This method requires an IBM Personal Computer or an IBMPC compatible computer with at least 128K of RAM, with one/more disk drives; a DOS (disk operating system), a version of 1.10 or 2.00; a serial/parallel interface printer; and a monitor. The test comes with a five page booklet of instructions and four screens of instructions which can be retrieved at any time. The 210 items are presented in question form, with three possible answers -- like, uncertain, dislike. The result is a 6 to 10 page report with five sections: 1) demographic; 2) introduction to the report; 3) a list of all twelve interest categories ranked by percentiles representing the percent of the weighted score compared to the total possible weighted score for each category; 4) a listing of all the individual items answered (L,U,D); and 5) a narrative description of the top three interest areas in terms of the G.O.E. Interest Categories. These are divided into subcategories which are described. Examples of jobs within each area are provided along with corresponding D.O.T. titles and numbers. Lastly, the reader is referred to sources of additional information, the D.O.T. and the G.O.E. Advantages of the VIP are the user-friendly aspects of the program, the brief time required for administration, immediately available results for review and feedback, and printout(s) available for independent vocational exploration by the counselee. The disadvantages include the inclusion of occupations which are unrealistic in terms of the job market and which then detract from the face validity of the report for the consumer.

The California Occupational Preference System Interest Inventory (COPS) (Knapp & Knapp, 1974, 1982), is an interest inventory that provides job activity interest scores related to occupational clusters keyed to curriculum choices and two major sources of job information, the D.O.T. and the Occupational Outlook Handbook (O.O.H.) (U.S. Department of Labor, 1990). Written on a sixth through eighth grade vocabulary level, there are 168 items describing activities performed in a wide variety of occupations with a 4-point response scale--like very much, like moderately, dislike moderately, and dislike very much. The profile of the client's likes and dislikes is based on the assumption that people tend to excel, or at least devote more energy to activities they like. Scores are obtained for 14 scales representing clusters of occupations at two levels, professional and skilled, within five major occupational areas. The authors claim that the occupational clusters group together those occupations which are most similar in terms of activity preference, i.e., "surgeon" is not grouped with medical record librarian under "health" but rather under the Professional Science

and Written Communications occupational clusters respectively.

Professional occupations typically require college training and/or advanced degrees and are characterized by a high degree of autonomy and responsibility with stringent personal qualifications of aptitude and personality to be met. With the skilled occupations, specialized training is usually required from the trade school level to the associate degree level. These jobs demand less responsibility and offer less autonomy. The COPS may be used from grade 8 through adulthood and is said to be of equal assistance to the vocationally oriented, non-college student, as well as the professionally oriented, college bound student. A plotted interest profile shows the student's relative standing in each occupational cluster as compared with the occupational interests of other students, at the high school and community college level. The COPS-P, or Professional-level interest inventory, is intended more specifically for those interested in higher level, professional occupations/careers and the college-bound.

Administration time takes twenty minutes as does self-scoring; however, the manual does not specify a reading level for the self-contained interpretive booklet. Because of the personal involvement of the examinee in both administration and scoring, an expanded awareness of the measurement process occurs which is then reinforced by the immediate feedback of the results.

The Self-Interpretation Profile and Guide of the COPS provides a general description of each occupational cluster, specific sample occupations within each cluster, related courses of study, possible college majors, some specific skills and abilities needed in these jobs, and suggested activities in which to gain experience. Each occupational title is keyed to either the D.O.T. or O.O.H., major sources of occupational information, and the COP System Career Cluster Booklets, also available from the publisher. In addition, the manual provides an appendix containing an explanation of the D.O.T.'s Data, People, Things digit coding system. It is important to keep in mind, however, that information provided on construct and concurrent validity is weak and vague, there is little information available on predictive validity, and specific information about the nature of the norm groups is limited.

The Strong Campbell Interest Inventory, Revised, Form T325 (SCII) (Strong, Campbell & Hansen, 1985) compares a person's interests to those of people happily and successfully employed in a wide variety of occupations. It employs 325 items to inquire about a respondent's interest in a wide range of occupations, occupational activities, hobbies, leisure activities, school subjects, and types of people. Thus, it gives persons information about themselves and what will help them make decisions about their life plans, permitting counselors to discuss broad themes in addition to specific occupations. The SCII consists of seven parts which yield scores on 6 General Occupational Themes based on Holland's typology (Holland, 1973) which reflect overall occupational orienta-

tion, 23 Basic Interest Scales, which report consistency of interests or aversions in 23 specific areas and 107 Occupational Scales, which indicate degree of similarity between the respondent's interests and the interests of persons in a wide range of occupations. Additionally, the SCII yields a measure of introversion - extroversion and degree of comfort in an academic environment. Invalid or unusual profiles may be identified through the 26 Administrative Indexes provided. The User's Guide for SVIB-SCII (Hansen, 1984) is available to counselors to facilitate the interpretive process.

The SCII requires thirty minutes for administration, a 6th grade reading level, and has been found to be most beneficial with persons over 17 years of age, the point at which interests begin to solidify for most people. Moreover, the inventories must be machine scored. With regard to individuals with schizophrenia, however, it is important to note the following statements from among the conclusions of the Final Report of the Vocational Assessment Project, 1979-1980 (New Jersey State Department of Education, Trenton Division of Vocational Education, 1980):

"For most schizophrenic clients, the SCII does not discriminate occupational interest patterns. For this reason, its use is not recommended." (p.110). "...The intercorrelations among the general occupational themes are high, ranging from .44 to .80. This probably means that there was very little interest patterning on the SCII for schizophrenic clients (n=63). Profiles tend to be flat, indicating a lack of differentiation of interests with many responding like or dislike to most questions on the inventory" (p. 60).

## APTITUDE TESTING

Aptitude tests are designed to measure the capacity of an individual to learn and/or develop proficiency in a particular endeavor, assuming appropriate training is provided. Achievement tests, on the other hand, are intended to measure how much a person has learned in information and skills as a result of previous education and/or training. In actuality, the two are intercorrelated quite highly. Aptitude tests provide an objective method of identifying strengths and deficit areas in individuals who are uncertain about their own capabilities as they relate to particular academic and vocational pursuits. They are also of value with clients who may hold either a very aggrandized or self-derogatory view of their own capabilities.

The Career Ability Placement Survey (CAPS) (Knapp & Knapp, 1981) was developed to meet the need for a brief measure of abilities related to occupations and careers. A major goal for its development was to provide a battery yielding the greatest interpretive usefulness per unit of testing time, which resulted in the

development of eight five-minute ability tests. The aptitude areas measured include: Mechanical Reasoning, Spatial Relations, Verbal Ability, Numerical Ability, Word Knowledge, Language Usage, Perceptual Speed and Accuracy, and Manual Speed and Dexterity. Total administration time is approximately 51 minutes, and when used in conjunction with the Career Occupational Preference System of career clusters, provides an individual with a profile or picture of his/her abilities in terms of these occupational clusters. The format includes one-page, non-reusable booklets with instructions and example problems on the front side, test items on the reverse side. Tests are hand-scorable, with machine scoring available, and may be scored by the examinees themselves.

Scores on the CAPS are meant to reflect relative ability in eight major ability dimensions and may be interpreted in two ways; profiles in the form of stanines and a CAPS profile which involves various combinations of stanine scores keyed to the COPS system of occupational clusters. The authors claim that each cluster score is based on a combination of individual ability stanine scores, representing those dimensions which, historically, have been shown to yield the greatest predictive validity for success in jobs in each cluster. In determining the ability requirements of jobs within a given cluster, validity indices for tests measuring abilities corresponding to those measured by the CAPS test were obtained from a number of sources, including the General Aptitude Test Battery (GATB) (U. S. Department of Labor, 1947-83), the Employee Aptitude Survey Technical Report (Ruch & Ruch, 1963), and the worker trait components of the D.O.T. (U.S. Department of Labor 1977). Judgments were then made as to which CAPS ability dimensions were most relevant to the requirements of the majority of jobs in each occupational cluster. Norms are available for grades 8 through 12 and community college level. Norms for adult psychiatric clients are also available, although in general, these do not differ greatly from the national norms (Katz, Goldstein, Geckle, Morrissey & Daily, 1991). Additionally, the CAPS offers certain psychometric, administrative and clinical advantages over the more commonly used GATB described below (Katz, Beers, Geckle & Goldstein, 1989).

The General Aptitude Test Battery (GATB) (U. S. Department of Labor, 1947-91) was designed to assess vocationally significant aptitudes useful in vocational counseling, job selection, and job placement. The GATB consists of twelve subtests measuring nine aptitudes: General Learning Ability, Verbal, Numerical, and Spatial Aptitude, Form Perception, Clerical Perception, Motor Coordination, Finger Dexterity, and Manual Dexterity. Scores are presented as standard scores, with a mean of 100 and SD of 20. Screening criteria for the GATB include a 6th grade reading level, examinees preferably between the ages of 16 and 54; without defects in hearing, visual impairment, or use of the hands or arms; and the ability to stand independently for the manual portions of the test.

Formal training for test administrators is required prior to release of testing material. The GATB is available in two forms and was designed as a group test which requires 2.5 hours of administration time and approximately 30 minutes to hand score, although machine-scoring is available. Scores are converted into nine aptitude scores which are compared to requirements for specific job areas, Occupational Aptitude Patterns (OAPs), or to specific job requirements, Specific Aptitude Test Batteries (SATBs), where applicable. Performance on the OAPs is interpreted in terms of High (H), Medium (M), or Low (L) scores on the 66 OAPs. The 66 OAPs, covering more than 1200 occupations, are combinations of aptitudes with associated cutting scores for groups of occupations.

An OAP may be defined as "The combination of aptitudes and minimum scores required to perform satisfactorily the major tasks of each occupation identified with each pattern." OAP scores should be considered as guidelines, not cutoff scores. Each OAP is scored as either High (the examinee's scores met or exceeded those of workers judged to be satisfactory in a particular occupation), Medium (examinee's scores came within one standard deviation of those workers judged to be satisfactory), or Low (examinee's scores were more than one standard deviation below those of workers judged to be satisfactory in a particular occupation). There are over 400 SATBs, which are combinations of two, three, or four aptitudes with associated cutting scores for specific occupations, to which an individual examinee's scores may be compared as well.

The GATB was originally normed in 1952 on 4000 workers representing a random sample of the "general working population." All samples are clearly and accurately defined. The manual provides extensive information on reliability and the GATB's validity is one of its strong points, having been validated in over 450 separate jobs. It is probably the best validated test of this type available. However, according to the Reviewer in Buros (1972), the battery runs the risk of becoming obsolete, since much of the validation research has been on semi-skilled occupations and not on technical jobs, and the method of validation has not changed. In addition, with specific reference to the use of the GATB with the psychiatrically disabled, the New Jersey State Department of Education (1980) conducted a study in an effort to improve the vocational rehabilitation programs for persons with schizophrenia by designing an effective vocational assessment phase. The inactive records of 120 schizophrenic clients at 3 sheltered workshops in New Jersey, for whom 91 GATB profiles were available, were examined to determine the validity and reliability of the assessment instruments being used. The study's authors concluded:

"Although age and years of education between the schizophrenic sample and the general population were comparable, the mean scores on all GATB subtests were lower for the schizophrenic sample compared to the general population. The largest difference between schizophrenics and normals

were on parts 9, 10, 11, and 12. This comparison indicates that the schizophrenic clients performed poorly on all parts of the GATB, particularly those which involve manual and finger dexterity." (p. 84)... "It is recommended that the GATB be used with extreme caution since it seems to have limited construct validity. It probably underestimates the aptitude of schizophrenic clients." (p. 110).

Moreover, while the specific occupations listed under the various OAPs are meaningful, relevant, and easily understood by clients, many are unskilled or semi-skilled positions in manufacturing, i.e., glass blower, spool threader, etc., for which there is a shrinking or non-existent job market. Finally, because of the time required to administer the GATB, clients with psychiatric disabilities quite often fatigue easily and have difficulty in concentrating for the time periods required. This is a significant problem since no occupational results may be obtained when any of the subsets are incomplete.

#### WORK-RELATED PREFERENCES/WORK VALUES/NEEDS

Some measure of the motivational and personal values dimension of work is needed, as these factors often figure significantly in career choice. The perceived worth of a career or work goal certainly influences the motivation of the person with mental illness to overcome the fear of risk associated with any type of change, the fear of failure which might result from unsuccessful completion of a program of vocational rehabilitation, and to sustain him or herself through an often difficult, frustrating, perhaps lengthy period of training/retraining. While these personal values are less tangible and less easily and accurately measured, they are probably at least as important to examine as any "hard data" such as aptitude test scores. Preconceived notions about the worker's role, working condition preferences, perceptions of work-related stressors, the client's conception of tangible and intangible reinforcers, and his or her prioritization of these are important and may be quite different from what the typical, white, middle-class, college-educated counselor values, perhaps assumes everyone values, at least hopes that his or her clients' value; or worse, thinks that his or her clients should value.

The Career Orientation Placement and Evaluation Survey (COPES) (Knapp & Knapp, 1978), was designed to assist individuals in their career development and choices through increased self-awareness by measuring those personal values which fall under a vocational domain, the perceived importance of the work one does. The COPES consists of 160 two-choice, paired comparison items, 16 for each of the 8 value scales, which can be self-administered in from 30 to 50 minutes and is hand-scorable. Examinees are instructed that the statements represent "values which people consider to be important in their work and the activities they do," and are asked to choose the statement which best completes the sentence "I value activities or jobs in which (I).....". The 8 value

scales, based on a system of polarities, are:

- Investigative vs. Accepting
- Practical vs. Carefree
- Independence vs. Conformity
- Leadership vs. Supportive
- Orderliness vs. Non-Compulsive
- Recognition vs. Privacy
- Aesthetic vs. Realistic
- Social vs. Self-Concern

According to the manual, scores are interpreted in terms of a profile which compares the individual's scores with those from the normative sample, given in percentiles. Despite the dearth of validity and reliability information available on the COPES, it is very useful as a counseling tool, since it provides a basis for more in-depth discussion of such important factors as: sources of motivation for pursuing vocational goals, the kinds of work roles and environments in which the individual would feel most comfortable and the nature of the tasks, amount of responsibility, and the kind of interpersonal interactions which the client would enjoy or at the very least be able to tolerate.

The COPES provides an initial basis and quick overview of the kinds of issues which will assume greater significance later in the vocational rehabilitation process, particularly at the time of job placement. For example, with one client, the differences between being a janitor on the night shift for a cleaning company and performing the same kinds of duties on the daylight shift for a hospital made all the difference in his success in the workplace.

It is important to note that with clients with psychiatric disabilities, the counselor cannot interpret the COPES strictly according to the manual. That is, a very high score on the Independence scale should not be followed with plans to avoid all jobs which require conformity to social conventions or adherence to rules and regulations. Rather, such a finding may be useful in exploring what is behind the client's strong desire to be free from or rebel against social conventions or authorities. A discussion of the fact that in reality there are very few occupations which permit such "total freedom" could lead to a productive dialogue concerning some adjustments the client might have to make. How to deal with this issue in a constructive manner on the job could affect his or her ability to get through a training program or to maintain employment. Moreover, many adolescents will indicate a strong preference for being the leader, "the boss", without any awareness of the stress of the increased responsibilities for autonomous functioning, decision-making, and good judgment. The COPES when is useful both as a general indicator and a jumping off point, with regard

the client's awareness of him/herself and what he/she hopes to attain through working. It serves to make the client more aware of the process and complexities involved in making good career choices and helps to modify the sometimes narrow, simplistic view of career decision-making and planning of a career-immature individual.

Edwards Personal Preference Schedule (EPPS) (Edwards, 1953, 1959).

The EPPS was designed as an instrument for research and counseling purposes to provide a quick and convenient measure of a number of relatively independent normal personality variables: achievement, deference, order, exhibition, autonomy, affiliation, intraception, succorance, dominance, abasement, nurturance, change, endurance, heterosexuality, and aggression. There are 225 items, each containing two short statements from which individuals select the statement which best describes themselves. It is untimed, self-administered in 40 to 55 minutes and may be hand-scored in 10 minutes. Norms are available for male and female college students and for a male and female adult population.

Despite a caution in the manual that the EPPS was designed for use with normal persons and is not appropriate for use with severely disturbed clients, we have found the instrument to be of great usefulness clinically. What needs the client is presently feeling most strongly, how these needs are being met, what role education or work might have in this need fulfillment process, etc., are issues which can provide a basis for discussion of client perceived needs while serving to red flag potential problem areas.

A word of caution to potential users of this test seem appropriate, however. It has been our experience that in light of the highly personal nature of much of the content of the EPPS, many clients regard it as highly personal and confidential and are sensitive as to what kinds of information about themselves they consider necessary for their "vocational counselor" to know about them. Some clients become very defensive and angry after having completed the EPPS, and we have had clients flatly refuse to return the completed form. In order to reduce or eliminate the possibility of an angry, defensive reaction on the part of the client, it is most helpful if the counselor carefully and thoroughly explains the nature of the instrument, the purpose for its use, how the client and counselor may benefit from the results, and that the results will be reviewed with the client.

#### PRELIMINARY PLANNING

To a great degree, an individual's ability to integrate into the world of work is contingent upon his or her capacity to formulate a realistic occupational goal. The vocational assessment procedures, described earlier in this chapter, can be instrumental in assisting clients with the complex process of generating a feasible career or prevocational plan. By providing a profile of characteristics which are relevant to career decision making, the assessment results facilitate future planning. They can enable a systematic exploration of occupational fields

which might be particularly advantageous, fields to avoid and/or types of academic remediation which might be beneficial. The value of a vocational assessment largely rests upon the counselor's understanding of how to utilize the results in a manner which is most likely to be helpful to a client. The remaining portion of this chapter will provide an introduction to the use of vocational results in preliminary planning with clients. Preliminary planning is a term we are using to denote the process of sharing vocational assessment results with clients in order to help them develop realistic educational or vocational plans. Within this context, a realistic plan is one which is likely to be successful by virtue of being compatible with one's interests, abilities and tolerance for specific stressors. The extent to which a plan is realistic is also governed by general employment trends and whether the plan is defined by subgoals of manageable proportions.

The process of formulating a realistic educational or occupational plan is typically a gradual multifaceted learning process which requires exploration of oneself and career opportunities. For some individuals, this requires learning to achieve a compromise between aspirations and existing opportunities and a willingness or ability to modify goals if insurmountable obstacles are present. Other individuals may need to learn to recognize and accept their skills and abilities; this involves internalizing that they could reasonably consider career plans they have regarded as attractive but unattainable. The vocational assessment provides an important foundation for preliminary planning because it enables individuals to test their assumptions against reasonably objective findings.

#### TIMELINESS

Judicious timing is necessary if a vocational assessment is to be of benefit to a client. The vocational assessment can serve an integral, natural role in future planning if consideration is paid to an individual's readiness for these procedures. If undertaken prematurely, the assessment results can be misleading, increase an individual's defensiveness and/or undermine his or her self-esteem. An initial determination must be made regarding whether a client's symptomatology will significantly effect the quality of the information derived from the assessment. This is important because a vocational assessment serves as a sample of opinions and abilities from which point inferences and generalizations are made. Formal assessment procedures, such as testing, need to be delayed when individuals are in acute phases of psychiatric disorders. Often individuals experience the presence of symptomatology on a fairly consistent basis. Under these circumstances formal assessment procedures may be appropriate but the impact of symptoms must be recognized and the results need to be interpreted accordingly because symptomatology can introduce distortion into all aspects of the assessment process. For example, pronounced depressive symptomatology may obscure the revelation of areas of interest on career interest inventories. Conversely, manic symptomatology often results in interest profiles which are

characterized by a confusing plethora of interests. Distortion in interest inventory results is less serious than the distortion symptomatology can have upon the measurement of abilities. Anxiety, distractibility and disorganization or blocking of thoughts all interfere with one's performance on measures of abilities. If these symptoms are present during testing, results may provide a picture of how the individual is performing at the present point in time but may underestimate future levels of performance.

The timing of an assessment also needs to be guided by the client's feelings regarding this type of appraisal. The optimal time for an assessment is when an individual presents with a desire to resolve questions regarding future plans by learning more about himself or herself. Vocational assessment procedures are not to be undertaken when clients are highly reluctant, although, resistance to testing can sometimes be diminished by exploring a client's apprehension. Embarrassment over skill deficits or wariness regarding the counselor's ability to view the test results in a helpful, nonjudgmental manner are concerns which may surface in this context. The counseling alliance may be strengthened as these issues are brought to light.

#### REALISM OF CAREER CHOICE

Assisting a client in the development of realistic occupational plans is a delicate, difficult process because vocational issues are often inextricably interwoven with the individual's view of himself or herself. For this reason, preliminary planning with a client requires more than a proficiency in testing or a solid knowledge of the world of work; it also requires well developed skills in psychotherapy. Because vocational counselors are often viewed as technicians, a client may be less inclined to raise emotionally laden issues in a vocational counseling session than in a psychotherapy session. This means the vocational counselor needs to be especially sensitive to the possibility that strong feelings may be present yet unarticulated. This degree of awareness and sensitivity is important throughout preliminary planning but is critical in the process of interpreting the results of vocational testing for use in preliminary planning.

One of the most common and painful situations occurs when a client presents with a highly valued but unrealistic career goal which clearly exceeds his or her capabilities. Quite often counselors receive referrals on individuals who successfully began ambitious careers prior to the onset of a chronic psychiatric illness. Equally frequent among referrals for psychiatric rehabilitation are individuals who have had minimal success in educational or career endeavors yet speak of strong beliefs that they could handle careers which require extensive preparation. What these individuals have in common is that their dreams of who they might become provide a measure of comfort when faced with the difficulties of everyday life.

Whereas it is important not to encourage a client to engage in an overly demanding career endeavor, it is equally important not to precipitously destroy

sustaining fantasies because these fantasies serve protective functions. The counselor needs to refrain from striving for realism "at any cost" and simultaneously avoid colluding with the client in hiding from reality. A gradual approach, in which alternatives to a cherished goal are generated and considered along side of it is useful. Often, entry level positions or limited training programs related to the career of interest can be recommended without removing the possibility of further career advancement in the future. For example, an individual who wants to become a registered nurse but who will not recognize the chances for success in this field are very slim could begin by training to be a home health care aide. Our experience has been that it is essential never to abruptly discourage a career plan and that it is far easier for an individual to relinquish a valued but unrealistic goal if viable alternatives are presented.

Frequently, discussion of the values and influences which have led an individual to have very strong feelings about a particular career can help free him or her from the consuming pursuit of an unrealistic goal. Sometimes exploration reveals that a client is aspiring to an untenable career plan because of factors in his or her relationships with family members. Excessive competition with siblings may be an important issue. In other situations, the individual may be trying to meet the expectations of a parent who had difficulty accepting his son or daughter's disorder. If these issues are productively addressed, the client may achieve a greater freedom from the constraints of the past and be able to formulate a realistic career plan which permits an opportunity for success.

The following clinical example is provided to clarify the necessity of exploring personal issues which obstruct one's ability to relinquish a career goal which is clearly unfeasible.

Carol, at 42 years of age, had been pursuing the goal of becoming a medical technologist for over seven years in order to eventually work in genetic research. This endeavor required significant self-sacrifice and consumed a great deal of her daily efforts. At the time of referral for vocational assessment, she had nearly depleted all available funds for continued education. Nonetheless, she had a considerable number of academic requirements yet to complete. A review of her grade transcript revealed that she had performed well in many classes but had been consistently unable to pass courses in the areas of science and math, subjects which are integral to her chosen academic major. Whenever possible, she delayed taking these courses or opted to drop out of them. Her performance on the abilities portion of the vocational assessment revealed deficits in numerical abilities and verbal reasoning, and her composite profile suggested that she did not have the capabilities to meet the demands of her chosen profession.

Nonetheless, Carol tenaciously held to her goal. Not until a discussion of her personal values was undertaken did it become apparent that her pursuit of this goal was motivated by unresolved feelings about having previously given birth

to a child with a birth defect. This clarified the reason for her difficulty in accepting that her career goal was not realistic. She eventually decided to explore her feelings about the birth of her child in individual therapy prior to continuing with career counseling.

At this point, we have stressed the importance of assisting clients to realistically understand vocational alternatives. Realism, on the part of the clinician, is equally important and often difficult to consistently maintain. Problems in realism on the part of the clinician can stem from more than one source. In order for a counselor to be able to provide realistic career guidance, there must be an understanding both of the value and limitations of information derived from the assessment.

Most vocational batteries suggest a list of occupations which are correlated with an individual's interest and abilities profile. Whereas these lists often provide valuable suggestions, they can also be misleading for several reasons. First, some of the occupations listed rarely exist in the job market. A review of occupations listed on well established vocational assessment batteries reveals such occupations as archivist, blacksmith, merchant marine, shellfish grower and reptile farmer. Others appear on the surface to be more reasonable occupations but may, in reality, present very limited opportunities due to either local or nation-wide changes in specific industries and fields. Occupations which once prospered may no longer provide economic opportunities for new individuals entering the field. Therefore the clinician needs to be well informed of employment trends when making specific occupational recommendations on the basis of the assessment results alone. Sources such as the Occupational Outlook Handbook published quarterly by the Federal Government can help the clinician develop a more realistic understanding of the economic opportunities available in specific fields. Local newspapers and publications are also available in this regard.

The career alternatives suggested by the individual's career interest and abilities profiles only provide a framework for exploring the appropriateness of a range of potential careers. The degree to which an occupation is congruent with an individual's measured interests and abilities is a very important consideration in career decision-making, but it is not the only factor which needs to be considered. It is important to remember that other attributes related to success in specific occupations are not accounted for in this process.

Another threat to realism, on the part of the clinician, can occur if test results are interpreted in a literal or mechanistic manner. Just as clients often believe the answers to problems of career planning lie solely in test results, counselors may hold similar misconceptions. The test results are to be understood in the context of a more general appraisal of an individual's overall functioning. The maxim which reminds us to see both the forest and the trees applies to the use of test results. It is important to carefully examine the test results themselves without

losing sight of the individual's life circumstances and general adjustment. Samler (1964) emphasized this point, "It is misleading to identify high mental ability and not to find out whether it is available for use, what needs energize the individual, what defenses may block his productivity - or may as a kind of secondary gain, reinforce it" (p. 413).

Recommendations regarding potential careers must be formulated with consideration to the individual's social skill repertoire, tolerance for specific stressors, psychological health and capacity to sustain goal directed behavior. Appraisal of these considerations requires clinical judgment because these determinations must be made in a subjective manner. Consequently, they are frequently affected by the clinician's feelings about specific individuals or psychiatric clients in general. In order to provide realistic career guidance, counselors need to be aware of factors which pose threats to their capacity to accurately appraise a client's functioning in domains which very much affect occupational potential but are not measurable by standard procedures. Counselors need to be attuned to inner urges to rescue or overprotect clients. Attempts to rescue a client often result in overestimating his or her capabilities; this tendency may be set in motion by either strong attraction or identification with a particular client. Underestimation of a client's potential for work may be a part of general "paternalistic" attitudes towards psychiatric clients or may be a response to an individual client who tends to elicit this response from others in order to control interactions.

### Employability

It has been estimated that 60-80% of terminations by employers stem from difficulties handling nontechnical aspects of employment (Couchman, 1974). This indicates that interest, aptitude and specific job related skills are necessary but not sufficient preconditions for success in any particular job. Of equal, if not greater importance, are general and specific employability factors. General employability factors pertain to those capabilities and attitudes that are required in most work settings. They include the ability to comply with social norms governing the role of a worker and the presence of coping mechanisms and skills which are strong enough that the pressures of employment are not likely to result in deterioration. Specific employability factors pertain to aspects of an individual's attitudes, psychological functioning, and social skill-fulness which has a bearing upon his or her ability to adapt to a range of employment situations. Whereas an individual may demonstrate general employability, there may be indicators that his or her characteristics may preclude employment in specific settings. For example, a client may function well when working in rather socially isolated settings but be unable to handle the social complexities which surface in settings where there are numerous employees. While these factors must be

considered carefully in preliminary planning, they generally are not accessible through formal testing.

Neff (1980) underscored the importance and difficulty of assessing an individual's ability to handle the complex social demands which are integral to work roles: "It is not too much to say that the ability to work is as much a social process, as it is cognitive or motor. The difficulty is that our capability for measuring cognitive or motor skills is far better developed than our ability to assess the subtle and delicate social adjustments which are at least as important" (p. 23)

As noted previously, the vocational assessment includes detailed interviews which focus upon an overview of an individual's attitudes towards work and an overview of his or her educational and employment history. A great deal of information which enables the evaluation of specific and general employability factors can surface in this manner. For example, a thorough vocational history will include questions which clarify the types of situations the individual needed to face on each previous job. Aspects which were gratifying or problematic are identified. Particular attention should be paid to the degree of social contact each position required and the client's ability to meet these demands. Discussion of the reasons for leaving each particular job frequently clarifies whether there is a history of problems interacting with supervisors or co-workers. Patterns pertaining to an individual's ability to cope with work in general or specific types of work can emerge both through an overview of the client's educational and vocational history and a detailed exploration of aspects of this history.

Quite frequently, the information obtained through this type of inquiry, combined with the results of formal assessment procedures and observations of the client's interactions in the sessions, provides a foundation which is solid enough to permit differential predictions regarding the client's occupational potential. However, at times, the counselor and client may be faced with important questions regarding the appropriateness of future plans which cannot be clarified through the previously described approaches. A vocational evaluation undertaken through the use of work samples, simulated work environments, volunteer or supported employment experiences may then be indicated. These types of procedures are rarely undertaken in most mental health settings and typically occur in vocational rehabilitation facilities or on-site. The use of work samples and simulated work environments as major approaches to vocational evaluation developed from the premise that "the most accurate way to assess work behavior is to actually observe individuals while they work" (Neff, 1966).

#### Work Samples

A work sample is "a well-defined work activity involving tasks, materials, and tools which are identical or similar to those in an actual job or cluster of jobs"

(Task Force #2, 1975, p. 55). Vocational rehabilitation programs which utilize a work sample approach to assessment generally administer a series of work samples to a client; this individual's performance on these measures is compared to a norm group which is typically comprised of individuals employed in corresponding occupations. The extended nature of this type of approach to vocational evaluation provides an opportunity to assess concrete skills and an individual's characteristic approach to work tasks.

In contrast to the use of paper and pencil assessment measures and interview formats, work samples permit the actual observation of clients as they attempt to complete tasks related to a range of jobs. Work samples are generally regarded as a positive alternative to psychometric measures because of their comparatively higher face validity, construct validity and predictive validity with regard to work performance (Pruitt, 1977). They have been viewed as particularly useful for clients with limited verbal skills or histories of educational deficiencies.

Despite the widespread use of work samples and their obvious merits, the quality of information derived through this assessment approach varies greatly and is contingent upon the skills of the vocational evaluator. In order to provide meaningful information which clarifies a client's personal strengths and limitations as related to a range of vocational activities, the vocational evaluation must be carefully planned and implemented with consideration to the client's perception of the experience of being evaluated. A systematic plan for evaluation needs to be established with the client's active involvement prior to administering work samples. The choice of work samples needs to be guided by the client's interests and the types of questions about his or her capabilities which led to the referral for a vocational evaluation. Unless the client has an understanding of the rationale behind the tasks to be performed, the evaluation will be experienced as meaningless or intrusive. This all too frequently can lead to half-hearted performance on the part of the individual being evaluated and/or judgments of the client as generally "unmotivated." This set of conditions may lead to the formulation of inaccurate conclusions regarding the client's potential for specific types of work or work in general. Although the face validity of work samples is greater than that of many psychometric measures used in vocational assessment, our experience has been that many clients fail to understand why they are being asked to complete specific tasks. The issue of work sample evaluations with individuals who are chronically mentally ill, particularly those who carry a diagnosis of schizophrenia, is highly illustrative of this very situation. The following case discussion highlights the complexities involved when individuals who are psychiatrically disabled are placed in traditional vocational evaluation settings which rely on work sample techniques as part of the vocational assessment process.

John is a thirty-year-old male who was diagnosed as suffering from an acute schizophrenic reaction four years previously. Until that time he had been employed as a security systems installer and had acquired training a number of years earlier at a local technical training program. While his social adjustment prior to his breakdown was marginal, he had been able to work successfully. John was placed on a rather potent psychotropic medication and continued to experience a number of side effects including serious motor involvement which he experienced as uncontrollable arm movements and motor agitation resembling a primary motor disorder. After remaining in his parent's home with no outside activity over the four year period, John was referred for vocational and psychological services. At the time of referral, John was motivated to return to the work place, preferably in his old line of work.

After an extensive neurological and psychological evaluation, John was referred to a local vocational center for evaluation. The evaluation was set up as a two-day per week experience as there was real concern regarding John's current abilities to deal with the stress of a highly structured environment, since he had been essentially socially and personally isolated, except for the local bars, for the preceding four years. John was placed in a work sample evaluation involving the assembly of electric lamps, as the vocational center judged this experience to closely resemble the electrical wiring and circuitry work which John had done previously. Within one month John withdrew himself from the program stating that he wanted to do security wiring work and that he was getting nothing out of lamp assembly. He then proceeded to send out resumes to various security system businesses with no success. At the same time, John's one month evaluation came from the vocational evaluation center. The report described his work skills in great detail and, from a vocational evaluation standpoint, the report was informative, explicit and well detailed. However, mention was made of John's lack of attendance on a number of occasions, and while phone contact was made with him to "remind him of the importance of attending on a regularly scheduled basis," no one at the workshop had bothered to talk with John about his experience there and thus were totally unaware of his negative reaction to the experience and his inability to see a relationship between work sample tasks and his occupation of choice. The report concluded with a recommendation that John continue in the evaluation program "for the purposes of assessing his emotional stability in the work setting and determining his vocational potential." The real issue, John's concrete thinking and inability to make connections between the here and now and his future aspirations, was never recognized.

#### Situational Assessment

Evaluation in simulated work settings, also known as situational assessment, refers to the process of appraising an individual's capabilities in a setting

which is a realistic approximation of an actual work environment. Although the use of work samples provides an opportunity to observe clients as they work, situational assessments provide a richer source of information on the individual's work personality. The concept of work personality has been defined by Gellman (1967) as "...the characteristic pattern of work activity displayed by a person in a work situation. The work personality incorporates work attitudes, behavioral work patterns, value systems, incentives and abilities. It is the behavioral configuration regarded as necessary to function effectively in a work setting. It is a constellation distinguishing work roles from other societal roles" (p.283).

Situational assessments help answer questions pertaining to general and specific employability factors by providing information which may not have been accessible through other assessment procedures. For example, the question of whether a particular individual is able to hold gainful employment is one which is better suited to a situational assessment rather than sole reliance on interviews and psychometric testing. Extended and repeated observations of an individual in a realistic work setting enable the development of a more comprehensive understanding of an individual's work related strengths and deficiencies. A client's ability to sustain attention to tasks and engage in prolonged focused activity can be assessed. Response and need for supervision can be explored along with the individual's ability to handle the pressures which inevitably accompany entering a novel work situation. The client's ability to evaluate the quality of his or her work is frequently assessed. An individual's ability and/or willingness to comply with social norms regarding proper work attire, grooming, and prompt consistent attendance can also be addressed through this type of evaluation. Furthermore, situational assessments can provide an understanding of whether a client is able to interact with supervisors and co-workers in an adaptive manner. Questions pertaining to the client's ability to demonstrate adequate social judgment, independent problem solving, self-direction and self-control in a setting can frequently be answered.

The following case illustration is provided to illustrate how assessment procedures can be integrated into career counseling in order to facilitate systematic career decision making. A comprehensive description of the individual's scores on all assessment measures is not presented; rather, the salient factors which facilitate career decision making will be highlighted.

At the time of referral for career counseling, Edith was 37 years old and contemplating a career change. She had been diagnosed with schizophrenia, paranoid type and had a history of psychiatric treatment which dated back to her mid-twenties. Edith had been able to maintain employment as a nurse until age 33 at which time her difficulties functioning in the role of a nurse reached insurmountable proportions. Her hypersensitivity to criticism and strong dependency needs led to frequent intense feelings of rejection by other hospital staff.

### Psychiatric Rehabilitation: A Handbook for Practitioners

Her tendency towards grandiosity combined with deficits in social judgment resulted in the alienation of supervisors and co-workers. At times she felt far more capable than the doctors and her supervisor and on these occasions she would accuse them of providing improper treatment. At other times she was troubled by feelings that treatment responsibilities were overwhelming and exceeded her capabilities. Following her fifth psychiatric hospitalization she decided to leave the nursing profession. Edith initially expressed interest in the fields of computer programming, interior design and accounting.

Following several interviews which focused on gaining an understanding of her educational and vocational history, current social functioning and thoughts regarding future career plans, a career interest inventory was administered. Elevated interest scores corresponded to the career clusters which subsumed clerical, artistic, professional business and health care occupations. Edith's career interest scores were used to expand the range of careers under consideration. Although her verbally expressed interests had not included clerical occupations, when her interest inventory scores were reviewed she noted that many of the occupations classified under the clerical career cluster seemed appealing to her. Her responses on a work values inventory underscored the value she placed on working in a setting which provides a high degree of structure, supervision and clearly stated rules and regulations. A strong preference for supportive rather than leadership roles was also evident through the results. Appearing superficially as a contrast to the aggressiveness she demonstrated in nursing, she accounted for this discrepancy by indicating that despite periodic grandiosity she basically felt "safer" when working under a higher degree of structure and supervision.

The discussion which emanated from a review of her profile on the work values inventory was instrumental in her being able to clarify the type of work environment which would be least stressful to her, a major consideration in her career planning due to the difficulties she had experienced in coping with work related pressures. Her major career choices were discussed with respect to the types of work environments and pressures she could expect to encounter.

Edith's performance on a vocational abilities battery revealed definite strengths in the areas of word knowledge, language usage and perceptual speed and accuracy. Her numerical abilities were slightly below average as was her score on a measure of inductive and deductive logic. A review of these test scores helped her narrow her career considerations. She eventually ruled out the field of accounting due to the level of her mathematical skills and became more interested in fields which would enable her to utilize her well developed language skills and strong attention to detail.

A period of exploration through the use of career resource information and occupations of interest was evaluated with respect to her abilities,

### Vocational Assessment

work conditions and employment trends. She ultimately was able to identify a specific career field, medical records technician, which appeared to be most compatible with the information she had gained about her interests, needs and capabilities. This was viewed as a particularly advantageous choice because it combined her interests in medicine and clerical work, enabled her to use her most well developed abilities, and did not require her to exercise a great deal of leadership and social judgment. At the end of several months of career counseling, Edith entered an associate degree program in order to prepare her for employment as a medical records technician.

Throughout this chapter, the reader has been reminded that only tentative conclusions can be drawn on the basis of the information derived through various assessment procedures. This is because clinicians working with vocational evaluation procedures are faced with an extremely difficult task - that of predicting how an individual will be able to meet the demands of a work role at a future point in time. Problems predicting human behavior are well known in psychiatry. Given the fluctuating nature of chronic and/or severe psychiatric disorders, the widely varying demands of individual jobs and work environments, and the complexity of human nature, a great deal of inference and clinical judgement is involved and the potential for error must be recognized. While appraising the individual's capabilities, one must be mindful of the fact that situational variables may be impinging upon the validity of assessment results. Among these variables are the client's feelings about the assessment process and his or her reactions to the professionals encountered in the evaluation settings. Changes in medication, personal concerns and the skill of evaluators also have the potential to impact significantly upon the results of an assessment. This is not to say that vocational assessment procedures cannot provide valuable information which can contribute to realistic vocational planning. Rather, it is intended as a caution that the conclusions formed in a vocational assessment need to be understood and discussed with clients as provisional in nature. When undertaken carefully, the results of a vocational assessment can provide a reasonably accurate statement of the individual's interest, work personality, strengths and limitations at the present point in time and provide a basis for limited predictions of future vocational potential.

# The Clinical Use of the Career Ability Placement Survey vs. the GATB with Persons Having Psychiatric Disabilities

By Lynda J. Katz  
Sue R. Beers  
Michelle Geckle  
and Gerald Goldstein

Date of Acceptance: October 20, 1988

*The purpose of this study was to investigate the clinical utility of the Career Ability Placement Survey (CAPS) as a tool in the vocational assessment of persons having a psychiatric disability. The CAPS and the General Aptitude Test Battery (GATB) were administered to a sample of 91 individuals with varied DSM-III psychiatric diagnoses. Vocational aptitude scores yielded by the CAPS were compared to those obtained on conceptually similar tests of the GATB. Correlation coefficients were used to evaluate the relationship between the two measures. In addition, the independence or degree of differentiation of the tests within each battery was assessed and confirmed by factor analysis. High positive correlations were obtained for conceptually similar tests. While test intercorrelations within each battery exhibited an acceptable level of independence, greater independence was found within the CAPS structure. Factor analysis confirmed that the CAPS contained a three-factor solution, whereas the GATB showed a two-factor structure. These results, coupled with the fact that the CAPS is more efficiently administered, indicated that the CAPS might have clinical advantages when used with this population.*

The Rehabilitation Act of 1973 (PL93-112) and its subsequent amendments (Rehabilitation Acts Amendment, 1986) gives priority to the provision of vocational rehabilitation services to persons having severe disabilities including those with psychiatric disorders as preparation for their entrance into the force. Among the vocational rehabilitation services authorized in the Act is that of vocational assessment.

However, in contrast to the successful use of psychometric measures to assess the vocational capacity and aptitudes of persons with physical disabilities, the use of vocational assessment procedures with persons who have psychiatric disabilities has been problematic.

Anthony and Jansen (1984) cited six studies which evaluated the predictive validity of traditional psychological and vocational tests with persons who were psychiatrically disabled. These tests included the Wechsler Adult Intelligence Scale (WAIS), the General Aptitude Test Battery (GATB), and other routinely used psychological test batteries. Results of these studies indicated that intelligence, aptitude, and personality tests were poor predictors of future work performance for this population. However, it must be pointed out that the predictive validity of vocational aptitude tests, in particular, relate to potential success in particular occupations. Vocational aptitude tests were never intended to predict global concepts such as future work performance. Moreover, hospital recidivism rates and loss of employment resulting from the exacerbation of psychiatric disorders were major contributing factors to subsequent vocational outcomes in all of these studies.

With these cautions in mind, vocational counselors can view vocational aptitude testing as an initial assessment tool in the rehabilitation counseling process with persons having psychiatric disabilities. Aptitude tests traditionally have provided a method of assessing areas of strengths and deficits in individuals who might be uncertain of their own academic or vocational potential. Aptitude test results are of value when working with individuals who may have either an inflated or self-depreciating view of their capabilities. They are also useful with those persons who have little substantive or accurate knowledge of the world of work. It is often the case that persons with psychiatric disabilities, by virtue of the age of onset of their illness and its severe impact on major life events such as the choice of a career or retention of employment once in the market place, have particular knowledge deficits for which aptitude testing has been shown to be highly appropriate and useful.

The efficacy of aptitude testing with respect to self-knowledge and vocational planning with clients having schizophrenic disorders was demonstrated by Bidwell (1969). Her results

showed that clients chose vocational goals congruent with their own understanding of their aptitudes and interests but were not generally aware of their actual aptitudes and interests. Anthony, Howell, and Danley (1984) underscored the special vocational counseling and job readiness needs of persons having psychiatric disabilities stating, "More time is needed to go through the process because of the clients' vocational immaturity. More energy is needed to form a collaborative relationship with clients who are used to having things done to and for them rather than with them" (p. 233). They suggested a deliberate refocusing of the helping process on those specific skills and supports needed by the clients themselves.

Miller and Benjamin (1975), advocating that the unique needs of special populations should act as an impetus to develop vocational rehabilitation programs tailored to the individuals actually served, called for an expansion of strategies used in career guidance programs. To meet the vocational rehabilitation needs of these special populations including persons with psychiatric disabilities, however, vocational counselors have been forced to use vocational assessment strategies currently at their disposal. Often the psychometric properties of these measures in terms of their development and standardization have not allowed for accurate assessment of persons with psychiatric disabilities. Floyd (1964) stressed that as vocational counselors formulate plans to meet the needs of this population, they tend to use instruments with which they are most familiar and which have, to some extent, known empirical validity with a nondisabled population. This a priori decision is still necessitated today due to the lack of validity studies on vocational aptitude measures used with clients who have psychiatric disabilities.

The General Aptitude Test Battery (GATB) (U.S. Department of Labor, 1947-1979) is a multiple aptitude battery developed by the United States Employment Service for use in occupational counseling programs. The battery consists of 12 tests measuring the following 9 aptitudes: Intelligence, Verbal Aptitude, Numerical Aptitude, Spatial Aptitude, Form Perception, Clerical Perception, Motor Coordination, Finger Dexterity, and Manual Dexterity. Eight of the tests are paper and pencil tests and four are performance tests which require special equipment for their administration. A trained technician administers the battery; it is timed and requires 2 1/2 hours to complete. The battery yields Occupational Aptitude Patterns (OAPs), combinations of three GATB aptitudes and associated cutting scores for groups of occupations having similar aptitude requirements. An individual's degree of aptitude for various occupations associated with the 66 OAPs is indicated with a letter grade of High, Medium, or Low as outlined in the test manual (USDL, 1979).

The GATB is one of the most widely used vocational aptitude measures. The battery has been employed with a variety of special populations and disability groups, such as juveniles at a diagnostic center, persons having mental retardation or learning problems, high school drop-outs, special education students, and persons with hearing problems (Mueller, 1964; Dy, 1968; Droege, 1968; Helwig, 1972; Kujoth, 1973; on, 1975; Botterbusch & Droege, 1972; Sanderson, 1974; Droege & Mugaas, 1976). As testimony to its continued and

highly extensive use in the job referral process, in 1987, the U.S. Department of Labor directed the National Academy of Science to review the GATB in terms of Validity Generalization, the basis for referral to all 12,000 jobs in the Dictionary of Occupational Titles with particular concern around persons with disabilities (Washington Update, October 22, 1987).

Little work, however, has been done in evaluating the usefulness of the GATB with persons having psychiatric disabilities. In one of the few studies reported, Ciardiello (1981) evaluated the GATB as a predictive measure of job placement success for 66 clients with schizophrenia in a workshop setting. In general, GATB scores for this sample were significantly ( $p < .01$ ) lower than scores for a general population, with largest differences on the Assemble and Disassemble parts of the Finger Dexterity Scale. In a discriminate function analysis the Assemble test of the GATB was found to be the best single predictor of job placement ( $p < .01$ ). This finding suggested that those clients with higher scores on this subtest were more likely to successfully complete sheltered workshop programs where work experiences required finger dexterity and subsequently to be placed in jobs. The study concluded that a standardized vocational instrument such as the GATB offered the possibility of making practical predictions regarding job placement for clients with schizophrenia.

The use of the GATB in a clinical setting with individuals who have a psychiatric disability raises several issues of significant practical and logistical concern, namely: (1) the 2 1/2 hour administration time; (2) the training requirements for administration; (3) the specialized equipment and space needs; (4) the time-consuming scoring procedures in which there is a high probability for error rate; and, (5) the fact that the test is geared to group rather than individual administration. From a therapeutic perspective, group testing of persons having psychiatric disabilities may be highly threatening and anxiety provoking, especially to inpatients. Moreover, part of the process of psychiatric rehabilitation is the establishment of rapport with an individual, a process best accomplished on a one-to-one basis. Finally, the rigorous testing procedures required are not conducive to "best effort" participation on the part of this clientele due to factors such as fatigue, distractibility, previous failure experiences, and test anxiety.

The Career Ability Placement Survey (CAPS) (Knapp & Knapp, 1984) is a battery of eight 5-minute paper and pencil tests which includes measures of Mechanical Reasoning, Spatial Relations, Verbal Reasoning, Numerical Ability, Language Usage, Word Knowledge, Perceptual Speed and Accuracy, and Manual Speed and Dexterity. The battery was first published in 1981 as a standardized measure of abilities related to occupations and careers. It is designed to be used in conjunction with the California Occupational Preference System Interest Inventory (COPS) career clusters, a group of 14 skilled and professional job classifications (Knapp & Knapp, 1984).

The CAPS was normed on nearly 7,000 students in grades through 12 across five geographical regions of the county as well as on a sample of 1700 community college students (Knapp & Knapp, 1984). The test manual reports correlations of the CAPS with the GATB, the Employee Aptitude Survey (EAS), the Differential Aptitude Test (DAT), the Iowa Tests of Educa-

tional Development (ITED), the Metropolitan Achievement Tests (MAT), and school marks using various 8th, 9th, and 10th grade samples. A predictive validity study involving over 2,000 high school graduates who had been administered the CAPS while in their high school years is ongoing. Preliminary results indicate a 97% hit rate. A hit was defined as the correspondence of the college goal or present job to a CAPS career area designated by the previously obtained CAPS scores.

The CAPS has not been extensively used or empirically studied with special populations, however, it appears to present some advantages for use with persons having psychiatric disabilities. Specifically, (1) the total testing time for counselors working with these persons is less than one hour; (2) the series of eight tests is administered in the office setting, one-on-one with the counselor; (3) no special apparatus or space is required; and, (4) no special training is required for administration. Furthermore, the test can be scored by the client, another method of investing him or her in the rehabilitation process. This opportunity for immediate feedback increases the "face validity" of the instrument with individual clients because of the direct link which can be made between the ability scores and the fourteen career clusters identified.

For these reasons, it seemed desirable to determine whether the tests could be viewed as comparable in terms of their results with a population of individuals having a psychiatric disability. If so, the use of the CAPS in a clinical setting would be more soundly supported. In this study, vocational aptitude scores yielded by the CAPS were examined and compared to those obtained from the GATB, a test which has been researched in a continuing program of developmental and occupational validation since its publication in 1947.

The following issues were addressed:

1. What is the relationship between the GATB individual aptitude scores and the CAPS ability scores? It might be expected that certain CAPS abilities would be related to selected GATB aptitudes. For example, the CAPS Manual identifies the CAPS Spatial Relations, Word Knowledge, Numerical Ability, and Perceptual Speed and Accuracy tests as conceptually similar to the GATB measures of Spatial Aptitude, Verbal Aptitude, Numerical Aptitude, and Clerical Perception respectively. Therefore, a strong positive relationship between these scores would be anticipated (Knapp & Knapp, 1984).
2. Do the tests within the GATB battery and the tests within the CAPS battery remain sufficiently independent or differentiated to yield separate measures of aptitudes or abilities when a sample of persons with psychiatric disabilities is tested?
3. How do the factor solutions that account for the variances of each battery compare?

**Method**

**Subjects**

Ninety-one individuals (24 outpatients and 67 inpatients), selected at random, who were seen as either inpatients or outpatients at a large, urban, university-based psychiatric facility were involved in this study. Ages ranged from 14 to 50 years (mean = 23.9, SD = 9.48). Eighty-two subjects were White, 7 were Black, and 1 represented another minority. Education

obtained averaged 11.2 years with a range of 7 to 18 years (Median = 11.0). The mean Full Scale IQ as measured by the Wechsler Adult Intelligence Scale - Revised (WAIS-R) or the Wechsler Intelligence Scale for Children - Revised (WTSC-R) was 94.11, with a range of 68.00 to 128.00 (SD = 12.79). A mean Verbal IQ of 94.40 (SD = 12.49) compared to a mean Performance IQ of 94.53 (SD = 12.87).

The subjects had been previously diagnosed using the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders (DSM-III)*, Third Edition, 1980. 42.9% (n = 39) of the group had more than one DSM-III diagnosis. Overall, 30% of the diagnoses were disorders usually first evident in childhood or adolescence; 28.2% fell in the category of an affective disorder; 14.6% were personality disorder, 13.6% were schizophrenic disorders, and 13.6% were anxiety or adjustment disorders.

**Procedure**

Between 1982 and 1986 randomly selected inpatients and outpatients referred to the Department of Neuropsychological Assessment and Rehabilitation Services (Western Psychiatric Institute and Clinic, University of Pittsburgh) for vocational assessment were administered both the GATB and the CAPS. Pearson product moment correlations were calculated between the GATB aptitude scores and the CAPS ability scores in order to assess whether the relationship of the conceptually similar tests identified by Knapp & Knapp (1984) was still apparent when the tests were used specifically with a psychiatric population. To further evaluate the results of these tests in

comparison to those reported during test development, the independence of the abilities or aptitudes within each battery was examined. A Pearson product moment intercorrelation matrix was calculated for the 9 GATB aptitudes, the 12 GATB test scores, and also for the 8 CAPS ability scores. Principal components factor analysis was then carried out for each battery. Adequately determined factors were rotated to simple structures by the varimax procedures outlined in Gorsuch (1982).

**Results**

**Correlation of GATB Aptitudes and CAPS Abilities**

The statistically significant correlations between the GATB individual aptitude scores and the CAPS ability scores are included in Table 1. Correlations are .60 or above ( $p < .01$ ) for tests which the CAPS' authors identify as conceptually similar. For example, CAPS Word Knowledge correlates with GATB Verbal Aptitude at .81 and CAPS Perceptual Speed and Accuracy correlates with GATB Clerical Perception at .65. Other tests with overlapping content, CAPS Word Knowledge/GATB Intelligence and CAPS Language Usage/GATB Verbal Aptitude, showed the expected high correlations while dissimilar tests showed the desirable low correlations.

Before any decision could be reached concerning the use of the CAPS as opposed to the GATB, it was necessary to determine not only whether the conceptually similar tests selected from the two batteries showed high correlations for this sample of persons with psychiatric disabilities but also whether the correlations of this sample were similar to those obtained when a normal population was compared using the same

tests. In general the correla-

tions of the GATB aptitudes and CAPS abilities produced by this sample (See Table 2) were similar in direction and size to those reported for the normal population in the CAPS test manual (Knapp & Knapp, 1984). There appeared to be enough similarity to suggest that the relative performance on the two test batteries of clients in this sample would be comparable to the performance of normal populations when conceptually matched aptitudes were examined.

**Inter-test Correlation and Factor Analysis**

The performance of this sample was also evaluated by: (1) assessing the degree of independence of the individual tests of each battery; and (2) comparing the results to those provided by each test developer. The intercorrelations among the vocational aptitudes for each battery provided information regard-

ing the differentiation of the measured aptitudes when that particular battery was used to assess this special client group.

Intercorrelations among the GATB aptitude scores are presented in Table 3. All intercorrelations were significant

( $p < .01$ ).

Coefficients for this sample range from .15 (Spatial Aptitude/Motor Coordination) to .81 (Intelligence/Numerical Aptitude). Intelligence also shows high correlations with Verbal Aptitude and

Spatial Aptitude, .80 and .69 respectively. The median intercorrelation is .49. Results for this sample were similar to intercorrelations of GATB aptitude scores based on a sample of 2,649 persons as reported in the GATB test manual. The coefficients reported for that sample of a normal population ranged from .16 (Spatial Aptitude/Motor Coordination) to .78 (Intelligence/Numerical Aptitude). The median intercorrelation for the group was .39 (USDL, 1970).

The intercorrelations of the GATB aptitudes for this sample generally agreed with the results of samples from a normal population (USDL, 1970). However, since Intelligence, Verbal, and Numerical Aptitudes are composed of scores from

some of the same tests, these aptitudes would be expected to show higher correlations among themselves than they do with the other aptitudes. Because these aptitudes were related in this way, they were excluded from consideration when assessing the independence of the aptitudes. After excluding the G, V, and N aptitudes, the remaining GATB aptitudes correlated

at a generally higher level than did the CAPS abilities. Of the 33 coefficients considered, 13 were above .50 and only one was below .25.

to obtain a more accurate measure of the independence of each test, a correlation matrix of the GATB test scores was evaluated. The correlation matrix of the 12 GATB test scores

is presented in Table 4. Values of the significant ( $p < .05$ ) correlation coefficients for this sample range from .18 (Place/Three Dimensional Space) to .72 (Assemble/Turn). The median intercorrelation was .44. Several of the tests

showed a rather high correlation. For example, Name Comparison correlated with Computation at .71, Vocabulary with Computation at .70, and Vocabulary with Name Comparison at .67.

Table 5 presents the statistically significant ( $p < .05$ )

intercorrelations among the CAPS abilities for the 91 subjects. Intercorrelations for this sample range from .14 (Numerical Ability/Mechanical Reasoning) to .70 (Word Knowledge/Language Usage) with a median coefficient of .305. The CAPS test manual presents intercorrelations based on samples of 422 tenth grade students and 197 community college freshman. Results from these samples show a similar range of .15 (Manual Speed and Dexterity/Spatial Relations) to .67 (Word Knowledge/Language Usage) with a median coefficient of .35 for the tenth grade students and .01 (Manual Speed and Dexterity/Mechanical Reasoning) to .63 (Word Knowledge/Language Usage) with a median coefficient of .29 (Knapp &

Knapp, 1981). In general, intercorrelations for the tests in the CAPS battery for this sample are as low or somewhat lower than those reported for a normal population.

Anastasi (1982) suggests that when assessing a test battery it is important to inspect the intercorrelations within the battery because "Tests correlating highly with each other represent

needless duplication" (p. 175). Generally, the CAPS intercorrelations were lower than those of the GATB. Only 2 of the 24 significant CAPS coefficients were over .50, with 12 coefficients .25 or lower. In comparison, 22 of the 65 significant GATB test score coefficients were above .50 and only 3 were lower than .25. These results suggest that the CAPS abilities are more in-

dependent than the GATB aptitudes for this sample of clients having psychiatric disabilities.

Principal components factor analysis was carried out on each

Gorsuch (1983) when dealing with less than 40 variables and when the number of factors is expected to be between  $\sqrt{5}$  and  $\sqrt{3}$ . Table 6 shows the eigenvalues, communalities, and percentages of variance of the two extracted factors. The factor matrix after orthogonal rotation to simple structures using the varimax solution is presented in Table 7. The two factors necessary to account for the correlation matrix might be designated as cognitive and psychomotor.

Initial principal components analysis of the CAPS correlation matrix resulted in three factors with eigenvalues greater than 1.0. Table 8 lists the eigenvalues, communalities, and percentages of variance of the three extracted factors. The factor matrix of the CAPS after orthogonal rotation to simple structure using the varimax solution is shown in Table 9. These three factors might be labeled verbal, perceptual, and psychomotor.

The GATB correlation matrix of test scores produced a two-factor solution that accounted for 64.8% of the variance. The CAPS matrix yielded a three factor solution, accounting for 70.0% of the variance. Inspection of Table 9 reveals that only one CAPS ability, Verbal Reasoning, loaded fairly evenly on two of the three factors. The factor loading of the GATB, on the other hand, indicated that two of the tests, Form Matching and Tool Matching, loaded on both factors almost identically. These results might indicate that although the CAPS is a shorter test, it assesses three independent constructs rather than the two independent constructs of the GATB.

**Discussion**

The purpose of this study was to determine the clinical utility of the CAPS versus the more well established GATB with a population of individuals who were psychiatrically disabled. Superior clinical utility was viewed as being based upon client acceptance, ease of administration, reduced period of actual testing time, and the capacity of the assessment instrument to yield a differentiated aptitude structure.

battery in order to test this hypothesis. Initial principal components analysis of the GATB data resulted in two factors with an eigenvalue greater than 1.0. This criterion is suggested by

favor the CAPS because it is briefer and time constraints are less demanding. It is also designed for individual rather than group administration. Although the GATB can be administered individually, this is not usually recommended. Perhaps more significantly, however, the CAPS was found to generate a more differentiated aptitude structure than did the GATB. This conclusion was demonstrated by lower intercorrelations among the CAPS ability scores than among the GATB aptitude scores. Confirmation of this conclusion was obtained from the factor analytic results. The CAPS yielded three factors that met acceptable extraction criteria, while the GATB only yielded two factors.

Correlations between apparently corresponding tests from the two batteries were reasonably high, suggesting that the two procedures assess about the same ability domains. However, the more differentiated structure of these domains

**Table 9**  
Varimax Solution of CAPS

Ability	FACTOR 1	FACTOR 2	FACTOR 3
Mechanical Reasoning	.025	.819	.048
Spatial Relations	.185	.840	.099
Verbal Reasoning	.573	.494	.054
Numerical Ability	.755	.073	.163
Language Usage	.864	.051	.173
Work Knowledge	.820	.170	.105
Perceptual Speed & Accuracy	.407	-.009	.717
Manual Speed & Dexterity	.034	.152	.889

in the case of the CAPS would appear to allow for the formulation of more specific predictions concerning vocational aptitudes. We would speculate that this structural difference is related to difficulty level considerations. A test battery that is too difficult with regard to content or time constraints for a particular population is more likely to generate higher intercorrelations among its components than would be the case for a test battery having a more appropriate difficulty level.

It should be emphasized that the present study does not prove that one test procedure has better predictive validity than the other. It is still necessary to compare the accuracy of the advice given to clients on the basis of the OAPS and CAPS ratings. Furthermore, the present findings may be refined by considering subgroups of clients with different diagnoses. An examination of predictive validity and results for different diagnostic groups could enhance the clinical usefulness of both procedures. This study does point out, however, that because of its psychometric properties and practical considerations such as simple format and individual administration, the CAPS replicates the domains assessed by the GATB but may have certain advantages in the vocational counseling of clients who have psychiatric disabilities.

# Can the Performance of Psychiatric Patients on the General Aptitude Test Battery be Predicted from the Career Ability Placement Survey?

By Lynda J. Katz  
Gerald Goldstein  
Michelle Geckle, and  
Angela Eichenmuller

Date of Acceptance: July 3, 1990

*The study evaluated the accuracy with which one could estimate General Aptitude Test Battery (GATB) scores on the basis of performance on the Career Ability Placement Survey (CAPS) in a sample of 147 psychiatric patients who had received both procedures. Multiple regression analysis was used in which CAPS scales were used as independent variables and GATB scales as dependent variables. Multiple correlation coefficients (Rs) were found to be statistically significant for all twelve GATB scales. A cross-validation achieved by splitting the sample in half and performing separate multiple regression analyses for each subsample was successful, indicating that the regression coefficients were stable. Stepwise analyses indicated which CAPS scales were the most powerful predictors of the various GATB scales. Analysis of the residual scores indicated that predictive accuracy increased as scores approached average levels. It was also noted that the CAPS predicted more accurately to the GATB paper-and-pencil tests than to the performance tests. It was concluded that the CAPS can predict GATB scores reasonably accurately, but caution should be exercised when predicting scores of individuals with extremely high or low CAPS scores, or when estimating GATB performance test scores.*

**K**atz, Beers, Geckle and Goldstein (1989) compared the General Aptitude Test Battery (GATB) (1970) with the Career Ability Placement Survey (CAPS) (Knapp & Knapp, 1984) with the aim of determining which of the two procedures was clinically more advantageous for the vocational assessment of individuals with psychiatric disabilities. Both the GATB and the CAPS are batteries of cognitive, perceptual and motor tests

commonly used to evaluate vocational aptitudes. The GATB consists of eight paper-and-pencil tests and four tests that require the use of apparatus (a board, pegs, rivets and washers). The CAPS consists of eight paper-and-pencil tests.

Utilizing correlational and factor analyses, Katz et al. reached what may be summarized as three conclusions. First, there are robust, significant correlations between conceptually similar CAPS and GATB components. Second, the CAPS yields a more differentiated factor structure in psychiatric patients than does the GATB. Finally, they concluded that in view of the above findings and the fact that the CAPS is a briefer and more efficiently administered procedure than the GATB, it may be the instrument of choice for vocational assessment of psychiatric patients.

Despite these considerations, the GATB remains the "gold standard" for vocational assessment, and is very commonly used for job referral in both the general population and a wide variety of clinical populations. A recent review of the GATB conducted by the National Academy of Science (Hartigan & Wigdor, 1989) provided a generally favorable report with regard to its predictive validity. As a general conclusion, this document states:

A thorough evaluation of the General Aptitude Test Battery (GATB) leads us to conclude that the test has modest levels of validity for predicting job performance, and that these predictive validities are strong enough to produce some enhancement of worker performance for individual employers who use test information in selecting employees. (p. 231)

The massive endeavor made to form that conclusion has not yet been accomplished in the case of the CAPS. Therefore, while the CAPS may have numerous advantages in terms of its appropriateness for psychiatric patients, the availability of GATB scores, or GATB score equivalents, may be to the advantage of those patients because of the wide application and acceptance of the GATB.

In view of these considerations, it appeared that some advantages could be gained if the capability became available of estimating GATB scores from CAPS data. The finding of high correlations between CAPS and GATB scales reported by Katz et al. lent some hope to the possibility of achieving such a goal in a psychometrically satisfactory manner. That is, multiple

regression equations could be generated between sets of CAPS scores as independent variables and GATB scores as the dependent measures. If such equations yielded sufficiently high multiple correlation coefficients, then predicted GATB scores could be generated from CAPS scores with acceptable accuracy levels. If this undertaking proved successful, then patients would be able to benefit from the psychometric and administrative advantages of the CAPS, while at the same time having access to an accurate set of GATB score estimates. The study reported on here was an attempt to achieve that goal in a heterogeneous sample of psychiatric patients.

### METHOD

**Subjects.** The sample consisted of 147 patients referred for vocational assessment to the Neuropsychological Assessment and Rehabilitation Services of Western Psychiatric Institute and Clinic. The mean age was 26.47 years ( $SD = 10.08$ ) with a range of 14 to 53 years. The mean educational level was 11.75 years ( $SD = 2.3$ ) with a range of 7 to 18 years. There were 78 female and 69 male subjects. The Axis I or II DSM-III<sup>2</sup> psychiatric diagnoses (APA, 1980) were 5 nonparanoid schizophrenics, 15 paranoid schizophrenics, 1 atypical psychosis, 29 unipolar mood disorders, 14 bipolar mood disorders, 8 schizoaffective disorders, 6 anxiety disorders, 8 dysthymic or cyclothymic disorders, 7 personality disorders, 1 adjustment disorder, 16 situational reactions, 10 substance use disorders, 14 disorders first evident in infancy, childhood or adolescence, 10 eating disorders, 1 client with mental retardation, 1 organic mental disorder, and 1 specific developmental disorder.

**Procedure.** All subjects included in the study received both the CAPS and the GATB, which were individually administered as parts of their vocational assessments. Results were computer scored and filed in a database for further analysis. The data analysis consisted of a series of multiple regression analyses with the eight CAPS ability scores used as independent variables and the 12 GATB subtest scores as the dependent variables. The GATB test scores were used rather than the aptitude scores since the aptitude scores are not orthogonal. That is, some of the aptitude scores are based on items included in more than one of the individual tests. A separate equation was written for each of the twelve GATB test scores.

Initially, the sample was split into two halves on an odd-even basis in order to do a cross-validation. Separate sets of regression equations were computed for the two subgroups and a determination was made as to whether or not the corresponding regression equations in each subgroup differed at a statistically significant level from each other. The statistical test used was an analysis of variance testing for equality of lines across groups. The procedure is described in Dixon (1985). Basically, a nonsignificant F-ratio indicates that the two subgroups have similar regression equations. If that is the case, it is permissible to combine the two subgroups and calculate regression equations for the total sample. Following these analyses, regression equations were recomputed using the stepwise method in order to determine which combinations of CAPS scales are the most powerful predictors of the various GATB scales. An analysis of

the residual scores, or differences between actual scores and those predicted by the regression equations, was also conducted in order to detect possible differences in predictive accuracy along ranges of scores.

### RESULTS

**Initial Validation and Cross-Validation.** As indicated, the sample was initially split in half and separate sets of regression equations were computed for each half. Then analyses of variance testing for equalities of lines across groups were performed. The multiple correlation coefficients ( $R_s$ ), F-ratios

GATB Scale	Group 1	Group 2	F	p
	(n = 74)	(n = 73)		
	R	R		
Name Comparison	.73	.75	1.21	> .05
Computation	.80	.75	.95	> .05
3-Dimensional Space	.72	.71	.75	> .05
Vocabulary	.81	.82	.99	> .05
Tool Matching	.66	.71	1.27	> .05
Arithmetic Reasoning	.71	.78	1.56	> .05
Form Matching	.72	.61	1.19	> .05
Mark Making	.69	.78	.37	> .05
Place (Pegs)	.53	.67	.42	> .05
Turn (Pegs)	.63	.48	.96	> .05
Assembly (Rivets)	.58	.50	.39	> .05
Disassembly (Rivets)	.57	.62	.49	> .05

and associated probabilities for each of these analyses are presented in Table 1. None of the F-ratios were statistically significant. Thus, cross-validation was successful for all twelve equations in that none of the corresponding pairs of sets of equations differed significantly from each other. We therefore combined the two subsamples and recomputed the regression equations for the total sample. These equations and their associated  $R_s$  are presented in Table 2. The  $R_s$  range from .50 to .80, with the percentages of explained variance ( $R^2$ ) ranging from 25% to 64%. All of the  $R_s$  are statistically significant ( $p < .001$ ), but actual application of the equations depends, of course, upon one's tolerance level for unexplained variance ( $1 - R^2$ ).

**Stepwise Analyses.** These analyses were conducted in order to determine the most powerful CAPS predictor sets for each of the GATB subtests. Stepwise analysis allows for identification of the most powerful predictor variable, and also compute the cumulative increments in explained variance provided by the addition of predictors. Table 3 contains the CAPS scale entered into the regression equations by order of entry for each of the GATB tests as well as the increment in explained variance contributed by each scale entered. Entry of scales was stopped when the probability value of the F-to-enter exceeded .05. This value is the default assigned by the SPSS<sup>X</sup> REGRES

SION (SPSS<sup>X</sup>, 1986) program used for the analysis. In general, there were logical relationships between the CAPS scores entered and the GATB score being predicted. For example, the Perceptual Speed and Accuracy, Language Usage, and Numerical Abilities CAPS scales were entered to predict the GATB Name Comparison Scale. While Numerical Ability does not seem entirely logical, it only contributed 2% to the total explained variance of 51%.

**Analysis of Residual Scores.** Residual scores were examined in order to identify situations in which computing GATB scores from the CAPS based regression equations would lead to substantially inaccurate predictions. Residual scores are the algebraic difference between an actually obtained score and the score predicted by a regression equation. As might be anticipated, a regression to the mean phenomenon was noted in which extremely high GATB scores tended to be underestimated by the CAPS. Similarly, extremely low CAPS scores overestimated GATB scores. This finding was confirmed by

plotting standardized scatterplots for each of the GATB scales in which z-scores of the residuals were plotted against test scores in z-score form. In every case, clearly linear relationships were observed with positive or negative residual scores increasing as the GATB score in question deviated from its sample mean. For illustrative purposes we present the scatterplots for the GATB Name Comparison, Three-Dimensional Space, and Assembly scales in Figures 1, 2 and 3. These scales were chosen in order to present representative data for a verbal test, a spatial ability test and a motor dexterity test. In each case the same linear pattern emerges, indicating that regression to the mean appears to be the major basis for predictive error.

#### DISCUSSION

The major conclusion based upon these multiple regression analyses is that reasonably accurate predictions of GATB sub-test scores can be made on the basis of CAPS performance within the average range of abilities. Caution should be exer-

cised with regard to application of the regression equations presented when the CAPS scores are extremely high or low. If they are high, GATB scores will most likely be underestimated, while if they are low, the GATB scores will probably be overestimated. As indicated, this effect is a regression to the mean phenomenon.

While all of the Rs were highly statistically significant, there was some variation in percentage of explained variance. The multiple correlation coefficient for the GATB Vocabulary scale was .80; it was .50 for the GATB Assembly scale. Thus while robust multiple correlations were found in all cases, predictive confidence may be modified somewhat on the basis of their varying magnitudes.

It was encouraging to find in the stepwise analyses that there was a logical relationship between scales taken from the two batteries. For example, the first two CAPS scales entered into the regression equation for the GATB Vocabulary scale were the CAPS Language Usage and Word Knowledge scales. Correspondingly, the first CAPS variables entered for the GATB Disassembly scale were the Perceptual Speed and Spatial Relations scales. These results suggest that the CAPS and GATB assess similar ability domains, as was also pointed out by Katz et al. (1989).

Referring back to Katz et al.'s factor analyses, the CAPS variables entered into the regression equations for GATB scales that loaded on GATB factor 1, a verbal factor, also loaded on CAPS factor 1, also a verbal factor. A similar relationship was found for CAPS factor 3, a psychomotor factor. Scales loading on CAPS factor 2, the perceptual factor, provided substantial explained variance to the regression equation for the GATB 3-

Dimensional Space scale, although CAPS factor 2 did not have an equivalent in Katz et al.'s factor analysis of the GATB.

In attempting to answer the question raised in the title of this paper concerning predicting GATB scores from CAPS scores, we would first note that there are strong conceptual relationships between the two aptitude batteries, in that they appear to assess comparable ability domains. However, with regard to prediction of scores in individual cases, some cautions should be exercised. First, the regression equations presented here should be used with caution, or should not be used at all when the CAPS profile consists of extremely high or low scores. If the profile is variable, estimates for high and low scores will probably be less accurate than they will be for average level scores. If the regression equations are used under these circumstances, one should understand that GATB estimates made from extremely high CAPS scores will tend to underestimate what the individual would obtain if he or she actually took the GATB, while the opposite is true for extremely low CAPS scores. Users of these tests may not wish to employ the regression equations in the case of clients known to be of exceptionally high or low intelligence. When an estimate of intelligence is not available and the client produces extreme CAPS scores, it may be desirable to administer the GATB. It is suggested that more confidence can be placed in prediction made concerning the GATB pencil-and-paper tests than is the case for the performance tests. The Rs were higher for the former type of test.

These findings do not address themselves to the matter of whether the CAPS or the GATB has superior predictive validity in terms of vocational adjustment. They do, however,

indicate that both procedures assess roughly comparable domains of ability in psychiatric patients. Furthermore, the regression equations provided here allow, in appropriate cases, for making reasonably accurate estimates of GATB scores through the use of a briefer procedure with apparently greater clinical acceptability for psychiatric patients.

# Adult Psychiatric Norms for the Career Ability Placement Survey (CAPS)

By Lynda J. Katz, Gerald Goldstein, Michelle Geckle, Judith Morrissey and Rosalind Daily

## Abstract

*Adult psychiatric patient norms are presented for the Career Ability Placement Survey (CAPS) based upon a sample of 500 psychiatric patients ranging in age from 14 thru 59. Separate norm tables are presented for the total sample, for subjects who completed 10 thru 12 years of education, and for subjects who received at least 1 year of college education. Statistically significant gender differences were found for some of the CAPS scales. A table providing separate norms for males and females is presented for those scales. It was noted that, in general, the patient norms obtained did not deviate greatly from the national norms.*

The Career Ability Placement Survey (CAPS) (Knapp & Knapp, 1984) is widely used in vocational evaluations as a method of assessing employment relevant patterns of ability. It is similar in intent to other vocational assessment procedures such as the General Aptitude Test Battery (GATB) and the Differential Aptitude Test. It consists of eight scales: Mechanical Reasoning, Spatial Relations, Verbal Reasoning, Numerical Ability, Language Usage, Word Knowledge, Perceptual Speed and Accuracy and Manual Speed and Dexterity. Raw scores from each of these scales are converted to stanine scores, and may be plotted on an ability profile. The scores may also be plotted on the CAPS Career Profile Sheet allowing for comparison between scores obtained and ability levels required for fourteen major occupational areas.

The eight stanine scores form the basis for the information derived from the CAPS Career Profile Sheet, and ultimately for the portion of career planning that is based upon performance on the CAPS. The norms for setting the cutting points for the stanines were developed by testing large national samples of intermediate, high school and community college students. However, the CAPS may be used for adults no longer in school and in special populations of adults. The special population considered here is adults with psychiatric disabilities. Aptitude testing is commonly used for such individuals (Anthony & Jansen, 1984; Bidwell, 1969), but typically they are no longer in school when the tests are administered. Furthermore, certain characteristics associated with these individuals' psychiatric disorders are capable of influencing performance on ability tests. Therefore, the fact that ability tests are administered to individuals who (1) are no longer in school and (2) have mental illness, may indicate that available national norms, despite their adequacy in a general student population, may not be appropriate for such individuals.

Inappropriate norms for an individual are generally conceived of as those that are based upon samples of subjects that are not composed of peers of the test-taker in some respect. In the case of ability tests, educational peers are generally used. However, in the case of the CAPS, the normative samples consisted of individuals currently in school, as opposed to psychiatric patient test-

takers, who are usually assessed in clinical settings following completion of their educations. Furthermore, individuals with mental illness were not specifically represented in the CAPS national normative samples. A major consequence of inappropriate norms is disproportionate representation. Reschly (In Press) defines disproportionate representation as follows: "Disproportionate representation occurs whenever an identifiable group has significantly greater or fewer members in a particular classification than would be expected from their actual numbers or percentages in the general population" (p.155) In the case of the CAPS, that would translate to the possibility that individuals with psychiatric disorders may be classified into the various stanine groups in a distribution that is substantially deviant from what is found in the general population. While such classification may ultimately be predictive of actual vocational success, it may have unfortunate consequences for the counseling process, since the client's ability levels may be evaluated with reference to an inappropriate peer group.

It is not being suggested that the national CAPS norms are de facto inappropriate for psychiatric patients. However, that may be the case, and it would be worthwhile to evaluate the matter. If psychiatric norms are needed and developed, their availability would allow the counselor not only to assess the client's ability levels relative to the general population, but also relative to others no longer in school, and with disabilities or illnesses similar to her's or his. The CAPS was chosen for this study because of considerations raised in an article by Katz, Beers, Geckle and Goldstein (1989) in which it was pointed out that CAPS has psychometric and administrative advantages for psychiatric patients over the more commonly used GATB.

## METHOD

### Subjects

The sample consisted of 500 psychiatric patients referred to the Neuropsychological Assessment and Rehabilitation Services of Western Psychiatric Institute and Clinic for vocational evaluations. The large majority of subjects were in outpatient status, but a small number of them received their evaluations while still inpatients pending discharge. The sample's diagnostic composition appeared to be reasonably representative of general psychiatric facilities. The percentages in each major diagnostic category were as follows: organic mental disorders (3%); schizophrenic disorders (18%); mood disorders (30%); anxiety disorders (9%); personality disorders (5%); substance use disorders (3%); eating disorders (7%); adjustment disorders (10%); conduct disorders (5%); specific developmental disorders (3%); and other disorders originating in childhood (1%), with the remaining 6% having other miscellaneous diagnoses. There were 238 male and 162 female subjects. Three hundred and ninety-eight subjects were white, 94 were Afro-Americans, and the remainder belonged to

other ethnic minority groups. The mean age was 28.23 years (SD = 10.22) with a range of 14 through 59 years of age. The mean educational level was 12.24 years (SD = 2.16), with a range of from 8 through 19 years of education.

### Procedure

The CAPS was individually administered by trained specialists as part of a more comprehensive rehabilitation evaluation. Scoring was accomplished by computer and the results were entered into a data base. Protocols with incomplete data, or judged by the tester to be invalid, were not included in the study.

The major data analyses were directed toward producing tables comparable to those found in the CAPS manual (Knapp & Knapp, 1984) that convert raw scores on each of the eight scales to stanines. In the system used, the stanines are set at 4th, 11th, 23rd, 40th, 60th, 77th, 89th, 96th percentiles, and range from 1 representing very low performance to 9 representing very high performance. The manual contains conversion tables for each scale for individuals in grades 8-9, in grades 10-11-12, and in community college. In this study, tables were produced for subjects in grades 10-11-12, and for community college; there were not enough subjects to produce meaningful 8-9 grade tables. Subjects with less than a 10th grade education were included in the tables for the total sample of 500, but were excluded from the tables prepared for subjects with appropriate educational levels for the 10-11-12 grade and community college tables.

In addition to preparing separate education related tables, separate tables for females and males were constructed. The CAPS manual does not present separate norms for females and males, but the researchers were uncertain about the presence of significant gender differences in an adult psychiatric sample. A multivariate analysis of variance (MANOVA) was performed in order to evaluate the statistical significance of obtained gender differences. This analysis also examined data for the presence of a significant interaction between gender and educational level. In those cases in which statistically significant ( $p < .05$ ) gender difference were found, separate conversion tables for females and males were constructed.

## RESULTS

### The Tables of Norms

The stanine score conversions for the total psychiatric sample and the CAPS manual 10-11-12 grade conversions are presented in Table 1. The 10-11-12 grade table was chosen for comparison because the mean educational

<sup>1</sup> Grade 10-11-12 norms were used.

level of the psychiatric sample (12.24 years) fell into that range. Inspection of Table 1 indicates only a modest discrepancy between the psychiatric and national sample norms. The direction

of the discrepancy varies from scale to scale. For example, in the case of the Mechanical Reasoning Scale, relatively lower scores were required by the psychiatric patients for assignment to particular stanines than was the case for the national sample. Thus, for example, psychiatric patients with scores of 10-11 were classed 7th stanine, while scores of 12-13 are required for the national sample. However, in the case of the Manual Speed and Dexterity Scale, the opposite relationship occurred. Here, for example, scores between 295 and 330 placed national sample subjects into the 7th stanine, while psychiatric patients required scores ranging between 316 and 377 for placement into that stanine.

Comparisons between patients and national sample subjects with high school level educations are presented in Table 2. Essentially the same relationship are seen here as was the case

for the total sample. That is, the raw score to stanine conversions are not very deviant from each other in two samples, with scale to scale variations between patients and the national sample regarding whether or not relatively higher or lower score ranges are required for assignment to a particular stanine.

The community college data are presented in Table 3.

In this case, the decision was made to include all patients who completed one year or more of college education. Thus, some of the patients received more than a two year community college education. The reason for that decision was that no national norms are available for people with more than community college education, and so the national norm table for the community college group is the most appropriate one to use for individuals with advanced educations. It is therefore likely to be the one used by clinicians that administer the CAPS to adults who have more than two years of college education. Inspection of Table 3 indicates the same pattern as was seen in the other comparisons. The

Is for stanine assignment in both the national sample and the

patient group are more rigorous relative to the high school samples. For example, at the high school level, scores of 19-22 in the national sample or 20-22 in the patient sample are required for assignment to the 7th stanine on the Language Usage Scale. In the case of the community college table, the comparable values are 22-23 for the national sample and 25-26 for the patients.

### Gender Differences

The CAPS manual does not contain separate norm tables for females and males; in this study, it was decided to examine the matter of possible gender differences on the various scales for the following reasons. First, the existence of known gender differences regarding certain of the abilities assessed by the CAPS has been documented (Mancoby & Jacklin, 1974). Secondly, while gender differences may not emerge in the child and young adult samples used for national norms, such differences may appear in relatively older adults.

The major statistical method used was a factorial design multivariate analysis of variance (MANOVA), with the CAPS scales as the dependent measures, and gender and education as the two factors, or independent variables. Subjects were divided into high and a low education group on the basis of a median split. Thus, subjects with 13 or more years of education were placed in the high education group, and the other subjects were placed in the low education group. Education was considered in order to rule out the possibility that apparent gender differences could be artifacts of gender differences in educational level. The results of the MANOVA are summarized in Table 4.

Table 4

### MANOVA Results Comparing Subjects with Relatively High and Low Levels of Education and Female and Male Subjects

Effect	Exact F (d.f. = 8/488)	p
Education	18.71	<.001
Gender	17.11	<.001
Education X Gender	1.41	NS

### Univariate F-Tests (d.f. = 1, 495)

Scale	F (Ed.)	p	F (Ge.)	p	F (Ed. x Ge.)	p
Mechanical Reasoning	19.57	<.001	31.30	<.001	.02	NS
Spatial Relations	22.10	<.001	2.51	NS	.02	NS
Verbal Reasoning	26.92	<.001	4.16	<.05	.16	NS
Numerical Ability	74.30	<.001	.00	NS	3.30	NS
Language Usage	107.66	<.001	41.55	<.001	4.04	<.05

Manual Speed & Dexterity	2.67	NS	6.68	<.01	1.49	NS

NS = not statistically significant; Ed. = Educational Level  
Ge. = Gender

There are significant overall main effect for both educational level and gender. That is, males differed significantly from females on the multivariate series of CAPS scores, as did the higher education group from the lower education group. However, the overall education level by gender interaction was not statistically significant.

cant; this finding indicates that the gender differences found are not generally confounded with educational level. The only possible exception is the Language Usage scale in which there was a statistically significant interaction ( $p < .05$ ) between gender and educational level. However, the absence of overall significance substantially vitiates the meaningfulness of that finding.

Significance tests for gender, educational, and interactional effects for the individual CAPS scales are also presented in Table 4. The education effect was statistically significant for all scales except the Manual Speed and Dexterity scale. Females were found to perform better than males at statistically significant ( $p < .05$ ) levels on the Verbal Reasoning, Language Usage, Word Knowledge, Perceptual Speed and Accuracy, and Manual Speed and Dexterity scales. Males did significantly better than females only on the Mechanical Reasoning. A normative table presenting raw score to stanine conversions by gender for the sample is presented in Table 5.

**DISCUSSION**

The major purpose of this article is to present normative data on the CAPS for adult psychiatric patients. However, the data obtained would suggest that the norms developed with our 500 psychiatric patients do not differ substantially from those based upon the national sample. This finding is somewhat surprising in view of the widespread beliefs and extensive literature concerning cognitive impairments in individuals with chronic mental disorders. While in most cases lower raw scores were required for assignment to a particular stanine in the psychiatric sample relative to the national sample, sometimes the reverse occurred. For example, in the case of the high school norms (Table 2), the range of scores for assignment to the eight stanine of the Manual Speed and Dexterity scale is 331-375 for the national sample, but 355-416 for the patient sample. It is not being suggested that this difference is statistically or clinically significant, but it does indicate that the ability levels of the psychiatric sample were not uniformly underestimated because of utilization of an inappropriate normative sample. Thus, the patient norms presented here may be applied, but the CAPS user would not typically substantially overestimate or underestimate an adult psychiatric patient's capacities by utilizing the national sample norms. In effect, the present investigation supports the conclusion made by Katz et al. (1989) that the CAPS is a psychometrically satisfactory instrument for adult psychiatric patients.

Despite the fact that the patients were sometimes administered the CAPS long after they completed their educations, while the national sample consisted of individuals still in school, the impact of education was strong in both groups. For example, in the case of the Numerical Ability scale, in the national high school sample, a score of 11 or 12 is required for assignment to the fifth stanine, while a score of 12 or 13 is required for the community college sample. In the case of the patients, the comparable scores are 9 or 10 in the high school sample, and 12 or 13 in the college sample. Comparisons between Tables 2 and 3 provide a consistent pattern of educational influence in both the patient and national samples. It would therefore appear that education has an impact despite the length of time since its completion, and the presence or absence of a psychiatric disorder.

The significance of the gender differences found is apparently of some relevance, since it affects stanine assignment. Referring to Table 5, it will be noted, for example, that females require a score of 7 to be assigned to the fifth stanine of the

## Author Notes

Mechanical Reasoning scale; males require a score of 8 or 9. Conversely, on the Language Usage scale, females require a score ranging between 15 and 18 to be assigned to the fifth stanine, while males only require scores ranging from 11 to 14. As demonstrated above, these differences cannot be readily attributed to educational differences between males and females in the sample.

In summary, while adult psychiatric patient norms for the CAPS have been provided, it seems apparent that the use of the national norms would not be misleading when applied to psychiatric patients. Furthermore, the influence of education on test performance appears to be of comparable magnitude in the national and the patient samples. Gender differences were noted on several of the CAPS scales, for the most part favoring females. Whether or not these differences appear in groups other than adult psychiatric patients cannot be answered by the present study, but might merit further investigation.

SCHIZOPHRENIA IN THE 90'S

WHAT IS IT?

WHAT CAUSES IT?

HOW TO TREAT IT?

SCHNEIDERIAN FIRST RANK SYMPTOMS

1. AUDITORY HALLUCINATIONS IN WHICH THE VOICES SPEAK ONE'S THOUGHTS ALOUD
2. AUDITORY HALLUCINATIONS WITH TWO VOICES ARGUING
3. AUDITORY HALLUCINATIONS WITH THE VOICES COMMENTING ON ONE'S ACTIONS
4. HALLUCINATIONS OF TOUCH WHEN THE BODILY SENSATION IS IMPOSED BY SOME EXTERNAL AGENCY
5. WITHDRAWAL OF THOUGHTS FROM ONE'S MIND
6. INSERTION OF THOUGHTS INTO ONE'S MIND BY OTHERS
7. BELIEVING ONE'S THOUGHTS ARE BEING BROADCAST TO OTHERS, AS BY RADIO OR TELEVISION
  
8. INSERTION BY OTHERS OF FEELINGS INTO ONE'S MIND.
9. INSERTION BY OTHERS OF IRRESISTABLE IMPULSES INTO ONE'S MIND.
10. FEELING THAT ALL ONE'S ACTIONS ARE UNDER THE CONTROL OF OTHERS, LIKE AN AUTOMATION.
11. DELUSIONS OF PERCEPTION, AS WHEN ONE IS CERTAIN THAT A NORMAL REMARK HAS A SECRET MEANING FOR ONESELF.

DSM-III-R DIAGNOSTIC CRITERIA FOR SCHIZOPHRENIA

- A. PRESENCE OF CHARACTERISTIC PSYCHOTIC SYMPTOMS IN THE ACTIVE PHASE FOR AT LEAST ONE WEEK
- (1) TWO OF THE FOLLOWING DELUSIONS:  
PROMINENT HALLUCINATIONS  
INCOHERENCE OR LOOSENING OF ASSOCIATIONS  
CATATONIC BEHAVIOR  
FLAT OR INAPPROPRIATE AFFECT
  - (2) BIZZARE DELUSIONS
  - (3) PROMINENT HALLUCINATIONS, E.G., A VOICE WITH CONTENT HAVING NO APPARENT RELATION TO MOOD

- B. FUNCTIONING IN SUCH AREAS AS WORK, SOCIAL RELATIONS, AND SELF-CARE IS MARKEDLY BELOW LEVEL ACHIEVED BEFORE ONSET OF THE DISTURBANCE.
- C. SCHIZOAFFECTIVE DISORDER AND MOOD DISORDER HAVE BEEN RULED OUT.
- D. CONTINUOUS SIGNS OF THE DISTURBANCE FOR AT LEAST SIX MONTHS - MUST INCLUDE AN ACTIVE PHASE WITH SYMPTOMS AS NOTED IN A, WITH OR WITHOUT A PRODROMAL OR RESIDUAL PHASE.

D. (con't.)

PRODROMAL OR RESIDUAL SYMPTOMS

MARKED SOCIAL ISOLATION OR WITHDRAWAL

MARKED IMPAIRMENT IN ROLE FUNCTIONING

PECULIAR BEHAVIOR

IMPAIRMENT IN PERSONAL HYGIENE

BLUNTED OR INAPPROPRIATE AFFECT

DIGRESSIVE, VAGUE, OVER ELABORATE, OR CIRCUMSTANTIAL SPEECH, OR POVERTY OF SPEECH, OR POVERTY OF CONTENT OF SPEECH

ODD BELIEFS OR MAGICAL THINKING

UNUSUAL PERCEPTUAL EXPERIENCES

MARKED LACK OF INITIATIVE, INTERESTS, OR ENERGY

- E. IT CANNOT BE ESTABLISHED THAT AN ORGANIC FACTOR INITIATED AND MAINTAINED THE DISTURBANCE
- F. IF THERE IS HISTORY OF AUTISTIC DISORDER, THE ADDITIONAL DIAGNOSIS OF SCHIZOPHRENIA IS MADE ONLY IF PROMINENT DELUSIONS OR HALLUCINATIONS ARE ALSO PRESENT

SCHIZOPHRENIA	)	6 MONTHS DURATION

DEFICIT STATE SYMPTOMS

decreased plasma HVA

decreased CSF HVA

decreased prefrontal blood flow  
during frontal tasks

POSITIVE SYMPTOMS

increased activity in A10

increased plasma HVA and positive symptoms

higher plasma HVA concentration  
and responsiveness to neuroleptics

# A Neurodevelopmental Approach to the Classification of Schizophrenia

by Robin M. Murray, Eadbhard O'Callaghan, David J. Castle, and Shon W. Lewis

## Abstract

The conventional distinction between schizophrenia and manic depression has received little objective support from recent studies of phenomenology, outcome, or familial homotypy. Instead, much clinical, epidemiological, and morphological evidence suggests that within the broad range of Schneiderian schizophrenia there exists one form (congenital schizophrenia) that can be distinguished from other types, the manifestations of which are confined to adult life. We hypothesize that congenital schizophrenia is a consequence of aberrant brain development during fetal and neonatal life. Such patients show structural brain changes and cognitive impairment, and in their male predominance, early onset, and poor outcome, they reflect Kraepelin's original description of dementia praecox. We contend that adult-onset schizophrenia is itself heterogeneous. One important component is a relapsing and remitting disorder that is more frequent in females than in males, exhibits positive but not negative symptoms, and has much in common etiologically with affective psychosis. There also exists a very-late-onset group in which degenerative brain disorder is implicated.

In 1985 we put forward the view that it would soon be possible for psychiatry to move beyond the syndromal diagnosis of the psychoses (Murray et al. 1985a). In particular, we emphasized the value of distinguishing between genetic and environmental causes, and we suggested that the structural brain abnormalities found in a portion of sporadic cases of schizophrenia were consequences of environmental hazards operating during fetal or neonatal life.

Since that time, neuropathologic and neuroimaging research into schizophrenia has continued apace, and it is now commonplace to interpret the findings in neurodevelopmental terms (Feinberg 1983; Weinberger 1987; Murray et al. 1988; Cannon et al. 1989). Evidence of etiological heterogeneity has accumulated, and the different presentation of schizophrenia in males and females has aroused much interest. However, lines of research into genetics, epidemiology, brain abnormality, and gender differences have continued along largely separate paths and have not been integrated into a coherent theory. This article sets out to rally this new evidence and consider a theoretical framework in which it can be understood.

## The Present Position

There is little agreement about what constitute the essential features of schizophrenia. Until recently, most European psychiatrists believed that Schneider's first-rank symptoms represented the core of schizophrenia and could be used to distinguish it from other psychotic disorders. However, first-rank symptoms occur in a substantial minority of patients with affective psychosis (Carpenter et al. 1973; Wing and Nixon 1975), while first-rank symptoms are not exhibited at all by almost a third of schizophrenic patients (Mellor 1970; Koehler 1979), and the presence of such symptoms has no predictive value (Brockington et al. 1978). Furthermore, sophisticated statistical

Reprint requests should be sent to Dr. R.M. Murray, Dept. of Psychological Medicine, Institute of Psychiatry, De Crespigny Park, Denmark Hill, London SE5 8AF, United Kingdom.

approaches have failed to find a point of rarity between the clinical manifestations of schizophrenia and those of manic depression (Kendell and Gourlay 1970; Kendell and Brockington 1980).

**An Inevitable Deterioration?** In contrast to the broader Schneiderian criteria popular in Europe, American diagnostic criteria for schizophrenia have been narrowed so that they may better predict a course of progressive deterioration as described by Kraepelin (Murray and Foerster 1987). However, recent followup studies cast doubt on this pessimistic view of outcome. These studies have been comprehensively reviewed by Shepherd and colleagues (1989), but table 1 summarizes a number of those studies of long-term outcome in schizophrenia that used adequate samples (50 subjects or more) and included a majority of first-episode cases. As can be seen, most studies found that about a fourth of the cases showed good clinical and social recovery. Poor outcome is less easy to define, but all but one of the studies reported poor outcome in less than 50 percent of cases.

In examining the other side of the Kraepelinian coin, it is by no means clear that patients with affective disorder have an invariably good prognosis. Clayton (1981) suggested that as many as a third of bipolar patients have a poor outcome. Akiskal (1982) found that 26 percent of patients with primary depressive illness became social invalids, while Paykel and Weissman (1973) reported that poor social outcome was not uncommon. Lee and Murray (1988), who carried out an 18-year followup of 89 hospitalized primary depressive patients, noted that 35 percent had "very poor outcome," while 13 percent had subsequent episodes of schizoaffective disorder and 7 percent developed either chronic paranoid or schizophrenic psychoses.

When viewed collectively, the studies that have been mentioned suggest that the outcome in schizophrenia is not as bleak as Kraepelin believed, while that of affective psychosis is worse than he envisioned.

**Genetic Validity?** Many studies have confirmed that schizophrenia is familial (Murray et al. 1986; McGuffin et al. 1987), one of the most rig-

orous being that of Kendler and colleagues (1985). However, Kendler and colleagues reported that bipolar disorder occurred twice as frequently among the relatives of schizophrenic patients as among the relatives of a control group. There is also compelling evidence from family interview studies (Gershon et al. 1988) and family history studies (Foerster et al. 1991b) that morbid risk of unipolar affective disorder is higher in the relatives of probands with schizophrenia.

Furthermore, a number of large pedigrees containing some individuals affected by schizophrenia and others by bipolar affective disorder have been reported (Waddington and Youssef 1988; St. Clair et al. 1989; Pope and Yurgelun-Todd 1990). Diagnostic overlap also occurs in twin and triplet studies. For example, McGuffin and colleagues (1984, 1987) reviewed the Maudsley monozygotic (MZ) twin series originally described by Gottesman and Shields (1972) and noted the occurrence of five pairs in which the proband was diagnosed as having *DSM-III* (American Psychiatric Association 1980) schizophrenia,

Table 1. Long-term outcome of schizophrenia

Reference	Number of subjects	Average length of followup (years)	Functioning adequately without psychotic symptoms (%)	Intermediate (%)	Functioning poorly (e.g., prolonged hospitalization or suicide) (%)
Bleuler (1972)	208	5-23	30	34	35
Strauss and Carpenter (1972)	85	2	24	56	20
Tsuang et al. (1979)	200	35	20	25	55
Ciompi (1980)	282	37	36	40	23
Huber et al. (1980)	502	8-28	22	40	35
McGlashan (1984)	163	15	14	46	41
Harding et al. (1987)	253	20	26	37	38
Westermeyer and Harrow (1984)	153	3-5	21	21	45

yet the second twin received a diagnosis of affective disorder according to *DSM-III*.

Ødegård (1972) showed that it was those schizophrenic probands "without registered defect" (i.e., schizoaffective and allied conditions) whose relatives had an increased risk of affective psychosis. Relatives of schizophrenic probands "with severe defect" had a much lower risk of affective psychosis and a higher risk of schizophrenia. These data are consonant with many other studies. For example, McCabe and colleagues (1971) reported a morbid risk for affective disorder of 10 percent in the first-degree relatives of "good prognosis schizophrenia" but only 1.5 percent in the relatives of "poor prognosis schizophrenia." The pattern of morbid risk for schizophrenia was reversed in the relatives of good and poor-prognosis probands (3.6% and 11.6%, respectively). Pope and Lipinsky (1978, p. 817) concluded that "schizophrenics of the good prognosis categories show typically two to three times as much familial affective illness as schizophrenia; poor prognosis groups show a two to threefold difference in the opposite direction."

Kendler and Tsuang (1988), reviewing all published studies on the effect of schizophrenia or affective disorder in a relative on the prognosis of schizophrenia in the proband, including the Iowa 500 sample (Morrison et al. 1972), concluded that a family history of affective disorder confers a good outcome. In their own Iowa 500 sample, morbid risk of affective disorder was significantly higher in the relatives of good-outcome schizophrenic patients than in those with a poor outcome, who actually had lower family risk of affective disorder than was found in surgical control probands.

A study of MZ twins diagnosed by the Research Diagnostic Criteria (RDC; Spitzer et al. 1978) showed that the MZ co-twins of schizoaffective probands tended to be diagnosed as either suffering from schizoaffective disorder or major affective disorder but only rarely as schizophrenic or schizotypal personality disorder (SPD) (Murray et al. 1984; Murray and O'Callaghan 1991). On the other hand, the co-twins of schizophrenic probands were more frequently diagnosed with schizophrenia or SPD than as having schizoaffective or major affective disorder. The implication is that genetically RDC schizoaffective disorder is relatively distinct from RDC schizophrenia and that the latter is more closely related genetically to SPD than to affective disorder.

Six studies have shown increased rates of SPD in the relatives of *DSM-III*-defined schizophrenic patients (e.g., Kendler 1988). Furthermore, Kety and colleagues (1978) found rates of SPD in the relatives of adoptees with acute schizophrenia that were substantially lower than the rates in the relatives of adoptees with chronic schizophrenia. In their reanalysis using *DSM-III* criteria, Kendler and Gruenberg (1984) found SPD no more common in the biologic relatives of adoptees with atypical or schizophreniform disorders than in the relatives of control adoptees.

All of these studies are consistent with the notion that the appropriate genetic distinction is not between schizophrenia and affective psychosis but rather between acute schizophrenia, schizoaffective disorder, and affective psychosis on the one hand and chronic schizophrenia and SPD on the other. As Kety (1980, p. 426) states, "The group of acute functional psychoses differs so much

from classical schizophrenia that it is difficult to see what advantage inheres in our continuing to confound them."

**Summary of the Present Position.** The distinction between manic depression and schizophrenia in terms of phenomenology, outcome, and familial homotypy is flawed. The evidence we have reviewed suggests that the failure to establish a valid subdivision of the psychoses is a consequence of the distinction being made at the wrong point, and that Kraepelin's original narrow concept of dementia praecox represents a much more distinct entity than the modern notion of schizophrenia.

Unfortunately, dementia praecox became subsumed in a wider range of disorders that resemble it in Schneiderian symptomatology but differ markedly in etiology, epidemiology, and brain morphology. It is notable that the only group able to distinguish statistically between the clinical manifestations of schizophrenia and other psychiatric disorders used a much narrower concept of schizophrenia than is generally accepted (Cloninger et al. 1985). Schizophrenia, as defined by these authors, was familial and had a poor outcome, leading the authors to conclude that they had validated the disease concept.

### Neurodevelopmental Deviance In Schizophrenia

**Early Development.** The histories of schizophrenic patients are characterized by an excess of obstetric complications (OCs) versus normal controls and other psychiatric patients (McNeil and Kaij 1978; Lewis and Murray 1987). Furthermore, schizophrenic patients with a history of OCs develop the disorder an average

of 5 years earlier than those without such a history (Lewis et al. 1989). OCs are particularly associated with chronic rather than acute remitting schizophrenia (McNeil and Kaij 1978; Parnas 1990; Foerster et al. 1991a).

Murray and colleagues (1985a) suggested that OCs may be one of several environmental factors that may act independently to predispose individuals without an obvious genetic predisposition to the subsequent development of schizophrenia. An alternative view is that OCs may be an indirect indicator of some earlier insult to the nervous system or a secondary consequence of some genetic defect in neural development (Goodman 1988; Owen et al. 1988). The latter explanation seems unlikely given the lower frequency of OCs in schizophrenic patients with, rather than without, a family history of the disorder (Lewis and Murray 1987).

There is also evidence that maternal influenza during pregnancy can increase the risk to the fetus of later developing schizophrenia. Studies in Finland (Mednick et al. 1988) and England (O'Callaghan et al. 1991) have shown that after the 1957 pandemic of Asian flu there was a significant increase in the number of births of individuals who later developed schizophrenia. The "schizophrenogenic effect" of influenza epidemics is not confined to Asian flu; influenza epidemics in Denmark (Barr et al. 1990) and England (Sham et al., in press) over four and two decades, respectively, had a consistent risk-increasing effect on those individuals in the later part of their fetal life during the epidemic. Presumably, maternal influenza or some factor associated with it causes a subtle impairment of brain development in the fetus.

The excess of abnormal dermallymphic patterns and minor physi-

cal anomalies (MPAs) in schizophrenic patients (Gualtieri et al. 1982; Guy et al. 1983; Green et al. 1987) provides a further indication of developmental disruption. These trivial abnormalities in ectodermal development are of little consequence in themselves, but ectodermal development during fetal life closely parallels that of the central nervous system, and MPAs are known to occur in excess in patients with established developmental disorders (Smith 1976). Green and colleagues (1987, 1989) found MPAs to predict a younger age of onset of schizophrenia, while Waddington and colleagues (1990) reported that MPAs were more common among those who are cognitively impaired.

Premorbid cognitive dysfunction in schizophrenia is another important yet underresearched piece in this developmental jigsaw puzzle. In a comprehensive review, Aylward and colleagues (1984) concluded that preschizophrenic children showed deficits on standard IQ tests versus matched groups of peers or siblings with no later psychiatric disorder. Moreover, such deficits predicted early-onset, poor-prognosis illnesses.

Kraepelin had little doubt that some individuals with dementia praecox had behaved differently, even as children, from their siblings and peers. Recently, in a controlled, blind study that interviewed the mothers of 73 DSM-III-diagnosed psychotic patients, Foerster and colleagues (1991b, 1991c) confirmed the occurrence of childhood schizoid and schizotypal traits and poor social adjustment in a proportion of schizophrenic patients. Those schizophrenic patients who were abnormal as children had an early onset of psychosis and were characterized by either a family history of schizophrenia or a history of OCs or low birth weight.

**Structural Brain Abnormality.** Neuropathologic studies (Bogerts et al. 1985; Brown et al. 1986) show that, compared with control subjects, schizophrenic patients have slightly lighter brains and smaller temporal lobe structures, usually with an absence of gliosis (Bruton et al. 1990). Recently, Falkai and colleagues (1990) confirmed Jakob and Beckmann's (1986) findings of heterotopic pre-alpha cells in the entorhinal cortex of postmortem schizophrenic brains; both groups interpret these findings to be consequences of failure of neuronal migration. Since the migration of these cells is largely complete by birth, such findings suggest a developmental, rather than a degenerative, pathology.

Neuropathologic studies have, by necessity, been carried out on samples too small and patients too poorly documented to correlate clinical findings with structural changes. However, neuroimaging studies have been able to address this issue. Thus, it has been demonstrated that the cerebral ventricular enlargement found in a proportion of schizophrenic patients is not the result of treatment (Johnstone et al. 1976; Williams et al. 1985), is present at the onset of illness (Nyback et al. 1982; Weinberger et al. 1982), is nonprogressive in most cases, and may be associated with poor premorbid adjustment (Weinberger et al. 1980; Williams et al. 1985). Harvey and colleagues (1992), who found a diffuse reduction in the volume of cortical gray matter in schizophrenic patients on magnetic resonance imaging (MRI), reported that this reduction was associated with poor premorbid function.

Several studies have compared ventricular size in familial versus sporadic schizophrenic patients. The studies in which a difference was

found have generally found sporadic schizophrenic patients to have larger ventricles than familial schizophrenic patients, although the results have not been consistent (Murray et al. 1988; Lewis 1990). However, the important role of environmental factors has been put beyond doubt by studies of MZ twins discordant for schizophrenia (Reveley et al. 1982; Murray et al. 1985b; Suddath et al. 1990), showing that the affected twin has larger ventricles and less temporal lobe volume than the identical but well co-twin. It is not surprising that investigators have sought to establish whether the occurrence of OCs might be the critical factor. Of 10 studies that have looked for an association between quantitative computed tomography (CT) abnormalities and a history of OCs, 5 have found a statistically significant link (Lewis 1990). This point is impressive in view of the high chances of a Type 2 error as a result of low rates of OCs in most of these studies and the constraints on reliability of the data. It seems likely that OCs are one of a number of early environmental factors associated causally with ventricular enlargement. Maternal influenza may be another (O'Callaghan et al. 1991; Sham et al., in press).

Since only a subset of schizophrenic patients demonstrate structural brain changes, investigators have attempted to find the clinical parameters of this subpopulation. One of the most consistent findings is that of cognitive impairment (Johnstone et al. 1976), but significant relationships have also been reported with negative symptoms (Andreasen et al. 1982; Pearlson et al. 1984a), a poorer response to neuroleptics (Luchins et al. 1984), and poor outcome (Williams et al. 1985). The fact that not all studies have

confirmed these relationships may relate to the heterogeneity of schizophrenia. Johnstone and colleagues (1989a) noted that deficits in cognitive function were correlated with decreased brain area only in patients with early-onset psychosis. Early onset was also associated with poor academic and occupational performance and with negative symptoms. It is, therefore, notable that the pre-alpha cell abnormalities reported by Jakob and Beckmann (1986) and Falkai and colleagues (1990) were seen particularly in patients who presented before age 25.

Thus, there appears to be a subgroup of schizophrenic patients who demonstrate morphological brain changes that antedate the development of the positive clinical syndrome. These brain changes signify early developmental deviance and occur most commonly among those with poor premorbid adjustment, evidence of cognitive impairment, early onset, and poor outcome (Murray et al. 1988). The existence of such developmental abnormalities does not, of course, exclude the possibility that some schizophrenic patients, particularly those with onset in late life, have anatomic changes of a degenerative nature (Pearlson et al. 1991).

#### **Do Acute Psychotic Patients Have Evidence of Neurodevelopmental Abnormality?**

**Affective Psychosis.** Now that it is clear that a proportion of patients with schizophrenia have neurodevelopmental impairment, it is incumbent upon us to ascertain whether the same holds for affective psychosis. To our knowledge, there have been no systematic studies of MPAs in patients with affective disorder. There have been few studies of OCs

or of premorbid personality in such patients, but the previously-mentioned study of Foerster and colleagues (1991b, 1991c) did address both these issues. Evidence of OCs having occurred was obtained for 40 percent of probands with schizophrenia but for only 7 percent of probands with affective psychosis. Childhood personality and adjustment were unremarkable among those who went on to develop affective psychosis. Similarly, soft neurological signs are uncommon in patients with affective disorder (Woods et al. 1986), and O'Callaghan and colleagues (personal communication 1991) failed to find any relationship between exposure to influenza epidemics in fetal life and later affective disorder.

What of those other findings that have been associated with neurodevelopmental abnormality in schizophrenia? Unfortunately, the only substantial neuropathologic study of affective psychosis is that of Brown and colleagues (1986), who compared the brains of 26 schizophrenic patients with those of 41 unipolar depressive and 29 bipolar patients. The schizophrenic patients had larger cerebral ventricles, their brains were 6 percent lighter, and their parahippocampal cortices were 11 percent thinner than those of the patients with affective disorder. The schizophrenic patients showed dilation of the temporal horn of the lateral ventricle, but no such change was noted among the patients with affective disorder.

A number of CT and MRI studies have been carried out in patients with affective psychosis, but many of these studies have been concerned with elderly patients (Jacoby and Levy 1980) or with severe or resistant forms of the disorder (Standish-Barry et al. 1982; Targum et al.

1983; Luchins et al. 1984; Pearlson et al. 1984a, 1984b; Shima et al. 1984; Dolan et al. 1985; Roy-Byrne et al. 1988). Studies of more representative samples show that structural abnormality is less common in affective disorder than in schizophrenia. For example, Shettar and colleagues (1990) found no difference in temporal and hippocampal volume between depressed patients and controls; this finding contrasts with those of Sudath and colleagues (1989), who reported that schizophrenic subjects have less temporal volume than controls. Similarly, Johnstone and colleagues (1989b) reported that, while temporal lobe structures of manic-depressive patients, as determined by MRI, did not differ from controls, schizophrenic patients differed significantly from both controls and manic-depressive patients.

In contrast to schizophrenia, when structural abnormalities do occur in affective psychosis, they are associated with late rather than early onset (Jacoby and Levy 1980; Shima et al. 1984). Indeed, Sacchetti and colleagues (1990) suggest that when ventricular enlargement occurs in affective disorder, it does so in late-onset cases in which the affective disorder may be a manifestation of some primary brain disorder such as cerebral vascular disease. Pearlson and colleagues (1989) found both cognitive abnormalities and structural abnormalities to be a function of age in depressives. Direct evidence of the latter has come from our own controlled CT study of a consecutive series of psychotic patients under 50 years of age. The 43 *DSM-III* schizophrenic patients in the sample had a mean age at first admission of 22.7 years; age showed no correlation with ventricle brain ratio (VBR) (Spearman's rho = 0.07, NS). On the other hand, the 24 patients with

affective psychoses had a mean age of first admission of 24.8 years: age correlated positively with VBR ( $r = 0.60$ ;  $p = 0.002$ ).

**Acute Schizophrenia.** Thus, affective psychosis differs from early-onset, poor-outcome schizophrenia in that only the latter shows evidence of neurodevelopmental abnormality. But what about that third group of patients variously described as suffering from schizoaffective disorder, schizophreniform disorder, or acute or good-prognosis schizophrenia?

In terms of clinical manifestations such as abrupt onset, florid symptoms, good response to neuroleptics, and good outcome, these patients share many characteristics with affective psychotic patients. Such patients are also similar to affective psychotic patients in having an unremarkable childhood personality and in rarely having a history of OCs (McNeil and Kaij 1978; Parnas 1990; Foerster et al. 1991b, 1991c). Good-outcome schizophrenic patients seldom show cognitive impairment. For example, Lindenmeyer and colleagues (1989) found that 35 RDC schizoaffective patients showed significantly less cognitive abnormality than a comparison group of 35 RDC schizophrenic patients, matched for age and duration of illness.

We noted earlier that the rates of schizoaffective and affective disorder in the relatives of good-outcome schizophrenic patients are high, while rates of chronic schizophrenia and SPD are low. Schizophrenic patients with a relative who suffers from bipolar affective illness are especially likely to show affective symptoms during their own acute illness, to have a good outcome (Kendler and Tsuang 1988), and to have few residual symptoms in remission (Kendler and Hays 1983). Furthermore, Owen

and colleagues (1988, 1989), have shown that schizophrenic patients with a family history of affective disorder are less likely to have enlarged cerebral ventricles than are other schizophrenic patients. Other CT studies also suggest that good-outcome schizophrenic patients are less likely to have ventricular enlargement than chronic schizophrenic patients (Kolakowska et al. 1985).

## Gender

Males with schizophrenia have a far worse outcome than females (Salokangas and Stengard 1990) and more frequently exhibit classic and negative symptoms of schizophrenia (Lewine 1981; Goldstein and Link 1988; Castle and Murray 1991a). Males with schizophrenia have more cognitive (Haas et al. 1990) and neurologic abnormalities (Marcus et al. 1985) and more MPAs (Waddington et al. 1990). They also show more premorbid IQ (Aylward et al. 1984) and personality abnormalities (Foerster et al. 1991b, 1991c) and earlier onset of schizophrenia than females (Angermeyer and Kuhn 1988; Lewine 1988; Haas et al. 1990); the latter is not a consequence of the manner in which age of onset is defined (Loranger 1984; Häfner et al. 1989).

Although the incidence of broadly defined schizophrenia (e.g., according to International Classification of Diseases [ICD-9; World Health Organization 1978] guidelines) is equal in the sexes, when narrowly defined criteria such as *DSM-III* or those of Feighner and colleagues (1972) are applied, the incidence appears much higher in males than in females. Castle et al. (1991b) have shown that this gender difference is accounted for by an excess of severe schizophrenia among young (and not older) males, and that those young

male schizophrenic patients are especially likely to have shown premorbid abnormalities of personality and social adjustment.

It is interesting, therefore, that males with schizophrenia are more likely than their female counterparts to have a history of OCs (Wilcox and Nasrallah 1987; Pearlson et al. 1989; Foerster et al. 1991b, 1991c). Furthermore, males are more likely to exhibit structural brain abnormalities than females; Castle and Murray (1991a) reviewed 10 imaging studies (6 CT and 4 MRI) that report this. Bogerts and colleagues (1990) also found that the brains of male schizophrenic patients showed more neuro-pathologic abnormalities than those of their female counterparts.

It has recently become apparent that schizophrenia in females appears to be under greater genetic influence than male schizophrenia. Thus, the first-degree relatives of females with schizophrenia are at greater risk of psychosis than the relatives of males with schizophrenia (Bellodi et al. 1986; Goldstein et al. 1990; Pulver et al. 1992); similarly, female MZ twins have higher concordance rates than their male counterparts (Rosenthal 1970; Kringlen 1987).

Female schizophrenic patients have more affective symptoms than males (Castle and Murray 1991a). Further evidence of shared characteristics of female schizophrenic and affective psychotic patients comes from work concerning the season of the year when psychotic patients are admitted. It has long been known that patients with mania are more likely to be admitted to hospital during the hot summer months. However, in a study of first-admission patients in England and Wales, Takei and colleagues (in press) have shown that acute schizophrenic and paranoid schizophrenic patients (but not the

more chronic subtypes) have similar seasonality of admission; the summer peak is shared by female but not by male schizophrenic patients. These data suggest that a proportion of schizophrenic patients, particularly females with acute schizophrenia, and manic patients are subject to similar causal or precipitating factors.

These findings lead to the conclusion that sex differences in schizophrenia reflect the fact that a lower proportion of female than male patients have the neurodevelopmental, early-onset, and poor-outcome type (Castle and Murray 1991a). In contrast, female schizophrenic patients show more similarities to affective psychotic patients than do male schizophrenic patients.

### Neurodevelopmental Classification of Schizophrenia

Kraepelin (1893) did not originally include catatonic and paranoid deteriorating conditions in the category of dementia praecox, which he reserved for a severe condition predominantly affecting young men. In the 1896 edition of his textbook he indicated that dementia praecox was three times more common in men than in women, the majority of cases presented by age 22 years, and only 5 percent to 6 percent of patients admitted to his clinic suffered from dementia praecox. However, Kraepelin became persuaded that catatonia and paranoid deterioration were variants of dementia praecox. As a result of including these conditions, the sex distribution of the disorder became equal and the mean age of onset rose.

Subsequently, Bleuler (1911/1950) and then Schneider (1959) enlarged the concept of schizophrenia further by basing their diagnosis on phenom-

enology rather than on course and outcome. In the words of Berner (1991, p. 220), doing so resulted in a "tremendous extension of the boundaries of schizophrenia." Berner points out that in recent decades even German-speaking psychiatrists have become disillusioned with the Schneiderian concept of schizophrenia. His own view is that first-rank symptoms can arise not only in schizophrenia but also in affective psychosis and in paranoid psychoses. Berner's Vienna Research Criteria result in a much narrower concept of "endogenous schizophrenic schizophrenia," with a marked male predominance.

We agree that the modern concept of schizophrenia is too broad and suggest that it needs to be "unbundled." We believe that a classification of the functional psychoses based on a developmental principle would help toward achieving this goal. Such a classification would subdivide schizophrenia into three main groups: congenital schizophrenia, adult-onset schizophrenia, and late-onset schizophrenia.

**Congenital Schizophrenia.** By definition this term implies that abnormality is present, although not necessarily recognizable, at birth. We postulate that this type may arise as a consequence of a genetic defect that results in decreased cortical volume and smaller temporal lobe structures, which are visualized by neuroimaging and seen in postmortem evidence of migration failure of the pre-alpha cells in the entorhinal cortex (Jones and Murray 1991). A similar clinical and neuropathologic picture may also result from early environmental hazard or some combinations of genetic predisposition and environmental hazard. The results that have been implicated include maternal influenza, OCs, and

perhaps early brain injury and infections. What these insults have in common is their occurrence at an early point of neurodevelopment.

Patients with congenital or neurodevelopmental schizophrenia are more likely to have evidence of MPAs and to have shown abnormal personality or social impairment in childhood. Such individuals present to the psychiatric services early, exhibit negative symptoms, and show morphological brain changes and cognitive impairment. In their clinical presentation (age of onset, male predominance, and poor outcome), these patients reflect the original description of dementia praecox by Kraepelin.

**Adult-Onset Schizophrenia.** Our contention is that many patients who exhibit Schneiderian symptoms and are currently classified under the category of schizophrenia are not suffering from dementia praecox. Such patients have little in common etiologically with cases of dementia praecox and lack the developmental attributes of congenital schizophrenia. Adult-onset schizophrenia probably encompasses several distinct conditions, but its subclassification is not yet clear.

The most numerous patients within the group appear to be those individuals with a disorder that is genetically related to affective disorder. In essence, we postulate that there exists an adult-onset psychotic disorder in which the phenotypic expression of the mutant gene or genes ranges from classic manic depression through schizoaffective disorder to acute schizophrenia.

This concept of a relapsing and remitting psychosis, capable of producing not only affective but also "positive" schizophrenic symptoms, owes much to the work of Berner

(1991). Furthermore, like the Vienna school, we conclude that many patients with first-rank symptoms cannot be assigned to either dementia praecox or affective psychosis. Such cases include the paranoid psychoses and the drug-induced psychoses.

It may be argued that the neurodevelopment of patients with adult onset is unlikely to have been entirely normal, or why else would they have reacted to circumstances or drugs in such an abnormal way? We would rejoin that while such patients may eventually be found to show deviant neurotransmitter or neurophysiologic patterns of developmental origin, they show no evidence of the grosser "neurologic" abnormalities found in the congenital cases.

**Late-Onset Schizophrenia.** The foregoing discussion leaves unresolved the place of late-onset schizophrenia, or late paraphrenia. Such patients usually present after the age of 60 and have good premorbid functioning in the intellectual and occupational spheres. It is implausible, therefore, that they suffer from a neurodevelopmental disorder. Further factors suggesting that late paraphrenic patients are distinct from the congenital cases include a massive excess of females in almost all studies (see Harris and Jeste 1988), paranoid rather than schizotypal premorbid personality (Kay and Roth 1961; Post 1966; Kay et al. 1976), and an association with auditory and visual sensory deficit (Cooper 1976; Kay et al. 1976).

Family studies of late paraphrenia (reviewed by Castle and Murray, in press) are fraught with methodological shortcomings but tend to show rates of schizophrenia in siblings that are intermediate between those for younger probands and the general

population. Furthermore, rates of affective disorder in relatives are high (Post 1966), compatible with the notion that some late paraphrenic patients have an illness etiologically related to the affective psychoses.

Recently, attention has focused on the evidence that a significant number of late paraphrenic patients show evidence of intellectual decline (Holden 1987) and that MRI studies have revealed excessive white-matter changes in some such patients (reviewed by Castle and Murray, in press). A number of studies have shown a higher VBR in late-onset schizophrenic patients, than in control subjects (Naguib and Levy 1987; Rabins et al. 1987; Jeste and Harris 1990) and suggested that this finding reflects some underlying degenerative cerebral pathology.

Thus, those patients labeled "late paraphrenic" form a heterogeneous group, some having an illness relating to paranoid personality, some to sensory deprivation, some to affective illness, and some to late-onset organic change. Organic brain dysfunction is increasingly being recognized as the underlying "final common pathway" in many such patients (Castle and Murray, in press).

## Conclusion

The pillars supporting the Kraepelinian dichotomy of the functional psychoses are crumbling. There are two main interpretations of the relevant data. The first is that schizophrenia and manic depression are a single disorder lying along a continuum with a single etiology. Our interpretation is diametrically opposed to such a view. We contend that several genetic and environmental etiologies underlie the functional psychoses but that a crucial distinction exists between those cases with neu-

rodevelopmental etiology (congenital schizophrenia) and those other forms, the manifestations of which are confined to adult life.

#### The Authors

Robin M. Murray, M.D., D.Sc., is Professor and Chairman of the Department of Psychological Medicine, King's College Hospital and Institute of Psychiatry, De Crespigny Park, Denmark Hill, London, United Kingdom. Eadbhard O'Callaghan, M.R.C.Psych., and David J. Castle, M.R.C.Psych., are Research Psychiatrists, Department of Psychological Medicine, Institute of Psychiatry, De Crespigny Park, Denmark Hill, London, United Kingdom. Shon W. Lewis, M.Phil., M.R.C.Psych., is Senior Lecturer, Department of Psychological Medicine, Charing Cross and Westminster Hospitals, Hammer-smith, United Kingdom.

# Dopamine in Schizophrenia: A Review and Reconceptualization

Kenneth L. Davis, M.D., René S. Kahn, M.D., Grant Ko, M.D.,  
and Michael Davidson, M.D.

**Objective:** The initial hypothesis that schizophrenia is a manifestation of hyperdopaminergia has recently been faulted. However, several new findings suggest that abnormal, although not necessarily excessive, dopamine activity is an important factor in schizophrenia. The authors discuss these findings and their implications. **Method:** All published studies regarding dopamine and schizophrenia and all studies on the role of dopamine in cognition were reviewed. Attention has focused on post-mortem studies, positron emission tomography, neuroleptic drug actions, plasma levels of the dopamine metabolite homovanillic acid (HVA), and cerebral blood flow. **Results:** Evidence, particularly from intracellular recording studies in animals and plasma HVA measurements, suggests that neuroleptics act by reducing dopamine activity in mesolimbic dopamine neurons. Post-mortem studies have shown high dopamine and HVA concentrations in various subcortical brain regions and greater than normal dopamine receptor densities in the brains of schizophrenic patients. On the other hand, the negative/deficit symptom complex of schizophrenia may be associated with low dopamine activity in the prefrontal cortex. Recent animal and human studies suggest that prefrontal dopamine neurons inhibit subcortical dopamine activity. The authors hypothesize that schizophrenia is characterized by abnormally low prefrontal dopamine activity (causing deficit symptoms) leading to excessive dopamine activity in mesolimbic dopamine neurons (causing positive symptoms). **Conclusions:** The possible co-occurrence of high and low dopamine activity in schizophrenia has implications for the conceptualization of dopamine's role in schizophrenia. It would explain the concurrent presence of negative and positive symptoms. This hypothesis is testable and has important implications for treatment of schizophrenia and schizophrenia spectrum disorders.

(Am J Psychiatry 1991; 148:1474-1486)

When initially conceived, the dopamine hypothesis of schizophrenia posited that schizophrenic illness is a manifestation of a hyperdopaminergic state (1). The foundation of this hypothesis was mainly indirect evidence gained from the study of dopamine antagonists and agonists. Specifically, the ability of neuroleptics to displace dopamine antagonists in vitro robustly correlates with the clinical potency of these agents (2, 3). Conversely, drugs that increase dopamine activity generally worsen the symptoms of schizo-

phrenia (4-7). In the last decade faults with the dopamine hypothesis have been described as data have accumulated that are inconsistent with the notion of hyperdopaminergia in all schizophrenic patients. For example, a substantial proportion of schizophrenic patients are resistant to treatment with neuroleptics, suggesting that other neurochemical systems may have a pathogenetic role in these patients. Furthermore, schizophrenic-like symptoms are rarely, if ever, induced in nonschizophrenic individuals when they are administered drugs that augment dopaminergic activity. Moreover, neuroleptics are only partially effective in alleviating the negative, or deficit, symptoms of schizophrenic patients (8), particularly after resolution of the acute phase of the illness. This, in turn, suggests that deficit state symptoms may be unrelated to excessive dopamine activity. It has also become evident that a hypothesis of excessive dopamine activity in all brain regions of schizophrenic patients is untenable. The results of post-mortem (9-14) and cerebrospinal fluid

CSF) (15) studies of dopamine metabolites do not make a convincing case for a homogeneous dopamine excess in schizophrenia. However, several new findings have rekindled the enthusiasm for a dopaminergic mechanism in schizophrenia:

1. Cortical abnormalities consistent with hypodopaminergic function and their possible relationship to deficit state symptoms.

2. A reciprocal relationship between cortical hypodopaminergia and subcortical hyperdopaminergia.

3. A relationship between the concentration of the dopamine metabolite homovanillic acid (HVA) in plasma, schizophrenic symptoms, and responsiveness to neuroleptics.

All these findings, both supporting and refuting a role for dopamine in schizophrenia, will be reviewed in this article. They warrant a reconsideration of the relationship between dopaminergic activity and schizophrenia.

## HYPERDOPAMINERGIA

### Problems

The initial evidence that abnormally high dopamine activity is a pathogenetic mechanism in schizophrenia was the correlation between potency of dopamine receptor blockade and clinical efficacy of neuroleptics. However, the finding that clozapine, the only neuroleptic proven clinically effective for schizophrenic patients who are relatively refractory to other neuroleptics (16), displays one of the weakest  $D_2$  receptor binding affinities (2, 17, 18) challenges the hypothesis that neuroleptics are effective by virtue of their  $D_2$  receptor blockade alone. Clozapine's affinity for  $D_2$  receptors is one-tenth that of chlorpromazine (2, 17, 18), but in the studies comparing clozapine to chlorpromazine (16, 19-22) clozapine was more effective than chlorpromazine, generally at one-half the dose.

Moreover, it has been consistently found that chronic administration of clozapine does not increase [ $^3H$ ]spiroperidol binding in brain tissue (23-28), implying that it does not increase  $D_2$  receptor sensitivity. Since dopamine antagonists increase  $D_2$  receptor sensitivity after chronic administration,  $D_2$  blockade by clozapine must be minimal. Significantly, despite this apparent lack of potent  $D_2$  blockade, clozapine is a very (if not the most) effective antipsychotic.

Measurement of CSF concentrations of HVA provide additional evidence that a simple excess of dopamine activity is not associated with schizophrenia. A large number of studies measuring CSF HVA have been conducted and have been reviewed elsewhere (15). Many drug-free schizophrenic patients have normal or low CSF HVA concentrations (15, 29). One of the few consistent findings is that HVA concentration negatively correlates with the degree of cortical atrophy and ventricular enlargement. Since CSF HVA levels are affected by the site of lumbar puncture, motor activity, time of day, season, age, sex, height, and diet and since most studies have not controlled for some of these factors, it is difficult to interpret these data. Nevertheless, the results of CSF studies suggest that a homogeneous excess of dopamine (metabolism) as reflected in CSF is certainly not present in schizophrenia. However, post-mortem studies examining dopamine and HVA concentrations and dopamine receptors provide more compelling evidence of dopaminergic abnormalities in schizophrenia.

### Post-Mortem Studies

As shown in table 1, the HVA and dopamine concentrations in post-mortem brains of schizophrenic patients consistently show differences from the brains of normal subjects. However, the differences in the anatomical areas where the abnormalities are found are not consistent. For example, the concentrations of HVA in the caudate nucleus and nucleus accumbens

(30) and cortex (14) have been found to be higher in the brains of schizophrenic patients than in normal brains. The difference in caudate concentration was attributable to prior medication, while the finding in the accumbens applied only to the medication-free patients. Similarly, although one study (31) showed the dopamine concentration in the accumbens to be higher in schizophrenic patients than in comparison subjects, another study (32) showed more dopamine in the caudate of schizophrenic patients but not in the accumbens. Finally, Reynolds (12) reported excessive dopamine in the amygdala of schizophrenic patients, with the greatest excess in the left hemisphere. These inconsistencies may be due to differences in the medication status of the patients studied, varying analytical and statistical methods, or genuine anatomical specificity of dopamine abnormalities in schizophrenia.

Although not indicative of greater than normal dopamine turnover or activity, D<sub>2</sub>, but not D<sub>1</sub>, receptors have generally been found to be abnormally prevalent in the striatum of schizophrenic patients. Table 2 summarizes the dopamine receptor studies performed to date. These results have often been dismissed as simply reflecting neuroleptic treatment. However, most studies of patients who have been neuroleptic-free for at least 1 year before study or are drug naive show that these patients also have more striatal D<sub>2</sub> receptors than normal subjects. Other evidence from post-mortem studies, as well as preclinical pharmacological investigations, buttresses the argument that D<sub>2</sub> receptor excesses are not merely the result of neuroleptic treatment. A bimodal distribution of D<sub>2</sub> receptors in the brains of schizophrenic patients who have received neuroleptics indicates that neuroleptics do not uniformly increase D<sub>2</sub> receptor numbers in schizophrenic patients (33). The number of excess striatal dopamine receptors due to neuroleptic pretreatment in experimental animals is one-half of the difference be-

tween post-mortem tissue from schizophrenic and normal subjects (30, 31, 33-35). Rodents treated with neuroleptics have 30% more D<sub>2</sub> receptors than untreated rodents, whereas the brains of schizophrenic patients have 50% to 60% more D<sub>2</sub> receptors than those of normal subjects. Neuroleptic-treated patients with Alzheimer's disease or Huntington's disease have 25% more striatal dopamine receptors than do comparison subjects, whereas the number for schizophrenic patients exceeds that of comparison subjects by more than 100% (33), providing suggestive evidence that neuroleptics account for only some of the excess of D<sub>2</sub> receptors seen in schizophrenia. One study (36) showed greater D<sub>2</sub> receptor density but lower D<sub>1</sub> receptor density in the caudate nuclei in schizophrenic patients than in normal subjects. Thus, the available data strongly suggest that D<sub>2</sub> (but not D<sub>1</sub>) receptor density is higher than normal in schizophrenia and that this finding cannot be totally accounted for by medication history.

#### Positron Emission Tomography Studies

Positron emission tomography (PET) measurements of in vivo D<sub>2</sub> receptor affinity in humans have provided conflicting results. One group who studied 10 neuroleptic-naive schizophrenic patients and 11 healthy comparison subjects, using [<sup>11</sup>C]methylspiperone as a D<sub>2</sub> ligand, found more D<sub>2</sub> receptors in the patients than in normal comparison subjects (37). In contrast, when 15 (38) and 18 (39) similarly drug-naive schizophrenic patients were studied with [<sup>11</sup>C]raclopride, D<sub>2</sub> receptor density did not differ between the patients and normal subjects. However, an asymmetry in D<sub>2</sub> receptor density was found in the schizophrenic but not the normal subjects: D<sub>2</sub> receptor density was higher in the left than in the right putamen (39). When [<sup>76</sup>Br]bromospiperone was used to compare D<sub>2</sub> receptor density

in 12 schizophrenic patients (who either were drug naive or had been drug free for at least 1 year) and 12 comparison subjects, no group differences in  $D_2$  receptor density were found (40). However, the more acutely ill patients had a greater  $D_2$  receptor density in the striatum than the more chronically ill patients or the comparison subjects, suggesting that  $D_2$  receptor density may be state dependent. The conflicts in the data may be partially due to differing ligands. For instance, methylspiperone, but not raclopride, binds potently to 5-HT<sub>2</sub> receptors. Moreover, the methods with which the PET data were analyzed varied across studies. Finally, as the study using [<sup>76</sup>Br]bromospiperone suggests, differences in patient groups may partly explain the different  $D_2$  receptor densities found in schizophrenic patients. These data lead to no firm conclusions at this time.

### Mechanism of Action of Neuroleptics

The original notion that hyperdopaminergia is a pathogenetic mechanism in schizophrenia was, at the very least, too imprecise. For instance, there are multiple types of dopamine receptors.  $D_1$  receptors, which are coupled to adenylate cyclase, have a low affinity for [<sup>3</sup>H]spiperone and are located in the cortex of humans (41, 42).  $D_2$  receptors are negatively associated with adenylate cyclase, display a great affinity for [<sup>3</sup>H]spiperone (43), are most prominent in the striatal and limbic structures in humans, and, if present at all in the human cortex, have a low density (42, 44). The  $D_2$  receptor has recently been cloned, and two  $D_2$  subreceptors, labeled  $D_{2a}$  and  $D_{2b}$ , have been identified (45–50). The elucidation of the pharmacological, anatomical, and physiological differences between  $D_{2a}$  and  $D_{2b}$  receptors will add further complexity to the conceptualization of dopamine neurotransmission and further weaken any simplistic notions linking the action of neuroleptics to a unitary effect on all dopamine receptors. The cloning of a dopamine receptor (51) anatomically limited to limbic areas and resembling neither  $D_1$  nor  $D_2$ , and consequently named  $D_3$ , underscores the fact that the initial simplistic perception of the dopamine system urgently needs to be revised. Questions remain about which dopamine receptors are most critical to modulating the symptoms of schizophrenia, where they are located, and how they differ from dopamine receptors that are irrelevant to the actions of neuroleptics. Of particular interest in this regard are the recently cloned  $D_4$  and  $D_5$  receptors (52, 53).  $D_4$  receptors have a higher affinity for the atypical neuroleptic clozapine and thus have extraordinary implications for the development of a new generation of antipsychotic drugs.  $D_5$  receptors resemble  $D_1$  receptors but have a higher affinity for dopamine.

Anatomically, the dopamine system consists of a number of subsystems: nigrostriatal, mesolimbic, and mesocortical. The nigrostriatal system projects from the substantia nigra (also called A9) to the neostriatum (i.e., putamen and caudate). The mesolimbic system

has its cell bodies in the ventral tegmental area (also called A10) of the midbrain and in the substantia nigra and projects to the accumbens, olfactory tubercle, and amygdala. The mesocortical system has its cell bodies mainly in the ventral tegmental area, and its neurons project to the prefrontal cortex, as well as to the accumbens, septum, and olfactory tubercles (54, 55). The effects of neuroleptics on these different dopamine neuronal systems are not equivalent. A single dose of a neuroleptic increases dopamine neuron firing in the nigrostriatal and mesolimbic dopamine systems (56, 57). This is probably due to blockade of presynaptic  $D_2$  receptors and subsequent decreased inhibition of dopamine activity (57, 58). Chronic (3–4 weeks) neuroleptic administration decreases dopamine neuron firing in both A9 and A10 to below pretreatment levels, and this decrease can be reversed by apomorphine; this phenomenon is called depolarization blockade (58, 59). Atypical neuroleptics, i.e., antipsychotics that do not induce extrapyramidal side effects, such as clozapine, are anatomically more selective in their effect on dopamine neuronal firing than typical neuroleptics in that they induce depolarization blockade in A10 only (57–64). The particular affinity of clozapine for  $D_4$  receptors suggests that important differences among dopamine receptors can account for some aspects of clozapine's atypicality. On the basis of these data, it has been proposed that depolarization blockade in A9 is responsible for the induction of extrapyramidal effects, while depolarization blockade in A10 leads to the antipsychotic effects of neuroleptics (61). Thus, these studies suggest that excess dopamine activity in A10, and not a general excess of dopamine activity, may be related to psychosis.

Thus, the data so far reviewed suggest that the antipsychotic effects of neuroleptics are related to a decrease in firing in *specific* dopaminergic neurons (i.e., A10) and, by inference, that schizophrenia may be related to excessive activity of these, and therefore not all, dopaminergic neurons. This possibility underscores the imprecision of the initial hypothesis that schizophrenia is related to excessive dopamine function in general. This point is made even more poignant by the elucidation of numerous dopamine receptor subtypes, whose specific roles in the modulation of schizophrenic symptoms remain unknown and are a critical area for future research.

### Plasma HVA

The finding that depolarization blockade in A10 is a characteristic of all neuroleptics suggests that a decrease in dopamine firing (in A10) may be an important mechanism of action of antipsychotics. However, obtaining direct evidence linking the antipsychotic effect of neuroleptics to their effect on dopamine cell firing in humans has been impossible. Therefore, indirect measurements of dopamine activity must be obtained. Plasma levels of the dopamine metabolite HVA may be such a measure. The HVA found in plasma is

produced primarily by brain dopamine neurons and peripheral noradrenergic neurons. Secondary sources of HVA are peripheral dopamine and brain noradrenergic neurons. Animal and human studies (65-67) suggest that brain dopamine turnover is reflected by plasma HVA concentrations. Although the precise proportion of plasma HVA deriving from brain HVA has not been fully elucidated (68, 69), measurement of this dopamine metabolite in plasma of schizophrenic patients appears to be a valid method for investigating dopamine activity in this disorder provided certain conditions are met (70).

The results of studies on plasma HVA in humans are shown in tables 3-5. These findings are consistent with animal data, that is, neuroleptics initially increase and subsequently decrease dopamine firing. Thus, plasma

HVA concentrations rise dramatically during the first few days of neuroleptic treatment (66, 78). This rise in plasma HVA coincides with the increase in striatal dopamine firing observed in animals after acute administration of neuroleptics. After chronic (1 week or more) administration of neuroleptics, plasma HVA levels decrease to below baseline levels (71, 79), which is consistent with the depolarization blockade observed in animals after chronic administration of neuroleptics.

Indeed, studies examining plasma HVA concentrations in relation to response to neuroleptic treatment suggest an association between the effects of neuroleptics on dopamine activity and treatment outcome. The initial increase (78) and the subsequent decrease (71, 72, 80-83) after administration of neuroleptics are as-

sociated with clinical response to this treatment. Conversely, clinical decompensation after discontinuation of neuroleptic treatment is associated with increases in plasma HVA levels (71, 84, 85).

The suggestion that the therapeutic effects of neuroleptics are due to a decrease in dopamine activity is further supported by plasma HVA studies showing that greater severity of illness in schizophrenia is related to greater dopamine turnover. As table 3 indicates, several studies have found a positive correlation between plasma HVA level and clinical severity (73–75). Three studies (72, 76, 77) did not confirm this finding. The most likely explanation for the different results across studies is the number of plasma HVA samples taken as a basis for the correlational studies. The studies using more than one sampling of plasma HVA found significant positive correlations between plasma HVA and severity of symptoms, whereas studies using a single measurement of plasma HVA did not. The studies producing significant correlations between plasma HVA and severity of schizophrenic symptoms averaged three (75), four (73), or 13 (74) plasma HVA samples, whereas the studies that produced negative findings (72, 76, 77) assessed plasma HVA only once. Repeated plasma HVA measurements in the same individual therefore appear to increase the signal-to-noise ratio for plasma HVA by reducing the intraindividual variance in plasma HVA concentration.

However, the relationship between plasma HVA and schizophrenic illness is not straightforward. In one study (74), plasma HVA levels were lower in chronic, treatment-resistant schizophrenic patients than in normal subjects, although plasma HVA levels still correlated with symptom severity. Such results are consistent with the data derived from a study of urinary catecholamines in a similar group of chronically institutionalized patients (86), in whom lower levels of urinary catecholamines were also prominent. This seeming paradox—the fact that levels of dopamine metabolites can be lower in schizophrenic patients than in normal subjects but still positively correlate with symptom severity—is a key impetus to reformulating the complex role of dopamine in schizophrenia.

#### *Is There Hyperdopaminergia in Schizophrenia?*

Although the original basis for the hypothesis that dopamine activity is higher than normal in schizophre-

nia appears questionable, recent evidence, particularly that derived from intracellular recording studies in animals and plasma HVA studies in humans, suggests that neuroleptics act by reducing dopamine activity in mesolimbic dopamine neurons. Moreover, most post-mortem studies have shown higher than normal dopamine and HVA concentrations in various subcortical brain regions and greater than normal dopamine receptor density in the brains of schizophrenic patients (which is probably not a medication effect), although in vivo  $D_2$  receptor binding studies have provided more conflicting results. Still, direct comparisons of CSF, plasma, and urine HVA concentrations in schizophrenic patients and normal subjects do not support hyperdopaminergia and may suggest the opposite, that some brain regions could be hypodopaminergic. These apparent discrepancies may be partially explained by findings on the role of dopamine in the frontal cortex.

#### HYPODOPAMINERGIA AND FRONTAL LOBE DYSFUNCTION

There are data indicating that frontal lobe dysfunction may be associated with psychotic symptoms. Evidence of frontal lobe damage leading to abnormal behaviors strikingly similar to some of the more persistent symptoms observed in schizophrenia can be found in anecdotal and case series describing patients with frontal lobe injuries and primates with frontal lobe ablations (e.g., 87, 88). Although there is great interindividual variation in the severity and constancy of the symptoms that emerge in patients even with severely damaged frontal lobes, some of these symptoms bear a remarkable resemblance to the deficit state symptoms in schizophrenia. For example, orbitofrontal and anteromedial lesions often produce flattened affect.

Deficit state symptoms are thought to be enduring signs of schizophrenia and include apathy and avolition (8). Bleuler proposed that deficit state symptoms are pathognomonic signs of schizophrenia and are at the root of the poor social and work functions that characterize people with the chronic schizophrenic syndrome. Indeed, several observations from primates suggest that insufficient frontal cortical functioning is responsible for poor social skills. Monkeys with frontal lobe ablations have not only an inability to suppress

irrelevant stimuli, poor concentration, and impaired delayed response, but poor social function that is reminiscent of the deficit state symptoms which characterize schizophrenia. These monkeys have been observed to die isolated and alone after being chased from their groups by other animals (89). Also, like the symptoms of schizophrenia, which seem to emerge most prominently during adolescence, the emotional difficulties of monkeys with frontal lobe ablations appear not in infancy, but after the age of 24 months, the monkey equivalent of adolescence (90, 91). Indeed, any hypothesis involving the biological basis of schizophrenia must account for the striking prevalence of onset in late adolescence.

Frontal lobe dysfunction in schizophrenia, specifically hypofrontality, is demonstrable with measurements of cerebral blood flow (92–94). While performing the Wisconsin Card Sorting Test (95), a cognitive task linked to frontal lobe function, schizophrenic patients showed less increase in cerebral blood flow than normal subjects (96). Facility at the Wisconsin Card Sorting Test has been associated with the dorsolateral function of the frontal lobe (97, 98), and it is thought to represent the human test equivalent of the delayed response task used extensively with nonhuman primates as one of the most sensitive measures of frontally mediated cognitive function.

Of great interest is whether cortical hypofrontality could be reflected in dopamine metabolites emerging from (meso)cortical dopamine neurons. Because the mesocortical dopamine tract is relatively devoid of inhibitory autoreceptors, dopamine turnover in these neurons is far greater than in the mesolimbic neurons (99). Given the large volume and greater venous drainage of cortex than of striatum in human brain, the brain contribution to the pool of plasma and CSF HVA is likely to, at least partially, reflect frontal cortex dopamine activity. In fact, only frontal cortical concentrations of HVA significantly correlate with CSF concentrations of HVA in monkeys (100). Thus, CSF and plasma HVA must, in part, reflect mesocortical dopamine activity.

The contribution to CSF HVA of the mesocortical dopamine tract would be expected to be smaller in schizophrenic patients with cortical hypodopaminergia than in normal subjects. This hypothesis is supported by the finding that CSF HVA is lower in (some) schizophrenic patients, particularly those who respond poorly to neuroleptics, than in comparison groups (see 15). Furthermore, low prefrontal dopamine activity in schizophrenic patients could also explain the consistent finding of a negative correlation between CSF HVA and ventricle-brain ratio (101–103) and, more specifically, a negative correlation between prefrontal brain atrophy and CSF HVA (104). That cortical hypofunction is associated with low cortical dopamine activity is suggested by the finding that lack of increase in blood flow during prefrontal tasks in schizophrenic patients is strongly correlated with low CSF HVA concentrations (105). Moreover, blood flow in the pre-

frontal cortex increases in schizophrenic patients after administration of the dopamine agonists amphetamine (106) and apomorphine (107), suggesting that the hypofrontality found in schizophrenic patients can be redressed by increasing dopamine activity in the prefrontal cortex. The increase in prefrontal blood flow after amphetamine administration correlated significantly with improved performance on the Wisconsin Card Sorting Test (106), strongly suggesting that increasing dopamine activity improves cognition related to prefrontal cortical activity.

Further evidence that dopamine function may be abnormally low in (some) schizophrenic patients comes from studies examining dopamine metabolites in these patients. In addition, plasma HVA has been studied in chronically institutionalized schizophrenic patients with relatively low levels of positive symptoms and prominent deficit symptoms (74). These patients had significantly lower levels of plasma HVA than the age-, gender-, and weight-matched comparison group. This finding corroborates the low concentrations of HVA in the urine of chronic schizophrenic patients (86).

Finally, indirect evidence that dopamine activity is low in (some) schizophrenic patients is suggested by clinical similarities between schizophrenic patients and those with Parkinson's disease. The cognitive and motivational defects in patients with Parkinson's disease are strikingly similar to the deficit symptoms in schizophrenic patients. It has been suggested that these Parkinson's disease symptoms result from low cortical dopamine activity (108), and they diminish after treatment with dopamine agonists (109). Deficit schizophrenic symptoms may also improve after administration of dopamine agonists (110, 111).

Hence, the abnormally low prefrontal activity commonly revealed in schizophrenic patients may be related to the negative/deficit symptom complex and is associated with insufficient activity of mesocortical dopamine neurons.

#### A MODIFIED DOPAMINE HYPOTHESIS OF SCHIZOPHRENIA

##### *Linking Hypo- and Hyperdopaminergia*

The data reviewed so far suggest that schizophrenia can be characterized by hypodopaminergia in mesocortical and hyperdopaminergia in mesolimbic dopamine neurons in at least some patients. There are data indicating that the two conditions, cortical hypodopaminergia and subcortical hyperdopaminergia, may be related.

Lesions of dopamine neurons in the prefrontal cortex of rats, induced with the neurotoxin 6-hydroxydopamine, have resulted in increased levels of dopamine, HVA, and dihydroxyphenylacetic acid (DOPAC) in the striatum (112, 113) and accumbens (112–114) in most but not all (115) studies. These

lesions also resulted in an increase in  $D_2$  receptor binding sites (112, 113, 116) in the accumbens. Moreover, lesions in the prefrontal cortex augment the responsiveness of the striatal dopamine system to amphetamine (as expressed by increased locomotor activity and circling behavior) (112) and to apomorphine (as expressed by enhanced stereotyped behavior) (117). Conversely, injection of the dopamine agonist apomorphine in the prefrontal cortex of rats reduced the levels of the dopamine metabolites HVA and DOPAC by about 20% in the striatum, suggesting that increasing prefrontal cortical dopamine activity decreases striatal dopamine turnover (117). When the cortical lesion includes noradrenergic pathways, an effect on subcortical dopamine is not found (115), pointing out the important modulatory and permissive role norepinephrine plays in the reciprocal interaction between mesocortical dopaminergic and subcortical dopaminergic activity. However, these findings have not been consistently replicated. In one study (117), surgical ablation of the prefrontal cortex did not result in an increase in striatal dopamine or DOPAC, and the behavioral response to apomorphine was not confirmed when stereotactic injections of ibotenic acid were used to destroy prefrontal dopamine fibers (118). The methods used to destroy prefrontal cortical dopamine fibers in these two studies differed significantly from those using hydroxydopamine plus desipramine and may explain these discrepant results.

Post-stroke patients provided the first evidence that low frontal cortical activity is associated with greater subcortical dopamine activity in humans. Rodents with unilaterally high levels of striatal dopamine turn away from the side with more dopamine ("contraversive turning behavior"). Thus, if cortical lesions increase striatal dopamine, unilateral cortical lesions should unilaterally increase dopamine in the striatum and thus lead to contraversive turning behavior. Indeed, 23 patients with unilateral ischemic frontal cortical lesions (119) showed more contraversive turning behavior than normal subjects. Inasmuch as contraversive turning behavior is due to asymmetrically increased striatal dopamine activity, these data suggest that cortical lesions increase striatal dopamine activity.

Thus, there are circumstances under which low prefrontal dopamine activity may lead to greater than normal subcortical dopamine turnover and  $D_2$  receptor sensitivity. This relationship has obvious implications for a conceptualization of the role of dopamine in schizophrenia, as the data previously reviewed indicate that schizophrenia may be characterized by abnormally low tonic activity of ascending dopamine neurons to the cortex and subsequent high activity in the subcortical dopamine nuclei. This hypothesis is particularly appealing since it would explain the (concurrent) presence of negative and positive symptoms in schizophrenic patients and the finding of both low plasma HVA levels and a positive correlation between severity of psychosis and plasma HVA levels in schizophrenic patients (74). Deficit state symptoms can be

related to low prefrontal dopamine activity, low plasma HVA, low CSF HVA, and low prefrontal blood flow during frontal tasks; positive symptoms are related to high dopamine activity in A10, a direct correlation between plasma HVA and positive symptoms, and an association between higher plasma HVA concentration and responsiveness to neuroleptics.

#### *Unanswered Questions*

This review and reconceptualization of the role of dopamine in schizophrenia has repeatedly stressed that dopaminergic transmission correlates with the symptoms of the disease. In contrast, dopaminergic mechanisms have not been linked with either pathogenesis or etiology. In fact, there is compelling evidence that hyperdopaminergic transmission is unlikely to be the primary or sole event in either the etiology or pathogenesis of schizophrenia. Rather, modulation of symptoms by dopamine is more consonant with the effects of neuroleptics and the inability of enhanced dopaminergic activity to induce psychosis in normal subjects. Hence, the primary abnormality or abnormalities that make the symptoms of schizophrenia amenable to manipulation by dopaminergic neurotransmission remain undetermined.

It is possible that cortical hypodopaminergia changes a schizophrenic patient's brain in a manner that makes it vulnerable to the psychotomimetic effects of direct or indirect dopamine agonists. However, this speculation remains to be tested, and other possibilities must ultimately be considered. For example, a low concentration of 5-HT<sub>2</sub> receptors in the frontal cortex (120) or a dysplasia of glutamate afferents to frontal cortex (121) may be a critical abnormality that establishes the substrate necessary for sensitivity to dopaminergic manipulations.

Yet another unanswered question is the relationship between morphometric abnormalities in schizophrenia and dopaminergic neurotransmission. A consistent inverse relationship between ventricle size and CSF HVA level has been found (101–103), but more precision in linking abnormalities in brain morphology, cytology, and dopaminergic mechanisms is needed. Increasing attention will inevitably be given to hippocampal and other medial and anterior temporal lobe structures and dopaminergic innervation. Fortunately, advances in immunohistochemistry, quantitative morphology, and molecular biology make possible the simultaneous elucidation of structure and neurochemistry. The availability of adequate human tissue may be the largest obstacle to this work.

Experiments with animals (112–118) have focused on the effect of cortical manipulations on subcortical dopamine neurotransmission. They have established that in some cases subcortical dopaminergic variables can be influenced by changes in cortical dopamine concentrations. Left unaddressed is whether mesolimbic alterations can produce cortical hypodopaminergia. The answer to this question is central to elucidating the

sequence of changes in dopaminergic neurotransmission during the elaboration of schizophrenic illness. The temporal sequence has implications for whether deficit state symptoms are always a part of the premorbid state of schizophrenia or whether the first appearance of deficit state symptoms can coincide with or occur after the initial psychotic event.

Finally, an elaboration of the neurochemistry of the symptoms of schizophrenia must deal with the relationship between age and symptom onset. The onset of schizophrenia is exquisitely age dependent. As has been pointed out (122), late adolescence is a time of active modification of cortical organization and changes in dopamine concentrations. The relationship between such changes and the possible development of cortical hypodopaminergia needs to be determined. Late life is another period in which the incidence of psychosis increases. This may be related to the decrease in dopamine activity in the prefrontal cortex found with increasing age (123). Thus, late-life psychoses may also prove a fertile area in which to elucidate the role of dopamine in psychotic symptoms.

## IMPLICATIONS

### *Treatment*

It has been commonly noted that the premorbid state of schizophrenic patients is characterized by social withdrawal, isolation, and many other deficit state symptoms, although they are not as pronounced as they are after the schizophrenic illness has begun. As noted, this premorbid condition is consistent with hypodopaminergia in the cortex and raises the question of whether hypodopaminergia is an early dysfunction in schizophrenia and a harbinger of the hyperdopaminergia to follow. If true, might this stage be amenable to intervention with dopamine agonists? Since mesocortical dopamine neurons are primarily of the D<sub>1</sub> type, one would expect selective D<sub>1</sub> or D<sub>5</sub> agonists to be particularly helpful at this stage. Would the administration of D<sub>1</sub> or D<sub>5</sub> agonists to offspring of schizophrenic patients who display negative symptoms prevent the subsequent development of psychosis? Moreover, consistent with the finding by Jaskiw et al. (124) that increasing prefrontal cortical dopamine activity reduces striatal dopamine activity, D<sub>1</sub> or D<sub>5</sub> agonists would be expected to decrease the hypothesized excessive dopamine activity in subcortical dopamine neurons and thus be useful (in combination with traditional D<sub>2</sub> antagonists) in the treatment of acute psychoses as well. Preliminary data on nonresponsive patients treated in this manner are consistent with this notion (125).

Symptoms of schizophrenia can routinely be exacerbated by the administration of drugs that enhance dopamine activity (4-7). All these agents increase dopamine neurotransmission at multiple subtypes of

dopamine receptors, but is activation of all subtypes necessary? It can be argued that whereas D<sub>2</sub>, D<sub>3</sub>, or D<sub>4</sub> stimulation at mesolimbic sites would be psychotomimetic for schizophrenic patients, D<sub>1</sub> or D<sub>5</sub> stimulation may not have the same effect. The determination of the ability, or inability, of D<sub>1</sub> or D<sub>5</sub> agonists to exacerbate schizophrenic symptoms is of great theoretical interest.

### *Schizophrenia Spectrum Disorder*

Although a premorbid schizoid state can precede a schizophrenic episode, the schizoid personality disorder can be persistent and unassociated with the development of psychosis. Nonetheless this "schizophrenia spectrum disorder" is genetically related to schizophrenia (126, 127). If schizoid individuals share with schizophrenic patients the negative symptom of asociality, it seems logical to wonder if D<sub>1</sub> or D<sub>5</sub> agonists might be an effective treatment for the schizoid personality; they might enhance sociality. Thus, a clinical trial of a D<sub>1</sub> or D<sub>5</sub> agonist offers a test of one aspect of this reconceptualized role of dopamine in schizophrenia.

Differences in the relative presence of the positive and negative symptoms of schizophrenia among the full range of schizophrenia spectrum disorders also have key implications for this reconceptualization and are a fertile area of inquiry. There may be dramatic differences in overt symptoms of psychosis between patients with schizoid or schizotypal personality disorders and patients with schizophreniform episodes or schizophrenia. In contrast, negative symptoms, such as asociality and anhedonia, are shared by patients in the schizophrenia spectrum who may differ substantially in terms of positive symptoms. This observation raises the question of whether all individuals with cortical hypodopaminergia inevitably develop subcortical hyperdopaminergia and psychosis. Differences in the reciprocal relationship between cortical and subcortical dopamine may be the reason few patients with schizoid personality become psychotic, in contrast to schizophrenic patients, who may still manifest schizoid function when in remission or residual states. Elucidating these differences could offer new strategies for developing antipsychotic drugs. Hence, comparative investigations of schizophrenia and the spectrum disorders seem valuable. Indeed, such studies might have as their goal the elucidation of the biological and environmental factors that mediate subcortical hyperdopaminergia after cortical hypodopaminergia.

### *Future Research*

The cloning of the D<sub>2</sub> receptor in rodents (45) and humans (48) and the eventual cloning of the D<sub>1</sub> receptor will facilitate the further elaboration of the role of dopamine in schizophrenia. There are at least two D<sub>2</sub> isotypes. Possible differences in the neuroanatomical distribution and function between these different D<sub>2</sub> receptors, as well as among the likely subtypes of the D<sub>1</sub> receptor, need to be elucidated. Already there are

suggestions that the protein sequences of D<sub>2</sub> subtypes differ in the region binding G proteins (50). The possibility that D<sub>5</sub> receptors have a greater affinity for dopamine than D<sub>1</sub> receptors makes the D<sub>5</sub> receptor a particularly intriguing target for strategies designed to reverse cortical hypodopaminergia. Similarly, the cloning of D<sub>3</sub>, D<sub>4</sub>, and D<sub>5</sub> and the elucidation of the biology associated with them may contribute to the understanding of the reciprocal relationship between mesocortical and mesolimbic dopaminergic activity. It might even prove possible to identify the dopamine receptors most critical to the antipsychotic action of neuroleptics and to devise drugs that are far more specific, and have fewer adverse effects, than those presently available. Such a possibility is already suggested by the affinity of clozapine for D<sub>4</sub> receptors.

Regional differences in dopamine activity profoundly affect strategies for measuring dopamine function in schizophrenic patients. Whether dopamine activity is greater or less than that in normal subjects depends on a host of factors, including the relative contribution of the different dopamine tracts to the dopamine variable being measured in any particular patient. CSF and plasma dopamine metabolites and neuroendocrine measures linked to dopamine activity provide different windows onto dopamine systems. They should not be regarded as equivalent. Furthermore, the profile of a patient's symptoms also influences net measures of dopamine activity. Hence, not all schizophrenic patients show the same differences in dopamine activity compared to comparison groups. For example, older schizophrenic patients, who have fewer positive symptoms and relatively more profound deficit states, would be expected to have a very different pattern of dopamine measurements than younger schizophrenic patients, who have prominent positive symptoms. There is in fact evidence for a 2.2% decrease in D<sub>2</sub> receptor density per decade after the age of 20 (128). Moreover, dopamine synthesis diminishes with age (because of decreased tyrosine hydroxylase activity) in humans (for review, see 129). Past contradictory findings must be interpreted with these considerations in mind. Hence, studies of dopamine function in schizophrenia will have to deal with far more variables than have ever been previously considered, including symptoms and the brain regions contributing to the dopaminergic variable being measured.

Finally, it would be surprising if neurotransmitter systems other than dopamine were not involved in the pathogenesis of schizophrenia. There is, for instance, considerable evidence that noradrenergic abnormalities are present in schizophrenia (for review, see 130). A role for serotonergic abnormalities in schizophrenia has been suggested as well (see 131). As previously noted, it is difficult to induce most of the positive symptoms of schizophrenia in nonschizophrenic individuals through the administration of dopaminergic enhancers. In contrast, schizophrenic patients routinely experience exacerbations of symptoms when they receive either direct or indirect dopamine ago-

nists. Thus, neurotransmitter or neuromodulatory abnormalities that are extradopaminergic must be invoked to explain the fundamental difference between schizophrenic and nonpsychotic individuals and to account for the sensitivity of schizophrenic patients to manipulation of dopaminergic neurotransmission.

Nevertheless, the evidence that abnormalities in the dopamine systems affect the modulation of the symptoms of schizophrenia is compelling. Many aspects of the reconceptualization of the role of dopamine in schizophrenia are testable. We hope these ideas will renew interest in the relationship between dopamine and schizophrenia and stimulate investigation of many of the concepts that arise from this reconceptualization. Undoubtedly, many of these notions will prove overly simplistic, but the gathering of more data will, by further reformulations, inevitably bring us closer to an understanding of the pathophysiology of schizophrenia.

## Psychosocial family intervention in schizophrenia: a review of empirical studies

DOMINIC H. LAM<sup>1</sup>

*From the MRC Social and Community Psychiatry Unit, Institute of Psychiatry, London*

**SYNOPSIS** This paper reviews the recent empirical studies on psychosocial family intervention in schizophrenia. Six family educational intervention studies and five more intensive family work studies with 2-year follow-up have been included. A series of questions is asked relating to the effects of such interventions, the efficacy of the different educational models, the active ingredients of these multi-component treatment packages, and the contribution of this new generation of studies to our understanding of the mechanisms through which these interventions work. Suggestions for further research are made. Finally, from the published manuals, the common components of these diverse, multi-component treatment packages of different family-intervention studies are identified.

### INTRODUCTION

The past decade has witnessed a proliferation of studies of psychosocial intervention with families in which a member suffers from schizophrenia. The impetus has been partly fuelled by the findings that 30 to 40% of schizophrenic patients relapsed on medication (Leff & Wing, 1971; Johnson, 1976) and partly because of the success of the Expressed Emotion (EE) measure in predicting relapse in schizophrenic patients (Brown *et al.* 1972; Leff & Vaughn, 1985). It is hoped that, if the stressful family atmosphere can be modified, patients will have fewer relapses.

The psychosocial family interventions reviewed in this paper have certain principles in common. First, it is assumed that it is useful to regard schizophrenia as an illness. Secondly, the family is no longer implicated in the aetiology of the illness. Instead the burden borne by the family in caring for a deeply disturbed or impaired individual is acknowledged. Support is provided and the relatives are enlisted as therapeutic agents. Thirdly, the psychosocial interventions offered are part of a treatment package in conjunction with routine drug treatment and out-patient clinical management. The

aims of the interventions are broadly the prevention of relapse (secondary prevention) and improvement in the patient's level of functioning. The aim of the paper is to review the short-term and long-term effectiveness of the different intervention studies. Better designed studies with longer follow-ups have been published since the review articles by Barrowclough & Tarrier (1984) and Strachan (1986). These have varied from a short course of education to more intensive family work. In this article, the intervention studies of family education are reviewed first, followed by more intensive studies of family treatment. A series of questions is asked relating to the effectiveness of such intervention packages, the contribution of the new generation of studies to our understanding of the mechanism through which the interventions work, the efficacy of the different methods of family education, and the active ingredients of these multi-component treatment packages. Some broad psychological theories that might inform us on how these interventions work are discussed and suggestions for future research are made. Finally, the published treatment descriptions and manuals are used to identify the common components of the diverse, multi-component intervention packages of different family work studies.

## FAMILY EDUCATION

Barter (1984) defined psycho-education as 'the use of educational techniques, methods and approaches to aid in the recovery from the disabling effects of mental illness or as an adjunct to the treatment of the mentally ill, usually within the framework of another ongoing treatment approach or as part of a research programme'. This definition broadly applies to the family education studies reviewed in this article. The popularity of education for families of the mentally ill is due to the gradual realization by professionals that the primary burden and responsibility for care of a mentally ill person lies essentially in the family (Katschnig & Konieczna, 1989). This is particularly true in countries where the emphasis on the care of the mentally ill is in the community. In the case of schizophrenia, the popularity is also due to the influential research finding regarding EE. Brown *et al.* (1972) speculated quite early on that high EE is due to a relative's lack of knowledge about the illness. Leff & Vaughn (1985) suggested that high EE relatives tended to believe patients had control over their symptoms, whereas low EE relatives believed that patients were genuinely ill and had very little control over their disturbed behaviour. By helping relatives to understand that patients had a genuine illness and very limited control over their symptoms, it is hoped that better understanding on the part of the relatives would attenuate their critical behaviour.

## EDUCATION STUDIES

Table 1 summarizes the contents of the education packages, the method by which the education was delivered and the number of education sessions of the various studies. Six studies of schizophrenia family education are included in this section. The education packages in the studies reviewed are of short duration ranging from 1 session to 6 sessions in a single family or multi-family group. The studies by McGill *et al.* (1983), Berkowitz *et al.* (1984) and Barrowclough *et al.* (1987) are part of more intensive family interventions. They are included here for the purpose of comparison. Furthermore, the study by Abramowitz & Coursey (1989) devoted

one session to teaching explicitly some psychological techniques of coping, using a problem-solving approach (Beck, 1976) and cognitive rehearsal (Beck *et al.* 1979). However, it is subsumed under family education, as the main purpose of 6-session intervention was to offer education and support to the carers with little focus on family therapeutic issues.

### Discussion

#### 1. *What are the effects of family education?*

A direct comparison of the effects of the educational intervention studies is impossible because no two studies used the same design. The studies also differ in the content of the educational package. The time of post-intervention assessment varied from immediately (McGill *et al.* 1983; Berkowitz *et al.* 1984; Smith & Birchwood, 1987; Abramowitz & Coursey, 1989), to one-week (Barrowclough *et al.* 1987), 2-month (Cozolino *et al.* 1988), 6-month (Smith & Birchwood, 1987) or up to 9-month follow-up (McGill *et al.* 1983; Berkowitz *et al.* 1984). Furthermore, the findings of the 9-month follow-up of McGill *et al.* and Berkowitz *et al.* cannot be attributed to the initial education packages alone as their families received ongoing family work in the intervening 9 months. However, the studies taken as a whole do suggest the following.

*A. Gain in knowledge* A gain in knowledge has been reported in all the studies reviewed here with the exception of Cozolino *et al.*'s study which consisted of only one educational session. Berkowitz *et al.* (1984) reported that at immediate post-intervention, more relatives in the experimental group who received education knew about the diagnosis. However, there was no significant difference between their experimental group and their control group who did not receive education in terms of their knowledge of symptomatology. At the 9-month follow-up, more relatives in the experimental group knew about the diagnosis and the symptoms. Barrowclough *et al.* (1987) reported that a post-intervention assessment at an interval of one week showed relatives had an increase in their scores and a significant change from the negative or neutral answers to positive answers in the 'Knowledge About Schizophrenia Interview', except in the section on medication. There was no significant difference in the change scores

Table 1. The number of sessions, content of the package and method of delivery of the various educational programmes

Author	No. of sessions	Content	Method of delivery
McGill <i>et al.</i> (1983)	Two sessions	Nature of schizophrenia, symptomatology, role of environmental stress and drugs, and side effects	1. Didactic with patient present as expert 2. Single family
Berkowitz <i>et al.</i> (1984)	Two sessions	Diagnosis, symptomatology, aetiology, course and outcome, and management	1. Didactic with patient absent 2. Single family
Barrowclough <i>et al.</i> (1987)	Two sessions	Diagnosis, symptomatology, aetiology, medication, course and outcome and management	1. Interactive with patient and relatives brought together at the end of second session 2. Single family
Smith & Birchwood (1987)	Four weekly sessions	Concepts of schizophrenia, cause and epidemiology, symptomatology, treatment and outcome, and hospital and community resources	1. Oral presentation with audio-visual aids, booklets and homework assignment v. booklet through the post and homework assignment 2. Multi-family in the oral presentation condition
Cozolino <i>et al.</i> (1988)	One 3 h session	Diagnosis, symptomatology, aetiology, course and outcome, medication, management, and alternative treatment	1. Didactic with patient absent 2. Multi-family sessions
Abramowitz & Coursey (1989)	Six 2 h sessions every 2 weeks	Understanding of illness, medication, appropriate expectation, management, community resources and advocacy groups, problem-solving approach, developing family network and support	1. Didactic with patient absent 2. Encourage sharing of experience, solution, support and encouragement 3. Multi-family seminars

between the more or less critical relatives suggesting that the critical relatives were equally capable of change. Furthermore, there was a near-significant finding that the relatives of the more recent onset patients showed a greater change score, suggesting those relatives were more amenable to the educational approach. However, similar to Berkowitz *et al.*'s findings, a significant proportion of relatives in Barrowclough *et al.*'s study showed very little gain in knowledge of the aetiology of schizophrenia. Smith & Birchwood's (1987) showed that the relatives in both postal- and group-education groups had significantly increased scores on the Knowledge Questionnaire immediately after receiving education and at the 6-month follow-up compared to the baseline.

*B. Change in belief systems* The evidence to date suggests that education on its own has a very limited impact on the relatives' belief systems. Berkowitz *et al.* (1984) reported that at post intervention more high EE relatives in the experimental group were optimistic than in the control group about the patient's future; and more high EE relatives in the experimental group saw the patient as an individual. Smith & Birchwood (1987) found that the education

package did not affect the relatives' belief system: such as the family's beliefs and expectations about their role in treatment; the effectiveness of medical treatment, the patient's control over the symptoms; and the family's worry about the individual and his behaviour. The only significant finding in terms of the relatives' beliefs was a significant increase in optimism concerning the family's role in treatment in the group-education condition. Unfortunately this effect was not maintained at the 6-month follow-up. Cozolino *et al.* (1988) also found their education package had no effect on the attitudes of the relatives in terms of being hostile or critical, how bothersome these symptoms were, controllability of the symptoms, and symptom stability over time. While high EE relatives did show significantly more critical attribution at pre-intervention and some reduction of negative attribution after family education, they remained more negative towards the patients than low EE relatives. Cozolino *et al.* also reported that their intervention had no significant effect on the understandability of the illness. However, there was a non-significant tendency that education may have an impact on the relatives' self-blame (the control group blamed themselves more, while the experimental group blamed themselves

less). Similarly, Abramowitz & Coursey (1989) reported that there was no significant effect on the negative feelings towards the patient or subjective self-efficacy.

*C. Effect on the relatives' distress and burden*  
The earlier studies by McGill *et al.* (1983), Berkowitz *et al.* (1984) and Barrowclough *et al.* (1987) were influenced by the thinking that high EE in relatives might be caused by a lack of knowledge. Hence gains in knowledge were the logical outcome measure. No direct assessment was made of the effect of education on the relatives' fears and worries, anxieties, distress and burden, and the relatives' subjective feelings of support. The second generation of education studies included here all represented an attempt to evaluate the impact of the educational package on the relatives' reported distress and burden. Smith & Birchwood (1987) reported that there was a non-specific effect of reduction in reported burden at the 6-month follow-up in both the group- and postal-education conditions as measured by the 22-item Family Distress Scale (Pasamanick *et al.* 1967). The reported gain in relatives' optimism in the group condition and the significant gain in the relatives' distress, as measured by the relative's Symptom Rating Test (Kellner & Sheffield, 1973), in both conditions at post-intervention had disappeared at the 6-month follow-up. Likewise, Cozolino *et al.* (1989) reported that high EE relatives in the experimental group felt more supported than the high EE relatives in the control group. However, there was no significant difference in the subjective feeling of support between the low EE relatives in the two groups. Abramowitz & Coursey (1989) used a variety of measures at immediate post-intervention. These included State and Trait Anxiety (Spielberger *et al.* 1970); Relative Distress Scale (Greene, 1982) with three subscales of personal distress, negative feelings towards the patient and disruption of family life; and Generalized Self-Efficacy Scale (Tipton & Worthington, 1984). Results showed significantly less trait anxiety, less personal distress and family disruption in the experimental groups at post intervention. Unfortunately, no longer-term follow-up has been done. To sum up, some positive findings at post-intervention have been reported by both Smith & Birchwood (1987) and Abramowitz &

Coursey (1989). However, the long-term effect is dubious or unknown.

*D. Change in behaviour and relapse rate*  
Cozolino *et al.* (1988) reported that their education package had no effect on the frequency of argument as measured in the 12 typical situations in the Family Conflict Scale (Lieberman *et al.*, unpublished document) and the number of hours of contact per week. The longer-term effectiveness of the education packages at 9 months of the two earlier studies by McGill *et al.* (1983) and Berkowitz *et al.* (1984) are difficult to evaluate as the education is part of an ongoing intervention study. However Tarrier *et al.* (1988) reported the high EE education-only control group had a relapse rate of 43% compared to 53% of the high EE control group at nine months, and 53% and 60% respectively at two years. Similarly, the low EE education only control group had a relapse rate of 22% compared to 20% in the routine management low EE group at 9 months. These results indicated that education alone was not effective in preventing relapse in this population.

## 2. What is the best model of family education?

Tarrier & Barrowclough (1986) suggested that an interactive model of education which take into account the person's lay model of the illness with the content tailored towards the individual family would be a more effective way to educate the relatives. Their didactic educational sessions were more interactive, taking the relatives' lay model of schizophrenia seriously and emphasizing the areas in which the relatives were ignorant. Whether the interactive model of education is more effective is difficult to assess as Barrowclough *et al.*'s instrument of functional values of knowledge was not used in any other study. However, both Berkowitz *et al.* (1984) and Barrowclough *et al.* (1987) commented on how little the relatives had learned about aetiology, indicating that the relatives clung on to their own concept of what caused the patient to be 'ill' rather firmly whether an interactive mode or the more traditional mode of education was used.

Smith & Birchwood's (1987) study was the only one that attempted to evaluate the different

methods by which family education was carried out. Relatives were randomly allocated into a group-education condition or a postal-education condition. The group-education was carried out in 4 weekly semi-structured seminars in a multi-family setting with audio-visual aids. Discussion was encouraged and homework was given. The postal-condition consisted of the printed material with homework sent through the post. The result demonstrated that at post-intervention there was a gain in optimism concerning the relatives' role in treatment in the group-education condition, which was not maintained at the 6-month follow-up. The significant reductions on the relatives' distress and reduction in reported burden as well as a gain in knowledge occurred in both the group- and the postal-education conditions. However, the relatives in the group condition learnt more about schizophrenia than those in the postal condition, even though all relatives in both conditions showed evidence of a gain in knowledge. Hence, the results did not support the superiority of either of the two methods of information delivery, except that relatives in the group-education condition learnt significantly more than those in the postal-education condition.

In all the studies reviewed here, the patient is normally absent from the family education sessions so that the relatives could ask questions without any inhibitions. The exception is McGill *et al.*'s (1983) study in which the patient was included in the education sessions as an expert who had some first-hand experience of the illness. In Barrowclough *et al.*'s study, the relatives were educated alone. However, the patient went through the same educational procedure separately if their mental state allowed it and the relatives and patient were brought together at the end of the second session for further discussions. Unfortunately there are no direct data to support the superiority of either of these two practices.

Lastly, the timing of offering family education needs to be explored. Smith & Birchwood (1987), and Abramowitz & Coursey (1989), offered education to families when the patients did not necessarily have an acute exacerbation of their illness. The other four studies offered education to families after a recent acute episode, and in some cases the patients were still hospitalized. The relative effectiveness of these two practices

is not known as no direct comparison between these studies is possible. However it does appear from the studies by McGill *et al.* (1983), Berkowitz *et al.* (1984), and Barrowclough *et al.* (1987) that the families could absorb information when the patients were unwell. Furthermore, engaging the families when the patients were in remission could be a problem. Smith & Birchwood (1987) reported that 39.5% of families approached for the study either refused to take part in the study or dropped out prior to the start of the study. Similarly, Abramowitz & Coursey (1989) reported 37% of their families who were initially circulated about the education programme showed no response. Hence, the education process should start at a crisis point when information is most needed.

To sum up, there is no evidence to support whether education could be more effective when carried out in an interactive mode, with the patients included in the sessions, or when the family has experienced a recent crisis. However, there is some evidence that relatives learn more in a face-to-face semi-structured seminar and showed more optimism concerning their role in treatment in the short term than through written material. There is also some evidence that it is easier to engage the family when they have experienced a recent crisis.

### Conclusion

As a whole, the studies reviewed did not show any substantial beneficial effect of brief educational packages, other than a gain in knowledge. There is also some evidence that the relatives' burden and distress were alleviated to some extent. However, the most encouraging findings were reported by Abramowitz & Coursey (1989) which represented an attempt to provide a short-term intervention with a mix of educational and problem-solving approaches. At post-intervention, the package appeared to be promising. However, the longer-term effectiveness of the intervention is unknown.

Berkowitz *et al.* (1984) concluded that family education was a good form of family engagement because it was relatively non-threatening and provided a good grounding for further therapeutic work. They also suggested that some imparting of knowledge is important for the non-specific effect of the process. Relatives might not remember enough of the details of the

aetiology to score. However, the process might reduce guilt and enhance the feeling of being supported. Smith & Birchwood also reported no correlation between knowledge gain and attitudinal change, stress and burden in the relatives. They argued that the relatives' subjective feelings of being more knowledgeable could lead to improvement in their cognitive mastery and hence reduce their feelings of uncertainty, helplessness and hopelessness. MacCarthy (1988) argued that educating relatives is also a moral issue. The consumers have the right to be informed and their demand for information is often great. Furthermore, the provision of knowledge is consistent with a psychological model of problem-solving coping (Carver *et al.* 1989) in which knowledge is essential for planning, taking direct action, seeking assistance, screening out other activities and sometimes even forcing oneself to wait.

To sum up, the evidence to date tends to caution against the organization of short education packages without other intervention components. Despite some evidence of short-term gain in reducing distress and burden, families need more input than brief education packages. The studies which included education as part of the larger intervention packages are reviewed next.

#### FAMILY INTERVENTION IN SCHIZOPHRENIA

The inclusion criteria of the studies in this section were as follows.

(1) The subjects had a diagnosis of schizophrenia based on some standard research tool such as the PSE (Wing *et al.* 1974) or RDC (Spitzer *et al.* 1978).

(2) A design was used in which subjects were randomly allocated to a control/comparison group or an experimental group.

(3) The experimental group received some form of psychosocial family intervention.

(4) An effort was made to control for the effects of drugs.

To date, 5 major family intervention studies in schizophrenia have been published with 2-year outcomes (Leff *et al.* 1982, 1985, 1988, 1990; Falloon *et al.* 1982, 1985, 1987; Hogarty *et al.* 1986, 1987; Tarrier *et al.* 1988, 1989). The earlier studies by Weakland *et al.* (1974),

Palazoli *et al.* (1978) and Bowen (1978), were excluded because none of these studies randomly allocated subjects into a control/comparison group. The study by Goldstein *et al.* (1978) was also excluded as its main objective was to assess the effect of a short-term crisis-orientated family therapy on the survival of patients. No outcome beyond that of the 6-month post intervention has been reported for the whole sample, two-thirds of which was suffering from a first episode. Hence it is of uncertain long-term effectiveness and difficult to know whether it would generalize to a more chronic sample. (For a review of these studies, see Strachan, 1986 and Barrowclough & Tarrier, 1984.) Included in this review is the study by Kottgen *et al.* (1984). This is a potentially important study as it adopted a radically different therapeutic approach and had a significantly worse outcome. Unfortunately, in addition to the psychodynamic orientation, this study was different from the other published studies reviewed here in some crucial respects. Vaughn (1986) pointed out three major differences: difference in relapse criteria, possible misclassification of families into the low EE category, and the failure to analyse separately the low EE low-contact group who lived away from home. Because of these differences, a comparison between this study and the other published studies is impossible. However, the study does sound a note of caution about this type of more psychodynamic intervention.

Table 2 summarizes the aims of the six studies, the characteristics of the samples, the selection criteria, and the comparison groups. The five successful family treatment studies reviewed in this section are different from classical family therapy. There is no assumption that the origin of pathological behaviour lies with pathological interactions in the family. Irrespective of the aetiology of schizophrenia, the therapist accepts a disease model that carries implications of the need for retraining, rehabilitation and the avoidance of situations that lead to distress. (See Berkowitz *et al.* 1981 for a more detailed discussion of the implications of disease model and labelling.) The therapist also bears in mind the constraints of the illness in carrying out the intervention. Hence goals are set in small steps in line with the patient's progress in mental functioning. A delicate balance is struck between getting the patient to improve his functioning

and over-stimulation leading to stress and ultimately relapse. The studies reviewed here also had some weaknesses, which are perhaps worth mentioning here. For example in Leff *et al.*'s (1982) study, the PSE assessor was not blind to the subject's treatment condition. As the authors pointed out, an increase in the intensity of symptoms is more subjective. An independent assessor was brought in for these cases; and he did not always agree with the original assessor. In Falloon *et al.*'s (1982) study, a weakness in the design was that no process research was carried out into the therapists' competence in carrying out the two types of treatment or the extent to which the therapists adhered to the treatment manuals. Since the same therapists were used in both treatment conditions, they could have had different expectations of the effectiveness of the two treatment conditions. Alternatively, the therapists could have been more or less competent in one or the other mode of treatment, hence affecting outcome. In Tarrier *et al.*'s (1989) study, the patients' relapse at the 2-years follow-up was largely dependent on hospital admissions. Independent assessors blind to the patients' treatment conditions went through the patient's admission notes. If the admission was due to a recurrence or exacerbation of psychotic symptoms, then the patient was classified as having relapsed. Lastly, in Leff *et al.*'s (1988) study, 5 of the 11 families refused to attend any relatives' groups. Even though there was no statistical difference in the relapse rates between the family treatment and relatives' group conditions, the relative effectiveness of the two treatment conditions needs to be replicated for a firm conclusion due to the high attrition rate in the relatives' group and the small number of families in the study.

### Discussion

In this section a series of questions related to the effectiveness of the interventions, the mechanisms through which they work, the possible active ingredients and the studies' common ingredients are explored.

#### 1. What are the effects of the family intervention?

A. Patients' mental state Other than the controversial study by Kottgen *et al.* (1984), the

above studies conducted by different teams and at different geographical locations have demonstrated consistently a robust effect that family intervention is effective in preventing schizophrenic relapse at 9 months or one year. The relapse rates of the family treatment group ranged from 6 to 23%, compared with 40 to 53% in the comparison groups. By 24 months, the effect is less impressive as a fairly high proportion of patients has relapsed in the family treatment group in most studies. This ranged from 17 to 44%, compared with 59 to 83% in the comparison of high EE groups. In fact the relapse rate in most studies was about 40% in the family treatment group. It looks as if the existing intervention packages serve to delay rather than to prevent relapse in the longer term. This is supported by the clinical observation that relapses in patients from low EE families are not grossly under-represented in hospitals. However, with the exception of Falloon *et al.*'s study which showed a favourable outcome of 17% relapse at the 2-year follow-up, the therapeutic contact between the therapeutic team and the patients was minimal or non-existent after the initial 9 months. For example, in Leff *et al.*'s first study, the medians for both further family sessions and relatives' group were both 1.1. In their second study, only one family attended the group regularly beyond the initial 9 months. Similarly, in Tarrier *et al.*'s study, only one family was seen regularly once every 6 months by the family treatment team. The model used in these interventions was one akin to the acute medical model of cure in which the patient is expected to recover after an intensive course of treatment and rehabilitation. However, these studies were conducted within the limit of research design. With an illness such as schizophrenia, perhaps a model that entails working on a continual basis with families would be more appropriate as recommended by Tarrier *et al.* (1989). A comparatively more flexible and intense form of therapeutic contact between 9 months and 2 years might lead to a better outcome at the end of the period.

In addition to relapse rate, Falloon *et al.* (1982, 1985) reported other outcome measures including Clinical Exacerbation (defined as a recurrence of florid symptoms that lasted at least a week or necessitated a change of medication); Target Symptom Rating done

Table 2. Characteristics of samples, selection criteria, comparison groups, aims of intervention and outcome of the various studies

Study	Sample	Selection criteria	Comparison groups	Aims of intervention	9 months/1 year	2 years
Leff <i>et al.</i> (1982, 1985)	24 patients randomly allocated to treatment groups mean age: 39 yr expt. group 30 yr control group 30 yr mean no. of previous admissions: 2.3 expt. group 2.3 control group 1.7	(1) PSE schizophrenia (2) High EE family (3) High contact (4) Age between 16 and 65 years	(1) Experimental group of psychosocial treatment consisted of family education, family therapy and relatives' group + routine clinical management (2) Control group of routine clinical management	(1) To manipulate EE and investigate the causal relationship between EE and relapse (2) To compare the relative effectiveness of psychosocial intervention with routine out-patient care only	9% in expt. group relapsed 50% in control group relapsed	40% in expt. group relapsed (including 2 patients who committed suicide) 78% in control group relapsed
Falloon <i>et al.</i> (1982, 1985)	36 patients randomly allocated to treatment groups mean age: 25.0 yr expt. group 26.2 yr control group 26.2 yr mean no. of previous admissions: 3.1 expt. group 3.1 control group 2.9	(1) PSE schizophrenia (2) High EE families (except 3 families who are included because of high risk according to other criteria) (3) Daily contact with their biological parents (4) Age between 18 and 45 yr	(1) Experimental group of behavioural family treatment (2) Control group of individual treatment	(1) To compare the effectiveness of family treatment with individual supportive treatment in the prevention of relapse	6% in the expt. group relapsed 44% in the control group relapsed	17% in expt. group relapsed 83% in the control group relapsed
Hogarty <i>et al.</i> (1986, 1987)	103 patients randomly allocated to treatment groups mean age of whole sample 27 yr ( $\pm 7.7$ ) mean no. of previous hospital admissions 2.7 ( $\pm 3.1$ )	(1) RDC schizophrenia or schizo-affective psychosis (2) 1 out of 3 months prior to admission living in a high EE household (not necessarily high contact) (3) Age between 17 and 55 yr	(1) Family treatment (22 pt.) (2) Social skill training (23 pt.) (3) Family treatment and social skill training (23 pt.) (4) Control group of outpatient management (35 pt.)	(1) To reduce the emotional climate of the home (2) To maintain reasonable expectation in the family on patients' performance	23% relapsed in family treatment group 30% relapsed in social skill training group 9% relapsed in the combined group 49% relapsed in control group	34% relapsed in family treatment group 42% relapsed in social skill training group 25% relapsed in the combined group 66.7% relapsed in the control group

Tarnier <i>et al.</i> (1988, 1989)	83 patients allocated to groups using stratified random allocation taking into account no. of previous episodes and presence of residual symptoms mean age 35.3 yr ( $\pm 12.8$ ) mean no. of previous episodes 2.8 ( $\pm 3.6$ )	(1) PSE schizophrenia for 3 months prior to admission and intending to return home on discharge (2) Lived with relative (3) Age between 16 and 64 yr	Four high EE groups: (1) Inactive behavioural treatment (16 pts) (2) Symbolic behavioural treatment (16 pts) (3) Education only (16 pts) (4) Routine treatment (16 pts) Two low EE groups: (1) Education only (9 pts) (2) Routine treatment (10 pts)	(1) To eliminate components of high EE (2) To maximize the patients' level of functioning	High EE group relapse rate 17% in Enactive behaviour group 8% in Symbolic behaviour group 43% in Education only group 53% in Routine treatment group Low EE groups relapse rate 22% in Education only group 20% in Routine treatment group	Relapse rate 33% in behaviour treatment group (Enactive + Symbolic) 59% in control high EE group 33% in control low EE group			
Kottgen <i>et al.</i> (1984)	49 patients allocated into groups	(1) PSE schizophrenia (2) Age between 18 and 30 yr	(1) High EE experimental group of relatives' and patients' groups (15 pts) (2) High EE control group of conventional treatment (14 pts) (3) Low EE control group of conventional treatment (20 pts)	(1) To air pent-up feeling and exchange views in the relative's group (2) To aid patients to acquire a peer group (3) To disentangle the emotional knots in high EE families (4) To provide understanding and more detached relationship	33.3% relapsed in high EE expt. group 50.0% relapsed in high EE control group 45.0% relapsed in low EE control group	N.A.			
Leff <i>et al.</i> (1988, 1990)	24 patients randomly allocated into treatment groups mean age: Family therapy group 26 yr, Relatives group 27 yr mean no. of previous admissions: Family therapy 2.0 Relative group 2.5	(1) PSE schizophrenia (2) High EE household (3) High contact (4) Age between 16 and 65 yr	(1) Education + family therapy (2) Education + relatives group	To compare the effectiveness of relatives group and family therapy	8% in education + family group relapsed 33% in education + relatives' group relapsed	33% in education + family therapy group relapsed 36% in education + relatives' group relapsed			

monthly on 2 or 3 florid symptoms rated on a 7-point severity scale by the pharmaco-therapists who were blind to the therapy conditions; and Symptom Remission (defined as no florid symptoms in the previous month according to the PSE). Furthermore, Community Tenure (defined as the number of days the patient spent in a psychiatric hospital and the number of admissions) was calculated. A significant gain in all these measures had been reported in the family treatment group both at 9 months and 2 years. Leff *et al.* (1990) reported an improvement in negative symptoms at their 2-year follow-up among patients treated by family therapy alone and relatives' group alone. Unfortunately, as the authors pointed out, in the absence of a control group, this improvement in negative symptoms cannot be attributed entirely to the psycho-social intervention package.

*B. Patients' social functioning* Falloon *et al.* (1985, 1987) reported that both the family and individual interventions showed significant interactions with time in the ANCOVA with most social, clinical and family burden measures. However, the between-group difference always favoured the family approach. A survey of clinical records revealed that the family-treated patients had longer periods of employment or rehabilitation programmes at the 9-month follow-up. At 2 years, patients in the family-treated group had an average of 12.6 active months compared to 7.2 months in the control group. In terms of the adjustment of the family unit, the Family Adjustment Scale (SAS-SR, Weissman *et al.* 1978) completed by parents showed an improvement at the 9-month and 2-year follow-ups in both the experimental and control conditions. The self-reported Social Adjustment Scale, SAS-SR (Weissman *et al.* 1978), showed that there was a significantly greater overall social adjustment in the family treated group with a superior adjustment in leisure activities and family relationships at 9 months. Seven items from the Social Behaviour Assessment Scale (SBAS, Platt *et al.* 1980) were examined as an additional source of reporting from relatives. These revealed greater improvements in the patients' performance in household tasks, work or study activities and friendship outside the family in the family treated group at 9 months. At 24 months, the performance of the

family treated group was superior in household tasks and decision-making, with leisure activity approaching significance. Hence, the authors concluded that there was an indirect effect in patients' social functioning even though the family treatment consisted of a generic problem-solving approach and not techniques that aimed at social functioning *per se*. Falloon *et al.* also reported that social rehabilitation was difficult for many patients, particularly social activities with friends because of the fear of rejection.

Similarly Barrowclough & Tarrier (1990) reported a significant improvement in the high EE group on the Withdrawal, Interpersonal Functioning and Prosocial Activities subscales as well as the overall score of the Social Adjustment Scale (Birchwood *et al.* 1990) over the 9 months. In the high EE control group, patients showed a significant improvement in the Interpersonal Functioning subscale but a significant deterioration in the Withdrawal subscale. The patients in the low EE control group showed significant improvement in the overall score and a significant improvement on the Interpersonal Functioning and Independence subscales from post-discharge to 9 months. Hence the high EE treatment group had significant improvements in three sub-scales and the overall score at the 9-month follow-up whereas the high EE control group had a significant improvement in one subscale but deterioration in another. Unfortunately, the information on the patients' social functioning was obtained only from the relative who had most contact with the patient. No other source of information (such as the patient's self-report) was used. As 76% of the patients in the study lived with only a single relative and 77% of the patients were from high EE households, a high proportion of the relatives from whom the patients' social performance was rated were initially high EE relatives. Therefore, the level of social functioning reported at baseline in high EE households could simply be due to a bias in reporting by the critical or hostile relatives. As the relatives changed from high to low EE status at the 9-month follow-up, there could be a more objective report of the patient's social performance. Hence the change in the Social Adjustment Scale could be confounded by the reporting relative's attitude as reflected in the EE rating.

*C. Relatives' burden and distress* Falloon *et al.* (1985, 1987) reported that the family-treated group reported greater interference in family life at the baseline but improved at 9 months according to the SBAS when the individually treated group reported greater family life interference. However, at the 2-year follow-up, both groups showed improvement. The most striking improvement was in the individually treated group which was associated with a greater improvement in social functioning. The subjective burden derived from the SBAS was significantly reduced only in the family-treated group at both the 9-month and 2-year follow-ups. The Hopkins Symptom Checklist (Lipman *et al.* 1968) was used for parental symptoms. There were significantly fewer mothers in the family-treated group who complained about somatization and obsessive-compulsive symptoms at both 9-month and 2-year follow-ups. This effect did not apply to the fathers in the study. Hence the effects of the intervention programme were mixed. Tarrier *et al.* (1988) also measured the subjective distress and burden of the relatives. However, to date no report on the stress and burden on the family has been published.

*D. Change in family atmosphere* One of the major aims of most of the studies is the reduction of adverse family atmosphere. This is reflected by a repeat of some assessment of family climate, most commonly EE assessment. The outcome has been by and large successful. For example, Leff *et al.* (1982, 1988) and Tarrier *et al.* (1988) reported that at the 9-month follow-up, there was a significant reduction in critical comments in the experimental group. Tarrier *et al.* (1988) also found a significant reduction in the emotional over-involvement and warmth in the behavioural groups at 9 months. Similarly Leff *et al.* (1990) found a significant reduction in emotional over-involvement at 2 years. In Hogarty *et al.*'s study, unfortunately 23% in the experimental group and 52% in the control declined a second Camberwell Family Interview (CFI) from which the EE rating was derived. For those who refused, the research team ventured to guess their EE status. The proportion of families changed from high to low EE status at 1-year follow-up were: 17% in the control group, 30% in the social skill training

group, 43% in the family-treatment group and 35% in the combined treatment group. However, this finding must be interpreted with caution because of the high proportion of relatives who refused to have a second CFI. Unfortunately in Falloon *et al.*'s (1982, 1985) study, no repeat of EE measure was carried out. However at 9 months, Doane *et al.* (1986), using a direct interactive procedure called Affective Style Measure, reported 88% of the family-treated group had a reduction in criticism or intrusiveness or both, whereas 50% in the control group had an increased score in one or both measures.

## 2. How does it work?

In Hogarty *et al.*'s (1986) study, the best treatment outcome at 9 months in the combined condition consisted of seeing patients once a week and the families bi-weekly for a considerable period of time. Hence this group had far more therapeutic input than any of the other groups in his study. Similarly, in Leff *et al.*'s (1982, 1988), Falloon *et al.*'s (1982) and Tarrier *et al.*'s (1988) studies, the family-treatment groups had proportionately more therapeutic contacts than their comparison groups. The effect of treatment could be due to the non-specific effect of greater therapeutic contacts. As a result, there is greater understanding of the rationale of medical treatment and greater vigilance from the family to ensure its compliance. This postulation is consistent with Falloon *et al.*'s finding that patients in their family-treated condition were better at complying with drugs. In fact Falloon's family treatment included training for the patient and families to recognize early prodromes of relapse and the medication was actively monitored by clinicians. Hogarty *et al.* (1986) commented on the estimated relapse rates amongst controls of 54 to 60% at one year in the studies by Leff *et al.* (1982, 1985) and Falloon *et al.* (1982) were similar to those of placebo groups in other published drug controlled, maintenance studies. He concluded such a high relapse rate might include drug defaulters. However, in the two studies by Leff *et al.* and in the study by Hogarty *et al.* most patients in both the family-treated and comparison groups received depot injections. This rather supported Leff *et al.*'s (1985) argument that the presence of high EE families

placed the patients at an increased risk of relapse. In any case, the relapse rates of the treatment groups in Hogarty *et al.*'s study were a significant improvement compared to 49% of relapse in the drug-treatment group. Moreover, Tarrier *et al.*'s systematic monitoring of the patients' medication on a 4-point scale has ruled out the possibility that the effectiveness of their intervention was due to drug compliance. Hence their outcomes did not seem to be due to drugs entirely. Hogarty *et al.* also found that family treatment was effective for both the drug compliant and drug non-compliant subjects. Hence there is some evidence that family treatment is effective, independent of greater drug compliance.

Another possible mechanism for the confounding effect of greater therapeutic contact is better liaison between the therapists and the clinical team so that the clinical team could intervene more promptly or frequently at an earlier stage before a full-blown relapse had set in. This is consistent with the community care of schizophrenia programmes reported by Test (1990) and Hoult *et al.* (1983) who demonstrated some success in maintaining schizophrenic patients in the community by providing direct and close support to the patients and their families. However, Tarrier *et al.*'s study showed that there was no difference in the patients' contact with the clinical team between their family-treated and comparison groups. Falloon *et al.* also demonstrated that the patients in the family-treated group needed less medication. Therefore, it is unlikely that the treatment effect is due to either greater compliance with drugs, more energetic drug treatment or more contact with the clinical team. Moreover, Tarrier (1989) reported there was no significant difference in the number of life events the patients had experienced between the family intervention group and the comparison groups.

Furthermore in the studies reviewed here there is no comparison group where therapists worked with the families in a placebo-treatment way. However, the non-specific effects of simply working with the family are, to some degree, negated by the negative outcome of Kottgen *et al.*'s (1984) study. Even through Kottgen *et al.*'s criteria for relapse were different from other studies reviewed here, the proportions of patients who relapsed were similar across the

treatment and control groups. Hence the effectiveness of family treatment may indeed depend on certain therapeutic ingredients rather than simply on regular contacts.

With the exception of Falloon *et al.*'s study, EE served both as a predictor and as an outcome measure which was then related to patients' relapse. Across studies, none of the patients whose family changed from high to low EE relapsed at 9 months. However, there is accumulating evidence that EE can change spontaneously over time. Brown *et al.* (1972) found about 30% of high EE relatives changed from high to low EE spontaneously. Similarly, Tarrier *et al.* (1988) reported a significant change in the high EE control groups over time. In fact, a small proportion of non-critical relatives became critical over time. Since EE is a measure taken initially at a crisis point, it might fluctuate with the patient's mental state. As the patients become more stable, the EE level may come down. The relationship between EE, intervention and relapse is probably quite complex which a unidirectional model would be unable to explain. Furthermore, it does not look as if reducing EE is the only mechanism through which these interventions work. Hogarty *et al.* found that in the combined treatment group, a change from high to low EE was not necessary for good outcome. Leff *et al.* (1982) also found that a reduction in face-to-face contact was effective in preventing relapse in households that did not change to low EE status. This led to Kuipers & Bebbington's (1988) postulation that when the intervention is directly with the patient, good outcome may not necessarily be related to reduction in EE. Brown *et al.* (1972) and Barrowclough & Tarrier (1990) reported that high EE was related to poorer social functioning in the patients. The intervention studies reviewed here have either directly or indirectly tried to improve the patients' social functioning. Leff's and Hogarty's teams used a structured behavioural approach explicitly to improve self-care and social functioning. The problem-solving approach used by Falloon's and Tarrier's teams was capable of dealing with these issues if indeed self-care and social functioning were the problems. The evidence to date provided no strong evidence whether increasing the patient's level of social functioning had a protective effect. Hogarty

*et al.* (1974) reported a delayed effect of their Major Role Therapy (MRT). There was no significant effect of MRT for the whole 24 months after hospital discharge. However, MRT did reduce relapse rate among those who survived the first 6 months in the community. Hogarty *et al.* (1979) reported that there was a clear trend that long-acting fluphenazine decanoate and social therapy reduced the risk of relapse when the whole period of 24 months was taken into account. However, the result was not significant as their sample of 105 did not have enough statistical power to demonstrate a significant interaction. Hogarty *et al.* (1986) was the only study that looked at EE and social skill training. They reported that the relapse rate of social skill training in patients whose families remained as high EE at the one-year follow up was not significantly better than that of controls. Hence it looks as if the effect of improved social functioning, change of EE status and the patients' relapse are more interactive than a simple causal relationship.

### 3. What are the active ingredients?

None of the studies reviewed here directly tested the active ingredients in these multi-component therapeutic packages, other than Tarrier *et al.*'s study. This is probably a reflection of how difficult it is to study the active ingredients of any psychological treatment package. Kazdin & Wilson (1978), O'Leary & Berkovec (1978) and Leff (1981) have all commented on the inadequacy of a placebo treatment in psychological treatments. A placebo psychological treatment that generates the same amount of credibility and expectancy of outcome would probably contain some active ingredients. Tarrier *et al.* attempted to do away with the placebo treatment concept by having two levels of instruction in their behavioural groups. It was hypothesized that the enactive level would be more effective than the symbolic level. Unfortunately, the outcome did not support their prediction. However, the education-only control group showed that education alone did not have any effect on relapse either in the high or low EE groups. It does not look as if education alone contains the sufficient ingredient.

To date, there seem to be enough studies with good research designs to demonstrate the effectiveness of family treatment in schizophrenia.

To recapitulate, the effectiveness did not seem to be due to better drug compliance or more contact with the clinical teams. There is also evidence that the effectiveness of these interventions is not simply due to the non-specific effect of working with the family. Hence it could be justified to use a different approach of the dismantling methodology (Kazdin, 1980) in order to tease out the active ingredients from the 'flavours and fillers'. The outcome differences of patients receiving the full treatment can be compared with other groups undergoing variant interventions, each of which lacks one or more specific components of the full package. Part-treatments that produce effects equivalent to those of the full-treatment condition are likely to contain the active ingredients.

Furthermore, some indication by the consumers about the helpful aspects of the intervention packages may throw some light on the active ingredients. Questionnaires on the global satisfaction of the consumers are often unhelpful and tautological. They may involve some subjective averaging of the session or treatment course as a whole. The specific impact of significant interactions between the therapists and the clients is often untapped. The techniques developed by Elliott (1985) and Bloch *et al.* (1979) in which the clients and the therapists were requested to provide a brief account of the helpful events during the sessions may be a more useful way directly to tap into the impact of the therapy on the relatives and patients, giving some indication of possible active ingredients.

### 4. What are the common components in these treatment packages?

A survey of the treatment packages reveals a number of common components in these studies even though the interventions are confusingly labelled as psycho-education, behavioural family work or family therapy/relatives' group. However, most of these approaches have a common heritage stemming from the earlier works of Liberman *et al.* (1978). Berkowitz *et al.* (1990) described in detail the treatment technique used by Leff's team; Hogarty *et al.*'s family treatment was based on Anderson *et al.*'s (1986) psycho-education model; Falloon (1984) published his problem-solving family treatment approach; and finally Barrowclough & Tarrier (1987) described their treatment approach in a paper.

Kottgen *et al.*'s (1984) psychodynamic intervention package is excluded as the study showed no significant effect of their interventions.

*A. A positive approach and genuine working relationship* In all the above therapeutic models there is an explicit emphasis on the positive aspects of the family and the family's ability to change, rather than blaming the family. Instead the therapists attempt to understand every family member's perspective and emphasize the positive intentions of the family. Hence Falloon's team assumed that the family wanted to help and that the coping behaviour of the family members represented the person's best effort even though it may have looked undesirable to the professionals. Like all the other three models, they focused on the strength and needs of the family unit. Often, the family's intention was positively reframed even though it seemed undesirable to the therapists. Furthermore, the Rogerian principles of empathy, warmth and genuineness are emphasized. Relatives are respected as individuals with their own needs and their burden of caring for a family member suffering from schizophrenia is acknowledged. Hence, families are taught better ways to deal with problems rather than the therapist being punitive with the family's undesirable coping.

*B. Providing structure and stability* Hogarty's team taught families that intense interpersonal involvement and permissiveness would lead to stress and reinforce inappropriate behaviour. Similar to the model adopted by Leff's and Falloon's teams, relatives were told that patients were more likely to respond to appropriate limit setting while maintaining a moderate interpersonal distance. In all the above therapeutic approaches, contracts of regular contacts were clearly spelled out to provide some structure and stability to the families who might be experiencing a lot of the unpredictability that a schizophrenic patient could bring. Both Leff and Hogarty's teams even made a special effort to be available over the telephone between sessions to exert structure and reinforce coping. Falloon's team provided a 7-day per-week, 24-hour crisis contact service either via the telephone or domiciliary counselling.

*C. Focus on 'here and now'* In all the in-

tervention packages, the focus of work is the problems and the stress the family faces. During the assessment stages, attempts are made to find out the family's past and present coping strategies and to understand the family's strengths and weaknesses. However, the general emphasis is how the family react to each other, the individual member's perception of the problem and their ways of coping. Moreover the therapist exerted quite a tight control over the family atmosphere by discouraging criticism, over-involvement, permissiveness; and encouraging realistic expectations and better coping strategies.

*D. Use of family concepts* The models used by Hogarty's and Leff's teams emphasized the importance of avoiding unclear family structures. Hence the therapist attempted to eliminate diffuse generational and interpersonal boundaries by supporting a marital coalition and encouraging respect for interpersonal boundaries. Family boundaries were firmed up by strengthening parental boundaries or marital alliance and promoting independence and separation if appropriate. Falloon's model of behavioural family work had less emphasis on the aforementioned family concepts. However, Falloon's work did emphasize the behavioural analysis of the family unit as a whole, identifying the role that specific problem behaviour plays in the functioning of the family. In working with the family, the assets of the individual members as well as the family unit were called upon to work through problems.

*E. Cognitive restructuring* The education component provides a model for relatives to make sense both of the patient's and their own behaviour and feelings. Hence the patient is no longer seen to be malicious and deliberately failing to control their very disturbing behaviour. Relatives may also understand that delusional accusation is real to the patient and develop better ways to handle situations rather than heated arguments or counter-accusations. By stating clearly that there is no evidence of schizophrenia being caused by the family, the family education also helps to reduce guilt which is common among these families. In the models used by Leff's and Hogarty's teams, guilt is further reduced for some over-involved relatives

by the therapist's assertion that it is important to attend to the relative's own needs in order to be able to cope better.

*F. A behavioural approach* The family work reviewed above all had the behavioural components of assessing strength and needs, agreeing realistic goals, setting priorities, breaking goals into small behavioural steps, task assignment and reviewing. This behavioural approach was used in Hogarty's and Leff's work with families to set limits, improve patients' functioning and the families' coping. Similarly, Tarrier's team applied detailed behaviour analysis in their intervention. In Falloon's team, these steps were subsumed under a framework of problem-solving. Furthermore, Falloon's team used behavioural strategies to deal with persisting delusions and hallucinations.

*G. Improving communication* Berkowitz *et al.* (1990) commented on how low EE relatives express their feelings directly, not with anger or any guilt-inducing element. Hence, care is taken to train families to express requests for change in a clear, simple and specific way in the context of problem-solving rather than generalizing. In all the packages some emphasis was placed on communication as a means of correcting erosion of interpersonal boundaries in family units. Family members were trained not to speak for each other and to express clear supportive or reinforcing statements to each other whenever appropriate. With Tarrier's team, communication would be identified as an area of change if it was poor or inadequate. Of all the models reviewed here, Falloon's model was the most explicit in terms of communication training including detailed steps on rehearsal, feedback, coaching, repeated rehearsal, practice and generalization.

*5. What theories could inform psychosocial family treatment in schizophrenia?*

It is important to link theoretical framework with treatment studies as ultimately only theoretical advances could increase the specificity and quality of family interventions. One of the problems in identifying the general mechanisms through which these intervention packages work is the fact that these intervention studies are by and large empirically driven. Despite

nearly thirty years of research, EE remains an empirical concept, the origin of which is not understood. Furthermore EE has been shown to have predictive power not just on relapse in schizophrenia, but also on relapse in depression (Vaughn & Leff, 1976; Hooley *et al.* 1986); on success in maintaining weight loss in previously obese women (Fishmann-Havstad & Marston, 1984); and on which families would drop out from the family treatment of anorexia nervosa (Szmuckler *et al.* 1985). Since there is no unified theory incorporating the nature and development of high/low EE families, and since EE has shown predictive validity across a range of conditions, one can only speculate on the broad and general mechanisms that are possible candidates for effecting therapeutic change in these intervention studies.

One general theory that may be important to all these intervention studies is Coping (Lazarus, 1966). Coping refers to the cognitive-behavioural effort to master, reduce or tolerate the internal and/or external demands that are created by the stressful transaction (Folkman, 1984). A common component in all the successful intervention packages is the use of therapeutic technique to help solve the family problems or reduce them to a tolerable level. By educating and working closely with these families, the therapists taught the families a problem-focused coping approach. As the families learnt more about the nature, outcome and ways to help the patients stay well, their appraisal of the stressor might change, enabling them to assess more objectively their coping resources, including the material assets, social support, etc. Furthermore, the reduction of guilt and the support provided by the therapists could reduce the heightened emotions among the relatives. This reduction in heightened emotion is seen as important for effective coping as heightened arousal interferes with cognitive activities necessary for problem-focused coping (Lazarus, 1966; Sarason, 1972; Khan, 1964). In Tarrier's intervention package, the relatives were explicitly taught relaxation and other cognitive-behavioural techniques to reduce their anxiety. Finally, effective coping involves knowing when to accept a situation which there is very little one can do to change, hence focusing on tolerance or acceptance. Because of the therapists' intimate knowledge of the individual patient, the therapists could advise when

to show more acceptance and hold off unrealistic expectation for change. As the patient's clinical state improves, more change is instituted accordingly.

Tarrier (1989) speculated, in keeping the diathesis-stress model, that the way family intervention works is the reduction of stress in the environment. He postulated that if schizophrenic patients have dysfunctions in information processing and arousal regulation, a complex, vague, or emotionally charged environment (typically found in high EE households) would lead to information overload and reappearance of positive symptoms. Conversely, if the environmental stimuli are clear, simple and free of excess emotions, the patients are unlikely to relapse. Hence family intervention works if it succeeds in reducing stress in the environment.

Another theory that might be informative is attribution theory (Weiner, 1986). Leff & Vaughn (1985) and Brewin (1988) postulated that if the relatives believed that the patients had control over their illness, negative symptoms and problem behaviour would elicit criticism and hostility. Emotional over-involvement in relatives is often perceived as a result of guilt, which Weiner (1986) suggested is associated with negative outcomes attributed to internal and controllable causes by oneself. Hence it is tempting to construe success in therapy as associated with attributional change in the relative regarding the onset and symptoms of the illness. Brewin *et al.* (1990) coded spontaneous attributions by relatives in the CFI and found that critical and hostile relatives indeed made more attributions to factors personal to and controllable by the patients, compared with low EE and emotional over-involved relatives. However, the attribution by the emotionally over-involved relatives did not differ from the low EE relatives. Hence the predictions are only partly borne out. However, the number of emotionally over-involved relatives in the study was small and might not have enough statistical power to show any significant difference. Tarrier *et al.*'s (1988) study showed simply providing the family with information about the illness was not effective in preventing relapse or increasing the patients' level of functioning. If the new information is in conflict with the person's pre-

existing beliefs, a more structured approach such as trying out different coping strategies to have a different experience may be necessary to effect a shift in beliefs. A study with a larger number of families and attribution measured before and after intervention should shed light on the topic.

## CONCLUSION

The family treatments reviewed here consist of labour-intensive packages. However, the beneficial effect of preventing relapse in the first 9 months has been established repeatedly. Even allowing for the intense efforts by the therapeutic teams, the interventions were cost-effective compared to hospital in-patient treatment. Cardin *et al.* (1986) established that the cost of family treatment was 19% less than the control group who needed more crisis management and hospitalization. Furthermore, the benefit for the patients of not being disrupted by frequent hospital admissions is probably beyond that of financial considerations for the health service. Patients would have longer spells to carry through their commitments in the community. Less frequent hospital admissions would probably lead to less stigmatization and better self-esteem.

One criticism is the use of high EE as a selection criterion for intervention. Thus, the needs of the low EE families are by and large neglected (Birchwood & Smith, 1987). The relatives in low EE families may condone or make undue allowance for negative symptoms, thus providing an atmosphere not conducive to promoting the patients' social functioning. This criticism is justified in terms of service provision, in which all client groups should be provided with the best possible care. However, in terms of research, it makes sense to demonstrate the effect of treatment in the 'high risk' group defined on some established criterion such as EE, in order to establish its efficacy. Demonstrating that a treatment package is effective in a defined sub-group of patients does not necessarily mean neglecting the other sub-groups. Whether patients in low EE households respond to some therapeutic approaches to improve their level of social and role functioning is an empirical question that needs to be

examined. Schizophrenic patients with negative symptoms may need a different approach. As patients suffering from schizophrenia have such a wide variety of problems, ultimately different strategies may have to be developed.

For further research, a wide variety of outcome measures including the patients' social and role performance, the relatives' level of distress and burden and their subjective report of the impact of the intervention on the family members should be included in addition to patients' relapse. These outcome measures should be taken from different perspectives, e.g. the families, the patients and possibly the therapists. Furthermore, the process of change should be spelled out more carefully and measured. For example, if the aim of the family intervention is to promote more adaptive coping, this should be directly measured before and after intervention in order to promote our understanding of the outcome.

A related but different line of research that is urgently needed is the evaluation of the training of clinicians to use these techniques to work with families. So far, the interventions have been carried out by highly motivated and highly skilled research teams. The replication of the outcomes of such interventions by people who are slightly more distant from such therapeutic packages might make the outcomes more convincing. This would involve packaging the training in a format which would enable ready acquisition of the necessary skills and devising a criterion-based competence scale to facilitate quality assurance and guide trainees to acquire the requisite skills. Furthermore, some process research which involves analysis of the recorded sessions to ensure the therapists' adherence to the treatment manuals is necessary in order to guarantee that the treatment is delivered as intended, and contains the crucial components. The MRC Social and Community Psychiatry Unit is in the process of developing such a training package with appropriate scales to measure competence of trainees and treatment adherence. Tarrier & Barrowclough (1990) also reported their involvement in the evaluation of a systematic training and supervision programme for community psychiatric nurses as well as the development of the Behaviour Family Therapy Skill Measure scale by Laporta *et al.* (1989).

The author is most grateful for the comments on an earlier draft from Paul Bebbington, Christine Vaughn, Julian Leff and Mick Power.

## The Unipolar-Bipolar Distinction in the Characterological Mood Disorders

DANIEL N. KLEIN, PH.D.,<sup>1</sup> ELLEN B. TAYLOR, M.A.,<sup>1</sup> KATHRYN HARDING, B.A.,<sup>2</sup>  
AND SUSAN DICKSTEIN, M.A.<sup>2</sup>

The present study explored the validity of the unipolar-bipolar distinction in the characterological mood disorders. Thirteen cyclothymic and 32 primary early-onset dysthymic outpatients, diagnosed according to DSM-III-R, were compared on demographic, clinical, personality, and family history variables. The cyclothymics exhibited significantly higher levels of depressive symptomatology and extraversion and had a higher rate of bipolar I disorder in their first-degree relatives than the dysthymics. In addition, a significantly greater proportion of cyclothymics than dysthymics had a family history of drug abuse. The groups did not differ significantly on gender, overall rates of affective disorders in relatives, or a number of symptoms which have been reported to distinguish unipolar and bipolar depressives. Although these data require replication due to the small sample and large number of analyses conducted, they provide at least partial support for extending the unipolar-bipolar distinction to the characterological mood disorders.

Although it remains controversial (Akiskal, 1983a; Brockington et al., 1982; Taylor and Abrams, 1980), the unipolar-bipolar distinction is the most widely used and best validated subtyping distinction within the affective disorders (Depue and Monroe, 1978; Perris, 1982). In recent years, there has been increasing evidence linking unipolar and bipolar illness to dysthymia and cyclothymia, two forms of chronic mood disturbance that are phenotypically similar to unipolar and bipolar disorder. Thus, cyclothymia appears to be related to bipolar illness with respect to phenomenology, course, family history, neuroendocrine functioning, and pharmacological response (Akiskal et al., 1977; Depue et al., 1981, 1985; Klein et al., 1985). Similarly, studies exploring phenomenology, course, family history, sleep neurophysiology, and pharmacological treatment indicate that there is a relationship between unipolar disorder and at least some forms of dysthymia (Akiskal, 1983b; Klein et al., 1988a, 1988c; Kovacs et al., 1984). These data suggest that cyclothymia and dysthymia may differ in ways that parallel the differences between unipolar and bipolar disorders. Indeed, the

unipolar-bipolar distinction was recently extended to the characterological mood disorders in DSM-III-R (American Psychiatric Association [APA], 1987), where cyclothymia is classified as one of the bipolar disorders, and dysthymia is grouped with the depressive disorders. To the best of our knowledge, however, no studies directly comparing cyclothymic and dysthymic subjects have been reported. Hence, as part of a larger study of the assessment and classification of chronic mood disorders (Klein et al., 1988b, 1988c, 1988d, 1989), we compared groups of cyclothymic and dysthymic outpatients to explore the validity of the unipolar-bipolar distinction in the characterological mood disorders.

Unipolar and bipolar depressives appear to differ in a number of respects: a) when depressed, bipolar patients tend to exhibit higher rates of psychomotor retardation and hypersomnia and lower rates of psychomotor agitation, hyposomnia, anxiety, and somatization than unipolar patients (Biegel and Murphy, 1971; Detre et al., 1972; Katz et al., 1982; Kupfer et al., 1974); b) bipolar patients exhibit higher levels of extraversion on personality inventories than unipolar patients (Akiskal et al., 1983; Hirschfeld and Klerman, 1979); c) bipolar patients tend to have an earlier age of onset and a greater number of episodes than unipolar patients (Angst et al., 1973; Depue and Monroe, 1978; Perris, 1966); d) bipolar probands have higher rates of affective, particularly bipolar, disorder in their relatives than unipolar patients (Andreasen et al., 1987; Perris, 1966; Weissman et al., 1984); e) the prevalence of bipolar disorder is approximately equal in men and women, whereas unipolar disorder is approximately twice as common in women as in men

(Boyd and Weissman, 1982; Perris, 1982; Weissman et al., 1988b); f) lithium appears to be more effective in preventing recurrences in bipolar than unipolar disorder (Prien et al., 1984); and g) antidepressants may precipitate manic or hypomanic episodes in bipolar but not in unipolar patients (Bunney, 1978; Wehr and Goodwin, 1987).

In the present report, we explored whether the demographic, clinical, family history, and personality differences between unipolar and bipolar disorder were also evident in comparisons of cyclothymics and dysthymics. Due to the heterogeneity of dysthymic disorder (Akiskal, 1983b), we limited our dysthymic sample to patients meeting DSM-III-R (APA, 1987) criteria for the primary and early-onset subtypes, as this is the subgroup which corresponds most closely to the classical concept of characterological depression (Klein et al., 1988a, 1988c; Kocsis and Frances, 1987).

## Methods

### Subjects

Subjects included 13 cyclothymics and 32 primary early-onset dysthymics diagnosed according to DSM-III-R criteria. Six (46%) of the cyclothymics and 19 (59%) of the dysthymics exhibited major depressive episodes superimposed on their chronic minor mood disorders and hence could also be characterized as having bipolar II disorder (Fieve and Dunner, 1975; Spitzer et al., 1978) and double depression (Keller and Shapiro, 1982), respectively. Subjects were drawn from a larger project in which 550 consecutive outpatients at a community mental health center and a university-based clinic were given the General Behavior Inventory (GBI; Depue et al., 1981; Depue and Klein, 1988), a screening inventory for chronic and recurrent unipolar and bipolar affective conditions, before their intake session (see Klein et al., 1989). Using a stratified random sampling method, which sampled disproportionately heavily from the upper range of the distribution of GBI scores, 177 patients were selected and administered a structured diagnostic interview. These subjects were highly representative of the larger population ( $N = 550$ ) from which they were drawn with respect to age, gender, race, marital status, occupation, and education. When GBI scores were compared with blind diagnoses based on the structured interviews, the GBI exhibited good to excellent negative predictive power and acceptable positive predictive power for chronic unipolar and bipolar conditions (Depue and Klein, 1988; Klein et al., 1989). The cyclothymics and dysthymics had equal probabilities of being selected by the sampling procedure; hence, it was not necessary to weight subjects as a function of the probability of inclusion.

### Measures

All patients received structured diagnostic interviews based on the Schedule for Affective Disorders and Schizophrenia (SADS; Endicott and Spitzer, 1978). For the purposes of the present study, however, the SADS was modified in several respects: a) a number of items were added to provide a more thorough assessment of chronic minor mood disorders (Klein et al., 1985, 1986); b) information necessary to derive DSM-III (APA, 1980) diagnoses was elicited. Although the study was initiated before the publication of DSM-III-R, all information necessary to derive DSM-III-R diagnoses of cyclothymia, dysthymia, and the dysthymia subtypes was also available; c) additional sections assessing eating and borderline and schizotypal personality disorders derived from other diagnostic interviews (Robins et al., 1981; Stangl et al., 1985) were included; and d) a section assessing Schneider's (1958) construct of the depressive personality was also included (Akiskal, 1983b). Particular care was taken to ensure that depressive personality traits were scored only if they had been present since early adolescence and were evident outside of major depressive episodes. We have previously reported that the scale has good interrater reliability and is not significantly affected by clinical state (Klein et al., 1988a, 1988c).

Data on all first-degree relatives over age 17 were systematically collected using the Family History Research Diagnostic Criteria (FH-RDC) interview guide (Andreasen et al., 1977). For the present study, the FH-RDC were modified by requiring hospitalization, psychosis, or marked impairment in functioning as a criterion for diagnosing manic disorder. Patients meeting FH-RDC criteria for mania, but not meeting this additional criterion, were diagnosed as hypomanic.

Interviews were administered within the first few treatment sessions by a clinical psychology faculty member and several advanced graduate students. As detailed elsewhere, interrater reliability was excellent (Klein et al., 1988c).

Patients also completed a number of inventories, including the Eysenck Personality Questionnaire (EPQ) extraversion scale (Eysenck and Eysenck, 1975); the Multidimensional Personality Questionnaire (MPQ) achievement scale, a measure of achievement orientation, and abbreviated stress reactivity scale, which is conceptually and empirically closely related to Eysenck's construct of neuroticism (Tellegen, 1982); and the Depressive Experiences Questionnaire (DEQ) dependency and self-criticism scales (Blatt et al., 1976). Data on comorbidity and family history were unavailable for one cyclothymic subject, and two subjects in each group failed to complete the personality inventories.

### Data Analysis

The Weinberg abridged method (Slater and Cowie, 1971) was used to calculate bezugziffern (BZs) for the age-corrected prevalence rates of psychiatric disorders in relatives. The risk periods used were ages 18 to 59 for the affective disorders and ages 18 to 39 for schizophrenia, alcoholism, and drug abuse. Antisocial personality disorder, by definition, is manifested by age 18 (APA, 1980, 1987), hence age corrections were not used for this condition. Typically, differences in morbid risks are calculated by pooling all relatives from all families in each group and computing a modified  $\chi^2$  statistic (Breborrowicz and Trzebiatowska-Trzeciak, 1976). However, this procedure violates the assumption of independence of observations and can significantly bias results (Fabsitz et al., 1985; Weissman et al., 1986). This problem is compounded in family history, as opposed to family interview studies, where the information on all relatives comes from the same source. Moreover, in family history studies, the traditional procedure substantially inflates the degrees of freedom, because the number of subjects in the analysis is really the number of probands rather than the number of relatives. To address these problems, in the present study age-corrected prevalence rates were calculated separately within the family of each proband, and the family, rather than the relative, was used as the unit of analysis.

Cyclothymics and dysthymics were compared using *t*-tests for continuous variables and  $\chi^2$  tests with Yates correction for categorical variables. Separate, rather than pooled, variance estimates were used for *t*-tests when the variances differed significantly between groups. All tests were two-tailed.

## Results

### Demographics

The patients' demographic characteristics are presented in Table 1. The groups did not differ significantly on gender, race, age, education, socioeconomic status, or marital status.

### Clinical Characteristics, Comorbidity, and Symptomatology

The data on clinical characteristics and comorbidity are presented in Table 2. As expected, the cyclothymic patients obtained significantly higher scores than the dysthymic patients on the GBI hypomania scale,  $t[43] = 7.12, p < .001$ . However, the groups did not differ significantly on the GBI depression scale.

There was a trend for the dysthymic patients to have an earlier age of onset than the cyclothymic patients,  $t[43] = 1.79, p = .08$ . In contrast, the cyclothymic patients exhibited a significantly higher level of interviewer-rated depressive symptomatology (assessed by summing the severity ratings for all DSM-III major depression and melancholia symptom items) than the dysthymic patients  $t[43] = 2.29, p < .03$ . In addition, there was a trend for the cyclothymic patients to exhibit greater impairment on the Global Assessment Scale (GAS; Endicott et al., 1976) than the dysthymic patients  $t[43] = 1.71, p < .10$ .

The cyclothymic and dysthymic patients did not differ with respect to comorbidity or prior treatment. Most patients in both groups had experienced at least one lifetime episode of major depression after the onset of their characterological mood disorder. In addition, both groups exhibited high rates of comorbid anxiety, substance use, and severe (antisocial, borderline, or schizotypal) personality disorders. Finally, most patients in both groups had sought treatment on multiple occasions in the past.

Cyclothymic and dysthymic patients generally exhibited similar patterns of symptoms, with no differences being evident on rates of psychomotor retardation, hypersomnia, hyposomnia, anxiety, or somatic complaints. However, there was a trend for a greater proportion of cyclothymic (62%) than dysthymic (28%) patients to report psychomotor agitation during their depressed periods,  $\chi^2[1] = 3.08, p < .08$ .

### Personality

The cyclothymic patients exhibited a significantly higher level of extraversion on the EPQ ( $\bar{X} \pm SD = 14.7 \pm 4.6$ ) than the dysthymic patients ( $8.0 \pm 5.3$ ),  $t[39] = 3.56, p < .001$ . In addition, there was a trend

TABLE 2  
*Clinical Characteristics of Cyclothymic and Dysthymic Patients*

N	Age of Onset	Severity of Depression	GAS	GBI		Major Depression <sup>a</sup>	Anxiety Disorder <sup>a</sup>	Eating Disorder <sup>a</sup>	Substance Abuse or Dependence <sup>a</sup>	Antisocial, Borderline, or Schizotypal Personality Disorders	No. of Past Treatment Episodes	
				Hypomania	Depression							
Cyclothymic patients	13	11.7 ± 4.3 <sup>b</sup>	43.3 ± 4.8	41.2 ± 6.9	18.5 ± 3.7	30.5 ± 7.8	10(77) <sup>c</sup>	8(67)	4(33)	5(42)	6(50)	2.3 ± 1.3

<sup>b</sup>  $\bar{X}$  ± SD.

<sup>c</sup> Numbers in parentheses, percentages.

for the dysthymic patients to exhibit a higher level of depressive personality traits ( $5.5 \pm 1.3$ ) than the cyclothymic patients ( $4.5 \pm 1.3$ ),  $t[43] = 1.96$ ,  $p < .06$ . The groups did not differ on the MPQ achievement and stress reactivity or DEQ dependency and self-criticism scales.

#### Family History

The cyclothymic and dysthymic patients did not differ on the number or age and gender distributions of first-degree relatives. A significantly higher proportion of cyclothymic (25%) than dysthymic (0%) patients had a family history of mania,  $\chi^2[1] = 5.10$ ,  $p = .02$ . Similar proportions of patients in each group had family histories of any affective, bipolar II, and nonbipolar depressive disorder, schizophrenia, alcoholism, and antisocial personality. However, a significantly higher proportion of cyclothymic (42%) than dysthymic (9%) patients had a family history of drug use disorder,  $\chi^2[1] = 4.14$ ,  $p = .04$ .

The age-corrected lifetime prevalence rates for any affective, bipolar I, bipolar II, and nonbipolar depressive disorder, antisocial personality, alcoholism, and drug use disorder are presented in Table 3. Due to the extremely low rate of schizophrenia in relatives, these data are not presented. Similar to the analyses above, the relatives of cyclothymic probands had a significantly higher rate of bipolar I disorder than the relatives of dysthymic probands,  $t[42] = 2.94$ ,  $p = .005$ . In addition, there was a trend for the relatives of cyclothymic probands to have a higher rate of drug use disorder than the family members of dysthymic probands,  $t[12.2] = 2.02$ ,  $p < .07$ .

#### Discussion

These results provide partial support for the unipolar-bipolar distinction within the characterological mood disorders. Thus, cyclothymic patients reported significantly higher rates of bipolar I disorder in their relatives and exhibited significantly higher levels of extraversion than dysthymic patients. In addition, cy-

clothymic patients exhibited a significantly higher level of interviewer- but not self-rated depressive symptoms, and a significantly greater proportion had family histories of drug abuse than dysthymics. This last finding should be interpreted cautiously, however, as the difference on rates of drug use disorder in family members only reached a trend level of significance ( $p < .07$ ).

In light of the greater drug abuse in the relatives of cyclothymic than dysthymic probands, it is conceivable that the excess of bipolar I disorder in the cyclothymics' relatives was caused by misdiagnosing behavior due to substance abuse as manic. However, this explanation appears unlikely inasmuch as none of the bipolar I relatives of cyclothymic probands also exhibited alcoholism or drug abuse.

There were also a number of negative findings in the present study. Contrary to expectations, the cyclothymic and dysthymic patients did not differ on gender or overall rates of affective disorders in relatives. In addition, the groups generally exhibited a similar pattern of depressive symptoms.

In the present study, there was a trend for the dysthymic patients to report an earlier age of onset than the cyclothymic patients. Whereas full syndromal bipolar illness typically has an earlier onset than unipolar disorder (Angst et al., 1973; Depue and Monroe, 1978; Perris, 1982), the present data are consistent with reports indicating that cyclothymia typically begins in early adolescence (Akiskal et al., 1977; Depue et al., 1981; Klein et al., 1985), whereas early-onset dysthymia frequently begins in early childhood (Akiskal, 1983b). In addition, this finding is consistent with evidence indicating that whereas prepubertal major depression is not uncommon, mania rarely develops before adolescence (Carlson, 1984).

One of the more striking findings in the present study was the high proportion of cyclothymic and dysthymic patients with lifetime histories of major depression. These data are consistent with previous studies indicating that most patients with characterological

TABLE 3  
*Lifetime Prevalence of Psychopathology in Relatives of Cyclothymic and Dysthymic Probands*

	N	Affective Disorder	Bipolar I Disorder	Bipolar II Disorder	Nonbipolar Depressive Disorder	Antisocial Personality Disorder	Alcoholism	Drug Use Disorder
Cyclothymic patients	12	.56 ± .33	.09 ± .18	.12 ± .19	.38 ± .31	.02 ± .07	.27 ± .25	.17 ± .24
Dysthymic patients	32	.49 ± .29	.00 ± .00	.07 ± .15	.44 ± .28	.06 ± .13	.17 ± .27	.03 ± .09

mood disorders have a history of superimposed major depressive episodes (Keller and Shapiro, 1982; Kocsis and Frances, 1987; Rounsaville et al., 1980). Whereas this is particularly evident in clinical settings, recent evidence suggests that it may also hold for nonclinical samples (Weissman et al., 1988a). In addition, the present study found considerable comorbidity between both cyclothymia and dysthymia and the anxiety, substance use, and personality disorders. These data are also consistent with previous reports of high comorbidity with nonaffective conditions in characterological mood disorders (Akiskal, 1983b; Akiskal et al., 1977; Kocsis and Frances, 1987).

In interpreting the results of the present study, several limitations should be considered. First, the clinical and family history data were not collected independently; hence, it is possible that the higher rate of bipolar I disorder in the relatives of cyclothymic probands rather than dysthymic probands was due to biases created by knowledge of the probands' diagnoses. In addition, relatives were not directly interviewed; hence, it is possible that probands' reports were biased by their own conditions (Cohen, 1988). Whereas these possibilities cannot be excluded, it is important to note that a family history diagnosis of bipolar I disorder in the present study required evidence of hospitalization, psychosis, or marked impairment in functioning. Because these are relatively objective indices of severe psychopathology, this requirement should have minimized the effects of rater and informant bias. In addition, the groups did not differ on the rate of bipolar II disorder in relatives, a "softer," more subjective diagnosis that should be particularly susceptible to rater and informant biases.

Second, the assessments of patients' personalities in the present study were probably biased by their clinical states (Akiskal et al., 1983; Hirschfeld et al., 1983). However, this bias cannot account for the differences between cyclothymic and dysthymic patients on EPQ extraversion, because extraversion seems to be less susceptible to state effects than most personality traits (Hirschfeld et al., 1983). In addition, to the degree that state depression influences extraversion, it should lower scores on this measure. The fact that the cyclothymic patients exhibited a significantly higher level of depressive symptoms than the dysthymic pa-

tients would serve to attenuate rather than to inflate group differences.

Third, most patients had experienced superimposed major depressive episodes at some point in their lives. Hence, the present sample did not consist of "pure" cyclothymic and dysthymic patients. As noted above, however, these patients do appear to be representative of cyclothymia and dysthymia in clinical settings (Akiskal, 1983b; Akiskal et al., 1977; Kocsis and Frances, 1987). Moreover, even cyclothymic and dysthymic subjects in the community appear to have high rates of superimposed major depression (Depue et al., 1981; Weissman et al., 1988a).

Finally, the present sample was relatively small; hence, there may not have been sufficient power to detect some significant differences. At the same time, a relatively large number of statistical tests were used, increasing the chances of a type I error. However, the major findings were consistent with the unipolar-bipolar literature and were substantial in magnitude, suggesting that the results are probably valid.

Overall, then, the results of the present study provide at least partial support for extending the unipolar-bipolar distinction from major affective illness to the characterological mood disorders. However, it will be important to replicate this study using a larger sample, "pure" cyclothymic and dysthymic subjects with no history of major depressive episodes, and blind, direct interviews with relatives.

## Mood Disorders: Pharmacologic Prevention of Recurrences

### Consensus Development Panel

---

*This report represents the consensus of a panel of representatives from psychiatry, psychology, pharmacology, epidemiology, internal medicine, and the general public regarding the use of pharmacologic agents to prevent recurrences of mood disorders. The panel concluded that recurrent mood disorders, which have a high prevalence and serious consequences, are underdiagnosed and undertreated. Applying appropriate strategies to the management and use of pharmacologic agents will enhance the likelihood of compliance and the prevention of recurrence with a minimum of bothersome side effects. Such strategies should be used within the context of a supportive relationship among doctor, patient, and family.*

(Am J Psychiatry 142:469-476, 1985)

---

Mood disorders, also called affective illnesses, are common and serious conditions. It is estimated that at any given time 3% to 4% of the population of the United States will be suffering from a major depressive or manic episode. Recurrences are frequent. During the past decade, clinical and research interest in mood disorders has expanded beyond the treatment of acute episodes to include consideration of long-term maintenance treatment aimed at preventing or reducing the frequency and intensity of further attacks. This

---

From the Consensus Development Conference sponsored by the National Institute of Mental Health and the Office of Medical Applications of Research, National Institutes of Health, April 24-26, 1984. Received Sept. 19, 1984; accepted Nov. 19, 1984. Address reprint requests to Michael J. Bernstein, OMAR, NIH, Bldg. 1, Rm. 216, Bethesda, MD 20205.

The members of the Consensus Development Panel are listed in appendix 1.

An extensive bibliography on recurrent mood disorders is available on request from Mr. Bernstein.

The opinions and conclusions presented in this paper are those of the Consensus Development Panel and do not necessarily reflect the opinions and conclusions of the American Psychiatric Association.

broadening of focus has occurred in the context of improved approaches to the description and classification of these disorders and newer epidemiologic studies. Recent evidence has demonstrated the recurrent and chronic nature of these illnesses and the extent to which they represent a continual source of distress and dysfunction for affected individuals and their families, as well as a substantial burden to society. Interest in preventive maintenance treatment has been stimulated further by results from recent long-term trials involving antidepressant drugs and lithium.

The need to consider the longitudinal nature of affective disorders in treatment planning has raised many issues of concern about whether, when, and how to use psychopharmacologic agents to protect patients against recurring episodes of depression or mania. In an effort to resolve questions surrounding these issues, the National Institutes of Health, in conjunction with the National Institute of Mental Health, convened a Consensus Development Conference on Mood Disorders: Pharmacologic Prevention of Recurrences on April 24-26, 1984. After a day and a half of presentations by experts in the field, a consensus panel including representatives of psychiatry, psychology, pharmacology, epidemiology, internal medicine, and the general public considered the scientific evidence and agreed on answers to the following key questions:

1. How common are recurrent mood disorders, and what are the variations in the course of these illnesses?
2. What groups of patients with mood disorders should be considered for preventive maintenance medication?
3. How effective are these medications in modifying the course of recurrent affective illness?
4. What principles guide selection of specific therapeutic agents for these groups?
5. What are the treatment strategies for using these medications on a long-term basis? What additional or alternative strategies are available for breakthrough episodes, treatment failures, or aspects of the illness unresponsive to medication?

6. What are the long-term risks and complications of preventive maintenance therapy? How should these be assessed and managed?
7. What research areas need further development?

## QUESTION 1

How common are recurrent mood disorders, and what are the variations in the course of these illnesses?

Recurrent major mood (affective) disorders are highly prevalent and have serious consequences. These conditions often are not accurately identified by either patients or clinicians and, even when correctly diagnosed, are often undertreated or not treated at all. Precision in differential diagnosis using explicit inclusion and exclusion criteria is essential to the identification and optimal treatment of these disorders.

"Depression" can refer either to a normal mood or to an illness requiring treatment. The normal mood, which consists of those transitory feelings of sadness or discouragement that everyone experiences during difficult times of life, is not what is being discussed in this report but, rather, the specific clinical syndromes of depression and mania. Within this clinical context, the symptoms of depression are many and varied. They may include loss of interest or pleasure in almost all usual activities; poor appetite or weight loss or increased appetite or weight gain; insomnia or hypersomnia; psychomotor agitation or retardation; decrease in sexual drive; loss of energy; fatigue; feelings of worthlessness, self-reproach, or excessive or inappropriate guilt; difficulty thinking or concentrating; and, most serious, suicidal thinking or attempts. Some individuals with manic syndromes may be euphoric, overconfident, and optimistic. However, their mood is typically brittle and deteriorates rapidly into irritability. Others may only be angry or irritable. These individuals may become more active, restless, and talkative; feel that their thoughts are racing; have an inflated sense of self-esteem; be distracted easily; and engage impulsively in activities that could have severe consequences, such as buying sprees, sexual indiscretions, violent behaviors, or foolish business investments. As a result, mania can be devastating to personal relationships and careers.

For the purposes of this report, a major recurrent mood disorder represents a full-blown syndrome of depression or mania, as defined by criteria set forth in *DSM-III*. Other affective disorders, such as single episodes of depression, chronic milder depression of at least 2 years' duration (dysthymic disorder), and mild depressive or hypomanic syndromes, are discussed only when they occur in patients who also have a recurrent major mood disorder. These other affective disorders also should be recognized as important causes of emotional impairment and often will benefit from treatment, but they are beyond the scope of this consensus statement. Depressive and manic states

caused by medical disorders (e.g., hypothyroidism) or exogenous agents (e.g., amphetamines) also are not considered.

The division of major mood disorders into *unipolar* and *bipolar* subtypes is clinically useful. Patients with unipolar disorder have episodes of depression only; patients with bipolar disorder have either episodes of mania or hypomania and depression or episodes of mania alone. Unipolar disorder is reported to be considerably more prevalent than bipolar disorder. Family and genetic (twin, adoption, and pedigree) studies provide compelling support for strong heritability of these disorders, especially bipolar disorder.

The rates of recurrence, variations in course of illness, and the results of clinical trials in this report are based on studies involving patients who sought treatment at inpatient and outpatient units affiliated with university medical centers. It is premature to generalize from these data on course and outcome for the entire population of persons with treatment mood disorders, which presumably includes a substantial number whose conditions remit spontaneously, who never seek treatment, or who are treated in other settings. However, the treatment recommendations derived from these studies are applicable to patients who suffer major recurrent mood disorders regardless of the setting in which they are seen.

*Variations in Patterns of Course of Illness*

"Relapse" refers to the exacerbation of an ongoing episode after an initial suppression of symptoms. "Recurrence" refers to a new episode following a complete recovery that has lasted for at least several months. Treatment for preventing a relapse is called "continuation therapy" and is distinguished from longer-term efforts to prevent completely or reduce the intensity and frequency of recurrence ("preventive treatment"). Thus, the sequence of treatment may be 1) an acute phase to control disabling symptoms (may be measured in weeks), 2) a continuation phase to avoid relapses of a single episode (may be measured in months), and 3) a preventive phase to avoid recurrences of new episodes over time (may be measured in years). This report addresses only the third item in the sequence—the preventive treatment of recurrent episodes of affective disorders.

Most of the information presented in this section on course of illness is based on the study of patients whose treatment was not under the control of research investigators, and a substantial proportion of these patients received either minimal or no treatment.

Most patients who have a manic episode go on to have a course marked by multiple recurrences of major depressive and manic episodes. The course of unipolar depression is more variable and less well established. Studies suggest that between 50% and 85% of patients with a major depressive episode who seek treatment at university medical centers will have at least one subsequent episode of depression in their lifetime. Between

10% and 15% of unipolar patients will have subsequent episodes that will involve manic or hypomanic symptoms, at which point they are reclassified as having a bipolar disorder. This reclassification occurs less frequently as patients become older and have an increased number of depressive episodes.

Although there are fewer studies of affective disorder in children and adolescents than in adult populations, emerging evidence suggests that these disorders do occur in childhood and, when present, may have a chronic, recurring course. It is reported that the lifetime incidence of major depression is as high as 30% by late adolescence in children who have at least one parent with a major affective illness.

Once mood disorders become recurrent, they have a course marked by high rates of relapse and recurrence and significant morbidity in subsequent episodes and in the intervals between episodes.

Fifteen percent to 20% of patients with a recurrent unipolar disorder do not recover fully from any given episode and have persistent symptoms for at least 2 years. Recently, similar rates have been reported for patients with bipolar disorder, who formerly were believed to have much higher rates of full recovery between episodes.

As many as 50% of patients with recurrent unipolar disorders who recover from a given episode are reported to have a recurrence within the first 2 years after recovery. The likelihood of recurrence is greatest in the 4 to 6 months following initial symptomatic recovery; this risk levels off markedly between 6 and 12 months and is still lower after the patient has been well for 18 months. Some evidence suggests that the length of well intervals between episodes decreases for the first few episodes and then remains steady, while the duration of episodes remains fairly constant. The rate of recurrence in bipolar patients is greater than in patients with unipolar conditions and does not decrease over time.

Some recurrent affective disorders have courses of illness marked by discrete episodes with minimal or no symptoms or impairment in social functioning in the intervals between episodes. Other patients have more insidious onsets of episodes, as well as less complete symptomatic recovery and more impairment in social functioning in the intervals between episodes. The proportion of patients in each of these groups is unknown. Patients who have either of these patterns also may have antecedent or concurrent nonaffective mental disorders.

#### *Factors That Increase Risk of Recurrence*

A substantial proportion of patients with recurrent mood disorders also suffer from a dysthymic disorder. If dysthymic symptoms persist after recovery from the major depressive syndrome, the risk of developing new episodes of major depression is especially high. The presence of a nonaffective psychiatric disorder such as alcoholism, drug dependence, or anxiety disorder and

an older age at onset also substantially increase the risk of recurrence in unipolar or bipolar recurrent disorders. In addition, the greater the number of previous episodes the patient has had, the higher the risk of recurrence.

#### *Health and Social Consequences*

Complications of affective disorders include attempted and completed suicide, increase in deaths from nonpsychiatric medical causes and accidents, impaired social functioning, impaired occupational functioning, impaired parenting, and marital discord. The rates of these events and their severity are substantial.

#### QUESTION 2

What groups of patients with mood disorders should be considered for preventive maintenance medication?

Before preventive medication is begun, the patient should have a careful medical evaluation to search for organic cause(s) of the affective syndrome or conditions that would contraindicate the use of one or another of the proposed treatments. A comprehensive medical history, physical examination, and appropriate laboratory tests are indicated. This evaluation should include an assessment by, or consultation with, a clinician skilled in the differential diagnosis of mental disorders.

#### *Bipolar Disorder*

Patients who have a manic episode are at high risk for recurrences. Manic episodes themselves are very disruptive. The likelihood of becoming psychotic (i.e., having delusions or hallucinations) when manic or depressed is great, and suicide risk is high. Therefore, the occurrence of a manic episode should *always* raise the question of preventive therapy.

Patients who have not had a full-blown manic episode, but have had a hypomanic and a depressive episode, are also at high risk for recurrence and are more likely to become psychotic when depressed than are patients with unipolar disorder. Therefore, careful consideration should be given to implementing preventive therapy in these patients. Other factors in this patient group that indicate a need to consider preventive therapy include number and recency of previous episodes of depression, family history of bipolar disorder, past suicide attempts, past psychotic episodes, past functional incapacity associated with episodes, and level of social functioning or affective symptoms between episodes. Each of these factors tends either to increase the likelihood of recurrence or to be associated with considerable disability and risk should a new episode occur.

### *Unipolar Disorder*

This condition is less frequently recurrent than the bipolar disorders, and the efficacy of the preventive treatments is less clearly established. Therefore, the decision of whether and when to initiate preventive therapy is more highly individualized for patients with unipolar disorders. It depends on identifying those unipolar patients with a high risk of recurrence. The presence of another mental disorder, a chronic medical disorder, or chronic affective symptoms each increases the rate of recurrence, as does older age at the onset of the first depressive episode. Psychotic features, serious suicide attempts, or serious functional impairment during recent episodes all predict increased severity in subsequent episodes. A family history of suicide, bipolar disorder, or psychotic affective episodes also is predictive of increased severity.

### *Additional Considerations*

Additional factors also play a role in the timing and decision to begin preventive therapy in patients who have never had a manic episode. A slow or incomplete response to treatment for a previous episode of depression would lead one to consider preventive therapy more closely. A rapid therapeutic response in a patient with long intervals between episodes argues against the initiation of preventive therapy. The potentially irreparable disruption that a depressive episode may exact on a patient's work, family, and social relationships also would increase the need for preventive therapy. The decision to use preventive treatment is complicated in women who are, or may become, pregnant. Special consideration is also needed for patients who find the presence of side effects disruptive or highly unpleasant. For such patients the decision involves the careful weighing of the potential benefits and risks of preventive treatment.

### QUESTION 3

How effective are these medications in modifying the course of recurrent affective illness?

### *Bipolar Disorder*

In a summary of 14 studies of bipolar disorder, the percentage of patients having a recurrent episode of either mania or depression during 1 year after the start of treatment was greatly reduced by lithium maintenance in contrast to placebo. In most of these studies, the number of recurrences was reduced by 50% compared with placebo, and the recurrences were less severe. However, rapidly cycling bipolar patients, i.e., those who have three or more episodes a year, often respond poorly.

Preventive treatment with lithium is equally effective against both manic and depressive recurrences in male

and female bipolar patients of all ages from early adulthood to old age; however, there are few data available for children and adolescents and for elderly patients.

The preventive effect of lithium may not develop fully for several months. An early recurrence of bipolar illness following initiation of treatment should not necessarily lead to its abandonment. Antidepressants have not been shown to be effective in preventing recurrence of manic episodes in patients with bipolar disorder.

### *Unipolar Disorder*

Many controlled studies have shown that preventive treatment with lithium or antidepressants (imipramine and amitriptyline) can substantially prevent recurrent episodes of unipolar depression. In most patients, lithium and tricyclics decrease the frequency and/or intensity of recurrences. In six studies with follow-up periods ranging from 5 months to 3 years, the percentages of patients who relapsed or had a recurrence on placebo were significantly greater than the percentages of patients who relapsed or had a recurrence on lithium. In a similar manner, a significant difference between tricyclic antidepressants and placebo was found in several studies. Most studies, however, have found lithium and tricyclics to be equally effective or lithium to be somewhat superior.

Individual patients may respond better to either lithium or tricyclics. One multicenter study suggests that patients whose last episode was severe have a better response to imipramine and that patients whose last episode was of only moderate intensity respond equally well to lithium and tricyclics. Research to date has not produced clear-cut guidelines for choosing one over the other when all other factors are equal, nor has it supported the combination of the two as superior to either alone.

Tricyclic antidepressants and lithium prevent recurrences of unipolar depression in both men and women of all ages from early adulthood to old age; however, few data are available for children and adolescents and for the elderly.

Successful prevention of recurrence may involve other important gains for patients, including increased stability of mood during intervals between episodes, regained self-esteem, renewed hope for the future, improved social relations, enhanced vocational abilities, and increased enjoyment of recreational activities.

Because the preventive treatment of recurrent mood disorders is clearly effective for large numbers of persons suffering from these conditions, and because a substantial proportion do not now seek treatment or are not accurately diagnosed, systematic efforts should be made to bring about a greater awareness and understanding by both health professionals and the public of the nature and effective treatment of these illnesses.

QUESTION 4

What principles guide selection of specific therapeutic agents for these groups?

*Decision to Initiate Preventive Treatment*

Repeated and candid discussions with the patient and the patient's spouse or other relatives are mandatory to ensure full understanding of potential advantages and risks of preventive treatment *as well as of no treatment*. These discussions should begin as early as possible after an acute episode is under control. The clinician should have complete information regarding the illness from the patient's and the family's perspective, and it is essential that patients and their families share in the decision-making process. The possible salutary effects of family and job stability should be explained thoroughly, and the known serious and troublesome side effects of each drug under consideration should be made clear. The necessity and importance of long-term monitoring, including required laboratory tests, should be understood fully. Compliance during treatment is improved greatly when all parties understand the therapeutic goals.

*Choice of Drugs*

Lithium is the drug of choice for preventing recurrences of bipolar disorder. In treating unipolar disorders, both lithium and tricyclic antidepressants have been shown to be effective for prevention. Since most patients will have been treated previously with tricyclic drugs for their depressive episodes, it is usually most appropriate to continue with the same drug, provided it has been effective and is well tolerated. Tricyclic antidepressants also may be preferable in older patients in whom renal function shows a normal decline with age. In addition, elderly individuals are more likely to be using other drugs to treat concurrent illnesses. Either these other agents or the illnesses themselves could interfere with lithium excretion and, thereby, predispose to toxicity. On the other hand, some older patients may be more vulnerable to certain side effects of the tricyclic antidepressants, such as urinary retention, cardiac arrhythmias, and increased intra-ocular pressure. Some clinicians recommend that lithium be used in both bipolar and unipolar patients to minimize the risk of an unexpected manic episode in a patient considered to be unipolar. In particular, lithium may be preferable for patients who have first-degree relatives with a history of bipolar illness or whose psychiatric history is uncertain, since some previously diagnosed unipolar depressions ultimately may prove to be bipolar. The consequences of an unexpected manic episode, which lithium is likely to prevent, are generally serious.

Only a few tricyclic antidepressants have been used in controlled studies of the preventive effect of these agents. It is likely, however, that all standard tricyclic

drugs are equally effective, although the question has not been studied empirically. On the other hand, some patients seem to respond to one tricyclic antidepressant after receiving no benefit from another, and side effects will differ from patient to patient and agent to agent. Thus, close monitoring is required, and some sequential courses of treatment with different antidepressants may be indicated.

QUESTION 5

What are the treatment strategies for using these medications on a long-term basis? What additional or alternative strategies are available for breakthrough episodes, treatment failures, or aspects of the illness unresponsive to medication?

*Use of Lithium and Tricyclic Antidepressants*

Specific clinical guidelines for the use of lithium and tricyclic antidepressants are available in various pharmacologic and psychiatric textbooks as well as articles in professional journals. Unfortunately, despite the interest in various biological tests for the diagnosis and treatment of mood disorders (the dexamethasone suppression test, thyrotropin-releasing hormone test, thyroid-stimulating hormone test, measurement of 3-methoxy-4-hydroxyphenethyleneglycol), no clear-cut guidelines for their use in the treatment of recurrent mood disorders have been established. What follows is only a brief outline of the use of these drugs as preventive agents.

Preventive doses of tricyclic antidepressants have not been adequately defined and, thus, physicians must be flexible in seeking to achieve optimal control. In general, doses similar to or somewhat lower than those used in treating the acute episode have been found effective. Studies of long-term preventive maintenance treatment with tricyclics have not adequately evaluated the effectiveness of dosages greater than 150 mg/day. Lithium in conventional forms is satisfactory. The goal in lithium treatment is to achieve serum concentrations between 0.6 and 0.8 meq/liter in most patients. While some patients may require higher concentrations, in general the physician is advised to maintain the patient on the lowest dose that prevents the return of symptoms because these lower concentrations are associated with fewer side effects.

*Duration of Treatment*

Duration of treatment must be determined on an individual basis, depending on the previous pattern of episodes, degree of impairment produced, the adverse consequences of a new recurrence, and the patient's ability to tolerate the drug. Data concerning the optimal duration of treatment are lacking. Most clinicians, as well as patients, would be loath to embark on a lifetime course of treatment. If the patient remains free

of recurrences during a period equivalent to several of the previous cycle lengths, a decision may be reached to discontinue treatment, provided that a family member or friend of the patient is available to alert the patient and, if necessary, the physician to symptoms of recurrence. In general, the stronger the indications for initiating preventive treatment, the longer its duration should be.

When tricyclics are discontinued after long-term exposure to the drug, the process should be gradual to avoid symptoms that sometimes occur after sudden cessation. Thus, decreases in doses may be spread over weeks or months, with larger decrements early in the withdrawal phase and smaller decrements once the daily dose becomes 50 mg or less. Discontinuation of lithium can be done abruptly or spread out over a couple of weeks. The latter is probably advisable for patients receiving relatively high doses. Neither drug is addictive or prone to abuse.

#### *Breakthrough Episodes*

Breakthrough episodes during preventive treatment are manifested by the emergence of clinically significant signs and symptoms of either mania or depression. Purely symptomatic treatment (e.g., sedative hypnotics or anxiolytics) should be delayed at this stage because close assessment over several weeks is desirable to be sure that a clinically significant recurrence of symptoms has occurred. When such breakthroughs occur during lithium treatment, the first step is to check serum lithium levels either to assure compliance or to justify an increased dose. The second step is to check the thyroid status, since hypothyroidism may mimic depression. The third step would be to add to the lithium an antipsychotic for manic breakthroughs or an antidepressant for depressive breakthroughs. These agents, however, should be used only temporarily for relief of the acute symptoms and should be withdrawn when these symptoms abate.

#### *Treatment Failures*

If the aforementioned measures fail, other treatments should be tried. Although many alternatives have been suggested, none has been extensively tested. Several reasonable alternatives are the replacement of lithium with carbamazepine, the addition of carbamazepine to lithium, or the replacement of tricyclic antidepressants with monoamine oxidase inhibitors for depressive treatment failures. Electroconvulsive therapy may also be considered for either manic or depressive treatment failures, particularly where suicidal risks seem high.

Some patients, usually those who have frequent and severe recurrences of depression that require large doses of tricyclic antidepressants, may experience more frequent episodes after use of these agents. When such a pattern is recognized, the minimal effective dose of tricyclic should be used. In some cases, allowing a

depressive episode to run its course without antidepressant treatment will break the cycle.

#### *Psychological Management of Patients in Preventive Therapy*

The problem of patient compliance, especially with lithium, has been well documented in several studies. Medication side effects as well as patient and family attitudes toward these illnesses and their treatment may each contribute to noncompliance. It is believed that the treating physician can make a considerable impact on treatment efficacy by counseling patients who are receiving preventive therapy, interviewing carefully, asking directly about particular side effects, eliciting patients' concerns, treating side effects as indicated, and providing information to ensure optimal adherence.

More specific psychotherapies or brief counseling sessions may be helpful in reducing the secondary consequences of chronic conditions that are often associated with recurrent major affective illness (e.g., occupational or marital disruptions). This treatment may be provided either by the treating physician or by another professional skilled in such services.

Three types of psychotherapy (cognitive, interpersonal, and behavioral) have been found helpful in alleviating depressive symptoms. Whether these specific psychotherapies or others also play an adjunctive role with pharmacotherapy in preventing recurrence has not been firmly established. Based on our present state of knowledge, for nearly all patients suffering from major recurrent mood disorders, psychotherapy should be used in combination with, not as a substitute for, pharmacotherapy for long-term preventive treatment.

#### QUESTION 6

What are the long-term risks and complications of preventive maintenance therapy? How should these be assessed and managed?

#### *Adverse Effects of Preventive Treatment*

The risks of preventive therapy with lithium or tricyclic antidepressants do not appear to differ appreciably from the adverse reactions to these drugs for treatment of acute episodes of mood disorders, with the exception of impaired thyroid function, which may increase in frequency over time on preventive lithium therapy. Because lower doses are frequently successful for prevention, side effects may, in fact, be less of a problem. The earlier fears of irreversible renal damage now seem to be unwarranted. Except during the first trimester of pregnancy, there are few significant permanent risks with either lithium or tricyclic therapy. There may be minor renal tubular defects and hypothyroidism brought on by long-term lithium therapy,

and a few patients may be at minimal risk for arrhythmias with extended treatment with tricyclic antidepressants. Tricyclics may lead to weight gain, orthostatic hypotension, subtle confusional states, and exacerbation of mania. Lithium may create symptoms of thirst, polyuria, tremor, diarrhea, weight gain, or, less commonly, hypothyroidism. Memory problems, tiredness, and a dulling of senses have been reported as additional complications of lithium that may contribute to noncompliance. Separation of these possible side effects from symptoms of the illness needs to be explored. A carefully supervised reduction in dose, reevaluation of thyroid status, or a therapeutic trial of antidepressants are ways in which the distinction may be achieved. Because patients with mania and depression are at high risk for suicide, supplies of medication should be limited. Adverse consequences of lithium on the fetus and nursing newborn should be made known to women who may become pregnant. Preventive use of lithium and tricyclic antidepressants in children and adolescents must be based on clinical judgment because risks and benefits have yet to be firmly established. Preliminary studies suggest that the potential problems are similar to those seen in adults.

*Monitoring for Adverse Effects*

Follow-up visits at regular intervals provide an opportunity to assess changes in clinical status, resolve compliance issues, institute appropriate medical interventions, and establish a basis for treatment during breakthrough episodes. More frequent contact is clearly necessary during periods of potential recurrence or change in clinical status. Clinical observation and laboratory tests provide useful benchmarks in the event of complications during long-term treatment. Current practice during treatment with lithium is to monitor serum lithium levels at intervals of 1 to 3 months and to assess serum creatinine values and thyroid-stimulating hormone (TSH) values every 6 to 12 months. Additional studies such as ECGs may be needed to elucidate other adverse effects.

Lithium intoxication is less likely in patients receiving low doses and with low serum concentrations as recommended here for preventive treatment. Patients should be advised always to keep well hydrated and immediately to report intercurrent illnesses that cause vomiting, diarrhea, or fever or treatment with or use of new drugs.

QUESTION 7

What research areas need further development?

There are many deficiencies in our knowledge of how best to prevent recurrent mood disorders.

The fundamental questions that underlie these deficiencies and need to be investigated are the following:

1. Why do some patients develop severe recurrent illnesses while others do not?
2. Why do some patients respond well to preventive treatment while others do not?
3. Why do some patients lose benefits after an initial response to treatment?

Answers to these questions will require information from therapeutic, epidemiologic, neurobiologic, and genetic studies. The results of such studies should elucidate basic mechanisms of the disorders themselves.

Some research strategies would include, for example, studies of high-risk populations (e.g., children of a parent with a mood disorder), development and testing of new therapeutic approaches, and identification of clinical and biochemical predictors of recurrence. The panel feels that priority should be given to the search for new knowledge about the pathogenesis of mood disorders. Such knowledge might then lead to new and more effective therapies for their treatment.

PANEL'S CONCLUSIONS

Recurrent mood disorders have a high prevalence and serious consequences but are currently underdiagnosed and undertreated. There are groups of patients with recurrent mood disorders for whom treatments are available that effectively reduce the frequency and intensity of subsequent episodes. Complete evaluation and careful differential diagnosis are required before initiating long-term preventive treatment. For patients with bipolar disorders, who are particularly likely to suffer recurrences, extensive studies have supported the efficacy of lithium in preventing recurrences.

While unipolar disorder is associated with a reduced rate of recurrence, both lithium and tricyclic antidepressants have been shown to be effective long-term preventive treatments for recurrent unipolar disorder.

Although the long-term use of these agents poses certain risks, they are not appreciably different from those of their use in acute situations. Applying appropriate strategies to the management and use of these drugs will enhance the likelihood of compliance and consequent prevention of recurrences with a minimum of bothersome side effects. Such strategies must be used within the context of an ongoing, supportive relationship among doctor, patient, and family.

Research priorities should be placed on basic research aimed at elucidating the etiology and pathogenesis of major mood disorders and the development of more effective treatments.

## ABSTRACT

This chapter will briefly review the current theories on the biochemical etiology of depression that are contributing toward the development of innovative somatic treatments. A description of clinically approved pharmacological treatments will be described in detail. Investigational pharmacological treatments that have demonstrated a high probability for general clinical use will also be discussed. Finally, a description of sleep deprivation will be included.

## INTRODUCTION

A revolutionary breakthrough for the treatment of depression occurred in the 1950s with the serendipitous discoveries that the tricyclic antidepressant (TCA) imipramine (used for agitation) and the monoamine oxidase inhibitor (MAOI) iproniazid, (used in the treatment of tuberculosis) proved to be effective treatments. Throughout the following decades, several other TCA's and MAOI's were formulated that were effective. The first TCA's were the tertiary amines imipramine, amitriptyline, trimipramine and doxepin. However, there are several problems associated with their use, namely the anticholinergic side effects (dry mouth, constipation, blurred vision, and urinary retention), antihistaminic effects (sedation and weight gain) and alpha adrenergic blockade (orthostatic hypotension and reflex tachycardia). Additionally, the TCA's demonstrated a potential to cause or exacerbate cardiac conduction delays. In part because of the adverse events with the tertiary amine TCA's, the secondary amine TCA's were developed. These included desipramine, nortriptyline and protriptyline. Other cyclic

agents, amoxapine, maprotiline and trazadone, followed. While these agents showed a slightly improved anticholinergic, antihistaminic and alpha adrenergic side effect profile compared to the tertiary amines, they were no more effective. Some of the newer cyclic agents demonstrated unique side effect profiles; namely, the rare occurrence of priapism reported in male patients taking trazadone, an increased incidence of seizures reported with maprotiline, and the potential risk of tardive dyskinesia associated with amoxapine secondary to its neuroleptic metabolite.

Because they all share a tricyclic or tetracyclic structure, these agents are often referred to as the heterocyclic antidepressants (HCA's). The acute effect of the HCA's involve reducing the re-uptake of norepinephrine and/or serotonin into the neurons, while some HCA's work more specifically on serotonin and others on norepinephrine.

Like the HCA's, several MAOI's have been developed as antidepressants, namely phenelzine (Nardil), isocarboxazid (Marplan) and tranylcypromine (Parnate). The mechanism of action of the MAOI's is through the irreversible inhibition of monoamine oxidase, the enzyme involved in the degradation of norepinephrine and serotonin, thereby increasing the amount of these amines available in the central nervous system.

While having less direct cardiotoxic effects compared to the HCA's, the MAOI's have anticholinergic side effects and more often cause orthostatic hypotension and weight gain. Another limiting factor in the use of MAOI's is the need to restrict tyramine ingestion as well as to avoid sympathomimetic agents to prevent a possible hypertensive/hyperthermic reaction.

In general, both the HCA's and the MAOI's have a delayed onset of two to three weeks. Electroconvulsive therapy (ECT) is another effective treatment for depression with a more rapid onset of action; however, it also has potential side effects, including memory loss.

From the suggested mechanism of these agents evolved several theories of the pathophysiology of depression. Because the conventional antidepressants have acute effects on serotonin and norepinephrine, early theories centered around biogenic amine depletion at specific sites in the central nervous system. Theories progressed to involve possible involvement of neurotransmitter receptors, since these agents cause delayed receptor changes on both noradrenergic and serotonin systems that more closely correlated with the antidepressant response. With increased techniques in the identification of new receptors and receptor subtypes, subsystems of previously identified neurotransmitters are being proposed to play a potential role in the pathophysiology of depression. Finally, hypotheses emerged regarding other systems such as GABA, acetylcholine, the neuroendocrine system and circadian rhythm oscillation. No one single mechanism has yet demonstrated a common final biochemical pathway that explains all hypotheses, and many researchers agree that depression is a heterogeneous disorder based on

different pathophysiological mechanisms with pathology located at various sites within the central nervous system and the body as a whole. This may explain the differential response to treatment by various antidepressants and also why 20-30 percent fail to respond to conventional antidepressant treatments.<sup>1</sup>

Since the release and widespread use of the HCA's and MAOI's, many somatic treatments for depression have been under investigation for improved antidepressant efficacy and to alleviate problems with safety, side effects, delayed onset of action and insufficient efficacy. Some of the investigational treatments are derived from agents already proven to be effective, others are designed based on novel hypotheses of the pathophysiology of depression, and some have been serendipitously found to have antidepressant effects that warrant further investigation. This chapter will review these newer treatments, first describing two recently released antidepressant compounds (fluoxetine and bupropion) and then reviewing promising investigational treatments that may be approved in the future for general use. Further, because of their novel mechanism of action, they may help define the pathophysiology of depression and depressive subtypes.

### Fluoxetine (Prozac)

Fluoxetine was the first in a group of compounds known as serotonin re-uptake blockers to be approved for use in the United States. Fluoxetine is chemically unrelated to conventional antidepressants and is pharmacologically unique in that it is a selective and potent inhibitor of neuronal serotonin uptake with minimal affinity for muscarinic, histaminic or noradrenergic receptors.<sup>2</sup> Fluoxetine has efficacy comparable to amitriptyline,<sup>3-5</sup> imipramine<sup>6</sup> and doxepin.<sup>7</sup> These clinical trials demonstrated a more favorable side effect profile for fluoxetine when evaluating anticholinergic, antihistaminic and alpha adrenergic side effects. Compared to conventional antidepressant agents, it lacks cardiotoxicity,<sup>8</sup> epileptogenic potential,<sup>9</sup> poses no special risk for the geriatric population<sup>9</sup> and is usually well-tolerated in overdose.<sup>10</sup> Side effects reported most frequently with fluoxetine are nausea, nervousness and insomnia.<sup>10</sup>

Fluoxetine has a plasma half-life of 1-3 days, with an active metabolite, norfluoxetine, whose plasma half-life is 7-15 days. It binds to plasma proteins to the extent of 94 percent.<sup>11</sup> Several drug interactions of clinical concern include the combination of L-tryptophan and fluoxetine since reports of this combination show evidence of severe agitation, restlessness, insomnia and gastrointestinal distress.<sup>9</sup> An increase of TCA levels, when used concomitantly with fluoxetine, has been reported.<sup>12</sup> It is recommended that the clinician wait at least five weeks before starting an MAOI after the discontinuation of fluoxetine, and wait 14 days from the discontinuation of the MAOI to start fluoxetine. This recommendation is based on three fatalities that occurred when tranylcypromine was prescribed

methylene blue	

subsequent to fluoxetine.<sup>13</sup> It is suggested that the proximal use of fluoxetine and an MAOI can have the potential to cause a serotonergic syndrome characterized by excitement, diaphoresis, rigidity, hyperthermia, hyperreflexia, coma and possibly death.<sup>13</sup>

Recommended dosing of fluoxetine is 20 mg per day, initially. A dose of 20 mg per day is adequate treatment of the majority of persons who respond to lower doses as high as 80 mg per day may be warranted, especially in the presence of depression is only partially responsive to lower doses. There is evidence that doses less than 20 mg may be effective in some patients; therefore, alternate-day dosing may be utilized.

Fluoxetine offers the potential benefit of an initial treatment for patients who do not respond to or cannot tolerate the side effects of conventional antidepressants. Further clinical studies are investigating the potential role that fluoxetine may have in the treatment of other psychiatric disorders, including Obsessive Compulsive and Panic Disorders.

#### **Bupropion (Wellbutrin)**

Bupropion is a unicyclic phenylaminoketone with demonstrated antidepressant efficacy. It appears to be chemically and pharmacologically distinct from other antidepressants.

le agents. The neurochemical mechanism of bupropion is not known. It appears to inhibit monoamine oxidase, and, compared to the TCA's, is a re-uptake blocker of the neuronal re-uptake of serotonin or norepinephrine.<sup>14</sup> Bupropion's mechanism of action focuses on the drug's in vivo inhibition of monoaminergic transmission.<sup>14</sup> Bupropion demonstrates antidepressant activity superior to placebo<sup>15</sup> and comparable to amitriptyline,<sup>16</sup> doxepin<sup>17</sup> and nortriptyline.<sup>18</sup> Clinical trials have generally demonstrated bupropion to have fewer anticholinergic and antihistaminic associated side effects compared to TCA's and to be well-tolerated in geriatric patients. Bupropion shows no significant alterations in pulse, blood pressure or orthostasis when compared to placebo in patients who had clinically significant orthostasis hypotension by TCA's.<sup>19</sup> No significant changes on the electrocardiogram were observed with therapeutic doses of bupropion.<sup>20</sup>

Commonly reported side effects include headache, agitation, dry mouth, and constipation.<sup>14</sup> The most serious adverse reaction encountered is seizure. Bupropion was first approved by the U.S. Food and Drug Administration for general use in 1985. The pharmaceutical company that marketed bupropion voluntarily withdrew the drug from the market in 1986 due to the incidence of seizures in bulimic patients receiving the drug. The incidence of seizures in bulimic patients receiving bupropion was investigated in a study of 4,262 depressed persons receiving bupropion in the dose range of 450 mg per day or less reports an incidence of seizures from 0.35 percent to 0.44 percent.<sup>21</sup> Because of these reports, it is recommended that bupropion not be used in persons with a seizure disorder or a past history of bulimia and/or anorexia, and that dosing not exceed 450 mg per day or more than 150 mg in any single dose. Care must also be taken when giving the drug in anyone predisposed to seizures or combining it with other agents that may also alter seizure threshold. Limited data on the interaction between bupropion and other antidepressants with other agents, especially those which can lower seizure threshold, suggest that caution should be exercised when bupropion is used in combination with other agents, especially those which can lower seizure threshold.

Bupropion is a novel agent with an antidepressant mechanism which is not typical of the TCA's. The drug's apparent unique mechanism of action and side effect profile makes the clinician to utilize it as an antidepressant, especially for patients who are unresponsive or could not tolerate the side effects of conventional antidepressants.

## HETEROCYCLIC COMPOUNDS

Several heterocyclic compounds under investigation in the United States are being evaluated because of their increased biochemical specificity and/or their more

BEST COPY AVAILABLE

favorable side effect profile as compared to standard preparations. Many of these compounds are available in other countries, particularly Europe, and demonstrate potential antidepressant properties.

### Clomipramine (Anafranil)

Clomipramine is a tricyclic compound whose antidepressant effects were first reported in 1964.<sup>22</sup> It has been widely used throughout the world for the treatment of depression and Obsessive Compulsive Disorder. Clomipramine is approved for the treatment of Obsessive Compulsive Disorder, with or without associated depression, in the United States, but lacks FDA approval for the treatment of depression.

Antidepressant efficacy of clomipramine is reported to be superior to placebo,<sup>23,24</sup> and comparable to amitriptyline,<sup>25,26</sup> imipramine,<sup>23,24,27,28</sup> doxepin,<sup>29</sup> and desipramine<sup>30</sup> in controlled studies. Based upon these studies, the side effect profile is generally comparable to the marketed HCA's. Mean daily dose of clomipramine ranges from 75-300 mg per day in the antidepressant efficacy studies.

Compared to the marketed HCA's, clomipramine is a potent re-uptake inhibitor of serotonin,<sup>31</sup> a property to which the drug's therapeutic effect for both depression and Obsessive Compulsive Disorder is at least partially attributed. However, clomipramine has an active metabolite desmethylclomipramine, a norepinephrine re-uptake inhibitor which may also play a role in the compound's antidepressant properties.<sup>32</sup> Because of its long-standing efficacy in the treatment of depression and its availability in the United States to treat Obsessive Compulsive Disorder, it is likely that clomipramine will be used by clinicians to treat depression, especially when accompanied by concomitant Obsessive Compulsive Disorder or in persons unresponsive to conventional treatment.

### Dothiepin

Dothiepin is a tricyclic compound structurally similar to amitriptyline and doxepin which has been widely used throughout Europe as an antidepressant since 1964. The antidepressant effects of dothiepin are thought to involve noradrenergic uptake inhibition and possibly enhancement of serotonergic neurotransmission.<sup>33</sup> Dothiepin down-regulates beta-adrenergic<sup>34</sup> and serotonin receptors (5HT<sub>2</sub>)<sup>35</sup> after chronic administration. Antidepressant efficacy of dothiepin is comparable to amitriptyline,<sup>36-43</sup> imipramine,<sup>44</sup> doxepin,<sup>45,46</sup> maprotiline,<sup>47</sup> fluoxetine<sup>48</sup> and trazadone.<sup>36,49</sup> It also has equivalent anxiolytic effects in anxiety associated with depression when compared to amitriptyline<sup>37</sup> and alprazolam,<sup>50</sup> and one study demonstrated its superiority over amitriptyline in anxiety symptoms associated

with depression.<sup>41</sup> The most commonly reported side effects associated with dothiepin include dry mouth, drowsiness, gastrointestinal disorders and dizziness.<sup>33</sup> The side effect profile of dothiepin is reported to be less problematic when compared to amitriptyline and imipramine,<sup>51,52</sup> and appears to be effective and tolerable in the geriatric depressed population.<sup>51,54</sup> The cardiac effects of dothiepin also appear to be less than those of other tricyclics.<sup>53</sup>

Based on the results of the previously described efficacy studies, the therapeutic dose range of dothiepin is between 75–225 mg per day. There is evidence that dothiepin has analgesic benefit in the treatment of fibromyalgia,<sup>55</sup> idiopathic facial pain syndrome<sup>56</sup> and rheumatoid arthritis associated with depression.<sup>57</sup> Several studies are currently under way in the United States that may help further define the role of dothiepin in the treatment of depression and related disorders.

### Lofepamine

Lofepamine is a tricyclic agent with desipramine as its major metabolite. It is available in Europe for the treatment of depression, and is under active investigation in the United States. Several studies suggest that lofepramine's antidepressant activity is due to the potent inhibition of norepinephrine re-uptake and that the drug may also potentiate serotonin neurotransmission.<sup>58</sup> Down-regulation of beta-adrenergic receptors is reported with long-term treatment.<sup>59</sup> Double-blind, controlled studies found that lofepramine had antidepressant efficacy when compared to amitriptyline,<sup>60–64</sup> imipramine<sup>65–69</sup> and maprotiline.<sup>58</sup> Lofepamine has a more favorable side effect profile compared to standard TCA's, especially in regard to anticholinergic effects, hypotension<sup>64,66</sup> and cardiovascular side effects.<sup>58</sup> The use of lofepramine in the geriatric depressed population is reported to be both efficacious and remarkably well-tolerated.<sup>70</sup> It remains controversial as to whether the antidepressant effect of lofepramine is solely from the action of its metabolite, desipramine, or whether the drug possesses additional inherent antidepressant properties.

### Mianserin

Mianserin is a tetracyclic compound that, in the 1960's while being evaluated for the treatment of migraines, was serendipitously found to have mood-lifting effects. This effect was so marked that the staff at the research center called mianserin the "good humor pill."<sup>71</sup> While there are methodological flaws in a few of the studies, controlled trials suggest mianserin has an antidepressant efficacy superior to placebo<sup>72</sup> and diazepam<sup>73</sup> and comparable to amitriptyline<sup>74,75</sup> and imipramine.<sup>74,76,77</sup> Mianserin appears to have a novel mechanism of action in that it produces a pronounced and acute blockade of presynaptic  $\alpha_2$  receptors

## 84 INNOVATIVE SOMATIC TREATMENTS FOR DEPRESSION

resulting in increased release of norepinephrine due to the inhibition of the negative feedback loop.<sup>71</sup> Mianserin does not appear to cause beta-receptor down-regulation,<sup>78</sup> and evidence suggests that its long-term administration increases responsiveness to serotonin in the brain.<sup>79</sup> Mianserin is a weak inhibitor of the muscarinic receptor and a potent inhibitor of the histamine receptor ( $H_1$ ),<sup>80</sup> which may explain its clinically significant lack of anticholinergic and sedative effects. Mianserin is not associated with electrocardiogram changes, including cardiac conduction.<sup>81</sup> Mianserin has been available in Europe for use as an antidepressant and is under active investigation in the United States. It is an agent with suggested novel antidepressant properties and a favorable side effect profile; however, there are reports of blood dyscrasias<sup>82</sup> and seizures<sup>83</sup> associated with its use, which may have an effect on its future marketing in the United States.

### Oxaprotiline

Oxaprotiline is a tetracyclic analogue of maprotiline that is a highly selective and potent inhibitor of norepinephrine re-uptake, and is associated with beta-adrenergic down-regulation with subchronic administration.<sup>84,85</sup> There is evidence that oxaprotiline has antidepressant efficacy with no appreciable side effects except for mild anticholinergic effects.<sup>86</sup> A double-blind, partial crossover study, comparing oxaprotiline to fluvoxamine (a selective serotonin re-uptake inhibitor) in a group of depressed patients who failed treatment with a cyclic agent, reports antidepressant efficacy for both agents.<sup>87</sup> It further found that nonresponders to the selective noradrenergic agent did not appear likely to respond to the serotonergic antidepressant fluvoxamine, and vice versa.<sup>87</sup>

## MONOAMINE OXIDASE INHIBITORS

Monoamine oxidase (MAO) is an enzyme found in several organ systems (including the brain) that is responsible for the degradation of several amines thought to be involved in the pathophysiology of depression. MAO-A preferentially degrades norepinephrine and serotonin and is responsible for the tyramine reactions seen with MAOI's. MAO-B preferentially degrades dopamine and PEA.<sup>88</sup> The MAOI's presently on the market as antidepressants are nonselective, affecting both MAO-A and MAO-B. They are also known as "irreversible" MAOI's because, when discontinued, the cell requires 2-3 weeks to regenerate new stores of MAO enzyme. Several MAOI's are being investigated to clarify their specific mechanism(s) of action with the hope for either greater efficacy or improved safety.

### Selective Monoamine Oxidase Inhibitors

Selegiline (Eldepryl). Selegiline is an irreversible MAOI available in the United States for the supplemental treatment of Parkinson's Disease. In low doses (10 mg per day), it is a selective inhibitor of MAO-B and, therefore, does not alter tyramine sensitivity.<sup>89</sup> Such selectivity may alleviate the need for dietary restrictions; however, in higher doses, selegiline appears to lose its selectivity and involved both MAO-A and MAO-B.<sup>89, 90</sup> There is evidence that selegiline elevates brain phenylethylamine (PEA) levels and gives rise to amphetamine and methamphetamine metabolites.<sup>90</sup> Selegiline has been reported to have antidepressant effects in doses selective for MAO-B inhibition when evaluated in open, uncontrolled trials<sup>92-94</sup> and other controlled studies have supported these earlier findings.<sup>95-96</sup> Furthermore, there is evidence that it shows a greater overall improvement in non-endogenous as compared to endogenous depressives,<sup>97</sup> and is possibly effective in atypical depressives.<sup>97</sup> Many of these studies used varying doses of selegiline in both the selective MAO-B dose range and the nonselective ranges. A recent controlled study reports that selegiline is no better than placebo in selective MAO-B doses (10 mg per day); however, its antidepressant efficacy is superior to placebo in nonselective inhibiting dose ranges (an average of 30 mg per day) and the occurrence of side effects is no greater when compared to placebo.<sup>96</sup> The overall trend in many of the studies demonstrating selegiline's efficacy suggests increased efficacy in doses between 20-40 mg per day, as well as showing a more favorable side effect profile as compared to conventional MAOIs. The mechanism of antidepressant action postulates the involvement of PEA or dopamine, supported by the efficacy studies using selective MAO-B inhibiting doses; norepinephrine and serotonin, supported by efficacy studies using the nonselective doses; and, possibly involving the direct or indirect effects of its metabolites, amphetamine and methamphetamine.

The potential to slow down the progress of Parkinson's disease by supplementing conventional therapy with selegiline has demonstrated the drug's novelty as a treatment for this disease via retarding the degenerative process.<sup>99</sup> Selegiline demonstrates potential benefits in Alzheimer's disease when used in selective MAO-B doses<sup>100</sup> and may prove to be a useful agent to treat other degenerative processes in the elderly.<sup>99</sup> Its availability for the treatment of Parkinson's Disease may provide a useful therapeutic tool in those who suffer from this disorder and associated depression. Further studies are needed to define its role in the treatment of depression and whether the lower doses associated with MAO-B selectivity are as safe and effective as the non-selective higher doses.

Pargyline (Eutonyl). Pargyline is an irreversible, partially selective inhibitor of MAO-B<sup>101</sup> that was marketed in the United States as an antihypertensive agent up to its withdrawal from pharmaceutical use. Several studies suggest that pargyline possesses antidepressant properties;<sup>102-104</sup> however, no well-controlled

studies have been reported, although pargyline-induced mania, a characteristic of potential antidepressant agents, is reported in the literature.<sup>105</sup> The side effect profile of pargyline demonstrates no clear advantages over the present conventional MAOI's, but it may play a potential role in the hypertensive depressed patient.

Clorgyline. Clorgyline is an irreversible selective MAO-A inhibitor that is marketed in Europe, with evidence of antidepressant efficacy based upon studies done in the United States. There is evidence that the efficacy of clorgyline is equal to imipramine<sup>106</sup> and superior to amitriptyline,<sup>107</sup> and, in unipolar and bipolar depressives, superior to pargyline.<sup>108</sup> Further, the use of clorgyline, alone or in combination with lithium, may be effective in cycling bipolar disorders refractory to monotherapy with lithium.<sup>109</sup>

#### Reversible Monoamine Oxidase Inhibitors

The reversible MAOI's may offer a potential advantage in the treatment of depression in that their effects on MAO metabolism disappears within 1-4 days after drug discontinuation.<sup>110</sup> The rapid return of MAO activity may reduce the likelihood of tyramine-induced hypertensive reactions and make concomitant or proximal use of otherwise contraindicated medications possible. Moclobemide is the most studied of these agents and is a reversible, selective MAO-A inhibitor with an antidepressant profile that compares favorably to amitriptyline.<sup>110</sup> A recent study demonstrated the drug's clear superiority over placebo with an onset of therapeutic activity in 3-7 days and a very mild side effect profile.<sup>111</sup> Other reversible selective MAO-A inhibitors under investigation include cimoxatone, amiflamine and brofaremine.<sup>112</sup>

#### THE SEROTONIN RE-UP TAKE INHIBITORS

The role of serotonin in affective disorders, coupled with the need for antidepressants with greater specificity and less side effects led to the development of the serotonin re-uptake blockers. There is increasing evidence that these compounds possess antidepressant effects and a side effect profile different than the conventional agents. Zimelidine was the first specific serotonin re-uptake inhibitor to be used as an antidepressant and was available in Europe for clinical use and under investigation in the United States until 1983, when it was withdrawn because of flu-like reactions and reports of Guillain-Barré syndrome.<sup>113</sup> Over the years, several other serotonin re-uptake inhibitors have been developed, with fluoxetine (Prozac) the first, and presently the only, specific compound of this class to be approved in the United States for use as an antidepressant.

All of the serotonin re-uptake inhibitors have a mechanism of action that blocks the re-uptake of serotonin back into the presynaptic neuron resulting in more serotonin in the synaptic cleft. These compounds have little, if any effect on muscarinic, histaminic and alpha-adrenergic receptors, which may explain their more favorable side effect profiles when compared to conventional agents.<sup>114</sup> For this class, the side effect profile is similar to fluoxetine, with the most commonly reported effects being gastrointestinal upset, insomnia and restlessness.<sup>115</sup>

### Fluvoxamine

Fluvoxamine is a potent serotonin re-uptake inhibitor available in Europe as an antidepressant and is presently being extensively studied throughout the United States. It is reported to have antidepressant efficacy greater than placebo<sup>116</sup> and comparable to imipramine.<sup>117-120</sup> Reviews of several clinical studies conclude that it does not cause cardiovascular side effects apart from a slight, clinically nonsignificant decrease in heart rate.<sup>121</sup> Fluvoxamine's potential therapeutic benefit is also actively being studied for Obsessive Compulsive and other anxiety disorders.

### Sertraline

Sertraline is a serotonin re-uptake inhibitor which possesses up to 10 times the potency of fluvoxamine and five times that of fluoxetine in its serotonin re-uptake properties.<sup>122</sup> Several studies suggest short- and long-term antidepressant efficacy superior to placebo<sup>123,124</sup> and comparable to amitriptyline.<sup>124</sup> Sertraline causes delayed down-regulation of beta-adrenergic receptors.<sup>125</sup> No significant cardiovascular effects have been reported with its use, and it has a side effect profile comparable to other serotonin re-uptake inhibitors.<sup>123</sup> Further studies of sertraline's safety and efficacy in depression and other psychiatric disorders remain active at this time.

### Citalopram

Citalopram is a potent inhibitor of serotonin re-uptake with no effect on the re-uptake of norepinephrine or dopamine. The compound has no anticholinergic, antihistaminic or alpha-adrenergic properties.<sup>126,127</sup> Citalopram is presently available in Denmark and has been actively studied in other European countries as an antidepressant. Open clinical trials indicate that citalopram is an effective antidepressant with little or no anticholinergic or cardiovascular side effects.<sup>128-132</sup> Controlled studies indicate that citalopram has antidepressant efficacy compara-

ble to maprotiline<sup>133</sup> and amitriptyline.<sup>134,135</sup> The most commonly reported side effects associated with citalopram include nausea, headache and sweating. A double-blind, crossover study reports a decreased alcohol intake in "early-stage problem drinkers."<sup>136</sup>

### Other Agents

Other specific serotonin re-uptake blockers under early investigation include paroxetine<sup>137</sup> and indaipine.<sup>138</sup>

## THE SEROTONERGIC 5-HT<sub>1A</sub> AGONISTS

Several new agents have been developed called the partial 5-HT<sub>1A</sub> agonists. Four of these have been extensively studied and demonstrate anxiolytic and possibly antidepressant properties. These agents include buspirone (Buspar),<sup>139,140</sup> gepirone,<sup>141</sup> and tandospirone (data on file Pfizer) and ipsapirone (data on file Bayer). All of these agents have similar chemical structures. They may prove to be of particular benefit in the treatment of anxiety due to their side effect profile, including a lack of impaired psychomotor functioning and a lack of abuse potential. However, their onset of anxiolytic action can take up to three weeks.

There is also increasing evidence that the 5-HT<sub>1A</sub> agonists may have antidepressant properties. Animal models that predict antidepressant efficacy are favorable for the 5-HT<sub>1A</sub> agonists.<sup>142</sup> Buspirone, presently marketed in the United States as an anxiolytic agent, is reported to have antidepressant effects in man.<sup>143-146</sup> Preliminary trials with ipsapirone, gepirone and tandospirone are suggestive of antidepressant activity.<sup>147</sup> The mechanism of the anxiolytic as well as possible antidepressant action of these drugs has yet to be fully elucidated, as their neuropharmacology is complex and several of them demonstrate their own novel and intrinsic properties. While these drugs are considered 5-HT<sub>1A</sub> agonists, there is also evidence that they have 5-HT<sub>1A</sub> antagonist properties as well.<sup>148</sup>

Buspirone and gepirone have little affinity for alpha-adrenergic binding sites, but show alpha<sub>1</sub>-adrenergic activity in some models.<sup>149</sup> Gepirone and buspirone have demonstrated decreased 5-HT<sub>2</sub> sensitivity after continuous treatment.<sup>150</sup> Finally, buspirone has mild dopaminergic activity, increases acetylcholine turnover, and may decrease GABA tone.<sup>151,152</sup> While having specific effects on the 5-HT<sub>1A</sub> receptor, these agents also have other neurochemical effects that may be influential on their anxiolytic or potential antidepressant mechanisms. Further studies with the 5-HT<sub>1A</sub> agonists are currently under way to confirm their efficacy and safety in depression, Generalized Anxiety Disorder, Panic Disorder, Obsessive Compulsive Disorder, Impulse Control Disorders, and Alcoholism.

## MISCELLANEOUS COMPOUNDS

Several compounds that differ from the previously mentioned agents, either because of their novel chemical structure or because of their mechanism(s) of action, will now be discussed.

## Adinazolam(Deracyn)

Alprazolam (Xanax) is a triazolobenzodiazepine presently marketed as an anxiolytic (with a neurochemical profile different than the classical benzodiazepines) that is reported to have specific antidepressant effects when compared to standard tricyclic antidepressants.<sup>153-158</sup> A new triazolobenzodiazepine, adinazolam, is being used in Europe and has been under active investigation in the United States as an antidepressant. Several well-controlled studies report the antidepressant superiority of adinazolam over placebo<sup>159-162</sup> and comparable to imipramine<sup>163</sup> and amitriptyline.<sup>164</sup> Finally, this agent has also been reported to induce mania.<sup>165</sup> The above-mentioned studies suggest that adinazolam has a rapid onset of action (often within two to seven days) and that the side effects more than placebo were transient drowsiness, confusion and decreased memory. Its antidepressant mechanism remains unclear. The compound binds to the benzodiazepine receptor; however, unlike classical benzodiazepines, after long-term treatment, it sensitizes neurons to serotonin.<sup>79</sup> Adinazolam does not block the re-uptake of serotonin or cause beta-adrenergic receptor down-regulation.<sup>166</sup> In summary, it is a novel compound, with possible rapid antidepressant effects that lacks many of the side effects of conventional antidepressants. Further studies are warranted to determine its role in the treatment of depression.

## Nefazodone

Nefazodone is a non-tricyclic triazolo structure chemically related to trazodone, with a pharmacological profile distinct from the heterocyclic antidepressant agents (data on file Bristol-Myers). The compound has potent and complex effects on serotonin receptors and modest effect on noradrenergic receptors, with little or no anticholinergic effects. Nefazodone is less potent than trazodone in its alpha blocking properties. Preliminary data from early clinical trials demonstrates the safety and indicates that the drug has antidepressant efficacy superior to placebo and comparable to imipramine. Several other clinical trials are underway to elaborate on the results of these early clinical trials.

### Venlafaxine

Venlafaxine is a structurally novel compound that inhibits the neuronal uptake of norepinephrine, serotonin, and dopamine. It does not have any monoamine oxidase inhibiting activity and shows no affinity for rat brain muscarinic, histaminic, or noradrenergic receptors. It also demonstrates an acute onset of noradrenergic receptor down-regulation, compared to conventional antidepressants that require chronic administration for down-regulation to occur. Studies performed in the United States suggest venlafaxine has antidepressant properties and has a well-tolerated side effect profile.<sup>167</sup> Further studies are underway to determine the role of venlafaxine in the treatment of depression.

### Fengabine

The predominant biological theories of depression focus on the central nervous system neurotransmitters norepinephrine, serotonin, and dopamine. More recently, the neurotransmitter GABA has been implicated in affective disorders. Drugs with GABAergic activity such as clonazepam, valproic acid, and carbamazepine all have therapeutic relevance in the treatment of affective disorders, especially bipolar disorder.<sup>168-170</sup> The GABA system is thought to play a possible role in the etiology of depression. There is evidence of a deficit in the GABAergic mechanisms in animal models for depression.<sup>171</sup> In fact, all TCA's and MAOI's, when administered repeatedly, cause up-regulation of specific GABA sites.<sup>172</sup> The GABA hypothesis of depression is most strongly supported by the reported antidepressant activity of GABA receptor agonists. Fengabine is one such GABA agonist that increases norepinephrine turnover and causes desensitization of beta-adrenergic receptor-linked adenylate-cyclase.<sup>173</sup> It does not modify beta, alpha, or alpha<sub>2</sub> receptors and is devoid of monoamine oxidase inhibiting activity.<sup>171,173,174</sup> A review of six double-blind studies reports that fengabine has comparable efficacy to amitriptyline, imipramine, and clomipramine in the treatment of depressive disorders. Side effects are reported to be more frequent in the comparison groups compared to those with fengabine.<sup>173</sup> However, one must be cautious regarding the conclusion of this review, since the total population of patients studied in these samples included not only persons with a diagnosis of unipolar depression, but also bipolar depressives, "minor" depressives, dysthymia, atypical depressives, and adjustment disorders with depressed mood. Despite the lack of uniform diagnosis in the studies of the drug's antidepressant efficacy, fengabine and pharmacologically related compounds continue to be studied.

### Sulpiride

There is evidence in the literature that several neuroleptic agents possess antidepressant properties. Among the neuroleptics cited for antidepressant ac-

BEST COPY AVAILABLE

tivity include thioridazine and perphenazine.<sup>112</sup> Obviously, these compounds carry the risk of any neuroleptic treatment, including tardive dyskinesia. The neuroleptic sulpiride is used in Europe for a number of psychiatric disorders. The potential for causing extrapyramidal side effects, sedation, and tardive dyskinesia is reported less with sulpiride than with other neuroleptics.<sup>175-179</sup> Several studies report antidepressant efficacy of sulpiride in depression.<sup>180-182</sup> The mechanism of pharmacological action of sulpiride differs from classic neuroleptics in several ways. Sulpiride demonstrates a preference for the pre-synaptic dopamine receptor and down-regulates dopamine auto-receptors.<sup>183</sup> The drug also antagonizes adrenergic receptors and mildly blocks post-synaptic adrenergic receptors.<sup>180</sup> Whether these mechanisms are involved in its proposed antidepressant activity has yet to be determined. While there are methodological flaws in the studies suggesting antidepressant properties of sulpiride, further controlled trials of the drug are warranted in persons with depression, depression associated with psychotic features, and schizoaffective disorder.

#### S-Adenosyl-L-Methionine(SAM)

SAM is an endogenous substance in mammalian tissue that shows potential mood-elevating effects in man.<sup>184</sup> Available for use in Europe, SAM has medicinal usefulness in several disorders, particularly for the treatment of osteoarthritis.<sup>185</sup> The first mood-elevating effects of SAM were discovered serendipitously in the 1970's when the substance was being investigated in schizophrenia and found to have mood-elevating properties.<sup>186</sup> Several open-label and single-blind trials suggest antidepressant effects of SAM using intravenous or intramuscular routes of administration.<sup>187,188</sup> Several double-blind trials reported SAM was equal or more effective antidepressant effects compared to amitriptyline, imipramine, and clomipramine.<sup>189-191</sup> In general, these studies show a trend toward a more rapid onset of action and less, if any, side effects with SAM. Precipitation of mania/hypomania has been reported with the use of SAM.<sup>192</sup> Its mechanism of antidepressant action remains unknown; however, the substance is an endogenous methyl donor for several central nervous system neurotransmitters, including serotonin, norepinephrine, and dopamine, all of which are implicated in the pathophysiology of depression.<sup>188</sup> SAM also has effects on the lipid composition of cell membranes, which may also be involved in the pathophysiology of affective disorders.<sup>193</sup> SAM also increases folate activity, which may also be involved in the pathogenesis of depressive disorders.<sup>194</sup> All of the above-mentioned studies are based on the use of intramuscular or intravenous routes of administration. The reason for this route of administration versus oral routes is based on limited investigation of the pharmacokinetics of SAM, suggesting that it has an unstable oral bioavailability. However, a recent open-label study using oral

SAM suggests antidepressant efficacy.<sup>186</sup> Further investigation into its oral bioavailability as well as further controlled studies using it in oral form are now proceeding. The evidence thus far suggests that SAM is a novel antidepressant agent.

### Methylene Blue

Methylene blue is a compound that is used in the treatment of various urological disorders. It is involved in the metabolism of vanadium, which has been implicated in the pathophysiology of bipolar disorder.<sup>195</sup> There is evidence that changes in the membrane transport of sodium may be of etiological importance in bipolar disorder and that alterations of plasma vanadium levels may be linked to such changes.<sup>196,197</sup> Methylene blue is reported to be of potential benefit in the treatment of both mania and depression.<sup>198-200</sup>

### SLEEP DEPRIVATION

It is firmly established that depression is associated with disturbances in sleep architecture, such as a decreased REM latency, decreased delta sleep, and intermittent wakefulness. It is also reported that antidepressants and electroconvulsive therapy can reverse these depression-associated sleep disturbances.<sup>201</sup> The 1960's heralded the first reported observation that sleep deprivation may be beneficial in the alleviation of depressive symptoms and can produce profound improvement in depressive symptoms within 24 hours.<sup>202</sup> A recent review of studies involving over 1,700 subjects report that an average of 59 percent of patients show a marked improvement of depressive symptoms the following day after a night of total sleep deprivation. Sixty-seven percent of subjects diagnosed with "endogenous" depression responded to sleep deprivation, with no difference noted between bipolar and unipolar depressives. Persons with "neurotic" depression had a response rate of 48 percent. Eighty-three percent of patients not receiving antidepressant medications relapsed into depression after the first night of sleep, compared with 59 percent on medication.<sup>203</sup> Lithium may also prevent a relapse in persons who show a positive response to sleep deprivation.<sup>204,205</sup>

### Conclusion

Since the advent of the TCA's and MAOI's in the 1950's and 1960's, there has been continued need to develop new antidepressants that have increased safety, less side effects, increased rapidity of response, and improved efficacy, especially in a subgroup who do not respond to conventional treatments. With the recent

introduction of drugs such as fluoxetine and bupropion, increased safety, greater specificity of biochemical mechanism, and/or a more favorable side effect profile has become available. However, these newer agents have side effects of their own, have not yet shown superiority over conventional antidepressants, and do not appear to fully alleviate the problem of depressive subtypes resistant to conventional somatic treatments.

Several agents, with potential antidepressant activity are either being used in other countries and/or are being investigated in the United States. Some of them are developed because of the similar chemical or pharmacological properties of other antidepressants; others are found serendipitously and found to have novel antidepressant mechanisms. With the advent of such potential agents, combined with improved research tools, several biochemical theories of depression have evolved. From the early theories of central amine depletion to present theories involving other neurotransmitters (i.e., GABA), receptor characteristics, and neuropeptides, most theories emerge from speculative action of antidepressant agents, and no final common biochemical pathway has been found for all of these agents. It is likely that depression is not a biologically homogenous disorder, but one that consists of various subtypes characterized by different responses to treatment.

To better define the specific antidepressant effects (and depressive subtypes), it is necessary to study new drugs in uniformly defined patients, a methodological drawback of many drug studies published in the literature. It is also important to include data on known depressive subtypes, namely atypical depression, depression with psychotic features, bipolar depression, dysthymia, and refractory depression. These subgroups are often excluded from initial antidepressant efficacy studies, yet make up a significant group for whom novel antidepressants may benefit. If potential antidepressant agents under early investigation show efficacy in only a minority of those treated, such agents should not be abandoned, but should be more actively investigated in depressive subtypes. The development of innovative antidepressants combined with more precise research approaches holds great promise for the understanding and treatment of affective disorders.

# Long-Term Treatments of Recurrent Depressive Disorders

Michael E. Thase, M.D.

Many, if not most, depressive disorders become recurrent conditions. It is now clear that virtually all recently remitted patients should receive 4 to 6 months of continuation therapy. Moreover, this phase of treatment should continue until the patient has achieved a clear-cut, durable period of recovery. Further, an extended course of maintenance pharmacotherapy is recommended for those patients at risk for subsequent recurrent episodes. In this paper, the rationale for long-term treatment is presented and common strategies are reviewed. Depressive disorders appear to become more autonomous, severe, and potentially refractory with each new episode. Thus, prevention of recurrent depression remains the best available strategy to ensure an optimal long-term outcome for patients with recurrent affective disorders.

*(J Clin Psychiatry 1992;53[9, suppl]:32-44)*

The major mood disorders are best understood as potentially recurrent and chronic conditions.<sup>1,2</sup> Both major depressive disorder and bipolar affective disorder convey a high likelihood of recurrence, and each new episode carries renewed risks of chronicity, psychosocial impairment, and suicide.<sup>1,2,6,7</sup> It is no longer sufficient to focus on resolution of acute symptomatology as the principal goal of treatment. Treatment strategies that provide long-term, preventative efficacy also are necessary in contemporary psychiatric practice. In this paper, issues pertaining to the use of long-term, prophylactic treatment strategies for depressive states are reviewed.

## THE NATURAL HISTORY OF DEPRESSION

Recent epidemiologic studies suggest that the age at onset of a first episode of mood disorder is becoming progressively younger<sup>8</sup> and, among younger age cohorts, the incidence of affective disorders appears to be increasing.<sup>9</sup> Thus, the already considerable public health

significance of the affective disorders will most certainly increase in the future.

About 10% of diagnosable cases of major affective disorder are bipolar.<sup>2,7,10</sup> Moreover, the number of chronic and recurrent cases exceeds the number of acute, first-episode disorders.<sup>10,11</sup> Reviews of the literature by Angst<sup>2</sup> and Zis and Goodwin<sup>1</sup> documented the high rates of relapse and recurrence in affective disorders in the 1970s. These findings subsequently were confirmed prospectively in a series of studies conducted under the auspices of the National Institute of Mental Health Collaborative Study on the Psychobiology of Depression (summarized by Keller<sup>6</sup>). If one assumes a lifetime risk for major depression of 5%,<sup>12</sup> an individual who has recovered from an initial episode of depression has at least a 10-fold greater risk of suffering another episode when compared to a person who has never been clinically depressed.<sup>6</sup> Further, bipolar and recurrent (unipolar) major depressions have at least a 70% risk of subsequent recurrences, i.e., a 12-fold elevation in risk compared to that in the general population.<sup>1-7</sup> Chronic minor depressions (i.e., dysthymia) have up to a 90% risk of subsequent major episodes.<sup>6</sup>

It is likely that the majority of depressed individuals in the United States continue to be either untreated or incorrectly diagnosed and/or inadequately treated.<sup>13,14</sup> While this state of affairs may be maintained by societal attitudes and stigma,<sup>15</sup> it also points to the generally favorable short-term prognosis of the mood disorders.<sup>1-7</sup> For example, even without definitive treatment most episodes of depressions last no longer than 1 year and between 80% and 90% have remitted within 2 years.<sup>6,16</sup> However, even such time-limited episodes of depression convey manifold adverse economic, interpersonal, and medical consequences.<sup>1-7,17-20</sup> For example, family dysfunction is quite common even in acute depressive epi-

sodes, and may persist despite subsequent clinical remission.<sup>18</sup> Impairments in leisure time pursuit and vocational functioning similarly may persist long after resolution of a depressive episode.<sup>19,20</sup> Further, alcoholism, sedativism, or other substance abuse may develop secondary to an untreated depressive syndrome,<sup>21,22</sup> and many depressed patients are heavy tobacco users.<sup>23</sup> And, for the unlucky proportion who do not remit spontaneously, an ingrained pattern of chronic depression conveys even more negative prognostic implications.<sup>24</sup>

In major depressive episodes, the onset of the syndrome often develops insidiously, i.e., over a matter of weeks or months.<sup>24</sup> In such cases prodromal symptoms may be identified that herald the onset of a major episode, including anxiety, irritability, changes in hedonic capacity, and poor concentration.<sup>25</sup> While most initial episodes of depression occur at times of life stress, only a minority of persons encountering such difficulties develop persistent depressive syndromes, which points to the role of underlying psychobiological vulnerability factors.<sup>25</sup> Such risk factors include a family history of affective disorder or alcoholism, a long-established pattern of maladaptive cognitive traits or interpersonal difficulties, chronic medical problems, or a history of early trauma or abuse.<sup>16,17,23,25</sup> Further, individuals with dysthymic disorder antedating the onset of a major depressive episode typically have a significantly greater number of vulnerability factors than acutely depressive patients with "well" baselines.<sup>23,25</sup> In more protracted depressive syndromes, it often is difficult to distinguish between those psychosocial and interpersonal factors that are antecedent to the affective illness and those factors that are consequences.<sup>17</sup>

### PHASES OF THE TREATMENT OF UNIPOLAR DEPRESSIVE DISORDER

An episode of unipolar depression is schematized in Figure 1. In this illustration, treatment is initiated at the nadir of the depressive episode and possible outcomes are defined by the "5 Rs": response, remission, relapse, recovery, and recurrence.<sup>26</sup> (A sixth possible "R," refractory depression, will not be discussed further in this manuscript.) The relationships between these outcomes and three interlocking phases of treatment, acute, continuation, and maintenance therapy, are described below.

#### Acute Treatment

The treatment modality first chosen for a depressive episode is generally predetermined by the patient's choice of mental health providers. For example, depressed persons treated by family practitioners are likely to receive pharmacotherapy and practical advice, whereas the clients of psychologists, social workers, and other therapists are almost certain to receive counseling

Figure 1. A Diagram of Five Possible Outcomes (Response, Remission, Relapse, Recovery, and Recurrence) During the Three Phases of Treatment of Depression (Acute, Continuation, and Maintenance)\*

\*From reference 122 with permission.

or psychotherapy.<sup>27</sup> At present, most psychiatrists seem to prefer using a combination of both modalities.<sup>27,28</sup> Better means of matching patients with potentially effective treatments would be preferred.

Regardless of which type of treatment is chosen, it is useful to conceptualize the initial therapeutic goal as a "treatment response." The term *treatment response* must be qualified by the fact that this outcome encompasses spontaneous remission and placebo response as well as a more specific response to the active treatment. A response generally corresponds to at least a 40% to 60% reduction of symptoms<sup>29</sup> and often can be achieved within 3 to 6 weeks after the initiation of antidepressant pharmacotherapy. Several newer forms of time-limited psychotherapy, which are available in manual form, such as Beck and colleagues' Cognitive Behavior Therapy (CBT)<sup>30</sup> and Klerman and colleagues' Interpersonal Psychotherapy (IPT),<sup>31</sup> appear to achieve comparable results over 12- to 16-week courses in uncomplicated outpatient cases.<sup>32,33</sup> In either case, however, failure to achieve a treatment response after an appropriately maximal trial (e.g., 6 to 8 weeks for pharmacotherapy and 12 to 16 weeks for psychotherapy) should lead the clinician to consider an alternate first-line treatment. Sequential courses of acute therapy thus should be provided until a patient achieves a clear-cut response.<sup>34</sup>

#### Stabilization and Continuation Therapy

The goals of the next phase of treatment, referred to as stabilization or continuation therapy, are (1) prevention of relapse and (2) "conversion" of a response into a remission.<sup>1</sup> Remission is defined as a level of functioning consistent with the patient's premorbid or "well" self.<sup>1,26</sup> During continuation therapy, the frequency of visits typically is reduced to every other week and, subsequently, monthly as the patient's remission solidifies. By convention, a stable remission must last for at least 4 to 6 months before it is assumed that the patient has re-

**Figure 2. A Comparison of Relapse Rates During the Continuation Phase of Treatment With Placebo, Tricyclic Antidepressants, or Combined Treatment**

<sup>a</sup>Data from reference 35.

<sup>b</sup>Data from reference 36.

covered from the index depressive episode.<sup>26</sup> Relapse, then, is defined by a return of depressive symptoms at a syndromal level at any time point between the initial treatment response and the end of continuation therapy.<sup>1,26</sup> Reviews of empirical studies of pharmacologic treatments indicate that the risk of relapse is particularly high following withdrawal of an antidepressant during the first 4 months after response; rates typically range from 40% to 60%, compared to relapse rates of only 10% to 30% during continuation pharmacotherapy.<sup>1,25,33</sup> Moreover, in our research experience at the University of Pittsburgh, provision of continued full-dose antidepressant pharmacotherapy in combination with interpersonal psychotherapy (IPT) reduces the risk of relapse to an almost negligible rate<sup>36</sup> (see Figure 2). Although systematic studies have not yet been completed in samples of chronic, treatment-resistant, and/or atypical cases, continuation pharmacotherapy with imipramine,<sup>37</sup> phenelzine,<sup>38</sup> and tranylcypromine<sup>1</sup> also appears to have significant prophylactic effects in preventing relapse in these more difficult depressive states.

Beyond premature withdrawal of pharmacotherapy, other risk factors for relapse include chronicity and severity of the index episode, noncompliance with treatment, the presence of residual (subsyndromal) depressive symptoms, severe personality pathology, older age, high levels of dysfunctional attitudes, poor social support, and ongoing or renewed psychosocial stressors.<sup>25,39-42</sup>

Depressive relapse also is observed following termination of time-limited psychotherapy.<sup>43-45</sup> For example, in a study conducted by our group at the University of Pittsburgh, patients treated with the CBT of Beck et al.

had a 31% relapse rate during the first year of follow-up, including 52% of the "responders" who had not achieved an 8-week remission prior to termination of therapy.<sup>45</sup> Further, we found that relapsers were more severely ill at baseline, had higher levels of dysfunctional attitudes, and were less likely to be married.<sup>45</sup> Thus, something akin to "continuation psychotherapy" may need to be developed to lessen the risk of relapse in high-risk cases following termination of a time-limited psychotherapy treatment protocol.<sup>46</sup>

The continuation phase of therapy ends when the patient meets criteria for recovery (i.e., after 4 to 6 months of sustained euthymia).<sup>1,26</sup> As will be discussed later in this review, it is hypothesized that the psychobiological correlates of the acute illness state have become quiescent during recovery.<sup>1</sup> Thus, a renewed period of depressive symptoms following recovery is conceptualized as the onset of a distinctly new episode of affective illness. However, because 10% to 15% of apparently recovered patients suffer recurrences within the first 8 weeks of discontinuing antidepressant medication,<sup>47</sup> it appears that time alone may not provide an adequate definition of recovery.

In some cases, it is difficult to distinguish between a precipitous symptomatic recurrence and anticholinergic withdrawal phenomena.<sup>48</sup> Anticholinergic withdrawal symptoms are elicited by too rapid a reduction in the dosage of selected heterocyclic agents, particularly tertiary amine tricyclics such as amitriptyline, imipramine, and clomipramine.<sup>48</sup> Because of this, it generally is not prudent to taper a heterocyclic antidepressant any faster than 25% of the total dose each week. In practice, some clinicians taper at an even slower rate. In any case, such antidepressant withdrawal-emergent worsening generally responds rapidly to resumption of the antidepressant dosage at the prior effective level.<sup>1</sup> It is not clear if similar tapering strategies are needed for the newer nontricyclic medications. Slow tapering is definitely not required for fluoxetine because of the long elimination half-life of the parent drug and its metabolite, norfluoxetine.<sup>49</sup>

### Maintenance Therapy

Maintenance pharmacotherapy should be considered at the end of continuation therapy for most patients with a history of prior episodes of depression.<sup>1,45,50</sup> This is particularly true for patients who have suffered episodes of depression within 2 or 3 years prior to the onset of the index episode.<sup>1,45,50</sup> For example, in our group's study of highly recurrent unipolar patients, nearly 85% suffered a recurrence within 3 years after the withdrawal of imipramine hydrochloride.<sup>51</sup> In addition to a history of frequent and/or multiple prior episodes of depression, other risk factors for recurrent depression include both early and late onset of depression (i.e., before age 25 or after age 60), chronicity, severity of the index episode, a seasonal

pattern of mood disturbance, and a family history of affective disorder.<sup>1,25,50</sup>

Prescribing a course of maintenance antidepressant therapy involves a careful assessment of the risks of recurrent illness, the expected benefits of continued treatment, and the potential costs of such treatment (in terms of both economics and side effects).<sup>1,34,50</sup> Maintenance treatment achieves optimal results when the clinician and patient have established a strong, collaborative alliance. One of the best ways to achieve this is a frank open discussion leading to the *shared* conclusion that the benefits of maintenance treatment outweigh the costs.<sup>52</sup>

The question "Do I need to take antidepressants forever?" comes up rather frequently when patients consider a maintenance treatment plan. Although pharmacotherapists may differ widely in their responses to this question, I do not recommend addressing the patient's concerns by using a biomedical metaphor based on an irreversible disease, such as citing the example of a diabetic who will need to take insulin for the rest of his or her life. In my opinion, such a bleak and potentially demoralizing assessment is not warranted. Rather, the metaphor of controlling hypertension with ongoing medication provides a more optimistic vehicle by which to discuss long-term treatment. Moreover, this model also offers the opportunity to discuss potential reductions of vulnerability through psychosocial and behavioral interventions (i.e., staying within the hypertension metaphor, via weight loss, salt restriction, exercise, and smoking cessation). As in pharmacologic treatment of hypertension, reassessment of the cost/benefit ratio can be performed collaboratively on a periodic basis, such as annually<sup>1</sup> or biannually.<sup>4</sup> On such occasions it is often useful to explore and address certain common but maladaptive assumptions that may be associated with noncompliance or patients' worries about the use of long-term medication ("I don't want to get hooked," "I feel dependent on this stuff," or "For once I'd like to be normal and not have to rely on these drugs to stay well").<sup>52</sup> Such discussions also may usefully include a spouse, parent, or significant other. In fact, it is our group's experience that the well-meaning but misguided lobbying of family members often provides the impetus for patients' requests to discontinue medication. In our long-term research clinic, we developed a psychoeducational workshop specifically to minimize these familial roadblocks to effective maintenance therapy.<sup>53</sup>

### Choice of Maintenance Treatment

Maintenance pharmacotherapy generally consists of the same antidepressant agent(s) that was effective during acute and continuation therapy.<sup>1,50</sup> Patients typically are seen monthly, and after a period of sustained recovery, some patients may need to be seen every other month or even less frequently. The tricyclics and lithium

carbonate have received the most extensive study, and in reviews of earlier research, both modalities have been shown to convey about a twofold or threefold protective effect over 18 to 36 months of maintenance therapy when compared with placebo.<sup>1,50,54</sup>

On the basis of available published literature, it could be argued that the tricyclic antidepressants are the treatment of choice for prophylaxis of recurrent unipolar depression.<sup>1,50</sup> However, this position is mainly due to the tenure of this family of antidepressants (relative to newer agents) and their greater use in the 1960s, 1970s, and 1980s (relative to MAOIs). There is only one published maintenance study directly comparing a TCA with an MAOI. In this placebo-controlled trial, Georgotas et al.<sup>55</sup> found that phenelzine, but not nortriptyline, was effective in preventing recurrent episodes of late-life depression. This unexpected finding requires replication. Other "open label" studies suggest that long-term MAOI treatment achieves a level of prophylaxis comparable to that seen with maintenance TCA therapy (see Thase<sup>1</sup>).

In a meta-analysis of early studies, Davis<sup>54</sup> documented that lithium salts clearly were efficacious in preventing depressive relapses and recurrences. European studies tend to provide the strongest support for the efficacy of long-term lithium prophylaxis of unipolar depression.<sup>56-58</sup> However, in a well-conducted multicenter American study,<sup>59</sup> unipolar patients randomly assigned to lithium carbonate maintenance treatment had a significantly poorer outcome than patients receiving imipramine hydrochloride, with or without concomitant lithium therapy. Moreover, lithium carbonate therapy was only marginally more effective than placebo in this study.<sup>59</sup> Similarly, in a recent trial conducted in the United Kingdom,<sup>60</sup> the combination of lithium and amitriptyline was found to be no more effective in preventing recurrence in unipolar depression than amitriptyline alone. Therefore, the routine use of lithium salts instead of, or in combination with, antidepressants does not appear well-justified in the maintenance treatment of unipolar depression. However, as will be discussed later, most cases of bipolar depression warrant lithium salts as a "foundation" maintenance therapy,<sup>1,50</sup> as do some cases of treatment-resistant unipolar depression.<sup>61</sup>

### Dosage of Maintenance Pharmacotherapy

Many clinicians were trained to reduce the dosage of antidepressant during long-term treatment, typically to a "maintenance dosage" of about one half that used during acute therapy.<sup>1,50</sup> Although this practice may have merit in the long-term treatment of schizophrenia, it may not be the most effective approach for prophylaxis of recurrent affective disorders. Specifically, our group has proposed that the 40% to 60% "survival" rates observed in most early studies of maintenance pharmacotherapy reflect suboptimal pharmacotherapy and could have been

**Figure 3. Cumulative Probability of Remaining Well in Trials of Maintenance Pharmacotherapy Using Reduced and Full Dosages of Imipramine**

Full imipramine dosage trial (mean = 216 mg/day); data from reference 51.  
 Reduced imipramine dosage trial (mean = 137 mg/day); data from reference 50.

improved upon by use of higher (i.e., therapeutic) dosages of medication.<sup>1,11</sup>

Results from several studies of unipolar depression support this contention. First, in a retrospective examination of cases treated in a university-affiliated mood disorders clinic, Peselow et al.<sup>62</sup> reported that patients who suffered recurrences were maintained on lower dosages of antidepressants than those who remained well. Second, in a study<sup>63</sup> comparing low (75 mg/day) and ultra-low (37.5 mg/day) dosages of maintenance maprotiline hydrochloride, significantly more recurrences occurred in the ultra-low dosage group. Third, an examination of our group's experiences conducting long-term treatment trials in the past 15 years yields similar evidence. As illustrated in Figure 3, the relapse rate of patients reduced to lower dosages of imipramine (i.e., 75 to 150 mg/day; mean dosage = 137 mg/day) in the aforementioned multicentered trial<sup>50</sup> was significantly higher than the rate observed in our group's more recent single-site study (mean dosage = 216 mg/day).<sup>51</sup> Further, because the relapse rates on placebo were virtually identical in the two studies, it can be inferred that the patients participating in these trials were at comparable risk for recurrence.

Although clearly suggestive, such observations warranted prospective confirmation. Data are now available

from a recently completed, double-blind study conducted by Frank and associates (Frank EF, Kupfer DJ, Perel JM, et al, 1992, Unpublished data). Twenty patients with highly recurrent unipolar depressions ( $\geq 4$  lifetime episodes) were randomly assigned after continuation therapy to either full-dose (approximate mean dosage = 200 mg/day; N = 10) or half-dose (approximate mean dosage = 100 mg/day; N = 10) maintenance imipramine pharmacotherapy. The recurrence rate in the half-dose group over 36 months was 70%, whereas only 30% of the patients in the full-dose group suffered recurrences. The full-dose maintenance treatment strategy has thus been shown to be significantly more effective than lower-dosage strategies in both retrospective and prospective comparisons.

**Side effect concerns.** The long-term side effects of conventional tricyclics, monoamine oxidase inhibitors, and lithium carbonate are, of course, one valid reason underlying the use of lower-dosage maintenance strategies.<sup>4,5</sup> Although long-term pharmacotherapy with these agents is tolerated by a majority of patients, ongoing problems with weight gain, dental caries (caused by chronic xerostomia), severe constipation, and sexual dysfunction may complicate maintenance treatment with heterocyclic agents. Further, such adverse experiences may lead to noncompliance, dosage reductions, and/or premature withdrawal of medication.<sup>1,50</sup> Clinical experience suggests comparable problems with weight gain, edema, insomnia, and sexual dysfunction during long-term MAOI therapy.<sup>1,50,64</sup> One study suggests that attrition due to intolerable side effects may be higher during long-term MAOI treatment than observed during maintenance tricyclic therapy.<sup>65</sup> Weight gain, acne, diarrhea, polyuria, tremor, and hypothyroidism have been shown to complicate long-term lithium therapy,<sup>4,50</sup> with the specter of chronic renal interstitial fibrosis lurking in the background.<sup>66</sup> Again, there is a clear need for alternative treatments.

**Long-term treatment with the newer antidepressants.** Side effect concerns have been a driving force behind the interest in the newer antidepressant agents, including so-called second generation agents (i.e., trazodone, maprotiline, and amoxapine), the selective serotonin reuptake inhibitors (SSRIs) (i.e., fluoxetine and sertraline), and the novel monocyclic antidepressant bupropion. There is no doubt that these agents are effective treatments for depressed outpatients, and they typically convey a significant advantage with respect to daily side effect burden. Several studies indicated that, while effective in preventing relapse and/or recurrence, the second generation agents maprotiline<sup>63,67</sup> and amoxapine<sup>68</sup> do not convey substantial advantages over the tricyclics with respect to the incidence of side effects. By contrast, the combination of efficacy and safety offered by the SSRIs has led to their rapid acceptance as the most common

**Figure 4. Summary of Relapse/Early Recurrence Rates for Placebo and Selective Serotonin Reuptake Inhibitors**

<sup>a</sup>Data from reference 69 (24-month study).  
<sup>b</sup>Data from reference 70 (44-week study).

newly prescribed antidepressants by American psychiatrists. Although extensive data on the long-term efficacy and safety of the SSRIs and bupropion are lacking, results from two controlled studies support the efficacy and tolerability of fluoxetine<sup>69,69</sup> and sertraline<sup>70</sup> during the first year of continuation/maintenance treatment (see Figure 4). Moreover, in the study of Doogan and Caillard,<sup>70</sup> sertraline could not be distinguished from inert placebo during long-term treatment in terms of side effect ratings and attrition rates. Open-label data also support the potential utility of trazodone<sup>71</sup> and bupropion<sup>72</sup> as long-term, preventative treatments.

#### How Long Should Pharmacotherapy Be Maintained?

There is no single, correct answer to this important question. Unlike continuation pharmacotherapy, which is indicated for virtually all patients and defined by a relatively narrow time frame, maintenance treatment may extend indefinitely.<sup>1,4,50</sup> A general answer would be "for as long as the benefits outweigh the costs." After the first 24 or 36 months of pharmacotherapy, however, empirical data to support this maintenance treatment plan are generally lacking.<sup>1,4,5</sup> On one hand, many thousands of patients have taken maintenance tricyclic and MAOI antidepressants and/or lithium salts for 10, 15, or even 20 years without markedly adverse side effects. On the other hand, the meta-analysis conducted by Belsher and Costello<sup>51</sup> suggests that the annualized risk of subsequent depressive episodes becomes rather small after 2 years of sustained recovery. Our group<sup>73</sup> recently completed a small but informative study of 20 unipolar patients who experienced 3 illness-free years during maintenance imipramine treatment. These patients subsequently were randomly assigned to either 2 more years of imipramine treatment (mean daily dose = 243 mg/day) or double-blind placebo substitution. The 2-year recurrence rate among 9 placebo-treated patients was 67%, compared

with 9% of 11 patients receiving ongoing imipramine treatment ( $p < .006$ ). Although the highly recurrent nature of this sample may bias the placebo group's recurrence rate upward, the clinical implication is clear: even after 3 years of sustained recovery there remains a significant risk of recurrent depression following withdrawal of maintenance pharmacotherapy.

#### What is the Role of Maintenance Psychotherapy?

Debates over the relative merits of psychotherapeutic and pharmacologic treatments of affective disorders often become polarized around issues of economic and interdisciplinary rivalries. The heterogeneous and biopsychosocial nature of the mood disorders provides ample room for the popular strategy of combining these modalities,<sup>1,2,3,4,74</sup> i.e., a position supported by a modest amount of empirical evidence from the acute-treatment literature.<sup>75</sup> However, it should be recognized that, at present, strong empirical justification for the routine combination of these forms of therapy as maintenance treatment strategies is lacking.

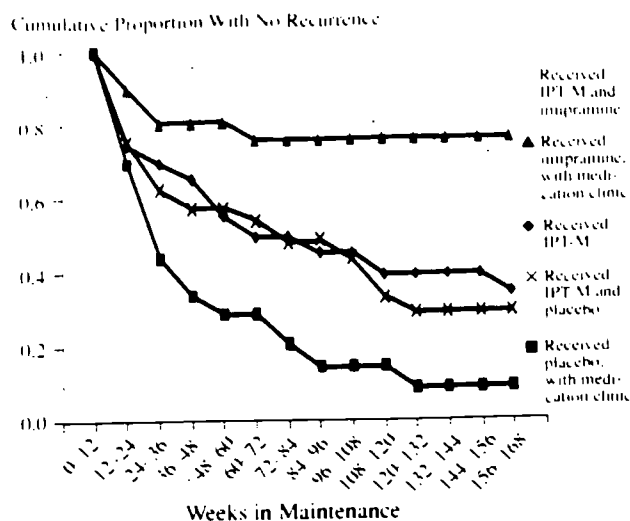

Only two studies have addressed the long-term impact of interpersonal psychotherapy in the continuation or maintenance phases of treatment.<sup>61,76</sup> In the first study,<sup>76</sup> 150 recently remitted nonbipolar women who had responded to acute pharmacotherapy with amitriptyline were randomly assigned to a 6-month course involving one of the following four strategies: individual interpersonally oriented psychotherapy; placebo pharmacotherapy; maintenance amitriptyline; or the combination of psychotherapy and pharmacotherapy. When compared with the amitriptyline only condition, psychotherapy plus pharmacotherapy showed no greater degree of prophylaxis. Further, the survival rate of the psychotherapy-treated cases withdrawn from amitriptyline was not significantly greater than that of the group treated with only placebo.<sup>76</sup> There was, however, evidence of improved interpersonal functioning in women treated with psychotherapy who maintained euthymia.<sup>77</sup>

In the more recent study, Frank and Kupfer<sup>74</sup> found that a systematized form of maintenance interpersonal psychotherapy (IPT-M),<sup>78</sup> provided on a monthly basis following an initial course of weekly sessions (in combination with pharmacotherapy), was significantly more effective in preventing recurrence than placebo.<sup>79,81</sup> However, IPT-M was found to be significantly less effective than maintenance imipramine pharmacotherapy.<sup>81</sup> Further, patients randomly assigned to receive the combination of IPT-M and imipramine *did not* show significantly superior prophylaxis when compared with those receiving pharmacotherapy alone (see Figure 5).<sup>81</sup>

A subsequent analysis of the therapeutic course of patients treated with IPT-M revealed a significant association between quality of therapeutic relationships and the prophylactic success of maintenance psychotherapy.<sup>79</sup>

**Figure 5. Cumulative Proportion With No Recurrences During Long-Term Treatment With Placebo or Imipramine and Interpersonal Psychotherapy, Singly and in Combination\***

\*From reference 51, with permission. Abbreviation: IPT-M = maintenance interpersonal psychotherapy.

Those patients who participated in high-quality therapeutic dyads (i.e., as defined by average session scores above the mean on a measure rating therapy adherence) were at significantly lower risk of relapse than the patients whose dyads were below the mean on this measure. Beyond the issue of the technical quality or specificity of therapy, many psychotherapists might argue that the "dosage" of therapy received is suboptimal. A study by Frank and colleagues is just starting in our Depression Prevention Clinic to try to ascertain if more frequent psychotherapeutic contact can enhance the preventative efficacy of maintenance IPT.

The CBT of Beck et al., the other main form of psychotherapy developed for use with depressed patients, has not yet been studied in long-term treatment trials. Nevertheless, results of a number of naturalistic follow-up studies suggest that lower relapse rates tended to be observed in patients treated with CBT over the first 6 to 24 months of follow-up when compared with patients withdrawn from TCAs.<sup>40-43</sup> In one study, the apparent prophylactic effect following successful CBT was comparable to that observed during continuation and maintenance pharmacotherapy.<sup>44</sup>

**SPECIAL TOPICS**

**Recurrence During Maintenance Therapy**

Controlled and naturalistic studies indicate that between 20% and 70% of patients with recurrent unipolar depression will ultimately suffer recurrences despite be-

ing maintained on antidepressant pharmacotherapy.<sup>45-48</sup> In our group's experience, noncompliance and other causes of inadequate blood drug levels are the leading reasons for such episodes.<sup>49-52</sup> Whenever feasible, a prudent first step in the evaluation of a "breakthrough" episode is to obtain a blood drug level. An unexplained reduction in blood level usually points to compliance problems, which warrant prompt psychoeducational and psychotherapeutic interventions.<sup>49-52</sup> It is imperative to ask patients directly about their medication compliance, and it is also useful to discuss recent changes in the patient's life circumstances in order to identify potential psychosocial correlates of the clinical worsening. On occasion, a patient may admit to decreasing or discontinuing antidepressant medication as a pathologic response to relationship difficulties or other stresses. Such episodes of conflict-related noncompliance are an important factor for concurrent psychotherapy during long-term medication treatment.<sup>49,53,78</sup>

For the newer agents, upward titration of the dosage may be considered an option in this scenario, particularly because valid blood level determinations are not yet available. However, this strategy does not address the likelihood that noncompliance was related to the recurrence. Moreover, a "routine" strategy to increase dosage in response to a breakthrough episode may lead to increased toxicity if the patient subsequently tries to remedy the problem by improving his or her compliance without telling the attending physician.

It also is important in the evaluation of treatment-emergent episodes to again review what other medications the patient is taking. Although elevations in blood levels also may result from a different type of noncompliance, higher than expected blood levels are more likely to reflect drug interactions and/or changes in hepatic metabolism. This is particularly relevant to the care of patients taking antidepressant drugs that have a therapeutic "window" of efficacy, such as nortriptyline. One common metabolic interaction occurs between inhaled tobacco smoke and tricyclic antidepressants. Smokers typically have a more rapid metabolism of TCAs due to hepatic enzyme induction, which may result in an unexplained increase in drug blood levels following cessation of smoking if the dosage is not reduced accordingly. Other important interactions include elevations of tricyclic levels in patients taking concomitant antidepressant therapy with fluoxetine, antipsychotic therapy with a phenothiazine, or antiulcer therapy with cimetidine.

The concept of neurophysiologic tolerance to the therapeutic effects of antidepressant agents has been proposed to account for some "breakthrough" cases.<sup>45</sup> Although this hypothesized effect has been reported for virtually all antidepressants, it should be noted that it is never possible to be certain that the patient's initial response was specifically due to the initiation of pharma-

cotherapy (vis-à-vis attention/placebo expectancy factors or spontaneous remission). Some clinicians opt to handle this type of breakthrough episode by adding lithium carbonate, whereas others prefer to switch to another antidepressant agent. Still others initially may handle the pharmacotherapy of a breakthrough episode more conservatively, emphasizing identification and resolution of potential stressors via intensified psychotherapy. There are simply no empirical data to guide such decisions. However, it is generally good practice to defer a major switch in the treatment plan for at least 1 or 2 weeks in order to differentiate a minor, stress-related symptom "flurry" from a bona fide recurrent episode.<sup>1,4</sup>

Patients suffering recurrent episodes despite pharmacotherapy require particularly close follow-up. Such renewed depressive symptomatology despite compliance with medication often is associated with suicidal ideation and/or loss in confidence in the treatment plan related to an understandable degree of demoralization. Further, access to a large "maintenance" supply of tricyclic antidepressants provides a particularly lethal method for use in a suicide attempt.<sup>14</sup>

#### Maintenance Therapy of Psychotic Depression

Psychotically depressed patients generally have more serious and incapacitating illnesses, with high risks of relapse and suicide during follow-up.<sup>15</sup> Many psychotically depressed patients require treatment with combined antidepressant/antipsychotic regimens. Amoxapine, which has modest antipsychotic potency when used as a monotherapy, also has been shown to be a useful treatment of psychotic depression.<sup>16</sup>

There are essentially no empirical data to guide clinicians' strategies for continuation and maintenance treatment of psychotic depression. Although it is clear that some patients relapse when the neuroleptic is withdrawn from a combined therapy regimen,<sup>17</sup> many clinicians prefer to discontinue the antipsychotic agent as soon as feasible because of the risk of tardive dyskinesia. Moreover, it is not known if amoxapine monotherapy is associated with a lower relative risk of tardive dyskinesia than antipsychotic-antidepressant combinations.

Until more definitive data are available, a strategy for continuation and maintenance treatment of psychotic depression is described below, extrapolated from long-term treatment strategies for severe nonpsychotic depression.<sup>1,50</sup> Specifically, it is recommended that the antidepressant/antipsychotic combination should be continued for at least 6 months, using the lowest possible dosage of neuroleptic necessary to maintain a sustained remission. Once criteria for recovery have been achieved, the antipsychotic may be slowly tapered over several months, *unless* the patient has previously suffered recurrences on antidepressant medication alone.

After discontinuation of the antipsychotic, it may be necessary to increase the antidepressant dosage in order to account for changes in metabolism.<sup>18</sup> Those patients who remain well following neuroleptic withdrawal are then maintained on antidepressant monotherapy for an indefinite time period, using the cost-benefit approach described earlier. Those patients who experience symptomatic exacerbations during withdrawal of the neuroleptic are restabilized using another period of combined continuation therapy. For patients who appear "neuroleptic-dependent," a thorough discussion of the risks of tardive dyskinesia and rationale for ongoing antipsychotic treatment is needed, as are periodic assessments of involuntary movements. The use of the novel antipsychotic clozapine in such cases clearly deserves consideration,<sup>19</sup> particularly when previously unaffected patients begin to manifest signs of tardive dyskinesia.

#### Maintenance Therapy Following Electroconvulsive Therapy

The risk of relapse is particularly high following electroconvulsive therapy (ECT).<sup>20-21</sup> Moreover, a successful course of ECT conveys, at best, only questionable protection against subsequent recurrent depressive episodes.<sup>22</sup> These risks are heightened by the current clinical utilization of ECT, which skews the population of treated cases to include an overrepresentation of vulnerable groups, including psychotically depressed, elderly, and treatment-resistant patients.<sup>21</sup>

In contemporary practice, virtually all patients receive continuation and maintenance pharmacotherapy following ECT. However, one recent study found that patients who had not responded to an adequate trial of tricyclic antidepressants prior to ECT should not receive the same agent for maintenance therapy. These patients had a high risk of relapse when resumed on these agents for continuation treatment, whereas significantly greater prophylaxis was obtained in those patients who were not treatment-resistant.<sup>21</sup>

Some clinicians use antidepressant/lithium salt combinations for prophylaxis of tricyclic-resistant patients following ECT, whereas others prefer switching to an MAOI or an alternate novel monotherapy. In cases of multiple prior relapses, some clinicians may recommend a sustained course of weekly or biweekly "maintenance" ECT treatments.<sup>24</sup> Despite the large proportion of treatment-resistant cases now referred for treatment with ECT, I have yet to see a patient who has a confirmed history of failure to benefit from *all* available antidepressant options. It is a somewhat curious notion (but nevertheless true) that, in this era of second- and third-generation antidepressants, the TCAs ultimately may be established as excellent post-ECT maintenance treatments for patients who have previously failed to respond to SSRIs or other newer agents.

### Maintenance Therapy of Bipolar Depression

Unlike unipolar depression patients, there is little agreement whether or not bipolar patients should receive sustained prophylactic treatment with antidepressant agents.<sup>73-75</sup> This controversy is due, in part, to concerns about induction of mania and rapid cycling during continuation or maintenance antidepressant pharmacotherapy.<sup>76-78</sup> It is clear that a pattern of rapid cycling can be induced by prescription of antidepressants in selected cases,<sup>79-81</sup> particularly among female patients and those with covert thyroid disease and/or bipolar II subtype. However, it is not clear that continuation antidepressant pharmacotherapy conveys any increased risk for most patients receiving concomitant therapy with a mood stabilizing agent such as lithium carbonate.<sup>75</sup> Further, precipitous withdrawal of antidepressants after a short period of acute treatment also may prove to be as implicated in the processes underlying rapid cycling and treatment-induced mania as continued pharmacotherapy.<sup>76</sup> Some doubt persists with respect to whether the pattern of rapid cycling is induced by the prescription of antidepressant per se or by an "on again/off again" pattern of prescription.<sup>77,82</sup> Nevertheless, most experts agree that use of antidepressants should be minimized once a patient begins to cycle rapidly.<sup>74,83,84</sup>

Although longer-term antidepressant therapy may not have consistent adverse effects for most patients suffering from bipolar depression, it is unfortunately true that available evidence provides only weak support for its efficacy as a maintenance treatment.<sup>74,85</sup> For example, several contemporary studies have found that the combination of tricyclic antidepressants and lithium carbonate was no more effective in preventing affective recurrences in bipolar disorder than lithium alone.<sup>86</sup> Pharmacotherapy with lithium salts (and, for lithium-intolerant or nonresponsive patients, carbamazepine or sodium valproate) thus remains the mainstay of prophylaxis.<sup>87</sup> And yet, depressive relapse and recurrence remain significant problems for bipolar patients during long-term monotherapy with these mood stabilizing agents.<sup>88,89</sup> Promising results have been observed with several alternate forms of antidepressant therapy, including fluoxetine,<sup>90</sup> bupropion,<sup>91</sup> and tranylcypromine,<sup>92,93</sup> either singly or in combination with lithium salts. These preliminary observations warrant more systematic study in larger samples.

### Psychobiology of Depressive Vulnerability

Continuation pharmacotherapy may be conceptualized using the metaphor of applying a cast to a broken limb, i.e., the treatment provides an external structure that strengthens or restrains a weakened or unstable system. For patients with multiple relapse or recurrence it must be assumed that the system is inherently unstable, in manner not unlike disunion of a fracture. As reviewed

Figure 1  
to 1r  
Level

Mean Urinary Free Cortisol Level

sh  
tr  
su  
in

adrenocortical (HPA) function.<sup>104,105</sup> These neurobiological disturbances, which are most pronounced in severe depressive states, provide a means by which the activity of the underlying illness state can be monitored in research studies and, possibly, may be associated with the need for ongoing pharmacotherapy.

Perhaps the best studied state-dependent correlate of severe depression is hypercortisolism, as reflected by either elevated urinary free cortisol excretion or dexamethasone nonsuppression.<sup>104,105</sup> Although most hypercortisolemic patients show reversal of these abnormalities following effective treatment, a minority of patients show persistent indices of HPA hyperfunction.<sup>104,105</sup> Moreover, higher relapse rates have been documented in patients with persistent hypercortisolism despite continuation pharmacotherapy.<sup>106-108</sup> Our group recently found a similar relationship between elevated urinary free cortisol levels and relapse in unmedicated outpatients treated with an intensive inpatient form of CBT (see Figure 6).<sup>109</sup>

A blunted thyrotropin response following intravenous infusion of thyrotropin-releasing hormone (TRH) also may reflect depressive vulnerability,<sup>110-113</sup> even though this abnormality may be a state-independent (i.e., trait-like) correlate of depression.<sup>99,114</sup> Several EEG sleep correlates of depression similarly have been shown to behave as more stable, trait-like indicators of affective illness, including reduced latency to the onset of the first rapid eye movement sleep period (i.e., reduced REM la-

n  
o-  
n.  
ep  
y-

tency), decreased percentage of slow wave sleep, and a relatively decreased number of computer-scored delta waves in the first non-REM sleep period (i.e., decreased delta ratio).<sup>104,105</sup> Several recent studies indicate that reduced REM latency<sup>114,115</sup> and decreased delta ratio values<sup>116</sup> predict an increased risk of recurrent depression after withdrawal of continuation pharmacotherapy. These observations, coupled with reports of increased risk of recurrence in persons with family histories of affective disorder,<sup>25</sup> suggest that more stable or persistent vulnerabilities also may serve as indicators of the risk of recurrent depression.

Investigations of the relationship between life stress and the psychobiologic correlates of affective illness provide an alternate approach to understanding depressive vulnerability.<sup>25,104,105,117</sup> It is commonly observed that severe forms of unipolar and bipolar disorders appear to cycle quite autonomously, i.e., without clear-cut environmental provocation.<sup>2,9</sup> Expressed another way, highly recurrent affective disorders may require less in the way of precipitating adversity than first- or second-episode cases.<sup>117</sup> Post<sup>117</sup> proposed that the neurophysiologic model of kindling may extend to affective illness, such that repeated exposures to the neurochemical and neuroendocrine correlates of depression may alter central nervous system structure and/or function. This could account for the marked vulnerability seen in highly recurrent and/or chronic cases,<sup>118</sup> as well as the tendency for severity of depression to worsen with repeated episodes.<sup>118</sup> In this regard, Sapolsky<sup>119</sup> has shown in primates that the chronic stress resulting from social subordination alters the HPA responses in a way analogous to those seen in severe recurrent depressions. Gold and colleagues<sup>120</sup> further point out that exposure to environmental stresses during critical periods of mammalian development may subsequently cause altered neuroregulatory and homeostatic responses later in life, when the animals are mature. Finally, normal aging also alters the inhibitory function of hippocampal glucocorticoid receptors such that smaller amounts of perceived stress may provoke sustained or pathologic hypercortisolism.<sup>121</sup> The potential neurobiological ravages of each new episode of severe depression, coupled with altered stress responsivity resulting from early trauma and/or age-related changes, may go a long way toward explaining why some recurrent depressive disorders become autonomous and, at times, intractable illnesses. At present, the best way to prevent the development of intractable affective illness is to prevent the recurrence of an index-treated episode.

### SUMMARY

A majority of persons who become clinically depressed will, at some point, suffer another episode. Fur-

ther, factors such as psychosocial vulnerability and inadequate treatment may lead to relapse, chronicity, and elevated risks of recurrent depression episodes. The interaction of psychosocial and biological vulnerability factors may cause a "kindling" of affective illness, such that each new episode is more autonomous and/or severe. The best strategy to avoid this deteriorative process begins with provision of a vigorous course of acute therapy, resulting in a complete remission. When pertinent, the psychosocial vulnerability factors appear to warrant the combined use of psychotherapy and pharmacotherapy. This is followed by a course of continuation therapy until the patient has achieved a full recovery. Ongoing maintenance therapy, which may extend for years, is indicated in cases of recurrent depression and for those with heightened vulnerability. Full dosages of antidepressants are recommended for use in continuation and maintenance pharmacotherapy and more complex regimens are often needed in cases of refractory, psychotic, and bipolar depression. The newer antidepressant agents have great promise as long-term treatments by reducing the side effects that may lead to noncompliance and/or premature termination of therapy.

*Drug names:* amitriptyline (Elavil and others), amoxapine (Asenden), bupropion (Wellbutrin), carbamazepine (Tegretol and others), cimetidine (Tagamet), clomipramine (Anafranil), clozapine (Clozaril), fluoxetine (Prozac), imipramine (Tofranil and others), maprotiline (Ludiomil), nortriptyline (Pamelor and others), phenelzine (Nardil), sertraline (Zoloft), tranylcypromine (Parnate), trazodone (Desyrel and others).

## **ANXIETY DISORDERS**

**Panic Disorder with Agoraphobia**

**Panic Disorder without Agoraphobia**

**Agoraphobia without history of Panic Disorder**

**Social Phobia**

**Simple Phobia**

**Obsessive Compulsive Disorder**

**Post-traumatic Stress Disorder**

**Generalized Anxiety Disorder**

- 1. P H O B I A - an overwhelming fear of a specific object or event**  
**no real danger**  
**ends when object/event is removed**
- 2. P A N I C A T T A C K - an overwhelming fear not related to a specific event/situation/object**  
**begins and ends abruptly**
- 3. A N X I E T Y - a persistent, generalized tension - uneasiness not triggered by an external event**

## ANXIETY DISORDERS

### Key Features

#### ANXIETY

Panic Disorder

OCD

GAD

#### AVOIDANCE BEHAVIOR

Panic Disorder with Agoraphobia

OCD

Phobic Disorders

### PANIC DISORDERS

- recurrent panic attacks
- at least 4 characteristic associated symptoms
- lasts minutes to hours
- unexpected nature not triggered by situations in which individual is the focus of attention (social phobia)
- sudden onset
- associated symptoms

## **PANIC DISORDER WITH AGORAPHOBIA**

fear of being in places or situations from which escape might be difficult or embarrassing or in which help might not be available in the event of a panic attack

## **SOCIAL PHOBIA**

- persistent fear in one or more situations
- person exposed to scrutiny  
may be event limited
- avoidant behavior interferes with occupational functioning  
or usual social activities

## **SIMPLE PHOBIA**

- persistent fear of circumacribed  
stimulus "specific"
- immediate anxiety response
- marked anticipatory anxiety

**O B S E S S I V E C O M P U L S I V E D I S O R D E R  
(O C D)**

recurrent obsessions or compulsions

severity -- marked distress

interferes significantly with routines, occupational functioning,  
usual social activities

**O B S E S S I O N S** - ideas, thoughts, impulses, urges

**C O M P U L S I O N S** - repetitive, purposeful, and  
intentional behaviors performed in response to an  
obsession, according to certain rules or in stereo-typed  
fashion

- recognition that behavior is unreasonable
- efforts to resist accompanied by increased anxiety

**P O S T - T R A U M A T I C S T R E S S D I S O R D E R**

event outside range of usual human experience

- reexperience event
- avoidance of stimuli associated with the event
- numbing of general responsiveness (emotional anesthesia)
- increased arousal
- greater than one month duration
- difficulty with sleep, nightmares, hypervigilance, exaggerated  
startle response

**G E N E R A L I Z E D A N X I E T Y D I S O R D E R  
(G A D)**

unrealistic or excessive anxiety regarding two or more life  
circumstances six months or longer

symptoms:

- motor tension
- autonomic hyperactivity
- vigilance and scanning

## Comparison of Benzodiazepine Antianxiety Drugs

GENERIC DRUG	TRADE NAME	ADULT DOSE <sup>1</sup>	HALF-LIFE	ABSORPTION RAPIDITY
Alprazolam	Xanax	0.5 mg, TID	short	intermediate
Chlordiazepoxide	Librium and others	10 mg, TID	long	intermediate
Clorazepate	Tranxene	7.5 mg TID	long	fast <sup>2</sup>
Diazepam	Valium	5 mg, TID	long	very fast
Flurazepam <sup>3</sup>	Dalmene	15-130 mg, hs	long	fast
Halazepam	Paxipam	20 mg	long	intermediate
Lorazepam	Ativan	1 mg, BID	short	intermediate
Oxazepam	Serax	10 mg, TID	short	slower
Prazepam	Centrax Verstran	10 mg, BID	long	slowest <sup>2</sup>
Temazepam <sup>3</sup>	Restoril	30 mg, hs	short	slow
Triazolam <sup>3</sup>	Halcion	0.25-0.5 mg, hs	short	very fast

<sup>1</sup> Geriatric patients should receive 30-50% less than the usual adult dose.

<sup>2</sup> These drugs are pro drugs for desmethyldiazepam: the parent drug is rapidly converted to the active metabolite.

<sup>3</sup> Sedative/hypnotic agent used to increase the onset and duration of sleep.

## I. INTRODUCTION

### A. Anxiety: A Definition

Anxiety is a universal human response to routine stress and emotional conflict that is experienced both psychologically and physiologically. It is important to distinguish "normal" anxiety from "pathological" anxiety or **anxiety disorder**. Pathological anxiety may be distinguished from normal by its autonomy, intensity, duration, or associated behavior. When "autonomous," anxiety appears to have a "life of its own," with minimal basis in identifiable environmental stimuli. The "intensity" of symptomatic distress for pathological anxiety frequently exceeds the patient's capacity to bear the discomfort; the experience, therefore, is unlikely to engender a healthy, adaptive response. When symptoms recur or persist over time, the duration of anxious suffering will typically indicate pathology. Finally, pathological anxiety may trigger such stereotyped behavioral responses as avoidance or lifestyle constriction.

Similar to fear, anxiety symptoms are generally of two types: the first is a sustained state of increased arousal, concern, worry, and vigilance resembling the uncertainty, caution, and alerted stance of an individual passing through a potentially dangerous setting, like a dark, deserted alleyway; the second type resembles the state of alarm, terror, or panic that would be triggered by an actual sudden life threat, as if an assailant had suddenly emerged from that same alleyway. The former, analogous to generalized or anticipatory anxiety, does not appear to be just a milder variant of the latter, which resembles panic attacks. Panic attacks themselves

ROSENBAUM, M.D.** • Clinical Psychopharmacology Unit, Massachusetts Hospital, Boston, Massachusetts 02114; Department of Psychiatry, Harvard Medical School, Massachusetts 02115. **ALAN J. GELENBERG, M.D.** • Department of Psychiatry, Arizona Health Sciences Center, Tucson, Arizona 85724.

vary in intensity and symptoms and include mild and limited symptom attacks as well as major attacks. Pharmacological and familial studies suggest a clinically relevant distinction between these two anxiety states.

## **B. Symptoms**

Anxiety is experienced cognitively, affectively, physically, and behaviorally.

### **1. Cognitive**

The cognitive experience of anxiety typically involves apprehensive, vigilant, and pessimistic appraisal of circumstances. For a panic attack, the cognitive component is one of catastrophic thinking, with appraisal of the attack as a life-threatening ailment or one likely to lead to insanity or great embarrassment. With generalized or anticipatory anxiety, the cognitive response is more one of rumination, worry, and overconcern.

### **2. Affective**

Anxiety is a dysphoric state of emotional arousal that frequently drives the sufferer to seek relief. Many who have suffered panic attacks, for example, describe the event as one of the most unpleasant experiences of their life; they would go to any length to avoid a subsequent similar experience.

### **3. Physical**

The intensity of physical symptoms of anxiety varies, as does the primary somatic locus of anxious suffering among individuals. Typical symptoms are cardiac (palpitations, tachycardia, chest tightness), respiratory (hyperventilation, dyspnea, shortness of breath), neurological (dizziness, paresthesias, tremulousness), or gastrointestinal (nausea, intestinal cramping, diarrhea). Other autonomic symptoms frequently occur (hot or cold flashes, diaphoresis, dry mouth).

### **4. Behavioral**

Possible behavioral concomitants of anxiety include avoidance, flight, a freeze response, help-seeking behavior, or other maladaptive attempts to diminish the experience, such as excessively dependent behavior or rituals.

## **II. MODELS**

As innate responses for protecting the human organism and enhancing survival, panic and vigilance are normal in the face of threatening stimuli. As "anx-

iety" or psychopathological symptoms, other factors besides actual physical threat must be implicated as "triggers" or cause. Of several explanatory models, the *biological* places emphasis on the wiring and juices of the central nervous system, the *psychodynamic* on meanings and memories, and the *behavioral* on learning and behavior.

### A. Biological

Recent animal and neuronal receptor studies emphasize two central systems as being principally involved in fear and pathological anxiety.<sup>1-2</sup> One critical component involves central noradrenergic mechanisms, with particular importance placed on the locus ceruleus (LC), a small retropontine structure that is the primary central nervous system (CNS) source of the neuromodulator norepinephrine. When this nucleus is stimulated in primates, for example, an acute fear response can usually be elicited with distress vocalizations, fear behaviors, and flight. Alternatively, destruction of the LC may lead to abnormal complacency in the face of threat. Biochemical perturbations that increase LC firing elicit anxious responses in animal and man that are blocked by agents that decrease LC firing, some of which are in clinical use as antipanic agents.

A second system involves "benzodiazepine receptors" with particularly relevant concentrations in limbic system structures, especially the septohippocampal areas. One role of the limbic system is to "scan" environmental inputs for life-supporting and threatening cues and to monitor internal or bodily sensations. Vigilance (or its psychopathological equivalent, generalized anxiety) may reflect limbic system arousal. Benzodiazepine receptors in high concentration in relevant limbic system structures may play a role in modulating limbic alert, arousal, and behavioral inhibition by increased binding of the inhibitory neurotransmitter  $\gamma$ -aminobutyric acid (GABA). As one might expect, there are neuronal connections between the LC and the limbic system that coordinate among surveillance, alert, and alarm. Although it is unlikely that any one system or substance is the source or cause of anxiety, the discovery of neuronal receptors for which benzodiazepines have particularly high affinity suggests the existence of ligands that may regulate the experience of anxiety as either endogenous anxiolytics or anxiogens. The fact that neuronal connections and neurotransmitters mediate emotional experience, however, does not of itself minimize the importance of nonpharmacological therapies for anxiety, which also may ultimately act by mobilizing these endogenous anxiety-regulating factors.

Other important clues to a biological basis of anxiety<sup>3</sup> include the observed familial and probably genetic transmission of disorder, the apparently unique sensitivity of patients with panic disorder to certain physiological provocations (e.g., lactate, CO<sub>2</sub>), asymmetric blood flow in limbic structures on positron emission tomography (PET) scans of panic patients, and temperamental differences in very young children of patients with anxiety disorder.

If anxiety proneness has a biological basis, one would assume evolution had a

reason to select for this characteristic. The anxious individual may have been important to the survival of the larger group by serving as a sentinel, being more alert to danger and more concerned with situations posing threat such as places of restricted escape. Further, many normative "anxious" responses are necessary for survival, such as separation anxiety. The reaction to acute separation in infant primates, for example, takes a form analogous to that of a panic attack, with intense arousal, distress, and care-seeking behavior. The sense of terror experienced by the infant on separation from the mother may be the prototype panic attack, which is reactivated in later life as the consequences of earlier failures at separation and individuation or of early trauma or in those genetically predisposed.

The simplest model for panic and anxiety may be that fear and anxiety are protective and that any good security system must include a surveillance, alarm, and help-seeking mechanism. Further, as anyone with a home security system knows, otherwise well-designed systems frequently have "bugs" and tend to "false alarm" or are triggered by ordinary events because of an excessively sensitive threshold. The problem remains, however, to find either the "bug" or the mechanism to regulate downward the sensitivity to inappropriate activation.

## B. Behavioral

Behavioral understanding of anxiety disorder antecedents focuses on learning. Anxiety symptoms or avoidant behavior become associated with benign settings or objects as a result of generalization from earlier traumatic experiences. For example, a child ridiculed by peers because of a mistake during "show and tell" pairs embarrassment and shame with speaking before groups and thereafter manifests anticipatory anxiety and avoidance of public speaking. Self-defeating cognitive "habits" sustain the syndrome with unrealistic catastrophic thinking "expecting the worst." For panic disorder, misinterpretation of bodily stimuli with exaggerated cognitive and behavioral responses also serves to maintain the response. In this model, anxiety occurs when an individual encounters a signal that "predicts" a painful or feared event. Thus, learning theory presumes some real or perceived prior traumatic experience to condition the anxious response.

## C. Psychodynamic

Psychoanalysts view anxiety as a manifestation of intrapsychic conflict and describe a continuum of responses. Secondary anxiety signals the ego to mobilize defenses to deal with a stress or conflict. "The anxiety acts as a warning that danger is impending; but the danger is one that the individual is capable of coping with; it is not yet overwhelming or inevitable."<sup>4</sup> Psychoanalysts also have described how anxiety is central to symptom formation and the development of the neuroses (i.e., obsessive compulsive, phobic, etc.). The symptoms

are the end product of the mixture of elements from both an unconscious impulse and the

ego defenses directed against it. The symptoms are a compromise formation, the result . . . of vectors of forces showing the summated effects of all the elements.<sup>4</sup>

For example, a ladylike and very proper middle-aged woman little given to displays of emotion—and certainly not anger—becomes manifestly anxious when she is alone with her husband. The clinician learns that the symptoms started after the woman learned of her husband's recent infidelity. She is brimming with a sense of outrage toward her husband, but these feelings are intolerable to her. When they threaten to surface, she becomes overtly anxious.

More recent psychodynamic observations, emphasizing object relations, point to the role of internalized objects and their critical function in maintaining affective stability under stress. An adequate developmental experience typically generates internalized objects (introjects) that provide a soothing function, regulating the individual's internal milieu, in the face of distress; the absence of these internal regulators allows the organism to fragment and to experience anxiety in various situations.

Phobic disorders whose sufferers may experience panic, anticipatory, or no anxiety symptoms at all (depending on the success of avoidance behavior) serve to illustrate the differing models. The biological view would recognize the stereotyped nature of phobias, that most objects and situations in everyday life that truly threaten us are rarely selected as phobic stimuli. Children, for example, proceed normally through various developmental phobias (stranger, separation, darkness, etc.), but rarely become phobic of objects and situations that are associated with danger (e.g., electric outlets, roads). Further, most phobic stimuli (e.g., snakes, spiders, close spaces) have meaning in the context of biological preparedness<sup>5</sup> and were presumably selected for by evolution. Psychodynamic observations underscore the use of defense mechanisms such as displacement and the contribution of meanings and symbolic representations of phobic objects and situations. Learning theory, on the other hand, would predict some real or perceived prior traumatic experience with the object or situation. As with most human experience, anxiety rarely can be reduced to one explanatory framework. Clinical observation and research indicate contributing roles for all three models as determinants of behavior and as guides to therapeutic strategies. It is likely that an inherited "anxiety proneness" renders the development of an anxiety disorder more likely, but the onset, course, and shape of the disorder are greatly influenced by development, life events, and relationships.

### III. DIFFERENTIAL DIAGNOSIS

Most patients with anxiety symptoms are initially evaluated by a primary care physician, internist, cardiologist, or neurologist for various somatic complaints. Given the predominance of physical symptoms in the experience of anxiety, the differential diagnosis of anxiety symptoms is complicated. Anxiety may be a consequence of a medical illness. An anxiety disorder (e.g., panic) may have been triggered by a medical illness (e.g., hyperthyroidism) but continue on its own after the inciting disorder is treated. Anxiety may be **associated** or linked with certain

medical conditions (e.g., panic disorder with mitral valve prolapse, peptic ulcer disease, irritable bowel, hypertension). Anxiety may **mimic** a variety of medical ailments or, in turn, be mimicked by them. Thus, standard medical procedures, including history, physical, and laboratory examination, are indicated in evaluating a patient with anxietylike symptoms. Given the frequency of coexisting medical problems in psychiatric patients, physical symptoms should not be presumed to reflect anxiety. Because anxietylike symptoms accompany most psychopathological states and many organic problems, the differential diagnosis of anxiety is extensive.

## A. Medical

A list of all possible organic causes of anxiety could constitute the index of a medical textbook. Endocrine disorders, such as hyperthyroidism, may reproduce severe anxiety symptoms. Similarly, hypoglycemia, whether caused by an insulinoma or by exogenously administered insulin, can result in anxietylike symptoms, as can secreting tumors such as carcinoid and pheochromocytoma. Patients with various neurological abnormalities—including encephalopathies of diverse etiologies, postconcussion syndrome, and seizure disorders—may report anxiety. Others with severe pulmonary disease and hypoxia also report anxietylike symptoms. Excesses of stimulant drugs (including caffeine) and withdrawal from sedative drugs (including alcohol) can be culprits as well.

It would be impossible to memorize all the possible physical causes of anxiety, and it would be a useless exercise to sit before an anxious patient with a checklist. Rather, the clinician should maintain a high index of suspicion and complete a thorough assessment. When taking a history, inquire about past and present medical illnesses and medications, other treatments, and doctors consulted. Inquire also about the use of over-the-counter drugs as well as “recreational” substances. Hallucinogens, for example, may precipitate a “bad trip” or panic attack. Always ask about alcohol and estimate the amount of caffeine consumption.

Complete a careful review of systems. Although the presence of certain symptoms may not have emerged initially when taking a history from an anxious patient, the systems review may reveal a pattern—such as skin and hair changes, heat intolerance, and weight loss (possible hyperthyroidism)—that can suggest further diagnostic evaluation.

The clinician should complete a routine physical examination with specific attention to areas highlighted by the history. Laboratory tests can be ordered on the basis of findings from the history and physical examination and anticipated medication therapy.

## B. Psychiatric

Anxiety accompanies most psychiatric disorders. Patients with schizophrenia, other psychoses, affective disorders, borderline states, and personality disturbances

may present with severe anxiety. Before prescribing an antianxiety drug, the clinician should complete a thorough evaluation. Psychoses, affective disorders, personality disturbances, and organic brain syndromes should be considered in the differential diagnosis of anxiety. Once the clinician determines the diagnosis, the general rule is to treat the primary disorder specifically—antipsychotic drugs for schizophrenia, antidepressants for depression, antianxiety treatments for generalized anxiety disorders, etc. On the other hand, it is important to recall that psychiatric disorders may coexist; an anxiety disorder may be comorbid with other axis I psychiatric syndromes listed in the third revised edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-III-R)*. Among the most difficult psychiatric differential diagnoses is the differentiation of a DSM-III-R axis I disorder such as an anxiety disorder from an axis II diagnosis in a patient with substantial underlying character pathology such as an individual with avoidant or borderline personality. In the latter case, the individual may describe himself as anxious or depressed when the internal state is more accurately one of emptiness, aloneness, boredom, or fragmentation as a consequence of interpersonal upheavals. Although the presence of an axis II disorder does not exclude treatment of anxiety symptoms, it is important to recognize when character pathology contributes to ongoing symptomatic distress.

#### IV. ANXIETY DISORDERS

Current nomenclature identifies nine specific subtypes of anxiety disorders: panic disorder with agoraphobia, panic disorder without agoraphobia, agoraphobia without history of panic disorder, social phobia, simple phobia, obsessive-compulsive disorder, posttraumatic stress disorder, generalized anxiety disorder, and anxiety disorder not otherwise specified. Anxiety disorders are the most common form of psychiatric illness in this country, with 15–20% of the population having experienced one of these conditions at some time in their lives.

##### A. Panic Disorder

Patients with this diagnosis have experienced at least one unexpected panic attack and have either experienced four panic attacks in a 4-week period in their life or one panic attack followed by at least a month of sustained fear of having a subsequent attack. The features of a panic attack include the experience of at least four of the symptoms listed in Table 1 developing suddenly or within 10 min of the onset of the first symptom noticed.

A panic attack is an intensely distressing experience, usually lasting a few to several minutes, with fairly stereotyped physical, cognitive, and behavioral components. Patients with panic disorder may experience these attacks intermittently or in clusters and may develop a number of complications, including persistent anxiousness, phobic avoidance, depression, and alcoholism or other drug overuse.

The physical symptoms of a panic attack include cardiac, respiratory, neu-

**TABLE 1. Symptoms of Panic Attacks**

- 
1. Shortness of breath (dyspnea) or smothering sensations
  2. Dizziness, unsteady feelings, or faintness
  3. Palpitations or accelerated heart rate (tachycardia)
  4. Trembling or shaking
  5. Sweating
  6. Choking
  7. Nausea or abdominal distress
  8. Depersonalization
  9. Numbness or tingling sensations (paresthesias)
  10. Flashes (hot flashes) or chills
  11. Chest pain or discomfort
  12. Fear of dying
  13. Fear of going crazy or of doing something uncontrolled
- 

rological, gastrointestinal, and other reactions. Cognitively, the patient feels a sense of terror or fear of losing control, dying, or going crazy. Behaviorally, the patient often flees from the setting in which the attack is experienced to a safe, secure, or familiar place or person. Help-seeking behavior is characteristic of a person having panic disorder.

The patient may vividly remember the initial or "herald" attack, which appears in some cases to "turn on" the disorder. Although this first spell is often unexpected ("out of the blue") and intense, later attacks may be either spontaneous and unexpected or preceded by a buildup of anticipatory anxiety. The latter type, called a situational attack, occurs in settings where the patients might sense being at risk for panic or the site of prior attacks, such as a crowded room or stores. Major attacks involve four or more of the symptoms in Table 1. Episodes involving fewer symptoms are considered "limited symptom" attacks.

The typical onset of panic disorder is in early adult life. The illness afflicts women two to three times more often than men. Adults with panic disorder (in particular, those who develop agoraphobia) frequently have a childhood history of separation anxiety symptoms,<sup>6</sup> particularly "school phobia." The disorder is clearly familial and may have a genetic basis.<sup>7</sup>

The onset of the disorder typically follows a major life event (such as a loss, threat of a loss, or other upheavals in work or home situations) or a physiological event such as medical illness (e.g., hyperthyroidism or vertigo) or drug use (e.g., marijuana or cocaine). However, a patient whose herald attack seems to be triggered by the use of cocaine, for example, may continue to have persistent or recurrent symptoms without further drug use. In light of the impressive paroxysmal physical symptoms of a panic attack, most sufferers ascribe the experience to a physical cause and seek evaluation and treatment initially from a nonpsychiatric physician. If the syndrome progresses without proper diagnosis, hypochondriacal behavior may result, followed by demoralization if relief is not obtained.

A panic attack, like an endogenous "false alarm," appears to turn on a state of

vigilance or "postpanic" anxiety that resembles generalized anxiety disorder. Between attacks, patients may remain symptomatic with a constant, low-level, anticipatory anxiety that may crescendo into full-blown panic in certain situations, sometimes unexpected. In this state of vigilance, the patient may develop mild or extensive phobic avoidance, usually of travel or places of restricted escape. This behavior may begin immediately following the onset of attacks, after a number of attacks, or never at all. In some cases, phobic avoidance evolves as a progressive constriction, and the patient increasingly avoids a variety of settings, in particular those where attacks have occurred. Thus, agoraphobia frequently occurs as a complication of panic attacks.

The demoralization that accompanies the sustained distress and progressive disability of panic disorder may extend to a major depressive episode with characteristic signs and symptoms. The relationship between panic and depression, however, is a complicated one. Although some patients manifest no depressive symptoms, for others, it is unclear which disorder is primary when the onset of symptoms is concurrent.

Alcohol use can temporarily tame the distress of panic disorder, but the patient soon experiences rebound symptoms, setting the stage for alcohol overuse. Thus, it is not surprising that more than 10% of adult alcoholics may meet criteria for a diagnosis of panic disorder.

The mortality rate of patients with panic disorder may be higher than that of others. Data suggest that there is increased premature mortality from suicide and, for men, from cardiovascular illness.<sup>8</sup> Mitral valve prolapse is also diagnosed much more frequently in panic patients than in either the normal population or patients with generalized anxiety disorder.

Although there are a number of treatment strategies, including pharmacological and behavioral interventions, that can minimize or prevent the symptoms and complications of this disorder, many patients suffer residual symptoms or go many years with their disorder before coming to treatment. Epidemiologic studies suggest that panic disorder and agoraphobia occur in as much as 3% to 6% of the population.

## B. Phobic Disorders

There are three general categories of phobic disorders: agoraphobia, social phobia, and simple phobia. **Agoraphobia** is the fear of settings or places of restricted escape, where help might not be available in the event of an emergency, as with a panic attack. Patients suffer travel restrictions and may endure a variety of agoraphobic situations (such as crowds, restaurants, stores, bridges, tunnels, airplanes, or restricted-access highways) with considerable distress or may remain homebound or unable to travel without a companion. Some patients suffer agoraphobia without a clear history of typical panic attacks.

**Social phobics** experience anxious distress in situations where the patient is the

focus of scrutiny by others and fears humiliation or embarrassment. A common circumscribed social phobia is stage fright and fear of public speaking. Other examples include the inability to sign one's name in public or to use public lavatories. Social phobic anxiety may resemble the lower-grade, "generalized" variety or be experienced with the intensity of a panic attack. Social phobia is distinguished from normal anxiety, in part, by the extent of avoidance or social and occupational limitation. Social phobia may also be global with generalized anxiety or panic symptoms in any social setting, whenever the sufferer is in the presence of others, with relative relief available only when alone or with very familiar people.

Social phobias have a 6-month prevalence rate of about 1.5%. They typically have their onset in late adolescence and afflict men and women in roughly equal numbers. This disorder is generally considered underdiagnosed and undertreated. There may be considerable overlap in the presentation of social phobia and panic disorder. Although patients with either disorder may avoid or need to flee from meetings or other social gatherings, social phobics are generally more comfortable when they are alone, in contrast to patients with panic disorder. Similar to panic disorder and agoraphobia, social phobia is frequently complicated by alcohol overuse.

**Simple phobias** are the irrational fear of and need to avoid specific objects or settings, such as insects or animals, or specific situations (e.g., airplanes, heights). If the object or situation is encountered, the individual suffers intense anxiety that may reach the level of panic.

### C. Generalized Anxiety Disorder

In the past, patients who suffered anxiety, whether of the generalized or panic form, had been termed "anxiety neurotics," but observations of patient's responses to drug treatments initiated a "pharmacological dissection" of anxiety disorders. Patients who suffered panic attacks, agoraphobia, or "phobic anxiety states" showed preferential responses to medications that were not "anxiolytic" *per se* (e.g., certain tricyclic and monoamine oxidase inhibitor antidepressants). Standard anxiolytic medications such as benzodiazepines were relatively ineffective in preventing panic attacks but were useful in controlling other forms of generalized anxiety.

Generalized anxiety disorder is diagnosed if the patient has suffered from persistent anxiety for 6 months or more. These episodes are manifested by unrealistic or excessive worry (not related to having a panic attack) and by various symptoms such as motor tension, autonomic hyperactivity, as well as vigilance and scanning behavior that are unrelated to any specific medical or organic cause.

Although generalized anxiety may represent the most prevalent form of anxiety symptoms, its actual prevalence as opposed to reactive anxiety symptoms resulting from transient stressful life situations is unknown. As described (see Section III), anxiousness may be featured in a number of medical and psychiatric conditions; for example, persisting and severe anxiousness may be the presenting symptom of a major depressive disorder. Selection of treatments for persistent anxiety without

panic attacks is also controversial. Stress management techniques, other cognitive and behavioral interventions, and various psychotherapeutic interventions may be useful in dealing with relationships and life situations that exacerbate persisting anxiety. On the other hand, substantial numbers of patients with persistent anxiety may obtain long-lasting relief and improvement in function from pharmacotherapy with traditional anxiolytics, antidepressants, and newer antianxiety agents. In lieu of maintenance treatment, short-term pharmacotherapy may help deal with the peaks of stressful anxiety.

## **D. Other DSM-III Adult Anxiety Disorders**

### **1. Obsessive Compulsive Disorder**

Patients with obsessive compulsive disorder (OCD) suffer (1) recurrent unwanted and senseless thoughts that are distressing and intrusive but are unable to be suppressed (obsessions) or (2) compulsions, the need to repeat certain behaviors or rituals in a stereotyped fashion to avoid or diminish intense anxiety.

Although many OCD patients suffer from persistent anxiety symptoms or panic attacks, particularly when confronted with triggers for obsessional rumination or when restrained from carrying out compulsive rituals, the inclusion of OCD among anxiety disorders may not be a good fit for many OCD sufferers. Indeed, OCD may have several forms, including compulsive washing or checking, fears of contamination, primary obsessional slowness, and religious or bizarre ritual behaviors. Obsessive compulsive disorder is frequently an exceptionally disabling syndrome, but, for diagnosis, other causes for obsessive thoughts such as bulimia (with food obsessions) or psychosis must be considered. Depression may also exist with OCD symptoms. Because of the bizarre nature of some obsessions, many patients with the disorder are frequently misdiagnosed as having schizophrenia. The 6-month prevalence rate of OCD is between 1% and 2%. The onset of OCD is generally before the age of 25. As with other disorders, proposed etiologies include psychodynamic, neurochemical (e.g., serotonin dysfunction), neurological (e.g., basal ganglia dysfunction), and behavioral or learning models.<sup>9</sup> There is only a partial overlap between OCD and compulsive personality disorder; OCD also aggregates in families of sufferers of such other disorders as tics and Tourette's syndrome.

### **2. Posttraumatic Stress Disorder**

Patients with this condition may manifest symptoms resembling other anxiety disorders such as panic attacks, but the disorder begins at the time of experiencing or witnessing a life-threatening, violent, or other catastrophic event. Subsequently, the patient reexperiences the traumatic event in vivid memories, recurrent dreams, or other experiences (such as flashbacks). Anxiety symptoms, the tendency to startle easily, sleep dysfunction, and the need to avoid stimuli reminiscent of the original event, all characterize this syndrome.

The actual prevalence of posttraumatic stress disorder (PTSD) is uncertain, but it is estimated that 1% of the general population suffers from it. Of course, this disorder is more prevalent in populations exposed to trauma such as civilians after attack and particularly in wounded Vietnam veterans. PTSD patients have been described as suffering enduring vigilance for and sensitivity to threat with excessive alertness and overreactivity to stimuli. Like panic patients, they manifest increased autonomic arousal, and those who go on to suffer PTSD after trauma may have had more frequent childhood history of behavioral problems as well.

### 3. Adjustment Disorder with Anxious Mood

This category, although not a DSM-III-R diagnosis, serves to describe the great number of patients who experience transient periods of pathological anxiety associated with interpersonal, occupational, or other upheavals in their lives. Symptoms are generally time-limited but may achieve sufficient intensity to require treatment.

## V. ANTIANXIETY AGENTS

The various anxiety syndromes are mainly treated with two general classes of medication: **antidepressants** (chiefly tricyclic antidepressants and monoamine oxidase inhibitors) and various **antianxiety agents**, most often the **benzodiazepines**. The antidepressant medications are discussed in detail in Chapter 2. The following section focuses primarily on the benzodiazepines. Other agents less commonly used to medicate anxiety are discussed at the end of this section. (See Table 4 and Section VI for a clinical discussion of how these drugs are used to medicate the subtypes of anxiety disorders.)

### A. Benzodiazepines

The popularity of this class of antianxiety drugs has generated such articles as "The Benzodiazepine Bonanza" and "Valiumania." From 1964 through 1973, the number of antianxiety drug prescriptions filled in United States drug stores increased dramatically. Most were for the benzodiazepines chlordiazepoxide (Librium<sup>®</sup> and others) and diazepam (Valium<sup>®</sup> and others). This trend did reverse, possibly because of adverse publicity among physicians and the lay public. Even with declining general use, over 60 million prescriptions for benzodiazepines were filled in the United States in 1979.<sup>10</sup> Fifteen percent of respondents to one U.S. survey reported using antianxiety agents in the 1970s—a figure comparable to that reported for other developed countries.<sup>11</sup>

Chlordiazepoxide, the first benzodiazepine antianxiety agent synthesized, was marketed in 1960. Three years afterwards, diazepam was introduced and rapidly became the most widely prescribed drug in the world. The popularity of these agents has spawned a number of chemical siblings.

In the following sections, we discuss the eight benzodiazepine drugs currently labeled for antianxiety use in the United States: chlordiazepoxide, clorazepate (Tranxene® and others), diazepam, lorazepam (Ativan® and others), oxazepam (Serax® and others), prazepam (Centrax® and others), halazepam (Paxipam®), and alprazolam (Xanax®). Two other benzodiazepines, flurazepam (Dalmane® and others) and temazepam (Restoril® and others), are marketed for insomnia. Clonazepam (Klonopin®), widely used for treating panic disorder, is labeled for the treatment of epilepsy. The labeled indication for benzodiazepine use (e.g., anxiety versus insomnia) probably has more to do with marketing decisions than with unique pharmacological profiles of the agents.

Benzodiazepines, as noted earlier, are the most widely prescribed antianxiety agents in the world. In fact, they are the most widely prescribed drugs of any type. Their popularity is generally deserved. Clinically, they are highly effective for alleviating acute anxiety, and, in most cases, they probably retain relative efficacy over time. Toxicologically, they are remarkably safe in situations of overdose, and their overall record of safety is unparalleled. Although they are by no means perfect (indeed, much of this chapter is devoted to caveats about their use), benzodiazepine drugs represent a definite step forward in the pharmacological treatment of anxiety.

## 1. Chemistry

Molecular structures of the eight benzodiazepines currently labeled for anxiolytic use are shown in Fig. 1. There are several subtypes of benzodiazepines with some differences in their pharmacology (see Table 2). Diazepam is a prototype of the 2-ketobenzodiazepines, whose other members include desmethyldiazepam (the active agent during administration of clorazepate, prazepam, and halazepam). These drugs are all biotransformed by hepatic oxidative reactions and have long elimination half-lives.

Oxazepam, lorazepam, and the hypnotic temazepam are 3-OH benzodiazepines. They are metabolized by conjugation and have short to intermediate half-lives. Alprazolam is a triazolobenzodiazepine, which also undergoes oxidation in the liver, but whose rate of elimination is considerably more rapid than that of the 2-ketobenzodiazepines. Chlordiazepoxide is chemically distinct but pharmacologically similar to the 2-keto drugs. Clonazepam is a 7-nitrobenzodiazepine, which has a distinct biotransformation.

## 2. Pharmacological Effects and Mechanism of Action

Benzodiazepines reduce the effects of anxietylike behavior in animals. For example, in a commonly employed behavioral paradigm, the presence of a light in a rat's cage is followed shortly by a painful electric shock. The animal soon learns the "meaning" of the light and, in its presence, manifests anxiety: shaking, tachycardia, crouching, urinating, and defecating. If he had previously been working on a task (e.g., pressing a bar to obtain food) in the presence of the light (i.e., the anxiety condition), he stops working and remains immobilized. However, administration of

FIGURE 1. Benzodiazepines for the treatment of anxiety.

a benzodiazepine would allow the animal to keep on working despite the anxiety-producing stimulus.

Benzodiazepines block nervous system stimulation that originates in the brain-stem reticular system and diminish activity in areas associated with emotion such as the septal region, amygdala, hippocampus, and hypothalamus. Benzodiazepines

**TABLE 2. Benzodiazepine Antianxiety Drugs**

Drug	Approximate dose equivalents (mg)	Available dosage forms	Rapidity of absorption	Active metabolites	Half-life (hr)
Alprazolam (Xanax®)	0.5	0.25-, 0.5-, and 1.0-mg tablets	Intermediate	α-Hydroxyalprazolam, desmethylalprazolam, 4-hydroxyalprazolam	6 to 20
Chlordiazepoxide (Librium® and others)	10	5-, 10-, 25-mg tablets and capsules, 100-mg/2-ml ampule	Intermediate	Desmethylchlordiazepoxide, demoxepam, desmethyldiazepam, oxazepam	5 to 30
Clorazepate (Tranxene®)	7.5	3.75-, 7.5-, and 15-mg capsules (Tranxene®)	Fast	Desmethyldiazepam, <sup>a</sup> oxazepam	30 to 200
Diazepam (Valium®)	5	2-, 5-, 10-mg tablets, 10-mg/2-ml ampules, 50-mg/10-ml vials, 10-mg/2-ml syringe	Fastest	Desmethyldiazepam, oxazepam	20 to 100
Halazepam (Paxipam®)	20	20-, 40-mg tablets	Intermediate	Desmethyldiazepam, oxazepam	Ca. 14 (parent), 50 to 100 desmethyl-diazepam
Lorazepam (Ativan®)	1	0.5-, 1-, 2-mg tablets, 2- and 4-mg/ml syringes, 2- and 4-mg/ml vials <sup>b</sup>	Intermediate	None	5 to 15
Oxazepam (Serax®)	15	10-, 15-, 30-mg capsules, 15-mg tablets	Slower	None	5 to 15
Prazepam (Centrax®)	10	5-, 10-mg capsules, 10-mg tablets	Slowest	Desmethyldiazepam, <sup>a</sup> oxazepam	30 to 200

<sup>a</sup> These drugs are pro drugs for desmethyldiazepam; the parent compound is rapidly converted to the active metabolite.

<sup>b</sup> As of this writing, approved by FDA only for preanesthetic use.

raise the seizure threshold and increase the frequency and activity of brain waves—effects that resemble those of other sedative-hypnotic drugs such as barbiturates.

In one experiment, a single dose of diazepam administered to a group of healthy volunteers impaired both immediate and delayed free recall by interfering with the acquisition of new information. Retention remained unaffected. After 3 weeks of diazepam administration, partial tolerance developed to the memory impairment, and 1 week following discontinuation of diazepam, memory returned to normal.<sup>12</sup>

The benzodiazepines' mechanism of action has not been completely elucidated. They interact with specific brain receptors, and they probably resemble an endogenous ligand to these receptors. Benzodiazepine receptors are located in areas of the brain that might explain some of the pharmacological activity of benzodiazepine drugs.<sup>13</sup> Benzodiazepine receptors in the limbic system (hippocampus and olfactory bulb) may mediate antianxiety effects; receptors in the cortex might explain anticonvulsant activity; and receptors in the thalamic nuclei could be involved in sedative effects. The interaction between drug and benzodiazepine receptor allows increased activity of the inhibitory neurotransmitter  $\gamma$ -aminobutyric acid (GABA).

Prolonged administration of benzodiazepine compounds may "turn off" the synthesis of endogenous benzodiazepinelike substances. Various withdrawal effects following drug discontinuation could, in turn, be caused by changes in receptors that follow long-term administration. The time required for recovery from benzodiazepine withdrawal symptoms would then reflect the time it takes either to regenerate an endogenous ligand or to reset receptor sensitivity.

The effects of benzodiazepines on the other organ systems show a strikingly benign pattern. Although decreased respiration, blood pressure, and cardiac output may be observed, they are unlikely to be of clinical consequence. In fact, clinicians have safely administered these drugs to large numbers of patients with disease of the heart, blood vessels, and lungs.

Diazepam, especially, produces significant skeletal muscle relaxation, probably by direct action on spinal neurons. Physicians have administered this drug to many patients with skeletal muscle spasm, spasticity, and other muscle disorders, although its efficacy remains to be proved beyond doubt.

### 3. Kinetics

The rate at which a drug is absorbed from the gastrointestinal tract determines to a large degree the rapidity of onset and intensity of its acute effects.<sup>14</sup> Among benzodiazepine compounds, the rate of absorption varies considerably (see Table 2). Thus, diazepam and clorazepate reach the blood rapidly and produce prompt and intense effects following a single oral dose: peak concentrations of diazepam may be reached within an hour (even more rapidly in children), which could account for occasional reports of euphoria with diazepam. On the other end of the absorption spectrum, prazepam (and, to a lesser degree, oxazepam) is more slowly absorbed.

resulting in a less intense and more delayed onset of action and side effects after single doses.

For any drug, absorption is most rapid when medication is taken on an empty stomach. Anything that delays gastric emptying, such as food or aluminum-containing antacids, will slow drug absorption, resulting in delayed onset and diminished intensity of acute clinical effects.

After a single dose of a benzodiazepine drug, its action is terminated primarily by drug distribution, which correlates with its lipid solubility. Thus, diazepam, the most lipid-soluble benzodiazepine, is rapidly and extensively distributed to body tissues following a single oral dose. Even though diazepam has a long elimination half-life, following a single dose its duration of action is relatively brief. Moreover, some degree of central nervous system tolerance also appears to diminish the initial action of the drug, even before blood levels have shown much decline. Less extensively distributed drugs, such as lorazepam, have a longer duration of action after a single dose, even though lorazepam's elimination half-life is much briefer than diazepam's.

Plasma concentrations of benzodiazepine drugs (and their active metabolites) probably correlate to some degree with clinical response, although this relationship is complicated by tolerance that develops within the central nervous system. At present, measurements of benzodiazepine concentrations in blood are not of general clinical use, although studies have correlated unwanted effects of these drugs with blood levels, which may provide clues to problems of overdose and withdrawal.<sup>15</sup>

Benzodiazepines bind tightly to plasma protein and are highly lipophilic, which means they are difficult to remove from the body by dialysis. They probably recirculate enterohepatically, which could account for an occasional secondary rise in blood levels several hours after the initial rise.

Benzodiazepines are metabolized in the hepatic microsomal enzyme system. Many are biotransformed into desmethyldiazepam—a major active metabolite of diazepam and halazepam and a metabolite of chlordiazepoxide. In addition, clorazepate and prazepam have little pharmacological activity themselves but serve as precursors for desmethyldiazepam. The conversion of clorazepate to desmethyldiazepam occurs rapidly but depends on an acid medium in the stomach, which is compromised by the presence of antacids or food. The transformation of prazepam to desmethyldiazepam occurs more slowly, accounting for the gradual onset of effects with that drug. The metabolic pathways that transform drugs to desmethyldiazepam are influenced by factors such as age, liver disease, or the coadministration of other drugs that may affect hepatic oxidizing activity.

Three benzodiazepines—oxazepam, lorazepam, and the hypnotic temazepam—have no active metabolites and are simply conjugated with glucuronide in the liver. The elimination half-lives of these compounds are in the short to intermediate range. Their metabolism is less affected by the presence of liver disease, the extremes of age, or drug interactions.

Of what use to a clinician is a drug's half-life? First, the half-life determines the time required to achieve a "steady-state" concentration, which occurs in about

four half-lives. (At steady state, the amount of drug excreted equals the amount ingested, i.e., a dynamic equilibrium.) Until a drug reaches steady state, it is accumulating, which means that the optimal dosage cannot yet be determined for a given patient. For example, an elderly woman in a nursing home may gradually become more sedated over the first several weeks on a chlordiazepoxide regimen. The drug is continuing to accumulate in her body until steady state is achieved, which may take longer in an elderly patient. For this reason, the clinician must be aware of this lag and adjust dosage accordingly.

A second significance of the half-life is with regard to the frequency of dosing. Drugs with half-lives greater than 24 hr often may be administered in once-daily doses, whereas drugs with short half-lives should be administered more frequently to achieve constant clinical effects. A third implication concerns the other end of the treatment program—termination. Drugs with long half-lives have more built-in tapering: when they are discontinued, their rates of egress from the body are relatively slow. Even so, all benzodiazepines should be discontinued by tapering rather than by abrupt discontinuation, but this is even more of a concern with short-half-life agents.

#### 4. Adverse Effects

The most common unwanted effects of the benzodiazepines (as for other central nervous system depressants) are drowsiness and ataxia, which acutely correlate with elevated blood concentrations of the drugs (and active metabolites). At even higher levels, gross psychomotor impairment and marked sedation occur. The elderly may be more vulnerable to these reactions because they usually achieve higher blood (and tissue) drug levels for a given dose and also because the aging brain is more sensitive to the effects of sedatives.

An increased tendency to express hostility, particularly in group settings, has been reported with diazepam, chlordiazepoxide, and alprazolam but may be less of a problem with oxazepam. Data on this point remain inconclusive,<sup>16</sup> but clinicians may wish to avoid high-potency benzodiazepines in patients who have trouble containing their anger. Occasional patients become depressed during chronic benzodiazepine therapy, but whether this is a causal association remains in doubt.

Aside from the effects noted above, adverse reactions with benzodiazepines tend to be uncommon and are rarely serious. Occasional patients experience increased appetite and weight gain, cutaneous (usually allergic) reactions, nausea, headache, and assorted endocrine changes. Rare reports describe agranulocytosis and cholestatic jaundice, but unusual events in association with drug therapy do not prove an association with the drug. A few investigators have raised the possibility of a relationship between diazepam use and mammary tumors in laboratory animals and in humans; however, a careful review of the data does not support a causal association.<sup>17</sup>

## 5. Toxicity

Probably the nicest feature about the benzodiazepines is their very high therapeutic index—the ratio of toxic to therapeutic doses. Although frequently ingested in overdose attempts, benzodiazepines alone almost never cause fatalities.<sup>18,19</sup> The combination of a benzodiazepine with alcohol or other sedative-hypnotic agents is more hazardous, although it is unclear whether or not the benzodiazepines actually contribute to the lethality of the combination.<sup>20</sup>

Whenever possible, the use of any drug during pregnancy should be avoided. Some but not all data suggest that benzodiazepines taken during the first trimester may cause an increased incidence of cleft lip/cleft palate. Used late in pregnancy or during nursing, benzodiazepines have been associated with a “floppy infant syndrome.” Other observations in infants whose mothers have taken benzodiazepines have included multiple congenital deformities, intrauterine growth retardation, withdrawal symptoms, neonatal depression with poor sucking and hypotonia, hyperbilirubinemia, hypothermia, increased carbon dioxide tension and acidosis, and cardiac arrhythmias (many of which may be coincidental)<sup>21</sup> (see Chapter 10).

## 6. Tolerance, Dependence, and Withdrawal Reactions

Benzodiazepine drugs have been sought out for “recreational” purposes, i.e., to induce a euphoric state, a “high.” Some may have a greater abuse potential than others, conceivably related to their pharmacokinetics (e.g., rapid absorption and onset of action). In general, given the extent of therapeutic use, however, the specific abuse of these drugs has been relatively rare. On the other hand, clinicians typically should not prescribe the benzodiazepines to patients with a history of substance abuse, particularly with sedative-hypnotics. Any suggestion that a patient is taking more of the drug than prescribed should be viewed with concern.

Benzodiazepine withdrawal leads to reactions similar to those observed with other sedative-hypnotic compounds (e.g., barbiturates, alcohol). Cross-tolerance exists among these various classes, and one agent usually can treat a withdrawal syndrome from another. In fact, benzodiazepines are frequently employed in treatment of alcohol-withdrawal syndromes.

We used to believe that withdrawal reactions to benzodiazepines were relatively rare and occurred only when the drugs were used in dosages considerably in excess of therapeutic recommendations. More recently, however, clinicians have observed that patients taking benzodiazepines for long periods of time—even at standard doses—are vulnerable to withdrawal reactions when the drug is abruptly discontinued (possibly because of a “turning off” of endogenous benzodiazepine substances)<sup>22</sup> and to withdrawal symptoms after discontinuing short-term use of some agents, such as alprazolam.

Mild withdrawal symptoms include insomnia, dizziness, headache, anorexia, vertigo, tinnitus, blurred vision, and shakiness. Some of these symptoms may

represent a recurrence of anxiety that had been contained by the benzodiazepine. However, if after discontinuing the drug these symptoms increase over several weeks and then begin to wane, a rebound or withdrawal reaction is more likely.

Severe signs of benzodiazepine withdrawal include hypotension, hyperthermia, neuromuscular irritability, psychosis, and seizures. Short-acting benzodiazepines, with their relatively rapid egress from the body, might cause a higher incidence of severe withdrawal reactions, including convulsions.

### Benzodiazepine Withdrawal Syndrome

Anxiety	Blurred vision
Agitation	Diarrhea
Tremulousness	Hypotension
Insomnia	Hyperthermia
Dizziness	Neuromuscular irritability
Headaches	Psychosis
Tinnitus	Seizures

### 7. Drug Interactions

Benzodiazepines interact with relatively few other drugs, so they can be coadministered safely with various medical and psychiatric medications. Benzodiazepines have relatively little tendency to induce hepatic microsomal enzymes, especially in comparison with barbiturates and other sedative-hypnotics, which means they usually can be administered to patients taking anticoagulants.

A common pharmacodynamic interaction (i.e., additive effects on target organs) is the **enhancement of central nervous system depression when a benzodiazepine is coadministered with another sedative, including alcohol**. It is doubtful whether coadministration of alcohol with diazepam can increase blood concentrations of diazepam (a pharmacokinetic interaction).

A handful of pharmacokinetic interactions involving benzodiazepines have been reported (see Table 3). In general, benzodiazepines that undergo conjugation as the only metabolic step in biotransformation (i.e., oxazepam, lorazepam, temazepam) have the fewest kinetic interactions. Diazepam increases plasma levels of the anticonvulsant phenytoin (Dilantin<sup>®</sup> and others) and of the cardiac drug digoxin (Lanoxin<sup>®</sup> and others). When disulfiram is coadministered with chlordiazepoxide and diazepam, blood levels of the benzodiazepines can rise. Antacids should not be administered at the same time as clorazepate, since they will diminish the biotransformation of clorazepate to the active compound desmethyldiazepam, thus reducing its potency. Antacids and foods slow the absorption of other benzodiazepines but do not diminish the total amount absorbed. Cimetidine (Tagamet<sup>®</sup>), used for the treatment of acid peptic disease, increases the blood levels of long-

TABLE 3. Benzodiazepine Interactions<sup>a</sup>

Diazepam (Valium®)	↑ Phenytoin (Dilantin® and others) levels
Diazepam	↑ Digoxin (Lanoxin® and others) levels
Disulfiram (Antabuse®)	↑ Chlordiazepoxide (Librium® and others, diazepam levels
Antacids	↓ Clorazepate (Tranxene®) absorption; slower chlordiazepoxide, diazepam absorption
Food	Slower diazepam absorption

Alcohol	? ↑ Diazepam levels; potentiates CNS-depressant effects

<sup>a</sup>From Gelenberg.<sup>23</sup>

acting benzodiazepines (e.g., diazepam, chlordiazepoxide, clorazepate, prazepam) but does not appear to affect the short-acting agents (e.g., lorazepam, oxazepam, temazepam).<sup>23</sup>

## 8. Nonpsychiatric Uses

Benzodiazepines have a number of uses outside of psychiatry: as anticonvulsants, for premedication before surgery and other procedures (such as cardioversion and endoscopy), in treatment of alcoholic withdrawal states, and as muscle relaxants in such diverse conditions as muscle strain, tetanus, spasticity, and stiff-man syndrome.

## B. Buspirone

In light of such evident benzodiazepine drawbacks as sedation, visual motor and memory effects, possible abuse, and discontinuation syndromes, there was considerable enthusiasm and eager anticipation for the new nonbenzodiazepine anxiolytic buspirone (BuSpar®). With a pharmacological profile quite different from other anxiolytic agents, this azaspirodecanedione is a lipophilic heterocyclic compound that lacks sedative, anticonvulsant, or muscle relaxant properties and thus has been deemed "anxioselective." Considerable research and clinical experience documents lack of abuse potential, and the drug has no significant interactions with either alcohol or other central nervous system depressants. The mechanism of action of buspirone does not appear to involve interaction with a benzodiazepine-GABA receptor. It does have a number of complex interactions with dopamine receptors, particularly presynaptic ones, as well as postsynaptic 5-HT<sub>1A</sub> (serotonin) receptors, for which it is a partial agonist. Despite its effects on dopamine receptors, it does not appear to be a neuroleptic or to have a neuroleptic side-effect and risks profile.

A considerable body of clinical trials indicates that buspirone's effectiveness is

comparable with that of benzodiazepines in the treatment of generalized anxiety.<sup>24</sup> There is some evidence that patients with prior treatment with benzodiazepines do rather less well with buspirone than treatment-naive patients.<sup>25</sup> Buspirone is available in 5-mg tablets, and the typical range of effective doses is between 5 mg t.i.d. and 15 mg t.i.d.

Despite reports to the contrary, many clinicians and patients have found buspirone to be a generally disappointing alternative to benzodiazepines. Ineffective in panic attacks, it has proven less than optimal in the treatment of many patients with generalized anxiety as well. Part of the explanation may be that the prescribing of buspirone requires a strategy similar to that of antidepressants, since there is a latency to respond of several days and, for individual patients, a critical dose threshold needed to achieve maximum benefit. Even with optimizing treatment by strategies of dose titration and sufficient duration of treatment, many patients still fail to show improvement. Nonetheless, some successes are achieved (some patients continued on benzodiazepines have improved or required lower doses of the benzodiazepine when buspirone was added). Given its several advantages, and despite uncertainties about general efficacy, a trial of buspirone is to be recommended for persistently anxious patients; for those who do respond to it, their course of treatment, and particularly their eventual discontinuation, may prove less complicated.

### C. Other Antianxiety Agents

With the availability of the benzodiazepines, most previously employed anti-anxiety drugs have become obsolete. However, there are times when a physician may seek an alternative, for instance, in a patient liable to substance abuse. In addition, a doctor may "inherit" a patient who is already taking another type of drug, and thus we should all have some familiarity with other antianxiety compounds.

#### 1. Antihistamines

Because of their sedative effects, drugs that block central and peripheral histamine receptors (primarily H<sub>1</sub>) have, largely in the past, been occasionally used to calm anxious patients. Of the antihistamine drugs, clinicians prescribe hydroxyzine (Atarax<sup>®</sup>, Vistaril<sup>®</sup>, and others) most often. As shown in Fig. 2, it is chemically unrelated to the antipsychotics, antidepressants, benzodiazepines, or meprobamate.

Data about hydroxyzine metabolism in man are sparse. Apparently the drug is rapidly absorbed, begins to act within 15 to 30 min after a single oral dose, reaches peak plasma levels within 1 hr, and maintains its effect for at least 24 hr. In addition to its sedative and antianxiety effects, hydroxyzine also possesses antiemetic and antihistaminic properties. It may be more sedating than the benzodiazepines, although in some patients it can cause agitation. Although not as effective an anxiolytic as the benzodiazepines, hydroxyzine does not cause physical dependence or abuse; therefore, it may be used as an alternative for patients prone to drug depen-

Phenobarbital

Hydroxyzine

Meprobamate

FIGURE 2. Other drugs used for the treatment of anxiety.

dence. Usual daily doses range from 200 to 400 mg per day in two to four divided doses, which can be administered intramuscularly as well as orally.

In addition to the treatment of anxiety, hydroxyzine has been used for motion sickness, as a preanesthetic medication, and to treat allergic dermatoses. It is not effective for treating alcohol withdrawal syndromes.

Fatal overdose is uncommon with hydroxyzine, and withdrawal reactions have

not been observed. Occasionally, cases of abnormal involuntary movements have been reported with antihistamines. Hydroxyzine may be teratogenic when administered to a pregnant woman, but this has not been studied definitively. Whereas benzodiazepines and most other sedative-hypnotic drugs elevate the seizure threshold, antihistamines depress the threshold and thus should be used with caution in patients with seizure disorders. Both peripheral and central anticholinergic toxicity can occur with antihistamine drugs; the elderly tend to be more sensitive to these actions. On a pharmacodynamic basis, hydroxyzine may show additive toxicity with other drugs that possess CNS-depressing antihistaminic or anticholinergic activity.

## 2. Barbiturates

The benzodiazepines, which have a much more favorable clinical profile, have largely replaced the formerly popular barbiturates for the treatment of anxiety. Barbiturates are classified according to their duration of action, speed of metabolic degradation, and hypnotic potency. Rapidly acting barbiturates are primarily inactivated through metabolism by the hepatic microsomal enzymes of the liver, whereas phenobarbital is eliminated largely unchanged by the kidney.

Barbiturates have a wide variety of effects on the body. They are CNS depressants and, in doses only several times greater than therapeutic, can depress the central respiratory drive. In toxic doses, barbiturates also depress cardiac contractility. Barbiturates interfere with the microsomal drug-metabolizing system in the liver and thus interact with various other drugs.

Barbiturates, most notably phenobarbital (Tedral® and others), probably have some degree of efficacy in the treatment of anxiety, but they seem to be less effective than the benzodiazepines and produce more sedation. It is likely that tolerance develops to antianxiety effects, which most probably result from their sedative activity. Clinical use of these agents is further complicated by the drugs' tendency to induce dependence, to cause serious withdrawal reactions, and to be dangerous in overdoses.

A barbiturate overdose can be extremely serious. Doses in excess of ten times a standard hypnotic dose are generally dangerous. Death occurs in approximately 0.5% to 12% of cases. Short-acting barbiturates are more toxic than the longer-acting agents: 2 to 3 g of amobarbital (Amytal® and others), secobarbital (Seconal®), or pentobarbital (Nembutal® and others) can cause death; in contrast, a lethal dose of the long-acting phenobarbital begins at about 6 to 10 g. Similarly, lethal blood concentrations may be 6 mg/100 ml for phenobarbital and barbital but only 1 mg/100 ml for shorter-acting agents. Obviously, the presence of alcohol or other central nervous system depressants can cause death at lower barbiturate concentrations.

Patients who are moderately intoxicated with barbiturates show central nervous system signs: nystagmus, slurred speech, sedation, and ataxia. More severe levels of intoxication can lead to coma, depressed reflexes, and diminished cardiac con-

tractility. Treatment consists of support of vital functions. Elimination of the drug may be hastened by the use of dialysis or hemoperfusion.

Adverse effects of barbiturates primarily reflect CNS depression. The dose necessary to affect respiration is not much higher than the therapeutic dosage, which gives these drugs a relatively low therapeutic index. Withdrawal reactions are similar to those described for the benzodiazepines but are likely to be much more severe, associated with a high incidence of seizures, and potentially fatal.

Aside from potentiating the sedative and CNS-depressing effects of other similar drugs, barbiturates can interact pharmacokinetically with many other agents, especially oral anticoagulants. **It is best to avoid coadministering barbiturates with anticoagulants**, but if it is unavoidable, the clinician should closely monitor the anticoagulant dosage and prothrombin time.

Barbiturates are contraindicated in patients with acute intermittent porphyria.

### 3. Propanediols

Meprobamate (Miltown® and others) and tybamate (no longer available in the United States), two propanediols, are labeled for use as antianxiety agents. Meprobamate was an extremely popular drug in the 1950s, but controlled studies have failed to demonstrate its superiority over the barbiturates for treating anxiety. For a vast majority of anxious patients, there is little reason to prescribe one of these drugs. Moreover, adverse effects, interactions, liability to abuse, and withdrawal syndromes resemble those observed with the barbiturates.

The structure of meprobamate is depicted in Fig. 2. The propanediols, similarly to the barbiturates, are metabolized mainly by hepatic microsomal oxidases and also induce these enzymes. The half-life of meprobamate is about 12 hr, and that of tybamate about half as long.

Pharmacological and clinical effects, toxicity, hazards, tolerance, withdrawal reactions, and interactions of meprobamate and tybamate are all similar to those of the barbiturates.

### 4. $\beta$ Blockers

Propranolol (Inderal® and others) block  $\beta$ -noradrenergic receptors in the peripheral sympathetic nervous system and probably centrally as well. Although some  $\beta$  blockers discriminate between  $\beta_1$  (cardiac) and  $\beta_2$  (pulmonary) receptors, propranolol blocks both receptors competitively and without discrimination. Propranolol's structure is depicted in Fig. 2. Propranolol is almost completely absorbed following oral administration, but only about one-third of the administered drug reaches the systemic circulation, largely because of extensive first-pass metabolism in the liver. As with most drugs, plasma concentrations after a given dose of the drug vary widely among different people. The acute half-life of propranolol is about 3 hr, but with chronic administration it increases to about 4 hr. The drug is largely bound to plasma protein, which may make total blood concentrations less reliable as

earlier, asthma is a contraindication to the use of this drug. Patients taking insulin for the control of diabetes may be more susceptible to hypoglycemia when they take propranolol. Other unwanted effects include nausea, vomiting, diarrhea and constipation, depression, delirium, psychosis, and allergic reactions.

### 5. Antipsychotic Drugs

At times, clinicians use antipsychotic drugs for the control of anxiety. However, phenothiazines and related compounds are generally less effective for treating anxiety than the benzodiazepines, and the former produce a wider range of more serious adverse reactions, particularly long-term neurological effects (namely, tardive dyskinesia). For these reasons, minimize the use of antipsychotic drugs to treat nonpsychotic anxiety. Occasionally, considerations of abuse, failure to achieve satisfactory response with benzodiazepines, or the presence of overwhelming anxiety (as in the borderline personality) may suggest the use of low doses of an antipsychotic drug. In such cases, the physician should administer the lowest effective dose for the shortest period of time, carefully monitor the patient, periodically reevaluate the dose, and use necessary precautions (see Chapter 4).

### D. Antidepressants

Although last in our list of available agents for treatment of chronic anxiety, antidepressant agents in general are an underutilized class of drugs for the treatment of persisting anxiety, even when not associated with depression (see Chapter 2). Failure to appreciate the possible efficacy of antidepressants, not just for panic attacks but also for generalized anxiety,<sup>26</sup> may result from the fact that these agents require adequate doses and duration of treatment, as in the treatment of depression. Although such anxiolytics as the benzodiazepines may demonstrate efficacy within the first few hours or days of dosing, antidepressants may require several days or weeks to be efficacious; thus, clinicians may have overlooked their usefulness when compared to the more rapidly acting alternatives. Nonetheless, where benzodiazepines and tricyclic antidepressants have been compared, by the end of 6 weeks, antidepressants are typically comparable in efficacy to the benzodiazepines (and may go on to offer greater improvement). For clinical settings where a clinician wishes to avoid the administration of a benzodiazepine, therapeutic trials of antidepressants may be worth considering.

## VI. PHARMACOTHERAPY OF ANXIETY

### A. Introduction

Of all the anxiolytic drugs we have just reviewed, the benzodiazepines are the most popular: they are both highly effective and have a broad margin of safety. The

and cognitive strategies will possibly be sufficient. Optimal results frequently call for a multimodal approach.

Reviewing alcohol or other substance use history is critical, as is a general review of systems and prescribed medications. Physical examination, laboratory assessments (which may include electrolytes, calcium, magnesium, as well as liver and thyroid function tests), and an electrocardiogram (EKG) are useful baseline measures.

### C. Discussing Treatment with the Patient

Once a decision is made to prescribe antianxiety medication, the physician should discuss the treatment plan and advise the patient about potential hazards such as possible problems driving, morning rebound or sedative carryover, and dangers of taking alcohol or other sedative-hypnotic drugs concomitantly. In addition, the clinician will want to suggest that prescription of an antianxiety agent is intended for a limited period of time and that the need for medication will be reevaluated regularly. Also, women who may become pregnant should be advised about potential hazards to the fetus.

### D. Panic Attacks

Although treatment of panic attacks early in the course of the disorder may prevent complications, many patients seek treatment after years of symptoms and disability. Even in the face of chronicity, however, most patients achieve substantial if not dramatic benefit with antipanic pharmacotherapy as well as behavioral and cognitive therapies. Given the apparent primacy of the panic attack in the distress and evolution of complications of panic disorder, one approach is to initiate antipanic medications for patients continuing to experience panic attacks, with the expectation of regression and remission of complications once the attacks have ceased. For patients with residual phobic avoidance despite prevention of panic attacks, behavioral and cognitive strategies are employed. (For some patients, behavioral and cognitive strategies are employed initially, especially when symptoms are limited to phobic situations and where the frequency and intensity of unexpected panic are minimal. Pharmacotherapy is subsequently applied if emergence or exacerbation of panic or depression attends the behavioral program.)

Imipramine (Tofranil® and others) has well-established efficacy in panic disorder,<sup>27</sup> usually in the same dosage range as for treatment of depression (150–300 mg/day), but some patients do well at lower doses.

Other tricyclic antidepressants are probably also effective [for example, desipramine (Norpramin® and others) is frequently employed to decrease the anticholinergic burden], but the drawbacks include delayed onset of benefit and treatment emergent adverse effects. In addition to such usual side effects as dry mouth,

possibility of early relapse upon discontinuation. The abuse potential of alprazolam may be similar to other benzodiazepines and varies widely among clinical populations. Most well-informed panic and agoraphobic patients who have endured severe distress over time treat their medication with respect and understand the wisdom in maintaining the lowest effective dose. Thus, unless there is evidence that a particular patient is more at risk for abuse, the use of this agent is usually safe for this disorder. As with any benzodiazepine, without controlled prescribing for targeted symptoms, inappropriate use may occur.

Because alprazolam is a relatively short-half-life and high-potency benzodiazepine, discontinuing treatment without a **very gradual taper** tailored to the individual patient's sensitivity to decreasing doses may be followed by rebound symptoms (worsened anxiety) or a withdrawal syndrome.

With these drawbacks in mind, some clinicians initiate treatment with alprazolam and a tricyclic antidepressant with the goal of tapering alprazolam early and continuing treatment with the antidepressant. Although the combination is certainly effective, there is no evidence that the discontinuation of alprazolam is facilitated by this strategy. For patients who require a high-potency benzodiazepine but suffer rebound symptoms, the longer-acting high-potency benzodiazepine clonazepam has proved effective.<sup>28</sup>

With milligram-for-milligram potency about twice that of alprazolam, clonazepam's usually effective dose range for panic patients is between 1 and 3 mg/day given in the morning and at bedtime. Sedation will be the limiting factor in dose titration and is managed by initiating treatment with a low bedtime dose and titrating upward if symptoms persist and as sedation resolves. Initial doses as low as 0.25 mg at bedtime may be used in drug-naïve patients or those particularly sensitive to benzodiazepines. Greater doses may be given at bedtime than in the morning to minimize sedation, but many patients function without sedation on equal a.m. and h.s. doses.

The effect of a given daily dose on panic attacks and generalized anxiety will be apparent within a few days. Some patients (fewer than 10%) develop depressive symptoms on clonazepam. Resolution of depressive symptoms typically occurs by lowering the dose or by introducing an antidepressant; clonazepam often can then be tapered with expectation of continued response to the antidepressant; combined treatment can be pursued if anxiety symptoms incompletely resolve with the antidepressant.

Despite the "pharmacological dissection" of anxiety neurosis into antidepressant-responsive panic disorder and benzodiazepine-responsive generalized anxiety disorder, increasing evidence suggests that a number of other benzodiazepines such as diazepam, clorazepate, and lorazepam also improve panic disorder. Whether their efficacy is indeed comparable to alprazolam and clonazepam is insufficiently studied; with a clearly effective shorter-acting alprazolam and longer-acting clonazepam, the need for additional antipanic benzodiazepines is not pressing.

A number of other agents have benefited some patients with panic disorder either alone or adjunctively with standard agents including  $\beta$  blockers, verapamil

qualone (no longer available in the United States) and others], the benzodiazepines are more selectively anxiolytic, with less sedation and less morbidity and mortality in overdose and acute withdrawal. Since using a benzodiazepine represents a clinical decision to offer symptomatic relief, it is critical to evaluate the patient's ability to function.

Ideally, benzodiazepine drugs should be administered for short-term use, typically around a period of stress, and always within the context of an ongoing therapeutic relationship. The physician should see the patient for a follow-up visit within a week or two to assess the patient's overall clinical status and response to the medication.

In the real world, however, many patients are on maintenance therapy and take benzodiazepines for months and even years. Is this ever justified, and, if so, what are the risks? To address the latter first, benzodiazepines carry a potential for dependence, abuse, and withdrawal reactions (although all are probably less severe than with other sedatives). Furthermore, the probability of withdrawal reactions (and perhaps the severity) increases with the chronicity of exposure. Also, in occasional patients, long-term use of benzodiazepines may produce chronic sedation and apathy (probably because of excessive levels). To avoid promoting abusive, overly long, and unsupervised use of these substances, physicians should not prescribe large quantities of benzodiazepine drugs or give multiple refills.

Despite our best intentions, however, some patients do take benzodiazepines chronically and function in a relatively stable manner. How does one identify these patients, and how should they be managed? The answer is: empirically. If a patient has been taking a benzodiazepine drug for weeks or a few months, the physician should attempt gradually to taper the agent. Even at low doses and with small decremental decreases, the patient may experience a reemergence of anxiety. The clinician's dilemma is to differentiate between rebound and relapse. If the patient is able to bear the distress, the clinician should recommend that the patient maintain the lower dose or the drug-free state for approximately 2-4 weeks. Some patients will become symptom-free before that time, suggesting that rebound or withdrawal effects accounted for the transient worsening. In other patients, symptoms emerging after tapering persist, suggesting continued need for the drug. If anxiety symptoms (not a withdrawal reaction) regularly reemerge when the dose is tapered, and the patient has not shown a tendency to abuse the drug (e.g., to get "high," to increase the dose beyond the physician's prescription), then the most prudent course may be to allow the patient to continue chronically with the medication. Of course, the clinician should attempt to taper the drug periodically, possibly every 6 to 12 months, to find the lowest effective dose that can control symptoms (see Table 4 for dosage recommendations).

Tolerance does develop to the sedative effects of benzodiazepines, but it is less clear whether tolerance develops to their sleep-maintaining and antianxiety effects. The benzodiazepines probably do retain at least a proportion of their efficacy over many months and possibly longer.

Physicians should advise all patients who are taking benzodiazepines to consult

4. If medication is indicated, discuss plans with the patient
  - a. Outline potential hazards (e.g., problems driving, hangover, additive effects with other drugs)
  - b. Propose a short-term trial of drug therapy
  - c. Discuss the need for periodic reevaluation
  - d. Outline the potential harm to the fetus for women of childbearing age
5. Prescribe short-acting agents in divided doses; long-acting agents may be administered once or twice a day
6. Give benzodiazepines in low doses initially (in small, nonrefillable prescriptions) and increase until
  - a. Anxiety is adequately contained
  - b. Significant adverse reactions (particularly drowsiness) occur
  - c. Recommended dose limits are reached
7. Discontinue drugs slowly (i.e., over several weeks—longer after prolonged therapy or with very high doses)
8. Consider nonbenzodiazepine antianxiety medications for patients who may abuse drugs
9. Only provide ongoing benzodiazepine therapy for patients who
  - a. Have significant anxiety without medication
  - b. Do not respond to other treatment measures
  - c. Do not show signs of abuse
10. Reevaluate drug use
  - a. When symptoms do not respond adequately to treatment
  - b. When the patient requests increasing doses or requires high doses or prolonged administration
  - c. When the period of acute stress passes or after several weeks of acute administration
  - d. Every few months in patients on chronic medication

## 2. Choosing a Specific Benzodiazepine

The choice of a specific benzodiazepine is usually not critical, since all are equally effective for generalized anxiety symptoms. However, the clinician should consider pharmacokinetic differences that may help tailor the drug to the patient and situation. For example, the rapidity with which a specific benzodiazepine is ab-

## Biological Factors in Obsessive-Compulsive Disorders

Samuel M. Turner, Deborah C. Beidel, and R. Swami Nathan  
Western Psychiatric Institute and Clinic, University of Pittsburgh School of Medicine

Biological variables in obsessive-compulsive disorder are reviewed. In several areas of inquiry, aberrations in obsessive-compulsive patients have been noted. Biological areas of inquiry include genetic, neuroanatomical, neurophysiological, neuropsychological, and biochemical factors. The available data at this time point to a chronic overaroused state in the obsessive-compulsive. However, they are too preliminary at this juncture to formulate one specific hypothesis. In addition, a diathesis-stress model is called for to accommodate the available data. Finally, it is suggested that the hypothesis of chronic overarousal implicated in this condition can serve a valuable heuristic function.

In recent years, there has been a reemergence of interest in biological approaches to psychopathology. This is particularly true with respect to schizophrenia and affective disorders. More recently, there has been increased interest in biological parameters associated with anxiety disorders, including obsessive-compulsive disorders (OCD). The purpose of this article is to review the major findings from genetic, neuroanatomical, neurophysiological, neuropsychological, and biochemical studies of OCD. Although these findings in many instances are rather disparate, they suggest intriguing possibilities, and some suggestions for future research are put forth.

Obsessive-compulsive disorder is a relatively rare, extremely debilitating condition which is highly refractory to treatment; see the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III; American Psychiatric Association [APA], 1980). The syndrome is manifested in cognitive and motoric components and may be accompanied by mood disorders such as anxiety and depression. The DSM-III (APA, 1980) definition of obsessive-compulsive disorder is:

---

The authors wish to express their appreciation to Rolf G. Jacob, Richard Stiller, and Ralph E. Tarter for their helpful comments on an earlier version of this article.

Requests for reprints should be sent to Samuel M. Turner, Western Psychiatric Institute and Clinic, University of Pittsburgh School of Medicine, 8311 O'Hara, Pittsburgh, PA 15213.

Obsessions are recurrent, persistent ideas, thoughts, images or impulses that are ego-dystonic; that is, they are not experienced as voluntarily produced, but rather as thoughts that invade consciousness and are experienced as senseless or repugnant. Attempts are made to ignore or suppress them. Compulsions are repetitive and seemingly purposeful behaviors that are performed according to certain rules or in a stereotyped fashion. The behavior is not an end in itself, but is designed to produce or prevent some future event or situation. (p. 234)

Salzman and Thaler (1981) noted several consistent characteristics of the disorder: (a) thoughts or actions over which an individual believes there is a lack of voluntary control; (b) the presence of anxiety due to the ego-dystonic nature of the thoughts; and (c) knowledge that the thoughts and actions are senseless and unreasonable, which nevertheless does not alter the need to perform the compulsive acts.

Obsessions are intrusive and unwanted thoughts, and the content is usually senseless and/or repulsive. Fears include worry over germs or contamination, over contracting an illness such as cancer, or about being responsible for someone's death or injury. Compulsions are repetitive, excessive, and unnecessary overt acts, which are the result of strong subjective urges, although strictly speaking the behaviors are under the individual's voluntary control. Two common forms of compulsions are excessive checking (e.g., oven gas jets, windows and locks, personal articles) and cleaning or washing of one's person or domicile (Turner & Michelson, 1984). Some individuals experience cognitive rituals (SturGIS & Meyer, 1981), in which a discrete

number of steps must be performed for the act to be successfully completed. If there is any deviation, the individual must begin the sequence again. An example of a cognitive ritual would be the recitation of a series of statements or numbers. Regardless of form, rituals usually serve an anxiety-reducing function. In addition, obsessive-compulsives sometimes attribute magical qualities to their rituals, thinking the rituals have the power to ward off undesirable events. The compulsions can become so overwhelming that other activities become restricted because of time spent engaged in the compulsive behavior. In addition, family members are often drawn into the rituals and must likewise perform certain circumscribed acts. The course of obsessive-compulsive disorder is considered chronic with periodic exacerbation and diminution of the symptoms (DSM-III; APA, 1980).

#### Epidemiology

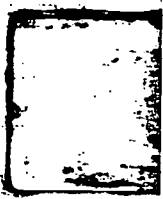

As is the case for all of the anxiety disorders, extensive epidemiological data are not available for obsessive-compulsive disorder. Thus, we know little about its incidence and prevalence or cultural patterns. As noted, obsessive-compulsive disorder is rare; it is estimated to affect 3% of the neurotic population or 0.05% of the general population (Sturgis & Meyer, 1981). Onset usually occurs in early adulthood (DSM-III; APA, 1980), and social behavior may be markedly impaired. Obsessives are reported to have celibacy rates as high as 72% (Coryell, 1981), to marry later, and to have lower rates of fertility (Turner & Michelson, 1984). Similarly, other epidemiological investigations (deSilva, Rachman, & Seligman, 1977; Hare, Rice, & Slater, 1971) reported high celibacy rates, particularly among men; they suggested this is proportional to severity of the illness. This pattern may be related either to specific obsessions (fear of contamination or infection) or to social isolation accompanying the secretive nature of the disorder and the restrictive rituals. Also, this pattern may be specific to Western cultures. Akhtar (1978) investigated marriage, celibacy, and fertility patterns in a sample of Indian obsessive-compulsive patients. In comparison with Indians suffering

from generalized anxiety disorder and with obsessionals from other countries, the Indian obsessionals demonstrated lower rates of bachelorhood and celibacy. The obsessionals reported higher fertility rates than either comparison group. Akhtar attributed this discrepancy to the cultural demands and social taboos in India and the obsessional's inability to resist the pressures of conformity.

#### *Relation to Other Psychiatric Disorders*

Obsessive-compulsive symptoms are often found in other psychiatric conditions. The disorders known to have obsessional features are Lesch-Nyhaus Syndrome, anorexia nervosa, mental retardation, organic brain syndrome, epilepsy, head trauma, Parkinson's Disease, depression, schizophrenia, and Tourette's Syndrome. This list indicates there are a number of disorders with obsessional features similar to those found in obsessive-compulsive disorders. Moreover, a number of biological hypotheses regarding etiology of these disorders have been postulated, suggesting OCD might also have biological underpinnings. Before discussing biological abnormalities in OCD, we present evidence for the similarities of the symptom features between these disorders and OCD. In a later section, we evaluate the evidence for a shared biological base between these disorders and OCD where there has been sufficient research.

Schizophrenics often experience delusional thoughts and hallucinations that may be considered obsessional. For the most part, these are easily distinguishable, because the schizophrenic does not believe these thoughts are senseless and therefore they are not experienced as ego-dystonic (DSM-III; APA, 1980). Individuals who experience closed head injuries are sometimes reported to develop ritualistic or stereotypic behavior that may resemble compulsions. In these cases, the ritualistic behavior of the organically impaired group is more likely the result of impaired cognitive processes that prevent integration of new learning or the ability to vary performance on a particular task. On a clinical basis, the stereotypic behaviors do not appear to serve an anxiety-reducing function, nor do they appear to be purposeful in any fashion

as in the case of obsessive-compulsive behavior. Moreover, organically impaired individuals do not appear to experience such behavior as being problematic (Turner & Michelson, 1984).

The existence of obsessive-compulsive symptoms in Tourette's disorder is striking, and this has been suggested as supporting a link between the two conditions (Elkins, Rapoport, & Lipsky, 1980). Various reports in the literature have indicated that obsessive-compulsive symptoms occur in the range of 33% to 89% of patients diagnosed as suffering from Tourette's syndrome (Cohen, Detlor, Young, & Shaywitz, 1980; Nee, Caine, Polinsky, Eldridge, & Ebert, 1980; Yaryura-Tobias, 1977). Additionally, obsessive-compulsive symptoms often appear in first-degree relatives of patients with Tourette's disorder (Montgomery, Clayton, & Friedhoff, 1982). In both disorders there are motoric manifestations. The behaviors are quite different, however. In Tourette's disorder, the uncontrollable behaviors consist of circumscribed body movements such as tics, extremity jerks, or involuntary vocalizations such as barks or grunts. This differs from OCD patients in two ways: First, the behaviors of the OCD patient are not limited to specific body movements and tend to be related to specific obsessive ideation. Further, rituals in OCD patients may be strictly cognitive. Second, rituals seen in OCD serve a purpose (e.g., compulsive handwashing prevents the possibility of infection). Nevertheless, the high percentage of Tourette's individuals who suffer concomitant OCD symptomatology is important in view of the proposed neurochemical aberration in Tourette's disorder. Pharmacological interventions such as L-dopa can precipitate Tourette's (Feinberg & Carroll, 1979), and some neuroleptics (such as Haloperidol) improve the condition, presumably by blocking dopamine receptors (Shapiro, Shapiro, Bruun, & Sweet, 1978). Because L-dopa and Haloperidol affect dopamine levels in the brain, and Tourette's syndrome patients and OCD patients have a number of similarities, the question arises as to the relation of the neurotransmitter dopamine in these disorders. We discuss the possible role of dopamine in OCD in a later section.

There is considerable evidence of an association between OCD and depression (Turner & Michelson, 1984). A significant proportion of individuals experience both disorders simultaneously. Gittelson (1966) reviewed the case histories of 398 patients with a diagnosis of psychotic depression. Thirty-one percent of the cases exhibited obsessional thoughts during the depressive episode. Kendal and Discipio (1970) reported high scores on the Leyton Obsessional Inventory for patients during a depressive episode. Interestingly, these scores were not substantially reduced after recovery from the depressive disorder. In addition, these authors reported that patients with obsessional personality features prior to a depressive episode were more likely to manifest obsessional thoughts during their illness. As further support that there is some overlap in these conditions, the incidence of depressive symptoms in OCD has been reported to range from 17% to 35% (Vaughn, 1976) to 34% (Sturgis & Meyer, 1981) to 66% (Solyom, Zamanyadeh, Ledwich, & Kenny, 1971). In a more recent study, Turner (1984) reported that 79% of a sample of 43 OCD patients requesting outpatient treatment in the Anxiety Disorders Clinic at Western Psychiatric Institute and Clinic over a 2-year period scored 17 or above on the Beck Depression Inventory, indicating a significant degree of depression. In a sample of 22 obsessive-compulsives, 91% scored a *t* score of 70 or above on the MMPI Depression scale. Thus, it is clear that depressive symptoms are part of the clinical picture in many OCD cases.

Because some level of depression often accompanies OCD, determining a primary diagnosis is sometimes difficult. One method used is to establish an etiological time line for the two disorders. In most OCD cases, patients report the appearance of depressive symptomatology after the onset of OCD (Sturgis & Meyer, 1981). Rachman and Hodgson (1980) reported that although 55% of their patients did not feel depressed at the onset of their obsessive-compulsive behaviors, there were many cases of secondary depression over the course of the illness. Similarly, Welner, Reich, Robins, Fishman, and Van Doren (1976) found that the pattern of OCD fol-

lowed by depression was three times as likely to occur as that of an initial depression followed by OCD. Insel, Kalin, Guttmacher, Cohen, and Murphy (1982) reported the case of a woman diagnosed as OCD who, 3 months after onset of the disorder, developed depressive symptoms. Twelve years before, this woman had suffered a major depressive disorder unaccompanied by obsessive-compulsive symptoms. The woman was able to differentiate the two depressive episodes by describing the depressive feelings accompanying her OCD as being entirely different from the subjective quality of "being totally blue" that she experienced as part of her major depressive episode. Although speculation on the link between OCD and depression has existed for some time, it is clear that both conditions can and do occur independently. This example seems to indicate that a patient can discriminate depression associated with OCD from a separate depressive illness. However, the covariation of the symptom picture, and the hypothesized involvement of similar neurotransmitters in both conditions, make this a fertile area for further inquiry.

#### Genetic and Family Studies

As early as 1868, Griesinger reported obsessional symptoms in relatives of obsessive-compulsive patients (Inouye, 1972). The difficulty in determining a genetic or biological predisposition for OCD is similar to that for other psychiatric disorders. It is necessary to control or determine the influence of environmental factors.

Investigators examining genetic predisposition in OCD have used two major approaches: Family studies and twin studies. A major difficulty in all of these studies is the lack of consistent diagnosis of the disorder. Inouye (1965) described four pairs of twins in which the index cases were diagnosed as obsessive-compulsive disorder. The behaviors exhibited by one male proband included tics, uncontrollable yelling and blinking, and feeling compelled to stick needles into his body. These behaviors were first observed to have occurred at the age of 7. The behaviors of a second proband began at the age of 9 and included tics, coprolalia, grimacing, yelling,

and moving of extremities. Using DSM-III criteria, both of these cases would appear to be consistent with a diagnosis of Tourette's Syndrome rather than OCD. Similarly, Tarsh (1978) described a pair of dizygotic twins in which one twin exhibited symptoms specifically about her body weight. She felt she was grossly overweight, which was factually incorrect. She worried constantly about her weight and refused to be weighed. In addition, she reportedly spent a great deal of time standing in front of a mirror counting her ribs. Although no information about actual weight loss was provided, the symptom pattern is suggestive of an eating disorder, perhaps anorexia nervosa, rather than obsessive-compulsive disorder.

Thus, in reviewing the genetic and family studies, clear determination of the diagnosis of OCD is somewhat difficult. Similar difficulties arise in determining whether relatives have obsessive-compulsive disorder or compulsive personality traits. Certain individuals may exhibit behaviors resembling symptoms of obsessive-compulsive disorder. However, they do not manifest true obsessions and compulsions. Rather they are perfectionistic and preoccupied with trivial details, rules, and order; they lack the ability to express warm and tender emotions; they insist that others submit to their way of doing things; they are excessively devoted to work and productivity; and they are indecisive (DSM-III; APA, 1980). The similarities between obsessive-compulsive disorder and the compulsive personality style are such that it may, at times, be difficult to clearly differentiate the two conditions. Therefore, concordance rates may vary dependent upon the definition used (Carey & Gottesman, 1981). Finally, most information has been gathered from case records rather than actual interviews with the probands and relatives. With these precautions in mind, evidence for a genetic basis in OCD is presented.

In one recent study of family patterns of OCD symptomatology, 27 patients with obsessive-compulsive disorder and their biological parents were interviewed (Insel, Hoover, & Murphy, 1983). The patients did not report any OCD symptoms in their parents. One proband, however, did report 2 son who had

Table 1  
*Incidence of Concordance for MZ and DZ Twins for Proband Diagnosed as Obsessive-Compulsive Disorder*

Study	Monozygotic		Dizygotic	
	Concordant	Discordant	Concordant	Discordant
Inouye (1965)	8	2	2	2
Inouye (1972)	27	8	0	7
Tarsh (1978)	0	0	1	0
McGuffin & Mawson (1980)	2	0	0	0
Carey & Gottesman (1981)	5	10	1	14

*Note.* Inouye (1972) is a compilation of 15 studies of incidence of obsessive-compulsive disorder in twins.

compulsive checking behavior. Additionally, there was evidence of affective and depressive spectrum disorder in a subset of the parents. A second method of assessing OCD was the administration of the Leyton Obsessional Inventory to a subset of 10 patients' parents. Three of the 20 parents (2 parents for each patient) who completed the inventory scored more than two standard deviations above the mean. These parents appeared to have obsessional features without the corresponding resistance and interference noted in OCD patients. In effect, while exhibiting similar behaviors, the parents did not view their own behavior as maladaptive or interfering in their daily lives. The authors suggested that obsessional behavior could represent an inheritable "obsessional factor" which under certain environmental conditions might be manifested in symptomatic behavior.

Carey and Gottesman (1981) examined family patterns in relatives of OCD patients. They reported 6.2% of parents, 3.2% of siblings, and 6.2% of the children of index cases suffered an identifiable obsessive-compulsive illness, whereas 8.3% of parents, 6.4% of siblings, and 9.3% of children had obsessional features to their personalities. Although these incidence rates are higher than those found in the general population, such family studies do not rule out the effects of modeling or other psychological factors in the development of the disorder. The stronger weight given to twin studies over family incidence reports rests on the assumption that the environment affects twins equally; therefore, different concordance rates for MZ and DZ twins should reflect genetic inheritance. In evaluating concordance, rates must be compared with that

produced by chance alone. Marks, Crowe, Drewe, Young, and Dewhurst (1969) calculated the chance concordance rate for OCD in MZ twins as follows: Accepting the .05% frequency of OCD in the general population and the estimate that 1 in 200 adults is an identical twin, then 1 in 400,000 could be expected to be a MZ twin with OCD. Thus, 1 in 800 million would be the expected probability of a pair of MZ twins with the same disorder. In fact, the concordance rate for OCD far exceeds this chance probability. The incidence of concordance and discordance for MZ and DZ twins in which the proband is diagnosed as OCD is presented in Table 1.

In a review of 15 early studies of incidence of OCD in twins, Inouye (1972) reported 27 MZ pairs concordant and 8 pairs discordant for OCD, whereas for DZ twins the rates were zero concordant and 7 discordant pairs. However, due to discrepancies in diagnoses and brevity of some of the case records, caution is advised in interpreting these data.

Carey and Gottesman (1981) reported a high concordance rate for OCD in monozygotic twins. The investigators reviewed 30 years of hospital case records (1948-1979) at the Maudsley and Bethlehem hospitals in England, selecting individuals who upon admission were diagnosed as obsessional neurosis or phobic neurosis. Fifty one twin probands (30 obsessional and 21 phobic), their twins, and their first-degree relatives agreed to personal interviews. All probands in the sample met DSM-III criteria for obsessive-compulsive disorder or phobic disorder. The interview included developmental and marital history, psychiatric status as measured by the

Present State Examination, the Leyton Obsessional Inventory, and a list of 20 common phobias. Two types of concordance rates were reported: Concordance for a twin receiving treatment for OCD and concordance for obsessional symptomatology with or without concomitant treatment. Concordance rates for those twins receiving treatment were 33% for MZ twins and 7% for DZ twins. For obsessional behaviors with or without treatment, the rates were 87% and 47%, respectively. This study also used a comparison group of unspecified phobic probands and established concordance rates in the twins for this disorder. Rates for the phobic twin receiving treatment was 13% for MZ and 8% for DZ twins.

There are no adoptive studies for OCD similar to those used in examining biological components of schizophrenia and affective disorders (Carey & Gottesman, 1981). However, McGuffin and Mawson (1980) described two pairs of MZ twins concordant for OCD but who had been separated for several years prior to onset of the disorder. In addition, each twin did not have knowledge of the other's illness prior to development of their own symptoms. Despite this separation, there was a remarkable similarity in symptoms within each pair. In view of their separation before symptom onset, this report is significant in that obsessive-compulsive behavior in each twin cannot be attributed to modeling or other psychological processes.

It appears that the higher concordance rate in MZ twins would implicate more than environmental factors in the development of OCD (Carey & Gottesman, 1981). However, it is also clear that there is little evidence for a Mendelian or sex-linked transmission. Therefore, one might postulate decreased gene penetrance (McGuffin & Mawson, 1980) or a vulnerability model in which, given a sufficient level, environmental stressors would combine with a genetic predisposition to precipitate the disorder. There is need for further research, however, before any definitive conclusions regarding genetic hypotheses or a vulnerability model can be reached.

In addition to genetic predisposition, Snowdon (1979) observed that mean family size of obsessionals is smaller than for a matched group of controls. This is apparently

due to the tendency for some obsessive-compulsives to engage in low-frequency sexual contact, probably due to contamination fears. If obsessional symptoms do in fact run in families, this could explain lower fertility rates noted in families of individuals with OCD.

In determining evidence for a genetic basis in a disorder, gene linkage and genetic marker studies are often useful in postulating the location of the gene on a particular chromosome. *Linkage* is a term used to suggest that the gene alleles of two specific conditions may be found on the same chromosome. Suggestion of gene linkage is based on a high degree of covariance in phenotypic expression of two conditions. If the two conditions do covary, and the location of one of the alleles is known, one type of gene linkage would suggest that the loci of the second phenotypic condition is on the same chromosome. Thus, the particular site of an abnormality is identified. For example, the gene for a certain type of bipolar depressive condition has been posited to be located on the X chromosome between the locations for Xg blood group and certain forms of color blindness (Depue & Monroe, 1978). These conditions appear in tandem with bipolar affective states. An investigation of blood types and anancastic (obsessive) symptoms (Rinieris, Stefanis, Ravavilas, & Vaidakis, 1978) produced evidence of a significant association between blood group phenotype A and obsessional behavior. Patients with OCD had a significantly higher incidence of type A ( $p < .001$ ) and a significantly lower incidence of type O ( $p < .01$ ) than the general population. Depressives free of anancastic symptoms also demonstrated differences from normals, having a lower incidence of blood type A ( $p < .05$ ) and a higher incidence of blood type O ( $p < .05$ ). In comparison, schizophrenics and depressives with anancastic symptomatology did not differ from normal controls in incidence of blood type. One might hypothesize a continuum based on anancastic symptoms with phenotype A and identifiable OCD at one extreme, obsessional symptoms in depression and schizophrenia and perhaps decreased gene penetrance at the center, and depressive disorders without anancastic characteristics and a higher incidence of blood type O at the

other end. Although reminiscent of the bipolar linkage studies, the research in OCD is at a comparatively crude stage, and any conclusions drawn must be regarded as tenuous.

In summary, the studies reviewed thus far present some basis for hypothesizing a biological predisposition for the development of OCD. This predisposition may take the form of a genetic aberration or some type of structural weakness. The lack of adoption studies, however, makes it difficult to evaluate the impact of the environment in the development of the disorder. In addition, the rare occurrence of the disorder has no doubt prevented the large-scale investigations necessary to provide confirmation of these suppositions.

#### Neurophysiological and Neuropsychological Studies

##### *Evoked Potential Studies*

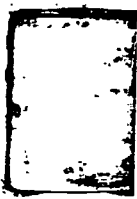

In an effort to establish neurophysiological correlates of OCD, Ciesielski, Beech, and Gordon (1981) recorded average evoked potentials on three types of visual stimulation tasks for a group of obsessional patients and a matched group of nonpsychiatric controls. They postulated that an abnormality of the central nervous system (CNS), leading to more rapid and fixed learning than considered normal, may explain the rigidity of behavior often seen in OCD. The OCD patients did not experiment with various response strategies as did nonpsychiatric controls. The authors suggested that instability in the arousal system could affect learning in this way, but they did not propose a specific anatomical site responsible for this instability. It is important to note, however, that this rigid style is characteristic of OCD patients and may be a result of the disorder, and not necessarily an antecedent. Variation in information processing was demonstrated in the obsessive group but only when the stimulus was complex (e.g., a patterned stimulation as opposed to a flash projection). The OCD group exhibited smaller amplitude of evoked potentials (EPs) and shorter latencies in pattern discrimination. This coincides with the findings of other investigators who have suggested that the nature of the OCD abnormality stems from an ability to become aroused in re-

sponse to low levels of stimulation (e.g., Beech, 1971). As a possible explanation for this increased arousal potential, Ciesielski et al. (1981) suggested that the faster latencies observed in the OCD group could reflect an abnormality of neurotransmitter inhibitory processes.

A follow-up investigation (Beech, Ciesielski, & Gordon, 1983) with 16 subjects—8 OCD patients and 8 controls—essentially confirmed the earlier Ciesielski et al. (1981) report. Obsessionals had shorter latencies and smaller amplitudes than normals, and this difference became more apparent as task difficulty increased. This study presents findings contradictory to Beech's (1971) suggestion of enhanced arousal in OCD because increased arousal should result in higher peak amplitudes. In addition, a theory of reduced inhibition as a basis of OCD based solely on evoked potentials is somewhat speculative as differences in information processing have been demonstrated in other psychiatric disorders (cf. Spring & Zubin, 1978). It is unclear at this juncture if the EP differences noted in this study can be attributed to some type of generalized deficit associated with the psychopathological state in general.

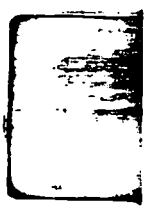

##### *EEG Studies*

The results of several studies have suggested cerebral dysfunction in anxiety-disorder patients based on electroencephalogram (EEG) recordings. In an early study, using a mixed group of anxiety patients, Crighel and Solomonovici (1968) reported EEG abnormalities in two groups of psychiatric patients, the first suffering from neurasthenia and the second group of neurotic patients also evidencing symptoms of anxiety and/or depression. Patients in the second group evidenced a significantly higher number of recordings characterized as containing EEG alterations. The abnormalities were of two types: (a) alterations of the temporal leads either unilaterally on the left side or bilaterally or (b) temporal spikes in addition to a fast and ample rhythm. The authors observed that these abnormalities usually indicate overexcitability of the temporo-amygdala complex. Because this complex is integral in the regulation of emotional behavior, abnormalities are likely to be re-

flected in altered mood states. Thus, one might expect the anxiety disorders (including OCD) to show the same pattern of abnormality. Further studies using EEG technology could help to clarify the role of the temporamygdala complex in OCD as well as all of the anxiety disorders.

In contrast to the previously mentioned study, which sampled patients with unspecified anxiety symptoms, others have restricted their investigations to EEG patterns in OCD patients. Epstein and Bailine (1971) described the sleep EEG patterns of three obsessionals, noting that abnormalities in the form of theta waves and spiking were localized to the temporal region and were similar to patterns of temporal lobe epileptics, again implicating possible amygdala or limbic dysfunction. Further, the authors suggested that these similarities may be reflected in the abnormal behavior patterns evidenced in each group (i.e., the stereotyped repetitive behavior seen in psychomotor epilepsy and the rituals of the obsessive-compulsive patient). Additionally, the authors hypothesized that dream imagery may be similar to obsessional symptomatology, as dreams are not felt to be under conscious control. However, in this assessment, dream imagery was unrelated to obsessional ideation. Therefore, it appears that a waking state is necessary for appearance of OCD symptoms. The authors suggested that while a waking state is necessary, it may not be identical to a normal waking state. An alteration in arousal mechanisms, creating an altered waking state, might allow the release of normally inhibited ideas or behaviors manifesting in forced, uncontrollable thoughts. This study is limited by the small sample size, and thus conclusions drawn from these data must be regarded as tenuous, but they do suggest that EEG technology might be useful in exploring brain functioning in OCD patients.

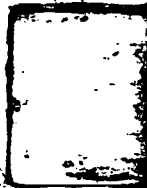

Flor-Henry, Yeudall, Koles, and Howarth (1979) studied 11 OCD and 11 control patients, recording EEG levels during resting periods and two cognitive tasks. The subjects also participated in neuropsychological testing. Unlike the results of other studies (Crighel & Solomonovici, 1968; Epstein & Bailine, 1971), there were no statistically significant differences in EEG recordings between groups

other than reduced left-temporal variability in OCD patients during the resting situation. Neuropsychological testing was consistent with a dominant frontal lobe dysfunction in 10 of the 11 patients. However, this study is subject to major methodological difficulties. Control subjects were not recruited for this particular study. Rather, hospital case records were reviewed and patients were matched on the variables of age, education, and full-scale IQ. No further description of the control group was provided. Thus, it is unknown if the control group comprised normal individuals or a group of psychiatric patients. If it was the latter, the control group's neuropsychological performance might not be representative of that of a nonpsychiatric sample. Also, although there were significant differences between groups on some of the neuropsychological variables, results were not consistent within the obsessive group and therefore cannot be considered characteristic of the entire sample.

In summary, the previously mentioned studies present some evidence for abnormal EEG patterns in obsessive-compulsive patients. The abnormalities are inconsistent and do not present a clear indication of the location of the disturbance. Several authors hypothesized that overarousal (Crighel & Solomonovici, 1968) or altered waking states (Epstein & Bailine, 1971) may be a contributory factor in the disorder. Such disturbances might implicate a dysfunction in one of the known arousal systems, although mere overactivity cannot explain the primary OCD behavior. However, a chronic state of overarousal might well leave one more vulnerable to the development of OCD. Therefore, the overarousal hypothesis is worthy of further study, and EEG technology is one way this might be done.

#### Neuroanatomical Studies

Although twin studies and diffuse EEG abnormalities provide some evidence for a genetic or biological predisposition for OCD, such hypotheses are limited as they do not specify an anatomical site that might be implicated in the disorder. In comparison with OCD, the etiology of several of the disorders previously listed (epilepsy, head

trauma, organic brain syndrome, and Parkinson's Disease) which also have some characteristics similar to OCD, can be associated with the malfunction of specific neuroanatomical regions. The association of brain region to disorder is clearest in the case of Parkinson's Disease, where the basal ganglia have been identified as the malfunctioning anatomical site. Certain forms of epilepsy, in particular temporal lobe epilepsy, or psychomotor epilepsy, are associated with seizure foci in the temporal lobe. In each of these disorders, the symptoms include motoric stereotypy and repetition that resembles the repetitive, ritualistic acts of the obsessive-compulsive. There is some indirect evidence from the animal literature relating OCD-like behaviors to specific areas of the brain. Pitman (1982) provided the following case description of a hippocampectomized rat.

He is remarkable for his intense and rigid behavior, which others find difficult to modify. . . . At work on a task, he often overdoes it and persists beyond the point at which others would give up. His behavior is sometimes quite peculiar in that he engages in odd rituals, which bear no relation to the task at hand. These [behaviors] often appear superstitious. (p. 139)

Pitman (1982) noted the behavior of these rats with damaged limbic structures was similar to the behavioral style characteristic of OCD patients.

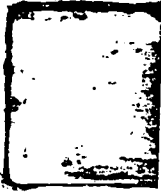

Similar behavior in rats with hippocampal lesions has been reported by Devenport, Devenport, and Holloway (1981) and Morris, Garrud, Rawlins, and O'Keefe (1982). Thus, these data suggest a starting place in the search for a specific CNS site which may be involved in the disorder. In addition, hypotheses of neurophysiological dysfunction have been suggested as a means of explaining some of the more puzzling aspects of OCD, including the observation that performance of the rituals sometimes serves to increase rather than decrease anxiety (Turner & Michelson, 1984) or why alterations in mood rather than environmental events seem to precipitate the behavior (Ciesielski et al., 1981).

#### *Leucotomies*

The rationale for the use of psychosurgery to alleviate OCD evolved from animal studies

in which bilateral frontal lobe ablations in chimpanzees resulted in decreases in levels of experimentally induced anxiety and frustration (Kelly, 1973). Spurred by these reports, Moniz (1936, cited in Kelly, 1973) suggested that similar psychosurgical procedures could be effective in patients exhibiting anxiety and obsessions. In further support of the importance of the cingulate regions, it has been reported that anterior capsulotomy (involving the cingulate region) was useful in relieving symptoms of OCD (Fodstad, Strandman, Karlsson, & West, 1982). The limbic system, long acknowledged as an anatomical site for emotional behavior (Papez, 1937), has been the target of surgical intervention in the treatment of OCD. The object of leucotomy operations has been to disconnect the orbital and medial frontal cortex from the limbic circuit (Kelly, 1973). Although early leucotomies were performed without much regard for precise anatomical location, later efforts were targeted at the lower medial quadrant of the frontal lobes, orbital convexity, and cingulate gyri. Kelly (1973) reported 17 cases of obsessional neurosis treated by limbic leucotomy. Seventy-five percent were reported as much improved or improved 6 weeks after their operations. Self-report measures used to assess psychological changes included the Maudsley Personality Inventory, the Beck Depression Inventory, the Hamilton Depression Scale, the Taylor Manifest Anxiety Scale, and the Middlesex Hospital Questionnaire. Following the surgery, decreases were reported in neuroticism, depression, anxiety, and obsessions. There were concomitant decreases in physiological arousal evidenced by a reduction in forearm blood flow, heart rate, and blood pressure. There was no decrease in intellectual functioning as measured by the Wechsler Adult Intelligence Scale. Symptomatology of the other 25% was unchanged postoperatively. At 1-year follow-up, all treatment gains had been maintained. It is important to note that no specific measures of obsessions and compulsions were used in this study. Thus, this places some limitations on the findings. For a discussion of measurement issues in OCD, see Turner (1982) and Mavissakalian and Barlow (1981).

Kelly, Walter, and Sargent (1966) examined the physiological effects of leucotomy on psy-

chiatric patients with various diagnoses. Forty consecutive patients selected for psychosurgery were assessed pre- and postoperatively. Diagnostic categories included recurrent or agitated depression, chronic anxiety, phobic anxiety state, obsessional neurosis, and schizophrenia. However, the specific patient selection criteria and the procedures used to arrive at their diagnosis were not described. Bilateral frontal leucotomies or orbital undercutting techniques were used. Again, 75% of the patient group showed improvement and 25% remained unchanged. Preoperative baseline measures of physiological arousal were within normal limits for blood pressure and blood flow. Heart rate was slightly accelerated at 95 beats per min. At 6 weeks after treatment, all patients demonstrated significant decreases in all resting physiological measures. Those patients suffering from agitated depression and chronic anxiety improved the most, as measured by reductions in level of forearm blood flow, heart rate and blood pressure during resting periods, and stressful mental arithmetic tasks. In addition, self-reported levels of anxiety and scores on the Taylor Manifest Anxiety Scale significantly decreased. Patients suffering from schizophrenia, obsessional neurosis, and phobias did not evidence the same level of improvement 6 weeks postoperatively as those suffering from agitated depression and chronic anxiety. At 18-month follow-up (Kelly, Walter, Michell-Heggs, & Sargant, 1972), 50% of the obsessional patients showed a decrease in symptoms resulting from the leucotomy. The authors attributed this delayed improvement to the gradual relearning process the obsessional must undergo. They postulated that anxiety concomitant with OCD is limited to particular events (in comparison with generalized anxiety), and that the individual must have the opportunity to be repeatedly engaged in the idiosyncratic, previously anxiety-provoking situation before the beneficial effects of the leucotomy become evident. Again, no specific measures of obsessive ideation or compulsive behavior were used. Also, delayed improvement could be attributed to exposure to anxiety-provoking situations that occurred after treatment.

In a retrospective comparison of the effects of psychosurgery and other treatment inter-

ventions, Tan, Marks, and Marset (1971) compared the effect of bimedial leucotomy with other treatments for OCD in patients matched for sex, age, symptom duration, onset age, and OCD symptom severity. Although the exact nature of the other treatments was not delineated, the authors listed several interventions including drugs, electroconvulsive therapy (ECT), insulin, hypnosis, abreaction, and behavioral and dynamic psychotherapy. All subjects were diagnosed as suffering from obsessive-compulsive disorder. This study is also remarkable for its 5-year follow-up period. Categories of improvement included obsessions and compulsions, general anxiety, depression, and work adjustment. Independent ratings of improvement were made from hospital records using a 5-point rating scale used by two independent judges. After treatment, obsessions were significantly reduced in the leucotomy group but not in the control group. This difference held constant even at the 5-year follow-up period. For generalized anxiety, findings were again in favor of the leucotomy group during the first 3 months. However, at 5-year follow-up, the control subjects also were improved, thus negating the differences between the groups. Both groups also improved on the variable of depression. Work and social adjustment improved significantly more in the leucotomy group throughout the course of follow-up.

Decreases in OCD symptoms following dissociation of frontal-limbic neurons may make psychosurgery appear beneficial. However, the side effects of leucotomy can range from minimal to quite severe. Immediate side effects included urinary incontinence, headache, and transient confusion. Long-range side effects included poor memory and concentration, apathy, one case each of psychosis and epilepsy, sexual disorders, weight gain, and social disinhibition. The authors did point out that treatment gains were not "bought at the expense of a vegetable existence" (Tan et al., 1971, p. 160). Those who were unable to work adequately when assessed at the 5-year follow-up were those who retained their symptoms.

Leucotomy is an extremely controversial procedure and not widely accepted as an appropriate treatment intervention for OCD. The use of leucotomies in treatment of OCD,

however, highlights the intractable nature of the disorder and the frustration that often accompanies the treatment of these individuals. In at least one study, the author emphasized that leucotomy was not the treatment of first choice, that selection of candidates was made with extreme caution, and that leucotomies were considered only in severely refractory, long-term cases where psychosurgery was preferable to continued life with the severely debilitating condition. To our knowledge, in the United States psychosurgery is not used in the treatment of obsessive-compulsive disorders. Advances in pharmacologic (antidepressants) and behavioral therapies (e.g., flooding and response prevention) have added new techniques to the treatment armamentarium for OCD such that treatment prognosis is now quite good (Turner & Michelson, 1984). Thus, it does not appear that the use of psychosurgical procedures is necessary.

In summary, the findings of neuroanatomical studies suggest that cerebral dysfunction might well be a factor in obsessive-compulsive disorders. The results of the leucotomy studies have demonstrated that ablations of sections of the limbic system, or the association areas, reduce the severity of OCD symptoms. The direct mechanism through which this occurs is unknown. If the defective inhibitory ability in the arousal system of OCD patients, as proposed by the "alternate waking state hypothesis" put forth by Epstein and Bailine (1971) or the evoked potential deviation noted by Ciesielski et al. (1981) are correct, the effect of leucotomies may be to alter a chronically overaroused state.

A recent article by Bear (1983), equating areas of hemispheric dysfunction with specific emotional and behavioral patterns, may be useful in helping to synthesize the results of these disparate studies. Bear suggested that there are characteristic emotional patterns for temporal lobe epileptics dependent upon the involved hemisphere. Right-sided foci are characterized by an impulsive, aggressive pattern, whereas controlled, reflective profiles are typical for left-sided lesions. Left temporal lobe lesions show "ideative traits including religiosity, philosophic interests, sense of personal destiny, paranoid concerns, and hypergraphia" (Bear, 1983, p. 197). These behav-

ioral characteristics, in many instances, are not unlike the style of OCD patients, and it is interesting to note that some EEG studies of anxiety and OCD patients have documented abnormal activity in the left temporal region (Crighel & Solomonovici, 1968; Epstein & Bailine, 1971). In addition to left-right asymmetry, Bear (1983) discussed what he refers to as complementary parietofrontal and temporofrontal systems, each with independent limbic connections and specific functions. Although the temporofrontal system is important for the processing of affective information and autonomic responses, the parietofrontal system is responsible for emotionally appropriate arousal including recognition of threat. Within this second system, there is limbic input from the cingulate gyrus to the inferior parietal lobule and back to the cingulate. It appears this circuit mediates emotional arousal and rapid selective attention to stimuli important for goal attainment. Lesions in this area could interfere with surveillance, orientation, and arousal, with deficits manifesting as neglect, apathy, or abulia (Bear, 1983). If one can speculate on overstimulation in this area, then it might be expected to lead to overconcern as opposed to neglect or apathy, and abulia might be replaced by rigidity. If this is so, the function of this system might explain the success of cingulate leucotomies in ameliorating OCD systems.

Although these studies suggest potential sites for cerebral dysfunction in OCD patients, they do not specify the mechanism by which the symptoms occur. Moreover, a recent study comparing OCD patients with normals revealed no differences in gross anatomical features (Insel, Donnelly, Lalakea, Alterman, & Murphy, 1983). However, studies designed to examine the brain at a more basic level (i.e., neuronal concentrations) will need to be conducted before definitive statements can be made. In this regard, reliance upon post-mortem evaluations might be necessary.

#### Biochemical and Pharmacological Studies

Because mood disturbance has been noted as a feature of OCD, two biological tests used to assess for depression are worthy of note.

These are the Dexamethasone Suppression Test (DST) and sleep studies.

### *Dexamethasone Suppression Test*

The Dexamethasone Suppression Test (DST) consists of orally administering dexamethasone (1 mg) at 11 p.m. followed by measurement of plasma cortisol levels the following day at 8 a.m. and 4 p.m. In normal individuals, plasma cortisol remains suppressed for 24 hr following dexamethasone administration. Lack of suppression of plasma cortisol levels is thought to be a biological marker of depression. The DST has been suggested as one objective diagnostic test to identify major depressive disorder (Carrol et al., 1981). Although reports regarding the specificity of the test are inconsistent, approximately 40% to 60% of the patients with major depressive disorder show a pattern of cortisol nonsuppression (>5 micrograms/dl) after administration of dexamethasone (1 mg) the previous night (11 p.m.; Carroll et al., 1981). The DST has recently been used in the assessment of obsessive-compulsive patients. The DST was administered to 16 OCD patients, 7 of whom had secondary depressive symptoms (Insel, Kalin, Guttmacher, Cohen, & Murphy, 1982). In each of the 7 cases, depressive symptoms were secondary to the obsessive-compulsive disorder. Six (37.5%) of the 16 patients treated had an abnormal DST response. This percentage is approximately equivalent to the 40-60% figure of sensitivity cited in the literature for the number of depressed individuals who fail to suppress (Brown, Johnston, & Mayfield, 1979; Carrol et al., 1981). In OCD patients, there was a trend for those patients who had higher scores on a depression rating scale, and a family history of affective illness, to be DST nonsuppressors, again suggesting the possibility of a shared biological substrate for the two disorders. In another study, Åsberg, Thorén, and Bertilsson (1982) used the DST to assess 17 OCD patients in the manner recommended by Carrol et al. (1981). Seven of the 17 patients (41%) were found to be nonsuppressors. The authors contended that some cases of melancholia and obsessive-compulsive disorder may have the same biochemical

disturbance, despite the apparent differences in the clinical picture.

### *Sleep Studies*

Sleep patterns and sleep EEG recordings of OCD patients were contrasted with those of patients exhibiting primary depression and a group of matched normal controls (Insel, Gillin, et al., 1982). Seven of the fourteen OCD patients evidenced sufficient depressive symptoms to meet DSM-III criteria for major depressive disorder. However, in all OCD subjects, appearance of depressive symptoms was subsequent to onset of OCD. Results indicated that the OCD patients differed from the normal subjects on 8 of 17 sleep variables. In comparison with the normals, the EEG "disclosed a pattern of shallow, interrupted, insufficient, and shortened sleep." (Insel, Gillin, et al., 1982, p. 1375). Of particular interest was the reduction of Rapid Eye Movement (REM) latency and Stage 4 sleep in OCD patients, similar to the pattern noted in primary depressives. There was also a reduction of REM efficiency in patients with OCD, resulting from the intrusion of NREM or awake time. Sleep pattern of the OCD patients was similar to that of depressed patients, possibly providing further evidence of a link between the two disorders. These results, however, are tempered by reports of extreme anxiety on the part of the OCD patients regarding the sleep-monitoring procedure. Of the 18 patients invited to participate in the research, four refused because of concerns about contamination. Of the remaining 14, the authors related:

For many of the patients, particularly those with cleaning rituals, the sleep-recording procedures were a source of considerable distress. Two patients refused to allow recordings in their regular hospital bed for fear of contamination. Others insisted that they shower just before and after the sleep recordings. One patient who reluctantly consented to the sleep study withdrew after 2 nights amid intense preoccupations that the electrodes had contaminated her bed. (p. 1374)

Thus, the pattern of shallow, interrupted sleep could be attributed to either characteristics of OCD or a reaction to the sleep-monitoring procedure.

Although current research would suggest that behavioral strategies are the most effective

treatments for obsessions and compulsions, drugs also play an important role in certain cases. For example, Foa (1978) reported that for at least one subcategory of OCD, attempts at remediation of obsessional behavior will be ineffective until the depressive mood has been alleviated. Thus, pharmacological intervention has been accepted as an integral component in the treatment of OCD when depression is a particularly prominent feature. In addition to the antidepressants, other drugs frequently used in the treatment of OCD include antianxiety agents and neuroleptics.

#### *Antianxiety Agents*

Because of the severe anxiety often concomitant with OCD, anxiolytic agents have been widely used. Numerous studies have demonstrated that the performance of rituals is associated with decreased levels of anxiety or discomfort caused by the obsessions (e.g., Hodgson & Rachman, 1972; Rachman, 1976; Roper & Rachman, 1976; Roper, Rachman, & Hodgson, 1973). Therefore, reduction of anxiety might be expected to correlate with reduced OCD symptoms. However, Lader (1974) demonstrated that although physiological arousal and anxiety are often confused, level of physiological arousal does not always correlate with the subjectively perceived experience of anxiety. In particular, although anxiety may initially develop as a result of an increased level of arousal, diminution of the arousal does not necessarily result in decreased subjective feelings of anxiety. For example, anxiety patients treated with diazepam evidenced a decreased level of physiological arousal but no concomitant changes in perceived level of anxiety (Lader, 1974). In addition, propranolol (a betablocker) has been found to produce reduction in physiological arousal in OCD patients (Rabavilas, Boulougouris, Perissaki, & Stefanis, 1979). However, clinical ratings of symptoms did not decrease, and patients did not report themselves as less anxious or more content when using the drug. As Ananth (1976) concluded, although certain preparations may decrease arousal levels, they are ineffective in decreasing the primary symptoms of obsessions and compulsions. Thus, it does not

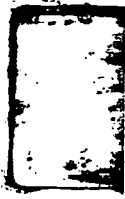

appear that anxiolytic agents are effective in the treatment of OCD, indicating the disorder is considerably more complex than simple increased level of arousal.

#### *Neuroleptics and L-Dopa*

Biochemical bases have been suggested for three of the final four disorders previously listed. Parkinson's Disease, schizophrenia, and Tourette's Syndrome all encompass behavior which, superficially or otherwise, resembles OCD. In these disorders the similarity pertains to the stereotypic, repetitive movements, except that the movements are assumed to be involuntary in these conditions. The hypothesized biochemical abnormality in each of the latter three conditions is aberrant dopaminergic functioning, with increased or excessive activity in the case of schizophrenia (Neale & Oltmanns, 1980) and Tourette's Syndrome (Shapiro et al., 1978) and decreased dopaminergic functioning in Parkinson's Disease (Iversen, 1977). Part of the effectiveness of neuroleptic medications is their ability to alter dopamine levels. Neuroleptics have been successfully used to treat schizophrenia and Tourette's Syndrome, and L-dopa has been found to eliminate the stereotypic and repetitive movements of Parkinson's Disease. As described, these conditions have behaviors similar to those seen in OCD. Thus, the possibility of dopamine involvement in OCD is raised. However, to our knowledge, there have been no studies investigating dopamine function in OCD.

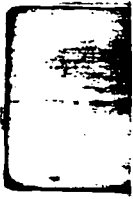

#### *Antidepressants*

In 1977, Yaryura-Tobias proposed a serotonin hypothesis for obsessive-compulsive disorders. The serotonin hypothesis states there are decreased functional levels of serotonin available at the synaptic cleft of OCD patients when compared with normals. Among the antidepressants, the drug clomipramine, which has a potent serotonergic action component, has been reported to be particularly effective in the treatment of this disorder (Thorén, Åsberg, Cronholm, Jörnstedt, & Träskman, 1980; Yaryura-Tobias, Berbirian,

Neziroglu, & Bhagavan, 1977). Ananth, Solym, Bryntwick, and Krishnappa (1979) reported that clomipramine resulted not only in a decrease in anxiety and depression, but also a significant reduction in the severity of obsessions. Although most of the clomipramine studies suffer from methodological inadequacies including the uncontrolled nature of the clinical reports, use of mixed diagnostic groups, different dose ranges and methods of administration of clomipramine, varying duration of treatment and absence of objective measures of the primary symptoms (Turner & Michelson, 1984), the preliminary results nevertheless raise the question that neurotransmitter deficits similar to those posited in some biological theories of depression may be operating in OCD.

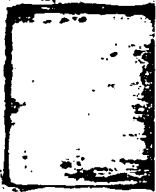

Because many OCD patients report feelings of depression, various antidepressants have been used in treatment. The amine hypothesis of affective disorders suggests a decreased availability of functional amines, including serotonin (5-HT) and norepinephrine (NE) in the brain, specifically at the neural synapses. Functional deficits of these neurotransmitters at the synaptic clefts have been suggested as being related to depressive states. There is evidence to suggest reduced serotonergic function in depressed patients. First, reduction in 5-HT levels or its metabolites has been noted in the cerebral spinal fluid (CSF) and blood of some depressed patients (Coppen & Wood, 1982). Similarly, a reduction has been observed in 5-HT levels in platelets of depressed patients (Meltzer, Arora, Baker, & Tricou, 1981; Tuomsito & Tukiainen, 1976). Antidepressants that affect the neurotransmitters serotonin and norepinephrine have been reported to have varying degrees of effectiveness in treating OCD. For a review of pharmacological interventions in OCD, see Ananth (1976, in press).

Of all the antidepressants, clomipramine has been demonstrated to be the most effective, with apparent antiobsessive properties discovered in an accidental fashion (Ananth, in press). The drug, being tested in depressed patients, was reported effective in eliminating secondary obsessional features. Several reviews of clomipramine as a treatment for OCD have been published (Ananth, 1976, in

press; Turner & Michelson, 1984). This article highlights the biochemical mechanisms that have been implicated as being responsible for its treatment efficacy.

Similar to the action of other antidepressants, clomipramine's action is thought to hinge on its ability to block the reuptake of certain neurotransmitters. The particular effectiveness of clomipramine in OCD treatment in comparison with other antidepressants has been linked to its preference for blocking serotonin reuptake, especially when administered intravenously. Clomipramine is a potent inhibitor of serotonin (5-HT) reuptake, with a lesser, but concurrent effect on norepinephrine (Waldmeier, Baumann, Grungrass, & Maitre, 1976). This is in contrast to other antidepressants (e.g., imipramine and amitriptyline) that are less selective for serotonin. Selectivity of clomipramine for 5-HT reuptake, coupled with its clinical effectiveness in reducing symptoms of OCD, could indicate a 5-HT disturbance in obsessive-compulsive disorder, which is the basis of the serotonin hypothesis discussed earlier (Yaryura-Tobias, 1977). In a test of the serotonin hypothesis, Yaryura-Tobias et al., (1977) examined blood serotonin levels in drug-free OCD patients and controls. Twenty patients diagnosed as suffering from obsessive-compulsive disorder and 11 normal control subjects recruited from the clinic staff participated in the research. In the first part of the study, baseline blood 5-HT and urinary 5-hydroxyindoleacetic acid (5-HIAA) levels were collected. The OCD patients had significantly lower levels of blood serotonin, and there was no significant difference in urinary excretion of the serotonin metabolite 5-HIAA. This suggests some disturbance in the synthesis of serotonin in OCD patients. In the second part of the experiment, OCD patients were administered clomipramine, 50 mg twice daily for 2 weeks. Blood and urine levels were collected again at the end of this period. In addition, clinicians rated improvement in symptoms at posttreatment. Following treatment with clomipramine, there was a further significant decrease in 5-HT, but no change in urinary 5-HIAA levels. The authors suggested this further reduction in 5-HT levels, but stable 5-HIAA excretion, could be ex-

plained by increased circulating levels of 5-HT being rapidly oxidized in the blood. Other studies also reported improvement in obsessional symptoms to be positively correlated with increased levels of clomipramine in the blood plasma, indicating increased availability for synthesis (Insel, Murphy, et al., 1983; Stern, Marks, & Mawson, 1980). In addition, the antiobsessional effect of clomipramine was reported to be significantly correlated with decreases in the levels of the serotonin metabolite 5-HIAA in the CSF, once again suggesting increased availability of serotonin for synthesis (Åsberg et al., 1982). The evidence provided by these investigations, including differing baseline serotonin levels, further decreases in blood platelet levels as a result of blocked reuptake, and decreased obsessions, lend support for the role of the serotonergic neurotransmitter system in OCD.

Depletion of CNS 5-HT in laboratory animals may provide evidence for a model of behavior associated with decreased serotonergic transmission. In cats, decreased availability of 5-HT by reserpine reduces 5-HT storage by acting on the storage vesicles and allowing increased intracellular catabolism, thus interfering with Stage-II sleep and reduction in REM efficiency (Jouvet, 1978). In Insel, Gillin, et al. (1982), OCD sleep study, Stage-II sleep and decreased REM efficiency were two of the variables found to differ between OCD patients and normals. In addition, serotonergic depletion in animals has been demonstrated to be related to stereotypic, repetitive behaviors. As one example, Abel (1974) administered *p*-chlorophenylalanine (*p*-CPA) which selectively depletes cerebral 5-HT in rats. Following administration of *p*-CPA, he observed hyperaggressivity and compulsive sexual activity in the males. He reported similar behavior in cats and rabbits. Abel (1974) hypothesized that 5-HT pathways may exert an inhibitory influence over sexual behavior, although it remains unclear if this is a result of an increase in general arousal or a direct effect on the mechanism of sexual behavior. Additional evidence to suggest that serotonergic neurons might play a role in limitation of behavior is provided by Shillitoe (1970). Depletion of 5-HT by *p*-CPA was associated with excessive

grooming behavior in rats to the point where they experienced total baldness. Although admittedly speculative, there appears to be some evidence of behavioral repetition in rats correlated with changes in levels of the neurotransmitter serotonin. The behaviors previously described are clearly reminiscent of behavior seen in OCD.

Further clinical studies using clomipramine have provided some support for the serotonin hypothesis. Thorén, Åsberg, Bertilsson, et al. (1980) examined CSF levels of 5-HIAA (a serotonin metabolite), homovanillic acid (HVA; a dopamine metabolite), and a noradrenergic metabolite 4-hydroxy-3-methoxyphenyl glycol (MHPG) in OCD patients before and after treatment with clomipramine. It should be noted that this study examined CSF levels of 5-HIAA and not urinary excretion levels as in the Yaryura-Tobias et al. (1977) study. CSF levels are thought to be a more direct indication of CNS activity. Twenty-four patients diagnosed as suffering from obsessive-compulsive disorder and 37 paid, healthy volunteers participated in the study. OCD patients were treated with one of three medications: clomipramine, 50 mg three times per day; nortriptyline, 50 mg twice daily; or a placebo. Treatment lasted for 6 weeks. Lumbar punctures were performed at pre- and posttreatment. Prior to treatment, mean concentrations of CSF 5-HIAA and CSF HVA did not differ between the OCD and control group. The level of CSF MHPG was more variable within the OCD group than the controls; 5 of the patients had higher levels of MHPG than any of the controls. In the nortriptyline group, treatment resulted in reduction in MHPG levels. After treatment with clomipramine, there was a significant reduction in both 5-HIAA and MHPG levels in the CSF and a slight but significant increase in HVA. In addition, there was an inverse relation between 5-HIAA and HVA levels; the more 5-HIAA decreased, the more HVA increased. With nortriptyline both levels increased, indicating that these two pharmacological agents differ in their effect on serotonin and dopamine receptors. This study also examined clomipramine responders and nonresponders. Responders were differentiated by significantly higher pretreatment levels of both CSF HVA and CSF 5-HIAA,

whereas MHPG did not differ between these two groups. There was a significant negative correlation between 5-HIAA level during the fifth week of treatment and obsessional symptom scores, indicating those patients with a marked reduction in 5-HIAA were the ones who improved clinically. There was also a significant negative correlation between plasma concentrations of clomipramine and reduction in scores on the Leyton Obsessional Inventory.

In contrast to 5-HT pretreatment differences found in blood platelets in the Yaryura-Tobias et al. (1977) study, CSF pretreatment levels of 5-HIAA, HVA, and MHPG in the Thorén, Åsberg, Bertilsson, et al. (1980) study did not differ between OCD patients and healthy controls. However, high pretreatment CSF 5-HIAA levels in the Thorén, Åsberg, Bertilsson, et al. (1980) study were correlated with improvement in obsessional behavior. They noted that there may be some evidence for biological subcategories of OCD similar to those proposed in the depression literature (cf. Depue & Monroe, 1978). They further noted that in depression there is a bimodal distribution of CSF 5-HIAA levels, and these two modes are representative of two distinct biological subgroups. Although the small sample size of this study with the OCD patients prevents the drawing of a similar conclusion with respect to OCD, the distribution of 5-HIAA CSF levels appears similarly bimodal. Therefore, there may be subclasses of OCD patients with different biological underpinnings that may lead to differential responsivity to treatment. Thorén, Åsberg, Bertilsson, et al. (1980) suggested this may explain why the high 5-HIAA group was more responsive to clomipramine. Finally, there was a U-shaped dosage response curve in which plasma drug levels below or exceeding 300n mole/L resulted in decreased effectiveness. One explanation for this is that above this level clomipramine may begin to block serotonin receptors in addition to blocking reuptake. On the basis of all the evidence, the authors concluded that the strong correlation between reduction in CSF level of 5-HIAA and diminution of obsessive symptoms is indicative of an antiobsessive effect of clomipramine, and that this effect is

related to its capacity to inhibit serotonin reuptake.

Further evidence of a role for serotonin in OCD is supported by research showing the 5-HT precursor amino-acid, L-tryptophan to be effective in treatment of OCD (Yaryura-Tobias & Bhagavan, 1977). Administration of this precursor is an alternative approach to clomipramine treatment in increasing steady-state levels of serotonin. Synthesis of serotonin is regulated by the amount of available L-tryptophan. Thus, increasing the precursor should result in an increase in the availability of serotonin for synthesis. Seven obsessive-compulsive patients were treated with 3 to 9 g of L-tryptophan in divided doses. Although criteria for improvement were not described, patients were reported to evidence considerable improvement after 1 month on the medication, and they continued to improve for up to 5 months afterward.

In summarizing the response to pharmacological intervention in obsessive-compulsive disorders, there appears to be some basis for a serotonin hypothesis. Differences in 5-HT blood plasma levels between OCD patients and normals and more variable CSF levels of MHPG within the OCD patient group have been reported. A high pretreatment level of 5-HIAA in one study was predictive of responsivity to clomipramine treatment. In addition, the decrease in CSF 5-HIAA and blood plasma 5-HT levels after clomipramine treatment indicates that increasing available levels of serotonin are correlated with a decrease in symptoms. However, thus far the biochemical evidence for this hypothesis is limited to peripheral measures of bioamine activity. Cerebral spinal fluid and blood and urine assessments are not without limitations. Exact relations between these peripheral measures and brain concentrations of the same substances have yet to be established. However, CSF metabolite concentration is considered to approximate more accurately brain concentration levels. Even if the levels were identical, there is no evidence to suggest neurotransmitter function is the same at both sites (Green & Costain, 1981). If the exact relation of peripheral neurotransmitter levels to CNS functioning was understood, this still would not clearly delineate their role in the pathogenesis of OCD. Differences in levels

may be pathogenic factors, or they may be secondary effects of the disorder and have no role in causality.

Despite the existence of some evidence for the role of serotonin in obsessive-compulsive disorders, there are difficulties in validating the hypothesis with current approved antidepressive drugs. The reason for this is that clomipramine and other widely used antidepressants also have an effect on the neurotransmitter norepinephrine. Hence, norepinephrine and serotonin are affected when these drugs are used. The clomipramine metabolite, demethylclomipramine, has been demonstrated to have effects on norepinephrine. Thus, the effect of clomipramine cannot entirely be attributed to its effect on serotonin. In a recent study using zimelidine, a specific serotonin blocker that has been withdrawn from use by the Food and Drug Administration, and desipramine (which preferentially inhibits norepinephrine reuptake), Insel and Mueller (1984) reported that neither zimelidine or desipramine had a significant effect on clinical ratings of obsessiveness in 13 OCD patients. However, when these patients were treated with clomipramine, they showed significant improvement on a global obsessional scale. The authors noted that CSF 5-HIAA did not significantly differ between zimelidine and clomipramine treatment. This indicates the ineffectiveness of zimelidine (a selective serotonin blocker) when compared with clomipramine (a serotonin and norepinephrine blocker) and raises questions regarding a singular central role for serotonin in OCD. Of course, these data are preliminary, and further studies with other antidepressants selective for serotonin (e.g., fluoxetine) will be necessary to delineate more explicitly the possible role of serotonin in OCD.

#### Summary and Discussion

It is clear from the previous discussion that we are not at a point where an integrated biological theory of OCD can be proposed. Although the findings reviewed here consistently suggest that biological factors are correlated with OCD, a truly integrated discussion of these findings would be premature. From the data discussed, it does not appear

that OCD is strictly a biological abnormality. Rather, the data suggest some type of biological predisposition that leaves an individual more vulnerable to the development of OCD, perhaps as a result of psychological stress.

The high concordance rate observed in monozygotic twins as opposed to dizygotic twins is comparable with concordance rates obtained in studies of schizophrenia and seems to suggest some type of genetic transmission. However, the absence of adoptive studies makes it impossible to rule out psychogenic or environmental factors. Moreover, the data that are available do not support a straightforward genetic model. It may well be that what is inherited is the tendency toward chronic elevated arousal or a tendency to respond in an overaroused fashion. It has long been noted that neurotic patients are subject to chronic overarousal which has been referred to as anxiety proneness (e.g., Carey & Gottesman, 1981). There is also some evidence that such individuals demonstrate resistance to habituation. In fact, Eysenck (1979) described a tendency for vulnerable individuals to show increases in arousal on repeated presentation of feared stimuli rather than extinction. This is known as the incubation effect or paradoxical enhancement of anxiety. If OCD patients are congenitally overaroused, this might explain their tendency to worry excessively and to overrespond to threatening stimuli, and the ability of such stimuli to elicit anxiety responses. In vulnerable individuals, such a process could be set off under circumstances such as the stress of giving birth or interpersonal conflict.

These significant events have been noted to be related to onset of OCD (Turner & Michelson, 1984). In a diathesis-stress model such as the one just described, the nature of psychological stress would determine the particular symptomatic expression in each individual. A recent study by Torgersen (1983) also provides evidence for genetic transmission of proneness to anxiety. Torgersen studied a subsample of 32 MZ and 53 DZ adult twins of the same sex who were part of a nationwide study of neurotic and borderline psychotic adult same-sex twins treated in Norway during the 1970s. The study was reported to have included almost all adult same-sex twin

patients born between 1910 and 1955 and who were admitted to an institution before 1977. Two hundred and ninety-nine pairs were personally interviewed. In 19 pairs, both twins were probands. Therefore, the total number of probands was 318. Among the findings reported by Torgersen was that no MZ twin had the same disorder as the corresponding proband. That is, the MZ twin had a high incidence of anxiety disorder but not necessarily the same disorder as the proband. The concordance for an anxiety disorder in the twin was higher in MZ than in DZ pairs in all the twin proband groups except generalized anxiety. These data lend further support for a genetic transmission of anxiety proneness rather than a specific anxiety disorder.

One caveat with respect to the genetic studies is in order. In examining these studies, caution is advised because of differential diagnostic procedures used to determine anxiety disorders. As we noted, it is unclear in some of the studies whether the symptoms manifested by first-degree relatives were true obsessive-compulsive disorder symptoms or compulsive personality characteristics. A distinction has been made based on this dichotomy (Slade, 1974).

As was previously discussed, the findings from neuropsychological and neurophysiological investigations and studies of the effects of leucotomies suggest possible neuroanatomical abnormalities in OCD. These aberrations include altered EEG patterns, differences in averaged evoked potential, and suggestions of dominant frontal lobe dysfunction. However, all of these studies have major methodological difficulties including small sample size, lack of comparison groups, and lack of information regarding base rates for these abnormalities in the general population. In addition, psychosurgical procedures involving lesions in certain sites have been shown to reduce symptoms of OCD. These results also point to an organism that is in a chronically overaroused state.

Serotonin has been the subject of considerable study in relation to OCD. Clinical studies of the antidepressant clomipramine have been used to support the role of serotonin. However, the major flaw in all of these studies is that they do not have adequate

measurement of OCD behaviors. In particular, there are no direct measures of obsessions and compulsions per se. Thus, it is difficult to assess the antiobsessive effect independent of mood. Moreover, the best designed study using the most sophisticated assessment strategy failed to reveal an antiobsessive effect for clomipramine. Rather, the effect was found only on measures of mood (Rachman et al., 1979). Biochemical abnormalities are found not only in studies of serotonin level, however. Recent reports have suggested that OCD patients also exhibit differing levels of norepinephrine when compared with normals. Thus, at this juncture, it is impossible to suggest a single biochemical factor as responsible for the disorder.

In view of the evidence presented, it would appear premature to attempt an explanation of OCD based on a single etiological hypothesis. It is possible that genetic predisposition, neuroanatomical involvement, and biochemical abnormalities (including serotonin and norepinephrine) may contribute to the pathogenesis of obsessive-compulsive disorders, each in varying degrees. It is also possible that the manifestations seen in these various systems are reflective of the same pathological process. The one unifying theme is that the disturbance in these systems is related in some way to emotional overarousal. Finally, it was also noted that a diathesis-stress model is called for to explain fully the current findings. At present, we know little about the complex interaction of these biological and environmental factors.

## Summary and conclusions

MICHAEL A. JENIKE

Department of Psychiatry, Harvard Medical School, Boston,  
Massachusetts, USA

### *History and treatment*

'I know it's stupid; I feel like a crazy person, yet I know that I am not crazy!' This is a typical statement from a patient suffering from obsessive-compulsive disorder (OCD) who has spent over six hours each day for the past ten years washing her hands, despite recognising its senselessness. Other patients are compelled to check and recheck for hours each day whether or not the stove is off or the doors locked. An internist calls the laboratory 15 times to confirm that he has heard the white cell count correctly. A pathologist cannot be sure that a slide does not reveal mycobacteria or that the edges of a surgical specimen are free from tumour cells, even after hours of viewing. Other patients endure endless hours of obsessive, intrusive thoughts each day. Careers come to an end and families disintegrate as a result of this often unrecognised, but usually treatable illness. Since it often begins in childhood (as early as two years of age) or in early adulthood (mean age of onset 20-22 years) and rarely remits without specific treatment, patients may suffer lifelong disability (JENIKE, 1989). Recent research suggests that OCD may well be more of a neurological illness than a psychiatric disorder. Professor Åsberg noted Carl Westphal's contribution to our understanding of these disorders - including trichotillomania, which has recently been rediscovered as a common entity responsive to pharmacotherapy and behavioural techniques. The early enthusiasm of psychoanalysts in seeking a cure for OCD led to disappointment and the realisation that psychodynamic psychotherapeutic approaches, although interesting, did not resolve symptoms. Åsberg reviewed early work demonstrating the efficacy in some patients of behavioural techniques - exposure *in vivo* with response prevention - and the controlled trials of clomipramine, which demonstrated its superiority over placebo and other tricyclic compounds. Concomitant affective symptomatology predicted a favourable response to clomipramine but was not a prerequisite for its effective action in OCD; even non-depressed patients improved, a finding confirmed in many later studies. Professor Åsberg concluded by noting that response to clomipramine may implicate the brain's serotonergic system in the pathophysiology of the disorder, and that OCD may be a heterogeneous condition with causes ranging from organic or neurological to biochemical disturbances.

### *Epidemiology of OCD*

Professor Rasmussen showed how common OCD really is. Once considered a rare disorder, it is now known to be one of the most common psychiatric disorders, with a lifetime prevalence of 1–2% of the population. Current estimates of prevalence are 50–100 times higher than earlier predictions, with rates double those of panic disorder and schizophrenia.

How could a disease be so prevalent and remain hidden from physicians? Possible reasons are that most patients are seen by non-psychiatric health professionals who may be unfamiliar with the disorder, and that patients are reluctant to elaborate on symptoms which they view as crazy or unique. Even spouses may be unaware that their mate is spending hours performing rituals each day. Freud's explanation (quoted in RAPOPORT, 1989) was that 'Sufferers from this disorder are able to keep their affliction a private matter. Concealment is made easier from the fact that they are quite well able to fulfil their social duties during a part of the day, once they have devoted a number of hours to their secret doings, hidden from view.' The need for medical vigilance is illustrated in a recent study (RASMUSSEN, 1985), in which 37% of patients presenting to a dermatology clinic with non-specific dermatitis had OCD, although none had ever sought treatment for it. It is recommended that screening questions for OCD should be a routine part of every mental status examination, especially in anxious and/or depressed patients.

Studies of the genetics of OCD have shown that about 25% of first-degree family members of patients also have OCD, and that another 15% have features of the illness; there was also a significantly increased incidence of multiple tics.

### *Social aspects of OCD*

The social consequences of OCD can be very severe. Some patients can only focus on their obsessive concerns and withdraw from work, family and friends. Family life can be severely disrupted if the patient loses his or her job, with a resultant loss of income. Professor Burrows noted the importance of including relatives in the treatment plan – all OCD patients attempt, often very successfully, to get family members to perform rituals in an effort to keep the patient 'happy'.

Professor Burrows presented an overview of behavioural treatments and pharmacological approaches in OCD, noting that the success rate is quite high considering the disabling nature of the symptoms. Maximum therapeutic benefit is often not evident until after 10–12 weeks on an effective drug.

### *Neurobiology of OCD*

Some of the most exciting work over the last five years has involved investigations combining sophisticated neuropsychological techniques and high technology. Professor Rapoport reviewed some of the data suggesting that the basal ganglia and frontal lobes may be aetiologically important in OCD.

The serotonergic theory derives from two convergent lines of evidence. Firstly, drugs known to have potent effects on the serotonergic system, such as clomipramine, are effective in treating OCD, while less potent serotonergic agents are not helpful. Secondly, recent studies using the serotonergic agonist mCPP suggest that clomipramine works by downregulating serotonergic responsiveness. A major problem with this hypothesis is that desmethylclomipramine, the main metabolite of clomipramine, is a potent noradrenergic reuptake blocker, and thus clomipramine is not a purely serotonergic drug but a more complex drug with effects on other neurotransmitter systems including histamine and dopamine. The dopaminergic system is also potentially implicated by the considerable clinical overlap of OCD with Tourette's syndrome, though effective treatment for these two disorders is usually quite different. Professor Rapoport next reviewed aspects of neuroendocrine dysfunction in OCD. Several studies from the National Institute of Mental Health have found an exacerbation of OCD symptoms during early puberty, with some female patients experiencing increased symptoms immediately before their menses; a controlled study is currently under way to evaluate this relationship. Anti-androgen treatment has produced remission of OCD in five patients. The different incidence of OCD before and after puberty could be due to the effects of an androgenic hormone.

Recent research has implicated the basal ganglia in OCD. Patients who developed von Economo's encephalitis in the early part of this century sometimes suffered symptoms remarkably similar to OCD: at autopsy, lesions in the basal ganglia were found. Tourette's syndrome, also believed to involve the basal ganglia, is well known to be associated with OCD. Other researchers have demonstrated a high prevalence of tic disorders in OCD patients who do not have Tourette's syndrome. Sydenham's chorea is another basal ganglia disorder associated with a high prevalence of OCD. Surgical lesions which sever the connections between the frontal lobes and basal ganglia are sometimes therapeutic. Careful CT scanning has found the caudate nuclei in OCD patients to be smaller than in controls. As assessed by PET, there is increased metabolism in the caudate nuclei and frontal lobes of OCD patients compared to controls.

In conclusion, Professor Rapoport set out a model of how the basal ganglia and frontal lobes might be involved in the production of OCD symptoms. Such models need to take into account the episodic and variable nature of symptoms, not only from patient to patient but within the same patient over time.

### *Management of the patient with OCD*

Some 90% of patients with OCD can be helped by serotonin reuptake blockers and behaviour therapy, either used alone or, more commonly, in combination. Professor Greist noted that behaviour therapy – exposure and response prevention – is extremely effective, especially for patients with overt rituals, and should be offered to all patients with persistent symptoms. Behaviour therapies are still not widely used in psychiatry, partly because they are labour-intensive and because most clinicians lack the relevant training and experience. Recent techniques, however, emphasise less frequent medical visits and

focus on home treatment, with patients performing homework by themselves or with the help of selected family members.

Good results have been obtained with the newer anti-obsessional medications. By far the best studied is clomipramine, with at least 12 carefully controlled double-blind trials confirming its efficacy against placebo and other antidepressants. New medications such as fluvoxamine and fluoxetine are currently under investigation, and preliminary evidence suggests that they are also effective.

It is important to remember that, on average, symptoms are reduced by around 30–40% with drug therapy; although significant symptoms remain, the majority of patients feel much better. When combined with behaviour therapy, up to 90% of patients improve. Relapse after withdrawal of medication is usual; however, few of the patients who relapsed in the two reports to date had received behaviour therapy. It is likely that behaviour therapy may not only enhance the response to medication but may also lower relapse rates.

Finally, Professor Greist discussed psychosurgical procedures for severely disabled patients with treatment-resistant OCD, and concluded that surgery does have a part to play in overall management.

#### *Clomipramine as an effective treatment for OCD*

Dr DeVeugh-Geiss presented data from three multicentre studies in the USA comparing clomipramine to placebo. Two of the studies were conducted at 21 centres and involved adults only; the third study was conducted at five centres and involved children and adolescents aged 10–17 years.

A total of 520 adults and 60 children and adolescents were studied; about half received clomipramine and half placebo. A very low rate of placebo response was found (4–5%). Patients who received clomipramine improved by 35–42%, representing not only statistical significance but clinically relevant improvement as well. Clomipramine was well tolerated in doses up to 250 mg daily.

#### *PET studies in patients undergoing capsulotomy*

Noting earlier work showing increased metabolic rates for glucose (as assessed by PET scanning) in patients with OCD, Dr Mindus used similar techniques on five patients with chronic, intractable, and incapacitating OCD who underwent capsulotomy. This procedure, which is effective in reducing OCD symptoms, is performed by interrupting fibres in the anterior limb of the internal capsule, a procedure believed to remove direct interconnections between the frontal lobes and the limbic system. PET scans, done ten days prior to and 12 months after capsulotomy, confirmed previous reports of disordered metabolism in the frontal lobes and caudate. Interestingly, the preoperative scans

found the opposite of previous scans – a *lower* metabolic rate compared to healthy controls.

In an attempt to explain these contradictory findings Dr Mindus suggested that his patients were more severely and chronically incapacitated than patients in earlier studies, and that they were refractory to conventional therapy. In contrast, patients in earlier studies had been ill for a shorter period of time, all were outpatients, and most responded later to conventional medications. Perhaps the increased metabolic activity represents a relatively acute process while more chronic 'burned out' patients show decreased activity. This is a testable hypothesis.

### *What is the spectrum of OCD?*

Our knowledge of OCD has grown rapidly over the last few years (JENIKE et al, 1990), but a number of major problems remain. It is unclear what disorders should be included within the category of OCD. Many illnesses can present with frank obsessive-compulsive symptoms – Tourette's syndrome, schizophrenia, major depressive disorders, and organic mental disorders. In these cases the obsessions and compulsions are presumed to be secondary to the primary illness. There are also a few syndromes whose symptoms are so similar to OCD that diagnostic distinctions are not always clear; in these cases treatments similar to those employed in OCD have often been successful. These syndromes include trichotillomania, non-symptomatic hypochondriasis, dysmorphophobia, globus hystericus, bowel and urinary obsessions, compulsive face-picking, and fear of acquired immunodeficiency syndrome (AIDS). Many patients with eating disorders, besides being obsessed with food, also have obsessive-compulsive rituals such as repetitive hand-washing. Some patients who mutilate themselves may do so primarily to relieve anxiety, and may therefore be considered to have OCD.

In DSM-III-R, a number of related disorders are classified as impulse control disorders – kleptomania, pathological gambling, pyromania, and trichotillomania. Perhaps compulsive shopping and severe nail-biting should also be included in this category.

Whether these disorders are related in some fundamental way to OCD is not yet clear: a better understanding of their pathophysiology is required. The finding that many of them, including trichotillomania, respond to serotonergic drugs such as clomipramine, but not to adrenergic agents such as desipramine, suggests similarities. Whether habits like nail-biting, face-picking or smoking will respond to serotonergic agents remains to be seen.

Recognition of these disorders in medical practice is particularly important since effective treatments are available. Understanding their pathophysiology will not only benefit patients, but may also shed light on the biology of certainty, doubt, motivation and satisfaction.

## *What is the relationship between OCD and obsessive-compulsive personality disorder?*

A persistent area of confusion among clinicians concerns the relationship between OCD and obsessive-compulsive personality disorder (OCPD). Often viewing them as the same disorder, clinicians attempt treatments that are unlikely to succeed. For example, although traditional psychodynamic psychotherapy produces little change in the obsessions and compulsions of OCD, it may be of some value in patients with OCPD. Conversely, although behaviour therapy and anti-obsessional medication have been shown in controlled trials to be very effective in OCD, there is no evidence that they are helpful in OCPD.

Having similar names adds to the confusion between these two *distinct* diagnostic entities. In European psychiatry the adjective anankastic is still used to describe the obsessional personality, probably because it is helpful to have a separate word to distinguish obsessional personality from OCD.

Furthermore, in DSM-III-R, OCD is listed as a complication of OCPD, along with major depression and dysthymia, suggesting that OCPD patients may develop OCD as a complication in much the same way as they become depressed or dysthymic. OCD is not listed as a complication of any other personality disorder in DSM-III-R, suggesting that OCD and OCPD are in some way fundamentally related or that one may lead or predispose to the other.

Currently there is no evidence that OCPD patients are more likely to develop OCD than patients with any other personality disorder. Further confusing the issue is the fact that a few patients meet the criteria for both OCD and OCPD.

### *OCD in the elderly*

There is almost nothing written about OCD in the elderly. Data from the Massachusetts General Hospital OCD clinic and research unit showed that only one of 100 consecutive outpatients had *onset* of the disorder after the age of 50. However, reviewing data from a later group of 183 consecutively evaluated patients, showed that 22 (12%) were over 50 when first seen at the clinic, and eight (4%) were 60 or older. Thus the percentage of elderly patients is not insignificant. Many had never received treatment and, of those who had (some for decades), most had never received proper treatment. The majority of these elderly patients were markedly improved after a few months of appropriate treatment, usually behaviour therapy and psychotropic medication.

### *Serotonin and OCD*

Some of the work implicating serotonin in the pathophysiology of OCD has been reviewed in this volume. Over the next decade, new and more specific probes (both agonists and antagonists) for each type of serotonergic receptor are likely to become available. Two serotonergic receptors have already been cloned and their structure described. As Professor Rapoport said, the question is no longer 'Does OCD represent a neuropsychiatric disorder?' but rather

'What is the site and nature of the lesion?' This indicates the direction that research is likely to take over the next decade.

### *Better treatments, and predictors of response and relapse*

Today's drugs are very much more powerful and effective than older agents in the treatment of OCD. In general, however, patients still only improve by 30-40%, over 15% do not respond to medication at all, and we cannot predict which patients will respond to which medication. The use of a second medication to enhance or augment a partial response to a primary anti-obsessional drug may become more common in future, but to date there are only anecdotal reports; placebo-controlled trials are lacking.

More data on the efficacy of the various types of neurosurgical procedure for OCD are required, as are better data on relapse rates following discontinuation of drug therapy; currently these range between 25 and 90%. The possible protective effect of behaviour therapy against relapse has not been studied.

### *The Obsessive-Compulsive Foundation*

Over three years ago a group of OCD patients started the OC Foundation (PO Box 9573, New Haven, CT 06535, USA), which today provides referral recommendations and advice to sufferers around the world. Patients can contact the Foundation directly to find out about local clinics that specialise in obsessive-compulsive and related disorders. Their newsletter keeps patients and physicians informed of new developments.

# Cognitive-Behavioral and Pharmacological Treatments of Social Phobia

## A Controlled Study

Cheryl Shea Gelernter, PhD; Thomas W. Uhde, MD; Peter Cimbalic, PhD; Diane B. Arnkoff, PhD; Bernard J. Vittone, MD; Manuel E. Tancer, MD; John J. Bartko, PhD

• Sixty-five patients with social phobia were treated in a study that compared a cognitive-behavioral group treatment program with pharmacotherapy with alprazolam, phenelzine sulfate, or pill-placebo plus instructions for self-directed exposure to phobic stimuli. Statistically significant repeated-measures effects were shown on all measures, indicating that the treatments studied were associated with substantial improvements in patients with severe and chronic social phobia. Patients who were treated with phenelzine were rated by clinicians as more improved on a measure of work and social disability than patients who were treated with alprazolam or placebo (patients in the cognitive-behavior therapy group were not rated on this measure). Subjects showed positive cognitive changes from before to after treatment, and there were no differences between treatment groups on the cognitive measure. We discuss the implications of these findings within the context of demographic and clinical predictors of response.

(*Arch Gen Psychiatry*. 1991;48:938-945)

Although social phobia was classified as a discrete syndrome more than 20 years ago,<sup>1,2</sup> it was not until 1980 that the American Psychiatric Association formally recognized social phobia as a discrete diagnostic entity.<sup>3</sup> During the last decade, reviewers of the social phobia literature have noted that this syndrome is among the least studied of the major anxiety disorders and have called for further research to address gaps in our knowledge con-

cerning definition, prevalence, etiology, pathophysiology, assessment, and treatment.<sup>4,6</sup> In their review of the social phobia literature, Liebowitz et al<sup>6</sup> observed that this disorder has not been viewed by psychopharmacologists as a distinct syndrome worthy of independent study. Consequently, there are few controlled evaluations of treatments of social phobia.

The drug that has been most studied for the treatment of social phobia is the monoamine oxidase inhibitor phenelzine sulfate; four controlled drug trials have been conducted that evaluated its effectiveness<sup>7-10</sup> in treating patients with mixed or unspecified phobic conditions. The results of these early drug studies hinted at possible phenelzine efficacy for social anxiety, but limitations in the design of these studies made it difficult to reach definitive conclusions regarding the therapeutic benefits of monoamine oxidase inhibitor medications in the treatment of social phobia. Specifically, these older studies treated mixed samples of phobic patients, including patients with social phobia and agoraphobia, and the results were not reported by diagnosis, making it impossible to determine whether the patients with social phobia, as a separate group, improved at all. These investigations suggested a need for future studies with well-defined subject samples, adequate medication dosages and treatment duration, more comprehensive assessments, and well-controlled, double-blind designs.

Two later trials of phenelzine in samples of patients with pure social phobia yielded additional data that supported the efficacy of phenelzine for treatment of these patients. The first, an open pilot study, found that all patients who were treated with phenelzine achieved moderate to marked improvement.<sup>11</sup> The second study has been the only well-controlled investigation of phenelzine in a sample of patients with pure social phobia reported to date. In this latter study, Liebowitz and colleagues<sup>12</sup> published an interim report of a double-blind, placebo-controlled comparison of phenelzine and atenolol, a  $\beta$ -adrenergic blocker, in a sample of patients who met *DSM-III* criteria for social phobia. Preliminary data from this ongoing study have suggested that phenelzine, but not atenolol, may be an effective treatment of social phobia. However, these findings should be interpreted con-

Accepted for publication February 14, 1991.

servatively, given the interim nature of the report and the presentation of only selected results from newly developed outcome measures.

Data regarding benzodiazepine treatments of social phobia are minimal. Although case reports<sup>13</sup> and open clinical trials<sup>14</sup> have suggested that alprazolam, a triazolobenzodiazepine useful in the treatment of panic disorder,<sup>15,16</sup> reduces social anxiety, no controlled study investigating the effectiveness of alprazolam has been conducted for social phobia.

Considered together, these data suggest possible phenelzine and alprazolam efficacy with social phobia. However, given the disparate patient population in the older studies and the preliminary nature and/or relatively small sample size of more recent trials, the value of these agents (ie, phenelzine and alprazolam) as treatments of pure social phobia remains to be established.

Relatively few studies of cognitive-behavioral therapies in clinical populations of patients with social phobia have been conducted. The research in this area has focused on the efficacy of cognitive restructuring and exposure techniques, applied in isolation or as a part of a multicomponent treatment package. Results of these clinical studies have suggested that cognitive restructuring and exposure interventions are effective in the treatment of social anxiety.<sup>17-25</sup> However, no investigation has been conducted to establish the relative efficacy of cognitive-behavioral strategies and pharmacological approaches to the treatment of social phobia. The present investigation addressed this question by comparing the effects of a cognitive-behavioral group treatment with pharmacotherapy (phenelzine, alprazolam, and pill-placebo) plus instructions for self-directed exposure to phobic stimuli. To our knowledge, this is the first methodologically rigorous investigation that compares pharmacotherapies for social phobia and the first controlled study that compares two pharmacotherapies with psychotherapy for this disorder.

## PATIENTS AND METHODS

The majority of the patients who participated in this investigation were selected from a pool of respondents to a newspaper article in the "Health Section" of the *Washington Post* that described social phobia and a research program for its treatment at the National Institute of Mental Health, Bethesda, Md. Others came from a variety of referral sources, including other units at the National Institute of Mental Health and private practitioners. To be considered for participation, subjects had to be aged 18 to 60 years, free of medications, or able to discontinue any medications other than oral contraceptives, and willing to accept random assignment to treatment in a double-blind procedure. Prospective patients were sent a screening packet that contained a brief description of the program and two screening measures for social phobia. Treatment applicants who reported subjectively distressing levels of social phobic anxiety and avoidance on either of the screening measures, ie, the Social Phobia Subscale of the Fear Questionnaire<sup>26</sup> and the Social Avoidance and Distress Scale,<sup>27</sup> were prescreened via telephone by one of us (C.S.G.). Eligible candidates for the treatment program were invited to the National Institute of Mental Health for a structured diagnostic interview.

In the next phase of the screening process, the patients were evaluated by one of two clinical psychology doctoral candidates with the use of the Anxiety Disorders Interview Schedule-Revised<sup>28</sup> and a modified form of the Schedule for Affective Disorders and Schizophrenia-Lifetime version.<sup>29</sup> Criteria for inclusion were a primary diagnosis of social phobia by *DSM-III* criteria and good physical health. Criteria for exclusion were (1) *DSM-*

*III* diagnosis of major depression, melancholic subtype; (2) pregnancy or the intention to become pregnant during the 6 months of the study; (3) a history of psychosis; (4) an active substance abuse problem; (5) presence of a medical condition that would contraindicate treatment with alprazolam or phenelzine; and (6) an inability to comply with rigorous protocol requirements, including drug and dietary restrictions. Patients were permitted to be in concurrent psychotherapy while they were participating in this protocol.

Sixty-five patients were admitted to the active phase of the study, and 59 completed the treatment program and the follow-up assessment. Forty-eight patients (74%) had chief complaints of anxiety and avoidance of specific social situations. Seventeen patients (26%) complained of more generalized and pervasive social fears. Patients were classified as having specific social phobia if their main fear (the phobic situation for which they sought treatment) involved one or two of the following activities: public speaking, eating in public, writing while they were being observed, or using a public rest room. Those patients who reported fears of interacting in most social situations were designated as having generalized social phobia. This subtyping is consistent with *DSM-III-R* criteria. Differences among the treatment groups in distributions of these fears were not significant.

The sample comprised 24 men (37%) and 41 women (63%), with a mean age of 36.5 years (SD, 9.6 years; age range, 18 to 60 years). Fifty-nine patients (91%) were white, and six (9%) were black or other minority. There were 32 married patients (49%), 29 single patients (45%), and four divorced or widowed patients (6%). Forty-two patients (64%) had at least a college education, with 16 patients (24%) having also completed graduate or professional training. Fourteen patients (22%) had completed some college, and seven patients (11%) had completed no higher education after high school. Two patients (3%) had not completed secondary school. Forty-eight patients (74%) were employed full-time, and five patients (8%) worked part-time. Twelve patients (18%) were not employed. There were no statistically significant differences among treatment groups on any of the demographic variables by  $\chi^2$  test results.

Although 27 patients (42%) had a history of major depression, only nine patients (14%) had affective disturbances (ie, dysthymic disorder) at the time of this study, and no patients currently met criteria for major depression. Several patients, however, met criteria for an additional *DSM-III* anxiety disorder, including generalized anxiety disorder ( $n = 19$  [29%]), panic disorder ( $n = 3$  [5%]), and panic disorder with agoraphobia ( $n = 1$  [2%]). Thirty-eight patients (58%) had received prior treatment of their psychiatric conditions. There were no significant differences among treatment groups in terms of these characteristics, except for a significantly greater number of patients who had experienced a spontaneous panic attack in their lifetime in the phenelzine-treated group and significantly fewer patients who had previously sought treatment in the cognitive-behavioral therapy group.

## Treatments

Subjects were randomly assigned to one of four treatment conditions: (1) cognitive-behavioral therapy, (2) pharmacotherapy with phenelzine and instructions for self-exposure to phobic stimuli, (3) pharmacotherapy with alprazolam and instructions for exposure, or (4) pill-placebo and instructions for exposure. Treatment assignments were made following completion of the pretest assessment. Fifteen subjects were assigned to each of the drug and placebo conditions, and 20 were assigned to the cognitive-behavioral therapy group. The difference in treatment group sizes resulted from a stratified randomization schedule (ie, one that assigned more patients to cognitive-behavioral therapy early in the subject selection process) that was designed to expedite the initiation of two 10-patient cognitive-behavioral therapy groups. Each of the treatments was 12 weeks in duration, and all patients were seen once weekly.

Subjects in the active medication and placebo conditions were seen individually, while subjects in the cognitive-behavioral therapy condition were treated in a group format.

At the first and fourth treatment sessions, all patients made ratings of treatment credibility and outcome expectancy using the Reactions to Treatment Questionnaire,<sup>30</sup> a measure that comprised a series of 10-point scales with higher numbers indicating greater credibility or more positive outcome expectancies. Analyses of variance (ANOVAs) of items from the Reactions to Treatment Questionnaire revealed that the four treatment groups did not show important statistical differences in their assessments of treatment credibility and outcome expectancy. It appeared, therefore, that the drug and cognitive-behavioral treatments were presented in a credible fashion and that patients in both the drug and cognitive-behavioral conditions held high expectancies for improvement. Thus, any resultant differences among groups on outcome measures were not likely to be due to credibility or expectancy effects.

**Cognitive-Behavioral Therapy.**—The cognitive-behavioral therapy condition was conducted in a group format by a team that comprised two clinical psychologists with postdoctoral training in cognitive therapy and experience in treating anxiety disorders. Two groups of 10 patients each met weekly for 2-hour sessions that were run according to a detailed social phobia treatment manual.<sup>30</sup> Major treatment components were cognitive-restructuring techniques, in-session-simulated social exposures, and personalized homework assignments that required both the use of cognitive-restructuring techniques and real-life exposure to previously avoided social situations. Therapists were oriented to the treatment protocol by an experienced cognitive therapist (D.B.A.), who remained available for consultation throughout the treatment program. All group sessions were audiotaped so that a manipulation check could later be performed. Two of us (C.S.G. and D.B.A.) monitored a sample of these tapes to assess adherence to the treatment manual.

**Drug Treatments.**—Medications were prescribed on an individual basis in a double-blind procedure by one of three psychiatrists (M.E.T., B.J.V., and T.W.U.) who met weekly with each subject for 15- to 30-minute sessions. During the weekly sessions, physicians made ratings of patients' symptoms and impairment, adjusted medication doses, and firmly encouraged patients to push themselves into phobic situations. The physician's adherence to the treatment protocol was monitored by one of us (C.S.G.) who periodically observed or audiotaped patient visits to check that patients received nonspecific, supportive contacts with a focus on encouragement to engage in exposure. Subjects took medication four times daily on a fixed dosage schedule. Dosages began at 0.7 mg/d of alprazolam and 10 mg/d of phenelzine sulfate and were increased within 4 weeks to a maximum of 6.3 mg/d of alprazolam or 90 mg/d of phenelzine sulfate. Placebos and active medications were prepared by the pharmacy at the National Institutes of Health, Bethesda, Md, in identical capsules. The pharmacy staff established and maintained the key to the medication blind. Dosages were increased until all social phobic symptoms had disappeared, until side effects precluded further increases, or until the maximum dosage was reached. The mean dose of alprazolam prescribed was 4.2 mg/d (SD, 1.3 mg/d; range, 2.1 to 6.3 mg/d), and the mean dose of phenelzine sulfate prescribed was 55 mg/d (SD, 16 mg/d; range, 30 to 90 mg/d). At the end of the 12th week, capsules were tapered and discontinued according to a planned 4-week dosage-dependent schedule, although the blinded physicians were allowed to adjust the rate of taper according to their clinical discretion (range, 2 to 5 weeks). Response to the taper schedule was variable; only one patient experienced withdrawal symptoms to an extent that warranted discharge on medication. No other patients reported symptoms of withdrawal at follow-up.

#### Assessment of Outcome

**Scales.**—Subjects were assessed at pretest (baseline), weekly during the treatment phase, at posttest (during the 12th week of

treatment before discontinuation of treatment), and at follow-up (2 months following discontinuation of treatment). This report will focus on pretest, posttest, and follow-up data from self-report and physician-rated measures of social phobic and related symptoms and of overall functioning.

The self-report measures were the Social Avoidance and Distress Scale,<sup>37</sup> Fear of Negative Evaluation Scale,<sup>37</sup> Fear Questionnaire,<sup>38</sup> 21-item Beck Depression Inventory,<sup>31</sup> the State and Trait forms of the Spielberger State-Trait Anxiety Inventory,<sup>32</sup> the Social Interaction Self-Statement Test,<sup>33</sup> and the Work and Social Disability Scale.<sup>34</sup> The Social Avoidance and Distress Scale (range, 0 to 28) and Fear of Negative Evaluation Scale (range, 0 to 30) were developed to measure the experience of anxiety and avoidance of social situations and the fear of being evaluated negatively by others. The Fear Questionnaire (range of the Social Phobia Subscale, 0 to 40) was designed to measure change in severity of phobic avoidance and distress. The 21-item Beck Depression Inventory (range, 0 to 63) measures manifestations of depression. The State and Trait forms of the Spielberger State-Trait Anxiety Inventory, both with a range of 20 to 80, measure state and trait anxiety. The Social Interaction Self-Statement Test assesses how frequently subjects make certain facilitative and inhibiting self-statements during social interactions. It yields separate scores (range, 15 to 75) for positive and negative self-statements. The Social Interaction Self-Statement Test was administered at pretest and posttest immediately after a behavioral assessment that involved exposure to the patient's target phobic situation (eg, giving a speech, informal conversation with a stranger, writing while observed). With the exception of the Social Interaction Self-Statement Test, patients completed this self-report battery at pretest, posttest, and follow-up. The physician-rated measure was the Work and Social Disability Scale,<sup>34</sup> a five-point measure of symptoms and related impairment in work and social functioning (1 = no disability, 2 = mild, 3 = moderate, 4 = marked, and 5 = severe). It was rated by the treating physicians at pretest, posttest, and follow-up during routine pharmacotherapy sessions.

**Analyses.**—Three statistical methods were utilized to assess treatment effects as follows: (1) Outcome was assessed by analyses of covariance (ANCOVAs), with pretest scores serving as the covariate, to examine differential effects among the four treatment conditions.<sup>35</sup> (2) To investigate treatment response across time within groups, repeated-measures ANOVAs were performed on the physician and patient-rated scales. (3) Finally, the patients were categorized as "responders" vs "nonresponders" after treatment according to whether subjects were below or above the mean (ie, 8.8) for the general population on the Social Phobia Subscale of the Fear Questionnaire.<sup>36,37</sup> The Fear Questionnaire was chosen retrospectively to dichotomize the patients into responders and nonresponders because this measure has been found to be a valid and reliable measure of social phobic symptoms and accurately reflects change in response to treatment.<sup>36</sup>

Conservative Huynhfeldt probabilities were used for all ANOVAs, and post hoc analyses employed Bonferroni's *t* test. Bonferroni's *t* test is used for within-experiment tests. Post hoc comparisons are at the protected type I error of 5%. All probabilities less than .05 are considered to be significant, although selected probabilities less than .10 are presented in the written text or tables.

#### RESULTS

Of the 65 patients admitted, six (9.2%) failed to complete the treatment program. Three subjects (15%) in the cognitive-behavioral therapy group and three (6.7%) in a drug condition (two in the phenelzine-treated group and one in the alprazolam-treated group) terminated early. Of the patients in the cognitive-behavioral therapy group who dropped out, two terminated within the first 2 weeks of treatment because they did not perceive the treatment as appropriate for their problems, and one withdrew because his father was terminally ill. The patient in the

\*Fs are for time effect, group effect, and group × time interaction, respectively, for each self-report measure. There were significant time effects on all rating scales. Within each scale, means not showing the same subscript differ significantly from each other. ANOVAs indicates analyses of variance; NS, not significant.

†AL indicates pharmacotherapy with alprazolam and instructions for exposure; PH, pharmacotherapy with phenelzine and instructions for exposure; PP, pill-placebo and instructions for exposure; and CBT, cognitive-behavioral therapy.

alprazolam-treated group who dropped out was extremely sensitive to the medication and was unable to tolerate even low doses without disabling side effects. The two patients in the phenelzine-treated group who dropped out left the program within the first few days, before actually starting active treatment, because of anxiety about taking blind medications. Data from one patient who was treated with alprazolam were discarded from outcome analyses because it was revealed at follow-up that he had been noncompliant with the medication regimen. Because of missing data on some measures, not all analyses reflect the full complete sample size of 58. Differences among the treatment groups in attrition rates were examined by  $\chi^2$  tests and were not statistically significant.

No significant differences among treatment groups appeared in the analyses of pretreatment scores on the main outcome measures, indicating that random assignment to the treatment groups was effective.

### Self-report Questionnaires

Repeated-measures ANOVAs showed a significant effect for time on each of the self-report scales (Table 1). Patients in all four treatment conditions showed significant within-group changes on every self-report measure from pretest to posttest and follow-up. On all but one measure, the Social Avoidance and Distress Scale, subjects maintained treatment gains at follow-up. On the Social Avoidance and Distress Scale, patients showed a significant score increment (greater avoidance) at follow-up, but they continued to report significantly less social avoidance and distress than they had at baseline. Because of space limitations, only three scales are presented in Table 1. Complete tables are available from the authors by request.

While the repeated-measures ANOVAs indicated that all four treatments decreased distress, the ANCOVAs indicated that no treatment was superior to the others. That is, the ANCOVAs (not presented) on the posttest and follow-up data failed, with one exception, to reveal significant differences among treatment

groups on the self-report questionnaires. A significant difference among treatment groups was demonstrated by ANCOVA on the Trait form of the Spielberger State-Trait Anxiety Inventory. Bonferroni's *t* tests revealed that at both posttest and follow-up, phenelzine-treated patients rated themselves as significantly less characteristically anxious than any of the other three groups, which did not differ significantly from each other.

From a practical perspective, it is often useful to categorize patients as responders vs nonresponders. For this purpose, we operationally identified any patient whose rating after treatment on the social phobia subscale of the Fear Questionnaire (see "Patients and Methods" section; this is a measure of phobic avoidance) was below the mean for the general population as a responder. Conversely, patients with ratings above the mean for the general population (ie, 8.8) were identified as nonresponders. This is a very rigid criterion for response and, in fact, would exclude patients who had demonstrated meaningful change.

However, we were interested in identifying those patients who we thought had demonstrated clear-cut and unequivocal improvement. Despite the inherent limitations of this strategy, it is noteworthy that 69% of the phenelzine-treated group would be categorized as responders compared with 38%, 24%, and 20% of the alprazolam-treated, cognitive-behavioral-treated, and placebo-treated patients, respectively. While two of the patients in the phenelzine-treated group had values below the population mean of 8.8 at pretreatment, there were no significant between-group differences on this measure at pretest. If these two individuals are eliminated from the data analysis, seven (63%) of the 11 patients with social phobia would still be designated as responders to phenelzine. The percentage of responders among the four groups was analyzed via a  $4 \times 2 \chi^2$  ( $\chi^2 = 6.5$ ,  $df = 3$ ,  $P < .09$ ).

In summary, patients reported significantly less fear of negative evaluation, social avoidance and distress, work and social disability, state and trait anxiety, and depression at posttest and

Table 2.—Repeated Measures ANOVA on the Physician-Rated Work and Social Disability Scale\*

follow-up compared with baseline. The patients also reported a significant reduction in negative self-statements and an increase in positive self-statements at posttest. Thus, while cognitive change was the expressed goal of only one treatment condition in this study, all groups changed cognitively with no significant differences among groups.

#### Physicians' Ratings

The Work and Social Disability Scale (range, 0 to 5, with higher numbers indicating greater disability) was rated by physicians at all assessment points. Since they were not blind to the patients' treatment status, group therapists did not rate group members on this scale. As indicated in Table 2, repeated-measures ANOVAs yielded significant time effects. All three medication-treated groups showed significant baseline to posttreatment change. Bonferroni's *t* tests showed that all three groups were significantly improved over baseline at both posttest and follow-up. The phenelzine-treated patients maintained their gains at follow-up. The placebo-treated group showed a nonsignificant increase on this scale from posttest to follow-up but remained somewhat improved over baseline.

As shown in Table 2, there was a significant effect of treatment at posttest and follow-up. Again, only a three-group comparison among the alprazolam-, phenelzine-, and placebo-treated patients was made on this measure. Bonferroni's *t* tests demonstrated that the alprazolam- and phenelzine-treated patients were rated as significantly less impaired than the placebo-treated patients at posttest. Two months later, when the medications had been discontinued, this pattern changed. At follow-up, the phenelzine-treated group continued to be rated as significantly less impaired than the placebo-treated group. The alprazolam-treated group, while remaining somewhat improved over baseline, was not significantly different from the placebo-treated group at follow-up. These findings were unchanged when covarying for baseline scores; that is, the ANCOVAs of posttest ( $F [2, 34] = 6.85, P < .003$ ) and of follow-up ratings ( $F [2, 32] = 3.7, P < .04$ ) revealed a significant effect of treatment condition on work and social disability. With post hoc testing of the adjusted means, significant treatment differences ( $P < .05$ ) were demonstrated at the identical posttest and follow-up time points presented in Table 2.

#### COMMENT

Well-designed comparative outcome research that examines the relative efficacy of cognitive-behavioral techniques and pharmacotherapy for social phobia has been lacking, a deficiency that this study has attempted to address. Its purpose was to examine the relative efficacy of alprazolam, phenelzine, and a cognitive-behavioral group treatment package. We compared treatment re-

sponses of 65 patients who were randomly assigned to one of four treatment conditions: alprazolam plus instructions for exposure, phenelzine plus instructions for exposure, pill-placebo plus instructions for exposure, or a group treatment package that comprised cognitive-restructuring and exposure techniques.

The results indicate that both cognitive-behavioral therapy and pharmacotherapies are effective treatments for some patients with social phobia and that, as a group, patients with social phobia seem to be responsive to treatment. Covariance analyses of self-report ratings at posttest and at follow-up failed, with only one exception, to show any significant difference among groups. The one exception was on the Trait Scale of the Spielberger State-Trait Anxiety Inventory, a self-report scale that measures the propensity to experience anxiety in stressful circumstances. On this measure, the phenelzine-treated group rated themselves as significantly less characteristically anxious at posttest and follow-up than any of the other treatment groups.

The data partially support the view that the active pharmacotherapies are superior to placebo. Analyses of the physicians' Work and Social Disability Scale ratings did not address the question of relative efficacy of the psychotherapy and pharmacotherapy because the patients who received psychotherapy were not rated on this scale. However, within the context of the drug conditions, these ratings indicated that the drugs were superior to placebo at posttest. At follow-up, the phenelzine-treated group continued to be rated as significantly less impaired than the placebo-treated group.

While our results failed to demonstrate definitively the consistent superiority of one treatment condition over the others, statistically significant repeated-measures effects were shown on all measures, indicating that the treatments were associated with substantial improvements in severe and chronic social phobia. Many patients in all conditions showed dramatic therapeutic gains on subjective ratings of social avoidance and distress, fear of negative evaluation, positive and negative self-statements and on physician and self-ratings of work and social disability. Improvements were also demonstrated on measures of anxiety and depression. Posttest and follow-up levels on these measures were comparable with those achieved in other treatment-outcome studies on social phobia that used similar interventions.<sup>20</sup>

Fig 1.—Pretest, posttest, and follow-up group means on the Fear Questionnaire (FQ)—Social Phobia Subscale compared with normative data from the adult general population. Triangles indicate the alprazolam-treated group; closed circles, phenzelzine-treated group; squares, placebo-treated group; open circles, cognitive-behavioral therapy group; and  $\bar{x}_N$ , general population mean.

We looked at how our patients' posttest and follow-up ratings on the Social Phobia Subscale of the Fear Questionnaire compared with norms from a large ( $N = 172$ ), randomly selected sample of adults in the general population (Fig 1).<sup>36,37</sup> Each of the four treatment groups had mean pretest ratings on this scale that approached or exceeded 2 SDs above the mean for the general population, indicating that ours was indeed a severely affected clinical sample. At posttest, all four treatment groups (placebo included) fell within 1 SD of the mean for the comparison group, suggesting that each of the treatment groups had, as a whole, achieved clinically significant change. However, there was a considerable amount of variability in individual responses to each of the treatments (Fig 2). Within each treatment condition, some patients made dramatic pretest to posttest changes, while in every group except the phenzelzine-treated condition, there was at least one patient who rated himself as slightly more avoidant at posttest than at pretest. This trend was most apparent in the placebo-treated group.

While data supporting claims of differential efficacy among the treatments are substantially limited and controversial, we find convincing support for the conclusion that all of the treatments were associated with substantial and, in many cases, meaningful changes in severe and chronic social phobia. Patients with social phobia are, however, a heterogeneous group who respond to treatment differently, according, presumably, to different clinical and biological characteristics of their illness. In future investigations, therefore, it will be important to examine the clinical and biological characteristics of partial and complete responders and nonresponders to delineate predictors of treatment response.

Our finding that the placebo-treated group improved as much as the other specific treatment groups on self-report

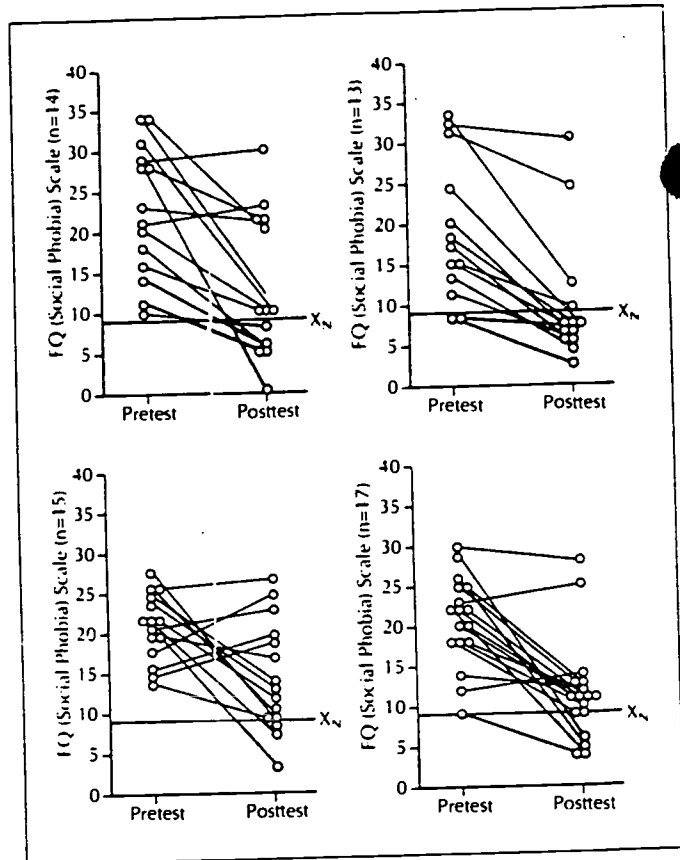

Fig 2.—Pretest to posttest change on the Social Phobia Subscale of the Fear Questionnaire (FQ) by treatment group. Top left, Alprazolam-treated group. Top right, Phenzelzine-treated group. Bottom left, Placebo-treated group. Bottom right, Cognitive-behavioral therapy group.  $\bar{x}_N$  indicates general population mean.

measures is somewhat misleading and directly related to the design of our study. That is, we strongly encouraged self-directed exposure as part of each treatment condition, including the placebo-treated group. Our study was designed in this manner to enhance external validity as all clinicians who treat social phobia will, at the minimum, encourage their patients to confront fearful situations. Accordingly, we underscore that our study lacked a true "no-treatment" control group. The specific effects of cognitive-behavioral therapy and drug treatments, therefore, are difficult to separate from the effects of self-directed exposure that was an integral part of the four treatment conditions; it was not surprising that all treatments were associated with statistically significant improvement. In fact, findings from the literature support the efficacy of exposure treatments of other anxiety disorders, with approximately 65% to 75% of patients with clinical phobias showing substantial improvements with exposure treatments.<sup>4</sup> Findings from previous studies also have suggested that exposure alone can be an effective treatment of social phobia.<sup>18,23,24</sup> Thus, the improvements in our pill-placebo and active treatment groups probably were mediated, in part, by the exposure component of the program.

An alternative explanation could be that the therapeutic gains were exclusively related to increased exposure. While the study design prohibits tests of this hypothesis, our finding that clinicians rated drug-treated patients significantly less disabled at posttest than the placebo-

treated group argues against this explanation. A no-treatment control condition would have been useful.

The treatments differed in their abilities to promote temporally stable improvements. The alprazolam-treated group responded to treatment discontinuation with a higher relapse rate. They showed significant decreases in work and social disability while they were receiving the medication and significant increases in disability ratings with discontinuation, unlike the phenelzine-treated patients. In fact, a high percentage of phenelzine-treated patients maintained a clinically relevant response. While the placebo-treated patients were significantly improved over baseline at follow-up, a very small percentage (13%) were actually judged to be unequivocal responders (ie, they had ratings below the mean for the general population on the Fear Questionnaire). The patients in the cognitive-behavioral therapy group also demonstrated clinically relevant changes on all self-report measures at posttest compared with pretest values. However, unlike the alprazolam-treated group, there was no loss of efficacy 2 months after the patients had been discharged. In fact, there was some evidence to suggest that cognitive-behavioral therapy might be associated with even greater improvement at follow-up. This preliminary finding is provocative, and future investigations should include a long-term follow-up to clarify this.

In summary, this study has demonstrated that social phobia is amenable to a variety of treatment approaches. Two findings (that the percentage of unequivocal responders in the phenelzine-treated group [63%] exceeded the percentage of responders in any other treatment group and that patients treated with phenelzine tended to maintain therapeutic gains when medication was discontinued, while those in the alprazolam-treated group tended to relapse) suggest a trend toward greater efficacy for phenelzine in the treatment of social phobia. We caution, however, that there was not a statistically significant difference among the four groups in the percentage of unequivocal responders, nor were there any significant differences among the four groups in the main repeated-measures analyses of primary outcome measures. Also, while the phenelzine-treated group maintained treatment gains, the cognitive-behavioral therapy group showed further improvement at follow-up.

We conclude that both cognitive-behavioral therapy and pharmacotherapies (alprazolam or phenelzine) are effective treatments, when combined with exposure, for some patients who are suffering with this disorder. Both pharmacotherapy and psychotherapy can be associated with marked cognitive and behavioral changes, but no single treatment can yet be designated as most effective. Thus, depending on the training and inclination of the clinician and the preferences of the patient, it would be reasonable to use any of these modalities. The only unreasonable choice would be a decision not to treat.

This study is limited by its short-term focus. Future research can establish the time course of therapeutic gains. Future research is needed also to examine the relationship of cognitive change to reductions in avoidance and symptom relief, to identify the mechanisms by which these cognitive changes are best achieved, and to delineate predictors of response to both cognitive-behavioral and drug therapies. Combined approaches to the treatment of social phobia should also be examined. Future treatment studies should also examine the question of

whether generalized and specific social phobic subtypes respond differentially to various treatments.

Work on the manuscript was supported in part by Research Training in Mental Health Epidemiology grant T32MH14235 from the National Institute of Mental Health, Bethesda, Md (Dr Gelernter).

Dr Gelernter was a Guest Researcher with Dr Uhde at the time of this study, which was conducted at the National Institute of Mental Health and the subject of Dr Gelernter's doctoral dissertation for the Department of Psychology, The Catholic University of America, Washington, DC.

The authors extend their thanks to the following individuals for their contributions to this investigation: Regina Ottaviani, PhD, Vincent Greenwood, PhD, and Murray Stein, MD, for treatment services; Richard Heimberg, PhD, for consultation on the cognitive-behavioral treatment package; David Barlow, PhD, and Peter DiNardo, PhD, and their staff at the State University of New York at Albany for training on the Anxiety Disorders Interview Schedule-Revised; Carole Palmer, Rahn Bruhr, PhD, Linda Berman, MA, Karen Cammuso, PhD, Heather Wood, MA, Steven Sinclair, Diana Roscow, and Kirstin Mikalaukas for their help with behavioral assessments; Barbara Curchack Routhieux and Margarita Osorio for their assistance in organizing the data; Joel Gelernter, MD, for his valuable comments on earlier drafts of the manuscript; and Robert Post, MD, for his ongoing support and scientific input into the research programs of the Section on Anxiety and Affective Disorders, National Institute of Mental Health.

PERSONALITY DISORDERS - AXIS II DIAGNOSIS

LEAST RELIABLE OF ANY OF MAJOR CATEGORIES IN DSM-III-R

- NO SHARP BOUNDARIES
- NORMAL  $\longleftrightarrow$  AXIS-I DIAGNOSIS
- EXTENT TO WHICH CURRENT BEHAVIORS REPRESENT ENDURING TRAITS

PERSONALITY DISORDERS

enduring patterns of perceiving, relating to,  
and thinking about ----- TRAITS

- exhibited in a wide range of important social and personal contexts
- inflexible and maladaptive
- recognized by adolescence or earlier
- continue throughout most of adult life
- certain are related to corresponding diagnostic categories in childhood, adolescence
- grouped into three clusters

# PERSONALITY DISORDERS

- Pervasiveness
- Inflexibility
- Enduring patterns
- Blind spots or socially undesirable features
- Maladaptivity and impairment

## PERSONALITY DISORDER CATEGORIES

CLUSTER A (PERSONS OFTEN APPEAR ODD OR ECCENTRIC)

PARANOID      SCHIZOID      SCHIZOTYPAL

CLUSTER B (PERSONS OFTEN APPEAR DRAMATIC, EMOTIONAL, OR ERRATIC)

ANTISOCIAL  
HISTRIONIC

BORDERLINE  
NARCISSISTIC

CLUSTER C (PERSONS OFTEN APPEAR ANXIOUS OR FEARFUL)

AVOIDANT  
DEPENDENT

OBSESSIVE COMPULSIVE  
PASSIVE AGGRESSIVE

PERSONALITY DISORDER NOT OTHERWISE SPECIFIED (NOS)

## PERSONALITY DISORDERS FACE VALIDITY STUDY

1. 8 of three largest overlaps in meaning occurred for pairs of disorders in different clusters

2. three pairs of personality disorders had high degrees of overlap:

avoidant --> dependent ----- 13%

histrionic --> narcissistic ----- 26%

schizotypal --> paranoid ----- 16%

3. other patterns of overlap:

avoidant, schizoid, schizotypal

antisocial - sadistic

histrionic, O-C, P-A,

with narcissistic

narcissism may be general personality disorder concept -- that is significant component of a number of disorders

4. histrionic -- only 3/8 criteria correctly assigned

schizotypal

avoidant -- lowest prototypical ratings

## **BORDERLINE PERSONALITY DISORDER**

- (1) Unstable / intense interpersonal relationships**
- (2) Impulsiveness - 2 area**
- (3) Affective instability**
- (4) Inappropriate, intense anger**
- (5) Recurrent suicidal threats - self-mutilating behaviors**
- (6) Identity disturbance**
- (7) Feelings of emptiness / boredom**
- (8) Efforts to avoid real or imagined abandonment**

### **Three Clusters of Pathology**

#### **AFFECTIVE INSTABILITY**

**MAO's**

#### **TRANSIENT PSYCHOTIC PHENOMENA**

**HALDOL**

#### **IMPULSIVE/AGGRESSIVE BEHAVIOR**

**LITHIUM  
PROZAC**

## PSYCHOTHERAPEUTIC APPROACHES -- COMMONALITIES

- (1) Relationship between the therapist and the patient
- (2) Therapist's active role
- (3) Need to set limits
- (4) Flexibility in implementation of treatment
- (5) Countertransference often evoked

# Epidemiology of Borderline Personality Disorder

Thomas A. Widiger, Ph.D.  
Myrna M. Weissman, Ph.D.

*The limited epidemiological data available on borderline personality disorder suggest that the prevalence of the disorder is between .2 and 1.8 percent in the general community, 15 percent among psychiatric inpatients, and 50 percent among psychiatric inpatients with a diagnosis of personality disorder. No data on the incidence—the rate of new cases—of the disorder have been reported, and inferences about incidence based on prevalence rates are complicated by differences in the formal designation of personality disorders before and after DSM-III was issued. Current findings suggest that about 76 percent of borderline patients are female. Epidemiological study of borderline personality disorder has been hindered by the lack of a brief semistructured interview that can be used with large population samples and that does not require substantial clinical expertise. The authors discuss alternative research methods, including use of lay interviewers, recoding of existing data, telephone interviews, and self-report inventories.*

Dr. Widiger is professor of psychology at the University of Kentucky, 115 Kastle Hall, Lexington, Kentucky 40506. Dr. Weissman is professor of epidemiology in psychiatry at Columbia University—New York State Psychiatric Institute in New York City. This paper is part of a special section on borderline personality disorder.

Epidemiology is the study of the distribution and determinants of disorders (1,2). Epidemiologic studies yield data on prevalence rate (the number of cases of a given condition at a particular time) and incidence rate (the number of new cases in a population), as well as on correlates (conditions and variables associated with occurrence of the disorder) and factors associated with risk of developing a disorder.

Borderline personality disorder has been of considerable clinical and theoretical interest, and a review of its epidemiology is certainly warranted. However, epidemiologic research requires systematic, reliable sampling of large numbers of representative cases within explicitly defined community and clinical populations (3); it is therefore very expensive. Epidemiologic research in psychiatry has benefited substantially from the development of specific, explicit diagnostic criteria and structured interviews that can be administered by lay interviewers (4). Epidemiological research on the personality disorders, however, has been hindered by difficulty in defining a disorder of personality using a brief list of specific symptoms and difficulty in assessing such a disorder by a concise set of simple and direct questions that require little or no inference or judgment on the part of the rater (5-7).

Antisocial personality disorder was the only personality disorder to be included in the Epidemiologic Catchment Area (ECA) study sponsored by the National Institute of Mental Health (8). The *DSM-III-R* diagnosis of antisocial personality disorder has the most specific and ex-

PLICIT diagnostic criteria of the personality disorders, but the validity of these criteria has been controversial precisely because of their specificity (9,10). Use of a brief list of specific questions to assess an equally concise set of criteria to diagnose borderline personality disorder would be even more difficult and controversial (11). The most popular semistructured interview for assessing borderline personality disorder is the Diagnostic Interview for Borderlines—Revised (DIB-R), which takes about an hour to administer and requires "substantial clinical experience" (12, p. 12).

Because of these limitations, there are few data on the epidemiology of borderline personality disorder in large community samples. In this paper, we review existing studies and provide estimates of epidemiologic parameters based on data reported in these studies. Our discussion is necessarily confined to questions of prevalence, incidence, and sex ratio, for which there still remains substantial controversy and dispute. We conclude our review with a discussion of alternative approaches to obtaining epidemiologic data on borderline personality disorder.

## Prevalence

Based on epidemiologic studies conducted before *DSM-III* was issued, Merikangas and Weissman (13) estimated the prevalence of borderline personality disorder within the community to be between .2 percent (14) and 1.7 percent (15). The latter figure is remarkably close to more recent estimates. Swartz and associates (16) recoded data collected in Durham, North Carolina, using the Diagnostic Interview Schedule

(DIS) as part of the ECA study (8). The prevalence rate of borderline personality disorder among the 1,541 community residents in the sample, who were between ages 19 and 55, was 1.8 percent.

Zimmerman and Coryell (17) interviewed 797 relatives of normal control subjects and of schizophrenic and depressed patients using the Structured Interview for DSM-III Personality Disorders (SIDP) (18). They reported a prevalence rate of 1.6 percent for borderline personality disorder. One of the more curious findings was that borderline personality disorder was not the most prevalent personality disorder diagnosed in the sample. Six personality disorders were diagnosed more frequently than borderline personality disorder. A total of 3.3 percent of the subjects received a diagnosis of passive-aggressive personality disorder.

Zimmerman and Coryell (19) also administered the Personality Diagnostic Questionnaire (PDQ) (20), a self-report instrument, to 697 relatives of psychiatric patients and normal control subjects. The prevalence rate of borderline personality disorder based on the PDQ was 4.6 percent. Reich and colleagues (21) sent the PDQ to 379 adults randomly selected from a university community in Iowa with a population of more than 36,000. The prevalence rate of borderline personality disorder in the 235 respondents was 1.3 percent.

Widiger and Trull (22) identified 30 studies published between 1975 and 1988 that used a clinical interview and provided sufficient data to estimate prevalence of borderline personality disorder in specific populations of psychiatric patients. The average prevalence across eight outpatient studies that had no inclusion or exclusion sampling criteria was 8 percent; for the 14 inpatient studies with no exclusion or inclusion criteria the average prevalence was 15 percent. In four outpatient studies that were confined to patients with a personality disorder, the prevalence of borderline personality disorder was 27 percent, and in four inpatient studies that were confined to patients with a personality disorder, the prevalence rate was 51 percent.

Widiger and Trull (22) also summarized the results from 14 studies that examined the prevalence rate for all 11 personality disorders. Borderline personality disorder was typically the most prevalent, and the differences between the rate of that disorder and the rates of other personality disorders were substantial in some studies. In a study by Zanarini and colleagues (23) of inpatients admitted with a probable axis II diagnosis, borderline personality disorder was diagnosed in 60 percent of the cases. The next most frequently diagnosed personality disorder was histrionic personality disorder, with a prevalence rate of 42 percent (subjects in this study and in those discussed below could receive more than one diagnosis).

Standage and Ladha (24) reported that 70 percent of the cases in a sample drawn from a general hospital psychiatric inpatient unit were diagnosed with borderline personality disorder; the next highest prevalence was 55 percent for dependent personality disorder. In a study by Skodol and colleagues (25) of applicants for admission to a long-term treatment program for severe personality disorders, 62 percent of the subjects received a diagnosis of borderline personality disorder; 49 percent received a diagnosis of avoidant personality disorder.

Among a sample of outpatients studied by Morey (26), most of whom had a diagnosis of personality disorder, 32 percent had a diagnosis of borderline personality disorder and 22 percent had a diagnosis of histrionic personality disorder. Hyler and Lyons (27) found a 21 percent prevalence rate of borderline personality disorder in a sample composed mostly of outpatients referred by psychiatrists who treated a large number of patients with personality disorder; the next highest prevalence rate in the sample was 11 percent for obsessive-compulsive personality disorder.

The prevalence rates for most personality disorder diagnoses tend to be much lower in data sets drawn from hospital and clinic charts than would be suggested by results of studies using semistructured inter-

views (28,29), but the diagnosis of borderline personality disorder may provide one exception to this trend. Koenigsberg and others (30) obtained the medical chart diagnoses for 2,462 patients. Borderline personality disorder was diagnosed in 12 percent of the cases. The next most frequent personality disorder diagnosis was histrionic personality disorder, diagnosed in only 3 percent of the cases.

Loranger (31) studied the prevalence of personality disorder diagnoses in a sample of patients treated in a university-affiliated psychiatric hospital between 1981 and 1985, the first five years after *DSM-III* was issued. Of a total of 5,771 patients, 2,840 received a diagnosis of personality disorder. The most common diagnosis was atypical, mixed, or other personality disorder, diagnosed in 32.6 percent of 2,916 cases among the 5,771 patients. Borderline personality disorder was diagnosed in 26.7 percent of the cases, and the distant third was dependent personality disorder, diagnosed in 9.1 percent of the cases.

### Incidence

The high prevalence rates that have been obtained for borderline personality disorder call into question the validity of the diagnosis. Borderline personality disorder was not formally recognized as a diagnosis until 1980, but the disorder is now diagnosed more frequently than any other personality disorder. About 15 percent of all inpatients and half of all inpatients with a personality disorder receive this diagnosis (32).

Examination of the incidence of borderline personality disorder—the rate of new cases in the population at risk during a specified period of time (3)—could help clarify findings about the prevalence of the disorder. However, no data on the incidence of borderline personality disorder has been reported.

Loranger's study (31) of the prevalence of the disorder did include a comparison of clinical diagnoses made before and after *DSM-III* was issued. In that study, the most prevalent personality disorder diagnoses made between 1975 and 1979, before *DSM-III* became available, were

"other" (54.3 percent of 984 cases diagnosed with a personality disorder), hysterical personality (9.5 percent), antisocial personality (9.3 percent), schizoid personality (5.8 percent), and passive-aggressive personality (5.5 percent). From 1981 to 1985, after *DSM-III* was issued, the most prevalent diagnoses were atypical, mixed, or other (32.6 percent of 2,916 cases of personality disorder), borderline personality disorder (26.7 percent), dependent personality disorder (9.1 percent), narcissistic personality disorder (5.9 percent), and antisocial personality disorder (4.6 percent).

One could not, however, infer an increased incidence of borderline personality disorder from Loranger's data. These data show that the prevalence rate for any personality disorder diagnosis increased dramatically, from 19.1 percent of all cases before *DSM-III* to 49.2 percent of all cases after *DSM-III*. The increase appears to reflect the conversion to a multi-axial diagnostic system rather than an actual increased incidence of personality disorders. In the development of *DSM-III*, the principal reason personality disorders were placed on a separate axis was to encourage clinicians to overcome the tendency to miss or ignore the presence of a personality disorder in the context of a more florid or immediate clinical syndrome (33). Loranger's data suggest that this educational aim has been accomplished.

Millon (34) suggested that the current prevalence of borderline personality disorder does in fact reflect increased incidence. Millon wrote, "Our contemporary epidemic of borderline personality disorder can be best attributed to two broad socio-cultural trends that have come to characterize much of Western life this past quarter century, namely the emergence of social customs that exacerbate rather than remedy early, errant parent-child relationships and, second, the diminished power of formerly reparative institutions" (34, p. 355). Examples of divisive social customs include rapid industrialization, changing sex roles and increased divorce, poor role models in the media, and increased availability

of illegal drugs. Examples of diminished reparative institutions include declining schools and religious institutions and the absence of nurturing surrogates due to the scattering of the nuclear and extended family.

It could also be the case that 15 percent of all inpatients had borderline personality disorder before *DSM-III* but that they received instead the nonspecific diagnosis of "other" or a diagnosis of hysterical or passive-aggressive personality. Vaillant (35), however, has argued that the current prevalence rates may be somewhat iatrogenic. He wrote, "These disorders are still usually observed only in American cities that have opera houses and psychoanalytic institutes" (35, p. 543). There may be some truth in Vaillant's suggestion that the prevalence of borderline personality disorder reflects local interest. The high rates of borderline personality disorder reported by Koenigsberg and others (30) and Loranger (31) were found in studies conducted at Cornell University Medical College, where considerable attention has been given to the borderline diagnosis.

The excessive prevalence, however, is consistent with Kernberg's formulation (36) of borderline personality disorder as a borderline level of personality organization. Borderline personality organization does not refer to a distinct personality disorder but rather a level or degree of personality dysfunction. Borderline personality organization may be compared with other types of personality organization rather than with various types of personality disorders such as histrionic, antisocial, or schizotypal personality disorder. Borderline personality organization is distinguished from neurotic personality organization by a predominance of primitive defensive operations centering on the mechanism of splitting; it is distinguished from psychotic personality organization by its maintenance of a capacity for reality testing. Many if not most inpatients with a personality disorder would likely be functioning at a borderline level of personality organization.

The excessive prevalence of bor-

derline personality disorder is also consistent with an interpretation of the disorder as representing excessive neuroticism (37). A general trait of personality dysfunction, excessive neuroticism includes elements of impulsivity, hostility, anxiety, depression, self-consciousness, and vulnerability and would likely be characteristic of a substantial proportion of mentally ill patients.

#### Sex ratio

*DSM-III-R* states that borderline personality disorder is more commonly diagnosed in females than in males (38). Akhtar and others (39) verified this clinical impression in a meta-analysis of 23 studies. Across the 23 studies, the average percentage of cases of borderline personality disorder in which the patient was female was 77 percent. However, they included results from studies with overlapping data sets and biased samples. For example, they included the results of a study by Loranger and others (40) although the sample in that study was intentionally and explicitly limited to females. Widiger and Trull (22), however, identified 75 studies that provided nonoverlapping and unbiased estimates of the sex ratio for borderline personality disorder. In those studies the average percentage of cases involving female patients was 76 percent, with a 95 percent confidence interval of 73 to 80 percent, a finding consistent with that of Akhtar and associates.

Other researchers have argued, however, that the increased rate of borderline personality disorder in females reflects sex bias by diagnosing clinicians (41). Henry and Cohen (42) administered a 35-item questionnaire based on the features of borderline personality disorder to 277 college students (80 males and 197 females). Males scored significantly higher on items concerned with impulsivity, unstable relationships, identity disturbance, and feelings of emptiness.

Henry and Cohen indicated that because normal males acknowledge more borderline personality disorder symptoms than normal females, it was inconsistent that females would be more likely than males to receive

the diagnosis. They suggested that clinicians might consider borderline personality disorder traits to be congruent with the masculine sex role and thus find them more acceptable in males, whereas "in women these traits may be seen as less appropriate to [their] sex role, and therefore women may be more likely to be labeled as having borderline personality disorder" (42, p. 1529).

Henry and Cohen's hypothesis suggests that a self-report assessment of borderline personality disorder would provide a different sex ratio than diagnoses based on clinical interviews. However, this has not been the case. Females have typically scored higher than males on the Personality Diagnostic Questionnaire and on the scales for borderline personality disorder in the Minnesota Multiphasic Personality Inventory (MMPI) (43).

Kass and associates (44) and Reich (43) reported that the proportion of women who received a diagnosis of borderline personality disorder was not significantly higher than the proportion of women seen at the respective clinics where the data were collected. Both authors suggested that these findings are inconsistent with the sex bias hypothesis, since clinicians did not tend to give the diagnosis to more women than would be expected, given the number of women who sought treatment. However, there is no reason to presume that the proportion of women with borderline personality disorder should be equivalent to the proportion of women treated in a given setting. Simply because there are more females than males at a clinic does not suggest that there will be more females than males with every disorder (including borderline personality disorder) that is diagnosed at that clinic (45).

In their comparison of clinicians' diagnoses based on clinical impression versus clinicians' diagnoses based on a systematic assessment of each *DSM-III* criterion for borderline personality disorder, Morey and Ochoa (46) found that clinicians tended to give a diagnosis of borderline personality disorder to patients who met the criteria of suicidal ges-

tures, self-damaging impulsivity, and affective instability or any combination of these criteria, even though the patient lacked additional features of borderline personality disorder. Less experienced clinicians, psychodynamically oriented clinicians, and female clinicians were also more likely to give a diagnosis of borderline personality disorder, and white patients with a low income were more likely to receive this diagnosis. Females were only marginally more likely to be given a diagnosis of borderline personality disorder, and the effect of gender was insignificant compared with the other effects noted.

Widiger and Trull (22) compared the sex ratios obtained in studies of borderline personality disorder that used a semistructured interview ( $N=34$ ) to those obtained in studies that used an unstructured clinical interview ( $N=41$ ). If sex biases affect clinicians' diagnoses, one would expect the proportion of women with the diagnosis to be higher in studies that did not use a structured interview. However, the opposite result was found. The average proportion of women with the diagnosis of borderline personality disorder was 80 percent in studies that used a semistructured interview and 73 percent in studies that used an unstructured interview ( $z=3.05$ ,  $p<.01$ ).

#### Methodological innovations

A reasonable epidemiologic study of borderline personality disorder might require the administration of a semistructured interview by experienced clinicians to more than a thousand subjects chosen by a probability sampling. The cost of such a community study would be substantial and perhaps prohibitive. One may then ask whether an epidemiologic study of borderline personality disorder at this time would be worth the cost.

A large-scale epidemiologic study would likely provide useful estimates of prevalence, risk factors, and correlates, but these data would still be ambiguous because the validity of the diagnosis is still in question. It would be especially important to assess whether findings about the epidemiology of borderline personality

disorder could be adequately explained using more traditional concepts of personality disorder, such as dependent and histrionic personality disorder, or by more traditional concepts of personality, such as neuroticism. The inclusion of additional measures of personality and personality disorder would be very important to the internal validity of the study design but would escalate the cost considerably.

However, a variety of alternative approaches to assessment that might reduce the cost have been proposed. These strategies include the use of lay interviewers, use of data that have been recoded from earlier studies, telephone interviews, and self-report inventories. Each of these options will be discussed in turn.

**Lay interviewers.** The success of the ECA study was due in part to the development of a structured interview that could be administered by persons with little or no professional or clinical experience (4). Antisocial personality disorder could be included in the Diagnostic Interview Schedule form used in the ECA study because the criteria for this diagnosis, such as unemployment and illegal activity, require relatively little clinical inference and judgment. It is questionable whether a lay interviewer could assess the more subtle criteria for borderline personality disorder, such as identity disturbance or chronic feelings of emptiness and boredom (7).

However, lay interviewers could be trained to assess the criteria for borderline personality disorder; in fact, some studies of the disorder have successfully used them (47). One advantage is that lay interviewers lack the clinical assumptions and expectations that tend to bias findings (7). On the other hand, training and supervising them can be expensive. Widiger and associates (47) found that these activities required more time and effort than would have been required if experienced clinicians had been employed. However, only 84 subjects were interviewed in their study. The benefits of using lay interviewers may outweigh the cost when sample sizes exceed 500.

### *Recoding existing data sets.*

Swartz and associates (16) derived epidemiologic data on personality disorder by recoding data collected using the DIS in the ECA study. However, the DIS obtained axis I symptoms that had occurred during the past year such as suicide attempts, anxiety attacks, anxiety for one month or more, tenseness or jumpiness, and three or more depressive symptoms. These symptoms are likely to be seen in borderline patients during a one-year period, but inferring the presence of borderline personality disorder on the basis of axis I symptoms that are known to have occurred only during the last year risks confusing a personality disorder with a mood disorder.

It is not surprising that Swartz and associates found substantial comorbidity of borderline personality disorder with mood and anxiety disorders, given that the respective diagnoses were based on the same diagnostic criteria. In a separate report by Swartz and associates (48), diagnoses of borderline personality disorder using DIS data showed significant agreement with diagnoses using the DIB, but these findings could also raise questions about the validity of the DIB borderline personality disorder diagnosis. To the extent that borderline personality disorder can be diagnosed on the basis of axis I symptoms that have occurred during the past year, borderline personality disorder may be no more than another name for a nonspecific assortment of axis I symptomatology.

The recoding of existing data sets saves the expense of collecting new data, but one does need to ensure that the algorithm provides a valid facsimile of the diagnostic criteria for borderline personality disorder. It is particularly important to ensure that the symptoms are lifelong and chronic, given the ease with which axis I disorders are confused with axis II disorders (28,49).

*Telephone interviews.* Telephone interviews can provide a substantial savings in time and effort. The epidemiologic interviews of 797 subjects by Zimmerman and Coryell (17) were conducted for the most part by telephone. Only about 27

percent of those interviews were conducted in person.

Kendler (50) questioned the validity of these telephone assessments, which used the Structured Interview for DSM-III Personality Disorders. He noted, for example, that the SIDP requires observation of nonverbal responses to assess the schizotypal personality disorder criterion of inadequate rapport in face-to-face interactions (19).

There is also a risk that a telephone interview will provide an overly simplistic assessment. Zimmerman and Coryell (17) did not indicate the average length of each interview, nor did they provide any control for confidentiality (that is, the subjects may not have been alone during the interview). They indicated that there were no significant differences between the prevalence rates obtained using face-to-face interviews and those obtained using telephone interviews, but the actual data were not provided. Zimmerman and Coryell subsequently provided the correlation of the PDQ and SIDP scores for 697 of the subjects (19). Agreement about the presence of a diagnosis of borderline personality disorder was not substantial, but it was statistically significant ( $k=.30$ ,  $p<.05$ ); agreement in subjects' total scores on items assessing borderline personality disorder was also small, but again it was significant ( $r=.39$ ,  $p<.01$ ). Agreement was no better for the face-to-face interviews than for the telephone interviews.

Skepticism about the validity of telephone interviews for personality disorders is understandable, but most of the limitations would also apply to a self-report inventory. The criteria for borderline personality disorder may be assessed without face-to-face contact, and a telephone interview at least provides the opportunity for follow-up questions and probes that is not available in studies using a self-report inventory.

*Self-report inventories.* Self-report inventories have been the customary method used in psychological research on adaptive and maladaptive personality traits. One advantage is the ability to obtain the responses to a large number of struc-

ured questions from a large number of subjects in a systematic, objective, and reliable manner. The potential application of this methodology to epidemiologic research on personality disorders is evident. The recent revision of the Minnesota Multiphasic Personality Inventory involved to a large extent an epidemiologic study with self-report inventories (51).

The customary method for researching personality disorders has been with semistructured interviews. The major limitation of self-report inventories is the inability to conduct open-ended probes and to add or alter questions in response to statements by or observations of the subject. However, as one increases the structure of an interview to minimize professional inference and judgment to the point that a lay person can conduct the interview with direct questions that have structured responses, there may be little lost by simply providing a self-report questionnaire.

An additional concern about self-report inventories, however, is that responses may be affected substantially by the depressed, manic, or anxious state of the subject (49). In the epidemiologic study by Zimmerman and Coryell (19), there was a significant tendency for responses to the PDQ questionnaire to result in more diagnoses of personality disorder than responses to the SIDP interview. For example, a total of 4.6 percent of the subjects who answered the PDQ met criteria for borderline personality disorder, compared with 1.7 percent of subjects who responded to the SIDP. However, use of the SIDP resulted in more persons being diagnosed with a personality disorder than did use of the PDQ (13.5 percent, compared with 10.3 percent). In other words, the interviewers diagnosed more persons with a personality disorder but gave substantially fewer diagnoses for each individual.

The discrepancy between the SIDP and the PDQ was associated primarily with transient depression and the lie scale of the PDQ, which included items such as "I am the worst person in the world." This as-

sociation suggests that subjects' self-reports of their maladaptive personality traits were exaggerated. It is possible, however, that a different self-report inventory could provide more reliable results.

### Conclusions

Clinical research has suggested that borderline personality disorder is a prevalent personality disorder, particularly within inpatient samples. The frequency with which borderline personality disorder is diagnosed, however, may be inconsistent with the construct of the disorder as a distinct clinical condition. Rather, the excessive prevalence may be more consistent with an interpretation of borderline personality disorder as indicating a degree of personality dysfunction or disorganization.

Researchers are far from providing conclusive data about the epidemiology of borderline personality disorder within community samples, although substantial research on the disorder within clinical settings exists. A meta-analysis of the research to date suggests that about 76 percent of borderline patients are female, but even this basic finding is not without dispute.

The cost of conducting an extensive epidemiologic study of borderline personality disorder may be prohibitive, and this expense may not be warranted given the ambiguity of results obtained using currently available assessment instruments. In the meantime, alternative methodologies are worth pursuing, particularly the use of telephone interviews, lay interviewers, and self-report inventories.

This paper is part of a special section on borderline personality disorder.

*gest the use of a self-report questionnaire as a cost-effective screening test. Assessment problems, such as the need for longitudinal observation, are reviewed. Essential features of the recommended diagnostic approach include clarity about the diagnostic concept, consideration of the full range of diagnostic criteria, incorporation of recently developed diagnostic methodologies, care in distinguishing personality disorders from comorbid axis I syndromes, and complete assessment of the full range of axis II disorders.*

Borderline personality disorder is certainly common in treatment settings and may be so in the general population. In a 1989 review of systematic studies, Widiger and Frances (1) estimated that 11 percent of all psychiatric outpatients and 19 percent of all inpatients have the diagnosis. Borderline personality disorder may account for one-third of all outpatient diagnoses of personality disorder and almost two-thirds of all such inpatient diagnoses. In the

community, where less systematic research has been conducted, estimates vary widely from a low of .2 percent to a high of 15 percent.

Not only is borderline personality disorder common, but it also presents a considerable clinical challenge. The disorder can be difficult to diagnose and to treat and can predispose to, be accompanied by, or interfere with the treatment of many other mental disorders. The purpose of this paper is to offer a guide to assessment strategies for diagnosing borderline personality disorder.

## Concepts and criteria

The prevalence of borderline personality disorder varies not only by the setting in which an assessment is made but also by the definition of the disorder used. The borderline concept dates back 50 years. Over the years, however, the term borderline has had multiple meanings and has referred to diverse patient groups (2). Modern attempts to characterize borderline patients have emphasized definition by diagnostic criteria, culminating in the diagnostic criteria for borderline personality disorder

developed by Spitzer and colleagues (3) and adopted for *DSM-III* (4).

**Current concepts.** The three most commonly described concepts of borderline personality today are those of Gunderson and associates (5,6), those of Kernberg (7,8), and those described in *DSM-III* and *DSM-III-R* (4,9). Based on the work of Spitzer and colleagues (3), *DSM-III* divided patients often referred to as borderline into two groups, one characterized by instability of mood, interpersonal relationships, self-image, and impulse control and the other characterized by deficits in interpersonal relatedness and peculiarities of ideation, appearance, and behavior. The disorder of the former group was given the name borderline personality disorder, which was believed to be comparable to the concept of borderline that grew out of the psychoanalytic literature. The disorder of the latter group was designated schizotypal personality disorder, which was thought to describe persons with so-called borderline schizophrenia in the Danish adoption studies of schizophrenia (10,11). In this paper, we focus primarily on a descriptive model for the diagnosis of borderline personality disorder, as represented by *DSM-III* and *DSM-III-R* criteria rather than on a model based on developmental history or unconscious motivation.

Conceptually, the criteria of Gunderson and associates, Kernberg, and *DSM-III* for borderline personality disorder are similar but not identical. Gunderson's diagnosis includes characteristic dysphoric affects, such as anger, depression, anxiety, and emptiness; unstable interpersonal relationships; and poor impulse control leading to self-damaging acts. All of these criteria are included in *DSM-III*, but Gunderson also emphasizes brief psychotic experiences, dissociative states, or other cognitive distortions, which are not part of the *DSM-III* concept. *DSM-III*, on the other hand, includes a criterion of identity disturbance, which is not emphasized by Gunderson. Kernberg's concept of borderline personality organization emphasizes an unstable sense of self, use of primitive defense mechanisms, and temporary

lapses in—but overall maintenance of—reality testing. Kernberg's concept is hypothesized to cut across a number of severe personality disorder subtypes as described in *DSM-III*, for example, narcissistic, antisocial, and schizoid personality disorders (12).

Morey (13) has shown that *DSM-III-R* criteria for borderline personality disorder identify virtually the same patients as *DSM-III* criteria ( $k = .97$ ). The relationship between borderline personality disorder as diagnosed by *DSM-III* and the disorder as diagnosed by other criteria has been studied but is less clear. Of six studies that have applied *DSM-III* criteria and Gunderson's criteria to the same patients, two found the Gunderson concept to apply to more persons (14,15), one found that *DSM-III* fit more persons (16), and three found no difference (17–19).

Our group used a self-report instrument and a semistructured interview to assess borderline personality organization and its three subcomponents in a sample of patients with personality disorders (20,21). We found that, as predicted, patients with personality disorders theoretically at the borderline level of functioning tended to be intermediate between patients with diagnoses at the neurotic and psychotic levels (8).

Kernberg and associates (22) and Koenigsberg (23) reported modest agreement ( $k = .45$  and  $.49$ , respectively) between structural diagnoses of borderline personality organization and Gunderson's borderline diagnosis made by structured interview. Kullgren and Armelius (24) found that borderline personality organization described patients with a wide variety of *DSM-III* axis I and II disorders; 46 percent of patients with borderline personality organization had borderline personality disorder, but 20 percent of patients with borderline personality disorder did not have borderline personality organization.

Cases fitting multiple definitions of borderline personality disorder may be considered likely to represent true cases, but when discrepancies exist, mere disagreement is not informative. It is necessary to deter-

mine whether disagreements occur in cases near the diagnostic thresholds of the various systems and whether one definition is more useful than another for clinical or research purposes.

**Criteria and diagnostic categories.** *DSM-III* and *DSM-III-R* both define borderline personality disorder with a polythetic criteria set; any five of eight criteria are sufficient for the diagnosis. A polythetic format implies that all criteria are of equal diagnostic significance. Is this assumption warranted?

Individual traits or behaviors might be considered diagnostically relevant because they are very typical of a disorder or because they are very useful in differentiating one disorder from another. The most characteristic features need not be the most discriminating. The proportion of patients with the disorder who have a characteristic symptom is called the sensitivity of the symptom. A symptom's positive and negative predictive power, that is, its value in identifying or ruling out a disorder, are measures of its discriminative value.

In a review of 14 research studies, Widiger and Frances (1) found that impulsivity and affective instability were the most characteristic manifestations of borderline personality disorder but that physically self-damaging acts, unstable-intense interpersonal relationships, and impulsivity were the most diagnostically useful. Surveys of clinicians found that identity disturbance, intense and inappropriate anger, unstable relationships, and impulsivity were believed to be most typical (25,26). The majority of studies found the *DSM-III* criterion of intolerance of being alone to be poorly associated with a diagnosis of borderline personality disorder and to be rated as least typical by clinicians. This was the one criterion changed (to abandonment fears) in *DSM-III-R*.

Widiger and Frances (1) point out that the diagnostic importance of a symptom may vary depending on the setting in which a patient is seen and the differential diagnosis that is at issue. In outpatient settings, the relatively uncommon behaviors subsumed under physically self-damag-

ing acts have the highest positive predictive value for borderline personality disorder. Unstable-intense relationships are more rare and are more specific for borderline personality disorder among inpatients than among outpatients. Outpatients' relationships are apparently more commonly unstable regardless of their personality disorder diagnoses.

These analyses leave unanswered the question of whether there is a core set of symptoms for borderline personality disorder (27) and other symptoms that are a function of comorbid disorders, psychobiology, or severity, chronicity, or other non-specific aspects of a patient's psychopathology. Some symptoms, such as affective instability, are inevitably present in patients with comorbid mood disorders (see below) and may not turn out to be central features of the borderline construct at all. Furthermore, the requirement that five of eight criteria define borderline personality disorder is admittedly arbitrary (28,29). Should a patient who meets the three or four most characteristic and distinctive criteria not receive the diagnosis?

Until a system can be devised to weight particular criteria differentially and result in accurate diagnoses in a variety of settings and patient populations, the eight *DSM-III-R* criteria must be considered as defining a prototype. The more features a patient exhibits, the more certain the diagnosis. Subthreshold cases with highly typical or specific symptomatology may be viewed as provisional cases pending further evaluation. Subthreshold cases with mostly nonspecific symptoms, such as affective instability, anger, and fears of abandonment, strongly suggest that another disorder may be present.

Morey and Ochoa (30) have studied how closely practicing psychiatrists and psychologists adhere to *DSM-III* criteria in assigning diagnoses of personality disorders. Although clinicians diagnosed borderline personality disorder fairly consistently in accord with diagnostic criteria, some misdiagnosis relative to other personality disorders occurred. Less experienced clinicians

tended to diagnose borderline personality disorder when a patient did not meet the full criteria, and more experienced clinicians tended not to make the diagnosis even when patients actually met criteria. Poorer patients were more likely to receive a diagnosis without meeting criteria, while wealthier patients went undiagnosed despite sufficient symptomatology. There were weaker tendencies for psychodynamically oriented clinicians to overdiagnose and for psychologists to underdiagnose.

Borderline personality disorder is more commonly diagnosed in women than in men (31). Labeling processes have been implicated as contributing to the overrepresentation of women (32). Morey and Ochoa (30) found a relationship, though relatively weak, between a patient's gender and misdiagnosis: female patients tended to receive the diagnosis undeservedly. Interestingly, female clinicians tended to overdiagnose the disorder, and male clinicians tended to underdiagnose it.

However, in Morey and Ochoa's study (30), symptom patterns reflecting idiosyncratic diagnostic practice were more strongly associated with misdiagnosis than were demographic or practitioner variables. Among the symptoms of borderline personality disorder, suicidal threats and gestures were associated with overdiagnosis when present and with underdiagnosis when absent. Other evidence of impulsivity and affective instability were also associated with overdiagnosis. These results suggest that clinicians tend wrongly to equate mood disturbance and impulsive suicide attempts with borderline personality disorder. We return to the problem below.

### Diagnostic methods

The burgeoning interest in borderline personality disorder as a research focus (33,34) has spawned a plethora of tools to assist in the diagnostic process. There are currently five structured or semistructured interviews available to diagnose borderline personality disorder as well as the other personality disorders included in *DSM-III-R*, three others focused solely on borderline concepts, five self-report questionnaires

covering all of axis II, and one more self-report instrument specifically designed to assess borderline pathology. Table 1 lists these instruments and interviews along with some of their features.

A major difference between the interviews for axis II disorders is the format by which the questions are organized. The Structured Interview for *DSM-III-R* Personality Disorders (35), the Personality Disorder Examination (PDE) (36), and the revised version of Personality Interview Questions (PIQ-II) (37) are organized on the basis of six to 17 areas of functioning, such as work, affects, or interpersonal relations. Questions in the Structured Clinical Interview for *DSM-III-R* Personality Disorders (SCID-II) (38) and the Diagnostic Interview for Personality Disorders (DIPD) (39) are organized by the personality disorder that they are meant to explore.

All of the interviews are explicitly designed to be administered by experienced clinical personnel, except for the PIQ-II, which has been used in studies by trained lay interviewers. The Diagnostic Interview for Borderlines (DIB) (40) has recently been revised by Zanarini and colleagues (41) to improve its ability to distinguish patients with borderline personality disorder from patients with other axis II disorders. The DIB-R questions are grouped into sections on affect, cognition, impulse action patterns, and interpersonal relationships. The DIB-R differs from the DIB in that the nondiscriminating section on social adaptation has been deleted, impulse action patterns and characteristic disturbances in interpersonal relations have been given more diagnostic weight relative to the affect and cognition (formerly psychosis) sections, and the interview now focuses on the past two years of the patient's life. Some specific items have also been changed.

The characteristics of these instruments have been previously reviewed in detail (42-44). Here we mention briefly their ability to improve reliability of the diagnosis of borderline personality disorder and their validity.

**Reliability.** The reliability of

**Table 1**  
Features of interviews and self-report instruments for the assessment of borderline personality disorder

Interview or instrument	Author	Type	Diagnostic range	Special features
Structured Interview for DSM-III-R Personality Disorders	Pfohl et al. (35)	Interview	All axis II disorders	Patient and informant questions
Personality Disorder Examination	Loranger (36)	Interview	All axis II disorders	Detailed instruction manual
Structured Clinical Interview for DSM-III-R Personality Disorders	Spitzer et al. (38)	Interview	All axis II disorders	Axis I section; axis II screening questionnaire
Diagnostic Interview for Personality Disorders	Zanarini et al. (39)	Interview	All axis II disorders	Best test-retest reliability
Personality Interview Questions-II	Widiger (37)	Interview	All axis II disorders	Nine-point scale for traits and behaviors
Diagnostic Interview for Borderlines	Gunderson et al. (40)	Interview	Borderline personality disorder	Gunderson criteria
Borderline Personality Scale	Perry & Cooper (85)	Interview	Borderline personality disorder	Highly structured
Schedule for Interviewing Borderlines	Baron & Gruen (86)	Interview	Borderline personality disorder	Companion schizotypal section
Personality Diagnostic Questionnaire-Revised	Hyer et al. (48)	Self-report	All axis II disorders	Face valid items
Millon Clinical Multiaxial Inventory-II	Millon (51)	Self-report	All axis II disorders	Dimensions of axis I and axis II psychopathology
Wisconsin Personality Inventory (Revised)	Klein (87)	Self-report	All axis II disorders	Integrates structural analysis of social behavior model <sup>1</sup>
Schedule for Normal and Abnormal Personality	Clark (89)	Self-report	All axis II disorders	Normal and abnormal personality measures
Minnesota Multiphasic Personality Inventory (MMPI) scales for DSM-III personality disorders	Morey et al. (90)	Self-report	All axis II disorders	Constructed from MMPI item pool
Borderline Syndrome Index	Conte et al. (91)	Self-report	Borderline personality disorder	Includes schizotypal items

<sup>1</sup> Benjamin (88)

diagnostic judgments is usually expressed by the kappa statistic, a measure of agreement between two raters or ratings, corrected for the possibility of agreement by chance. A kappa of 0 means agreement is strictly by chance; a kappa of 1 indicates perfect agreement. Generally, kappas below .40 are considered poor, .40 to .60 fair, .60 to .75 good, and above .75 excellent (45).

Even though borderline personality disorder is defined by explicit diagnostic criteria in *DSM-III*, the reliability of the diagnosis as made in routine clinical practice has been found to be low ( $k = .29$ ) (46). This poor reliability is due, in part, to error introduced into the diagnostic process by variations in the amount and kinds of information available on which to base a diagnosis. Use of a

systematic routine for gathering information—that is, a semistructured interview or questionnaire—should reduce this source of diagnostic error.

Several studies that have assessed samples of patients and persons in the community using interviews for axis II disorders have found the reliability of the diagnosis of borderline personality disorder to be high ( $k = .70$  to  $.96$ ). The only exception appears to be the multisite reliability study of the SCID-II, in which a below-average kappa of .48 was obtained at the various sites studied (First MB, personal communication, 1991). This study used the more rigorous test-retest design involving independent reinterviews of subjects rather than the joint interview design in which two raters observe the same interview. In the study by

Zanarini and co-workers (39), however, test-retest reliability of the DIPD, which is very similar to the SCID-II, was found to be .85, suggesting that rigorous training of interviewers can result in very reliable diagnosis even when independent assessments are made.

Studies of the DIB have found reliability ranging from good to excellent (interrater  $k = .71$  to  $.80$ ; test-retest  $k = .71$ ) (15, 47). The only studies of a self-report questionnaire that involved separate administrations and categorical (as opposed to dimensional) measurement used the preliminary version of the Personality Diagnostic Questionnaire-Revised (PDQ-R) (48). The reliabilities obtained were acceptable ( $k = .55$  to  $.59$ ) (43, 49).

*Validity.* Measures of the associa-

tion between two diagnoses when one is considered indicative of true clinical status are sensitivity, specificity, and positive and negative predictive power. An instrument's sensitivity and specificity quantify its ability to identify true cases and noncases, respectively. Positive and negative predictive power show the proportion of putative cases and noncases, respectively, diagnosed by the instrument that are true cases and noncases according to the validity standard (50).

One measure of an instrument's validity is its ability to identify patients believed to have borderline personality disorder. Since the clinical diagnosis of borderline personality disorder has traditionally been unreliable and of debatable validity itself, it has been difficult to arrive at an appropriate standard against which to measure an instrument's performance.

Agreement between diagnoses of borderline personality disorder based on self-report instruments and those based on structured interviews is modest. Widiger and Frances (1) report kappas for the earlier version of the Millon Clinical Multiaxial Inventory (51) of .05 and .32 based on the studies of Piersma (52) and Reich and associates (53), respectively, and .43 for the earlier version of the PDQ-R (53). Several studies have reported that compared with interviews, self-report inventories tend to overdiagnose borderline personality disorder. When diagnoses based on the PDQ-R were compared with structured-interview diagnoses based on the SCID-II and the PDE, kappas of .53 and .46, respectively, were found (54). Using the convergence or divergence of interview results as measures of narrow and broad estimates of personality disorder, respectively, we found high sensitivity (.98 and .95) and negative predictive power (.94 and .83) for the diagnosis of borderline personality disorder based on the PDQ-R.

These results all suggest that a questionnaire diagnosis of borderline personality disorder may be a false positive, but the absence of a diagnosis by self-report is rarely associated with a diagnosis by structured in-

terview. Self-report questionnaires, therefore, seem to have a role in the assessment of borderline personality disorder as efficient and cost-effective screening tests.

Diagnoses that are based on semi-structured interviews have most commonly been compared with clinical diagnoses. For example, in revising the DIB, Zanarini and coworkers (41) used clinicians' principal axis II diagnoses as the standards. At a cutoff score of 8 (of a possible 10), the DIB-R had a sensitivity of .82, a specificity of .80, a positive predictive power of .74, and a negative predictive power of .87. The DIB-R is more effective than the DIB in discriminating patients with borderline personality disorder from patients with other types of personality disorders. The DIB was found by several investigators to be overinclusive (55,56).

Kavoussi and associates (57) and O'Boyle and Self (58) recently compared structured interviews. Kappas for borderline personality disorder measured by different instruments ranged from .18 to .62. Without a standard for comparison, it is impossible to say which instrument is "best." In searching for an appropriate validity standard for personality disorder instruments, our group (59-61) adapted Spitzer's LEAD standard (longitudinal expert evaluation using all data) (62). We found that diagnoses of borderline personality disorder made by using the SCID-II or the PDE (which agreed with each other at  $k=.53$ ) did not correspond particularly well to the diagnoses of an expert clinician who was given an opportunity to closely observe patients over time and had access to a variety of informants and sources of information.

Do these results mean that structured interviews are too variable to be useful? Such a conclusion would be premature since the reliability and validity of LEAD diagnoses are unknown. The soundest conclusion that might be drawn is that no single diagnostic instrument has clearly demonstrated superiority over others and that the results of research tools should be interpreted cautiously at present. A patient who is diagnosed

with borderline personality disorder by more than one instrument is more likely to be a valid case than a patient about whom the instruments disagree.

### Assessment problems

The difficulty of interviewing patients suspected of having borderline personality disorder can vary widely depending on circumstances. In a setting in which a motivated patient is applying for a highly desirable and selective treatment, the task is considerably easier than in an emergency room where a sullen patient is being evaluated involuntarily after a failed suicide attempt.

In general, borderline patients are dramatic and emotional. It may be difficult to keep a patient focused or to distinguish exaggeration from fact. Every statement may be extreme, due to characteristic black-and-white and all-or-nothing thinking. Splitting may also lead to apparent contradictions. Confrontation is used as a diagnostic probe in structural interviews of borderline patients (8), but even experienced interviewers have provoked impulsive patients to walk out.

Although the approach to differential diagnosis embodied in *DSM-III* and *DSM-III-R* does not emphasize the diagnostic importance of a patient's here-and-now interactions with a clinician, an evaluation interview provides a first-hand sample of a patient's personality style that is often strongly suggestive of a diagnosis. However, four general determinations are critical in assessing most personality disorders according to *DSM-III* or *DSM-III-R* criteria: pervasiveness; inflexible, enduring pattern; blind spots or socially undesirable features; and maladaptivity and impairment (63).

Borderline personality disorder pervasively influences regulation of affects, sense of self, cognitive processes, control of impulses, and interpersonal relationships. As mentioned above, clinicians may be tempted to make a diagnosis in the face of a particularly dramatic or characteristic symptom. The manifestations of borderline personality disorder should not be limited to one particular situation or occur in rela-

relationship to only one particular person. For example, involvement in uniquely stressful circumstances, such as a physically or sexually abusive relationship, may evoke a dramatic response from many people, not just those with borderline personality disorder.

Evidence of borderline personality disorder should be observable over time. Usually, two to five years is the minimum time necessary to indicate a stable personality pattern. Frequent changes in personality style, or evolution over time, might suggest another mental or physical disorder.

Physically self-damaging acts and other evidence of impulsivity might seem too onerous for some patients to admit, especially during initial contacts with mental health professionals. Difficulties in relationships may not be seen by the patient as his or her problem but as problems caused by others. An objective informant may be of assistance, but it is unlikely that someone intensely involved with a borderline patient will be objective.

Finally, although most behaviors of persons with borderline personality disorder seem maladaptive by definition, due to extensive comorbidity of borderline personality with other disorders (see below), it is important to document distress and social and occupational impairment secondary to the personality disorder itself and distinguish it from distress due to a superimposed disorder. Longitudinal observation frequently is required so that a patient may be seen after a psychosocial crisis or after an episode of an axis I disorder has resolved or improved (60).

**Comorbidity.** Borderline personality disorder has been found to be associated with so many other axis I and II diagnoses that its validity as an independent diagnostic entity has been questioned (64). Resolution of this controversy awaits future research. Using the *DSM-III-R* multi-axial system, which encourages multiple diagnoses, the clinician evaluating a patient with suspected borderline personality disorder should be alert to other diagnostic possibilities.

There is ample evidence that patients with borderline personality

disorder may have comorbid axis I disorders, such as mood (65-67), anxiety (68,69), substance use (69,70), and eating disorders (69,71). Dissociative, somatoform, factitious, and impulse control disorders have also been reported (69,72,73). When warranted, such diagnoses should be made in addition to borderline personality disorder.

The incidence and nature of psychosis in borderline personality disorder has been a subject of controversy (74). Currently, psychotic symptoms occurring in patients with borderline personality disorder are believed to be transient, stress-related, "quasi-psychotic" cognitive-perceptual distortions (75), which in severity may fall short of *DSM-III-R* definitions of psychosis. Comorbid axis I syndromes may help to guide treatment selection, especially pharmacologic treatment, and to estimate prognosis (76).

Borderline personality disorder has been shown to be associated with virtually all the other axis II disorders. In a review of 13 studies, Widiger and colleagues (77) reported that borderline personality disorder covaried most highly with histrionic, antisocial, and passive-aggressive personality disorders, followed by schizotypal, dependent, avoidant, narcissistic, and paranoid personality disorders. In an unpublished study (Oldham JM, Skodol AE, Kellman HD, Hyler SE, Rosnick L, Davies M, 1991), we found that when diagnoses were made using the SCID-II, borderline personality disorder and antisocial personality disorder were ten times more likely to occur together than for either to occur alone; histrionic and passive-aggressive personality disorders were four to five times more likely to occur with borderline personality disorder as diagnosed by either the SCID-II or the PDE.

Comorbid personality disorders influence the assessment of borderline personality disorder. Histrionic patients may exaggerate in reporting behaviors or traits, antisocial patients may lie, and passive-aggressive patients may resist efforts to evaluate them. Perry (78) has shown that patients with both borderline

personality disorder and antisocial personality disorder had less depression, on a lifetime basis, than patients with borderline personality disorder alone. Comorbid axis II conditions, therefore, may also influence course and outcome in borderline personality disorder.

### Significance and conclusions

Establishing a psychiatric diagnosis is not an end, but a means. To be justified, a diagnosis should convey information valuable in planning treatment or predicting outcome.

Personality disorders in general have been found to adversely affect the treatment outcome of a number of axis I disorders, including major depression, panic disorder, and obsessive-compulsive disorder (79). Less is known about individual personality disorders, but borderline personality disorder appears to follow this general rule.

However, newer psychopharmacologic agents, such as fluoxetine, have shown promise for treating both the depressive and impulsive symptoms of borderline personality disorder (80,81). New psychotherapeutic strategies are also being developed (82). Long-term follow-up studies, such as those of McGlashan (83), Stone and associates (84), and others, have shown that borderline personality disorder may persist for years but may also ameliorate over the long run, especially with treatment. Maximizing a patient's chance for recovery begins with careful assessment and diagnosis to ensure that all potentially relevant diagnostic factors have been considered.

Given the problems and challenges inherent in making an accurate diagnosis of borderline personality disorder, and the importance of doing so, we offer the following guidelines to assessment.

- Clinicians should be aware that concepts underlying the term borderline overlap but are not identical. Clinicians should understand what information is needed to make the diagnosis according to the concept of interest.

- Clinicians using *DSM-III-R* criteria should make sure that the required features are pervasive, inflexible, and enduring and that they

cause impairment in functioning.

● Self-report and semistructured instruments for diagnosing borderline personality disorder can be useful in clinical settings, but they are not necessary if accurate information needed for diagnosis can be gathered with a standard clinical interview.

● Comorbid axis I disorders, such as mood, anxiety, or psychoactive substance use disorders, should be identified in patients with borderline personality disorder; comorbid syndromes may help guide treatment.

● Clinicians should be alert to other personality disorders and traits, which may affect assessment and course in patients with borderline personality disorder.

# Biological and Pharmacological Aspects of Borderline Personality Disorder

Emil F. Coccaro, M.D.  
Richard J. Kavoussi, M.D.

*Biological and psychopharmacological research focusing on patients with a DSM-III-R diagnosis of borderline personality disorder suggests that the disorder may encompass three clusters of symptoms— affective instability, transient psychotic phenomena, and impulsive aggressive behavior— that have different underlying biological substrates that respond to different classes of pharmacological agents. Affective instability, which may be related to abnormalities in the brain's adrenergic and cholinergic systems, appears to respond to agents such as lithium and carbamazepine that are effective in treating major affective disorders. Abnormalities in central dopaminergic systems may underlie transient psychotic symptoms. This relationship is consistent with reports of beneficial effects of low-dose neuroleptics in treating some borderline patients. Abnormalities in central nervous system serotonergic functioning appear to underlie impulsive aggressive behaviors. These behaviors may respond to serotonergic agents such as fluoxetine.*

Dr. Coccaro is associate professor and Dr. Kavoussi is assistant professor in the clinical neuroscience research unit of the department of psychiatry at the Medical College of Pennsylvania, 3200 Henry Avenue, Philadelphia, Pennsylvania 19129. This paper is part of a special section on borderline personality disorder.

The pharmacological treatment of patients with borderline personality disorder can be difficult and extremely frustrating for both psychiatrist and patient. The *DSM-III-R* diagnosis of borderline personality disorder describes a heterogeneous group of patients, complicating the design and interpretation of studies about such treatment.

There is growing evidence that personality psychopathology does not occur as discrete categorical phenomena, but rather on a continuum with normal personality traits (1). Classifications of disorders based on dimensional criteria offer an advantage over classifications based on categorical definitions because clusters of symptoms can be more readily correlated with biological measures or treatment responses than can discrete symptoms.

In this paper we describe three clusters of psychopathology that have been observed in biological and pharmacological studies of patients with borderline personality disorder. The clusters are affective instability, transient psychotic phenomena, and impulsive aggressive behavior. We review evidence for the biological factors that may underlie these clusters and correlate these factors with strategies for psychopharmacologic treatment.

## Biological studies

**Affective instability.** The prominent symptoms of a *DSM-III-R* diagnosis of borderline personality disorder include marked shifts from baseline mood to depression, irritability, or anxiety, usually lasting a few hours and only rarely more than a few days. These symptoms may also occur in patients with other disorders of mood such as dysthymia, cyclothymia, hypomania, and bipolar

disorder (2). Hence, it is likely that the biological abnormalities found in patients with axis I mood disorders may also be found in borderline patients.

Some studies have suggested a relationship between severity of major depression and dysregulation of the hypothalamic-pituitary axis as measured by nonsuppression of plasma cortisol in response to orally administered dexamethasone (3). However, in borderline patients these values appear to reflect the effect of comorbid major depression rather than the underlying personality disorder, since patients with personality disorder who do not also have major depression do not show abnormal results on the dexamethasone suppression test (4-6).

Patients with affective disorders also have abnormal patterns in the response of thyroid-stimulating hormone to intravenous thyrotropin-releasing hormone (TRH) (7). However, as in the studies using the dexamethasone suppression test, borderline patients' abnormalities in response to TRH appear to be due to comorbid major depression (8-10). At this time, then, specific biologic markers underlying the affective symptoms of borderline personality disorder have not been found.

A potential index of affective disturbance in borderline patients is the behavioral response to central nervous system stimulants such as amphetamine and methylphenidate, which are known to produce elevations in mood. However, research on the effect of intravenous stimulants on borderline patients has produced conflicting results. Some studies have noted marked dysphoria in response to the stimulants (11); others have reported improvement in mood

(12). Hence, it appears that stimulants may improve affective symptoms in some borderline patients but may worsen these symptoms in others.

The brain's cholinergic systems may also play a role in the regulation of affect. In patients with major mood disorders, the cholinergic system appears to be highly sensitive to agents such as physostigmine, which increase central cholinergic activity and can produce depressive symptoms (13). These findings suggest that cholinergic dysfunction might also underlie affective instability in borderline patients. The observation that borderline patients appear to be more sensitive than control subjects to the effects of cholinergic system agonists in the experimental induction of REM sleep supports this possibility (14).

#### *Transient psychotic phenomena.*

Many borderline patients experience brief, stress-related psychotic symptoms, although these symptoms are not included in the *DSM-III-R* criteria for a diagnosis of borderline personality disorder (15). Studies of patients with axis I psychotic disorders have suggested biochemical models that may also apply to the occurrence of mild psychotic symptoms in borderline patients. Plasma levels of homovanillic acid, the major metabolite of dopamine, have been shown to have a positive correlation with global severity of psychosis in schizophrenic patients (16). A recent study of patients with a variety of *DSM-III-R* personality disorders found a positive relationship between plasma homovanillic acid and number of psychotic symptoms, such as magical thinking, illusions, and ideas of reference (17). This finding suggests that dopaminergic dysfunction may be involved in the psychotic symptoms seen in severely ill borderline patients.

#### *Impulsive aggressive behavior.*

Impulsivity, intense anger, and self-damaging acts constitute three of the eight *DSM-III-R* diagnostic criteria for borderline personality disorder. Some studies assessing *DSM* criteria have suggested that impulsivity, self-damaging acts, and unstable interpersonal relationships best dif-

ferentiate patients with borderline personality disorder from those with other personality disorders (18).

The major neurotransmitter implicated in impulsive, aggressive behavior and in suicidal behavior is serotonin (5-HT) (19). In two studies of patients with mixed personality disorders, cerebrospinal fluid levels of 5-hydroxyindolacetic acid (5-HIAA), the major metabolite of serotonin, correlated inversely with life history of aggressive behavior and suicide attempts (20,21). An inverse relationship between history of a serious suicide attempt and level of 5-HIAA was also found in a study of female borderline patients (22).

In other studies, the level of prolactin response to serotonin receptor agonists, an indirect measure of the level of sensitivity of serotonin receptors, correlated inversely with measures of behavioral aggression (23-26). In one study, patients who had shown impulsivity, intense anger, or self-damaging behavior had reduced prolactin release regardless of whether they met criteria for a *DSM-III* diagnosis of borderline personality disorder (23).

While abnormalities in serotonin functioning clearly play an important role in impulsive, aggressive, and suicidal behavior, other research suggests that these behaviors may be controlled by more than one neurotransmitter. Studies that have reported a relationship between reduced cerebrospinal fluid concentrations of homovanillic acid and history of suicidal behavior support the hypothesis that central dysfunctions in the catecholamine system producing abnormal levels of dopamine may affect impulsive aggressive behaviors (19, 27).

#### *Psychopharmacologic studies*

*Affective instability.* Before *DSM-III* criteria were developed, patients who suffered from rapidly shifting and intensely felt affective states were often given a diagnosis of "emotionally unstable character disorder" (28). Psychopharmacologists recognized that these patients responded better to lithium than to placebo or imipramine. This response suggests that some borderline patients suffer from a subclinical affective disorder

that is mediated by biological mechanisms similar to those that mediate bipolar disorder or cyclothymia.

In several early studies, patients with diagnoses of pseudoneurotic schizophrenia, a precursor to the diagnosis of borderline personality disorder, appeared to respond better to agents that enhance catecholamine function, including stimulants, imipramine, and tranylcypromine, than to placebo or to agents such as chlorpromazine and trifluoperazine that reduce catecholamine function (29,30). Patients with hysteroid dysphoria, a syndrome that involves repeated episodes of abruptly depressed mood in response to feeling rejected, appear to benefit from monoamine-oxidase-inhibiting antidepressants (31). A recent study comparing the effects of phenelzine and imipramine in patients with atypical depression found that phenelzine was more effective in patients who also met *DSM-III* criteria for borderline personality disorder (32). Thus it is possible that monoamine oxidase inhibitors may be more efficacious than tricyclic antidepressants in treating affective instability in borderline patients.

In one of the most comprehensive studies of pharmacotherapy of borderline personality disorder to date, four different agents were compared with placebo in 16 female patients with a *DSM-III* diagnosis of borderline personality disorder (33). The four agents were trifluoperazine, tranylcypromine, carbamazepine, and alprazolam. Patients received each agent for six weeks followed by a two-week period during which they received a placebo before being started on another agent. Tranylcypromine was most effective in improving dysphoria, while carbamazepine was most effective in diminishing episodes of impulsive behavior and behavioral dyscontrol.

Trifluoperazine was somewhat more efficacious than placebo in improving global ratings of treatment response but did not appear to affect any particular target symptom more than others. Finally, alprazolam was associated with a greater increase in behavioral dyscontrol, compared with placebo. Improvements in

mood associated with agents such as monoamine oxidase inhibitors that enhance catecholamine function support the hypothesis that affective symptoms in patients with borderline personality disorder may reflect a variant of axis I affective disorders and may involve dysregulation of catecholamine neurotransmission.

#### *Transient psychotic phenomena.*

Many studies have reported that low doses of neuroleptics are mildly to moderately effective in improving the global status of patients with borderline personality disorder (34-37). Some of these studies suggest further that the neuroleptics have specific efficacy in treating mild psychotic symptoms, such as suspiciousness, ideas of reference, odd communication, and social isolation, as well as impulsive behavior and hostility. Positive effects on some measures of depression and anxiety have also been found, but a decrease in troubling psychotic symptoms may have accounted for improvements in subjective measures of depression and anxiety.

In a controlled study, the efficacy of thiothixene compared with placebo was examined in 50 patients who had a *DSM-III* diagnosis of either borderline or schizotypal personality disorder (38). In addition, all patients had a history of a brief psychotic episode. Compared with patients who received placebo, patients who received thiothixene had significantly lower scores on Symptom Checklist (SCL-90) measures of psychoticism, illusions, ideas of reference, and phobic anxiety. Unlike subjects in previous studies, however, patients treated with thiothixene had no change in symptoms of depression.

Another controlled study compared haloperidol and amitriptyline to placebo in 90 patients with a diagnosis of borderline personality disorder made using the Diagnostic Interview for Borderlines (39). Haloperidol was superior to placebo and amitriptyline in relieving a variety of psychotic symptoms. Variables predicting favorable response to haloperidol included severe schizotypal symptoms, hostility, and suspiciousness. Results of these studies of anti-

psychotic medications known to affect dopamine functioning support a relationship between abnormalities in dopamine functioning in the brain and psychotic symptoms in patients with borderline personality disorder.

#### *Impulsive aggressive behavior.*

In addition to stabilizing affect, lithium has been found to decrease impulsive and aggressive behaviors in various populations of patients. A

---

**Although correlations between behavioral traits, biology, and drug therapy are useful as a guide in treating borderline patients, many other complicating factors must be taken into account.**

---

study comparing lithium, desipramine, and placebo in patients with borderline personality disorder found lithium to be superior to desipramine in improving global measures of behavior (40). In other studies, lithium was effective in suppressing impulsive aggressive behaviors in prison inmates (41,42). The mechanism of these effects is unknown, although lithium's ability to enhance presynaptic serotonergic transmission may play a role (43).

In at least three open trials, serotonergic reuptake inhibitors such as fluoxetine have been found to reduce global psychopathology and impulsive aggression in patients with borderline personality disorder (44-46). In one study, fluoxetine was also found to reduce depressive symptoms significantly (46). However, the drug had mixed effects on hostility and psychoticism and no effect in relieving anxiety or interpersonal sensitivity. In another nonblind study of borderline and schizotypal patients, a 12-week trial of fluoxetine was associated with a significant decrease in self-injurious behavior (47). Clearly, more study of the efficacy of serotonergic reuptake inhibitors in treating patients with borderline personality disorder is needed.

There is evidence that neuroleptics may reduce suicide proneness in patients with severe personality disorders who have made recurrent suicide attempts (27). In addition, as noted earlier, neuroleptics have been shown to reduce hostility in some borderline patients. While neuroleptics have been used to treat impulsive aggressive behavior, it is not clear whether antiaggressive effects are related to dopaminergic blockade or to the fact that neuroleptics may act as sedating agents.

#### **Selecting treatment**

The research we summarized suggests that the various clusters of symptoms in borderline personality disorder—*affective instability, transient psychotic phenomena, and impulsive aggressive behavior*—may be associated with different underlying biological abnormalities. In turn, some medications may be more effective than others in treating each of the symptom clusters. For example, abnormalities in the dopamine system seem to underlie illusions, paranoia, ideas of reference, and other mild psychotic symptoms. These symptoms appear to respond preferentially to low doses of neuroleptics, for example 1 to 2 mg of haloperidol or its equivalent, which act on brain dopamine systems. These medications are best used for relief of acute, stress-related symptoms, but may not be preferred for long-term use in borderline patients due to the risk of extrapyramidal side effects such as tardive dyskinesia.

Serotonergic dysfunctions seem to underlie impulsive, aggressive, and self-destructive behaviors. Agents such as lithium and fluoxetine that have serotonergic properties may be best suited for treating these behaviors. Finally, the mechanisms underlying affective instability in borderline patients appear to be related to those that operate in axis I affective disorders. The mechanisms include disruption in catecholamine and cholinergic functioning in the limbic system. Medications such as lithium and carbamazepine, which affect these systems, may be most effective in reducing mood lability in borderline patients. Monoamine oxidase inhibitors are more effective than tricy-

clic antidepressants in treating the affective disturbances that accompany borderline personality disorder.

Although correlations between behavioral traits, biology, and pharmacotherapy are useful as a guide in treating borderline patients, many other complicating factors must be taken into account. For example, the modes of action of currently available medications are not specific. Lithium has many modes of action, including stimulating transmission of serotonin. Lithium also reduces catecholaminergic functioning. Carbamazepine has membrane-stabilizing effects and has also been reported to increase plasma levels of tryptophan, a precursor of serotonin (48).

Agents that enhance catecholamine functioning, such as tricyclic antidepressants, may stabilize a patient's mood but may also lead to increased agitation and perhaps behavioral dyscontrol. It is hoped that medications available in the future will be more specific in their mechanism of action in the brain, leading to more specific and predictable pharmacologic responses in patients. Some currently available (or soon to be available) medications, including serotonin uptake blockers such as fluoxetine, paroxetine, sertraline, and fluvoxamine and serotonin agonists such as buspirone, gepirone, and eltoprine have specific biological effects that may be easier to correlate with behavioral responses.

Researchers and clinicians who are interested in the biological aspects of personality disorders must also be aware of the interaction between biological predispositions and environment in the development of personality pathology. Obviously, the way in which a particular physiologic abnormality manifests itself is mediated by the interaction of the individual and others in the environment—family members, peers, teachers, and entertainers.

When an affectively unstable person responds dramatically to seemingly trivial rejection or to fear of abandonment, others may blame the person for not having more control over his or her emotions. Unable to develop adequate coping skills to help regulate these shifts in affect,

the person may adapt by acting out to relieve tension or to obtain a helping response from others. Such patients may have difficulty developing an adequate internal representation of the self because they are likely to receive messages from significant others that contradict their own self-assessment. A combination of these innate and learned responses could be involved in the development of borderline personality disorder.

Very few borderline patients will respond to medications alone. Rather, treatment of borderline personality disorder with medication should be seen as a means of controlling disabling symptoms in the context of an overall treatment plan that includes individual, group, family, and behavioral therapy. However, additional research leading to a better understanding of the biology of these disorders will allow development of more specific pharmacological treatments and improved psychotherapeutic techniques that can be modified to suit an individual's innate temperament.

## Guidelines for Authors of Research Reports

*Hospital and Community Psychiatry* reviews material for publication with the understanding that it has not been previously published and is not being reviewed for publication elsewhere. Submit manuscripts (five copies) to the editor, John A. Talbott, M.D., *H&CP*, American Psychiatric Association, 1400 K Street, N.W., Washington, D.C. 20005. (Phone inquiries, 202-682-6070.)

Research reports may be submitted as regular articles or brief reports. Regular articles should not exceed 3,000 words, excluding references and tables, and should include a one-paragraph abstract (100 to 150 words). Brief reports should not exceed 1,200 words plus ten references and one table or figure.

Research reports should follow the standard format of introduction, methods, results, discussion, and conclusions. The purpose of the study and the type of study design should be stated in the last paragraph

of the introduction. If the purpose is not stated as a research question, it should be translatable into a research question.

Preferably in the methods section, authors should concisely describe the data analysis procedure in a manner understandable by nonstatisticians. Only the findings related directly to the research purpose or research question should be included in the results section and in tables. Other data should be omitted.

When reporting tests of significance, authors should include observed test statistic value, degrees of freedom, probability level, and, for t and F tests, whether repeated measures were used.

Peer reviewers will evaluate research reports submitted for publication for adherence to these guidelines. For additional information about *H&CP's* editorial requirements, see the August 1991 issue or contact the editorial office.

# Standardized Approaches to Individual Psychotherapy of Patients With Borderline Personality Disorder

M. Tracie Shea, Ph.D.

*Recent developments in individual psychotherapy for patients with borderline personality disorder include psychodynamic, interpersonal, behavioral, and cognitive treatments. The author provides an overview of standardized treatment approaches—that is, modes of treatment that have a clear theoretical rationale and specific strategies and techniques—for borderline personality disorder. Evaluations of the efficacy of these approaches are discussed. Although there is little empirically based knowledge about the effectiveness of these treatments, their adaptation for the specific treatment of borderline personality disorder represents an important step for treatment and research in this area.*

For patients with borderline personality disorder, individual psychotherapy is probably the most frequently used treatment modality. Early treatment approaches were primarily derivatives or modifications of psychoanalysis or psychoanalytically oriented psychotherapy. In recent years, alternative approaches, including behavioral and cognitive treatments, have been developed.

Dr. Shea is assistant professor in the department of psychiatry and human behavior at Brown University, Duncan Building, 345 Blackstone Boulevard, Providence, Rhode Island 02906. She is also a psychologist at the Veterans Affairs Medical Center in Providence. This paper is part of a special section on borderline personality disorder.

An important development in the field of psychotherapy is a movement toward clearer definition, or standardization, of treatments, which has been largely driven by efforts to evaluate the effectiveness of treatments for specific disorders. Detailed descriptions of the theoretical rationale, treatment goals, and specific therapeutic strategies and techniques, often referred to as "manuals," now exist for a number of psychotherapeutic treatment approaches. Early efforts in this direction were focused primarily on *DSM-III* axis I disorders, such as anxiety and depression, and there are now such manuals for the treatment of personality disorders.

The definition and diagnosis of borderline personality disorder has been a subject of much debate. Most of the more recent approaches to treatment have defined borderline personality disorder according to *DSM-III*, which uses a descriptive, objective approach with operationalized criteria related to affective instability, impulsivity, and self-destructiveness. Psychoanalytic approaches, in contrast, have tended to view borderline personality in terms of personality organization or ego functioning. The latter approach emphasizes intrapsychic structure, including the use of primitive defense mechanisms, as opposed to the more observable behavioral criteria and captures a broader range of patients than those defined by *DSM-III*. Many of the patients diagnosed by the psychostructural method would not meet *DSM-III* criteria, which identifies a more severely symptomatic subgroup of patients.

This paper provides an overview of the different forms of individual psychotherapy that have been devel-

oped or modified for use with patients with borderline personality disorder. Particular emphasis is placed on approaches that have been standardized. Psychodynamic, interpersonal, behavioral, and cognitive treatment approaches are included. Results of studies of the effectiveness of these treatment approaches are summarized. The large and clinically rich literature on various aspects of psychoanalytic theory and techniques is beyond the scope of this paper.

## Treatment approaches *Psychoanalytically oriented treatments*

Variations of psychoanalytic approaches can be broadly categorized into supportive and expressive forms of therapy. Aronson (1) has recently written a comprehensive historical review of the evolution of psychoanalytically oriented psychotherapy for borderline patients.

*Supportive approaches.* Supportive approaches evolved from the psychoanalytic tradition in the 1940s as a result of concern about limitations and possible dangers of the traditional psychoanalytic approaches for borderline patients. Advocates of the supportive approach stressed the need for different goals for these patients, such as improvement of adaptive functioning, rather than change in intrapsychic structure or other aspects of personality.

Supportive approaches focus on supporting and strengthening defenses and avoiding regression in treatment. Increased intensity of the transference relationship is viewed as potentially dangerous to the patient. Treatment is structured, with clear goals, much activity and direction from the therapist, and a focus on current problems and functioning.

Relationship factors are emphasized, including warmth, consistency, and availability of the therapist. Interpretations are generally avoided. Although Kernberg (2) is primarily an advocate of expressive therapy with borderline patients, he has developed a manual for supportive psychotherapy.

**Expressive approaches.** Largely influenced by Kernberg's work, the 1970s were marked by a shift away from supportive psychotherapy and back to more insight-oriented, interpretive techniques, more intensive therapy, and more ambitious treatment goals. Competing theories and models emerged, differing primarily in their emphasis on either conflict or deficit as key to borderline pathology. The different expressive approaches are similar in their use of a modified psychoanalytic approach, characterized by interpretive and uncovering techniques, the therapist's active role, a focus on here-and-now issues, and an emphasis on countertransference and limit setting (1).

Kernberg (3) has provided a detailed description of his expressive psychotherapy. Goals of the treatment include increased impulse control, anxiety tolerance, ability to modulate affect, and ability to develop stable, satisfying, and intimate relationships. Kernberg's conceptualization of borderline pathology emphasizes the dissociated, "split-off" aspects of the patient's internalized perceptions of self and others and the affect associated with these perceptions. Also emphasized are primitive defense mechanisms, such as splitting, which are used to maintain separation of aggressive from loving feelings and perceptions.

Treatment strategies are designed to integrate the dissociated feelings and perceptions and increase the patient's ability to experience self and others in a more realistic and integrated fashion. This goal is accomplished by repeated identification and clarification of the dissociated aspects and states as they appear in the relationship with the therapist. Defenses that maintain the dissociations and split-off states are also repeatedly interpreted and analyzed.

**Efficacy.** There are no controlled outcome studies of any of the psychoanalytically oriented treatments for borderline personality disorder. Naturalistic studies have been conducted, including the Menninger study (4) and more recent studies reported by Stone (5), Gunderson and colleagues (6,7), and Skodol and colleagues (8).

The Menninger study suggested a possible advantage of expressive treatment, combined with environmental structuring, compared with a supportive treatment approach for patients with borderline personality organization. The study by Waldinger and Gunderson (6) also suggested that for moderately impaired borderline patients who remain in treatment, intensive psychotherapy may be helpful (6). However, findings from most of these studies raise serious questions about the feasibility of long-term treatment of borderline patients, since many if not most patients fail to complete even six months of treatment. Patients who remain in treatment and show improvement may well be a higher-functioning subsample.

A pilot and feasibility study is currently under way to develop the methodology necessary to implement a controlled trial of Kernberg's expressive therapy (9). The treatment has been operationalized in a manual, a scale has been developed to assess adherence to the treatment techniques, and measures are being developed for therapist, patient, and process variables of interest (3,10). Preliminary findings from 31 patients suggest dropout rates comparable to those reported in other studies (39 percent by 12 weeks). Patients who completed six months of treatment showed improvement in some aspects of functioning. The continued work of this group should provide valuable data about the efficacy of psychoanalytically oriented expressive psychotherapy for patients with borderline personality disorder.

#### *Interpersonal approaches*

Given that maladaptive interpersonal behavior is a critical aspect of borderline personality disorder, an approach that focuses explicitly on

interpersonal interactions is clearly relevant. Some interpersonal theorists and researchers have begun to systematically apply their models to the axis II disorders, including borderline personality disorder. Benjamin (11,12), for example, has begun to outline a treatment approach based on her model of interpersonal behavior—structural analysis of social behavior (SASB). SASB is a system for classifying interpersonal behavior based on three dimensions: the focus of the behavior, that is, a focus on the other or on the self; affiliation, or the degree of friendliness or hostility of the behavior; and interdependence, or the degree of dominance or submission, and autonomy.

Benjamin has described each of the axis II personality disorders, including borderline personality disorder, in terms of the interpersonal patterns derived from SASB (11). The SASB interpersonal summary of borderline personality disorder emphasizes an intense fear of abandonment and a desire for protective nurturance; friendly dependence on a nurturer, which becomes hostile control if the caregiver fails to deliver enough; a belief that the provider likes dependency and neediness; and an internal response of vicious self-attack triggered by happiness or success (13).

Specific kinds of developmental experiences are thought to be associated with these affects and behaviors. Developmental factors include a chaotic environment, traumatic abandonment experiences, attack by important others in response to the individual's expression of self or happiness, and nurturance in response to sickness (11).

Principles of a treatment approach based on the SASB model, SASB-directed reconstructive learning therapy, have been outlined (13). The treatment stresses identification of the patient's interactive patterns and associated wishes and fears and understanding of the patterns' origins and current purposes. Six phases of treatment are identified: the development of a collaborative relationship between patient and therapist; insight, or identification of the patient's interactive patterns and

where they came from; facing of unconscious wishes and fears; grief after the decision to give up the old ways; panic after implementation of the decision to change; and emergence of a new self.

**Efficacy.** The interpersonal treatment approach has only recently been described, and no data about its effectiveness in treating any of the personality disorders are available.

### *Behavioral approaches*

Linehan (14) and Turner (15) have developed comprehensive treatment approaches for borderline personality disorder. Linehan's approach, called dialectical behavior therapy (DBT), is the most fully developed. It is conducted in both individual and group formats and incorporates a range of traditional behavioral strategies, as well as some unique strategies specifically relevant to borderline personality disorder.

Linehan emphasizes the borderline patient's inadequate affect regulation, which is largely due to biological factors and a childhood environment characterized by an absence of emotional validation. Behavioral strategies and techniques define explicit goals and targets in behaviorally operational terms and use traditional behavioral techniques, such as exposure techniques, skill training, contingency management, and cognitive modification. Four sequential group treatments are provided over the course of one year; the group treatments focus on interpersonal effectiveness, emotional control, and distress tolerance.

Treatment targets in individual DBT are defined in order of importance, including suicidal behaviors; behaviors interfering with the conduct of therapy; avoidance and escape behaviors; acquisition of behavioral skills, such as regulation of emotions, interpersonal effectiveness, distress tolerance, and self-management; and other goals unique to the individual patient. The focus of treatment shifts to other targets when problems in those areas arise (16). Treatment also emphasizes attention to the relationship between the therapist and patient.

**Efficacy.** Linehan (17) has reported results of a one-year trial of DBT,

compared with treatment as usual, for 44 severely dysfunctional, parasuicidal women with borderline personality disorder as defined by *DSM-III*. She found that patients in the DBT group had a much lower attrition rate (16.7 percent) than patients receiving the usual treatment (58.3 percent). Linehan also found that for DBT-treated patients the frequency and severity of parasuicidal behavior and the number of days of inpatient hospitalization were significantly reduced. The two treatment groups did not differ, however, on measures of depression, hopelessness, suicidal ideation, or reasons for living.

### *Cognitive therapy*

Cognitive therapy was developed for the treatment of depression and later modified for use with other axis I disorders, including anxiety disorders (18,19). Several cognitive theorists and clinicians have begun to write about their conceptualizations of borderline personality disorder and their use of cognitive treatment approaches with these patients (20-23). Beck (24), the developer of cognitive therapy, has recently written a treatment manual for cognitive therapy of personality disorders, including borderline personality disorder.

Cognitive and behavioral treatment approaches for borderline personality disorder overlap to some extent, as behavioral approaches often include cognitive techniques, and cognitive approaches use behavioral strategies. However, there are important differences in the focus of each approach and in assumptions about the primary mechanisms of pathology. Behavioral approaches place a primary emphasis on learning principles and patterns of reinforcement. Cognitive therapy assumes that maladaptive and distorted beliefs and cognitive processes underlie the symptoms and disturbances in affect and behavior. The primary strategies and techniques of cognitive therapy are thus directed toward identification and correction of the distorted beliefs, assumptions, and maladaptive cognitive processes.

Beck (24) has described three key assumptions typical of borderline patients that appear to play a central role in the disorder: the world is a

dangerous place; I am powerless and vulnerable; and I am inherently unacceptable. The belief of helplessness in a hostile world together with the belief that a source of security is absent results in a vacillation between autonomy and dependence.

Another key cognitive feature of borderline patients described by Beck is dichotomous thinking, or the tendency to evaluate experiences in terms of mutually exclusive categories such as good or bad, love or hate, and so forth. This tendency forces extreme evaluations of events, accompanied by extreme emotional responses and actions, and is believed to contribute to the abrupt mood swings and dramatic shifts in behavior characteristic of persons with borderline personality disorder.

Although many of the standard cognitive techniques are included in the treatment of borderline patients, certain modifications are required. The dysfunctional beliefs of patients with personality disorders are more persistent because they are more deeply ingrained in their cognitive organization. Changing the dysfunctional thought patterns requires considerably more time and effort than is necessary for axis I disorders.

Thus what Beck refers to as the "characterologic phase" of treatment geared toward structural change is incorporated in the therapy. There is an increased emphasis early in the treatment on building a relationship between the therapist and patient, particularly on the development of trust. Transference reactions are viewed as a rich source of material for uncovering dysfunctional thoughts and assumptions. Experiential techniques, such as the use of imagery and the reliving of childhood events, are considered to be particularly effective, since the affective experience induced by such techniques is important in bringing about cognitive change.

Because of the intensity of the borderline patient's beliefs, identifying, testing, and changing underlying assumptions requires acceptance of a much slower pace of change and a heavier reliance on behavioral experiments to test the validity of the beliefs. In addition to focusing on the

underlying assumptions and dichotomous thinking, interventions are used to increase control over emotions, improve impulse control, and strengthen the patient's sense of identity.

**Efficacy.** Little is known about the efficacy of cognitive therapy for borderline patients. No controlled studies are available, and existing findings are based primarily on clinical experience and case reports. Controlled studies are clearly needed to determine the possible effectiveness of this treatment approach with borderline patients.

### Discussion

The treatment approaches described represent a significant advance in the articulation and expansion of individual psychotherapies for patients with borderline personality disorder. They are characterized by clear explication of the theoretical rationale and well-developed conceptualization of borderline pathology as well as by descriptions of specific strategies and techniques.

Despite the differences in theories and techniques, these approaches have several features in common, which represent critical aspects of any form of treatment for borderline patients. All approaches, for example, stress the importance of careful attention to the relationship with the patient. This focus is particularly notable for the behavioral and cognitive approaches because they typically do not place as much emphasis on relationship issues. Establishing a trusting and collaborative relationship with borderline patients, which evolves more easily and requires less effort with many other kinds of patients, is itself a therapeutic accomplishment. Features of the therapeutic process that promote a strong therapeutic alliance are of critical importance in the success of any form of treatment with these patients.

A second common feature is the therapist's active role. While activity on the part of the therapist is typical of behavioral and cognitive therapies, the psychodynamic approaches also underscore the importance of the therapist's active role in treating these patients. This emphasis reflects

the patients' strong needs for structure and support, particularly in the context of interpretations and confrontations.

All of these approaches focus on the need to set limits. While most approaches stress limit setting as important for the patient's development, at least one author (Linehan) has pointed out the importance of setting limits to prevent the therapist from feeling frustration and resentment. Limit setting is considered essential to prevent the disruption of the treatment.

Any form of treatment for borderline patients requires flexibility in its implementation because of the shifting states and crises typical of these patients. This flexibility can be managed even within standardized approaches. In Linehan's dialectical behavior therapy, for example, the need for flexibility is built into the treatment by inclusion of a hierarchy of targets that shift according to the immediate status and problems of the patient.

Finally, regardless of the treatment approach, the therapist needs considerable skill, particularly including the ability to deal with the difficult countertransference issues often provoked.

Very little is known about the effectiveness of these treatments for borderline personality disorder. Systematic descriptions of the various approaches and development of measures of the therapist's competence and adherence to the treatment will allow increasingly rigorous research on efficacy. Investigations of strategies and techniques aimed at increasing compliance, particularly keeping patients in treatment, would be valuable. An important part of such investigations would be determining factors that promote the development of the therapeutic alliance. Other important targets for study include the ability of these treatments to reduce the life-threatening and self-destructive behaviors typical of borderline patients, an approach that Linehan has successfully taken in evaluating the efficacy of DBT.

Finally, an important question for all treatment approaches concerns

reasonable goals of treatment. How much improvement can be expected? Linehan has found that one year of DBT results in a significant reduction of self-destructive behaviors but has little effect on depression and hopelessness. Would a longer period of treatment result in improvement in the latter areas as well? If so, how much improvement? Can these patients expect elimination of serious depression or expect to be able to achieve stable and satisfying interpersonal relationships?

Clearly, these questions have no simple answers, and there is likely to be a range of outcomes for different patients. The identification of factors that are associated with different levels of outcome is another important question for research.

## Multiple Personality Disorder: A Challenge to Practitioners

Thomas J. Giancarlo

**ABSTRACT:** Multiple personality disorder is becoming better understood and thus more treatable. Because clinicians often treat child and adult victims of physical and sexual abuse, a potential trigger of multiple personality disorder, it is imperative that they become more skilled in diagnosing and treating this disorder.

MUCH HAS BEEN WRITTEN about multiple personality disorder in the past 10 years. Forms of multiple personality disorder have appeared throughout history; often it was considered proof of demonic possession. Reported cases go back as far as 1646 (Bliss, 1980). Numerous cases have been reported since that time, as students of the human psyche became interested in the mechanisms of the mind, especially dissociation. In the early part of the 20th century, however, the psychiatric profession showed less interest in dissociation and multiple personalities as a result of the psychoanalytic model's emphasis on repression. Moreover, the diagnosis of schizophrenia was used more often in the United States in the 1920s, resulting in a decline in the diagnosis of multiple personality. Bleuler stated that "schizophrenia produces different personalities existing side by side" (Rosenbaum, 1980, p. 1384). The lay public's view of schizophrenia as being a form of "split personality" evolved during this period (Bernheim & Levine, 1979). It wasn't until the 1970s that interest in dissociation and multiple personality was renewed, partly as a result of the publication of *Sybil* (Schreiber, 1974)—a book that reintroduced the public and the mental health profession to multiple personalities.

The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R) (American Psychiatric

Association, 1987) defines multiple personality disorder as follows:

- A. The existence of two or more distinct personalities or personality states (each with its own relatively enduring pattern of perceiving, relating to and thinking about the environment and one's self.)
- B. Each of these personality states at some time, and recurrently, takes full control of the individual's behavior (p. 106).

This definition is different from the 1980 edition of the manual (American Psychiatric Association, 1980), which stated that "each individual personality is complex and integrated with its own unique behavior patterns and social relationships" (p. 259). Putnam (1989a) reminds us that many secretive alter personalities actively avoid the "social relationships" mentioned in this definition. In addition, many of the alter personalities are "personality fragments," that is, entities with a persistent sense of self and a characteristic, consistent pattern of behavior but "with a more

limited range of function, emotion, or history" (Kluft, 1984b, p. 23). These fragments might appear only in specific contexts, such as a guardian personality that emerges to protect the body from injury or threat. However, as Lowenstein (1989) pointed out, current thought focuses less on the personalities as reified constructs and more on multiple personality disorder as a complex dissociative process, only one aspect of which is the creation of alter personalities.

### Etiology

Several models have attempted to describe the development of multiple personality disorder. Kluft's (1984a) four-factor theory posits that a person is a candidate for multiple personality disorder if he or she is sufficiently influenced by the following factors:

1. He or she has the biological and psychological potential to disassociate.
2. He or she is exposed to traumatic experiences that overwhelm normal means of coping with stress, thus causing the person to disassociate.
3. These dissociations assume forms such as the development of imaginary companions.
4. Significant others do not protect the individual from overwhelming stimuli and/or do not provide adequate soothing and other restorative experiences (e.g., a parent who does not recognize a child's stress and trauma and does not comfort the child in some way).

Putnam (1989a) believes that "we are all born with the potential for multiple personalities and over the course of normal development we more or less succeed in consolidating an integrated sense of self" (p. 51). He explains that in infancy our behavior is organized into a series of discrete states. Over time, and with the help of healthy caretakers, we learn to modulate the transitions between these behavioral states. Our success with this process allows us to sustain a given state longer and to present a "more unified sense of self across contextual changes" (p. 51).

Children are able to more easily enter dissociative states than are adults. Children are able to fantasize and to project feelings, motives, and thoughts onto objects such as dolls. An extension of this is the development of imaginary companions. Imaginary companions are often seen in normal children. However, many researchers believe that in children who are predisposed to multiple personality disorder, imaginary companions may be the prototypes for alter personalities. It may be

that these imaginary companions are endowed with certain characteristics and linked to specific types of circumstances, feelings, or experiences. Similar experiences occurring over time reinforce this process, building a kind of "life history" for that personality part (Putnam, 1989a). Putnam (1989a) further states that "the number of different alter personalities in adult MPD victims is significantly correlated with the number of different kinds of trauma suffered in childhood, suggesting that a child enters into different dissociative states depending upon the circumstances" (p. 54).

In general, then, a child with potential and predisposition for dissociation may use that naturally occurring psychological mechanism to cope when exposed to overwhelming stress. If similar circumstances recur, the child's dissociation may solidify into an alter personality system, especially if significant caretakers in that child's life fail to relieve that stress or, worse, contribute to the continuation or recurrence of that stress.

In a National Institute of Mental Health study of 100 cases of multiple personality disorder, Putnam, Guroff, Silberman, Barban, and Post (1986) found that 97% of the cases reported significant childhood trauma, 68% reported incest, 85% reported sexual abuse, and 80% reported physical abuse. Confinement abuse was common. In addition, various forms of emotional abuse were commonly reported, including threats of violent punishment or actual abuse of siblings or pets in the presence of the child. Approximately 40% reported witnessing a violent death. Clearly, the vast majority of persons with multiple personality disorder grew up in highly dysfunctional families where violence was common.

### Diagnosis

The classic presentation of multiple personality disorder is a client who is depressed, anxious, with blunted affect, a constricted range of feelings, often guilt ridden and masochistic, suffering both psychological and physiological symptoms, as well as time loss or distortion (Kluft, 1984a). Prior to being diagnosed with multiple personality disorder, these clients have usually been in and out of the mental health system for many years (seven years on average) (Putnam et al., 1986) and have received several different diagnoses, for example, depression, schizophrenia, manic-depressive illness, or borderline personality disorder. They may have been hospitalized and medicated for these diagnoses but typically have not

improved with treatment. At least 75% have made one or more serious suicide attempts, and approximately 33% have mutilated themselves (Putnam et al., 1986). Substance abuse is also quite common (Coons, 1984).

Trust is a major issue for persons with multiple personalities, just as it is for other victims of abuse. Self-protection and secrets are part and parcel of multiple personality disorder. Thus, much of the personal data needed to confirm the diagnosis is not readily available to the therapist early in treatment. The presenting personality may actively withhold information in order to protect the multiple personality system or because important personal material may just not be available to a given personality.

Most reports of clinical experience indicate that fewer than 10% of cases present with abundant evidence of the disorder (Kluft, 1985). Usually, it is only after some time in therapy that a therapist may begin to suspect multiple personality disorder. In addition to the criteria described earlier, Greaves (1980) noted several signs that may suggest the possibility of multiple personality disorder. These signs may appear only gradually and sporadically and can be easily overlooked.

- 1) Time distortion or time lapses, 2) Being told of disremembered behavior, 3) Observers' reports of notable changes, 4) Other personalities elicitable by hypnosis, 5) Use of "we" in a collective versus editorial sense, 6) Discovery of productions (such as writing or art) or objects among one's possession [sic] which neither can be recognized nor accounted for, 7) Severe headaches, 8) The hearing of voices, originating within, but separate, entreating toward good or bad deeds (Kluft, 1984b, p. 23).

Once the possibility of multiple personality disorder or other chronic dissociative disorder is suspected, the clinician should seek out information that will clarify the diagnosis. The therapist will need to explore with the client issues regarding "time loss" or other time distortion. For example, these might include time unaccounted for; behavior that can't be explained, such as purchases made and forgotten; connections with people unknown to the host or presenting personality; and fugue-like experiences wherein the person cannot account for why he or she is in a certain place or how he or she got there.

Such inquiries may begin to elicit in the client a pattern of experiences over his or her lifetime that describes the person's disjointed history. This may include an erratic work history, with

abrupt job changes, or equally erratic social and emotional relationships. The person may have been described as "moody" by friends or family and may have been accused of being a liar as a child. The person may evince some knowledge or skill—such as the ability to paint or to write creatively—and not know how he or she acquired it.

Fagan and McMahon (1984, p. 29) summarize the signs of multiple personality disorder or incipient multiple personality disorder in children. Because many of these indicators are seen in other diagnostic groups, the clinician needs to look for a pattern of these signs:

- "In another world." This may be evidence of the person switching back and forth among personalities.
  - Responds to or uses more than one name and may seem confused about other names or use the third person to refer to him- or herself.
  - Shows marked changes in personality, swinging from one set of characteristics to the opposite (shy to belligerent, demure to seductive, feminine to masculine, etc.).
  - Peculiar and perplexing forgetfulness. Confused about basic things such as possessions, teachers' names, and so forth.
  - Odd variations in physical skills and attributes: right handed vs. left handed, artistic ability, food preferences.
    - Inconsistent schoolwork.
    - Disruptive, delinquent, or peculiar behavior.
    - Perplexes professionals. They are unable to diagnose the problem or to help child change behavior with usual therapeutic approaches.
      - Lies. Denies lying in spite of clear evidence.
      - Discipline has little or no effect.
      - Discipline responded to by strong protestations of innocence or stoical detachment.
      - Delinquent behavior far beyond normal childhood acts.
        - Self-injurious, self-mutilating, reckless, takes physical risks.
        - Homicidal. Has severely injured other children or adults or attempted assault with a deadly weapon.
          - Suicidal—overt, serious attempts.
          - Precocious sexuality.
          - Truant.
          - Lonely. Often ignored, avoided, teased, or rejected by other children.
          - Many physical complaints, illnesses, or injuries. These may be hypochondriacal complaints or evidence of physical abuse.
          - Hysterical symptoms (sleepwalking, sudden

blindness, epileptic-like seizures, paralysis, loss of sensation).

The child may experience some or all of the following:

- Loses track of time, is disoriented with respect to time and/or place.
- Believes he or she is called by the wrong name.
- Hears voices inside his or her head.
- Feels as if he or she is frequently punished when innocent.
- Has imaginary playmates.
- Is lonely.

### Alter Personalities

A person may have two personalities, as was the case in early reports, or as many as several hundred, although many of these do not fit the definition of "personality" and are actually personality fragments. The average number found in several studies was 13 to 15 (Kluft, 1984c; Putnam et al., 1986). One major study (Putnam, 1984) explored the range of characteristics of alter personalities. One third of the therapists surveyed had seen patients change from being right-handed to left-handed and vice versa. One half of the subjects had personalities that responded differently to medication; 75% had personalities with different physical symptoms; 25% had alternate-personality-specific allergies; 75% had personalities claiming to be younger than 12; and 50% had opposite-sex personalities.

Tests were performed with multiple personality disorder patients versus a control group told to "fake" having alter personalities and switching between them (Putnam, 1989b). Tests on both groups included electroencephalograms (EEGs), galvanic skin response tests, and positron emission tomography (PET) scans.

Results indicated that the control group's faking did not sufficiently alter mental and physical results of the tests, whereas the multiple personality disorder group did. The various personalities of the multiple personality disorder patients showed real changes in all the tests as well as during the switching process.

Several types of alter personalities are common in multiple personality disorder. The personality that is most often in control of mind and body is considered the host personality. It is this personality who often presents for treatment and will typically fit the classic presentation described above.

Most people with this disorder have personalities that protect and help the person. Often they serve to protect the individual from persecutor personalities, which are also common in multiple personality disorder patients. The persecuting personality may be self-destructive and may consider him- or herself separate from the host and other personalities.

Sometimes patients have a special helper personality called the *inner-self helper* (Allison, 1974). This personality may be able to provide insight into the workings of the multiple personality system and may also help influence other personalities to cooperate with the therapist. This personality can become a great ally in the treatment process.

Child personalities are very common in multiple personality disorder systems. Some patients may have many child personalities, each of whom retains a tragic memory of the patient's childhood. A lot of the therapeutic work focuses on the child personalities in an effort to gain their trust and to work through long-stored and repressed memories.

Some of the alter personalities may not be aware of other personalities. Other personalities may be aware of all of them but still not know why they exist. Some personalities express the bond of sharing the same body with other personalities, whereas others consider themselves completely independent. Some memories are shared among some of the alter personalities. Other memories are held within an individual personality. The helper personalities often play a nurturing, almost parental role, with one or more of the child personalities. Often, the host does not know about the other personalities.

### Treatment

In discussing therapeutic goals with multiple personality disorder patients, Caul stated, "It seems to me that after treatment you want to end up with a functional unit, be it a corporation, a partnership or a one-owner business" (Hale, 1983, p. 106). The treatment goal for most cases of multiple personality disorder is fusion or integration of the personalities into a single unified personality with the concomitant goal of ending the time loss, amnesias, and physiological effects, such as headaches, that these patients experience.

Allison (1974), Bruan (1986), Caul (1978), and Putnam (1989a) have presented guidelines for treatment of this disorder:

1. Establish an atmosphere of safety and trust. This is essential to treatment because the client has been severely victimized in the past.
2. Make the diagnosis and share it with the available personalities.
3. Establish communication with the accessible personalities. This may be done directly or through hypnosis or keeping a journal.
4. Develop a contract with regard to therapy (i.e., limits, avoidance of self-harm, etc.).
5. Gather history on the individual and the system to determine the origin, functions, and problems of each alter personality.
6. Begin to work on the alter personalities' issues.
7. Map the system (i.e., the structure, relationships of the various personalities).
8. Increase communication among the alter personalities. This breaks down the amnesia barriers and the need for separateness is diminished.
9. Work toward recovery and integration of traumatic material.
10. Help patient to develop new coping skills and social supports.
11. Solidify the gains made.
12. Long-term follow-up.

The treatment process is dynamic; most of these steps are overlapping and ongoing. No one right way exists to do therapy with multiple personality disorder patients. Most experts agree that therapeutic effectiveness mainly requires good psychotherapy skills and knowledge about the particulars of the disorder.

The therapist needs to understand the degree of commitment needed for the therapeutic process of treating a multiple personality client. Most therapy lasts a year or longer, and many experts recommend that the client be seen more than once a week. In order to manage this therapy properly, the therapist needs to contract with the client regarding the limits of treatment, the safety of both the therapist and the client, the therapist's privacy, and the safety of the therapist's property. The contract should be negotiated with as many of the alter personalities as possible. Putnam (1989a) recommends a written contract.

Watkins and Watkins (1984) offer several bits of wisdom regarding the therapist-client relationship. In order to build and keep the trust necessary to complete this difficult work, "the patient must perceive the therapist as friendly, strong and unafraid" (p. 116). Eventually, all the alter personalities must believe that the therapist can handle anything that comes up in the treatment

process. Moreover, "it is vitally important that the therapist remain on good terms with every ego state" (p. 114). The therapist should keep the following principle in mind:

The first essential to be recognized by a therapist is that each personality has been created for a purpose to fill a need of the individual, and that one can seldom eliminate it, however malevolent it appears to be, unless the basic need or purpose is met in some more constructive way (p. 113).

This caveat corresponds to Kluff's (1984c) reminder that the therapist should treat all personalities similarly and that "treatment will sink or swim on the quality of the therapeutic alliances developed with the personalities" (p. 14).

The demands on the therapist can be very great, especially when treating his or her first multiple personality client. Because the disorder is relatively rare, most therapists will not have been exposed to extensive literature on the subject. When confronted with his or her first case, the practitioner may attempt to absorb as much knowledge as possible in a short period, which may create a crisis of competence for the therapist. Although it may be difficult to find a supervisor with more experience than the treating therapist, finding someone with experience with such cases can be invaluable. Also, diagnosis of this disorder will be met with skepticism by one's colleagues, resulting in feelings of professional isolation. One's own belief in the diagnosis may also falter from time to time.

These clients may need to be seen two or three times per week. Often, the process of contacting alter personalities and working through the traumatic experiences held in their memories is not easy to fit into a 50- or 60-minute session. The therapist must schedule carefully in order to accommodate other clients and to allow time to process the events of the session. In addition, because journaling is an excellent way for clients to continue therapeutic work outside of the sessions and for alter personalities to "contact" the therapist, the therapist may find himself spending additional time reading the journals of a cooperative client. When added to the time spent keeping notes, talking with colleagues about the case, and just thinking about it, the treatment process can begin to feel quite overwhelming.

The actual experience of being with a multiple personality disorder client—witnessing the switches from one personality to another, often

several times in a session, and watching a person relive, from several different perspectives, horribly traumatic episodes of abuse—can be very draining indeed. Being with a person who changes from a tough, swaggering male personality to a cowering, thumbsucking child to a lilted, hopeful "flower child" to a depressed, bland, woeful host personality in a matter of minutes can cause one to question his or her own sense of reality. My experience was echoed by a colleague who described being in an "altered state" during and after sessions with such a client and needing to "come down" and reorient before moving on to another activity. A combination support group and study group of therapists who work with multiple personality disorder clients may help the therapist to cope with these effects.

Therapists should have access to a psychiatrist, who can act as a supervisor or consultant, especially if the psychiatrist has some experience with multiple personality disorder. Although "there is no good evidence that medication of any type has a direct therapeutic effect on the dissociative process as manifested in MPD" (Putnam, 1989a, p. 253), medication may be used to control or ameliorate specific nondissociative symptoms, such as depression, that may interfere with psychotherapy. A psychiatrist can make periodic assessments of the efficacy of medication. Moreover, although outpatient treatment is preferred, the psychiatrist can be a valuable resource if brief hospitalization is necessary.

### Case Example

C was 35 years old, married, and the mother of four children. She was participating in a sexual abuse survivors' group as a result of flashbacks of sexual abuse by her mother. In the first group session she revealed graphic details of this abuse but in later sessions seemed unaware of what she had revealed. Her group therapist referred her to me in January 1988 with the goal of uncovering suspected traumatic material through hypnosis.

Prior to being in the survivors' group, C had undergone treatment intermittently since 1978 with at least six different therapists. She had been hospitalized twice for depression and had been treated with antidepressants. During the first session, her presentation fit the typical "host" personality pattern, namely, depressed, blunted affect, anxiety and phobias, and panic attacks. When asked what she wanted out of therapy, she listed work on the above symptoms. However, her first

stated goal was to become more "cohesive," in reference to her feeling of being scattered inside.

Several months before I met C, she wrote in her journal,

I needed to be covered to hide my own self from all that truly scared me because I couldn't face all the fears because there was no way to face them without admitting how badly I was really hurting and if I acknowledged the hurt there would be no way to get through it without admitting all the rest and if I admitted that then I would undo my own self.

She was aware of much but not all the physical abuse she had been subjected to. However, she had no clear memory of sexual abuse, only vague images of "hands" and "eyes." Confusing and conflicting memories and reports are often given by clients with multiple personality disorder.

Despite her stated desire for "cohesiveness," multiple personality disorder was not considered for at least two months in that the author was not familiar enough at that time with the indicators of multiple personality disorder. It wasn't until she had an abreaction after looking at a picture, brought in at my request, of herself at approximately three or four years old that I began to suspect the possibility of multiple personality disorder. At that time, she requested that we work on her fear of bees. I performed a simple hypnotic induction (multiple personality disorder clients are often hypnotized easily) by suggesting she take a deep breath, close her eyes, and "go inside" to find that part of herself that knows more about the bees. Again she had an abreaction, describing a scene in which she had a cage over her head. Her mother wielded an axe, saying she was going to cut C's head off. She also remembered another scene but she couldn't describe it. I asked her to draw it, and she drew a childlike picture of a baby in a crib, a woman with various implements, later discovered to be a shoe horn and a button hook. C was quite disturbed when drawing this but did not recall the scene upon awakening.

In another session, using the same techniques, C described a rape by a stranger when she was 13 years of age as well as mistreatment by her mother and grandmother. She began journaling at my request; multiple personality disorder was further suggested by the widely variant handwriting in her journals.

Upon referral to a psychiatrist, antidepressants were prescribed. As is often the case with such clients, the medications were not effective.

Moreover, the side effects were intolerable so the medication was discontinued.

The diagnosis of multiple personality disorder was made and shared with C. She became quite upset, feeling that she was bad. A week later, a shiver ran through my body as I greeted her in my waiting room. There was something different about her. When we were in my office I said, "You seem different today." When she offered no response, I asked "Who's here?" "I'm Nikki," was the reply. It turned out that Nikki, a male protector personality, had come to "check me out." The session was tense but formed the beginning of an extremely valuable alliance.

I eventually met many other personalities, including five child personalities, three helpers, and a persecutor who later became a helper before finally merging. Other personalities existed whom I didn't meet because they had been "banished" for unacceptable behavior. Each personality served a purpose: one to help untie the ropes that were used to tie her in bed and in the fruit cellar, another to deal with the rape and subsequent sexual experiences, another to "hold onto hope," another to take away the pain, another to deal with the abuse perpetrated by C's father, another to cope with abuses perpetrated by her mother, a "public" personality, the host personality, and others. During the course of therapy, several of these personalities merged, feeling that their issues had been addressed and their work done.

During therapy, boundaries between personalities weaken and blur. Although this is a desired goal, it threatens the system by disallowing customary dissociative means of coping with perceived danger. At this point, the therapeutic alliances and commitment to the goal of wholeness become critical. Not only must a particular personality reexperience the trauma during therapy, but in so doing painful memories "leak" across

boundaries into other personalities who had been shielded from the full impact of the abuses. Even the protector personalities begin to experience the pain.

The therapists must let clients know in advance that integration will be a difficult and painful process. Honesty is critical, and the therapist will be challenged throughout the treatment process. The relationship between therapist and client must be a corrective one; that is, it must not be perceived as dishonest and thus repetitive of the client's earlier experience with significant others.

C has often experienced despair during the therapeutic process and has often wished to give up or even die. The alliance established between Nikki and me, begun in that early session, as well as my alliances with other helpers (Tornado and Dreamer) have eased the burden of therapy. In addition, C has continued in the survivors' group, in which she has a warm and meaningful relationship with the group therapist. C has also developed a warm and gentle relationship with the psychiatric consultant. These relationships with loving and trustworthy women have helped her face her fears about women in general and her mother in particular. C's husband has had limited involvement in therapy sessions, per his wish. However, he has been very understanding of and supportive to C throughout this painful process. C's children have not yet been told about C's diagnosis but they are becoming involved in family sessions.

C is a bright and talented woman who has been an underachiever throughout much of her life. Her current goal is to return to college in order to discover what she is capable of doing. Her work is far from done, but everyone involved in the therapeutic process is optimistic that she will eventually free herself from this disorder and be able to build on the strengths she has developed.

## Chlorpromazine Database

### FORMULATIONS

Chlorpromazine hydrochloride tablets: 10 mg, 25 mg, 50 mg, 100 mg, 200 mg  
Chlorpromazine hydrochloride capsules: 30 mg, 75 mg, 150 mg, 200 mg, 300 mg  
Chlorpromazine hydrochloride syrup: 10 mg/5 ml; concentrate, 30 mg/5 ml  
Chlorpromazine suppositories: 25 mg, 100 mg  
Chlorpromazine hydrochloride injection: 25 mg/ml  
Brand names: Thorazine (SKF); Prompar (Parke-Davis); various generic brands

Table 3A.2.  
Expected Physiological Effects from Chlorpromazine Therapy for Monitoring<sup>a</sup>

Parameter	Drug Effect
<b>Cardiovascular status</b>	
Heart rate	Frequent slight tachycardia
ECC	Prolongation of Q-T interval, S-T segment depression
Blood pressure	Orthostatic hypotension is common; fall in blood pressure
<b>Respiratory function</b>	Slight decrease in respiratory rate
<b>Renal function</b>	
Serum creatinine and clearance, BUN	Normal values should not change in most adults; occasional apparent diuretic actions
<b>Hepatic function</b>	
SGOT, SGPT, alkaline phosphatase	Transient benign increases may occur during first month. Substantial increases accompanied by increases in bilirubin should prompt further assessment of liver function. Occasional hypersensitivity reaction and obstructive jaundice occurs, usually in 2nd to 4th week of therapy with high levels of alkaline phosphatase and bilirubin.
Triglyceride, cholesterol	Serum concentrations have been reported to show no changes or transient rises after initiation of therapy. High density lipoprotein cholesterol may decrease.
<b>Hematology status</b>	
CBC	Leukocytosis, leukopenia, and eosinophilia may occur. Agranulocytosis and thrombocytopenia are rare.
<b>Neuroendocrine status</b>	
Glucose tolerance	Acute doses may cause hyperglycemia and inhibit insulin secretion; little effect is due to chronic low doses.
Serum prolactin	Elevated in men and women throughout therapy; no tolerance develops.
<b>Other tests</b>	
Serum magnesium, serum calcium	Slight decreases during therapy have been noted with other phenothiazines.

<sup>a</sup>Abbreviations: BUN, blood urea nitrogen; SGOT, serum glutamic-oxaloacetic transaminase; SGPT, serum glutamic-pyruvic transaminase; CBC, complete blood count.

**Table 3A.3.**  
**Pharmacokinetic Parameters of Chlorpromazine**

Parameter	Range
Bioavailability	Nearly complete absorption; total bioavailability reduced from extensive presystemic elimination
Time of peak concentration after single dose	Between 30 minutes and 4 hours
Plasma protein binding	90% or above
Volume of distribution	10 to 35 liters/kg (mean of 20)
Total plasma clearance	IM: mean of 0.6 liter/min Oral: approaches or exceeds hepatic blood flow (1.5 liters/min)
Renal clearance	Negligible
Elimination half-life	Range of 6 to 118 hours; mean of 30
Active metabolites	7-Hydroxychlorpromazine
Therapeutic range	30 to 350 ng/ml for antipsychotic effects; greater than 750 ng/ml associated with frequent adverse effects.

## INDICATIONS

Given its diverse pharmacologic effects (Table 3A.1), chlorpromazine has many potential uses. The Food and Drug Administration (FDA)-approved uses in psychiatry include the management of psychotic disorders and of the manic state of bipolar affective disorders and the short-term treatment of severe agitation, hyperactivity, or aggressiveness in disturbed children. Nonpsychiatric uses include relief of intractable hiccups, acute intermittent porphyria, hyperthermia, and restlessness and apprehension before surgery and control of nausea and vomiting. Table 3A.4 is a list of disorders for which chlorpromazine has been tried.
